The pathogenesis of insomnia is still unclear and may be related to the dysfunction of neurotransmitters, inflammatory cytokines, neuroendocrine factors, melatonin, signal transduction pathways, neurotrophic factors, and intestinal flora in the brain. The ERK pathway belongs to the MAPK family and mediates various physiological and pathological processes such as cell proliferation, differentiation, apoptosis, oxidative stress, and immune inflammation. It plays an essential regulatory role in tumor pathogenesis, various inflammatory diseases, mental disorders, insomnia, and other diseases[4,5]. The ERK signaling pathway can be activated after receiving stimulation signals, which activates the downstream transcription factor NF-κB, affects the secretion of inflammatory cytokines [interleukin (1L)-1β, 1L-6, tumor necrosis factor (TNF)-α], and induces functional changes, thereby leading to insomnia and increasing the risk of chronic inflammatory diseases[6-8]. Abnormal activation of the ERK signaling pathway can also aggravate apoptosis and inflammatory injury in cardiomyocytes, leading to cardiac diseases. The administration of corresponding inhibitors can enhance myocardial reoxygenation capacity, inhibit apoptosis and the inflammatory response, reduce myocardial ischemia, and promote the recovery of cardiomyocyte function[9,10]. Clinical studies have found that acupuncture at Back-Shu point has an excellent therapeutic effect on insomnia, effectively improving depression, anxiety, memory loss, immunity decline and other clinical symptoms caused by insomnia[11]. Experimental studies have confirmed that the pathogenesis of insomnia is closely related to the ERK/NF-κB signaling pathway[12]. We hypothesize that inhibition of ERK/NF-κB signaling pathway activation may be a potential target in the treatment of insomnia.

In this study, a rat model of insomnia was established by intraperitoneal injection of p-chlorophenylalanine (PCPA). The rats were treated with acupuncture at Back-Shu point and injection of the ERK/NF-κB pathway inhibitor U0126, respectively. The sleep status, learning and memory ability, body

weight, mental state, response to external interference and other general behaviors were observed before and after treatment. The secretion levels of proinflammatory cytokines such as IL-1β, IL-6 and TNF-α in serum and the hippocampus, and the protein expression of ERK/NF-κB signaling pathway markers were detected to verify whether acupuncture at Back-Shu point could inhibit the ERK/NF-κB signaling pathway to relieve insomnia, providing new insights for the clinical treatment of insomnia.

MATERIALS AND METHODS

Forty male specific pathogen free (SPF) Sprague Dawley (SD) rats aged 12 wk weighing 200 ± 20 g were selected and were given water and food ad libitum. The rats, purchased from Henan Laboratory Animal Center, were housed at a room temperature of 20-24 °C, and relative humidity of 40%-60%. The 40 rats were randomly divided into 4 groups: Control group (Con), model group (Model), acupuncture group (Acupuncture), and U0126 group (U0126), with 10 rats in each group. Rats in the Model group were continuously injected with PCPA suspension (1 mL/kg) by intraperitoneal injection. Rats in the Con group were injected with the same amount of normal saline. Rats in the Acupuncture group received acupuncture 7 d in advance, which was performed continuously for 7 d. Rats in the U0126 group were injected with U0126 (0.2 mg/kg/d) (Alfa Chemical, Zhengzhou, Henan, China) *via* the tail vein 7 d in advance, once a day.

Drug treatment

Ultrapure water was heated to between 30-40 °C, sodium bicarbonate powder (Tianjin Hengxing Chemical Reagent, Tianjin, China) was slowly added to prepare a 5% NaHCO3 aqueous solution, and 0.9% physiological saline was added to dilute to a weak alkaline solution (pH 7-8). PCPA was then added and sonicated for 10 h to obtain a PCPA suspension.

Evaluation of the insomnia model

Twelve hours after PCPA suspension injection on day 3, three rats were randomly selected from the Con and Model groups to receive pentobarbital sodium (45 mg/kg). The rats were placed in the supine position on the experimental table to observe the righting reflex. The disappearance of the righting reflex for 1 min was considered the sleep latency, the time to recovery was the sleep time, and the rats varus 3 times within 30 s was the end index. The sleep latency and sleep time of rats were recorded, respectively.

Acupuncture intervention

The acupoints on both sides were "Xin Yu," "Gan Yu," "PI Yu," "Fei Yu," and "Shen Yu." Xin Yu: The 5th thoracic vertebra on the lower intercostal side; Pi Yu: The 12th thoracic vertebra on the lower intercostal side; Gan Yu: The spinous process of the 9th thoracic vertebra is opened 3 mm below; Fei Yu: The 3rd thoracic vertebra on the lower intercostal side; Shen Yu: The lower side of the 2nd lumbar spine. After disinfection, the operator held a millimeter needle (0.25 mm × 15 mm) in the right hand, which was quickly inserted into the acupoint to 6 mm. The needle was retained for 10 min, and then removed. Acupuncture began at 9:00 a.m. every day for 7 consecutive days.

Morris water maze test

The rats in each group were placed into the water maze for adaptive training 1 d before the experiment. The positioning navigation experiment was used to train the learning and memory ability of the rats. The rats were placed in quadrants I, II, III, and IV daily. The test time for each quadrant was 70 s. The escape latency period was the time from placed in the water to finding the landing platform. If the platform was not found within the specified time, the animal was actively placed on the platform for 15 s to induce learning and memory ability. The SuperMaze software recorded the movement trajectory and escape latency using a camera. The spatial exploration experiment was used to evaluate the spatial memory ability of the rats. The rats were placed in the water from the contralateral side of quadrant III and allowed to freely explore for 60 s. The SuperMaze software recorded the movement trajectory of the rats using a camera.

Enzyme-linked immunosorbent assay (ELISA)

After the last behavioral experiment, the rats were anesthetized by intraperitoneal injection of 10% chloral hydrate (30 mg/kg), placed supine on the rat board, blood was collected from the abdominal aorta, the animal was decapitated, and the hippocampus was isolated, homogenized, centrifuged, and the supernatant obtained. The expression levels of IL-1β, IL-6 and TNF-α in rat serum and the hippocampus were detected by ELISA according to the manufacturer's protocol (Multisciences, Hangzhou, Zhejiang, China). The absorption was measured at the wavelength of 450 nm.

Quantitative real-time PCR (qRT-PCR)

Total RNA in the hippocampus was extracted with Trizol reagent (Servicebio, Wuhan, Hubei, China). RNA concentration and purity were detected using a Nanodrop 2000 spectrophotometer. 1 μg RNA was reverse transcribed into cDNA according to the manufacturer's protocol (Servicebio, Wuhan, Hubei, China). The obtained cDNA was used as the template in qRT-PCR according to the instructions. The primer sequences were as follows:

GAPDH: F: CTGGAGAAACCTGCCAAGTATG; R: GGTGGAAGAATGGGAGTTGCT; Raf1: F: TGTTTGATGGCTCCAGTTGC; R: AGCGTGCTTTCTTACCTTTGTG; MEK2: F: TGAATGAGCCACCTCCCAAG; R: ATAGCCAGCCAGCGAAGTCC; ERK1/2: F: TTCAGGACCTCATGGAGACGG; R: GCCACATACTCGGTCAGAAAGC; NF-κB: F: GGGACTATGACTTGAATGCGG; R: CAGCCAGGTCCCGTGAAATA.

Western blot

Total protein in the hippocampus was extracted for Western blot detection. The protein samples were mixed with RAF-1, MEK-2, ERK1/2, NF-κB, and β-actin as an internal reference (all obtained from Servicebio, Wuhan, Hubei, China).

Immunohistochemistry

The paraffin sections were deparaffinized for antigen retrieval, washed three times with phosphate buffer saline (PBS), 5 min each time, and then serum-blocked and then added to primary antibody RAF-1 (1:200), primary antibody MEK-2 (1:200), primary antibody ERK1/2 (1:200), primary antibody NF-κB (1:200), and incubated overnight at 4 °C. The sections were washed 3 times with PBS, 5 min each time, diluted secondary antibody (1:1000) was added, incubated at room temperature for 50 min, washed 3 times with PBS, 5 min each time, DAB color developing solution (Servicebio, Wuhan, Hubei, China) was added dropwise, hematoxylin was used as the counterstain and returned to blue, then dehydrated and made transparent. After drying, the sections were mounted and observed under the microscope.

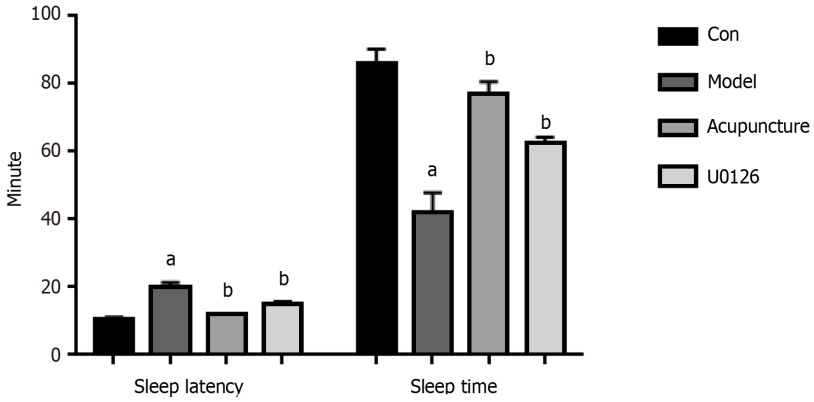
Statistical analysis

SPSS 24.0 software was used for statistical analysis of the experimental data, measurement data were expressed as mean ± SD, and the *t*-test (comparison between two groups) or LSD analysis of variance was used when normal distribution and homogeneity of variance were satisfied. For comparisons between multiple groups, the Dunnett's-T3 test was used to compare uneven variance, and $P < 0.05$ was considered statistically significant.

RESULTS

Acupuncture at Back-Shu point improved the general state and prolonged sleep time in rats

PCPA was injected intraperitoneally in rats to construct an insomnia model. Compared with the Con group, the sleep latency of rats in the Model group was prolonged and the sleep time was shortened, indicating that the insomnia rat model was successfully established (Figure 1). PCPA can cause general status and behavioral changes in rats[13]. Rats in the Model group showed a poor mental state, fighting and biting each other, with reduced food intake, increased drinking water, dull and damp hair, and poor hair glossiness. After acupuncture treatment, aggressive behavior in rats decreased, food intake increased, and water intake decreased (Table 1). Compared with rats in the Model group, the sleep latency of the Acupuncture group and the U0126 group was shortened and the sleep time was prolonged (Figure 1). In conclusion, acupuncture at Back-Shu acupoints improved cognitive behavioral changes and emotional disturbances caused by insomnia.



Effects of acupuncture at Back-Shu point on the behavior of insomnia rats

We carried out location experiments to evaluate the memory ability of rats. With the increase in training times, the average escape latency of rats in each group gradually shortened, showing that rats with increased training, remembered the platform. However, the trend in average escape latency in rats was basically the same. After treatment, compared with the Con group, the escape latency of the Model group was prolonged. Compared with the Model group, the escape latency of rats in the Acupuncture group and U0126 group was shortened (Figure 2A). The spatial exploration experiment was used to evaluate the spatial memory ability of rats. The movement trajectories of rats in the Model group showed that the movement trajectories of rats in the four quadrants were basically the same. In contrast, the trajectories of rats in the Con group and the Acupuncture group were primarily concentrated in quadrant III (Figure 2B). Compared with the Con group, the time taken to cross the original platform and the quadrants of the original platform were significantly reduced in the Model group. Compared with the Model group, the number of large crossings of the original platform and the quadrant of the original platform increased in the Acupuncture group and the U0126 group (Figure 2C). These results indicated that acupuncture treatment improved the learning and memory ability of rats and promoted

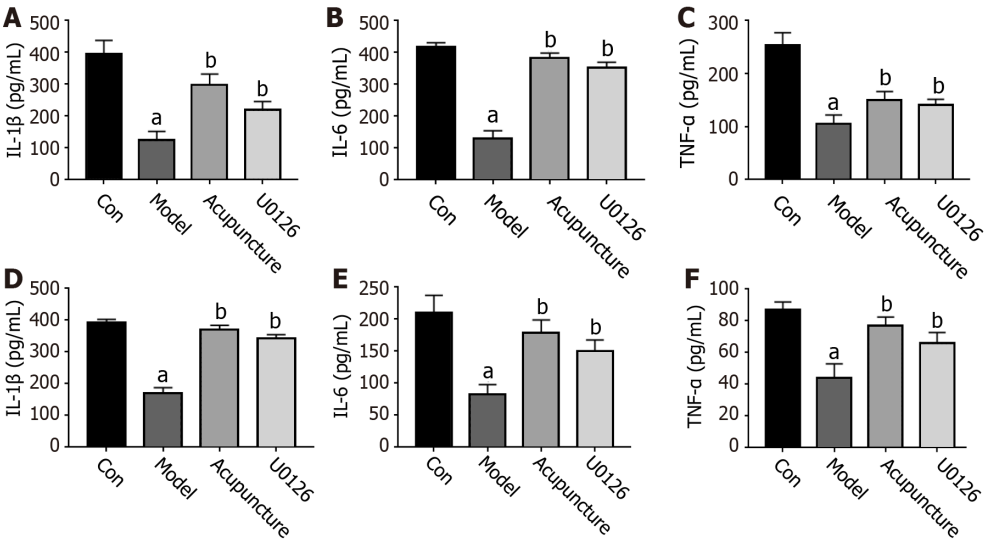
the recovery of learning and memory function.

Acupuncture at Back-Shu point increased inflammation in insomnia rats

Inflammatory cytokines act as mediating signals between the sleep-wake cycle and the immune system. Abnormal secretion of inflammatory cytokines can cause sleep-wake cycle disorder and lead to insomnia. As shown in Figure 3A-C, compared with the Con group, the secretion of inflammatory cytokines (IL-1β, IL-6 and TNF-α) in serum of the Model group was decreased. After acupuncture and U0126 treatment, the secretion of IL-1β, IL-6, and TNF-α in the serum of rats were significantly increased. In the rat hippocampus, we found the same trend in inflammatory cytokine secretion (Figure 3D-F).

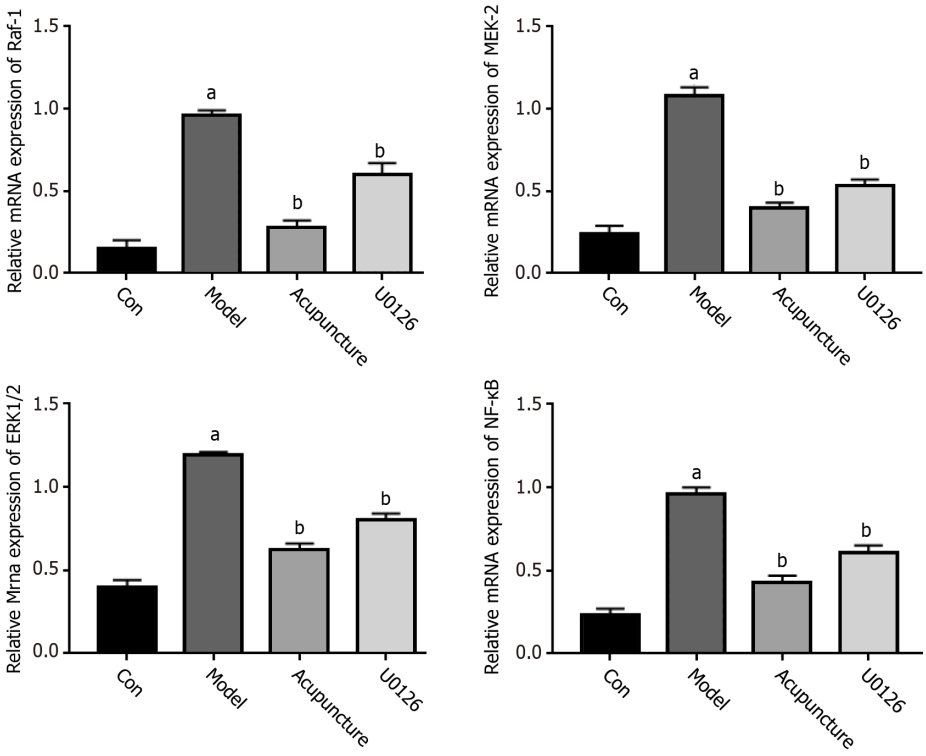
Acupuncture at Back-Shu point inhibited the ERK/NF-κB signaling pathway



The ERK/NF-κB signaling pathway is closely related to the body's immune system. It plays an important role in the synaptic plasticity of neurons in brain regions, which mainly regulates learning and memory processes. U0126 is a highly potent inhibitor of ERK1/2, MEK-1, and MEK-2. The qRT-PCR results showed that compared with the Con group, the mRNA expression levels of RAF-1, MEK-2, ERK1/2 and NF-κB in the hippocampus of the Model group were increased. In addition, acupuncture and U0126 significantly inhibited the expression of these genes (Figure 4). The protein expression levels of the ERK/NF-κB signaling pathway related genes were detected by Western blot and immunohistochemistry, and the results were consistent with the trend in mRNA expression (Figure 5). In conclusion, we believe that acupuncture at Back-Shu point can improve insomnia in rats by inhibiting the ERK/NF-κB signaling pathway.

DISCUSSION

Insomnia is a common disease that not only reduces patients' life quality, but also causes other physical diseases, significantly impacting patients' lives[14]. Due to their reproductive ability, easy feeding, easy modeling and experimental operation, and similar sleep-wake cycle and biological regulatory function to humans, rats were selected to construct the insomnia model in this study. PCPA can inhibit sleep and affect the expression of serotonin (5-HT). As an inhibitor of tryptophan hydroxylase, an essential enzyme in the process of 5-HT biosynthesis, PCPA can reduce the concentration of 5-HT in the brain and serum by inhibiting it, thus causing disorder of the sleep-wake cycle[15]. After intraperitoneal injection of PCPA in rats for three consecutive days, the rats showed circadian rhythm disorder, frequent daytime activity, wet and dark hair, increased aggression during stimulation, and mutual fighting and biting behaviors, which lasted for one week, which was consistent with the clinical symptoms caused by insomnia, indicating that the insomnia model was successfully established.



In traditional Chinese medicine, insomnia belongs to the category of "sleepless" and the Back-Shu point is the acupoint on the bladder meridian, which is closely related to the brain. Currently, the five acupoints most commonly used in treating insomnia by acupuncture at Back-Shu point are Xin Yu, Gan Yu, PI Yu, Fei Yu, and Shen Yu[16]. This study found that continuous application of acupuncture at Back-Shu point for seven days can promote appetite, prolong sleep time and improve the mental state, activity, and excessive behavior. The results of the Morris water maze test showed that compared with the Model group, the ability of positioning navigation and space exploration of rats in the Acupuncture group and U0126 group improved to varying degrees, the latency in seeking platform escape was shortened, and the number of swims across the platform was increased. In conclusion, the results show that acupuncture at the Back-Shu point can improve the cognitive behavior changes and emotional disorders caused by insomnia, improve learning and memory ability in rats, and promote learning and memory function recovery.

The sleep-wake cycle is bidirectional in the immune system. Activation of the immune system will change the sleep state, which can lead to increased sleep duration, and lead to the occurrence of insomnia[17]. Cytokines in the sleep-wake cycle and immune system mediate between signals, and through the receptor act on the peripheral nervous system or the central nervous system neurons, astrocytes and microglia, through afferent nerve fibers and blood to the brain signals, cause inflammation and then insomnia[18]. In recent years, the role of inflammatory cytokines in maintaining the NREM sleep cycle has been extensively studied in animal experiments. Anti-inflammatory factors (IL-4, IL-10) can reduce the duration of NREM sleep, and proinflammatory factors (1L-1β, IL-2, IL-6, TNF-α) can promote the duration and depth of NREM sleep[19-21]. The results of the present study showed that compared with the Con group, the proinflammatory cytokines, IL-6, 1L-1β and TNF-α in the Model group rats' serum and hippocampus were significantly decreased ($P < 0.01$), suggesting that insomnia can result in a proinflammatory cytokine secretion imbalance, affect the body's immune system, resulting in sleep cycle disorder, consistent with previous research results. Compared with the Model group, the secretion of IL-1β, IL-6 and TNF-α in the Acupuncture group and U0126 group were significantly increased, suggesting that acupuncture at Back-Shu point may participate in the regulation of sleep and the immune system, improve the secretion of proinflammatory cytokines, maintain the balance of cytokines, and promote recovery of the body's immune system and the improvement of insomnia.

The MAPK signaling family is divided into the ERK, JNK, ERK5/BMK1 and P38 MAPK signaling pathways, of which the ERK-mediated MAPK signaling pathway is considered a classical MAPK signal transduction pathway[22]. The ERK signaling pathway transfers extracellular signals into cells through the RAF-MEK-ERK cascade effect and then regulates the expression of downstream key target NF-κB, which affects the occurrence of diseases. RAF-1, MEK-2, ERK1/2 and NF-κB are essential targets in the RAF-MEK-ERK-NF-κB pathway, which regulate cell proliferation, apoptosis, differentiation and other physiological activities, and participate in the pathogenesis and clinical symptoms of insomnia[23-25]. This study showed that compared with the Con group, the mRNA and protein expression levels of RAF-1, MEK-2, ERK1/2 and NF-κB in the hippocampus of the Model group were significantly increased ($P < 0.01$), and the number of positive cells increased, suggesting that the pathogenesis of insomnia may

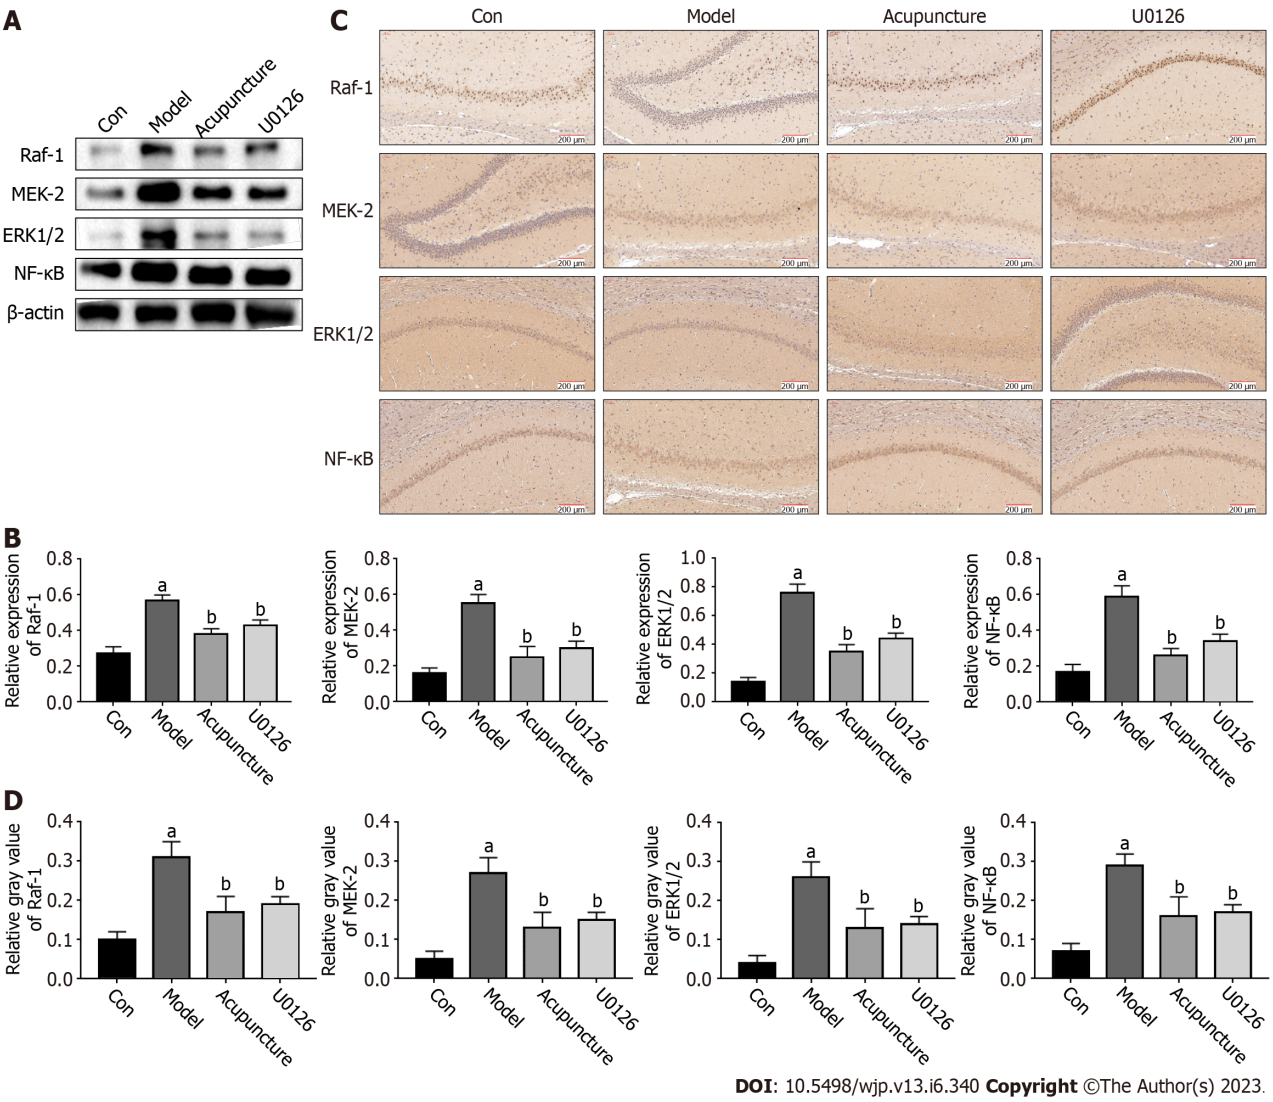

Figure 5 Acupuncture at Back-Shu point inhibited the ERK/NF-κB signaling pathway in rats. A: The expression of ERK/NF-κB pathway-related proteins in rat hippocampus was detected by western blot; B: The relative protein expression level of RAF-1, MEK-2, ERK1/2 and NF-κB in rat hippocampus; C: The expression levels of ERK/NF-κB pathway-related proteins in the hippocampus in rats were detected by immunohistochemistry, scale bars = 100 μm (× 200); D: The gray values of RAF-1, MEK-2, ERK1/2 and NF-κB. $^{a}P < 0.05$, compared to the Con group; $^{b}P < 0.05$, compared to the Model group.

be related to activation of the ERK/NF-κB pathway. To further investigate whether acupuncture at the Back-Shu point improves insomnia by inhibiting the ERK/NF-κB signaling pathway, U0126 was injected into the tail vein of rats. U0126, a highly efficient pathway inhibitor that selects ERK1/2, MEK-1, MEK-2 and other families, can simultaneously inhibit ERK and MEK through a non-competitive pathway, have an impact on the RAF-MEK-ERK cascade reaction, further inhibit cell apoptosis, migration, invasion, and regulate the expression of related proteins[25,26]. Studies have shown that U0126 can effectively inhibit the proliferation, migration and apoptosis of cancer cells *in vivo*, and antioxidant protection of neuronal cells; thus, it is widely used in the treatment of nerve damage, sleep disorders, decreased learning and memory ability, and cancer caused by hypoxia and ischemia[27-29]. Compared with the Model group, the mRNA and protein expression levels of RAF-1, MEK-2, ERK1/2 and NF-κB in the Acupuncture group and U0126 group were significantly down-regulated ($P < 0.01$), suggesting that acupuncture at Back-Shu point and injection of U0126 inhibited activation of the ERK/NF-κB signaling pathway.

CONCLUSION

In summary, acupuncture at Back-Shu point can promote appetite, prolong sleep time, improve learning and memory ability, maintain the balance of proinflammatory cytokine secretion, and improve rats' mental state, activity, and excessive behavior. We believe that the pathogenesis of insomnia may be related to activation of the ERK/NF-κB signaling pathway. Acupuncture at Back-Shu point may inhibit

conduction of the ERK/NF-κB signaling pathway, down-regulate the mRNA and protein expression of RAF-1, MEK-2, ERK1/2 and NF-κB in the pathway, increase the secretion levels of proinflammatory cytokines IL-1β, IL-6 and TNF-α, maintain the balance of cytokines, and protect nerve cells. Thus, acupuncture may promote the body's immune system recovery and play a role in the treatment of insomnia.

ARTICLE HIGHLIGHTS

Research background

The characteristics of insomnia are dissatisfaction with sleep, including difficulty beginning or maintaining sleep, waking up with/or early morning, accompanied by related daytime damage, such as fatigue and emotional disorders. Western medicine mainly uses sedatives and hypnotic drugs to treat insomnia, and long-term use is prone to drug resistance and other adverse reactions. Acupuncture has a good curative effect and unique advantages in the treatment of insomnia.

Research motivation

To explore the molecular mechanism of acupuncture at Back-Shu point for insomnia.

Research objectives

To provides a new insight into the treatment of insomnia by acupuncture at Back-Shu point from the perspective of traditional Chinese medicine.

Research methods

We first prepared a rat model of insomnia, and then carried out acupuncture for 7 consecutive days to explored the effect of acupuncture. The Morris water maze test was used to assess behavioral change. The detailed mechanism research was detected by RT-qPCR, ELISA, and Western blot.

Research results

Some Western drugs can improve insomnia symptoms, but their high drug dependence and adverse reactions limit their clinical application. Our study provides new insights into the treatment of insomnia symptoms from the perspective of traditional Chinese medicine. Our study fills a gap in the treatment of insomnia with acupuncture at Back-Shu point and provides a new treatment for insomnia.

Research conclusions

This study suggest that acupuncture at the Back-Shu point can improve the insomnia by inhibiting the ERK/NF-κB signaling pathway and increasing the release of inflammatory cytokines in the hippocampus. Acupuncture at the Back-Shu point has promoted the treatment of insomnia and benefited the public's sleep health.

Research perspectives

This paper provides new ideas for the treatment of insomnia from the perspective of acupuncture.

Abstract

BACKGROUND

In the diagnosis and treatment of cancer, it is important to evaluate the components of psychological adjustment. Considering the key role of nurses in providing care to patients, it is important to evaluate patients, to determine high-risk patients and to use tools with acceptable validity and reliability to develop care plans.

AIM

To analyze the Turkish validity and reliability of The Psychological Impact of Cancer Scale (PICS).

METHODS

This methodological study was conducted with 257 cancer patients admitted to the oncology-haematology clinic and outpatient clinic of a University Hospital between February and October 2021. After the translation process of the scale, content and construct validity were conducted. Exploratory factor analysis (EFA) and confirmatory factor analysis (CFA) was examined with construct validity, while item analyses and internal consistency analysis were conducted for reliability.

RESULTS

Analyses and assessment results showed that the content validity index of the scale was 0.96. In the exploratory factor analysis of the Turkish adaptation study, total variance rate explained was found as 84.98%. Factor loads of all items were between 0.82 and 0.94. It was found that Cronbach Alpha values were between

0.860 and 0.930 and total scale Cronbach Alpha value was 0.844. EFA and CFA showed that Turkish form of 12-item and 4-factor. The Psychological Impact of Cancer Scale was confirmed with no changes to the original scale. CFA revealed good fit indices.

CONCLUSION
Turkish PICS is a valid and reliable measurement tool for the evaluation of individual's psychological response to cancer diagnosis and treatment and for being used in clinical practice.

Key Words: Cancer; Patient; Psychological impact; Reliability; Validity

Core Tip: In the diagnosis and treatment of cancer, it is important to evaluate the components of psychological adjustment. Considering the key role of nurses in providing care to patients, it is important to evaluate patients, to determine high-risk patients and to use tools with acceptable validity and reliability to develop care plans. A valid and reliable intercultural adaptation of Turkish the Psychological Impact of Cancer Scale can be useful in making comparisons across settings and to be used in the psychological assessment of cancer in Turkish patients. Therefore, the aim of this study is to conduct validity and reliability of Turkish version of the scale. In this research, it was seen that the Turkish version of the 12-item and 4 sub-dimensional Cancer Psychological Impact Scale was confirmed without any change in the original scale form.

INTRODUCTION

Cancer is the second leading cause of death globally and it was evaluated as the cause of one in six deaths in 2020[1]. Cancer continues to grow globally by causing a huge physical, emotional and financial burden on individuals, families, societies and health systems. Survival rates in many cancer types continue to increase with early diagnosis, good treatment and quality care[1,2]. Cancer patients develop emotional, psychological and behavioural reactions before diagnosis, during diagnosis, during treatment, after treatment, during disease progression and during terminal / palliative periods. Due to the unexpected and difficult to control nature of cancer, it is known that the diagnosis and treatment process is disturbing and traumatic for the individual[3]. With this aspect, cancer, which can be associated with metaphors such as "war", "the angel of death", "winter" and "monster' by patients, may cause radical changes in the lives of individuals[4]. During the treatment phase, treatment methods such as examinations and surgery, chemotherapy and radiotherapy come to the fore according to the type of cancer[5]. It may cause a decrease in the quality of life during the treatment phase by disrupting many issues such as social life, activity, work life, sexual life, *etc*.[6-8]. These changes related to the process and treatment of cancer represent an important stress factor for any patient and create both physical and psychological threats to the patient[9,10]. Compared with the general population, studies have shown patients with malignancies to have higher rates of distress, anxiety and depression[11,12].

"The Psychological Impact of Cancer Scale (PICS)" which was developed by Hulbert-Williams *et al* [13] in 2019 for the evaluation of the components of psychological adjustment to cancer diagnosis and treatment is one of the measurement instruments with high validity and reliability. It is an easily applicable 12-item scale with which the psychological impact of cancer on patients can be evaluated [13]. Considering the key role of nurses in providing care to patients, it is important to use tools with acceptable validity and reliability to evaluate patients, to determine patients with high risk and to develop care plans[8]. A valid and reliable intercultural adaptation of Turkish the Psychological Impact of Cancer Scale can be useful in making comparisons across settings and to be used in the psychological assessment of cancer in Turkish patients. At the same time, the scale can be easily applied to cancer patients since it has a small number of items. The scale is expected to be useful in terms of evaluating the psychological impact of cancer on Turkish patients and will make it easier to decide whether patients need psychological support. For this purpose, the aim of the study is to conduct validity and reliability of Turkish version of the scale.

MATERIALS AND METHODS

Study design and sample

This methodological study was carried out at Oncology-Haematology clinic and outpatient clinic of a University between February and October 2021. Population of the study consisted of cancer patients receiving treatment between these dates. The sample included 257 volunteering patients who met the research criteria (having been diagnosed with cancer at least for 3 mo, being older than 18 years of age, not having any psychiatric problems and being able to communicate sufficiently) between the aforementioned dates. In scale adaptation studies, at least 5 individuals for each item should be reached for factor analysis. If it is not a problem to reach the sample, 10 individuals for each item should be reached. The Psychological Impact of Cancer Scale consists of a total of 12 items. Aiming to reach at least 10 cancer patients for each item, the study was completed with 257 patients[14].

Outcome Measurements

Personal Information Form: This form prepared by the researchers includes 9 questions to find out patients' socio-demographic and disease-related characteristics (age, gender, marital status, educational status, employment status, duration of disease, stage of disease, presence of another chronic disease and type of treatment).

PICS: It was developed by Hulbert-Williams *et al*[13] in 2019 to evaluate the psychological impact of the disease in cancer patients. 12-item PICS is used to evaluate the components of psychological compliance with cancer diagnosis and treatment. Each item is answered with "Totally suitable (1)", "Not suitable (2)", "Suitable (3)", "Totally suitable (4)". The scale is a 4-likert type scale. It consists of 4 factors: Cognitive distress (2, 6, 7); Cognitive avoidance (8, 10, 11); Emotional Distress (3, 5, 12); Spiritual Coping (1, 4, 9). Factor scores are calculated by adding the scores obtained from items in each scale. There are no reversely coded items[13].

Data Assessment: Study data were analysed with IBM SPSS (Statistical Package for Social Sciences) 22 and Scientific Software International, Inc. LISREL 8.8. In data analysis, number and percentage were used for evaluation of personal information. Content and construct validity were analysed with expert views, Barlett Tests, Kaiser-Meyer-Olkin Index (KMO), exploratory factor analysis (EFA), confirmatory factor analysis (CFA) and principle components analysis. In terms of reliability, internal consistency was determined with Cronbach's a coefficient, Pearson correlation analysis, item-total score correlation, composite reliability coefficient (CR) and average variance explained (AVE).

Ethical Considerations: Fırat University Non-Interventional Research Ethics Committee (2020/12 numbered) approved the study. Official permission was taken through e-mail from the researcher who developed the scale for adapting the scale into Turkish and using the scale in the study. Helsinki Declaration of Human Rights was adhered to while carrying out the study. Verbal consent was taken from study participants after the aim of the study was explained.

Stages in the adaptation of the scale to Turkish: Official permission was first obtained from the author *via* e-mail to adapt and use PICS in Turkish. Adaptation phase of the scale was carried out in five steps. Language validity was carried out in the first step; two linguists translated the scale into Turkish independently. Translation was followed with a form including the expressions in scale items, which was examined by two Turkish language experts. These experts examined whether scale items were suitable, checked Turkish language validity and cultural appropriateness and made corrections. Following the corrections, scale items were collected in a single form and they were back translated into the original language by a language expert[14]. Turkish form was found to be similar to the English form after the original scale and the translated form were compared.

In the second step, content validity was performed to prove both language and cultural equivalence and content validity of items with numerical values[15]. Content Validity Index (CVI) of the items was calculated with percentage of agreement between the opinions of at least 3 and at most 20 experts[16]. A pilot study was conducted in the third step. In scale adaptation studies, with the pilot study, a sample of about 30 should be reached, the scale should have an internal consistency value of ≥ 0.70 and it should be checked whether item total correlation is lower than 0.30[15]. In the present study, the pilot study was conducted with 30 cancer patients. With the pilot study, it was determined that the questions were understandable. The data of the pilot study were not included in study data. After the pilot study, the study was initiated without making any corrections in the light of this information. In the fourth step, EFA and CFA were conducted for construct validity[14,17]. Acceptable range of CFA goodness of fit values were found as $5 > \chi^2/df < 2$, RMSEA < 0.08, RMR < 0.08, SMR < 0.08, NFI > 0.80, CFI > 0.90, IFI > 0.90, GFI > 0.90, AGFI > 0.85, PGFI > 0.50, and PNFI > 0.50[14,18-20]. In the fifth step, to determine the reliability of the scale, test-retest reliability with an interval of two weeks in data collection stage, Cronbach alpha reliability coefficient Pearson Correlation analysis, item-total score correlation, composite reliability coefficient and mean explained variance were used[21-24].

RESULTS

Mean age of the patients was found as 59.32 ± 12.89 in the study. It was found that 51.4% of the patients were female, 53.7% were primary education graduates, 91.1% were married, 47.9% had a disease duration between 1-5 years, 40.5% were in stage 2, 86.4% were not employed, 67.3% were receiving only chemotherapy and 65.8% did not have another chronic disease.

Results on validity

Exploratory factor analysis: KMO value was 0.799 and χ^2 value was calculated as 2310.444 as a result of Barlett' s Test of Sphericity analysis in the study. Test results were found to be significant at $P = 0.000$ Level of significance (Table 1). The sample size was found to be adequate and suitable for factor analysis and this showed that the analysis could be continued[14,20].

In the exploratory factor analysis, it was found that the scale explained 84.98% of total variance (Table 2). Due to the number of factors in the EFA, Varimax factor rotation method was applied and the scale items were checked in terms of items with cross-loading. The factors with an eigenvalue of > 1 were evaluated while determining the factors. It was found that the scale items were grouped under 4 factors with factor load values found as > 0.30 (0.82-0.94). Varimax rotation method results showed that. It was found that there were no items that had to be deleted from the scale[14,25]. The values obtained showed that the scale consisted of 12 items and 4 factors.

CFA: In Table 3, CFA fit index values were found as: $\chi^2 = 116.49$, df = 47 ($P < 0.05$), $\chi^2/df = 2.47$, RMSEA = 0.076, CFI = 0.97, NFI = 0.95, IFI = 0.97, RMR = 0.034, SRMR = 0.059, GFI= 0.92, AGFI= 0.88, PGFI= 0.56 and PNFI = 0.68. It was found that model fit was acceptable and some values showed perfect fit[14, 18-20]. Figure 1 shows PATH diagram obtained with CFA.

In the study, it was found as a result of EFA and CFA that Turkish form of 12-item and 4-factor "PICS" was confirmed without any changes to the original scale form. All these results obtained show that the scale has high validity in Turkish culture.

Results regarding reliability

For reliability analysis, the data were reapplied two weeks later to 50 individuals from the sample on whom EFA was conducted. Test retest correlation coefficient was found as 0.923 for the whole scale, as .0951 for "Cognitive avoidance (F1)" factor, as 0.992 for "Cognitive distress (F2)" factor, as 0.904 for "Spiritual coping (F3)" factor and as 0.993 for "Emotional distress (F4)" factor (Table 4).

Cronbach Alpha coefficient was calculated to find out the internal reliability of the scale. It was found as 0.930 for "Cognitive avoidance" factor, as 0.0914 for "Cognitive distress" factor, as 0.899 for "Spiritual coping" factor and as 0.860 for "Emotional distress" factor. Total Cronbach Alpha coefficient was found as 0.844 (Table 4).

In this study, AVE value was found as 0.89 and CR value was 0.96 for cognitive avoidance factor; AVE value was 0.78 and CR value was 0.91 for cognitive distress factor; AVE value was 0.77 and CR value was 0.91 for spiritual coping factor, and AVE value was found as 0.67 and CR value was found as 0.86 for emotional distress factor. As a result, it was found that all CR values were higher than AVE values and AVE values were found to be higher than 0.50, which is the critical value (Table 4). When the item-total correlation coefficients of the scale were examined, it was found that all item total correlation coefficients were higher than 0.30 (0.41-0.63) (Table 2).

DISCUSSION

Content validity

Opinions of 5 experts were taken for content validity. CVI was used to evaluate expert opinions. The fact that CVI value was > 0.80 shows that there is agreement between expert opinions[26,27]. In the evaluation after expert opinions, CVI value was calculated as 0.96 in this study. This result shows that there is agreement among experts and the scale measures the subject sufficiently and content validity is met.

Construct validity

KMO and Bartlett's Sphericity test evaluated the appropriateness and sufficiency of the data for factor analysis. It is stated in literature that Bartlett's Sphericity test should be statistically significant and KMO value should be at least 0.60 for factor analysis[28]. In this study, Bartlett's Sphericity test value is 2310.444 and it is statistically significant ($P = 0.000$). KMO value was calculated as 0.799. These results show that data base and sample size are suitable for factor analysis[28]. The data base and sample size in this study are similar to those of Hulbert-Williams *et al*[13] who developed the original scale.

In order to determine the number of factors, eigenvalue was taken as ≥ 1 and it was found that the scale consisted of four factors (cognitive distress, cognitive avoidance, emotional distress, spiritual coping)[29,30]. The original scale also consists of four factors[13]. In the exploratory factor analysis, it

Item 9	0.882	0.536	0.5			0.831	
Item 3	0.798	0.543	0.67				0.83
Item 5	0.764	0.51	0.66				0.833
Item 12	0.812	0.54	0.66				0.831
Eigenvalue	-	-	-	2.686	2.587	2.52	2.406
Total explained variance (%) = 84.98%	-	-	-	22.382	21.555	21.001	20.051

was found that the 4-factor scale explained 84.98% of the total variance. In multi-factor scales, explained variance is desired to be over 40% and the higher total variance, the stronger the construct validity is[29,30]. In this study, high explained variance shows that construct validity is robust. It was decided in which factors the scale factors would be included by examining the factor loads. Factor load should be ≥ 0.30[25]. In this study, it was found that the factor loads of the items in the scale were between 0.82 and 0.94 and factor loads were very high. In this study, the fact that factor loads obtained from each scale were > 0.30 shows that the scale has a robust factor structure.

It is reported in literature that CFA should examine the construct revealed with exploratory factor analysis[31]. In this study, it was found with EFA that the scale has 4 factors, as in the original scale. For 4-factor CFA, factor loads of all factors were > 0.30 and goodness of fit indices were (GFI, NFI, CFI and IFI) > 0.90, RMSEA = 0.076. χ^2 value divided by degree of freedom was χ^2/df =2.47. A robust and significant correlation was found between the scale and factors. In literature, a model fit indicator of > 0.90, $\chi^2/df < 5$ and a RMSEA value of < 0.08 are considered as good fit indicators[14,18-20]. CFA results of the present study are in parallel with the criteria reported in literature. In their study, Hulbert-Williams *et al*[13] calculated RMESA value as 0.083. CFA results show that the data are consistent with the model, the four factor construct is confirmed, factors are associated with the scale and the items in each factor define their own factor sufficiently. In this study, EFA and CFA results supported construct validity and showed that the scale is a valid tool.

Reliability analysis

Cronbach's alpha coefficient shows whether the scale items measure the same characteristics and whether the items are correlated with the subject to be measured. Cronbach's alpha value is expected to be as close to 1 as possible. Cronbach's alpha coefficients between 0.60 and 0.80 show that the scale is reliable, while those between 0.80 and 1.00 show that the scale is highly reliable[23,29,32]. In this study, both total and factor α values of the scale are > 0.90. These results show that PICS Turkish version is a reliable measurement tool in evaluating the psychological reactions of patients towards cancer. Hulbert-

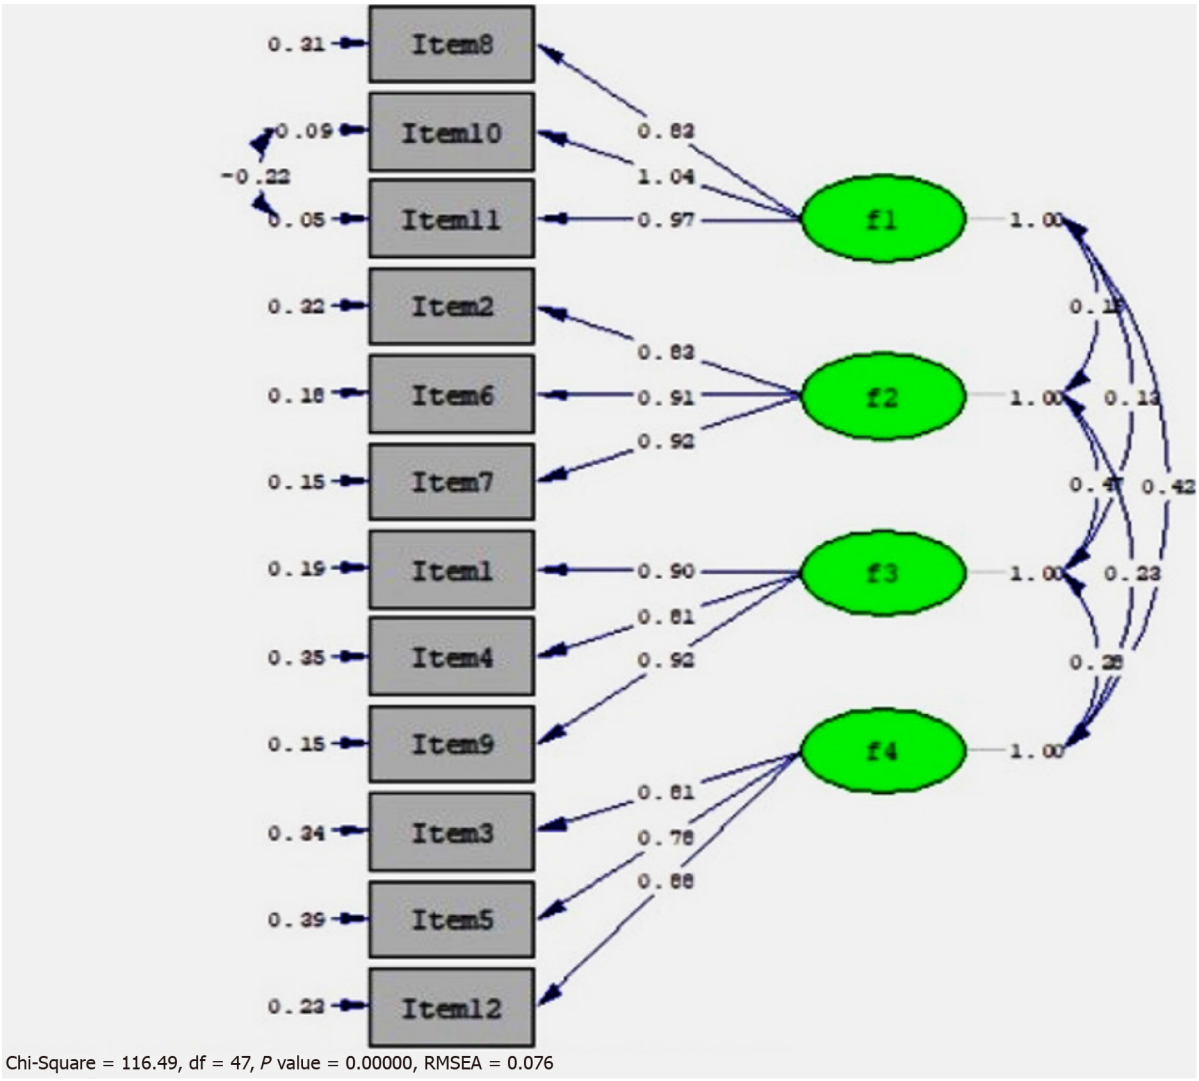
α: Cronbach Alpha Coefficient; *r*: Correlation; AVE: Average variance extracted; CR: Construct Reliability; PICS: Psychological Impact of Cancer Scale.



Williams *et al*[13] found the total Cronbach alpha of the scale as > 0,62. In this study, AVE value was 0.89 and CR value was 0.96 for cognitive avoidance factor; AVE value was 0.78 and CR value was 0.91 for cognitive distress factor; AVE value was 0.77 and CR value was 0.91 for spiritual coping factor, and AVE value was 0.67 and CR value was 0.86 for emotional distress factor. The fact that AVE value is > 0.50 and CR value is > 0.80 shows that the scale has good reliability[33]. In addition, values of CR > AVE; AVE > 0.5 are required for convergent validity[24]. As a result, it was found that all CR values were found to be higher than AVE values and AVE values were > 0.50, which is the critical value.

Item-total score analysis is recommended to prove whether the items in the scale measure the variable to be measured. Item-total score analysis explains the correlation between the scores obtained from each item of a scale[34]. In item-total score analysis, it is expected of the correlation to be positive and the correlation value to be > 0.20. When item-total correlation coefficients were examined in the present study, all item total correlation coefficients were found to be > 0.30 (0.41-0.63). Item-total correlation coefficients of the original scale were between 0.33 and 0.73. These results show that the tem-total correlation coefficients in the present study are similar to the original scale and item reliabilities are high.

One of the best ways to measure consistency of scales is test retest method[29,35]. No statistically significant difference was found between the two measurements obtained as a result of test-retest analysis (P > 0.01). Test-reliability coefficients of the scale items were found to be statistically significant in the evaluation of the correlation between first and second application scores of each item (P = 0.000).

Practical implications

The fact that the number of items is low will make implementation and evaluation stages easier. The scale can be easily administered to cancer patients. It is thought that using this scale will be beneficial in terms of evaluating the psychological impact of cancer on Turkish patients and will facilitate deciding

DOI: 10.5498/wjp.v13.i6.351 **Copyright** ©The Author(s) 2023.

Figure 1 Path diagram regarding the factor structure of the scale.

on whether patients require psychological support.

CONCLUSION

The present study shows that The Psychological Impact of Cancer Scale is a valid and reliable measurement tool in evaluating the psychological impact of cancer for Turkey sample. The scale can present new research opportunities for researchers who want to work in the field. In terms of researchers, it can be said that the scale is practical and economical since the number of items is low and the expressions are short in the scale.

ARTICLE HIGHLIGHTS

Research background

Cancer patients develop emotional, psychological and behavioural reactions before diagnosis, during diagnosis, during treatment, after treatment, during disease progression and during terminal /palliative periods.

Research motivation

Turkish scale adaptation.

Research objectives
To analyze the Turkish adaptation of The Psychological Impact of Cancer Scale (PICS).

Research methods
This methodological study was conducted with 257 cancer patients.

Research results
Cronbach Alpha value was 0.844. Exploratory factor analysis and Confirmatory factor analysis showed that Turkish form of 12-item and 4-factor.

Research conclusions
PICS Turkish version has acceptable validity. PICS is homogeneous and consistent for Turkish society. Healthcare professionals can use PICS.

Research perspectives
The use of the scale will be useful in evaluating the psychological impact of cancer on Turkish patients.

ACKNOWLEDGEMENTS

We are grateful to the individuals who participated in this study.

Abstract

BACKGROUND

Existing research has demonstrated that depression is positively related to smartphone addiction, but the role of sleep has not been discussed thoroughly, especially among engineering undergraduates affected by the coronavirus disease 2019 pandemic.

AIM

To evaluate sleep as a mediator of the association between smartphone addiction and depression among engineering undergraduates.

METHODS

Using a multistage stratified random sampling method, a cross-sectional survey was conducted among 692 engineering undergraduates from a top engineering university in China, and data were collected by self-reported electronic questionnaires. The data included demographic characteristics, such as age, gender, the Smartphone Addiction Scale-Short Version (SAS-SV), the 9-item Patient Health Questionnaire, and the Pittsburgh Sleep Quality Index. Pearson correlation and multiple linear regression analyses were used to examine the association between smartphone addiction and depression, while structural equation models were established to evaluate the possible mediating role of sleep.

RESULTS

Based on the cutoffs of the SAS-SV, the rate of smartphone addiction was 63.58 percent, with 56.21 percent for women and 65.68 percent for men, among 692 engineering students. The prevalence of depression among students was 14.16 percent, with 17.65 percent for women, and 13.18 percent for men. Smartphone addiction was positively correlated with depression, and sleep played a significant mediating effect between the two, accounting for 42.22 percent of the total effect. In addition, sleep latency, sleep disturbances, and daytime dysfunction significantly mediated the relationship between depression and smartphone addiction. The mediating effect of sleep latency was 0.014 [$P < 0.01$; 95% confidence interval (CI): 0.006-0.027], the mediating effect of sleep disturbances was 0.022 ($P < 0.01$; 95%CI: 0.011-0.040), and the mediating effect of daytime dysfunction was 0.040 ($P < 0.01$; 95%CI: 0.024-0.059). The influence of sleep latency, sleep disturbances, and daytime dysfunction accounted for 18.42%, 28.95%, and 52.63% of the total mediating effect, respectively.

CONCLUSION

The results of the study suggest that reducing excessive smartphone use and improving sleep quality can help alleviate depression.

Key Words: Smartphone addiction; Depression; Pittsburgh Sleep Quality Index; Engineering students; COVID-19; Mediating effect

Core Tip: This study described the prevalence of depression and smartphone addiction among engineering students during the coronavirus disease 2019 pandemic and analyzed the relationship between depression, smartphone addiction, and sleep. The results showed that there was an alarmingly high rate of smartphone addiction among engineering students, and they suffered from mild depression on average. Smartphone addiction and poor sleep were significant factors affecting depression, and sleep mediated the relationship between smartphone addiction and depression, including sleep latency, sleep disturbances, and daytime dysfunction.

INTRODUCTION

The prevalence of depression among college students has aroused broad public concern. A review of studies demonstrated that the pooled prevalence of depressive symptoms was 34%[1]. A recent study of American college students showed that 48.14% experienced moderate to severe levels of depression[2], and the prevalence rate of depression among Chinese college students from 1997 to 2015 reached 23.8% on average[3]. Furthermore, 41.8% of Chinese college students struggled with depressive disorders during the coronavirus disease 2019 (COVID-19) pandemic[4], especially those in places at high risk of COVID-19 spread who showed more severe depressive symptoms[5].

In particular, engineering undergraduates reported higher levels of depression than students in other majors[6]. The heavy academic burden and long study time create tremendous psychological pressure [7]. Previous studies noted that engineering students were under higher pressure than students with nonengineering majors[8,9]. They also had a higher prevalence of depression[10] and suffered from more severe depressive symptoms[8]. Given the importance of engineering education to national development and the adverse mental health of engineering students, it is crucial to identify the influencing factors of engineering students' depression in the context of the COVID-19 pandemic to develop interventions to improve their mental health.

Smartphone addiction is considered a behavioral addiction and refers to an excessive use of smartphones that interferes with users' daily life and has harmful effects[11]. Evidence from China indicated that the prevalence of smartphone addiction among college students ranges from 20% to 50% [12-14]. Notably, smartphone addiction is associated with mental health problems[15]. Smartphone addicts may suffer from social isolation and interpersonal relationship problems[16], musculoskeletal pain and neurological problems[17], emotion dysregulation[18], pressure, and anxiety[19], which may lead to depressive disorders. Previous empirical studies confirmed a positive correlation between

depression and smartphone addiction[20,21], and smartphone addiction exerted a significant effect on depression in different countries and regions[22,23]. However, the mechanism of smartphone addiction's relationship to depression has not been thoroughly discussed, so analyzing the pathway between smartphone addiction and depression is still an important area of study.

Sleep serves as the basis of personal emotional and physical health[24], and empirical studies have verified that poor sleep quality is significantly correlated with depression[25-28]. Some longitudinal studies have indicated that sleep disturbance triggers depression[29]. Lack of sleep makes individuals more sensitive to emotional and stressful stimuli[30], further increasing their risk of depression. According to the gratification theory of the internet, individuals extend their smartphone use time to obtain a sense of satisfaction[31]. Rich smartphone applications also cause addiction in people and make them lose their sense of time[31]. Therefore, problems such as sleep delay, lack of sleep, and poor sleep quality are very likely to occur among college students. Empirical studies have proven that smartphone addiction correlates significantly with poor sleep quality[32,33] and is considered a risk factor for poor sleep quality[34]. The literature in the field also implies that sleep plays a mediating role in smartphone addiction and depression; however, this has not been thoroughly discussed.

There are several research gaps according to the review of relevant studies. First, most of these studies are based on the general population of college students or medical students. More pertinent research needs to be explicitly explored for students of different majors, such as engineering students. Second, college students' mental health status has considerably changed since the outbreak of COVID-19, with a large proportion of students suffering from severe depression and anxiety. Therefore, it is necessary to explore the changes in depression, mobile phone addiction, and sleep status of college students under the influence of COVID-19 and investigate their relationship in this specific context. Third, the role of sleep in the relationship between mobile phone addiction and depression has been poorly analyzed. Although a few studies have confirmed that sleep mediates the relationship between smartphone addiction and depression[35], special attention has been given to engineering students, and the mediating role of sleep needs to be further discussed.

Therefore, this study carried out a cross-sectional survey among engineering students in the context of the COVID-19 pandemic. It adds to the literature mainly by analyzing the relationship between smartphone addiction, sleep, and depression among Chinese engineering students during COVID-19 and investigating the mediating role of sleep in the relationship between smartphone addiction and depression. Based on the extant empirical evidence, the present study hypothesized that there is a significant positive correlation between smartphone addiction and depressive symptoms (Hypothesis I) and that sleep significantly mediates the relationship between smartphone addiction and depression (Hypothesis II). Specifically, engineering students with higher levels of smartphone addiction in the context of the pandemic are more likely to struggle with sleep disorders, which further results in more severe depressive symptoms.

MATERIALS AND METHODS

Participants and procedure

The data were collected from an online survey of 692 engineering undergraduates at a top university in China in December 2021. This study adopted a multistage stratified random sampling method; first, five engineering schools were randomly selected from 25 engineering schools in the university, and then the respondents were randomly chosen according to the size of each school and the number of students in different years. Given the pandemic limiting the face-to-face investigation, the survey team sent electronic questionnaire links to the selected participants' mobile phone numbers or email accounts. All participants were notified of the purpose of the study and gave informed consent to participate. It took approximately 20 min on average to complete the questionnaire, after which students received a cash reward ranging from 8 CYN to 15 CNY. To avoid duplications or fraud in the online survey, the links were exclusive to each student and automatically became invalid after students completed and submitted the questionnaire. Participants were required to complete all questions before submitting the questionnaire. The participants in the study were Chinese engineering undergraduates aged 18-24. The study was reviewed by the ethics committee of Tianjin University and used the STROBE cross-sectional reporting guidelines.

The final sample comprised 153 females (22.11%) and 539 males (77.89%). The age of students ranged from 18 to 24 years old, and the mean age was 20.804 years old (SD = 1.109). Students were distributed evenly from freshmen to seniors, with 76 (10.98%), 242 (34.97%), 231 (33.38%), and 143 (20.67%), respectively. Among them, 608 (87.86%) were of Han nationality, and 84 (12.14%) were ethnic minorities. There were 439 (63.44%) only children and 253 (36.56%) with siblings. In terms of home location, 122 students (17.63%) were from rural areas, and 570 students (82.37%) were from towns. There were 343 (49.57%) students whose fathers completed tertiary education and 349 (50.43%) students whose fathers never received higher education. Regarding the types of high schools, 524 students (75.72%) attended the best local high schools, and 168 (24.28%) attended other high schools.

Measures

Depression: Students' depression was measured using the Patient Health Questionnaire-9 (PHQ-9), a part of the PHQ measuring depressive mood. The PHQ is a 3-page questionnaire self-assessed by patients[36], among which the 9-item depression module is used to measure depressive symptoms. Each item in the PHQ-9 ranges from 0 (no) to 3 (almost every day), and the total score ranges from 0 to 27, with higher scores representing more severe depression[37]. Most studies divide depression scores into five categories based on the severity of depression for practical applications, namely, minimal depressive symptoms (0-4), mild depression (5-9), moderate depression (10-14), moderately severe depression (15-19), and severe depression (20-27), and use a total score of no less than 10 as a reasonable threshold for screening depression[38].

Smartphone addiction: This study used the Smartphone Addiction Scale-Short Version (SAS-SV) to measure participants' smartphone addiction levels. The SAS-SV was adapted by Kwon *et al*[39] based on the SAS. They invited at least 6 experts to select 10 questions from the 33 questions in the SAS and verified that the CVI was greater than 0.78, and the average I-CVI and S-CVI/UA were 0.943 and 0.60. Kwon *et al*[39] verified a Cronbach's alpha correlation coefficient of 0.91 for the SAS-SV in Korea; thus, it was regarded as a suitable tool for assessing smartphone addiction. In this study, experts were invited to translate English SAS-SV questions into Chinese, and appropriate adaptations were made according to the actual situation. For example, in the original item, "constantly checking my smartphone so as not to miss conversations between other people on Twitter or Facebook", "Twitter or Facebook" was changed to "QQ or WeChat" to adapt to the Chinese context. The answers were reported on a 7-point scale, with 1 meaning "strongly disagree" and 7 meaning "strongly agree". The total SAS-SV scale ranges from 10 to 70. Previous studies confirmed that the critical values of male and female smartphone addiction were 31 and 33, respectively[40]. Since the original SAS-SV is a six-point scale with a score range of 10-60, the critical values of male and female smartphone addiction in the study are 36.2 and 38.5, respectively. SAS-SV has been proven reliable and valid in mainland China and Hong Kong. Luk *et al*[40] used the Chinese version of the SAS-SV to measure the smartphone use addiction of adults in Hong Kong and found that the SAS-SV had good internal consistency, with an α coefficient of 0.844. Cheung *et al*[41] tested the SAS-SV scale among Hong Kong children and adolescents, and the α coefficient was 0.86, indicating that the scale had good reliability and validity when applied to Chinese students.

Sleep quality: Sleep quality in the study was measured by the Pittsburgh Sleep Quality Index (PSQI), a 19-item self-assessment questionnaire. It included seven components: Sleep quality, sleep latency, sleep duration, habitual sleep efficiency, sleep disturbances, use of sleeping medication, and daytime dysfunction. The seven components, each scoring 0-3 points, constituted the sleep index, with higher scores denoting worse sleep quality[42].

Statistical analysis

First, descriptive statistical analysis was conducted to demonstrate the general situation of smartphone addiction, overall sleep quality, and depression among engineering students and to compare differences in gender subgroups with the t test. Second, the correlation between smartphone addiction, sleep, and depression was explored with Pearson's correlation analysis. Third, the influence of smartphone addiction on depression among engineering students was examined with multiple linear regression. Depression level was the outcome variable in the regression models, while smartphone addiction level and sleep quality were the core independent variables. It controlled for confounding variables such as students' age, gender, ethnicity, political status, only child status and family socioeconomic status. To identify the effects of different variables, we successively included control variables, smartphone addiction, and sleep in the multiple regression model. Specifically, Model 1, $Y = \beta_0 + \beta_1 x' + \varepsilon$, was developed first to include control variables on engineering students' depression. Mobile phone addiction was further included in Model 2, $Y = \beta_0 + \beta_1 x' + \beta_2 SA + \varepsilon$. The seven sleep index components were then incorporated into Model 3, $Y = \beta_0 + \beta_1 x' + \beta_2 SA + \beta_3 SleepQuality + \beta_4 SleepLatency + \beta_5 SleepDuration + \beta_6 HabitualSleepEfficiency + \beta_7 SleepDisturbances + \beta_8 SleepMedication + \beta_9 DaytimeDysfunction + \varepsilon$. Y denotes the level of depression of engineering students at college. SA represents the degree of smartphone addiction. "x'" represents the control variables, including students' age, gender, ethnicity, political status, only child status, family socioeconomic status, and whether their father received higher education. "ε" defines the error. Finally, a structural equation model was built to examine the mediating role of sleep in the relationship between smartphone addiction and depression. Data analysis was performed by Stata SE 15.

RESULTS

Descriptive statistics and correlations of variables

Table 1 shows the mean and SD of depression, smartphone addiction, and overall sleep quality. The

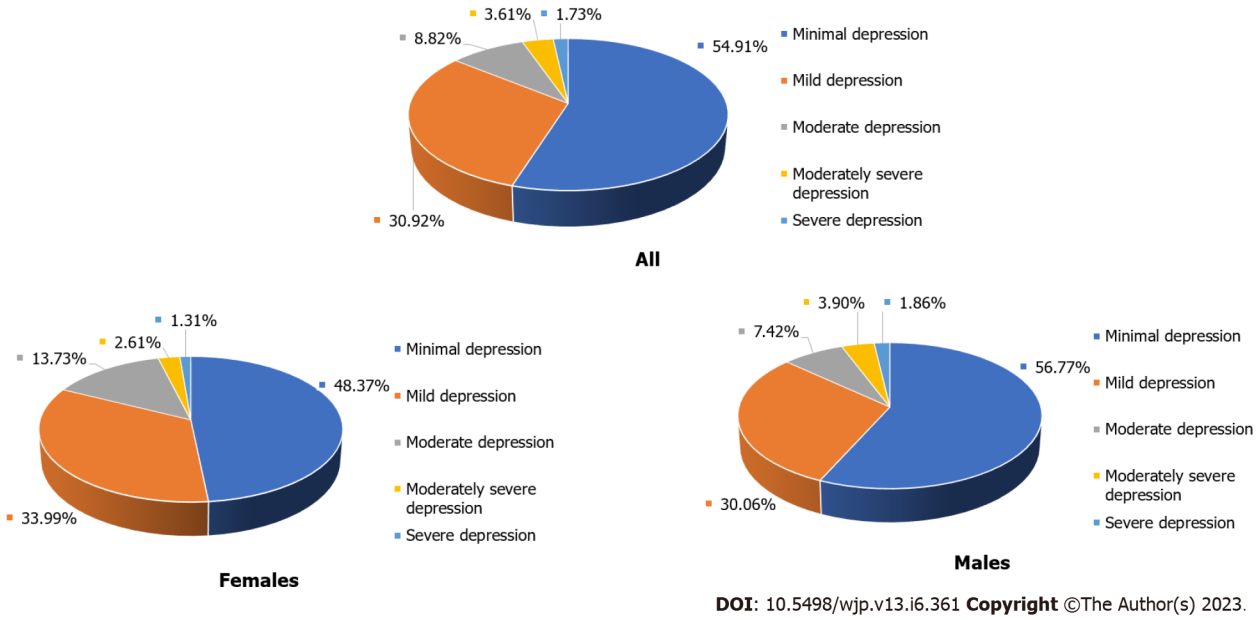
Bold represents statistically significant.

mean score of depression among engineering students was 5.082 (± 4.971); the average score of females was 5.425 (± 4.656), and the average score of males was 4.985 (± 5.056). In general, engineering students experienced mild depression at college, and there was no statistically significant difference in the mean level of depression between female and male students. Regarding the prevalence of depression (Figure 1), 54.91%, 30.92%, 8.82%, 3.61%, and 1.73% of the students exhibited minimal, mild, moderate, moderately severe, and severe depression, respectively. For female students, 82.36% had minimal or mild depression, while 3.92% had moderate or severe depression. For males, 86.83% had minimal or mild depression, whereas 5.76% struggled with moderately severe or severe depression. Given that the extant literature usually uses a PHQ-9 total score of no less than 10 to distinguish whether the participants suffer from depression, 14.16% of students experienced depression disorders (depression ≥ 10), and female and male students who suffered from depressive disorders accounted for 17.65% and 13.18%, respectively (Table 1, Figure 1).

The mean value of mobile phone addiction was 39.126 (± 11.252); the score for females was 39.000 (± 10.668), and the score of males was 39.161 (± 11.422). There was also no significant gender difference in the average mobile phone addiction level. It should be noted that 63.58% of engineering students were addicted to mobile phones, with 56.21% of females and 65.68% of males being addicted to mobile phones. The mean sleep quality score was 5.496 (± 2.827), with female students scoring 5.856 (± 3.023) and males scoring 5.393 (± 2.763). The sleep quality of females was significantly worse than that of males (P = 0.074). Specifically, among the seven components of the sleep quality index, day dysfunction showed a significant gender difference, with girls having higher perceived day dysfunction than boys (P < 0.010).

In sum, smartphone addiction among engineering students was alarming, with more than 60% exhibiting smartphone addiction, which is higher than that reported by most studies in other countries [43-46]. In addition, engineering students suffered from mild depression on average, and female students had more serious sleep problems than males.

The correlation analysis shown in Table 2 demonstrated that depression was positively correlated with mobile phone addiction, with a coefficient of 0.330 (P < 0.01). There was also a positive correlation between depression and PSQI, with a coefficient of 0.503 (P < 0.01). Mobile phone addiction and PSQI were significantly positively correlated with a coefficient of 0.250 (P < 0.01). In addition, depression was positively correlated with the seven components of the sleep index, among which daytime dysfunction had the strongest correlation with a coefficient of 0.414. Mobile phone addiction had a statistically significant positive correlation with sleep quality, sleep latency, sleep disturbances, and daytime dysfunction, among which the strongest correlation was also with daytime dysfunction, with a coefficient of 0.246. The results revealed that depression, smartphone addiction, and sleep index were closely related. The increased risk of smartphone addiction might not only predict the deterioration of sleep quality but also lead to an increase in depressive mood (Table 2).



Multivariate regression of depression on smartphone addiction and sleep

The regression model sequentially included the control variables, mobile phone addiction, and sleep index (Table 3). Model 1 shows the influence of engineering students' age, gender, nationality, political status, household registration, and other factors on depression (R^2 = 0.011). Model 2 further displays the

Figure 1 Prevalence of depression among engineering students, *n* = 692.

impact of smartphone addiction and control variables on depression ($R^2 = 0.116$). For every one-point increase in the mobile phone addiction score, the average depression score increased significantly by 0.141 among engineering students. Model 3 depicts the influence of the seven components of the sleep index, mobile phone addiction, and control variables ($R^2 = 0.352$). Sleep latency, sleep duration, sleep disturbance, sleep medication, daytime dysfunction, and smartphone addiction significantly affected the depressive mood of students, among which sleep disturbances had the most considerable effect. For every additional point scored by the sleep disturbances, the average depression score of students increased significantly by 1.817. The regression coefficient of smartphone addiction on depression in Model 3 was lower than that in Model 2, indicating that smartphone addiction may indirectly affect depressive mood by affecting sleep quality (Table 3).

Path analysis

This study further established a structural equation model of mobile phone addiction, sleep index, and depression based on correlation and regression analyses to explore possible mediating effects (Figure 2). According to the results in Table 4, the total effect of smartphone addiction on depression was 0.180 ($P <$ 0.01; 95%CI: 0.134-0.233), with the direct effect of smartphone addiction on depression being 0.104 ($P <$

Figure 2 Structural equation model of depression, *n* = 692.

DISCUSSION

This study analyzed the relationship between smartphone addiction and depression among engineering students, which has been extensively discussed in the extant literature, yet the underlying mechanisms need to be further explored and verified in diverse contexts and among different populations. The results generally support the hypotheses that smartphone addiction is a significant predictor of depression and that sleep mediates the effect of smartphone addiction on depression. Therefore, alleviating smartphone addiction and improving sleep quality could be an effective strategy to reduce the incidence of depression among engineering students.

The study found a high prevalence rate of smartphone addiction of 63.58% among engineering students in China, with that of male students at 65.68% and female students at 56.21%. The addiction rate appeared to be much higher than in other regions or populations, such as 11.8% in Taiwan[47], 36.8% in Nepal[48], and 41.93% of medical students in Asian countries[49]. There are two reasons for our study's high prevalence of smartphone addiction apart from different cultural backgrounds or various measurement tools. First, given that engineering students usually confront heavy learning tasks and relatively poor face-to-face communication, smartphones might be essential for them to release pressure and maintain social networking. Second, the survey was conducted amid the coronavirus pandemic, which may have exacerbated smartphone addiction among college students. Indeed, the risk of smartphone addiction increased due to the fear of contracting the disease, reduced social interactions due to lockdowns, and long hours of online education. Previous empirical studies confirmed that the smartphone addiction rate of college students in the beginning and fading periods of the pandemic was significantly lower than that in the severe period[50]. It should also be noted that the gender difference in mobile phone addiction in this study was insignificant, inconsistent with existing research findings [24]. This may be due to the small percentage of female engineering students and the widespread influence of online teaching on engineering students.

The prevalence of depression among engineering students in the study was 14.16%, and most students (85.83%) experienced minimal or mild depression during COVID-19. Relevant research found that the prevalence rate of depression among college students was 9.0% in China one month after the outbreak of COVID-19[51] and 34.19% in Spain in March 2020[52]. Forty-four percent of students experienced some depressive thoughts during the COVID-19 pandemic in the United States[53]. The prevalence of depression among engineering students in this study was within the rate range of previous studies, which may be related to the time of the survey. The study was conducted in December 2021, when the pandemic spread was effectively contained, and college students returned to school. The general situation had improved at this stage, and relevant fear and worries had been alleviated, although their study life was still partially affected by the pandemic.

Pearson correlation and multiple regression analysis verified Hypothesis I that smartphone addiction was a significant influencing factor of depression and that high levels of smartphone addiction caused more serious depressive symptoms among engineering students. The result was consistent with most previous studies that there was a positive correlation between mobile phone addiction and depression [21,22,54,55]. The influence of smartphone addiction on depression can be explained by the effect on physiological health and social relations. First, smartphone addiction may result in individuals' unhealthy states, including physical pain, sleep disorders, and inattention, leading to mental health problems such as depression[56]. Second, the overuse of smartphones may increase social isolation and aggravate social anxiety due to the reduction of face-to-face communication and the narrowing of social circles, thus increasing the risk of depression, according to displacement theory and Sullivan's interpersonal theory[57]. The longitudinal study by Herrero *et al*[58] strongly confirmed that smartphone addiction negatively affected college students' social support over time and generated high levels of depression.

For smartphone addiction as a predictor of poor sleep outcomes, the findings agree with most relevant research[59,60]. The overuse of smartphones may expose individuals to blue light from screens for a long time, affecting melatonin levels and thus normal circadian rhythm[61]. Furthermore, when users browse social networking sites through smartphones, the intensity of emotional synchronization may be amplified, resulting in emotional contagion[62]. Smartphone addiction affects the emotions of mobile phone users[35] and increases their psychological pressure[63], thus affecting their normal sleep procedure. In particular, the continuous use of smartphones may lead to bedtime procrastination[31]. The study also found that smartphone addiction was related to sleep quality but not sleep duration, which is consistent with the findings of relevant studies in this field[21,64,65].

Poor sleep positively predicted depressive symptoms in engineering students, especially the components of sleep latency, sleep duration, sleep disturbances, sleep medication, and daytime dysfunction. This finding partially coincides with prior studies[66,67]. Hypothesis II confirms that sleep plays a mediating role in the effect of smartphone addiction on depression, especially sleep latency, sleep disturbances and daytime dysfunction. In fact, poor sleep may affect the emotional regulation ability of the individual through a physiological mechanism[68], and a lack of sleep increases the threat across multiple domains of dysfunction[69]. Sleep is associated with depression at the molecular and neurophysiological levels, and abnormalities in these neurotransmitter systems associated with sleep disorders may contribute to the exacerbation of depression[70]. In addition, sleep disorders affect students' daytime function, resulting in daytime sleepiness, drowsiness, and inattention. This interferes with students' daily tasks and reduces their interest in activities, exposing them to stress and irritability and worsening depressive symptoms[67].

The role of daytime dysfunction was noticeable in both the direct and indirect effects of depression. The influence of daytime dysfunction on depression has been partially confirmed by studies[71,72]. Daytime dysfunction can be regarded as the primary link between night sleep and depression[73]. In fact, daytime dysfunction is closely related to fatigue and burnout[74]. People with high levels of daytime dysfunction tend to be more tired and therefore more vulnerable to depressive moods.

This study suggests that colleges and universities can alleviate depression among students by intervening in smartphone addiction and improving sleep. Studies have discussed effective interventions to reduce smartphone addiction, such as self-awareness and self-control, involuntary restriction, and peer support[75]. College students in adulthood should be soberly aware of the harm of smartphone addiction and seek scientific interventions when necessary. For instance, cognitive behavioral therapy (CBT) was proven effective in a meta-analysis of treatment interventions for adolescents with internet addiction[76]. The group mindfulness-based cognitive-behavioral intervention [77] and mind-body exercise (ME)[78] have been shown to be helpful in the intervention of smartphone addiction among Chinese college students. Thus, cognitive behavioral interventions and MEs (*e.g.*, QigongBaduanjin) should be encouraged. For involuntary restraint, using technology against it, a new mode of intervention for treating smartphone addiction, focuses on monitoring and limiting the use of smartphones with functionalities built into the smartphone and third-party apps. Empirical studies have found that ways to limit notifications and reduce screen time are becoming more widely accepted[79, 80]. Social support, such as favorable peer relationships and harmonious family relationships, is also a protective factor against smartphone addiction[81]. In addition, colleges and universities should also make efforts to expand the accessibility of mental health services to alleviate smartphone addiction.

In addition, physical exercise is the most common way to enhance sleep quality, and sleep therapy training is also practical in improving the sleep situation of college students[82]. For example, sleep training programs for university students with sleep problems proved feasible to significantly enhance students' sleep quality[83]. Psychological interventions such as cognitive behavior therapy for insomnia (CBT-I) have also been recommended to improve sleep[84]. Other interventions, such as improving sleep hygiene, relaxation, mindfulness and hypnotherapy, also play a role in improving sleep quality [85]. Therefore, college students should be encouraged to strengthen their physical exercise, improve their sleeping conditions and restrict mobile phone use to ensure sleep time and quality. For students with serious sleep problems, necessary psychological intervention and medical treatment should be carried out in time to avoid deterioration of the problem and more severe sleep disorders and psychological problems.

The study has several limitations. First, the self-reported data by students may have measurement errors. For example, students may underestimate their smartphone addiction tendency, sleep disorders, and depressive symptoms. Second, other possible influencing factors of depression, such as stress and self-esteem, were not included in this study's analysis framework for assessment. Third, there may exist sample selection bias in the analysis results since written informed consent was obtained before students entered the questionnaire, and those who refused to consent were not included in the sample of this study. Fourth, the cross-sectional data used in this study make it difficult to identify the causal relationship between smartphone addiction and depression. Future studies may investigate the causal relationship between smartphone addiction and depression based on longitudinal data and incorporate more factors into the theoretical mechanisms to discover more effective measures.

CONCLUSION

This cross-sectional study investigated the relationship between smartphone addiction and depression and examined the mediating role of sleep among engineering students in China. First, there was an alarmingly high rate of smartphone addiction among engineering students with no significant gender difference, which has become an urgent issue requiring attention from all parties. In addition, engineering students suffered from mild depression on average, and female students had more severe sleep problems than males. Second, smartphone addiction and sleep deterioration were significant factors affecting depression among engineering students, which might increase the risk of their depressive disorders. Third, sleep latency, sleep disturbances, and daytime dysfunction mediated the relationship between smartphone addiction and depression, among which daytime dysfunction had the most pronounced mediating effect.

The effects of smartphone addiction and sleep on depression may be complicated. Existing literature has confirmed that smartphone addiction could increase the risk of individual depression not only through social reasons (such as social difficulties and task conflicts) but also by affecting physiological functions (such as insomnia and physical pain). In addition, the mediating role of sleep should be considered thoroughly. Sleep disorders can increase the risk of depression by influencing students' emotional control and regulation function or affecting their learning behaviors. Therefore, depression can be alleviated by reducing the use of smartphones and improving sleep quality. Colleges and universities can take measures to relieve depressive problems and improve engineering students' mental health, such as enhancing their self-control ability, restricting mobile phone use, creating a soothing sleep environment, developing a daily routine, and improving physical fitness.

ARTICLE HIGHLIGHTS

Research background

It has been reported that engineering students have severe depressive symptoms, especially during the epidemic. Published research confirms a positive correlation between smartphone addiction and depression. Sleep may play a mediating role in the relationship between smartphone addiction and depression. However, this hypothesis has not been carefully studied in the engineering student population.

Research motivation

Although it is reasonable that sleep plays a mediating role in the relationship between smartphone addiction and depression, this hypothesis has not been discussed in detail. The motivation of this study is to explore the mediating role of sleep in the relationship between smartphone addiction and depression among engineering students.

Research objectives

To investigate whether sleep plays a significant mediating role in the relationship between smartphone addiction and depression among engineering students.

Research methods

During the coronavirus disease 2019 pandemic, we conducted an online survey of 692 engineering students from an engineering university in Beijing, China. The Smartphone Addiction Scale-Short Version was used to assess smartphone addiction. Depression was measured using the 9-item Patient Health Questionnaire. The Pittsburgh Sleep Quality Index was used to measure sleep. We used multivariate regression models and structural equation model analysis to evaluate sleep as a mediator.

Research results

Among 692 engineering students, the rate of smartphone addiction was 63.58%, and the prevalence of depression was 14.16%. According to a multivariate regression model, smartphone addiction and sleep significantly affect depression. Sleep plays a significant mediating role in the relationship between smartphone addiction and depression.

Research conclusions

Current research shows that sleep is a mediator between smartphone addiction and depression. Controlling smartphone use and improving sleep quality can help alleviate depression.

Research perspectives

Future longitudinal studies need to verify the mediating role of sleep in the association between smartphone addiction and depression. In addition, more variables (such as stress and anxiety) need to be controlled for and considered.

ORIGINAL ARTICLE

Observational Study

Prevalence of posttraumatic stress disorder following acute coronary syndrome and clinical characteristics of patients referred to cardiac rehabilitation

Ivana Sopek Merkaš, Nenad Lakušić, Zdenko Sonicki, Barbara Koret, Sandra Vuk Pisk, Igor Filipčić

Specialty type: Psychiatry

Provenance and peer review: Invited article; Externally peer reviewed.

Peer-review model: Single blind

Abstract

BACKGROUND

Studies have demonstrated that patients who have experienced acute coronary syndrome (ACS) have an increased risk of developing posttraumatic stress disorder (PTSD) and experiencing worse survival outcomes than those who do not develop PTSD. Nevertheless, the prevalence rates of PTSD following ACS vary widely across studies, and it is noteworthy that in most cases, the diagnosis of PTSD was based on self-report symptom questionnaires, rather than being established by psychiatrists. Additionally, the individual characteristics of patients who develop PTSD after ACS can differ widely, making it difficult to

identify any consistent patterns or predictors of the disorder.

AIM

To investigate the prevalence of PTSD among a large sample of patients undergoing cardiac rehabilitation (CR) after ACS, as well as their characteristics in comparison to a control group.

METHODS

The participants of this study are patients who have experienced ACS with or without undergoing percutaneous coronary intervention and are enrolled in a 3-wk CR program at the largest CR center in Croatia, the Special Hospital for Medical Rehabilitation Krapinske Toplice. Patient recruitment for the study took place over the course of one year, from January 1, 2022, to December 31, 2022, with a total of 504 participants. The expected average follow-up period for patients included in the study is about 18 mo, and currently ongoing. Using self-assessment questionnaire for PTSD criteria and clinical psychiatric interview, a group of patients with a PTSD diagnosis was identified. From the participants who do not have a PTSD diagnosis, patients who would match those with a PTSD diagnosis in terms of relevant clinical and medical stratification variables and during the same rehabilitation period were selected to enable comparability of the two groups.

RESULTS

A total of 507 patients who were enrolled in the CR program were approached to participate in the study. Three patients declined to participate in the study. The screening PTSD Checklist-Civilian Version questionnaire was completed by 504 patients. Out of the total sample of 504 patients, 74.2% were men (n = 374) and 25.8% were women (n = 130). The mean age of all participants was 56.7 years (55.8 for men and 59.1 for women). Among the 504 participants who completed the screening questionnaire, 80 met the cutoff criteria for the PTSD and qualified for further evaluation (15.9%). All 80 patients agreed to a psychiatric interview. Among them, 51 patients (10.1%) were diagnosed with clinical PTSD by a psychiatrist according to Diagnostic and Statistical Manual of Mental Disorders criteria. Among the variables analyzed, there was a noticeable difference in the percentage of theoretical maximum achieved on exercise testing between the PTSD and non-PTSD groups. Non-PTSD group achieved a significantly higher percentage of their maximum compared to the PTSD group (P = 0.035).

CONCLUSION

The preliminary results of the study indicate that a significant proportion of patients with PTSD induced by ACS are not receiving adequate treatment. Furthermore, the data suggest that these patients may exhibit reduced physical activity levels, which could be one of the possible underlying mechanisms in observed poor cardiovascular outcomes in this population. Identifying cardiac biomarkers is crucial for identifying patients at risk of developing PTSD and may derive benefits from personalized interventions based on the principles of precision medicine in multidisciplinary CR programs.

Core Tip: The preliminary results of the first large-scale study on a sample of cardiac rehabilitation (CR) patients with posttraumatic stress disorder induced by acute coronary syndrome indicate a significant number of patients who have a persistently increased risk of adverse events, and yet are still insufficiently recognized and treated. The study demonstrates that one possible mechanism of poorer outcomes is the avoidance of physical activity. A multidisciplinary approach involving cardiologists, psychiatrists, and psychologists is required for the identification and early intervention in these patients, and CR and comprehensive social support play a critical role.

INTRODUCTION

There is evidence to suggest that mental health disorders such as chronic stress, anxiety, and depression are linked to adverse cardiovascular outcomes[1,2]. In particular, stress-related disorders, especially posttraumatic stress disorder (PTSD)[3,4], have been identified as independent risk factors for acute cardiac events[5-7]. There are presumed different interaction mechanisms through which PTSD is associated with cardiovascular diseases. These include psychological (ability to adapt to stress, personality profile, personal traits, social interactions), behavioral (smoking, alcohol, diet, sleep disorders, adherence to prescribed therapy), and biological factors (neuroendocrine dysfunction involving metabolic syndrome, hypothalamic-pituitary-axis dysfunction, inflammation, renin-angiotensin system dysregulation, autonomic nervous system dysfunction)[7-9].

Furthermore, there is a growing recognition of acute coronary syndrome (ACS) as a potential precipitating event for PTSD[10-12], which is now increasingly acknowledged as a medical issue, prompting questions about its prevalence and clinical implications. It has been observed that patients who develop PTSD following an ACS have a higher risk of experiencing recurrent myocardial infarction (MI) and higher mortality rates[5,11,13]. A meta-analysis from 2012 reported a 12% prevalence of significant PTSD symptoms following ACS[11], while a 2021 systematic review found a prevalence range of 3% to 19%[13]. It's worth noting that the higher prevalence rates were observed when PTSD was assessed through self-report questionnaires compared to clinical diagnostic interviews conducted by a psychiatrist who made the diagnosis.

Reports on the characteristics of individuals who develop PTSD after ACS vary greatly, and there is no consensus on the specific demographic or biological risk factors that contribute to its development. In the systematic review from 2021 the authors reported several risk factors for PTSD following MI, including female gender, younger age and prior history of psychiatric disorders[13]. However, the individual characteristics of those who develop PTSD after ACS can differ widely, making it difficult to identify any consistent patterns or predictors of the disorder. Identifying patients at risk for persistent and severe ACS-induced PTSD based on demographic, biological and psychological factors could facilitate the implementation of early preventive measures[14].

While there is a significant correlation between PTSD and acute cardiac events, research on PTSD development following ACS is not as advanced. As a result, mechanisms of interaction are poorly understood. ACS-induced PTSD is associated with an increased risk of recurrence, but this risk is most prominent during the first year after the cardiovascular event, which is much shorter than the time frame required for many of the potential mechanisms linking PTSD to cardiovascular diseases[5]. Early identification and intervention are crucial, especially during this first year, when patients participate in cardiac rehabilitation (CR), which offers a unique opportunity for timely recognition and management of high-risk patients, potentially leading to improved outcomes.

MATERIALS AND METHODS

Study design

This ongoing observational, prospective, analytical case-control study presents preliminary findings on the number of patients who developed PTSD diagnosed by a psychiatrist after an ACS in a sample of patients undergoing CR, and their demographic, behavioral and biological characteristics compared to the control group.

Study subjects

This study enrolled patients who experienced ACS, with or without undergoing percutaneous coronary intervention (PCI), and who were participating in a 3-wk CR program at the at the Special Hospital for Medical Rehabilitation Krapinske Toplice, the largest CR center in Croatia. Patient recruitment for the study spanned a year (from January 1, 2022 to December 31, 2022), and the study ultimately included 504 participants. The expected follow-up period is approximately 18 mo and is currently ongoing. Inclusion criteria: Patients who have completed one month after an ACS (stressful event) before arriving at rehabilitation, both sexes, aged between 18 and 70 years. Exclusion criteria: Patients with a history of cardiac surgery, repeated MI, active psychiatric treatment, diagnosed psychiatric disorder or previously diagnosed PTSD from another cause, active malignancy, clinically unstable patients (acute heart failure, unstable coronary disease, acute infection), and patients who do not wish to participate in the study. Exclusion criteria are also applied to those who develop conditions that are defined as exclusion criteria during data collection, or those who no longer wish to participate in the study.

To identify patients with PTSD, a combination of self-assessment questionnaires and clinical psychiatric interviews were used. The initial screening of patients who agreed to participate in the study involved the use of the PTSD Checklist-Civilian Version (PCL-C) questionnaire[15,16]. For the purposes of this study, the recommended cutoff score for suggesting the possibility of PTSD based on the questionnaire was 30-35 points, given the civilian population. A combination of both scoring methods was employed, using a higher threshold score (35 points) and the requirement of a symptom pattern to

minimize the number of false positives. Participants who met the criteria based on the questionnaire underwent a clinical psychiatric interview, and those who were diagnosed with PTSD in accordance with Diagnostic and Statistical Manual of Mental Disorders (DSM-5) classification[17] by the psychiatrist were included in the group of patients with PTSD (Figure 1).

From the pool of study participants who did not receive a PTSD diagnosis, a subset of individuals was selected for further analysis based on clinically and medically relevant stratification variables such as age, gender, type of ACS [ST-elevation MI (STEMI), non-STEMI (NSTEMI), or unstable angina (UA)], who underwent rehabilitation during the same period. They form a second group of participants that matches the characteristics of those with a PTSD diagnosis, in order to enable comparability of the two groups.

Data collection

The study obtained medical data through a patient's anamnesis, including their age, gender, lifestyle habits such as smoking and alcohol consumption, family history of cardiovascular disease (positive or negative), comorbidities such as hypertension, dyslipidemia, diabetes, and body mass index (BMI). Additionally, diagnostic tests were conducted during the three-week rehabilitation period to obtain data on important biological characteristics [laboratory testing, exercise stress test (ergometry), echocardiogram].

Follow-up

The expected average follow-up period of patients in the study is approximately 18 mo and is currently ongoing. Both groups of patients will be contacted (letter sent by post along with questionnaires and subsequently contacted by phone). They will complete the PCL-C scale again, a questionnaire on quality of life, medication adherence, and report any adverse cardiovascular events. In case it is not possible to contact the patient, data will be obtained from family members or primary care physician. After the end of the study, further analysis of the collected data will follow, and the obtained results and conclusions should direct attention to a subpopulation of patients in terms of precision medicine (identification of specific groups of patients).

Statistical analysis

We used the SPSS 29.0.0.0 statistical software package, setting significance level at $P < 0.05$ (2-tailed). For clarity, we present all data in original units (mean ± SD, ranges). For calculations of differences between groups, the student' t test, χ^2 test, Fisher's exact test and Mann Whitney test were used.

Ethical considerations

The study protocol was approved by the ethics committee of the Special Hospital for Medical Rehabilitation Krapinske Toplice. Data regarding patients were extracted from routine medical and treatment records. Patient identities have not been revealed. Written informed consent was obtained from every patient who agreed to participate in the study. All the methods followed the guidelines of the Declaration of Helsinki for medical research involving human subjects.

RESULTS

A total of 507 patients who were enrolled in the CR program were approached to participate in the study, out of which 3 patients refused to participate. The PCL-C questionnaire was completed by 504 patients. Of these, 74.2% (n = 374) were men and 25.8% (n = 130) were women. The mean age of all participants was 56.7 years (55.8 years for men and 59.1 years for women). Out of the 504 participants, 80 individuals met the cutoff criteria for PTSD on the screening questionnaire and qualified for further evaluation, representing 15.9% of the total sample. All 80 patients agreed to psychiatric interview. Among them, 51 patients (10.1%) were diagnosed with clinical PTSD by a psychiatrist according to DSM-5 criteria (Figure 1, Table 1).

From 51 PTSD patients, 32 were male (62.7%) and 19 female (37.3%). The average age of male participants diagnosed with PTSD was 52.8 years (range 42-65), and for female it was 56.5 years (range 42-66). Of these PTSD patients, 39 suffered STEMI (76.5%), 12 NSTEMI (23.5%), and there were no cases of PTSD following UA (Table 2).

Patients' characteristic

This preliminary report of the study presents findings on the investigation of demographic, behavioral, and particularly biological factors, and examines the differences in individual characteristics between PTSD and non-PTSD group (which was formed based on clinically and medically relevant variables such as age, gender, type of ACS), and the results are summarized in the table (Table 3).

Among the variables included, the PTSD group had a significantly lower percentage of maximum exercise capacity achieved compared to the non-PTSD group (P = 0.03). No significant differences were

Table 1 All patients included in the study

General data	Value
Patients	504
Age	56.68 ± 7.82 (27-70)
Male patients	374 (74.21%)
Male patients age	55.85 ± 8.04 (27-70)
Female patients	130 (25.79%)
Female patients age	59.05 ± 6.6 (44-70)
PTSD patients after PCL-C questionnaire	80 (15.87%)
Diagnosed PTSD patients	51 (10.12%)

Data are given as mean ± SD (ranges) or values (percentages). PTSD: Posttraumatic stress disorder; PCL-C: Posttraumatic stress disorder Checklist-Civilian Version.

Table 2 Posttraumatic stress disorder/pairs included in the study

General data	Value
Patients in each group	51
Age	54.16 ± 6.64 (42-66)
Male patients	32 (62.75%)
Male patients age	52.78 ± 6.53 (42-65)
Female patients	19 (37.25%)
Female patients age	56.47 ± 6.32 (42-66)
STEMI	39 (76.47%)
NSTEMI	12 (23.53%)
UA	0 (0.0%)

Data are given as mean ± SD (ranges) or values (percentages). STEMI: ST-elevation myocardial infarction; NSTEMI: Non-ST elevation myocardial infarction; UA: Unstable angina.

found in commonly observed comorbidities in cardiology patients such as hypertension, diabetes, dyslipidemia, and BMI.

In the study, there were participants who underwent a second PCI as an elective procedure after an acute event and those who experienced cardiorespiratory arrest and other complications following MI. Within the PTSD group, 7 participants (13.7%) underwent an elective PCI during hospitalization due to MI, while in the non-PTSD group, the number was 12 (23.5%). Acute heart failure was reported as a complication of MI in one male participant from each group. Within the PTSD group, one participant had a complication of surgically treated ventricular septal defect, while in the non-PTSD group, one female participant experienced post-procedural atrial fibrillation that was successfully converted to sinus rhythm using amiodarone. In both groups, two patients experienced cardiac arrest and were successfully resuscitated. Complications occurring during the acute phase of ACS and repeated PCI did not prove to be significant risk factors for developing PTSD.

DISCUSSION

To our knowledge, this is the first study on a large sample of CR patients that investigates the prevalence of PTSD after ACS, characteristics of these patients, and possible factors important for clinicians to recognize such patients in a timely manner. Consistent with prior research, it has been demonstrated that the prevalence of PTSD is lower when diagnosed by a psychiatrist rather than relying solely on self- administrated questionnaires. The results confirm that the diagnosis of PTSD after ACS made by a psychiatrist is approximately 10%, which exceeds the prevalence reported in meta-analysis

Table 3 Characteristics of patients

Variable	PTSD	Non-PTSD	*P* value
BMI	29.09 ± 4.15 (21.9-41.9)	28.58 ± 4.15 (20.5-36.4)	0.5373
Smoking	31 (60.78%)	26 (50.98%)	0.3187
Alcohol use	0 (0.0%)	2 (3.92%)	0.495
Family history of cardiovascular diseases	23 (45.1%)	30 (58.82%)	0.1654
History of hypertension	26 (50.98%)	31 (60.78%)	0.3187
History of dyslipidemia	18 (35.29%)	19 (37.25%)	0.8368
History of diabetes	10 (19.61%)	7 (13.73%)	0.4254
LDL	2.15 ± 0.8 (1.1-4.5)	2.28 ± 0.64 (0.9-3.3)	0.3481
LVEF	53.27 ± 10.81 (25-75)	55.78 ± 9.12 (30-76)	0.2078
LVDd	52.2 ± 10.81 (43-66)	50.78 ± 9.12 (41-68)	0.2462
Theoretical maximum percentage in exercise test	88.55 ± 13.35 (46-114)	94.24 ± 13.58 (44-124)	0.0354
WATT in exercise test	126.96 ± 39 (50-200)	132.65 ± 47.83 (50-225)	0.512
METs in exercise test	6 ± 1.36 (2.8-9.89)	6.3 ± 1.45 (3.5-9.29)	0.2754
MPRH percentage in exercise test	76.76 ± 11.02 (54-103)	79.04 ± 9.76 (54-103)	0.2726
PCI in second act	7 (13.73%)	12 (23.53%)	0.2035
Positive exercise test	4 (7.84%)	4 (7.84%)	-
Acute complications	2 (3.92%)	2 (3.92%)	-
Arrest	2 (3.92%)	2 (3.92%)	-

Data are given as mean ± SD (ranges) or values (percentages). BMI: Body mass index; LDL: Low-density lipoprotein; LVEF: Left ventricular ejection fraction; LVDd: Left ventricular diastolic diameter; METs: Metabolic equivalents; MPHR: Maximal predicted heart rate; PCI: Percutaneous coronary intervention.

[11] and literature review[13], but similar prevalence has been reported[18]. If only a self-reported questionnaire is used to assess the PTSD symptoms, reported prevalence can be up to 16%. These findings highlight the significant impact of this clinical disorder on a substantial group of patients who

are often underdiagnosed and at increased risk for poor clinical outcomes.

The biological mechanisms in PTSD have been extensively reviewed and could potentially contribute to the modification of cardiac and vascular functions, ultimately leading to the development of cardiovascular events[19,20]. These mechanisms involve a complex set of pro-inflammatory, pro-atherogenic, pro-ischemic, neuro-hormonal, metabolic, and immune reactions. As presented in the table, numerous biological factors were examined regarding the ACS-induced PTSD (Table 3). While no significant differences were found in commonly observed comorbidities (hypertension, diabetes, dyslipidemia, BMI) as well as in left ventricular ejection fraction, the study introduced a novel approach by using results from an exercise stress test which showed a significant difference between the two groups. A standardized protocol is used to measure the maximum amount of oxygen an individual can consume during exercise (VO_2max) and to estimate the maximum watts a patient should attain during the exercise test[21]. The non-PTSP group achieved a significantly higher percentage of their theoretical maximum compared to the PTSP group. Recent research shows that patients with PTSD following ACS may avoid physical activity if they experience cardiac symptoms such as dyspnea and tachycardia, which can be reminiscent of the traumatic event[22]. Our study further confirms that this could be an underlying mechanism that contributes to the negative prognosis of patients with ACS-induced PTSD.

Complications related to ACS, repeated PCI, and even cardiac arrest during the acute phase did not show a significant association with the development of PTSD. However, previous study demonstrated that cardiac arrest-induced posttraumatic symptoms are linked to an increased risk of mortality and cardiovascular disease[23].

A recent meta-analysis provides further support evidence that the presence of PTSD is a risk factor for the subsequent development recurrent cardiac events, such as MI[24]. Due to the significant prevalence of PTSD after ACS, which was confirmed in this study, further research is needed to identify the mediating factors involved in the direct association between PTSD and the subsequent occurrence of adverse cardiovascular events in more precise medical terms.

The latest study highlights the increasing acknowledgement of the importance of social support and the role of CR, emphasizing comprehensive, multidisciplinary approach and early intervention has the potential to exert a favorable effect on the outcomes of these patients[25]. Early psychological assessment and intervention in ACS patients is important, and the inclusion of psychological interventions can improve patients' attendance and adherence to CR programs[26,27]. Therefore, it is essential not to downplay the role of such interventions following ACS. Recent studies suggest that mental health conditions may not be a barrier to CR and that CR may provide an opportunity for greater mental health care and support[28]. Therefore, a CR program with a multidisciplinary team including cardiologists, psychiatrists, and psychologists could be considered as a potential early intervention site, and by combining medical treatment, lifestyle modifications, and psychosocial support, patients may benefit from a more holistic approach to their care, which could lead to improved quality of life, reduced morbidity, and better long-term adherence to lifestyle changes.

Study advantages

The present study is the first large-scale study among rehabilitation patients, excluding patients with a preexisting psychiatric diagnosis (which is not the case in most previous studies, and it is important in explaining pathophysiology) or a history of MI, focusing on a more precise description of PTSD as a secondary risk factor in cardiology patients and revealing possible mechanism of interactions. One of the strengths of the study is also the use of psychiatrist-based diagnosis. By identification of potentially important biomarkers, it may be possible to predict which subgroup of patients is at a higher risk for developing PTSD after an ACS.

Study limitations

This is a preliminary report of an ongoing study, with patients still under follow-up. Some biological markers have not yet been included in the analysis, and comprehensive data analyses will be performed once all data is collected. We do not yet have information on whether all enrolled patients will remain in the follow-up and if we will have complete data for all patients by the end of the study.

CONCLUSION

This study is one of the largest cohorts to investigate the incidence of PTSD after ACS, and it is the first to consider the role of CR in this context, with the diagnosis made by a psychiatrist using the DSM-5 classification system. The preliminary findings of the study reports on substantial group of patients with PTSD induced by ACS (10.1%) and suggest that they may avoid physical activity, which could be one of the underlying mechanisms of the worse cardiovascular outcomes observed in this population. It is imperative to identify potential cardiac biomarkers that could aid in detecting increased cardiac risk in patients with secondary risk factor - ACS-induced PTSD, as current research in this area is limited. Further research is necessary, as there is significant potential value in identifying prognostically useful cardiac biomarkers to predict and prevent the onset of recurrent cardiovascular events and higher

morbidity and mortality rates in this group of patients.

After completing the follow-up period of the present study and conducting complex statistical analyses of all collected data, it may be possible to identify a specific subset of patients who are at risk of developing PTSD and may derive benefits from personalized interventions based on the principles of precision medicine. In this individualized approach, CR with a multidisciplinary team and the development of specific therapeutic and rehabilitation strategies can play a key role in improving quality of life and reducing overall mortality of this vulnerable and previously under-recognized subgroup of patients.

ARTICLE HIGHLIGHTS

Research background

Acute coronary syndrome (ACS) can be a stressor in the development of posttraumatic stress disorder (PTSD). Patients with PTSD after ACS have worse survival outcomes, and studies report different prevalence rates of PTSD following ACS. It is challenging to identify these patients and prevent their unfavorable outcomes.

Research motivation

Clinicians and cardiologists who deal with cardiac rehabilitation (CR) are increasingly noticing patients with elements of PTSD after ACS. The problem is their poorer outcomes, and CR with a multidisciplinary team (cardiologist, psychiatrist, psychologist) can be a place for early detection and intervention in these patients.

Research objectives

In this study we aim to investigate the prevalence of PTSD after ACS in patients undergoing CR and their demographic, behavioral, and biological characteristics. Identifying patients at risk for persistent and severe ACS-induced PTSD based on these characteristics could facilitate the implementation of early preventive measures.

Research methods

This is an ongoing prospective analytical case-control study. The study includes patients who have experienced ACS and are enrolled in a 3-wk CR program. A group of patients with PTSD diagnosis was identified using self-assessment questionnaires for PTSD criteria and clinical psychiatric interviews, and a control group was formed based on clinically relevant variables to enable comparison of these patient groups. Medical data were collected, and diagnostic tests were conducted to obtain data on important biological characteristics [laboratory testing, exercise test (ergometry), echocardiogram]. The expected average follow-up period for patients included in the study is approximately 18 mo.

Research results

Of 504 patients completed PTSD Checklist-Civilian Version questionnaire and 80 (15.9%) met the cutoff criteria for the PTSD and qualified for further evaluation by psychiatrists. Among them, 51 patients (10.1%) were diagnosed with clinical PTSD by a psychiatrist according to Diagnostic and Statistical Manual of Mental Disorders criteria. Among the variables analyzed, there was a noticeable difference in the percentage of theoretical maximum achieved on exercise testing between the PTSD and non-PTSD groups. Non-PTSD group achieved a significantly higher percentage of their maximum compared to the PTSD group (P = 0.035).

Research conclusions

This study found a significant proportion of patients with PTSD induced by ACS (10.1%), and these patients are under-recognized and not appropriately treated. The study also found that patients with PTSD achieved a lower theoretical maximum on exercise testing, suggesting that they may avoid physical activity, which could be one of the underlying mechanisms for the worse cardiovascular outcomes observed in this subpopulation of patients.

Research perspectives

Early identification of patients with ACS-induced PTSD and intervention are crucial, and CR provides a unique opportunity for timely recognition and management of high-risk patients, potently leading to improved outcomes. Future research could focus on identifying possible cardiac biomarkers to detect patients at risk of developing PTSD after ACS and apply personalized interventions based on the principle of precision medicine. Multidisciplinary CR programs may be particularly effective in addressing the complex needs of patients with ACS induced PTSD.

ACKNOWLEDGEMENTS

We thank all the medical staff who regularly perform diagnostic procedures that were used in the study and indirectly contributed to the successful completion of this study.

Abstract

BACKGROUND

Prior research has demonstrated that the brains of adolescents with depression exhibit distinct structural alterations. However, preliminary studies have documented the pathophysiological changes in certain brain regions, such as the cerebellum, highlighting a need for further research to support the current understanding of this disease.

AIM

To study brain changes in depressed adolescents.

METHODS

This study enrolled 34 adolescents with depression and 34 age-, sex-, and education-level-matched healthy control (HC) individuals. Structural and functional alterations were identified when comparing the brains of these two participant groups through voxel-based morphometry and cerebral blood flow (CBF) analysis, respectively. Associations between identified brain alterations and the severity of depressive symptoms were explored through Pearson correlation analyses.

RESULTS

The cerebellum, superior frontal gyrus, cingulate gyrus, pallidum, middle frontal gyrus, angular gyrus, thalamus, precentral gyrus, inferior temporal gyrus, superior temporal gyrus, inferior frontal gyrus, and supplementary motor areas of adolescents with depression showed an increase in brain volume compared to HC individuals. These patients with depression further presented with a pronounced drop in CBF in the left pallidum (group = 98, and peak t = - 4.4324), together with increased CBF in the right percental gyrus (PerCG) (group = 90, and peak t = 4.5382). In addition, 17-item Hamilton Depression Rating Scale scores were significantly correlated with the increased volume in the opercular portion of the left inferior frontal gyrus (r = - 0.5231, P < 0.01).

CONCLUSION

The right PerCG showed structural and CBF changes, indicating that research on this part of the brain could offer insight into the pathophysiological causes of impaired cognition.

Key Words: Voxel-based morphometry; Cerebral blood flow; Arterial spin labeling; Adolescent; Depression; The right percental gyrus

Core Tip: In this study, we first combined cerebral blood flow (CBF) and voxel-based morphometry (VBM) to study brain alterations in adolescent depression. We also found that the brain function (CBF) changes were mainly in the left pallidum and right precentral gyrus. Meanwhile, we detected alterations in the cerebellum. Our finding about a wide range of brain structure (VBM) changes in adolescent depression contributes to better treatment and prevention strategies for depression.

INTRODUCTION

Adolescents suffer from high rates of depression that contribute to adverse outcomes, including academic difficulties, substance abuse, behavioral issues, parental conflict, impaired peer interactions, and suicidality[1-3]. Depression rates are exceptionally high among children in middle school, with an incidence of up to 24.3%[4]. Clinical symptoms of depression include feelings of sadness, hopelessness, cognitive impairments, and reductions in motivation and pleasure. Overcoming depression can be particularly challenging among adolescents, with treatment failing to have any pronounced effect in 30%-50% of cases[5]. Recurrence rates are also very high[6], with most adolescents experiencing relapses multiple times in adulthood[7,8]. Adolescence is also a critical period for brain growth[9], and this disease can have a profound negative impact on such development[10]. Despite this fact, many studies have focused on the mental health of adults rather than exploring outcomes in vulnerable adolescent populations[11,12]. As a result, there is an urgent need for in-depth neurobiological research that investigates the pathophysiology of depression to develop effective treatments that can help free adolescents from the symptoms of this debilitating condition.

The results of imaging studies suggest that adolescents suffering from depression exhibit severe structural changes within their brains[13-15]. However, these reported findings have been inconsistent with some studies documenting the thinning of brain regions[16], whereas others note the thickening of certain areas[17]. These inconsistencies may result from a range of patient-specific confounding factors or pharmacological treatment effects. While cerebellar dysfunction has been documented in many disease states[18], changes in the cerebellum in depression remain overlooked mainly[19]. Recent research supports the cerebellum's function in the processing of emotion and its widely recognized role in the context of motor control[20]. Reductions in the gray matter volume in the cerebellum and anterior cerebellar vermis have been documented among adults with depression[21], and some evidence suggests the ability of cerebellar neurons to regulate depression-like behavioral development actively [22].

Given the poorly understood nature of the pathophysiological basis for depression among adolescents, efforts to detect and clarify morphological alterations associated with functional changes provide an opportunity to define these underlying pathogenic processes better. In a previous publication, we used cerebral blood flow (CBF) to assess Major Depressive Disorder(MDD) in adolescents and reported CBF alterations after treatment[22]. Voxel-based morphometry (VBM) is a

technique that is frequently applied to detect structural changes within the brain[23], allowing for the voxel-by-voxel classification of brain volumes in different regions to enable the systematic, reproducible comparison of regions among multiple individuals more effectively than the traditional region of interest (ROI)-based strategies. VBM can assess anatomical differences throughout the brain with a short execution time[23,24] and is widely used in studies of alterations in depressed brains[25-27]. Still, there are also conflicting and heterogeneous results reported by VBM and magnetic resonance imaging (MRI) whole brain analysis[16,17]. These examples encourage the further development of VBM in MDD investigations. CBF can also be detected noninvasively and quantitatively through arterial spin labeling (ASL), in which arterial blood magnetic labeling is leveraged as an endogenous tracer[28]. Investigations have utilized VBM and voxel-based pathophysiology to analyze MDD[29]. Because structural alterations are usually accompanied by functional abnormalities[30,31], we decided to extend our study approach to incorporate VBM with CBF. The current study's findings are consistent with the high repetitive rate of change obtained so far regarding depression[32-34]. The cerebellum's role in depressive symptoms was confirmed in a recent study[35], and elevated pallidum CBF was also detected in patients with mild traumatic brain injury that may lead to cognitive decline[36]. These repeats suggest a potential association between the changes we detected using VBM combined with CBF and MDD dysfunction. Accordingly, in the present study, VBM and CBF strategies were used to evaluate changes in the brains of adolescents with depression.

Regular examinations of a broader range of brain regions are required to understand the pathophysiology of depression in adolescents properly, and unmedicated young people diagnosed with first-episode depression are the perfect model for studies of disease-related brain alterations. For the present analysis, these patients were thus the primary subjects of interest in hopes of detecting previously unrecognized yet clinically significant abnormalities present in depressed adolescents that have yet to undergo pharmacological treatment. These approaches offer a promising means of exploring the pathophysiology of adolescent depression while also validating and expanding upon previously published results[37].

Through the application of VBM and CBF techniques, a series of complex structural and functional alterations were documented within the brains of adolescent patients with depression compared to a healthy control (HC) population. The cerebellum was expected to undergo alterations because of its crucial involvement in developmental processes, and depression-related structural and functional changes were anticipated to coincide in several brain regions. These were the two primary outcomes that were expected from the present research.

MATERIALS AND METHODS

Participants

From August 2020 to July 2022, adolescents with depression were recruited from the Department of Psychiatry at Chongqing Medical University's First Affiliated Hospital. The Mini International Neuropsychiatric Interview for Children and Adolescents (MINI-KID) was used by senior psychiatrists to confirm the diagnosis of depression in all cases, and symptom severity was assessed with the 17-item Hamilton Depression Rating Scale (HAMD-17). Patients eligible for study participation were individuals of Han ethnicity who were right-handed, exhibited a HAMD score ≥ 17, had no history of antidepressant treatment, were experiencing first-episode depression, had no history of psychotropic drug use, and had no history of anesthetic or sedative, or analgesic drug use within 1 mo before the study initiation. Patients were excluded if they had a history of prior mental health conditions, including schizophrenia or bipolar disorder, a history of drug abuse or dependence, exhibited MRI contraindications, or had been diagnosed with organic brain diseases or severe physical ailments.

Participants in the HC trial were selected from age-, gender-, and education-level-matched subjects with no personal history of mental illness or psychosis among first-degree relatives. The same exclusion criteria were applied for both patients with depression and HCs. In total, 34 treatment-naive first-episode adolescent depression patients and 34 HCs from 12-17 years of age were recruited for study participation.

The First Affiliated Hospital of Chongqing Medical University approved this study (NO. 2017-157). The legal guardians of all participants provided written informed consent, and all participants were provided with a comprehensive overview of the details of the study.

General data collection

Sociodemographic data were collected using a questionnaire regarding participant age, sex, and educational status. For the MINI-KID, the parents of eligible study participants were contacted and informed about this study, after which questionnaire and interview responses were obtained electronically. One professional interviewer conducted the interview processing, which was completed in under two days[38].

HAMD-17 surveys were administered by two psychiatrists with similar levels of training to assess symptom severity based on appropriate guidelines. Two examiners blinded to participant details independently performed all subsequent scoring to ensure the absence of subjectivity.

MRI data collection

MRI scanning was performed with a Signa 3.0 Tesla MRI instrument (GE Medical Systems, WI, United States), yielding T1-weighted, T2-weighted, and T2-fluid-attenuated inversion recovery (T2-Flair) imaging sequences. T2-Flair data were used to detect any evidence of potential brain disorders, with patients exhibiting such conditions being eliminated from further study inclusion.

Structural images were acquired with no gap using the following settings: the number of axial slices = 156, time repetition (TR) = 8.4 ms, echo time (TE) = 3.3 ms, flip angle (FA) = 12°, slice thickness = 1.0 mm, the field of view (FOV) = 240 mm × 240 mm, matrix = 240 × 240, and voxel dimension = 1 mm × 1 mm× 1 mm. Parameters used for ASL image acquisition were as follows: NEX 3, TE 9.8 ms, TR 4639 ms, FOV 240 mm × 240 mm, slice thickness 4.0 mm, post label delay time 1525 ms, 3D spiral k-space filling, points 512, arms 8, acquisition scan slices 40. During imaging, participants were directed to remain awake with their eyes closed, and foam padding was employed to restrict head movement.

Image processing

FSL-VBM was used to analyze structural images[39]. After the initial recovery of these images, they were segmented into white matter (WM), gray matter (GM), and cerebrospinal fluid regions, followed by nonlinear registration-based alignment of these images to the Montreal Neurological Institute (MNI) standard space. Native GM images were then re-registered nonlinearly to the resultant averaged images to produce a template specific to the present study. Native GM images were then registered to this template and modified as appropriate based on local contraction or expansion associated with nonlinear spatial transformation. The altered GM images were then smoothed with an isotropic Gaussian kernel with a sigma of 3 mm (FWHM = 6.9 mm) as per FSL recommendations[39].

ASL images were analyzed following the earlier reported studies[22,28].

Statistical analysis

SPSS 22.0 (IL, United States) was used to analyze all data. Data are reported as means ± SD and were compared between groups with two-way ANOVA, while comparisons between males and females were made using chi-square tests.

Analyses of GM and WM volumes included group-based comparisons of larger and smaller volumes in HC individuals relative to adolescents with depression. These analyses employed grand mean scaling and absolute threshold masking. Voxel-level GM and WM density were compared between these groups with two-sample t-tests using SPM5. Random Gaussian field theory was used to estimate significant differences among groups using a familywise error-corrected alpha of 0.05. Clusters were displayed as statistical parametric maps in standard anatomical space. Participant age, education status, and total intracranial volume were utilized as covariates when conducting two-way ANOVA analyses of smoothed CBF images, with an initial $P < 0.001$ thresholds for cluster-level false discovery rate (FDR) multiple comparison correction ($P < 0.05$). Regions of the brain affected by sex or group interactions for CBF perfusion were then acquired with the xjview software (https://www.alivelearn.net/xjview). Brain areas with interactive effects were selected as ROIs, and the CBF values for these ROIs were extracted using DPABI[40].

Relationships between brain alterations and depressive symptom severity were explored through Pearson correlation analyses with $P < 0.05$ as the significance threshold.

RESULTS

Participant characteristics

Table 1 provides details regarding the characteristics of the study participants. No differences in age, sex, or education level were detected between depressed adolescents and HCs ($P > 0.05$), whereas HAMD-17 scores differed significantly between these groups ($P < 0.001$).

Depression-related changes in VBM

FSL-VBM analyses exploring differences between groups highlighted increases in the volume of several regions of the brain following correction for multiple testing ($P < 0.05$), including the cerebellum, superior frontal gyrus, cingulate gyrus, pallidum, middle frontal gyrus, angular gyrus, thalamus, precentral gyrus, inferior temporal gyrus, superior temporal gyrus, inferior frontal gyrus, and supplementary motor area (Table 2, Figure 1). No regions of the brain exhibited depression-related decreases in brain volume.

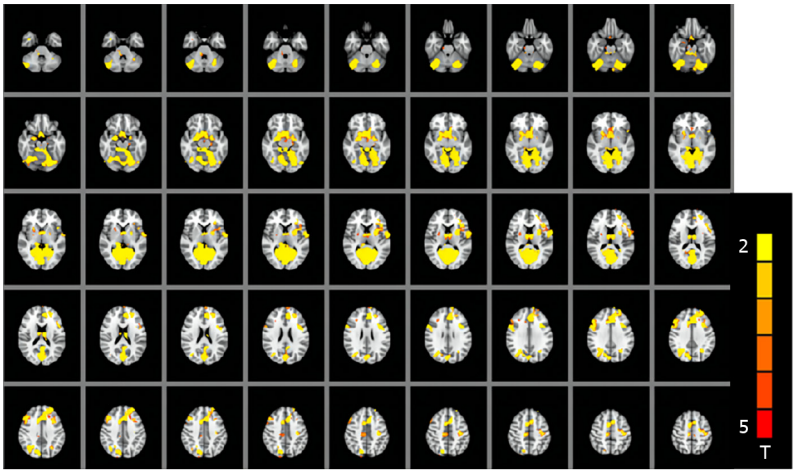
HCs: Healthy controls; MNI: Montreal Neurological Institute; FWE: Family wise error.

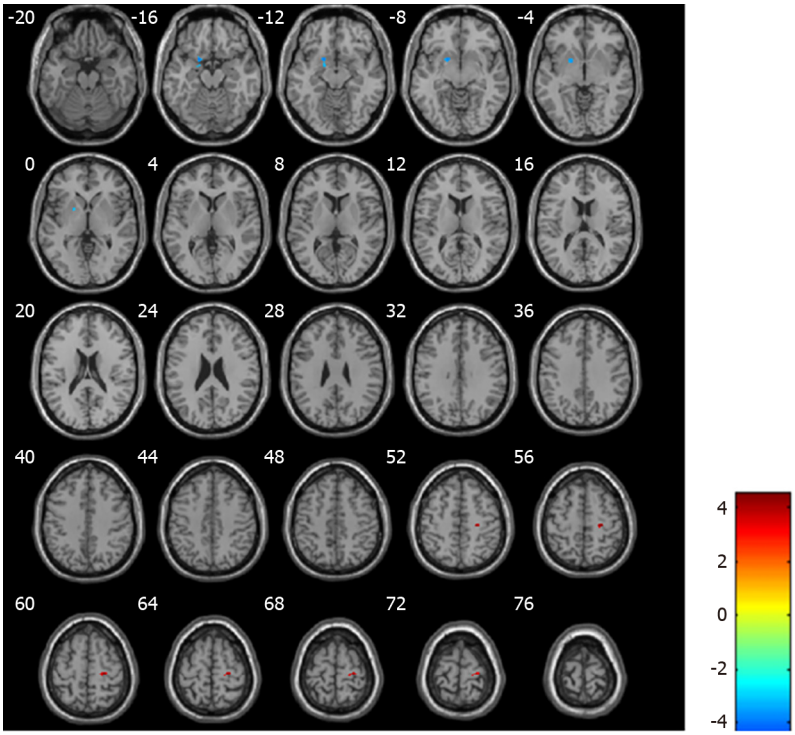
Depression-related changes in CBF



Adolescents with depression exhibited pronounced decreases in CBF in the left pallidum as compared to HCs (group = 98, and peak *t* = -4.4324), together with an increase in the right percental gyrus (PerCG) (group = 90, and peak *t* = 4.5382) (Figure 2). This analysis was performed using a cluster cut-off *P*-value < 0.001.

Correlations between brain alterations and depression severity

In patients with depression, HAMD-17 scores were significantly correlated with the increased volume of the opercular part of the left inferior frontal gyrus (IFG) (r = - 0.5231, *P* < 0.01). No correlations were detected between HAMD-17 scores and other changes in brain volume or CBF (*P* > 0.05).



DISCUSSION

The current findings showed that, in contrast to HCs, treatment-naive first-episode depression in adolescents is associated with CBF and brain volume modifications. Notably, increased volume of many

Figure 2 Differences in cerebral blood flow when comparing healthy controls and adolescents with depression. Blue and red indicate reductions and increases in cerebral blood flow, respectively.

brain regions was observed in adolescent depression patients, with increased CBF in the PerCG and decreased CBF in the left pallidum. HAMD-17 scores in these patients were also negatively correlated with the volume of the opercular portion of the left IFG. In particular, decreases in both volume and CBF were observed in the right PerCG, suggesting that this region may be an important area for future research to understand the pathophysiological bases of depression.

The PreCG regulates primary motor behaviors and has been reported to exhibit alterations in individuals with movement-related disorders, including amyotrophic lateral sclerosis[41] and akinetic-rigid Parkinson's disease[42]. Increased PreCG CBF is correlated with increased reaction time[43], pure apraxia of speech and other forms of impaired verbal fluency[44], and autism[45]. Several studies suggest a relationship between PreCGand emotion[46]. Depression can impair neural plasticity in the motor cortex, contributing to behavioral and cognitive alterations in affected patients[47]. Pathological alterations in the PreCG may thus be functionally linked to depression. An increase in PreCG GM volume has been reported[48,49], with the present results confirming these prior reports and

highlighting a link between these changes and altered CBF.

The left IFG plays a crucial role in the functional and structural brain network that underlies language in neurocognitive models of language perception[50]. The opercular portion of the left IFG is a crucial node connected to multiple cerebellar, cortical, and subcortical structures within the language network [51]. In the present study, adolescents with depression exhibited a correlation between HAMD-17 scores and the volume of this opercular portion of the left IFG, consistent with its potential association with depression severity.

The cerebellum is thought to be closely related to movement, with additional experimental evidence highlighting its association with attention and motor systems[52], as well as with cognition[53]. This link could explain depression-related symptoms, such as cognitive impairment, disinterest, and poor attention. Adolescent depression may affect the cerebellum, contributing to frequent episodes in adulthood. However, it is essential to highlight that the reported increase in the cerebellum in the present study contradicts other published studies in which cerebellar volume was shown to be reduced [54,55]. These differences may be attributable to variations in disease severity, assessment methodology, diagnoses, or treatment approaches.

Other regions exhibiting abnormal findings included the cingulate gyrus, an essential component of the pathophysiological basis for depression related to the makeup of the default mode network[56]. In clinical research, cingulate gyrus abnormalities have been reported in various psychiatric disorders[57]. Altered WM connectivity in adolescent depression patients has also been described[58], contributing to reduced default mode network connectivity closely related to depression incidence[59-61].

There are various drawbacks to this study. Firstly, the number of participants was relatively small, partly due to parental reservations about fMRI examinations. Secondly, the effects of resting state physiological noise derived from the heart and respiratory rhythms cannot be eliminated from these analyses. Lastly, this cross-sectional analysis could not detect disease progression-related changes in brain morphological characteristics, underscoring a need for future longitudinal research with multiple follow-up visits per patient to monitor better such changes and how they respond to treatment.

CONCLUSION

In summary, the present results demonstrate that adolescent depression patients exhibited various structural changes in the brain and altered CBF in the left pallidum and right PerCG. Considering the finding that the right PerCG demonstrated structural and CBF changes associated with depression in these adolescent subjects, research on the right PerCG may provide fresh perspectives on the pathophysiology of this devastating psychological disorder. This identification of novel evidence regarding changes in the cerebellum and other brain areas provides robust imaging evidence supporting the hypothesis that these regions are involved in cognition and disease-related pathogenesis. The future application of these findings has the potential to guide the better prevention and treatment of depression among adolescents.

ARTICLE HIGHLIGHTS

Research background

The prevalence of depression in adolescents is high and research is scarce. Therefore, it is urgent to investigate depressed adolescents.

Research motivation

In-depth neurobiological studies investigating the pathophysiology of depression are urgently needed to develop effective treatments to help adolescents escape the symptoms of this debilitating illness. Several studies have documented the role of the cerebellum in psychiatric disorders, which is rarely mentioned in the imaging of depression, emphasizing the need for further research on the depressed brain.

Research objectives

We aimed to detect structural and functional changes in depressed adolescents. These changes may be relevant to better prevention and treatment of adolescent depression. We found that adolescents with depression exhibit various structural changes in the brain and alter cerebral blood flow in the left syphilitic spiral and right percent gyrus.

Research methods

This study recruited 34 adolescents with depression and 34 matched healthy control (HC) individuals. Voxel-based morphometry (VBM) discovers structural changes in the brain; Cerebral blood flow (CBF)

explore functional changes in the brain; 17-item Hamilton Depression Rating Scale (HAMD-17) measures depression; *t*-test assess statistical differences.

Research results

We found that patients with adolescent depression exhibit various structural changes in the brain and altered CBF in the left pallidum and right percental gyrus. These findings may provide new insights into the pathophysiology of this disruptive psychological disorder and provide strong imaging evidence to support the hypothesis that these regions are involved in cognition and disease-related pathogenesis. Future applications of these findings have the potential to guide better prevention and treatment of depression in adolescents.

Research conclusions

New theory: Our study provides imaging evidence that supports the hypothesis that cerebellum is involved in cognition and disease-related pathogenesis. New method: We first combined VBM and CBF to examine the brains of depressed adolescents.

Research perspectives

Incorporating imaging data into the diagnosis of psychiatric disorders.

Abstract

With the gradual end of the coronavirus disease 2019 (COVID-19) pandemic, the reconstruction of students' mental health is urgently necessary. Digital interventions offer advantages such as high accessibility, anonymity, and accurate identification, which can promote the reconstruction of students' mental health through the provision of psychological support platforms, psychological assessment tools, and online mental health activities. However, we recognize that digital interventions must undergo many adjustments, and corresponding ethical norms require further clarification. It is crucial for different stakeholders to collaborate and work toward maximizing the effectiveness of digital interventions for the reconstruction of mental health after the COVID-19 pandemic.

Key Words: Digital interventions; Artificial intelligence; Big data; Students; Mental health

Core Tip: As the coronavirus disease 2019 (COVID-19) pandemic has gradually come to an end, a challenge that has emerged is how to restore the mental health of students after the pandemic. This paper contends that digital interventions are cutting-edge and that effective approaches should be fully utilized to address the impact of the COVID-19 pandemic on the mental health of students.

TO THE EDITOR

We have read the observational study titled "Investigating adolescent mental health of Chinese students during the coronavirus disease 2019 (COVID-19) pandemic: Multicenter cross-sectional comparative investigation" authored by Huang *et al*[1] and published in the 11th issue of the *World Journal of Psychiatry* in 2022. In this paper, the impact of the COVID-19 pandemic on the daily life and learning of adolescents was analyzed from four aspects: Time distribution, cohabitation groups, and positive and negative effects. The Patient Health Questionnaire-9 and the Generalized Anxiety Disorder Questionnaire- 7 were used to measure the impact of the COVID-19 pandemic on the mental health of adolescents. The results of the study indicated that there were significant differences in the time distribution of daily activities and cohabitation groups for adolescents before and after the COVID-19 pandemic. The academic performance of adolescents from different grades was negatively impacted by the pandemic, with distinct features observed for students at different grade levels; in particular, there was a significant increase in the rate of severe anxiety among junior high school students[1].

We believe that the conclusion of the article is highly valuable for discussion. The COVID-19 pandemic has greatly impacted the daily lives and learning of adolescents, and the mental health status of this population deserves more attention. Our previous research also showed that the prevalence rates of depression and anxiety among Asian university students range from approximately 20% to 40%[2,3], which are relatively high rates and have various negative effects on the daily lives of these students. Given the uniqueness of the COVID-19 pandemic, most studies suggest that the mental health of adolescents has shown a deteriorating trend during the pandemic[4,5]. Other studies have also reported results consistent with the findings of Huang *et al*[1], indicating that the incidence of mental disorders among adolescents, such as depression, anxiety, and stress, has decreased during the COVID-19 pandemic[6-8]. However, the mental health status of adolescents remains concerning. During the COVID-19 pandemic, the improvement of mental health among adolescents is often accompanied by an increase in attachment security and communication with parents, continuous optimization of organizational structures within schools, and gradual adaptation to daily life changes[7,9]. In our study, family, school, and individual factors were considered to be influencing factors of individual depression and anxiety levels, such as family relationships, parental education level, school environment, peer relationships, and lifestyle factors[2,3]. Therefore, general intervention measures should start from these three aspects, namely, enhancing family support for the mental state of adolescents, providing various forms of psychological counseling in schools, and adolescents themselves making efforts to maintain a positive attitude. These measures would improve the mental health status of adolescents during and after the COVID-19 pandemic.

Currently, there are abundant research findings on the impact of the COVID-19 pandemic on students' mental health. However, as the pandemic ends, it remains challenging to effectively address the mental health crisis caused by the pandemic and reshape positive mindsets in individuals. Digital therapy is emerging rapidly and gradually becoming a hot topic in the research and practice of mental health interventions. Digital interventions, carried out *via* the internet, big data, and artificial intelligence, provide a new form for screening, assessing, intervening and treating mental health problems[10,11]. Several studies have confirmed the effectiveness of digital interventions in the treatment of mental health[12-15]. Their advantages are mainly reflected in the following three aspects. First, digital interventions are highly accessible, which can alleviate the imbalance between the supply and demand of mental health services[16,17]. The COVID-19 pandemic was characterized by a sudden onset, long duration, and broad impact. The resulting mental health problems have become increasingly prominent, and many professional psychologists are needed to provide targeted mental health services. In fact, the public health system has a limited capacity to respond to emergencies, and mental health resources are limited[18]. In the context of the intelligence era, students can access various forms of digital intervention services through the internet and mobile platforms to address potential mental health problems in a timely manner[19]. Second, digital interventions are anonymous, which can reduce the risk of stigmatization. Due to concerns about stigmatization, many students have low willingness to seek psychological help, and their anxiety and depression may not be relieved in a timely manner[20]. With the use of digital interventions, students can access services anonymously at any time[21]. Third, digital interventions can accurately identify psychological health problems and provide effective solutions. Through health data tracking and intelligent analysis systems, digital interventions can accurately screen students with potential psychological health problems, making it easier to provide psychological counseling in a timely manner. In addition, based on the different needs of students, digital interventions can also provide personalized psychological support, making them more flexible and convenient to use[16,22].

It is worth noting that there are still some challenges in more extensive and efficient mining and application of digital psychological health interventions. First, students inevitably face the risk of information leakage when using applications and other mobile platforms. Various countries have not established an effective supervision and management system, and the corresponding ethical norms need to be further clarified[23,24]. Second, digital interventions are essential tools. Psychological health practitioners should combine their professional literacy and fully utilize the characteristics of digital technology to maximize the potential of digital interventions[25]. Finally, technology changes rapidly,

and digital psychological health interventions have not kept up with the pace[18]. Different stakeholders need to work together to inject new vitality into digital psychological health interventions using the latest artificial intelligence and virtual reality technologies.

The rapid development of artificial intelligence provides powerful support for the improvement and popularization of mental health services. In response to the challenges encountered in the application of digital psychological interventions, the latest research proposes suggestions from three aspects: Theory, practice, and future development trends. First, the theoretical foundation for the development of digital intervention needs to transform good clinical practice standards (such as CBT) into key components of mental health services[26]. Second, to improve the effectiveness of digital psychological interventions, a participatory design approach should be widely adopted[27], and cultural relevance should be integrated into mobile applications or online platforms[28,29]. Finally, future digital psychological interventions should fully utilize the latest developments in artificial intelligence, applying algorithms such as machine learning and deep learning to automatically identify and analyze emotional states and establish a mental health database. In addition, protecting user data privacy, reducing costs, and improving usability are also key issues that need to be addressed in the future[30,31]. Regarding the protection of user privacy, we believe that students' information literacy should be given attention. In the digital environment, students are vulnerable to data malfunctions and the unethical use of their data. To prevent this situation, students should be aware of the risks they may face in digital media, improve their digital literacy and safety awareness, effectively use and manage their digital archives, and have a healthy online/offline social life.

In conclusion, after the outbreak of the COVID-19 pandemic, restoring the mental health of students is urgently necessary. Digital interventions can promote the reconstruction of students' mental health by providing a platform for psychological support, offering psychological assessment tools, and facilitating online mental health activities. We believe that digital interventions should be actively adopted to support students' mental health and enhance social welfare.

ABOUT COVER

Editorial Board Member of *World Journal of Psychiatry*, Mary V Seeman, DSc, FRCP (C), MD, Emeritus Professor, Professor Emerita, Department of Psychiatry, University of Toronto, Toronto, ON M5P 3L6, Canada. mary.seeman@utoronto.ca

AIMS AND SCOPE

The primary aim of *World Journal of Psychiatry* (*WJP*, *World J Psychiatry*) is to provide scholars and readers from various fields of psychiatry with a platform to publish high-quality basic and clinical research articles and communicate their research findings online.

WJP mainly publishes articles reporting research results and findings obtained in the field of psychiatry and covering a wide range of topics including adolescent psychiatry, biological psychiatry, child psychiatry, community psychiatry, ethnopsychology, psychoanalysis, psychosomatic medicine, *etc*.

INDEXING/ABSTRACTING

The *WJP* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Current Contents/Clinical Medicine, Journal Citation Reports/Science Edition, PubMed, PubMed Central, Reference Citation Analysis, China National Knowledge Infrastructure, China Science and Technology Journal Database, and Superstar Journals Database. The 2023 Edition of Journal Citation Reports® cites the 2022 impact factor (IF) for *WJP* as 3.1; IF without journal self cites: 2.9; 5-year IF: 4.2; Journal Citation Indicator: 0.52; Ranking: 91 among 155 journals in psychiatry; and Quartile category: Q3.

Abstract

A condition of exposure to multiple stressors resulting in a mixed clinical picture spanning conventional categories without meeting any of them in full, encompasses a risk for a list of comorbidities preventing appropriate prevention and treatment. New transformative transdiagnostic approaches suggest changes spanning conventional categories. They base their systems of classification on biomarkers as well as on brain structural and functional dysregulation as associated with behavioral and emotional symptoms. These new approaches received critiques for not being specific enough and for suggesting a few biomarkers for psychopathology as a whole. Therefore, they put the value of differential diagnosis at risk of avoiding appropriate derived prevention and treatment. Multiplicity of stressors has been considered mostly during and following catastrophes, without considering the resulting mixed clinical picture and life event concomitant stressors. We herewith suggest a new category within the conventional classification systems: The Complex Stress Reaction Syndrome, for a condition of multiplicity of stressors, which showed a mixed clinical picture for daily life in the post coronavirus disease 2019 era, in the general population. We argue that this condition may be relevant to daily, regular life, across the lifespan, and beyond conditions of catastrophes. We further argue that this condition may worsen without professional care and it may develop into a severe

mental health disorder, more costly to health systems and the suffering individuals. Means for derived prevention and treatment are discussed.

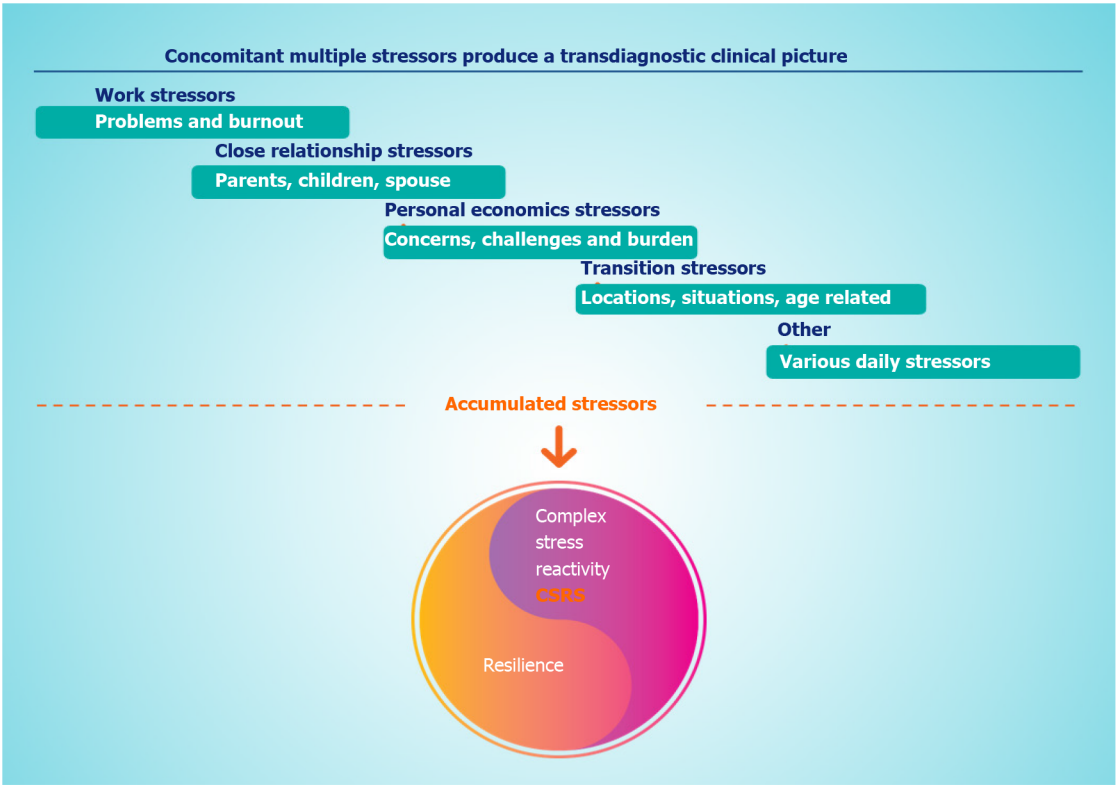
INTRODUCTION



Many people with mental health complaints present a mixed clinical picture. Often none of the com-plaints meet the full criteria of any of the conventional classifications. Possibly, several categories are met (though not completely), leading to a list of comorbidities. This precludes clear diagnosis, preven-tion and treatment.

There are at least 4 different suggestions to revise classical classifications into transdiagnostic appro-aches: Hierarchical Taxonomy to Psychopathology[1], Research Domain Criteria[2], Bipolar-Schizophrenia Network on intermediate phenotypes[3,4], and Neuroscience-Based Nomenclature[5]. These suggested new classification systems are based on neuroanatomic findings showing that several brain areas demonstrate similar functionality and structure in various conventional categories[6-9]. However, others have commented on these data that they lack specificity, as the biomarkers show relevance over too many mental disorders[10]. Thus, many current conventional classification categories are gathered in the transformative systems into one pool of psychopathology, preventing consequent application of accurate prevention and treatment per each disorder including the missing clinical attention to indivi-dual differences.

Part of the mixed clinical pictures involves the concomitant experience of multiple stressors. As it arises from our literature search using PubMed, Google Scholar and *Reference Citation Analysis* (RCA), the impact of multiple stressors has been discussed by cutting edge papers mostly in the context of disasters such as hurricanes, floods, wars and in drastic conditions experienced by refugees and immi-grants including the coronavirus disease 2019 (COVID-19) era, with similarities between the impacts in these types of conditions across the lifespan, *e.g.*[11-14]. The most common psychiatric outcomes reported are post-traumatic stress disorder (PTSD) and depression[15-20]. There are scarce reports on multiple stressors in daily life as related to the development of psychiatric disorders. Some of these reports relate to stressors in the workplace, economic hardships and the impact of urbanization[21-23]. Surprisingly, here also PTSD and depression are the common outcomes. The diagnosis of these two disorders in such different types of multiple stressors calls for attention and re-evaluation. Thus, the aim of the current paper is to suggest a new potential category for the conventional diagnostic system, which will include conditions of mixed clinical pictures with more than one stressor identified.

As clinicians, we encountered a condition in which many patients showed mixed symptomatology, spanning conventional categories, without fully meeting all the conventional criteria of any of these categories during the multi-stressor COVID-19 outbreak. Our literature review supported our observa-tions[24]. In a following empirical bi-national study, using representative, large samples[25], we further found that combinations of several mental health symptoms studied, PTSD, phobia, depression, anxiety and posttraumatic stress symptoms, were more prevalent than combinations of fewer symptoms, with no majorities-minorities differences in both Italy and Israel[25]. We termed this mixed clinical picture the Complex Stress Reaction Syndrome (CSRS). CSRS includes type A (a psychiatric part) and type B (a neuropsychiatric part for the long-COVID component, excluding systemic symptoms)[24,25]. As more cross-cultural studies of the CSRS are warranted, we are currently conducting such an international study with participants from 8 diverse countries located in the Middle East, Europe, Australia and North America.

In this paper we suggest that the CSRS type A (the psychiatric part, not including type B) may explain mixed clinical pictures in conditions of multiplicity of significant stressful life events in the post-COVID era. Thus, we argue that in the general population, experiencing concomitant multiplicity of life events-related stressors may account for the development of a mixed type of mental health disorder, not only in conditions of catastrophes (see Figure 1).

Figure 1 Accumulated stressors in daily life are associated with a mixed clinical picture in the general population. CSRS: Complex Stress Reaction Syndrome.

Differential diagnosis

For differential diagnosis, the CSRS (type A) may be compared to: (1) Diagnosis of adjustment disorder rules out PTSD and bereavement, and it displays a short stressor onset-symptoms occurrence latency; (2) PTSD diagnosis includes exposure to one frightening stressor; (3) Obsessional thoughts are ego-syntonic by definition. The behaviors related to extrinsic stressors are clearly not included in the obsessive-compulsive disorder (OCD) conventional category; (4) Diagnosis of acute stress disorder implies a simpler stressor and a specific symptom response; (5) The criteria for defining generalized anxiety disorder list excessive worrying (on diverse issues) and shifting back and forth among them, thus not implying the multiplicity of stressors and a mixed clinical picture; (6) The diagnosis of major depression disorder includes anhedonia, low affect, psychomotor agitation, unfitting guilt feelings, diminished drive and energy, trouble concentrating, and indecisiveness with no other types of symptomatology which are included in a mixed clinical picture; and (7) C-PTSD is described as the result of a series of traumatic events, which is repetitive and hard to escape but does not include a mixed clinical picture beyond the PTSD conventional criteria. It also describes a series of events and not the simul-taneous occurrence of multiple stressors as the possible etiological source for psychopathology.

Prevention

The impact of multiple concomitant stressors depends on individual subjective perception and stress reaction tendencies [26]. The immediate question is what can prevent the emergence of pathological stress reactions, spanning several conventional categories. In a previous study we found that close relationships may protect the individual across the types of psychopathology investigated, spanning anxiety, depression, PTSD and OCD criteria, in conditions of multiple stressors[27]. The means for illness prevention and enhanced coping are therefore suggested as keeping close relationships active. Public and media educational programs for conditions of multiplicity of life stressful events with transdiagnostic potential consequences, aimed at enhancing individual resilience by utilization of social networks, are herewith suggested, evidence-based[27,28].

Treatment

We suggest a combined treatment approach of interpersonal psychotherapy (IPT) and cognitive behavioral therapy (CBT), two evidence-based and cost-effective methods, designed as short-term thera-pies and found to be equally effective to medications[29] in comparative studies[30,31]. Enhanced close relationships by techniques of problematic interpersonal relations analysis, resolution and role playing adapted from IPT[32], may increase emotional tolerance to accumulating stress emerging from conco-mitant origins. Our suggested combined psychotherapeutic approach also requires the blending of CBT separate protocols, including techniques for stress reduction and correction of cognitive distortions, rather than following one protocol separately or as recently suggested, one mandatory unified protocol for all

types of symptomology[33-36].

We suggested previously that when exposed to multiplicity of stressors, the lack of clear goals implies the diffusion of actions[37]. This could be a risk factor for effective treatment of patients confronted with this type of condensed stressful experience. To overcome this risk and also to respect individual differen-ces, a patient-specific and session-specific therapeutic strategy of assigning clear goals for adaptive coping is warranted, rather than working through a reparation condition or just attempting to eliminate the identified external stressors.

DISCUSSION

The origins of CSRS

The CSRS emerged from the robust transdiagnostic clinical pictures during and following the pandemic[38]. The World Health Organization indicates a prevalence of 22% of a mixed picture including depre-ssion, anxiety, PTSD, and general distress, fatigue, irritability and anger in the general population fol-lowing the experience of war or natural disaster[39]. Transdiagnostic approaches to classifications were proposed even prior to the COVID-19 pandemic[1-4]. Here we argue that the impact of multiple stre-ssors in daily life is a neglected issue in traditional classifications.

What was probably different about the COVID-19 pandemic compared to previous catastrophes was its global scale and the fact that it was covered extensively by the social, electronic, and print media. This factor may be regarded as an additional stressor in daily life beyond disasters. Whether media use is a source of social support, especially for young people[27,40,41] or a daily life stressor in the form of bom-bardment of information[42], is still a topic under scientific debate and probably age-related with large inter-individual variance.

Although there is enough evidence to suggest that the mental health of the population deteriorated following the pandemic[43], there are suggestions that the extent of deterioration was less than anticipated[44,45]. In any case, epidemiological studies have shown that anxiety, depression, functional somatic, and even obsessional symptoms can coexist at the population or the community level[38,46,47], supporting our transdiagnostic views and the CSRS.

Inclusion of long COVID symptoms in the CSRS may create the same psychological *vs* physical dispute that we have witnessed with chronic fatigue syndrome or myalgic encephalomyelitis, but we include in the CSRS just neuropsychiatric symptoms, while systemic components of long COVID are excluded. In support of our view, studies that have already started appearing suggest that the long COVID syndrome is more likely to be associated with psychosocial factors rather than the COVID infection itself[48].

Thus, the origins of CSRS are rooted in the multi-faceted stress of the pandemic and its impact on mental health including its residuals in the post COVID era. The relevance of concomitant stressors included in daily life, under regular, non-catastrophic conditions, and their association with a mixed clinical picture, is gradually becoming apparent.

The CSRS within the debate on psychiatric nosology

Our opinion goes beyond conventional approaches for construction of psychiatric taxonomy. Alter-native concepts of psychiatric validity include controversies between validation of nosological struc-tures (typical for medicine) as compared to prototype, cluster and dimensional diagnosis of mental disorders[49]. While the field of psychiatry moved towards more medically oriented nomothetic knowledge, alternative groups which we follow in our empirical and review papers, suggest that the field has to move away from this type of knowledge towards a more ideographic and subjective appro-ach to psychopathology[49].

The main differences between the validity of dimensional diagnostics and that of traditional nosology are apparent in several aspects: (1) In traditional approaches, mental pathology is regarded as a strict drift from acceptable norms while the transdiagnostic views, similar to ours, suggest an axis between normal and psychopathological conditions; (2) In dimensional approaches co-existing psychopathological states appear in parallel along with personal strengths and capacities for resilience, unlike traditional nomenclature; (3) Dimensional approaches to the convergent and divergent validity of a cluster or co-existence of different pathologies without meeting a full criteria of any category in the conventional systems, such as the CSRS, do justice to the patient and the entire individual clinical picture he or she describes to the clinician, while traditional approaches prefer multiple comorbidities; and (4) The dimensional approaches such as the CSRS, unlike conventional systems, emphasize subjec-tive complaints of the patient (symptoms) rather than signs judged by the clinician. By that, these dimensional approaches are shifting the focus from the powerful societies of professionals towards the patient's subjectivity, and they recognize that professionals too, have their own subjective perspectives to consider before endorsing a diagnosis based only on signs.

Specifically, the CSRS has shown high reliability, as in two different countries and with two different methodologies similar results were found[25]. Additionally, the CSRS has shown high convergent and divergent validity as a combination of several identified stress symptoms, without meeting any full conventional category. These findings suggest a complex and unique type of reactivity to multiplicity of stressors. Other combinations suggested earlier, as complex anxiety and depression[50] or complex post traumatic stress disorder, showed validity for inclusion of just two conventional categories[51] while others showed a too wide range of inclusion, ruling out the potential judgement of divergent validly[10].

We acknowledge the importance of biological validation of psychiatric illness, but this still cannot be utilized for a treatment per any specified condition until the field of neuropsychiatric science advances considerably. The CSRS implies symptoms more than signs and subjectivity more than objectivity. The treatment derived from the CSRS would be patient-specific and session-specific, as human experience may go back and forth on the axis of elevated symptomology *vs* resilience and adaptive coping. There-fore, the notion of session-specific treatment requires the clinician's diagnostic

effort at every given session to reevaluate the patient's symptomology for progression *vs* regression and to offer treatment accordingly. We propose that the human experience transits along time that elapses and a condition may be judged for a given patient, in a given environment at a given moment, considering how the observed syndrome has been individually experience-shaped[52-55].

It was noted earlier that the empirical validation used as the basis of conventional categories has been mostly regression statistical analyses with a weak basis for causality[49]. Contrary to any etiological arguments, we argue that the CSRS represents an association between multiplicity of stressors and a mixed clinical picture, which is worth treating to avoid further increase in the patient's stress reactivity and future limitations of his or her resilience capacities.

We locate CSRS within the blend of the biopsychosocial model (BPS)[56] and the person-centered medicine (PCM) approach[57], as the novel CSRS is related to exogenic stressors (BPS) and occurs as a subjective complex stress reaction of the patient (PCM). Thus, as outlined here and according to our bi-national research design and findings[25], the CSRS falls within the post-modern dimensional appro-aches more than within any strict nosology, for better prevention and treatment. CSRS was designed and investigated from a humanistic perspective, arguing that mental health is not represented by the lack of psychopathology, while psychopathology, in turn, is a condition with an indication to treat and may be reversible.

CONCLUSION

Transdiagnostic considerations towards a change in the classification of mental disorders can be accom-plished within the existing systems without ruling out the importance of differential diagnosis if these conventional systems will start to include transdiagnostic phenomena as legitimate conditions for treatment and care. This reduces the risk of diagnosing too many comorbidities and by that precluding appropriate prevention and treatment. We argue that the syndrome termed as CSRS better identifies those patients reacting in a manner that spans several conventional diagnostic categories following exposure to concomitant multiple stressors. Unlike approaches that argue for complete transformation of conventional classifications[1-5], we claim that that a specific diagnosis concerning multiplicity of stressors that result in a mixed clinical picture, is a potential contribution to the revised Diagnostic and Statistical Manual of Mental Disorders and the International Classification of Diseases for more accurate derived prevention and treatment. The future will tell if the openness to include post-modern transdiagnostic approaches to accurately serve more patients in need and to facilitate clinical practice of each individual psychiatrist, will be part of the discussions on the next revisions of the Diagnostic and Statistical Manual of Mental Disorders and the International Classification of Diseases or whether the debate and crisis in psychiatry[58] will continue.

Abstract

Currently, a proportion of adolescents use alcohol, tobacco, and illicit drugs, which inevitably harms their health and academic progress. Adolescence is a peak period for substance use initiation and a critical time for preventing substance use problems. Various entities, such as families, schools, and communities, have implemented a variety of interventions to alleviate adolescent substance use problems, and schools play a unique role. To explore the types, characteristics, and effectiveness of substance use interventions in educational settings for adolescents, we conducted a scoping review and identified 32 studies after screening. We divided the 32 studies according to intervention type, including curriculum interventions focusing on cognitive-behavioral skill enhancement, exercise interventions, peer interventions and family-school cooperation, and electronic interventions. Except for the mixed results on electronic interventions, the results showed that the other interventions were beneficial to different extents in alleviating adolescent substance use problems. In addition, we analyzed and summarized the advantages and challenges of intervening in adolescent substance use in educational settings. Schools can use equipment and human resources to provide adolescents with various types of intervention measures, but they also face challenges such as stigmatization, ineffective coordination among multiple resources, and poor implementation effects. In the future, school-based intervention measures can fully utilize big data and artificial intelligence technology and collaborate with families and communities to intervene appropriately while paying attention to the comorbidity risks of substance use disorders and psychological health issues.

Key Words: Substance use; Prevention; Adolescents; Educational settings; Artificial intelligence; Digital interventions

Core Tip: Interventions in educational settings include curriculum interventions, physical activity interventions, peer interventions and family-school cooperation, and electronic interventions. Except for the mixed effectiveness of electronic interventions, all other intervention measures are beneficial in alleviating substance use problems among adolescents. Schools can utilize equipment and human resources to provide various types of interventions but also face challenges such as stigmatization and ineffective coordination between multiple resources. In the future, schools can fully utilize big data and artificial intelligence technologies, jointly intervene with families and communities, and appropriately address the comorbidity risks of substance use disorders and mental health issues.

INTRODUCTION

Currently, substance use and abuse among adolescents have become important global public health issues. Adolescence is a critical period for physical and psychological development, as well as for experiencing life, pursuing independence, and establishing intimate relationships[1]. Individuals are more susceptible to substance use risks in the adolescent stage than in other stages of life. Research has shown that adolescence is the peak time for the initiation of drug use[2]. The level and frequency of drug use among adolescents begin to increase in mid-adolescence and peak in early adulthood. The median age of onset of alcohol use in most countries is 16-19 years[3]. The global burden of disease study showed that drug use is a significant factor in the health burden in the adolescent and young adult population[4]. Early exposure to alcohol, tobacco, and other drugs may lead to violent or aggressive behavior in adolescents, making it difficult for them to adapt to school, family, and social environments[5]. Such exposure not only causes various negative health outcomes [1], but may also result in psychological health issues such as anxiety and depression in adolescents[6-9]. Therefore, it is essential to identify substance use problems in the adolescent population as early as possible and to take timely intervention measures.

Multiple research results indicate that adolescent substance use problems are the result of the combined action of various risk factors, such as personal, family, school, community, and societal factors. Substance use by parents or relatives in the family environment has an insidious influence on adolescents while also providing a channel for their substance exposure[10]. Adolescents who are in disadvantageous positions in life are more likely to use drugs to escape the pressure of reality[11]. Peer substance use in the school environment may stimulate the curiosity of adolescents or cause them to use drugs to fit in due to "peer pressure"[12]. Implementing intervention plans based on different subjects is an effective strategy to address adolescent substance use problems[13-16]. First, at the social level, clearly defining the scope of legal substance use and adopting strict regulatory measures can effectively reduce adolescents' negative substance use behavior[17]. For example, alcohol or tobacco price controls can be implemented through taxes[18-22], minimum age laws can be enforced[23], and the availability of inhalants can be minimized[24]. Second, at the family level, factors such as parenting style, family relationships, and family function can significantly predict adolescent drug abuse and related behaviors[25]. Family involvement has been found to be effective in treating adolescent substance use disorders. The basic principle of family-based intervention measures is to directly or indirectly establish more stable family relationships by providing training courses or developing intervention plans for parents and adolescents, thereby reducing the risk of adolescent substance use disorders[26-28]. For example, the Strong African American Families-Teen program effectively prevents drug use and emotional problems in black adolescents by offering 10 h of adolescent skills training courses and family courses[29]. Family matters (FM) helps parents identify family characteristics, behaviors, and attitudes that may affect adolescent drug use by regularly mailing families guidance manuals. Professional health education workers follow up on the use of the manuals by contacting parents after each mailing. The results of a study on FM showed that the complete intervention plans effectively reduced the rates of tobacco and alcohol use in adolescents [13]. Third, at the community level, some studies suggest that the community and its surrounding environment can play a positive role in adolescent substance use problems[16,30]. Community-based intervention plans usually require community leaders, community workers, and other stakeholders and professionals to work together. For example, in the Community Trials Intervention to Reduce High-Risk Drinking, community leaders use local policies and regulations to control the number of bars, retailers avoid selling alcohol to minors, and so on[13]. Clearly, intervention measures based on multiple stakeholders, such as those at the social, family, community, and school levels, can play an essential role in resolving adolescent substance use problems[16]. Multidimensional family therapy (MDFT) integrates family therapy, individual therapy, and drug counseling with multisystem intervention methods[31]. Multiple experiments have shown that MDFT is a more effective treatment method than other methods for adolescent drug abuse and comorbid mental symptoms[32].

In addition, as current adolescents are "digital natives", they have a "natural" attraction to digital interventions[33-35]. Technology-based intervention measures are mainly interactive digital activities aimed at preventing or delaying adolescent drug use from the aspects of knowledge, attitude, and behavior[36-38]. RealTeen is a web-based intervention measure that places youth in realistic drug use scenarios by using interactive skills-building sessions. Adolescents can

improve their self-awareness and social skills, thereby avoiding drug use[39,40]. Studies have shown that after intervention, participants have lower rates of use of alcohol, marijuana, and multiple drugs[39]. Specific intervention measures based on multiple subjects are shown in Table 1.

Compared with other context, such as families and communities, the educational environment in schools offers unique advantages for intervening in adolescent substance use. Considering the characteristics of adolescence, such as a long duration of schooling, close peer interaction, and intensive education, schools are an excellent place to intervene in adolescent substance use[1]. On the one hand, school can educate adolescents on the characteristics and harms of the use of substances, such as alcohol, tobacco, and illegal drugs, by offering relevant courses. On the other hand, peer interaction and practical activities in the school environment can make adolescents value education, help them form a correct attitude toward life, and prevent substance use problems before they happen[41,42].

Recent research has focused on the importance of schools in addressing adolescent substance use problems and exploring effective intervention measures from different perspectives. For example, intervention models have been constructed based on cultural backgrounds and family relationships, Botvin Life Skills Training has been used to train students in the school environment, and psychological training has been implemented to prevent substance use problems among adolescents. These measures aim to improve adolescent tobacco use problems[43-45].

The existing literature has proposed various intervention measures based on the seriousness of adolescent substance use problems. However, the vast majority of research only discusses school-based intervention as one of many intervention measures[46], and few studies have directly investigated preventive intervention measures for adolescent substance use from the perspective of the educational environment. Considering the changes in adolescent substance use problems before and after the pandemic, this paper, based on a comprehensive review of existing literature in this field, focuses on research results from the past seven years and further explores preventive intervention measures for adolescent substance use in the educational environment.

Objectives

Based on the unique advantages of schools in intervening with adolescent substance use and the richness of research in this field, we conducted a scoping review to understand specific intervention measures and their effectiveness in the current educational environment. Our research questions were as follows: (1) What are the intervention measures currently used in the educational environment to intervene with adolescent substance use? and (2) what are the characteristics and effects of these intervention measures?

LITERATURE REVIEW

Search strategy

To explore the types, characteristics, and effectiveness of intervention measures for adolescent substance use in the educational environment, we conducted a preliminary evaluation of relevant literature in this field. Literature searches were conducted in May 2023 in five databases: Web of Science Core Collection, PubMed, EBSCO, Scopus, and Google Scholar (selecting the top 200 most relevant articles). The following keywords and terms were used: (1) Substance use; (2) adolescent; (3) educational setting; and (4) prevention. The following string was used: ("substance use" [All Fields] OR "alcohol" [All Fields] OR "tobacco" [All Fields] OR "marijuana" [All Fields] OR ("illicit drug" [All Fields]) AND ("youth" [All Fields] OR "teenager" [All Fields] OR "adolescence" [All Fields]) AND ("school" [All Fields] OR "educational setting" [All Fields]) AND ("intervention" [All Fields]) OR "prevention" [All Fields]).

Study selection

The full screening process included three stages: (1) EndNote software was used to identify duplicate articles and retain those with more comprehensive information; (2) the first round of screening was conducted based on the inclusion and exclusion criteria, along with titles, abstracts, and keywords in EndNote; and (3) manual screening was performed based on the full text using Rayyan.

The inclusion criteria were as follows: (1) The age of the study subjects was 10-19 years (according to UNICEF, WHO, and UN Population Fund); (2) intervention measures were based in educational settings; (3) there was a specific, clear, and operational intervention plan for substance use problems; (4) the article was easily accessible; and (5) the article was published in English.

The exclusion criteria were as follows: (1) The age of the study subjects was outside the defined range; (2) intervention measures were based on other environments, such as family and community; (3) the article did not belong to the substance use problem category or only mentioned the topic briefly; (4) the article was a literature review, letter to the editor, or opinion piece; (5) the article was from the gray literature; and (6) the article was published in a language other than English. Please see Figure 1 for the specific screening process.

Data analysis

After screening, a total of 32 articles were obtained. Analyses and table summaries of the literature revealed that these articles could be grouped based on the type of intervention strategies used. The two primary themes and their associated subthemes are as follows: (1) Various types of intervention strategies and their effects include interventions that focus on cognitive-behavioral skill building, exercise, peer and family involvement, and electronic interventions; and (2) differences in substance use intervention strategies among adolescents in different educational stages.

Table 1 Multiagent-based adolescent substance use interventions

Implementation subject	Intervention method	Specific measures
Based on social intervention measures	Clarifying the scope of legal substance use and adopting strict regulatory measures	Manage the age, sales timeframe, permissible quantities, and pricing of substances and regulate users[18]
		Levy taxes on the alcohol or tobacco content of goods and tie them to fluctuations in consumer pricing[19]
		Implement and enforce laws mandating a minimum age limit and raise the age threshold for young people to purchase alcoholic beverages[18,23]
		Create community-specific regulations concerning the issuance of tobacco and alcohol licenses to minors and promote their enforcement within localities[24]
Based on family intervention measures	Providing training courses for parents and teenagers	Strong African American Families-Teen program: Deliver skill-building courses and family training sessions spanning 10 h and comprising 5 sessions to both parents and teenagers[29]
		Creating lasting family connections: Offer a 20-wk facilitator training program for parents and teenagers[13]
	Developing intervention plans	Families preparing the new generation plus: Execute a 10-wk prevention plan for nutrition and material use while emphasizing healthy eating and parenting strategies[26]
		Familias Unidas: Enforce a set of intervention measures aimed at enhancing parents' sense of efficacy and parenting skills (parent support networks), family meetings/home visits, parent-adolescent discussion circles, adolescent activity groups, supervised peer activities, and school counselor meetings)[27]
		Risk reduction therapy for adolescents: Intervention measures conducted by a professional therapist with a relevant master's degree at an outpatient clinic. Caregivers are obligated to attend a weekly session lasting between 60 min and 90 min[28]
Based on community intervention measures	Providing community intervention programs	Community trials intervention to reduce high-risk drinking: To modify the community's drinking behavior, offer responsible beverage service, reinforce law enforcement, and set up alcohol checkpoints[13]
		Deliver a 10-wk intervention plan for adolescents using the Health Rocks program and multiple disciplinary literacy strategies. Emphasize the effects of substance abuse on health and require adolescents to attend a one-hour theme-based instruction per week[30]
Based on technology intervention measures	Utilizing innovative intervention methods, such as the internet and big data	CLIMATE: Provide 6 lessons based primarily on social influence theories *via* CD-ROM and the Web. The lessons provide knowledge about how common substance use is as well as the negative outcomes it can lead to and teach methods to avoid substance use and the subsequent hazards[37]
		HeadOn: Require the involvement of students in decision-making related to substance use through interactive simulation scenarios[38]

LITERATURE RESULTS

Each section summarizes the mechanism and effects of various intervention measures (Tables 2-5).

Various types of intervention measures and their effects

Curriculum interventions focused on cognitive-behavioral skill enhancement[47,48]: The mechanism of these interventions involved two parts (Table 2): (1) Using traditional ethnic values and methods to prevent smoking, drug use, *etc.*[49] and connecting the psychological and social concepts of substance use with multicultural values[50] to regulate adolescent substance use behavior; and (2) implementing a series of courses to improve students' cognitive and behavioral skills[51], including knowledge about the characteristics and harms of alcohol, tobacco, and illicit drugs[52], communication[53], decision-making and other life skills[54,55], and methods to resist drug use pressure[56,57]. These interventions had positive effects on adolescent alcohol, cigarette, and marijuana use to varying degrees. A study conducted a randomized field trial with seventh- and ninth-grade students to implement a school-based intervention program, Take Charge of Your Life (TCYL), to prevent adolescent alcohol, tobacco, and drug use. The TCYL program follows the principles of substance abuse prevention programs, using counseling classes to help students understand the negative effects of alcohol, tobacco, and illicit drugs on individuals and society, and it requires students to learn communication, decision-making, assertiveness, and refusal skills. The results of the study showed that TCYL helped reduce the potential motivation for drug use and was beneficial for students who smoked marijuana[58] (Table 2).

Exercise interventions: Exercise is one of many health behaviors associated with good lifestyle habits[59]. Exercise programs to intervene in adolescent substance use problems help adolescents develop good lifestyle habits to reduce the willingness to engage in substance use and the frequency of substance use[60,61]. Werch *et al*[62] and Goldberg *et al*[63] primarily used exercise screening, counseling, and exercise training courses to reduce adolescent drinking behavior and improve health habits. More recently, new forms of exercise intervention have emerged in schools. Some examples

Table 2 Curriculum interventions focusing on cognitive-behavioral skill enhancement

Ref.	Age/gender	Scope of application			Method	Content	Effect	Location
		Alcohol	Tobacco	Illicit drugs				
Diaz Gomez *et al*[47], 2021	10-12 yr, all genders	Yes	Yes	-	Randomized controlled cluster study	Primavera is a prevention program that focuses on experiences and involves multiple modes of delivery. It spans several years and has a generic approach	Primavera is effective in decreasing alcohol consumption among school students	France
Kimber *et al*[48], 2009	Grades 7 to 9 (13-16 yrs), all genders	Yes	Yes	Yes	Nonrandomized five-year longit-udinal design	Teachers offer weekly lessons on social and emotional training to students	A particular group of people derived benefits from the program	Sweden
Hecht *et al* [49], 2003	Grade 7, all genders	Yes	Yes	Yes	Randomized controlled trial	Interventions based on culture are conducted through 10 specific lessons and a media campaign utilizing a model of cultural resilience	The intervention had a considerable and noteworthy effect on individual consumption of alcohol, cigarettes, and cannabis	United States
Unger *et al* [50], 2004	Grade 6, all genders	-	Yes	-	Participatory research	The Project Fun Learning About Vitality, Origins, and Respect is a curriculum that promotes multicultural education	The project successfully stopped hispanic boys from starting smoking but had no impact on other groups	United States
Walker *et al*[51], 2011	14-19 yr (Grade 9-12), all genders	-	-	Yes	Randomized controlled trial	Motivational enhancement therapy, educational feedback control, and delayed feedback control	Participants stated that they used cannabis less frequently and experienced fewer negative outcomes	United States
Faggiano *et al*[52], 2010	12-14 yr, all genders	Yes	Yes	Yes	Cluster randomized controlled trial	The program involved a 12-h curriculum that was developed using a thorough social influence approach	Alcohol abuse and marijuana use showed a consistent improvement, whereas smoking displayed no change	Spain, Belgium, Germany, Sweden, Greece, Italy, and Austria
Dent *et al* [53], 2001	14-17 yr, all genders	Yes	Yes	Yes	Randomized controlled trial	Project Toward No Drug Abuse: Standard care and classroom education program	Over a period of one year after the program, this population saw statistically significant changes in alcohol and illicit drug use	United States
Hanewink *et al*[54], 2004	Grades 5 and 6 (mean age 11.4 yr), all genders	-	Yes	-	Randomized controlled trial	The smoking prevention program utilized a life-skills approach and included 21 sessions	The program did not have a distinct impact on the current smoking rate (percentage of people who smoked in the past 4 wk)	Austria, Denmark, Luxemboug, and Germany
Botvin *et al* [55], 2001	Grades 7 to 9, all genders	Yes	-	-	Randomized controlled trial	A proactive approach that educates individuals on resisting alcohol and drug consumption, promoting healthy social norms, and providing material to encourage personal and social skill-building	The prevention program was effective in protecting against episodes of excessive drinking	United States
Botvin *et al* [56], 1999	Grade 7 (mean age 12.9 yr), girls	-	Yes	-	Randomized controlled trial	This program consists of 15 sessions aimed at teaching social resistance skills within a broader initiative that aims to promote general personal and social competence skills	The number of urban minority girls who started smoking or increased their smoking habits was significantly reduced	United States
Shope *et al* [57], 1998	Grade 6 (mean age 12 yr), all genders	Yes	Yes	Yes	Participatory research	The students in the curriculum group were taught about alcohol, tobacco (including cigarettes and smokeless	The curriculum achieved short-term effectiveness by considerably decreasing the rising rates of alcohol	United States

						tobacco), marijuana, and cocaine	consumption and addiction, tobacco use, cocaine intake, and other types of substance abuse	
Sloboda *et al*[58], 2009	Between seventh and ninth grade, all genders	Yes	Yes	Yes	Randomized field trial	TCYL offers students essential life skills, which include communication, decision-making, assertiveness, and refusal skills	TCYL had a negative impact on students' use of alcohol and tobacco as a result of medical treatment	United States

TCYL: Take charge of your life.

Paquette *et al*[68], 2019	Ages 13-17, all genders	Yes	-	Yes	Randomized controlled trial	"Amplifying Our Futures (Amp)" is a temporary intervention program that consists of four phases. It is designed for adolescents who are at low to moderate risk of using substances and is facilitated by trained companions aged 18-28 years old	Young peer intervention was valuable in educational environments	United States
Botvin *et al*[69], 1990	Grade 7, all genders	Yes	Yes	Yes	Cluster randomized controlled trial	Life skills training is a program designed to improve cognitive and behavioral skills, which is led by both experienced students and teachers in a classroom setting for a total of 20 sessions	Preventative programs have had a quantifiable effect on behavior related to substance use	United States
Furr-Holden *et al*[70], 2004	Grades 1-8, all genders	Yes	Yes	Yes	Randomized prevention trial	The classroom-centered intervention and the family-school partnership intervention	Two interventions had a clear protective effect against tobacco use	United States
Zavela *et al*[71], 2004	Grades 4-8, all genders	Yes	Yes	Yes	Control experiments and follow-up questionnaire	Say Yes First-To Rural Youth and Family Alcohol/Drug Prevention: An educational and case management approach to drug prevention	The students who were part of the program consumed less alcohol, tobacco and other drugs and had a lower occurrence of marijuana use throughout their lifetime	United States
Winters *et al*[72], 2012	Ages 14-17, all genders	Yes	-	Yes	Randomized controlled trial	BIs: Therapists used the principle of motivational interviewing to conduct topical sessions with parents and students	BIs showed a connection with decreased drug usage, with a greater impact when parents were included	United States

Bis: Brief interventions.

Horn *et al*[67] combined physical activity and smoking cessation interventions for adolescents. The research suggested that students who increased their exercise time by 20 min were more likely to reduce their daily smoking quantity (Table 3).

Peer and family-school interventions: On the one hand, peer support is a protective factor for substance use problems in adolescents, and the role of peers can provide screening and intervention measures that are suitable for adolescent development[68]. Botvin *et al*[69] showed that peer intervention programs were more effective than regular classroom teaching. The Amplifying Our Futures program, jointly designed by multiple stakeholders such as schools, communities, and adolescents, is implemented by trained young adults. The results on the program confirmed the value of peers in substance use intervention in adolescents[68]. In addition, some research indicated that forming a partnership between families and schools, strengthening communication and exchange between the two parties, and effectively involving parents in adolescent substance use intervention can help reduce adolescents' early substance use behavior[70-72] (Table 4).

Electronic interventions: Currently, the application of electronic interventions in adolescent substance use is relatively limited. Examples include (1) Having teenagers watch videos and public service announcements[73] or teaching adolescents about alcohol, tobacco, and cannabis using electronic learning modules or programs[74,75]; (2) designing internet-based intervention plans for teenagers[76,77]; and (3) adopting alcohol media literacy programs to enhance teenagers' media literacy skills and reduce the potential impact of substance use-related advertisements on teenagers[78]. However, researchers have not yet reached a consensus on the effectiveness of electronic interventions. It is suggested that internet-based intervention plans are convenient for reducing alcohol and cannabis use, and research results showed that students in the intervention group reduced alcohol use one year after completing the course[76]. However, a web-based program called Consider This, implemented by Buller *et al*[77], was found to be of little value in preventing adolescent substance use (Table 5).

Differences in substance use intervention measures for adolescents at different educational stages

Adolescence is a critical period for preventing substance use. Through a literature review and summary, we found that intervention measures for substance use among adolescents at different educational stages need to focus on different

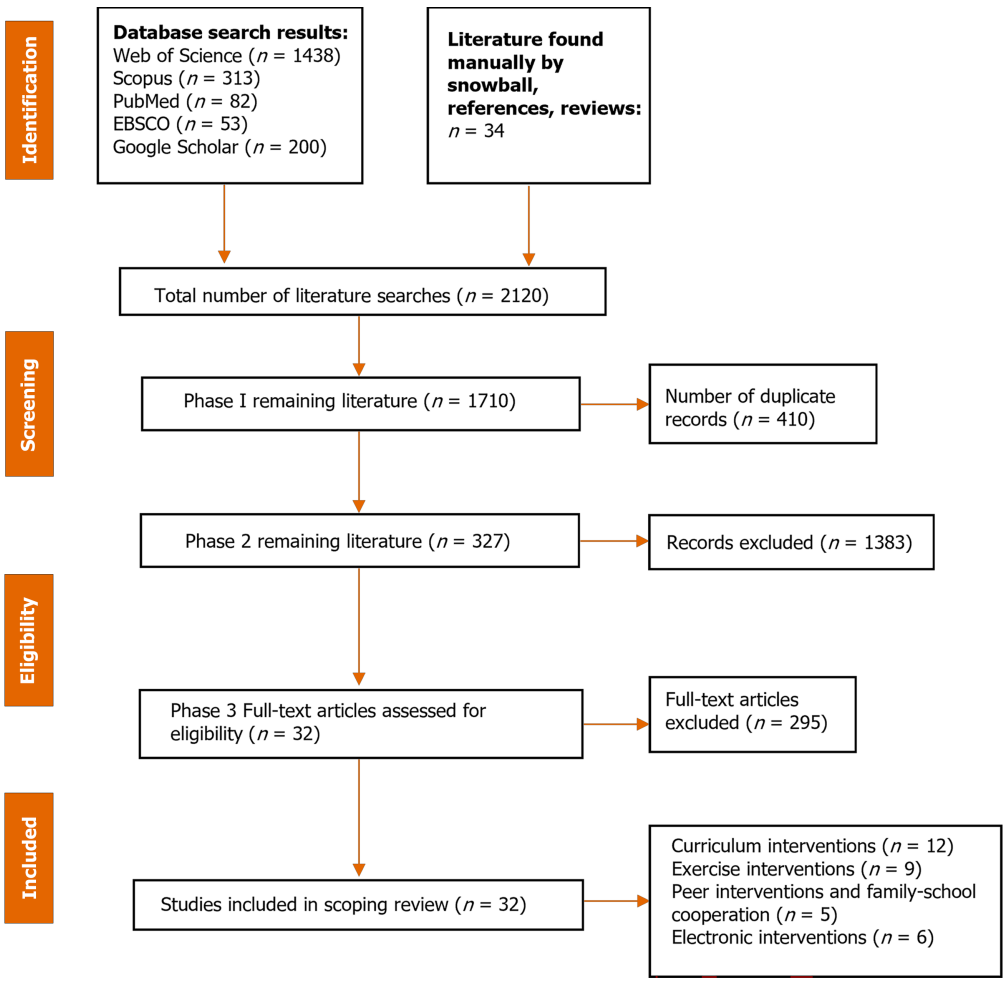

Table 5 Electronic interventions

		Alcohol	Tobacco	Illicit drugs				
Jennifer *et al*[73], 2006	Grade 7, all genders	Yes	Yes	Yes, marijuana	Randomized controlled trial	The usefulness of the Drug Resistance Strategies Project's Keepin' it REAL program aimed at preventing adolescent substance use was explored by studying students who participated in it through public service announcements and videotapes	Class videos influenced the use of drugs among teenagers, whereas PSAs did not have an impact	United States
Malmberg *et al*[74], 2014	11-15 yr, all genders	Yes	Yes	Yes	Randomized clustered trial	Healthy School and Drugs program: Digital modules for e-learning and comprehensive intervention	Both the e-learning and comprehensive intervention failed to prevent the initiation of alcohol, tobacco, or marijuana use	The Netherlands
Kiewik *et al*[75], 2017	12-16 yr, all genders	Yes	Yes	-	Pre-/post-intervention pilot study with a control group	"Prepared on time": A digital training program that follows the attitude-social influence-efficacy model	This research demonstrated that an electronic learning prevention program is feasible for teenagers with mild or moderate intellectual disability	The Netherlands
Newton *et al*[76], 2010	13 yr, grade 8, all genders	Yes	-	Yes	Cluster-randomized controlled trial	Internet-based prevention programs for school-age children: The Climate Schools: Alcohol and Cannabis course	After finishing the programs, students' understanding of alcohol and cannabis improved, and it also led to a decrease in the consumption of alcohol for up to twelve months	Australian
Buller *et al* [77], 2008	Grades 6 to 9, all genders	-	Yes	-	Randomized trials	Consider This: There were a total of 73 online activities divided into six modules: Introduction, media literacy, relationships, mind and body, decision making, and resistance strategies	The activities led to a decrease in smoking and/or a decrease in students' expectations of smoking in the future	Australia and United States
Gordon *et al*[78], 2017	9-12 yr, all genders	Yes	-	-	Qualitative assessment	Alcohol media literacy programs: Providing children with the necessary skills to question and critically evaluate the information they receive from media sources	Using culturally specific advertisements as a means to educate about the effects of alcohol proved to be a potent strategy	Australia

areas. One demonstration project on minimizing drug harm confirmed this view. In this project, a quasi-experimental intervention was conducted with middle school and high school students for four years. The results showed that education on minimizing drug harm was not suitable for middle school students[79]. We believe that this may be related to the developmental characteristics of adolescents at different educational stages. Adolescents in the upper grades of primary school and in the junior high school stage are in a semimature state and are more prone to imitate behaviors such as smoking and drinking due to curiosity or a psychological desire for conformity. Therefore, at this stage, interventions should focus on guiding adolescents' behavior and values. High school students are relatively mature and have higher levels of cognition and behavioral abilities. Some students in this group may already have varying degrees of substance use disorders. Therefore, interventions should focus on consolidating awareness education and preventing increase substance use.

Advantages and challenges of substance use interventions for adolescents in educational environments

Advantages: Educational environments provide convenient spaces for intervening in substance use among adolescents. The advantages can be summarized in the following five aspects. First, school environments are the context of various interpersonal relationships, including those involving peers, teachers, and administrative personnel. Support from interpersonal relationships is a protective factor against adolescent substance use[80]. Intervention plans for the school context can combine the strengths of multiple stakeholders and maintain a high level of interaction among participants [73]. Examples include peer group pressure interventions[81] and family-school cooperation interventions[70]. Second, schools have unique advantages in terms of facilities and human resources. Evidence suggests that collective interventions are effective in treating adolescent mental health problems and substance use disorders[82]. Schools are

DOI: 10.5498/wjp.v13.i7.409 **Copyright** ©The Author(s) 2023.

Figure 1 Literature screening process.

ideal places to conduct collective interventions. Teachers can use the school's basic equipment and multimedia devices to conduct general courses to prevent substance use disorders, teach students about the potential risks of substance use, and enhance their decision-making and drug refusal abilities[82]. Third, many behaviors of adolescents, including substance use, are related to their experiences in school. Therefore, intervention plans for the school context can change the external environment to which adolescents are exposed and have external validity[72]. Fourth, it is easy to conduct large-scale screening for substance use in educational environments. Effective early screening for substance use problems is essential for preventing or delaying the use of alcohol, tobacco, and illegal drugs during the vulnerable period of adolescent substance use problems. Schools can use standard screening tools to screen students regularly and universally to identify potential substance use problems as early as possible and implement targeted interventions in a timely manner. Fifth, research shows that there may be a mechanism of mutual influence between students' mental health problems such as anxiety and depression and their substance use behaviors[6,7]. These problems are not conducive to the healthy growth and academic progress of adolescents. Schools provide a favorable environment for addressing these issues. Intervention measures in the school context can alleviate the substance use behavior of at-risk groups, promote the physical and mental health and academic performance of students, and create a virtuous circle, benefiting more adolescents.

Challenges: There is no doubt that education settings face many challenges in providing effective substance use interventions for adolescents. First, intervening with students who already have substance use disorders in schools can potentially compromise their privacy, leading to stigmatization risks. When students are afraid of being labeled as having "drug use problems" and refuse school intervention measures, the work becomes difficult[72]. Second, school-based intervention programs often require approval from the school board and coordination among multiple departments. However, considering the school's image, the board may deny the existence of substance use problems at different levels in the school to avoid affecting its enrollment and future development[83]. In addition, it is difficult for multiple departments to reach a consensus on the design and implementation of an intervention plan, and there may be complex problems such as misunderstandings and slow progress during the implementation process. Third, providing substance use-related courses for adolescents undoubtedly increases the burden and pressure on teachers and administrators, perhaps because they need to receive training from professionals in advance and spend much time and energy on teaching. Teachers and administrators also bear pressure from their own teaching tasks and other administrative work,

which may lead to role conflict and role overload[84]. Therefore, schools may need to provide necessary incentives for the implementers of intervention plans to increase their motivation. Fourth, the school environment increases the availability of alcohol, tobacco, and illegal drugs. In a 2009 study on adolescent risk behavior, 23% of students reported being offered drugs in school[82]. This indicates that in addition to actively formulating intervention plans, schools still need to build a positive, environmentally friendly, and healthy campus environment to prevent the spread of the use of alcohol, tobacco, and illegal drugs in schools. Fifth, as "digital natives", adolescents have a higher acceptance of electronic interventions than older age groups. However, the effectiveness of electronic interventions for adolescents with substance use disorders is not ideal. In the context of rapid informatization, fully tapping the potential of internet interventions and further introducing digital intervention in educational settings remains a challenge for school health workers and researchers.

DISCUSSION

In the face of the public health challenges posed by adolescent substance use and abuse, schools have an important mission as ideal places to implement intervention plans. In addition to carrying out regular substance use screening and implementing intervention plans according to different categories (such as universal intervention measures for all students, selective intervention measures for students at high risk of substance use, and directive intervention measures for students with substance use disorders), in the future, school-based intervention measures can focus on introducing big data and artificial intelligence technology; integrating advantageous resources from families, schools, and communities; and combining psychological health interventions.

Fully utilizing big data and artificial intelligence technology. In recent years, with the rapid development of artificial intelligence, machine learning, and deep learning, digital intervention methods have rapidly emerged. Schools can use artificial intelligence technology to build a platform for adolescent health management, establish a management mechanism that spans the full process from substance use screening warnings to intervention tracking, and enhance the coverage and accuracy of screening warnings. This platform can also incorporate the psychological health status of adolescents, thereby supporting the creation of personalized health records. In addition, precise assessment and prediction of student substance use problems and hierarchical classification intervention tracking through artificial intelligence technology can reduce the incidence of risky behavior. It is worth noting that when introducing digital intervention methods such as intelligent robots and applications, effectiveness and risk assessments should be conducted, operational procedures should be refined, and the potential of digital interventions should be truly realized.

Resources from families, schools, communities should be integrated to form joint efforts. When schools intervene in adolescent substance use problems, they need to consider protective factors from families, and students also need to recognize the importance of social influences. Currently, there are a variety of diverse intervention measures based on individual entities such as families, communities, and schools, and their effectiveness is significant; however, there is a lack of linkage between these entities. In the future, schools can encourage parents and communities to actively participate in the project while ensuring the integrity of their own intervention plans and managing and coordinating resources.

Psychological health interventions should be integrated, and comorbidity risks should be emphasized. Early substance use in adolescents is related to their psychological health status[85]. Identifying potential psychological health problems in adolescents and intervening in a timely manner can help reduce substance use risks[86]. Therefore, the early identification and intervention of both cannot be separated. When schools screen students for psychological health problems, they should pay attention to substance use, and when implementing substance use interventions, they should pay attention to potential psychological health problems in high-risk groups. This not only maximizes the use of school resources but also prevents adolescents from engaging in risky behavior due to comorbidities.

Furthermore, since this study is a scoping review, we did not calculate specific variable values, nor did we conduct a bias risk analysis. This is a limitation of this study.

CONCLUSION

This article outlines substance use prevention interventions for adolescents in educational environments and their implementation effects. We found that overall intervention measures include curriculum interventions focusing on cognitive-behavioral skill enhancement, exercise interventions, peer interventions and family-school collaboration, and electronic interventions. Except for electronic interventions, which have uneven implementation effects, intervention measures are beneficial in alleviating adolescent substance use problems to varying degrees. In addition, adolescents in different educational stages have different developmental characteristics, and intervention measures should be more targeted and focused. The educational environment has unique advantages for implementing intervention plans, and equipment and human resources can be used to provide adolescents with various types of intervention measures. However, implementation of interventions in the educational environment also faces challenges such as stigmatization, inadequate coordination among multiple resources, and poor implementation effects. In the future, school-based intervention measures can make full use of artificial intelligence technology, jointly intervene with families and communities, and pay attention to the comorbidity risks of substance use disorders and mental health issues.

Abstract

BACKGROUND

There are few if any life-span population-based studies of psychiatric disorder-associated biomedical and biophysical disorders and diseases (morbidity).

AIM

To scope the present state of research regarding the biomedical and biophysical morbidity associated with affective and mental disorder in epidemiological samples, and to examine the life-span relationship between affective disorders and biomedical/biophysical disorders to illustrate a novel approach employing the odds ratio to represent the intensity of biomedical and biophysical morbidity associated in time in a population.

METHODS

A repeatable systematic literature search of PubMed was represented in summary. Additionally, a regional population-based dataset was constructed and analyzed to represent the age- and sex-specific diagnoses (International Classification of Diseases Version 9, ICD-9) for those with and without affective disorder. The analysis presents a novel index of the relative age-specific frequency of life-span biomedical and biophysical diagnoses associated with affective disorder.

RESULTS

The volume of biomedical and biophysical morbidity associated with mental disorder literature has increased, yet few studies measure comprehensive temporal hyper-morbidity (over-representation of diseases over time, either

before or after the index diagnostic event) in populations. Further, there have been only a few population-based studies examining the morbidity associated with affective disorder and only one that examines the full diagnostic range of lifespan morbidity. Substantial differences arose between males and females with more females than males having greater frequencies of diagnoses. The age-specific distributions of the maximum proportional diagnosis frequency ratios for each sex illustrate the greatest diagnosis-specific differences when comparing the biomedical and biophysical diagnoses of those with and without affective disorder when the same diagnosis was represented in each grouping at the same age.

CONCLUSION

Clinical research needs to focus on more than one or two comorbid biomedical or biophysical disorders at a time. Comprehensive population-based examination of the lifespan biomedical and biophysical multi-morbidity associated with affective disorder has the potential to directly inform clinical practice. Representing the proportional ratios of age-specific frequency of diagnoses for the full range of ICD-9 diagnoses is a novel analytical model. Diagnostic frequency appears a viable representation of a given disease state, such as affective disorder. Fortunately, the WPA has developed a global education section to better understand the biomedical and biophysical morbidity associated with all psychiatric disorders. This has been identified by the WPA as the psychiatric practice challenge of the 21st century.

Key Words: Biomedical/biophysical morbidity; Temporal hyper-morbidity; Mental disorder; Population; Epidemiology

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: The paper presents a scoping review of publications with focus on the biomedical and biophysical morbidities associated with psychiatric disorder and a novel example from a population of the relationship between affective disorder and the frequency of associated biomedical and biophysical morbidities across the lifespan.

INTRODUCTION

Numerous recent studies have examined the comorbidity of affective disorders and other mental processes[1-5] and disorders[6-9]. Less common is the study of biomedical or biophysical and affective disorder comorbidity. The studies that do address the comorbidity of affective disorders and biomedical diseases and disorders, predominantly focus on one singular biomedical diagnosis, such as diabetes[10-12] and chronic pain[13,14]. A few studies investigated a range of comorbid disorders, such as asthma, diabetes, epilepsy, food allergy, or juvenile arthritis arising within 6 mo of any mental problem[15]. In one study, biomedical markers have been identified indicating links between mental disorder and chronic physical illness[16]. Overall, the study of biomedical and biophysical morbidity in association with mental disorders has been constrained.

To date, while there have been some large sample studies of mental[17-20] and physical disorders[21-24], there have been few large sample studies examining relationship specifically between psychoses, such as affective disorders and biomedical/biophysical disorders. One large sample World Health Organization survey study found the number of medical conditions to increase with the number of psychotic symptoms within a 12 pre-survey month period[25]. In this study, a wide variety of medical conditions and health problems- such as angina, asthma, arthritis, tuberculosis, vision or hearing problems, mouth/teeth problems, alcohol consumption, smoking, and accidents - were reported to be more frequent in individuals with psychotic symptoms.

This altogether brief, focused, literature review outlines the constraints of studies focusing on psychiatric disorder-associated biomedical and biophysical morbidity. There is the need to introduce not only a broader perspective and definitions of morbidity, but also the need to find different approaches to its study.

The purpose of this study is twofold: First to present the current state of the art of biomedical and biophysical morbidity associated with mental disorder in large population-based samples in the published literature (PubMed). Secondly, both as an illustration and an example, we examined the lifespan association with affective psychoses of the full range of biomedical/biophysical diagnoses in a large 16-year regional population sample. We examined the full range of International Classification of Disease (ICD-9) biomedical and biophysical disorders and diseases in a population comparing those with affective disorder and those without any mental disorder. Further the paper presents a novel analysis and graphic representation of the frequency of biomedical and biophysical disorders and diseases of each specific ICD-9 disorder expressed as a ratio comparing the dependent groups.

The dataset in this study was originally compiled to investigate one *a priori* hypothesis in support of the original adverse childhood experience study[26-29]. The hypothesis assumed early adversity to be one gateway to subsequent mental disorder. Based on this assumption the hypothesis was that given the presence of any ICD-9 mental disorder diagnosis, biomedical and biophysical disorders would be proportionally greater than among those without any mental disorder. This proved to be the case with substantial over-representation of biomedical and biophysical disorders in those with any mental disorder[18].

The analysis underpinning the original study of this regional 16-year dataset was a relatively simple representation of the data in terms of odds ratios. Subsequently of interest was the temporal order of biomedical and biophysical disorders in relation to mental disorder and *vice versa*[20,22], in addition to the order of diagnoses in prospective age-defined cohorts[21,23].

MATERIALS AND METHODS

Literature search

Several PubMed searches of mesh and title terms provided an overview of the number of the current population-based psychiatric morbidity research publications (represented in tables associated with each searches' terms). Searching mesh and title terms provided an index of publication frequency with a focus on population, epidemiology, morbidity, and psychiatry. The details of each listed search result in PubMed recorded in Table 1 are repeatable. The results precisely list the total number of papers in each search. The position of the search (*e.g.*, title) indicates the importance of the terms in the search. In the results quotients are expressed in the terms of the results (number of publications) for the numerator expressed as a fraction of the results in generic search (unspecified position) for the denominator (#publications).

Cohort-study

The data for the population-based component of this study were collected under ethics ID REB15-1057. The data represented the health seeking population from the Calgary Health Zone in Alberta, Canada between April 1993 and November 2010. To receive payment all Alberta physicians, even practitioners in private clinics, directly bill the provincial health plan for each patient visit. The data consisted for each patient visit of a record that included an anonymous, encrypted, unique patient identifier, an ICD-9 diagnosis code, age, and sex. The analyzed data was grouped (dependent variable) according to the presence or absence of the ICD-9 diagnosis code 296 representing the affective disorders. The group wherein affective disorders were absent consisted of those without any mental disorders. The independent variable represented all biomedical and biophysical disorders linked within each group (+/- affective disorders). Additionally, the results were stratified on the variable age. The sexes were analyzed separately.

Analysis

The frequency of publications resulting from the PubMed literature searches were tabulated.

From the population-based based, the dependent groups were described in terms of age, sex, total frequency of diagnoses, counts of unique individuals together with the standard deviations and ranges.

The algorithm underpinning the comparative analysis of the groups with and without affective disorders ordered all diagnoses in sequence for individuals stratified by age within groups. Within each group for each diagnosis and each age, the total count of each diagnosis (frequency) was denominated by each age-specific sample size and represented as the proportion of the age-specific sample having a specific diagnosis in each group. For example, if each patient in each age-specific sample received one given diagnosis, the proportional value for that diagnosis would be one. If fewer than the total number of patients in each age-specific sample received a given diagnosis the proportional value would be less than one. If the age-specific sample received the diagnosis more than once each, then the proportional value would be greater than one. Novel in this analysis is the proportional value representing the intensity of any diagnosis within each age-specific strata of each dependent group.

Where age-specific diagnoses occurred in both dependent groups, between groups comparisons of the proportional diagnosis frequency ratio of each age-specific diagnosis for those with and without affective disorders was possible. While similar in formula construction to the odds ratio, the numerator of each group proportion represented each diagnosis' frequency (intensity) within the unique individuals at each specified age.

Ratio of Frequency Proportions of biomedical and biophysical disorders = [With/Without] affective disorder

The ratio of diagnosis frequency between the two groups, when greater than the value one, identifies that the intensity (frequency) of the diagnosis under comparison is greater in the dependent variable group with affective disorder. When the ratio of diagnosis frequency between the two groups is less than one, the diagnosis under comparison is greater in the dependent variable group without affective disorder. Diagnosis frequency within individuals is a way of representing the intensity of the associated disorders in the ratios of the compared groups.

Age-specific diagnoses could also occur in one group but not the other. Diagnoses that occurred only in one or the other group were noteworthy based on the possibility of conferring risk in the affective disorder groups or protection in the group without affective disorders. These diagnoses become asymptotic with the limit of value zero. Where a real frequency was greater in the group without affective disorder the value was between zero and one.

All ICD diagnoses were coded according to the numeric values of their natural codes, with V codes assigned values in the 1200 range and procedures (laboratory, anesthesiology, *etc.*) in the 1500 range.

Table 1 Volume of research publications for repeatable PubMed literature searches

Search condition	Frequency of results
"Consortium in Psychiatric Epidemiology"[Title]	0

"Psychiatric Epidemiology"[Title]	245
"ICPE" AND "psych*"	379
"ICPE" AND (psych*[Title])	60
morbid*[MeSH Terms] AND epidemiolog*[MeSH Terms] AND psych*[MeSH Terms]	165364
morbid*[MeSH Terms] AND epidemiolog*[MeSH Terms] AND mental[MeSH Terms]	0
((morbidity[MeSH Terms]) AND (epidemiology[MeSH Terms])) AND (psych*[MeSH Terms])	309
comorbidity[MeSH Terms] AND "epidemiology"[MeSH Terms] AND "psych*"[MeSH Terms]	56
"comorbidity"[Title] AND "epidemiology"[Title] AND "psych*"[Title]	18
((morbidity[Title]) AND (epidemiology[Title])) AND (population[Title])	12
((morbidity[Title]) AND (epidemiology[Title])) AND (psych*[Title])	10
((morbidity[Title]) AND (epidemiology[MeSH Terms])) AND (psych*[MeSH Terms])	8
"International Consortium in Psychiatric Epidemiology" - Articles found by citation matching	6
"morbidity"[Title] AND "epidemiology"[MeSH Terms] AND "psych*"[Title]	2
((morbidity[Title]) AND (epidemiology[Title])) AND (mental[Title])	1
(psych*) or (mental)	3347210

The representation of age-specific diagnoses provides an index of the frequency or intensity of occurrence over lifespan of the biomedical and biophysical diagnoses associated with affective disorder.

RESULTS

Literature Searches

Table 1 shows 17 searches. The last search represents all searchable fields of publications containing the wildcard psych@ and mental. The value of this search serves to denominate the largest value with the MeSH term search for the wildcard terms morbid*, epidemiolog*, and psych*. Of note the same search with mental replacing the wildcard term psych* produced zero results. The most generous quotient value indicates that 4.94% (165364/3347210) of the search research results had a precise focus on the MeSH terms. It may also be seen in Table 1 that when the MeSH terms are more precisely constrained (*e.g.*, morbidity, epidemiology, or comorbidity) there are substantially fewer results and even fewer when these terms are searched for in titles alone. Note that the PubMed graphic associated with the search resulting in 165364 articles showed that the articles per year peaked in 2019 with a total of 10239 articles published.

Population sample description

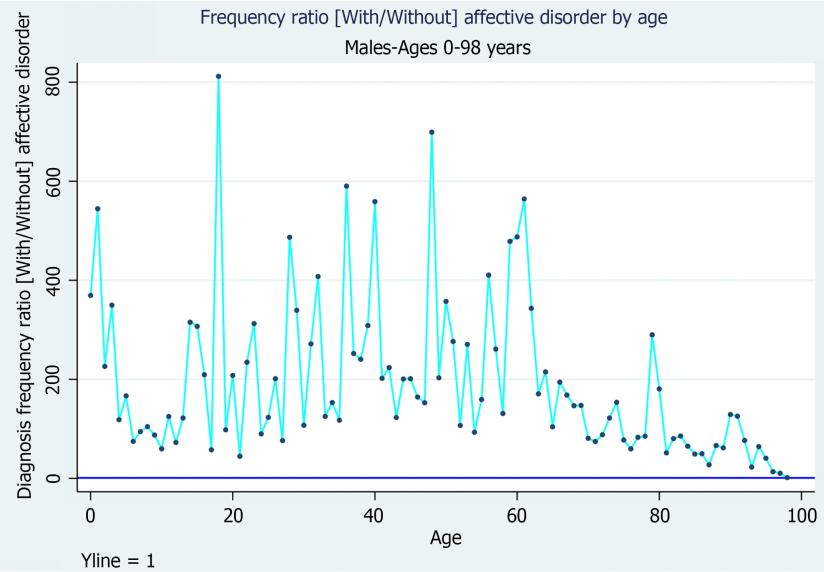

Table 2 describes the distributions of the groups with and without affective disorder. Note that the group without affective disorder consists of individuals without any other mental disorders. As well, there are more females than males with affective disorder and females have in total and on average a higher frequency of biomedical and biophysical diagnoses (mean = 291) compared to males (mean = 239). The average age of females is older than males in the group with affective disorder and younger in the group without affective disorder.

Note in the following graphs when the frequency of diagnosis ratios for each dependent group is equal to the value one, it means that the ratio of each group is equal. When greater than the value one, the ratio is greater in the group with affective disorders. When less than the value one, the ratio is greater in the group without affective disorders. Figure 1 shows the proportional total diagnosis frequency ratios > 1 distribution of associated biomedical and biophysical diagnoses by age comparing males with and without affective disorder. Figure 2 shows the proportional frequency ratios > 1 distribution of maximum values comparing in males comparing those with and without affective disorder. Figure 3 shows the complete proportional ratios > 1 distribution comparing males with and without affective disorder. Figure 4 shows the proportional total diagnosis frequency ratios > 1 distribution of associated biomedical and biophysical diagnoses by age comparing females with and without affective disorder. Figure 5 shows the proportional frequency ratios > 1 distribution of maximum values comparing in females comparing those with and without affective disorder.

Table 2 Demographics and diagnosis frequency of groups with and without affective disorder

Variables	Affective disorder	
Females	With	Without
Unique individuals	23637	141427
Mean age	47	38

Figure 1 Proportional total diagnosis frequency ratios > 1 distribution of associated biomedical and biophysical diagnoses by age comparing males with and without affective disorder.

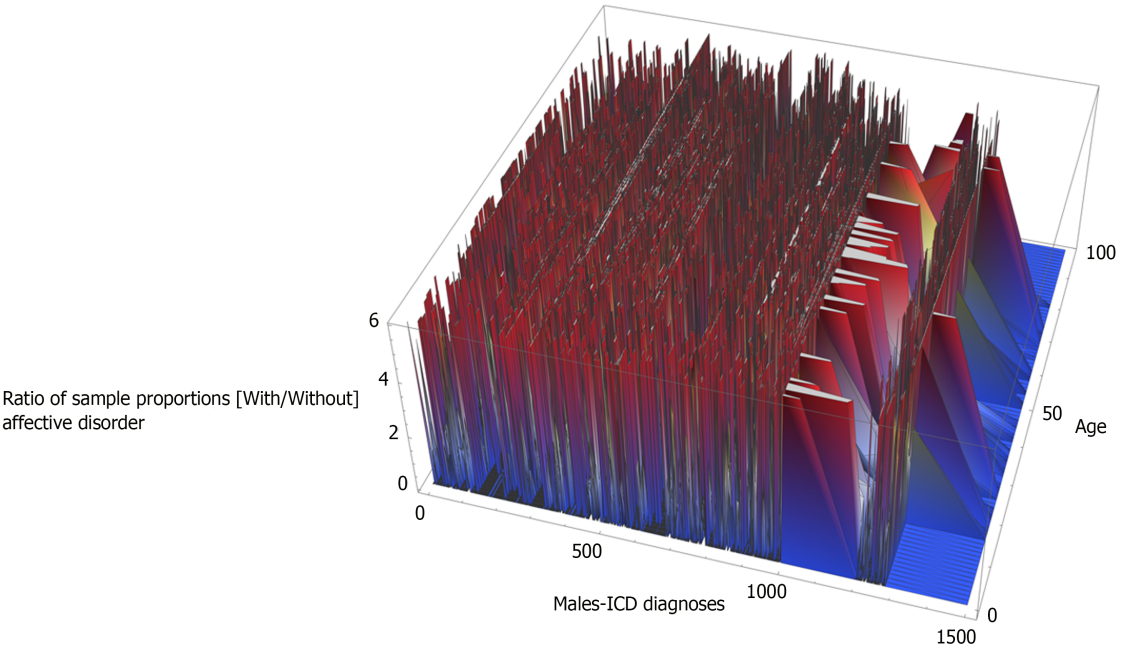

Figure 6 shows the complete proportional ratios > 1 distribution comparing females with and without affective disorder.

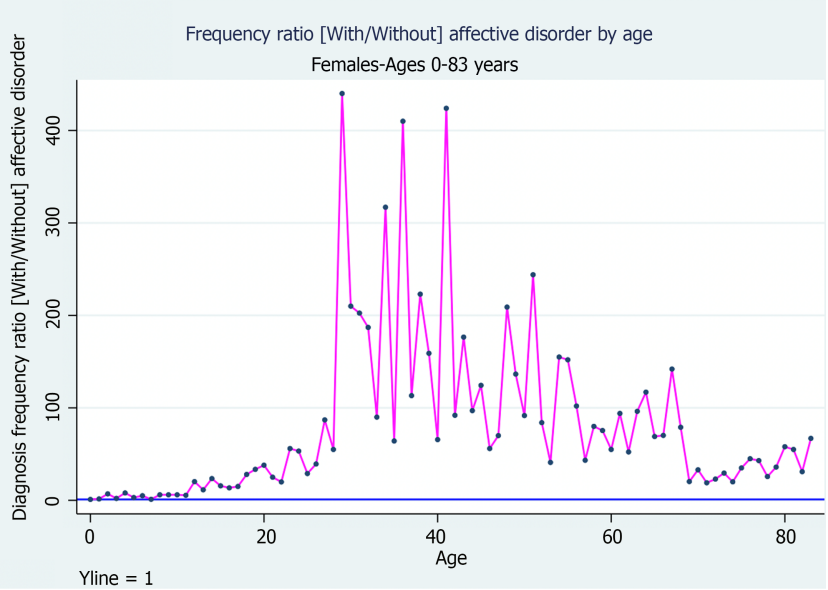
Overall, the reader might take away the following main points of the graphic representations of comparative unique frequency ratios of diagnosis for all ICD-9 diagnoses by age are as follow: (1) Those with affective disorder have greater frequencies of unique ICD-9 diagnoses across age; and (2) Males are substantially different than females.

DOI: 10.5498/wjp.v13.i7.423 **Copyright** ©The Author(s) 2023.

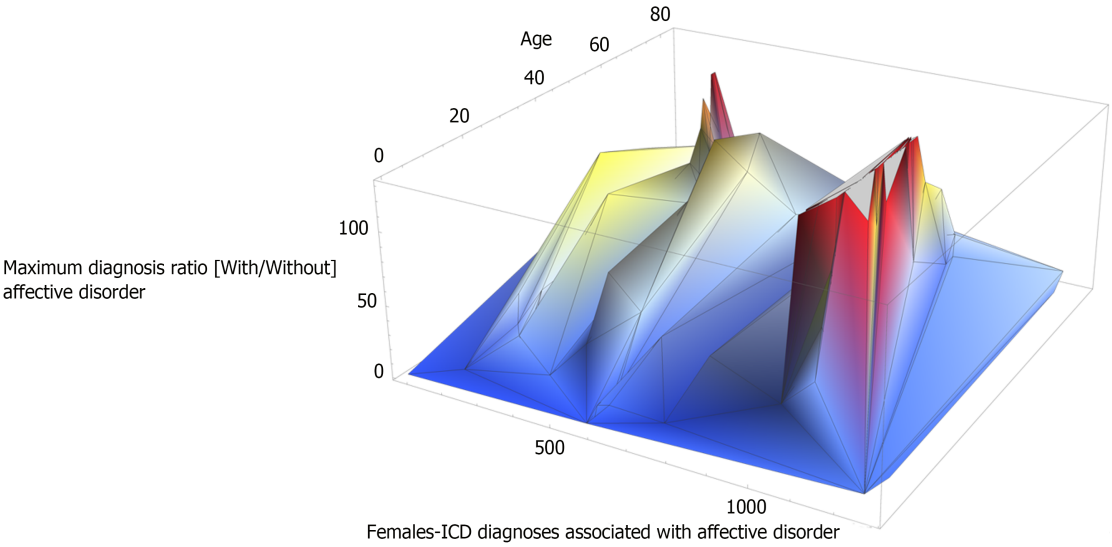
Figure 2 Proportional frequency ratios > 1 distribution of maximum values comparing in males comparing those with and without affective disorder.



DOI: 10.5498/wjp.v13.i7.423 **Copyright** ©The Author(s) 2023.

Figure 3 Complete proportional ratios > 1 distribution comparing males with and without affective disorder.

In Figures 1 and 4, the maximum proportional diagnosis frequency ratios' distributions for males and females across all ages most clearly illustrate the sex differences. For example, the age-specific maximum proportional diagnosis frequency ratios are greater for males earlier in life. The maximal values in Figures 1 and 4 are greater than Figures 2 and 5 and more so in Figures 3 and 6, as the values in the latter figures are distributed across the frequency of individual diagnoses for a given sample size, rather than quotients within the summed frequency across the range of all ICD disorders within in a given age-specific sample sizes comparing the groups with and without affective disorder.



Figures 2 and 5 illustrate the sex differences within the subset of age-specific proportional diagnosis frequency ratios distributions for males and females showing the maximum proportional diagnosis frequency ratio values for each age across the full range of ICD diagnoses. Note that the graphs truncate around the proportional diagnosis frequency ratio less than 800 for males and about 100 for females, indicating a much higher proportional frequency of age-specific diagnosis for males.

From the full distribution of age-specific proportional diagnosis frequency ratios distributions shown for males and females in Figures 3 and 6, it is apparent that females have more laboratory testing and procedures, while males have

Figure 5 Proportional frequency ratios > 1 distribution of maximum values comparing in females comparing those with and without affective disorder.

more V code diagnoses. Figures 3 and 6 both automatically truncate for visualization at the value 6.0 for both males and females when the full distributions are represented. The areas of the visible plateaus are relative to the height of each where the sequence of disorders by age reach their maximal peaks. Further, Figures 3 and 6 represent the ratios of the average frequency quotients for those with and without affective disorder, rather than the maximum values by age across all ICD disorders. Note the frequency of peaks closer at the value 1200 on the diagnosis axis comparing males and females, the frequency of V-Code peaks is greater for males across all ages. Similarly, note the frequency of peaks closer of the value 1500 on the diagnosis axis comparing males and females, the frequency of Laboratory Testing peaks is greater for females across all ages.

DISCUSSION

Our first purpose, examination of the volume of population-based morbidity literature, yields clear results. The PubMed search scope indicates that there has been a rapid increase in morbidity focused research after 1990 with a peak number of

DOI: 10.5498/wjp.v13.i7.423 **Copyright** ©The Author(s) 2023.

Figure 6 Complete proportional ratios > 1 distribution comparing females with and without affective disorder.

publications (n = 10238) in 2019. However, the specific publications cited in this paper indicate that only a minority (4.94%) specifically focus on mental disorder associated temporal biomedical and biophysical hyper-morbidity (Table 1). Even fewer account for the full range of morbidity in populations[18-24].

Our second purpose was the examination of affective disorder associated life-span multi-morbidity of biomedical and biophysical diagnoses in a 16-year population sample. Each age-specific grouping could enter or leave the dataset in any of the 16 years. Other studies of the same dataset focusing on prospective cohort samples (*e.g.*, < 1 year of age before January 1, 1995) in comparison to the same age group across the 16-year sample provide evidence indicating that all ages across the whole 16-year grouping in the current analysis does not unduly bias the results[23]. Thus, we are confident that the cumulative age specific results are similarly unbiased.

As expected, our results illustrate substantial differences between males and females: we found that more females than males were diagnosed with greater frequencies of diagnoses at different ages. This outcome is similar to epidemiological population based studies of affective disorder[30-33].

When comparing the same biomedical and biophysical diagnoses between the two groups at the same age, the age-specific distributions of the maximum proportional diagnosis frequency ratios for each sex showed the greatest diagnosis-specific differences between the two sexes.

Possibly of interest are the biomedical and biophysical diagnoses that do not overlap for males and females between the groups with and without affective disorder. The within group age-specific proportional distributions (not represented as between group ratios) of the non-overlapping diagnoses may in the affective disorder group represent diagnoses associated with increased etiological or sequelae risk over time. It may also be possible that non-overlapping diagnoses may in the group without affective disorder may represent protective diagnoses. These speculations, however, are well beyond the data limits of the present study, albeit such information as is presented may serve as a signpost for future research.

Strengths

Representing the full range of ICD-9 diagnoses as well as examining the proportional diagnosis frequency ratios of overlapping age-specific diagnoses is a novel data representation model. For example, the main difference in comparison to other formula, such as the odds ratio, is that the within-sample intensity of age-specific diagnoses may be represented and compared. The odds ratio generally counts unique individuals, and as such, features such as the frequency of given diagnoses are lost in the comparison. Diagnostic frequency may be an indicator of the severity or chronicity of a particular disease state.

Limitations

The PubMed searches were not thorough or reviewed in terms of content. The searches deviated from typical systematic reviews or meta-analyses. The searches employed a standardized approach only to illustrate the volume of morbidity-focused research.

While proportional diagnosis frequency ratios of overlapping age-specific diagnoses may be a novel form of life-span data representation, it is also important to consider the within group proportions of age-specific diagnoses. It was noted in the methods that when this value exceeded 1.0 the whole within sample had received the diagnosis. The proportional

diagnosis frequency ratios of overlapping age-specific diagnoses reported in this study were not limited to only those disorders having within group proportions greater than the value one. The main reason for this omission was to represent the proportional diagnosis frequency ratios available within the full range of ICD-9 diagnoses. Future work will address this limitation.

Finally, the foregoing novel analyses are a pointer to the complexity of any understanding of the temporal hyper-morbidity of affective disorders, save any mental disorder. For example, a next level of complexity in analysis requires the calculation of the conditional order of diagnoses within individuals. Conditional order is not simply the frequency of diagnoses for the dependent groups of individuals in time, (total of diagnoses on date 1, 2, 3…n) independent of the diagnosis that each individual experiences before or after any given diagnosis. The conditional sequence of diagnoses within individuals may reveal more information that is relevant to the etiology and prognosis of disorders arising before and after an index diagnosis of affective disorder.

CONCLUSION

The study of complex morbidity is emerging as a primary field of research[34] with multiple levels of definition[35]. Despite a rapid increase in morbidity focused research after 1990, a small minority of 4.94% specifically focus on mental disorder associated temporal biomedical and biophysical hyper-morbidity. The publications cited in this paper indicate only a few are focused on lifespan, biomedical and biophysical, population-based, temporal, hyper-morbidity[18-24]. The present study represents to the best of our knowledge the first comprehensive population-based examination of the lifespan biomedical and biophysical multi-morbidity that is associated with affective disorder. By employing a novel model of data representation, we were able to show the intensity of the affective disorder associated diagnoses. Based on the present results, a paradigm shift is required in terms of how in psychiatric and medical practice morbidity is conceptualized, defined, and studied[36,37]. An important step in re-defining morbidity is illustrated in the recent establishment of the World Psychiatric Association Comorbidity Section, wherein the study of morbidity is identified as central 21st century challenge for psychiatry[38,39].

ARTICLE HIGHLIGHTS

Research background

The latest series of publications based on “big-data” leading to this one, have also, in part, contributed to the formation and development of the World psychiatric Association Comorbidity Section.

Research motivation

This overall study was inspired by the Adverse childhood experiences (ACE) study. ACE are associated with lifespan morbidity and many leading causes of death in adulthood. The ACE study is a landmark research effort that investigated the relationship between childhood abuse and household dysfunction, and the leading causes of death in adulthood. The study found that individuals who experienced adverse childhood experiences such as physical, emotional, or sexual abuse, neglect, household dysfunction (*e.g.*, substance abuse, mental illness, incarceration, and divorce), are at higher risk for several chronic health conditions and premature death. The findings of the ACE study demonstrate the far-reaching impact that childhood experiences can have on adult health and well-being. The study's results highlight the importance of addressing childhood trauma and promoting healthy family environments to prevent chronic disease and improve overall health outcomes in adulthood.

Research objectives

To orient all divisions of medicine to the fact that big data has shown important lifespan links between mental disorder and biomedical and biophysical diseases, wherein mental disorder is fundamental linchpin in time, generally leading to hyper-morbidity and hyper-morbidity is a linchpin to mental disorder; and to develop algorithms identifying the precise (conditional) order for individuals and examining how these orders group may prove useful to both clinical practice and research into disease mechanism.

Research methods

We are now developing advanced algorithms for the reduction of data for representation. The example in this paper presents a novel approach to analysis based on the intensity or frequency of total and unique diagnoses by age for all individuals in a large population. In this paper, about 90 million diagnoses for about 0.75 million individuals are reduced to one graphic for each of males and females of age by frequency of diagnosis ratios for each of about 1000 ICD diagnoses.

Research results

It is apparent that there is greater temporal hyper-morbidity for those with affective disorder compared to those without any psychiatric diagnosis. When different publication results are compared, there are different disease vulnerabilities (*e.g.*, cancer and ulcerative colitis) related to different classes of psychiatric disorders and *vice versa*.

Research conclusions

Understanding temporal hyper-morbidity (and perhaps hypo-morbidity) is dependent on large population-based datasets. The results are fascinating in the sense that analyzing whole stable populations over time is more like accounting than statistical analysis and the results from the first population health index paper were intra-ocular (*e.g.*, over 50% of the population has a mental disorder over 16 years and over 3 times the biomedical and biophysical disorders.) This is in line with the World Psychiatry Association's identification of the 21st century's challenge is understanding and responding to mental disorder-related biomedical and biophysical morbidity.

Research perspectives

The conditional groupings are complex (as in the graphics of this paper), and like a classical 'road map' problem, and will likely depend on smart algorithms and artificial intelligence to unravel the clinical meaning for practice related to the next patient who walks through the door and mechanisms underlying groups such as autism, cancers, ulcerative colitis and viral pneumonia). The work to date is largely a signpost, pointing in a future direction. Even so, ChatGPT has already been directed to write several testable algorithms. As it stands, the population health index centered on mental disorder indeed represents an inflation-proof mechanism by which regions and nations may evaluate the cost/benefit impact of universal population-based prevention/promotion and early intervention investments and strategies.

Abstract

BACKGROUND

Genetic factors play an important role in the pathogenesis of panic disorder (PD). However, the effect of genetic variants on PD remains controversial.

AIM

To evaluate the associations between *glutamate decarboxylase 1 (GAD1)* gene polymorphisms and PD risk and assess the effect of *GAD1* gene polymorphisms on the severity of clinical symptoms in PD.

METHODS

We recruited 230 PD patients and 224 healthy controls in this study. All participants were assessed for anxiety and panic symptom severity using the Hamilton Anxiety Rating Scale (HAM-A) and Panic Disorder Severity Scale (PDSS). *GAD1* gene polymorphisms (rs1978340 and rs3749034) were genotyped and assessed for allele frequencies.

RESULTS

There were no significant differences between cases and controls in the genotype distributions or allele frequencies of *GAD1* (rs1978340 and rs3749034). In addition, the effect of *GAD1* (rs1978340 and rs3749034) on PD severity was not significant. However, regarding respiratory symptoms, patients with the *GAD1* rs1978340 A/A genotype had significantly higher scores than those with the A/G or G/G genotype.

CONCLUSION
Here, we showed that the A/A genotype of *GAD1* rs1978340 was associated with increased severity of respiratory symptoms in patients with PD.

Key Words: Panic disorder; Gene polymorphisms; Respiratory symptoms; Allele frequencies; Pathogenesis; Chinese population

Core Tip: The study found that the A/A genotype of *glutamate decarboxylase 1 (GAD1)* rs1978340 was associated with increased severity of respiratory symptoms in patients with panic disorder (PD). However, there were no significant differences between cases and controls in the genotype distributions or allele frequencies of *GAD1* (rs1978340 and rs3749034), and neither did *GAD1* (rs1978340 and rs3749034) have a significant effect on the severity of PD symptoms. These findings suggest that genetic factors may play a role in the pathogenesis of PD, particularly in respiratory symptoms, but further studies with larger sample sizes are needed to confirm these results.

INTRODUCTION

Panic disorder (PD), the most common anxiety disorder, is characterized by recurrent and unexpected panic attacks and has an estimated 12-mo and lifetime prevalence rates of 2.4% and 3.8%, respectively[1,2]; the lifetime prevalence rate of panic attacks is 13.2%[3]. PD typically occurs in young adults, and women are more likely to be affected than men. However, the etiology of PD is multifactorial and complex, involving genetic, environmental, psychological and neurobiological factors[2,3]. Recent studies examining twins and family shows that the heritability of panic disorder is 30%-40%, suggesting strong evidence for a genetic etiology[4]. To date, genetic studies have reported several susceptibility genes for PD such as *neuropeptide Y*, *catechol-O-methyltransferase* and particularly 5-HT system-related genes[5,6]. For example, a previous study found that patients with PD were characterized by significantly higher frequencies of the LL genotype and L allele variant of the 5-HT transporter-linked promoter region (5-HTTLPR)[7]. However, few of these findings have been replicated by other researchers, and the pathogenesis of PD remains unclear[8-12]. Therefore, other candidate gene polymorphisms in PD should be explored.

γ-Aminobutyric acid (GABA) is an important inhibitory neurotransmitter in the mammalian brain, and abnormalities in the GABAergic system have long been implicated in the pathophysiology of PD[13-15]. For example, a significant decrease in *GABA* has been detected in the anterior cingulate and medial prefrontal cortices of patients with PD[16]. The *GAD1* gene encodes the 67-kDa glutamic acid decarboxylase isoform (GAD67) and is the rate-limiting enzyme responsible for GABA biosynthesis from glutamic acid. The *GAD1* gene might play an important role in the GABAergic system. A previous study found a significant effect of rs1978340 on cingulate cortex GABA concentrations[17]. In addition, previous studies have indicated that *GAD1* rs3749034 is associated with mRNA expression[18]. Therefore, *GAD1* may be an important candidate gene in PD. Incidentally, previous reports have suggested that the *GAD1* single nucleotide polymorphisms (SNPs) rs3749034 or rs1978340 are significantly related to several psychiatric disorders such as bipolar disorder[19], schizophrenia[20], attention-deficit/hyperactivity disorder[21], and heroin dependence[22]. For instance, the allelic or genotypic frequencies of the rs1978340 polymorphism in heroin addicts significantly differ from those in normal controls[23]. However, few studies have examined the relationship between *GAD1* and PD, particularly in Chinese populations.

Previous genetic and chromosomal studies have yielded inconsistent results. It is likely that most cases of PD have a complex genetic basis. In addition, current data suggest that the genetic architecture underlying PD is heterogeneous and differs among cases[24]. PD is accompanied by various symptoms, including palpitations, accelerated heart rate, dyspnea, sweating, and chest pain. These symptoms may be linked to distinct genetic mechanisms, and genetic polymorphisms have been speculated to be linked to the discrete symptoms of PD. Hence, to test the hypothesis that the GAD1 polymorphism could be associated with PD, we have conducted a case-control study comparing the frequency of these SNPs (rs1978340 and rs3749034) in PD patients and healthy controls. Additionally, we examined the relationship between the presence of PD symptoms and these polymorphisms.

MATERIALS AND METHODS

Participants

A total of 230 patients with PD were recruited as in- and outpatients at the Department of Psychosomatics, Sichuan Provincial People's Hospital, from July 2012 to January 2016. Patients were qualified based on the following criteria: A primary diagnosis of PD performed by professional psychiatrists according to the standardized structured clinical interview of the diagnostic and statistical manual of mental disorders, fourth edition axis I disorders (SCID-I)[25], and no episodes of other psychiatric disorders in the past or at present. Additionally, 224 healthy controls (HCs) among community volunteers were recruited for the study during the same period. SCID-I was also performed by a trained clinical psychiatrist, and the HCs had no history of any psychiatric disorder or major psychiatric condition in their first-degree relatives. All participants in this study were Han Chinese, aged 18–60 years. None of the patients had acute or chronic somatic disorders, head trauma, or neurological illnesses. The study was approved by the Ethics Committee of the Sichuan Provincial People's Hospital [reference number: (2016) Ethics Review (29)]. All participants provided written informed consent before the initiation of study procedures.

Measures

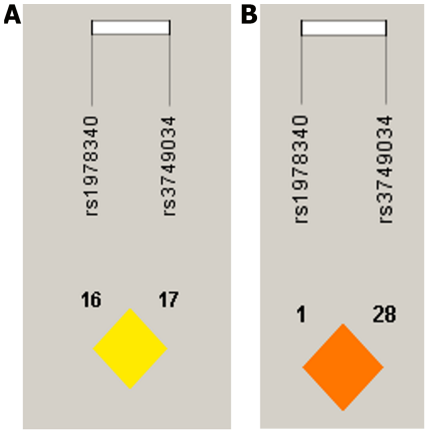
PDSS: The 7-item PDSS was used to assess the severity of panic symptoms for all patients, and participants were instructed to rate each item from 0 to 4 based on the severity of each symptom, with possible responses ranging from "none" to "extremely severe"[26]. The scale was translated into Chinese by Xiong[27], and the PDSS-Chinese version had good internal consistency (Cronbach's alpha) with an overall score of (0.83).

Hamilton anxiety rating scale

The Hamilton anxiety rating scale (HAM-A) scale comprises 14 items (anxious mood, tension, fear, insomnia, cognitive function, depressed mood, somatic anxiety (muscular system), somatic anxiety (sensory system), cardiovascular symptoms, respiratory symptoms, gastrointestinal symptoms, genitourinary symptoms, autonomic symptoms, and behavior at interview) with 5-level responses for each item, *i.e.*, scores 0, 1, 2, 3, and 4 indicating not present, mild, moderate, severe, and very severe, respectively[28]. A total score > 17 indicates mild anxiety symptoms; 18-24, mild-to-moderate anxiety symptoms; and 25-30, moderate-to-severe anxiety symptoms.

DNA extraction and SNP genotyping

For each participant, 3 mL of peripheral blood was collected in EDTA tubes. An automatic nucleic acid extractor (TGuide M16; Tiangen Biotech, Beijing, China) was used to extract genomic DNA. SNP genotyping was performed using an improved multiplex ligation detection reaction (iMLDR) technique developed by Genesky Bio-Tech (Shanghai, China). The multiplex polymerase chain reaction (PCR) reaction volume included 1 μL GC-I buffer (Takara Bio Inc., Shiga, Japan), 3.0 mmol/L Mg^{2+}, 0.3 mmol/L dNTP, 1 U HotStar Taq Polymerase (Qiagen, Hilden, Germany), 1 μL genomic DNA (5–10 ng/μL), and 1 μL Multiplex-PCR primer mix. The cycling program for PCR was 95 °C for 120 s, followed by 11 cycles of 94 °C for 20 s, 65 °C for 40 s, and 72 °C for 90 s, and each cycle decreased by 0.5 °C. The third step comprised 24 cycles at 94 °C for 20 s, 59 °C for 30 s, and finally, 72 °C for 2 min, and a hold at 4 °C. The PCR product was purified with 5 U SAP and 2 U Exonuclease I at 37 °C for 1 h and then inactivated at 75 °C for 15 min. The primer and probe information is provided in Supplementary Tables 1 and 2, respectively. The ligation reaction included 1 μL of 10× ligation buffer, 0.4 μL 3′ ligation primer (2 μM), 0.25 μL Tag DNA ligase, 6 μL ddH_2O mixture, 0.4 μL 5′ ligation primer (1 μM), and 2μL purified multiplex PCR product. The ligation cycling program comprised 38 cycles at 94 °C for 60 s, 56 °C for 4 min, and a hold at 4 °C. Sequencing was conducted in 0.5 μL 500 LIZ Size Standard, 0.5 μL ligation product, and 9 μL Hi-Di mixture (ABI3730XL; Applied Biosystems, Waltham, MA, United States). Raw data were analyzed using GeneMapper v4.1 software (Applied Biosystems). A random sample accounting for approximately 5% of the total DNA samples was directly sequenced using Big Dye-terminator version 3.1 and an ABI3730XL automated sequencer (Applied Biosystems) to confirm the iMLDR results.



Statistical analysis

SPSS version 13.0 software (SPSS Inc., Chicago, IL, United States) was used to analyze the data. Student's *t*-test was used for intergroup comparisons of continuous variables, and Pearson's chi-square test was used for categorical variables. The Hardy-Weinberg equilibrium (HWE) *P* values were tested using Pearson's chi-square test. Associations between SNPs and PD were determined based on the distribution of allelic frequencies and genetic models (additive, dominant, and recessive models). Odds ratios and 95% confidence intervals were calculated by unconditional logistic regression analysis using PLINK v1.07. Analysis of variance was performed to compare the clinical variables with different *GAD1* SNPs (rs1978340 and rs3749034). Bonferroni's correction was used to avoid Type I errors. For all analyses, statistical tests were two-tailed, and an alpha level of 0.05 was used to define statistical significance.

RESULTS

Demographic data and clinical manifestations

The analyzed sample comprised 230 PD cases (92 men and 138 women; mean age, 35.38 ± 9.55 years) and 224 controls (100 men and 124 women; mean age, 36.57 ± 8.43 years). Of these patients, 54% (n = 124) resided in urban locations, and

Figure 1 Linkage disequilibrium in *glutamate decarboxylase 1* polymorphisms (rs1978340 and rs3749034). A: Data from this study; B: Data from 1000 genomes.

46% (n = 106) resided in rural locations. No statistically significant differences were found between the cases and controls in terms of sex, age, or residential location (P > 0.05). For the PD patients, the mean course of PD was 2.80 ± 1.68 years, the mean PDSS score was 14.13 ± 3.74, and the mean HAM-A score was 22.07 ± 6.86 (Table 1).

Association of GAD1 (rs1978340 and rs3749034) polymorphisms with PD risk

HWE was measured in all genotyped individuals. *GAD1* (rs1978340 and rs3749034) polymorphisms fulfilled the HWE (P > 0.05) in both patients and HCs. The linkage disequilibrium evaluated in patients with PD and HCs for variants rs1978340 and rs3749034 of *GAD1* is shown in Figure 1 (R^2 > 0.9). The genotype and allele distributions of *GAD1* (rs1978340 and rs3749034) did not significantly differ between PD patients and HCs (P > 0.05) (Table 2).

Association of GAD1 (rs1978340 and rs3749034) polymorphisms with clinical manifestations in PD patients

There were no statistically significant differences in the total PDSS and sub-item scores among the three genotype groups of *GAD1* polymorphisms (rs1978340 and rs3749034; all P > 0.05) (Table 3).

However, there was a significant difference among the three groups with different *GAD1* rs1978340 genotypes in item 10 of the HAM-A score for PD (P < 0.01). In addition, post hoc analyses indicated that patients with the *GAD1* rs1978340 A/A genotype had significantly higher scores than those with the A/G or G/G genotypes (all P < 0.001), and the results remained significant after Bonferroni's multiple comparison adjustment (P < 0.01), reflecting a higher score for respiratory symptoms in patients with the *GAD1* rs1978340 A/A genotype than in those with the A/G or G/G genotype. However, there was no statistically significant difference among the three groups with different *GAD1* rs1978340 genotypes for the remaining items or HAM-A total scores (P > 0.05). Moreover, there was no significant association between *GAD1* rs3749034 and anxiety severity in PD patients (all P > 0.05) (Table 4).

DISCUSSION

In this study, regarding respiratory symptoms, which include chest tightness, choking, and breathing difficulty, we found that patients with the *GAD1* rs1978340 A/A genotype had significantly higher scores than those with the A/G or G/G genotypes. In other words, the present study showed that the *GAD1* rs1978340 A/A genotype was associated with increased severity of respiratory symptoms in patients with PD and demonstrated that the *GAD1* genotype might be related to symptomatic profiles rather than vulnerability to developing PD. In addition, our findings imply that different clinical features in PD patients are closely related to the heterogeneity of heredity. Compared with PD patients of the non-respiratory subtype (non-RS), previous studies have shown that patients with the RS subtype have a more extensive family history of PD[29]. Moreover, experimental animal research has provided evidence of the important role of GABAergic neurotransmission in the amygdala in modulating anxiety-related behaviors. For example, diminished GAD67 expression in the amygdala blunts the anxiolytic-like effects of diazepam in adult mice[30]. Furthermore, *GAD1* SNP rs1978340 is potentially functional because it affects GABA concentrations in the cingulate cortex[22]. In addition, the presence of *GAD1* rs1978340 allele A has been associated with a higher Glu/GABA ratio[31]. Clinical trials have shown that patients with PD and RS have a more rapid response to antidepressants and benzodiazepines than that of non-RS PD patients[32]. These findings contribute to our understanding of the mechanism linking *GAD1* rs1978340 with respiratory-related symptoms.

Similar findings suggest that patients with PD carrying the 5-HTTLPR s-allele experience the most severe panic and depressive symptoms[33]. Another study showed higher anxiety levels among A/G carriers than those among A/A carriers in patients[34]. It is evident that molecular genetics showed inconsistent results across different studies. This may be due to different sample sizes and ethnic differences. In addition, different clinical symptoms may be partly attributed

to different genetic backgrounds, leading to difficulties in reaching a consensus on the etiology of PD. Further studies with larger populations are needed to obtain precise results based on different symptom subtypes.

In this case-control study, we examined two SNPs (rs1978340 and rs3749034) in a Chinese population. The results revealed that there was no association between *GAD1* and PD. In addition, we did not observe a modulatory effect of *GAD1* (rs1978340 and rs3749034) on PD severity. Much evidence has indicated that *GAD1* gene polymorphisms may be involved in the etiology of several psychiatric disorders. However, only one study has found that *GAD1* variation is associated with PD in females[35]. The different results of these studies might be partly attributable to differences in sample size and sex. Moreover, samples from different ethnicities and meta-analyses are required to further test this association. The SNP coverage in the present study was limited, and other gene polymorphisms should be considered. In addition, the pathogenesis of PD may involve the interaction of multiple genes and signal pathway regulation, which may incorporate the combined effects of genetic and environmental factors. For example, a previous study suggested the effect of the interaction between 5-HTTLPR and separate life events on PD[36]. Finally, epigenetic mechanisms have been

suggested to play important roles at the intersection of genetic and environmental factors[37]. Environmental factors may influence biological processes through epigenetic mechanisms, particularly DNA methylation[38]. For instance, patients with PD exhibit significantly lower average *GAD1* methylation levels than those of HCs[39]. Another study showed that patients had significantly lower methylation of the *GAD1* promoter region on cytosine-phosphate-guanine 7 than that of HCs, and a significant negative association was found between the cg171674146 site and clinical severity[40]. Therefore,

epigenetic modifications may play an important role and should be further investigated in future studies.

CONCLUSION

In conclusion, the present study showed that the A/A genotype of GAD1 rs1978340 is associated with increased severity of respiratory symptoms in patients with PD. However, the results of our study should be considered in light of the following limitations: Since this was a small sample investigating the associations between *GAD1* gene polymorphisms and PD, it would be valuable to replicate our findings in a larger cohort. In addition, SNP coverage in the present study was limited, and other gene polymorphisms should be considered.

ARTICLE HIGHLIGHTS

Research background

Genetic factors are known to play a significant role in the development of panic disorder (PD). However, the impact of genetic variants on PD is still a subject of controversy.

Research motivation

γ-Aminobutyric acid (GABA) is an important neurotransmitter that inhibits brain activity. Previous reports have linked the *glutamate decarboxylase 1 (GAD1)* genetic variants to various psychiatric disorders, including bipolar disorder, schizophrenia, attention-deficit/hyperactivity disorder, and heroin dependence. However, few studies have examined the relationship between *GAD1* and PD, particularly in Chinese populations.

Research objectives

The main objectives of this study were to examine the associations between *GAD1* gene polymorphisms (rs1978340 and rs3749034) and PD risk, and to determine the effect of these polymorphisms on the severity of clinical symptoms, specifically respiratory symptoms, in individuals with PD.

Research methods

The study included a total of 230 PD patients and 224 healthy controls. All participants underwent assessments for anxiety and panic symptom severity using the Hamilton Anxiety Rating Scale (HAM-A) and Panic Disorder Severity Scale (PDSS). The GAD1 gene polymorphisms (rs1978340 and rs3749034) were genotyped, and allele frequencies were analyzed.

Research results

The study findings revealed no significant differences in the genotype distributions or allele frequencies of *GAD1* (rs1978340 and rs3749034) between the PD cases and the control group. Furthermore, the *GAD1* gene polymorphisms (rs1978340 and rs3749034) did not exhibit a significant effect on the overall severity of PD. However, in relation to respiratory symptoms, PD patients with the *GAD*1 rs1978340 A/A genotype demonstrated significantly higher scores compared to those with the A/G or G/G genotype.

Research conclusions

In conclusion, this study demonstrated that the A/A genotype of *GAD1* rs1978340 is associated with increased severity of respiratory symptoms in individuals with PD. However, no significant associations were found between *GAD1* gene polymorphisms and the risk of developing PD or the overall severity of the disorder.

Research perspectives

Further research is needed to explore other potential genetic factors involved in the development and severity of PD. Additionally, investigating the underlying mechanisms through which *GAD1* gene polymorphisms affect respiratory symptoms in PD patients could provide valuable insights for future studies.

Abstract

BACKGROUND

With the intensification of social aging, the susceptibility of the elderly population to diseases has attracted increasing attention, especially chronic heart failure (CHF) that accounts for a large proportion of the elderly.

AIM

To evaluate the application value of health concept model-based detailed behavioral care in elderly patients with CHF.

METHODS

This study recruited 116 elderly CHF patients admitted from October 2018 to October 2020 and grouped them according to the nursing care that they received. The elderly patients who underwent health concept model-based detailed behavioral care were included in a study group (SG; n = 62), and those who underwent routine detailed behavioral nursing intervention were included as a control group (CG; n = 54). Patients' negative emotions (NEs), quality of life (QoL), and nutritional status were assessed using the self-rating anxiety/depression scale (SAS/SDS), the Minnesota Living with Heart Failure Questionnaire (MLHFQ), and the Modified Quantitative Subjective Global Assessment (MQSGA) of nutrition, respectively. Differences in rehabilitation efficiency, NEs, cardiac function (CF) indexes, nutritional status, QoL, and nursing satisfaction were comparatively analyzed.

RESULTS

A higher response rate was recorded in the SG *vs* the CG after intervention (P < 0.05). After care, the left ventricular ejection fraction was higher while the left ventricular end-diastolic dimension and left ventricular end systolic diameter were lower in the SG compared with the CG (P < 0.05). The post-intervention SAS

and SDS scores, as well as MQSGA and MLHFQ scores, were also lower in the SG ($P < 0.05$). The SG was also superior to the CG in the overall nursing satisfaction rate ($P < 0.05$).

CONCLUSION

Health concept model-based detailed behavioral care has high application value in the nursing care of elderly CHF patients, and it can not only effectively enhance rehabilitation efficiency, but also mitigate patients' NEs and improve their CF and QoL.

Key Words: Chronic heart failure; Elderly patients; Health concept model; Detailed behavioral care; Patient mood; Quality of life; Nursing effect

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Elderly patients with chronic heart failure (CHF) are prone to negative emotions (NEs) such as depression and anxiety during treatment. Although some drugs can alleviate NEs, they are not conducive to the cardiac function of patients. Therefore, effective means should be explored clinically to improve the mood and quality of life of elderly patients with CHF.

INTRODUCTION

Chronic heart failure (CHF) is a clinically common cardiovascular disorder that may cause various complications[1,2]. The disease is difficult to treat with a high death rate, re-hospitalization rate, and bleak prognosis, resulting in great clinical attention to its treatment and nursing care[3]. In the current aging society, CHF patients account for a large proportion of the elderly population[4]. CHF in the elderly is characterized by a long course, multiple underlying comorbidities, and declined self-care ability, bringing huge economic burden to patients' families and society[5]. Elderly CHF patients are also predisposed to negative emotions (NEs) due to their age and unpredictable conditions[6]. Although drugs such as duloxetine can be used to relieve depression and other NEs, they may be disadvantageous to patients' cardiac function (CF)[7,8]. Effective nursing intervention is therefore extremely necessary, which is the key to improving patients' quality of life (QoL) and disease prognosis[9].

Conventional nursing intervention, being single and inflexible, cannot meet the actual needs of elderly CHF patients [10]. Health concept model-based detailed behavioral care, on the other hand, formulates nursing intervention programs through behavioral and social psychology, which encourages patients to take the initiative to adopt healthy behaviors, thus improving the treatment effect[11]. In addition, there is a positive correlation between health beliefs and healthy behaviors. Establishing correct health beliefs allows people to accept persuasion, change unhealthy behaviors, and actively adopt healthy behaviors[12]. At present, the health belief model has been widely used in the health education of various diseases with good effects achieved[13]. Besides, chronic and unremitting symptoms and long treatment process significantly reduces the QoL of CHF patients while causing NEs such as anxiety and depression[14]. Health education can mitigate the NEs of elderly CHF patients and enhance their disease awareness to mitigate their fear of the disease due to insufficient awareness[15].

Based on the above, this study explored the application value of health concept model-based detailed behavioral care in the care of elderly CHF patients.

MATERIALS AND METHODS

Patient information

The clinical data of 116 elderly patients with CHF admitted to the Affiliated Hangzhou First People's Hospital Zhejiang University School of Medicine from October 2018 to October 2020 were analyzed retrospectively. Patients who underwent health concept model-based detailed behavioral care were included in a study group (SG; $n = 62$, male-female ratio 40:22) and those who underwent routine detailed behavioral nursing intervention were included in a control group (CG; $n = 54$, male-female ratio 29:25).

Eligibility criteria

The enrolled patients all were aged ≥ 60 years, with a confirmed diagnosis of CHF[16], complete clinical data, and active cooperation with treatment. Patients and their families were informed and consented to participate in the study.

Patients with chronic obstructive pulmonary disease, cerebral toxicosis, hyperthyroidism, inability to eat normally, cognitive and consciousness disorders, serious infections, malignant diseases, and limited mobility or those who were otherwise unable to complete all care measures were excluded from the study.

Nursing methods

Patients in the CG were intervened by routine detailed behavioral nursing. Following the doctor's advice, patients were instructed to stay in bed or carry out appropriate activities. Besides, their body temperature and pulse were monitored on time until discharge, and their conditions were closely observed.

Patients in the SG received health concept model-based detailed behavioral care. Before carrying out the nursing work, the nursing staff introduced the disease to the elderly patients in detail, and guided them to relax and cooperate with the care. In addition, each patient's condition and physical function were assessed in a timely manner by means of echocardiography and 24-h continuous ECG monitoring, and the corresponding nursing plan was formulated based on the evaluation results. Furthermore, medication management was strengthened. The patient's indicators (*e.g.*, blood pressure and blood lipid) were strictly monitored and controlled within the reference range as far as possible to prevent complications. The emotional status of patients was always concerned during daily care. When they were found to develop NEs, the causes of unhealthy psychological states were analyzed in time, based on which targeted psychological nursing intervention was developed and implemented. During the nursing intervention, patients' bad daily behavioral habits were corrected, and they were guided to keep good hours to reduce the burden on their hearts. In addition, a certain amount of exercise was also ensured, which was realized by developing an appropriate exercise program for each patient to help improve his/her physical fitness and blood circulation. Moreover, a reasonable diet plan was formulated based on the patient's nutritional status and physical function. In the daily diet, patients were advised to take easy-to-digest, crude fiber, and light foods, and avoid oily and high-fat foods.

Outcome measures

The rehabilitation of the two groups of patients after nursing was compared. It was considered markedly effective if the patient had CF improvement ≥ grade II, with obviously improved condition. Effective referred to CF improvement > grade I and alleviation of clinical symptoms. Ineffective corresponded to CF improvement < grade I, non-improvement, or disease worsening[17]. Overall response rate was calculated as (markedly effective cases + effective cases)/total cases × 100%.

Alterations in CF indexes [left ventricular ejection fraction (LVEF), left ventricular end-diastolic dimension (LVEDD), and left ventricular end systolic diameter (LVESD)] were compared before and after care.

Assessment of patients' anxiety and depression was performed 7 d after nursing using the self-rating anxiety/depression scale (SAS/SDS)[18]. Both scales have a total score of 100, with the scores in direct proportion to anxious and depressive symptoms.

The Minnesota Living with Heart Failure Questionnaire (MLHFQ)[19], which comprises 3 dimensions and 21 items (8, 5, and 8 items in physical field, emotional field, and other fields, respectively), was used for QoL assessment of elderly CHF patients. The total score is 105 points, and the score is inversely proportional to the patient's QoL. Patients' overall nutritional status was evaluated by the Modified Quantitative Subjective Global Assessment (MQSGA) of nutrition[20], with a total score of 35 points, and the score is inversely proportional to the nutritional status.

Nursing satisfaction was investigated using the self-made nursing satisfaction questionnaire (total score: 100) from the aspects of comfort, health knowledge, working ability, service attitude, and comprehensive level. Patients or their families filled it out according to the actual situation. A score of > 90, 70-90, and < 70 points was considered as very satisfied, satisfied, and dissatisfied, respectively, and the total satisfaction = very satisfied + satisfied. The overall nursing satisfaction was compared.

Statistical analysis

In this study, SPSS 19.0 medical statistical analysis software was used to statistically analyze the collected data, with $P < 0.05$ regarded as the significance level for all analyses. The chi-square test (χ^2) was performed for counting data expressed as percentages (%). The mean ± SD was used to denote quantitative data, which all followed a normal distribution and were analyzed between groups by the independent sample *t* test and between different time points by the paired *t* test.

RESULTS

Patients' baseline data

Comparing patients' baseline data, it was found that the two patient cohorts were comparable in age, sex, course of disease, body mass index, systolic blood pressure, complications (hypertension, diabetes, coronary heart disease, and atrial fibrillation), CF grade[17], and heart rate ($P > 0.05$), as shown in Table 1.

Comparison of rehabilitation efficacy

Comparing the rehabilitation effects after intervention, it was found that the total rehabilitation effective rate in the SG

Table 1 Baseline data

		Study group (*n* = 62)	Control group (*n* = 54)	χ^2/t	*P* value
Age (years old)		78.16 ± 6.58	77.19 ± 6.94	0.772	0.442
Sex				1.400	0.237
	Male	40 (64.52)	29 (53.70)		
	Female	22 (35.48)	25 (46.30)		
Course of disease (years)		5.55 ± 1.34	5.43 ± 1.56	0.446	0.657
BMI (kg/m^2)		23.71 ± 3.27	23.93 ± 3.11	0.370	0.712
Systolic pressure (mmHg)		147.97 ± 12.45	149.94 ± 14.28	0.794	0.429
Complications					
	Hypertension	12 (19.35)	14 (25.93)	0.717	0.397
	Diabetes mellitus	8 (12.90)	10 (18.52)	0.694	0.404
	Coronary heart disease	29 (46.77)	23 (42.59)	0.204	0.652
	Atrial fibrillation	13 (20.97)	7 (12.96)	1.296	0.255
Cardiac function grade				2.772	0.250
	II	30 (48.39)	21 (38.89)		
	III	20 (32.26)	25 (46.30)		
	IV	12 (19.35)	8 (14.81)		
Heart rate (beats/min)		80.11 ± 5.24	80.98 ± 5.7	0.856	0.394

BMI: Body mass index.

Table 2 Rehabilitation efficacy

	Study group (*n* = 62)	Control group (*n* = 54)	χ^2	*P* value
Markedly effective	38 (61.29)	25 (46.30)		
Effective	21 (33.87)	20 (37.03)		
Ineffective	3 (4.84)	9 (16.67)		
Overall response	59 (95.16)	45 (83.33)	4.354	0.037

was 95.16%, significantly higher than that of the CG (83.33%; $P < 0.05$), as shown in Table 2.

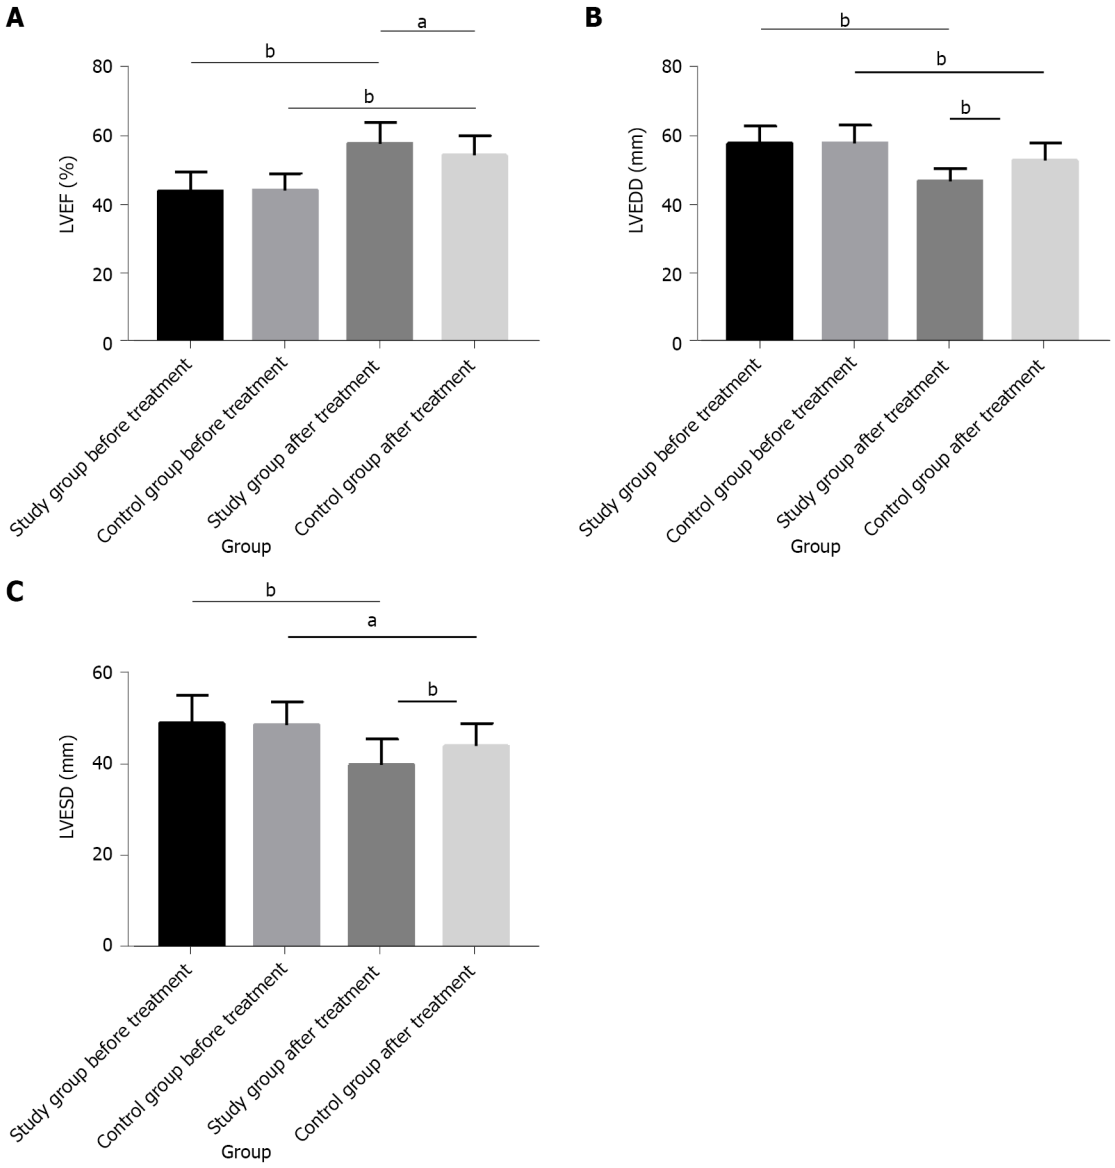
CF improvement

The observation of patients' CF revealed no evident difference in LVEF, LVEDD, and LVESD between the two groups prior to nursing intervention ($P > 0.05$), while elevated LVEF and decreased LVEDD and LVESD were found in both cohorts post intervention ($P < 0.05$). And in comparison with the CG, LVEF was higher while LVEDD and LVESD were lower in the SG ($P < 0.05$; Figure 1).

Relief of patients' NEs

We comparatively analyzed the relief of patients' NEs and found significantly reduced SAS and SDS scores in both cohorts after intervention ($P < 0.05$), with more significant reductions in the SG compared with the CG ($P < 0.05$; Figure 2).

Improvement of nutritional status and QoL of patients after nursing



Comparing the MQSGA and MLHFQ scores before and after patient care, it was found that both scores decreased after nursing ($P < 0.05$), with more significant reductions in the SG as compared to the CG ($P < 0.05$; Figure 3).

Comparison of patients' nursing satisfaction

Statistics on patient satisfaction revealed a nursing satisfaction of 93.55% in the SG, statistically higher than that of the CG (81.48%; $P < 0.05$; Table 3).

Table 3 Nursing satisfaction

	Study group (*n* = 62)	Control group (*n* = 54)	χ^2	*P* value
Very satisfied	35 (56.45)	27 (50.00)		
Satisfied	23 (37.10)	17 (31.48)		
Dissatisfied	4 (6.45)	10 (18.52)		
Total satisfaction	58 (93.55)	44 (81.48)	3.960	0.047

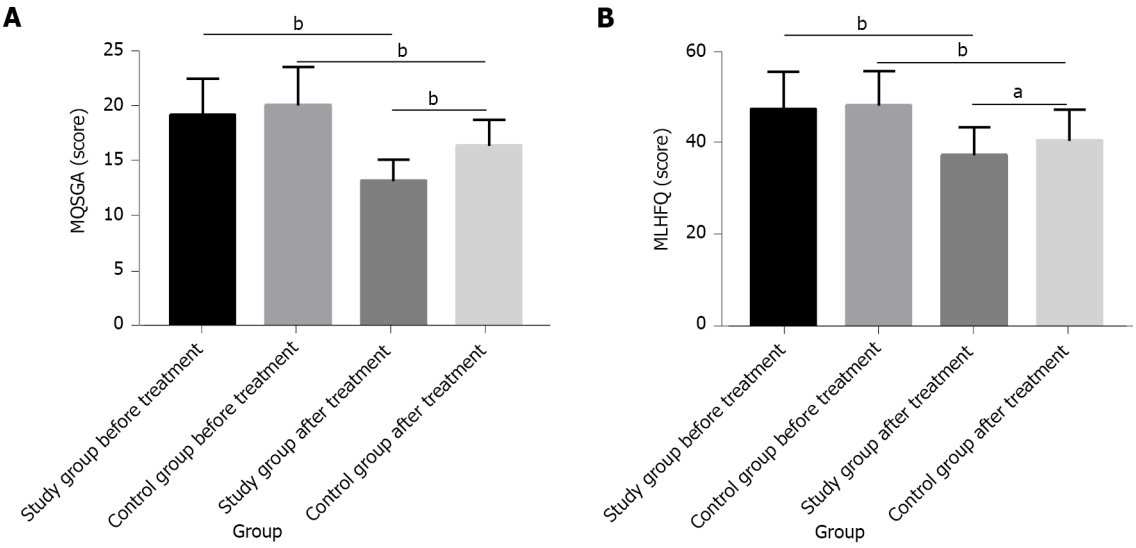
Figure 1 Comparison of patients' cardiac function. A: After nursing, the left ventricular ejection fraction of patients in both groups were significantly improved, with a higher level in the study group as compared to the control group; B: Left ventricular end diastolic diameter was significantly reduced in both groups after nursing, and was statistically lower in the study group compared with the control group; C: After nursing, left ventricular end systolic diameter in the two groups dropped obviously and was lower in the study group compared with the control group. [a]*P* < 0.01; [b]*P* < 0.001. LVEF: Left ventricular ejection fraction; LVEDD: Left ventricular end diastolic diameter; LVESD: Left ventricular end systolic diameter.



DISCUSSION

Due to CF abnormalities, CHF patients experience many physiological and psychological problems such as restricted daily activities, disordered sleep patterns, and depression, resulting in the need of care from family members in daily life [21]. However, there may be unsatisfactory nursing effects due to inadequate nursing training of family caregivers, and improper care may adversely impact patients both physically and psychologically. Educational interventions can

effectively improve people's awareness of various health issues, thus affecting patients' detailed behaviors. In recent years, an increasing number of researchers have devoted themselves to exploring a better nursing intervention model for CHF. For example, Taniguchi *et al*[22] adopted a self-monitoring outpatient care model for CHF patients, and Jin *et al*[23] suggested cluster care in their study[22,23].

This study put forward the view that health concept model-based detailed behavioral care can better promote the rehabilitation of elderly CHF patients and improve their CF than the routine one. Previous studies have also shown that interventions based on the health concept model can accelerate recovery from chronic diseases[24]. In addition, under the health concept model-based detailed behavioral care, appropriate exercise programs will be developed for patients, with the exercise intensity gradually increased according to the patient's tolerance, thus facilitating patient recovery. It has been shown that CF recovery in heart failure patients is accelerated with increasing intensity of exercise training. However, too much exercise in a short period of time will lead to poor exercise experience, reduced comfort, and increased NEs, which cannot motivate patients' treatment and compliance[25,26]. Therefore, we increased the amount of exercise step by step to play a better role in rehabilitation.

Middle-aged and aged people are more susceptible to coronary heart disease as their physical fitness will be partially degraded with age, which will affect their physical resistance and psychological status, reducing their QoL[27]. The detailed behavior nursing based on the health concept model can mitigate patients' NEs while enhancing their nutritional status and QoL. The introduction of a more nutritious diet into daily life, coupled with effective rehabilitation, resulted in significant improvements in the patient's nutritional status, QoL, and NEs. Li *et al*[28] mentioned in their study that intervention based on the health concept model can effectively improve the self-management ability of patients and enhance their professional knowledge during the intervention process, contributing to enhanced confidence in treatment and better QoL, which is similar to our research. In addition, detailed nursing can reflect the quality of care services. Nursing disputes arising from nursing defects, errors, and accidents should be effectively avoided during clinical treatment and nursing care. Meanwhile, ward inspections should be strengthened during treatment, so as to ensure nursing safety, enhance nursing service quality, and improve patient satisfaction[29,30]. In our research, health concept model-based detailed behavioral care also significantly outperformed conventional detailed behavioral nursing in terms of patient satisfaction, consistent with the satisfaction results of Smeulders *et al*[31] on patients with heart failure.

The novelty of this study lies in the comparative analysis of the clinical differences in the rehabilitation effect, CF, SAS, SDS, nutritional status, QoL, and nursing satisfaction between health concept model-based detailed behavioral care and routine detailed behavioral nursing in elderly CHF patients. However, this study also has some limitations. CHF is a long-term condition, but patient outcomes have not been explored in this study, resulting in little understanding of the impact of this care model on patient prognosis. Second, we only included patients aged over 60 years, since the elderly were the main patient group of CHF. However, it is still unclear whether our intervention methods are also applicable to those younger than 60 years, which needs to be explored by re-incorporating samples in subsequent studies.

CONCLUSION

In conclusion, health concept model-based detailed behavioral care has high application value in elderly CHF patients, which can improve patients' rehabilitation efficiency, significantly mitigate NEs, and enhance their CF and QoL.

ARTICLE HIGHLIGHTS

Research background

Chronic heart failure (CHF), a clinical condition that affects a large proportion of the elderly population, is characterized by a long course of disease, many complications, and decreased self-care ability, often bringing a huge economic burden to the families of patients and society.

Research motivation

To help people understand CHF in the elderly and provide reference for the clinical optimization of this disease.

Research objectives

To evaluate the application value of health concept model-based detailed behavioral care in elderly patients with CHF.

Research methods

Sixty-two cases of CHF who underwent health concept model-based detailed behavioral care were included in a study group, and patients' rehabilitation efficiency, negative emotions (NEs), cardiac function (CF) parameters, nutritional status, quality of life (QoL), and nursing satisfaction were recorded. In addition, 54 cases who underwent routine detailed behavioral care were included in a control group (CG) for analysis.

Research results

The rehabilitation efficiency and CF parameters of the study group were significantly improved after intervention. In addition, more significant alleviation in NEs and improvement in QoL were recorded in the study group as compared to the CG. A higher degree of overall nursing satisfaction was also noted in the research group.

Research conclusions

Health concept model-based detailed behavioral care has high application value in elderly patients with CHF, which can improve patients' rehabilitation efficiency, significantly relieve NEs, and enhance their CF and QoL.

Research perspectives

This study discusses the application value of health concept model-based detailed behavioral care in the nursing of elderly CHF patients, and focuses on patients' NEs and QoL, hoping to provide some references for improving the clinical care of such patients.

Abstract

BACKGROUND

Treatment-refractory schizophrenia (TRS), accounting for approximately 30% of all schizophrenia cases, has poor treatment response and prognosis despite treatment with antipsychotic drugs.

AIM

To analyze the therapeutic effectiveness of repetitive transcranial magnetic stimulation (rTMS) combined with olanzapine (OLZ) and amisulpride (AMI) for TRS and its influence on the patient's cognitive function.

METHODS

This study enrolled 114 TRS patients who received treatment at the First Affiliated Hospital of Zhengzhou University between July 2019 and July 2022. In addition to the basic OLZ + AMI therapy, 54 cases of the control group (Con group) received modified electroconvulsive therapy, while 60 cases of the research group (Res group) received rTMS. Data on therapeutic effectiveness, safety (incidence of drowsiness, headache, nausea, vomiting, or memory impairment), Positive and Negative Symptom Scale, Montreal Cognitive Assessment Scale, and Schizophrenia Quality of Life Scale were collected from both cohorts for comparative analyses.

RESULTS

The Res group elicited a higher overall response rate and better safety profile when compared with the Con group. Additionally, a significant reduction was observed in the post-treatment Positive and Negative Symptom Scale and Schizophrenia Quality of Life Scale scores of the Res group, presenting lower scores than those of the Con group. Furthermore, a significant increase in the Montreal

Cognitive Assessment Scale score was reported in the Res group, with higher scores than those of the Con group.

CONCLUSION
The treatment of TRS with rTMS and OLZ + AMI is effective and safe. Moreover, it can alleviate the patients' mental symptoms, improve their cognitive function and quality of life, and has a high clinical application value.

Key Words: Repetitive transcranial magnetic stimulation; Olanzapine; Amisulpride; Treatment-refractory schizophrenia; Therapeutic effectiveness; Cognitive function

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Patients with treatment-refractory schizophrenia always have an unsatisfactory treatment response and prognosis despite antipsychotic therapy, which poses significant challenges to clinical management. Therefore, it is necessary to continuously explore and validate effective treatments for treatment-refractory schizophrenia.

INTRODUCTION

Schizophrenia, a heterogeneous progressive mental illness that may lead to cognitive impairment in patients, has a great negative impact on the patient's social interaction and work[1]. The etiology of the disease is complicated and has been linked to environmental factors, hereditary factors, cortical excitation-to-inhibition imbalance, and subcortical dopamine dysfunction[2]. Schizophrenia is prone to occur in early adulthood, and its symptoms are classified as positive symptoms, such as hallucinations, delusions, and speech disorders, and negative symptoms, such as emotional retardation, abulia, and social barriers[3]. The overall prevalence of schizophrenia is approximately 0.4%, and the mortality rate of schizophrenia patients is 2-4 times that of the general population[4,5]. Treatment-refractory schizophrenia (TRS), accounting for approximately 30% of the total schizophrenia cases, has a poor treatment response and prognosis despite treatment with antipsychotic drugs, which also poses great clinical challenges[6,7]. Nevertheless, it is a compelling responsibility of physicians to explore effective treatment options for TRS.

Repetitive transcranial magnetic stimulation (rTMS), a non-invasive brain stimulation method, induces local neuronal activation in the brain regions *via* electromagnetic induction of electric fields, thus ameliorating the abnormal connections between the brain regions to a certain extent[8,9]. According to the research by Zhu *et al*[10], rTMS has a significant long-term ameliorating effect on working memory defects in schizophrenia patients. Olanzapine (OLZ) and amisulpride (AMI) are both first-line antipsychotic drugs, which are highly effective in reducing the Positive and Negative Syndrome Scale (PANSS) scores and alleviating the mental symptoms of the patients[11]. OLZ is a 5-hydroxytryptamine 2A/2C antagonist affecting the glucolipid metabolism[12] and an efficient AMP-activated protein kinase activator that enhances the AMP-activated protein kinase activity in the hypothalamus, thus mediating energy homeostasis and metabolic modulation during neuronal activity[13,14]. As for AMI, it is beneficial in relieving depressive symptoms and major negative symptoms as well as enhancing the patient's quality of life (QOL)[15].

We proposed that the combination of rTMS and OLZ + AMI has certain beneficial clinical effects in TRS patients.

MATERIALS AND METHODS

Patient information

This study selected 114 TRS patients who received treatment at the First Affiliated Hospital of Zhengzhou University between July 2019 and July 2022. Among them, 54 cases were included in the control group (Con group) treated with modified electroconvulsive therapy (mECT) and 60 cases in the research group (Res group) treated with rTMS; the patients in both groups received OLZ + AMI therapy. The patients in the Res and Con groups presented similar demographic data ($P > 0.05$), suggesting clinical comparability and feasibility during follow-up research.

Inclusion criteria: The inclusion criteria for this study were that patients of both groups fulfill the TRS diagnostic criteria and present complete medical records with no treatment-associated contraindications.

Exclusion criteria: Patients with a history of allergy to the study medications, serious diseases such as heart, lung, or kidney dysfunction, and mental retardation that hindered compliance and cooperation were excluded. Furthermore, pregnant and lactating women and drug abusers were excluded from this study.

Methods

The Con group patients were treated with mECT and OLZ + AMI, as described here. The patients received mECT 2-3 times a week using a Thymatron ECT therapeutic apparatus. The treatment frequency could be adjusted to once weekly according to the treatment effect up to a maximum of 8 times during the treatment course. The initial oral dose of OLZ was 5 mg once daily, and the drug dose could be gradually increased to 10-15 mg/d, depending on patient tolerance, for a total period of 8 wk. AMI was administered orally at an initial dose of 200 mg/d and increased according to patient tolerance and efficacy but not beyond a maximum daily dose of 1200 mg for a total period of 8 wk.

The Res group received rTMS combined with OLZ + AMI. An rTMS therapeutic instrument was used for treatment. The coil of the instrument was placed on the patient's forehead on the left, tangential to the scalp. The dorsolateral left frontal lobe was stimulated according to the threshold stimulation intensity of 80%-110% of the motor threshold, and the frequency was set at 20 Hz. The treatment time was 20 min, once a day, 5 times a week for 8 wk. OLZ and AMI were administered in the same way as that in the Con group.

Outcome measures

Clinical effectiveness: The PANSS scores were compared before and after treatment between the Res and Con groups. A decrease of more than 80% in the PANSS score was considered a "marked response," a decrease of 50%-79% was considered a "response," and failure to meet the above reduction criteria was considered as "non-response." The overall response rate (ORR) was the percentage of the sum of the number of "marked response" and "response" patients among the total number of cases.

Safety: We observed and recorded the number of cases of drowsiness, headache, nausea, vomiting, and memory impairment and calculated the overall incidence.

Severity of schizophrenia: All patients were assessed for schizophrenia severity using the PANSS (total score: 98) with positive and negative subscales. The higher the score, the more serious the symptoms of schizophrenia.

Cognitive function: The cognitive function (CF) of patients was evaluated using the Montreal Cognitive Assessment (MoCA), comprising eight items such as visuospatial/executive ability, memory, naming, and attention. On the 30-point scale, lower scores suggested worse CF.

QOL: The QOL of schizophrenia patients was evaluated using the Schizophrenia Quality of Life Scale (SQLS), comprising psychosocial factors (15 items, total score: 60), motivation and energy (7 items, total score: 28), and symptoms and adverse reactions (8 items, total score: 32). The score was inversely associated with the patient's QOL.

Statistical analysis

This study used Statistical Product and Service Solutions version 19.0 for data analysis; P-values < 0.05 were considered statistically significant. Sex and other categorical variables, expressed as the number of cases/percentages (n/%), were compared between the groups using the χ^2 test. Continuous variables, such as the PANSS scores, expressed as means ± standard error, were compared between the groups using the t-test.

RESULTS

General information

Sex, age, course of the disease, family history, marital status, and educational level did not differ significantly between the Res and Con groups, indicating possible comparability between them (P > 0.05) (Table 1).

Comparison of therapeutic effectiveness

The ORRs of the Con and Res groups were 72.22% and 93.33%, respectively, demonstrating significantly higher efficacy of rTMS and OLZ + AMI than that of mECT and OLZ + AMI (P < 0.05) (Table 2).

Comparison of safety

Observation and records of the occurrence of drowsiness, headache, nausea, vomiting, and memory impairment in both cohorts showed that the incidence of adverse events was statistically higher in the Con group than in the Res group (25.93% *vs* 8.33%, P < 0.05) (Table 3).

Comparison of mental symptoms

Analysis of the mental symptoms using the PANSS revealed that the scores did not differ significantly between the groups before treatment (P > 0.05). However, the scores reduced significantly after treatment in both groups (P < 0.05), with the Res group exhibiting lower scores than those of the Con group (P < 0.05) (Figure 1A).

Comparison of CF

CF, analyzed using the MoCA, did not differ significantly between the groups before treatment (P > 0.05). However, the MoCA scores increased significantly in both cohorts after treatment (P < 0.05), with higher scores in the Res group than in the Con group (P < 0.05) (Figure 1B).

Table 1 Demographic information

Categories	Control group, *n* = 54	Research group, *n* = 60	χ^2/t value	*P* value

High school and above	24 (44.44)	20 (33.33)		

Data are presented as *n* (%), unless otherwise indicated.

Table 2 Comparison of the therapeutic effectiveness of the two treatment methods

Indicators	Control group, *n* = 54	Research group, *n* = 60	χ^2 value	*P* value
Marked response	19 (35.19)	36 (60.00)	-	-
Response	20 (37.04)	20 (33.33)	-	-
Non-response	15 (27.78)	4 (6.67)	-	-
Overall response	39 (72.22)	56 (93.33)	9.120	0.003

Data are presented as *n* (%).

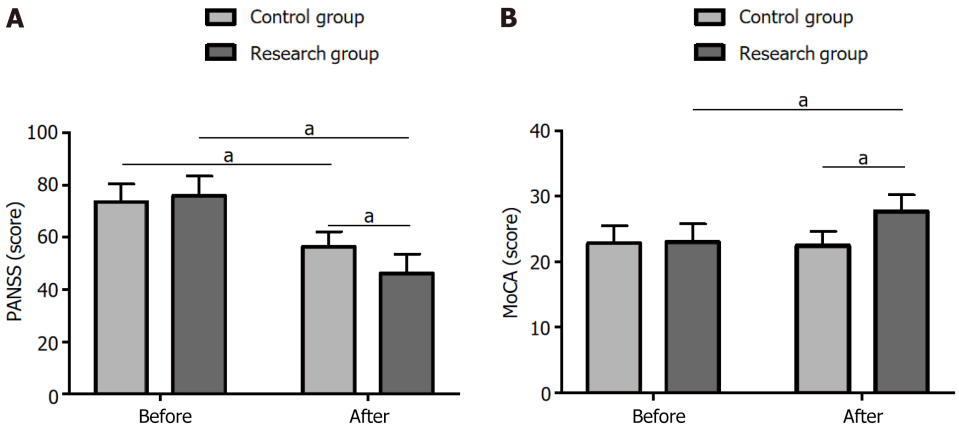

Table 3 Comparison of the safety of the two treatment methods

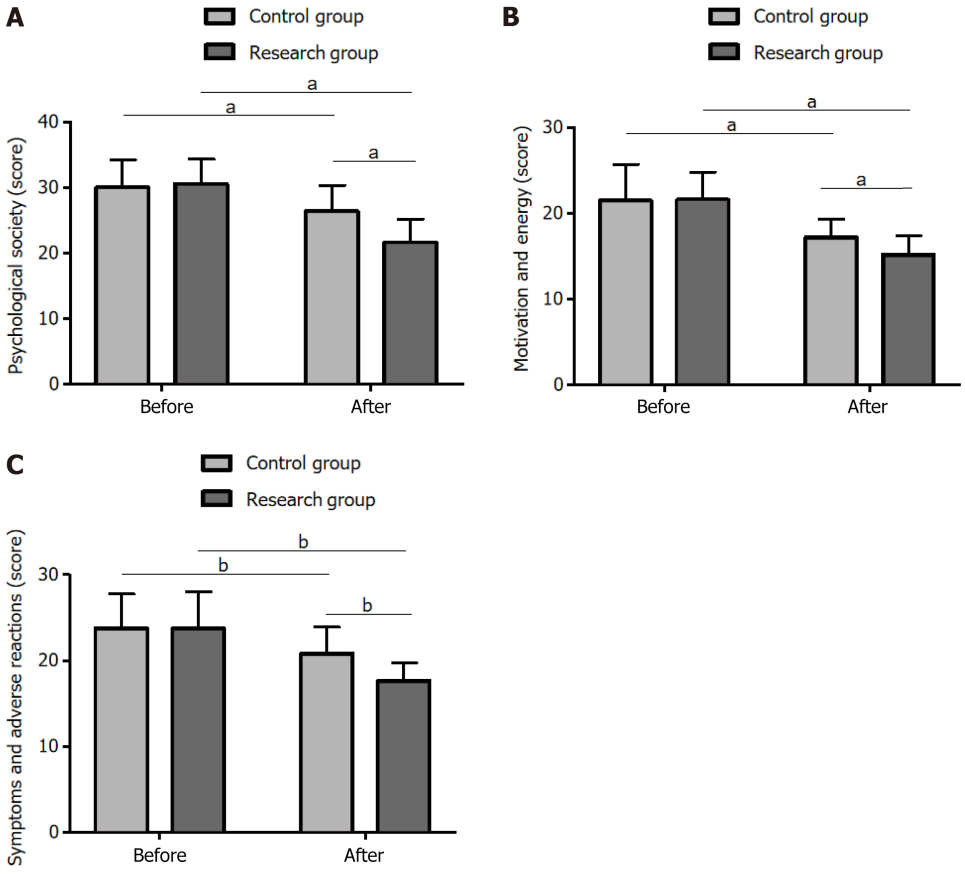
Indicators	Control group, *n* = 54	Research group, *n* = 60	χ^2 value	*P* value
Drowsiness	4 (7.41)	1 (1.67)	-	-
Headache	4 (7.41)	1 (1.67)	-	-
Nausea	3 (5.56)	2 (3.33)	-	-
Vomiting	2 (3.70)	1 (1.67)	-	-
Memory impairment	1 (1.85)	0 (0.00)	-	-
Total	14 (25.93)	5 (8.33)	6.333	0.012

Data are presented as *n* (%).



Comparison of QOL

The QOL assessment using the SQLS showed that the two groups did not differ statistically in the QOL before treatment ($P > 0.05$). However, the post-treatment QOL improved significantly, manifesting as significantly reduced SQLS scores in various dimensions ($P < 0.05$), with the Res group exhibiting better QOL (lower SQLS scores) than that of the Con group ($P < 0.05$) (Figure 2).

DISCUSSION

TRS, a chronic mental disorder, is associated with an increased risk of metabolic syndrome, including hypertension and diabetes, as well as cardiovascular diseases and death in patients[16]. The difficulty in treating this disease lies in the fact that a significant proportion of patients do not respond well to non-clozapine antipsychotic drugs, ECT, or other enhancement strategies, imposing an economic burden on families and the healthcare system[17,18].

This study comparatively analyzed the effectiveness and safety of two treatment modalities for TRS, mECT and OLZ + AMI (Con group) *vs* rTMS and OLZ + AMI (Res group), to provide clinical support and references for the formulation of effective treatment strategies for TRS patients to improve their clinical outcomes and reduce medical costs. Our research results identified a significantly higher ORR in the Res group than in the Con group (93.33% *vs* 72.22%), indicating the superior therapeutic effectiveness of rTMS and OLZ + AMI than that of mECT and OLZ + AMI for TRS. Kahn *et al*[19] reported that 45% of the 93 patients receiving AMI and 44% of those receiving OLZ achieved "response" in the first stage of treatment, indicating that AMI or OLZ monotherapy induced less than satisfactory effects in TRS patients.

Currently, there are limited studies on AMI + OLZ combination therapy, most of which focus on the comparison of AMI or OLZ monotherapy. For instance, Men *et al*[20] demonstrated equivalent clinical efficacy and safety of AMI and OLZ in the treatment of schizophrenia. In our study, the total incidence of drowsiness, headache, nausea, vomiting, and memory impairment was significantly lower in the Res group than in the Con group (8.33% *vs* 25.93%), suggesting that rTMS contributes to fewer adverse events and is more cost-effective when compared with mECT in the treatment of TRS patients.

Additionally, we analyzed and compared the mental symptoms, CF, and QOL of the cohorts before and after treatment using the PANSS, MoCA, and SQLS, respectively. The Res group showed significantly reduced PANSS and SQLS scores after treatment. Moreover, the post-treatment scores in the Res group were significantly lower than those before treatment and those in the Con group. On the other hand, the MoCA scores increased significantly in the Res group, and the post-treatment scores were higher than those before treatment and those in the Con group. This suggests that the combination of rTMS and OLZ + AMI has a significant effect on the improvement of mental symptoms, CF, and QOL in TRS patients.

An open-label clinical study indicated that OLZ and AMI have positive and equivalent effects on ameliorating the negative symptoms and cognitive impairment in schizophrenia patients[21]. Currently, antipsychotics alone cannot fully relieve social cognitive impairment and enhance functional outcomes in patients with mental illnesses, while rTMS is highly effective in improving their CF and mental symptoms[22]. Li *et al*[23] reported that a combination of rTMS and family intervention plays a synergistic role in schizophrenia patients, which is conducive to ameliorate the patients' negative symptoms and CF.

Additionally, an animal study confirmed that rTMS elicits an antidepressant effect by enhancing the endogenous cannabinoid signaling transduction and upregulating the endogenous cannabinoid 1 receptor and diacylglycerol lipase-α in the hippocampal astrocytes and neurons in rats under chronic and unpredictable stress[24]. It has also been noted that rTMS may modulate the cortical plasticity by affecting the permanent changes in the excitability of the cerebellar-thalamic-cortical pathway and that its mechanism of action in TRS could be related to its promotion of interconnection of the remote areas in the neural network system[25].

This study had several limitations that require further consideration. First, this was a single-center retrospective study; hence, the inclusion of more cases from multiple centers would be beneficial to improve the accuracy of the research results. Second, basic experiments should be supplemented to explore the underlying mechanism of the combination of rTMS and OLZ + AMI in treating TRS to understand this therapy and TRS better. Finally, the supplement of multivariate analyses influencing the efficacy of rTMS and OLZ + AMI in the treatment of TRS will help gain deeper insights regarding the pathways to enhance treatment efficacy. Future studies improving the aforementioned limitations are warranted.

CONCLUSION

rTMS in combination with OLZ + AMI may be preferred over the combination of mECT and OLZ + AMI for treating TRS, as the former has a clinical ORR as high as 93.33% and an adverse event rate as low as 8.33%. Moreover, this therapy has outstanding effects in relieving mental symptoms and improving CF and QOL; hence, it should be considered widely in clinical practice.

ARTICLE HIGHLIGHTS

Research background

Treatment-refractory schizophrenia (TRS) accounts for approximately 30% of all patients with schizophrenia, with unsatisfactory treatment response and poor patient prognosis despite antipsychotic therapy.

Research motivation

The treatment of TRS is difficult and challenging, but it is still the responsibility of doctors to explore effective treatment options for the disease.

Research objectives

To analyze the therapeutic effectiveness of repetitive transcranial magnetic stimulation (rTMS) combined with olanzapine (OLZ) and amisulpride (AMI) for TRS and its influence on the patients' cognitive function (CF).

Research methods

First, 114 TRS patients who received treatment between July 2019 and July 2022 were selected. On the basis of OLZ + AMI therapy, 54 cases in the control group (Con group) received modified electroconvulsive therapy, and 60 cases in the research group (Res group) were given rTMS. Information on the therapeutic effectiveness, safety (drowsiness, headache, nausea, vomiting, and memory impairment), Positive and Negative Symptom Scale, Montreal Cognitive Assessment Scale, and Schizophrenia Quality of Life Scale were collected from both patient cohorts for competitive analyses.

Research results

A higher overall response rate and a better safety profile of treatment were determined in the Res group compared with the Con group. In addition, marked reductions in the Positive and Negative Symptom Scale and Schizophrenia Quality of Life Scale scores were found in the Res group after treatment, which were lower compared with the Con group. A significant increase in the Montreal Cognitive Assessment Scale score was observed in the Res group, with higher scores than the Con group.

Research conclusions

rTMS plus OLZ + AMI was effective and safe in the treatment of TRS, which can alleviate the patients' mental symptoms and improve their CF and quality of life, with clinical promotion value.

Research perspectives

rTMS plus OLZ + AMI, with both clinical efficacy and safety, may be more suitable for TRS patients than modified electroconvulsive therapy plus OLZ + AMI. This therapy has significant advantages in relieving psychiatric symptoms and improving CF and quality of life, which is worth promoting clinically.

Abstract

BACKGROUND

Depression and anxiety were both ranked among the top 25 leading causes of global burden of diseases in 2019 prior to the coronavirus disease 2019 (COVID-19) pandemic. The pandemic affected, and in many cases threatened, the health and lives of millions of people across the globe and within the first year, global prevalence of anxiety and depression increased by 25% with the greatest influx in places highly affected by COVID-19.

AIM

To explore the psychological impact of the pandemic and resultant restrictions in different countries using an opportunistic sample and online questionnaire in different phases of the pandemic.

METHODS

A repeated, cross-sectional online international survey of adults, 16 years and above, was carried out in 10 countries (United Kingdom, India, Canada, Bangladesh, Ukraine, Hong Kong, Pakistan, Egypt, Bahrain, Saudi Arabia). The online questionnaire was based on published approaches to understand the psychological impact of COVID-19 and the resultant restrictions. Five standardised measures were included to explore levels of depression [patient health questionnaire (PHQ-9)], anxiety [generalized anxiety disorder (GAD) assessment], impact of trauma [the impact of events scale-revised (IES-R)], loneliness (a brief loneliness scale), and social support (The Multi-dimensional Scale of Perceived Social support).

RESULTS

There were two rounds of the online survey in 10 countries with 42866 participants in Round 1 and 92260 in Round 2. The largest number of participants recruited from the United Kingdom (112985 overall). The majority of participants reported receiving no support from mental health services throughout the pandemic. This study found that the daily cumulative COVID-19 cases had a statistically significant effect on PHQ-9, GAD-7, and IES-R scores. These scores significantly increased in the second round of surveys with the ordinary least squares regression results with regression discontinuity design specification (to control lockdown effects) confirming these results. The study findings imply that participants' mental health worsened with high cumulative COVID-19 cases.

CONCLUSION

Whist we are still living through the impact of COVID-19, this paper focuses on its impact on mental health, discusses the possible consequences and future implications. This study revealed that daily cumulative COVID-19 cases have a significant impact on depression, anxiety, and trauma. Increasing cumulative cases influenced and impacted education, employment, socialization and finances, to name but a few. Building a database of global evidence will allow for future planning of pandemics, particularly the impact on mental health of populations considering the cultural differences.

Key Words: COVID-19; Mental health; Global research; International; Pandemic; Impact

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: This study explores the effect of cumulative coronavirus disease 2019 cases on mental health, more specifically on anxiety, depression, and trauma. Negative impact on mental health was found internationally, with individuals struggling to receive support from mental health services. Results also show that as the pandemic continued, mental health scores got worse.

INTRODUCTION

Depression and anxiety conditions both ranked among the top 25 leading causes of global burden of diseases in 2019 prior to the coronavirus disease 2019 (COVID-19) pandemic[1]. On January 30, 2020, the World Health Organization (WHO) declared a public health emergency of international concern and governments were urged to prepare for the global spread of COVID-19 from East Asia[2]. The COVID-19 pandemic affected, and in many cases threatened the health and lives of millions of people across the globe[2].

In the first year of the COVID-19 pandemic, global prevalence of anxiety and depression increased by 25%, and overall, the pandemic was estimated to have caused 137.1 (95%UI: 92.5–190.6) additional disability adjusted life years per 100000 population for Major Depressive Disorder and 116.1 per 100000 population (95%UI: 79.3–163.80) for anxiety disorders according to a scientific brief released by the WHO[3]. A number of factors have been implicated including, but not limited to, the stress of social and self-isolation, loneliness, restrictions due to lockdowns[4,5], fear of infection and death of self and near ones, grief and bereavement, worries regarding jobs and finances, as well as impact on education, relationships and on carers[6].

Long COVID described the presence of persistent symptoms following infection from the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) virus[7]. This can last weeks or months after initial infection[7,8]. Common symptoms of long COVID include breathlessness, fatigue, headaches, and weakness as well as reduced quality of life[7, 9]. The most common mental health problems experienced by individuals with long COVID were anxiety, depression, and post-traumatic stress disorder (PTSD)[9,10]. A scoping review of 239 patients found that 3-mo post-COVID, 37.2% experienced PTSD, 35.6% experienced anxiety, and 46.9% were experiencing depression[11,12]. These effects were maintained at 6-mo[11]. Overall, symptoms were more prevalent in women and hospitalized patients[9]. A number of population groups have been shown to have been more adversely affected, including young people and women[7], individuals with vulnerabilities and pre-existing mental health conditions[9,11]. Evidence on healthcare workers, who were frontline during the pandemic has been equivocal with different studies showing a range of impact in this group[11, 13]. The greatest increases in depression and anxiety were found in places highly affected by COVID-19 as indicated by decreased human mobility and daily COVID-19 infection rates[3].

Each country across the globe has responded to the pandemic guided by their population, resources, number of cases, socio demographics, political landscape, and culture[14]. Given the unique situation we faced, the authors sought to explore the psychological impact of the pandemic and resultant restrictions in different countries, using an opportunistic sample and online questionnaire that was established at the beginning of the pandemic.

MATERIALS AND METHODS

Study design

This international study aimed to investigate and report the psychological impact of cumulative COVID-19 cases in the participant sites. A repeated, cross-sectional online international survey of adults, 16 years and above, was carried out in 10 countries (United Kingdom, India, Canada, Bangladesh, Ukraine, Hong Kong, Pakistan, Egypt, Bahrain, Saudi Arabia). The online questionnaire was based on published approaches, to understand the psychological impact of COVID-19 and the resultant restrictions. Five standardised measures were included to explore levels of depression [patient health questionnaire-9 (PHQ-9)][15], anxiety [generalized anxiety disorder (GAD)-7; Generalised Anxiety Disorder Assessment] [16], impact of trauma [the impact of events scale-revised (IES-R)][17], loneliness (a brief loneliness scale)[18], and social support (The Multi-dimensional Scale of Perceived Social support)[19]. Further details of the methodology are documented in earlier publications by the group[9,13].

Materials

The survey was repeated to capture the dynamic impact of the pandemic. The questionnaire was changed for each round depending on the stage of pandemic, government policies, and circumstances in each country at the time. In order to make the questionnaire relevant to each country, it was available in different languages and various adaptations were made to ensure that local culture and responses to the pandemic were considered. For this reason, each country published the questionnaire at a slightly different time and some of the questions were variable. As an example, the "Keyworker" status did not exist in many countries and was only used where relevant. Another example, in the Ukraine questionnaire version, the question about exceeding the recommended limits of alcohol was excluded because of the absence of such recommended limits.

Study distribution

In the United Kingdom, the survey was conducted thrice with the corresponding two rounds of the survey in the other countries. The dates of the surveys in the participant countries are noted below. The surveys were publicised to the general population including students and healthcare professionals through social media. Most countries collaborated internally to capture a wide population. As an example, the leads in Ukraine collaborated with Ukrainian organizations including Mental health for Ukraine Project, National Psychological Association of Ukraine, Ukrainian Association of Cognitive-Behavioural Therapy, and Zhytomyr State University to help further with dissemination. Due to the unusual circumstances of the time, this was the best way to disseminate the survey.

Southern Health NHS Foundation Trust in the United Kingdom led and co-ordinated the online survey with support from the participant countries. The survey was advertised to staff, patients, and the public with a weblink to the survey platform.

Data analysis

Cumulative COVID-19 case data has been derived from Microsoft Azure Open dataset, which is a population open dataset[20]. Mental health scores are derived from the online survey and is sample data. In both data, time is day. Although cumulative COVID-19 cases data is available daily (for around last two years), mental health scores in the study were not available for each day during that time. The availability of mental health scores on a specific day depended on whether the survey was conducted on that day by a participant.

The study has used regression analyses, using cross section data of all countries that participated in the study. Separate regression analysis was conducted for survey round 1 and 2. In both regressions, we used dummies for all individual characteristics listed in Table 1 as control variables. Vulnerabilities including requiring shielding, experience of coronavirus, pre-existing mental health conditions, and mental health support, had extremely low response rates therefore, we have recoded missing values into no category, to increase sample sizes in regressions.

In both regressions, the main independent variable, daily cumulative COVID-19 cases, is converted into million unit (by dividing COVID-19 case by 1000000). The purpose is to scale up its coefficients.

The relationship between average mental health scores and average cumulative COVID-19 cases maybe be contaminated or biased by lockdown effects. To control for such effects, we added lockdown dummy, trend and their interaction following the specification in regression discontinuity design (RDD).

RESULTS

Demographics

There were two rounds of the online survey in eight country groups as shown in Table 1. Egypt, Saudi Arabia, and Bahrain were analysed as a single group (labelled Arabic speaking countries). Hong Kong did not participate in the second round due to difficulties in recruitment. While there were three rounds in the United Kingdom, we have only used data from the corresponding two rounds with other participant countries. The United Kingdom has the largest number of participants in both rounds (29134 and 83851, respectively).

In the first round of the survey, participants who reported being healthcare professionals are higher in the United Kingdom (43%). In the second round, Arabic speaking countries had the highest number of participants who reported as healthcare professionals (66%), with a sample size of 909.

Age follows a bell shaped or downward distribution. Female participants were higher than male in most countries. In Canada, United Kingdom and Ukraine, most participants were White. Christian religion was reported the dominant religion in the Western countries. In round one in the Arabic speaking countries, most survey participants reported as Christians too. In most countries, survey participants did not report University education. Most survey participants lived in their own homes. Low proportion of participants reported experiencing COVID-19, but a high percent of participants followed social distancing guidelines. Most of the participants did not report any pre-existing physical health conditions. Alcohol consumption was reported by participants in Canada, United Kingdom, and Ukraine. Most participants did not report taking drugs. Majority participants did not report receiving support from mental health services. Where received, mental health support was reported through general practitioners and many participants did not respond to this question as it was only relevant if they reported experiencing mental health problems.

Mental health scales

Table 2 shows means and SD of PHQ-9, GAD-7 and IES-R by country and survey rounds, with number of respondents (*n*), missing observations and nonrespondents. In both rounds in each country, there were fewer respondents of PHQ-9 compared to nonrespondents. For the other two mental health scales, the gap between respondents and nonrespondents is not that large, with respondents being higher than nonrespondents in some cases. PHQ-9 can vary from 0 to 27, GAD-7 from 0 to 21, and IES-R from 0-88; however, average figures of PHQ-9 are lower than those of other two. IES-R has higher mean scores than others. Hong Kong, Indian, and Ukrainian participants have reported lower scores on the three scales compared with other countries. Bangladesh has highest mean scores on PHQ9, GAD7 and IES -R. All scores increased in round 2 of the surveys.

Cumulative COVID-19 cases

For each country, cumulative COVID-19 cases (the cumulative number of people who suffered coronavirus in official records) varied over time. Mental health scores (on the 3 scales: PHQ-9, GAD-7 and IES-R) in each country varied over time and by individuals' responses during the survey period.

Figure 1 shows a histogram of day/time by country. Two long bars in Bangladesh indicate that survey responses in both rounds were received during short windows, although the survey was open for three months each time in each site. The same pattern is seen in Canada and Hong Kong. Survey periods in Arabic speaking sites and Ukraine seem longer but scattered, meaning that for several days, survey data including mental health scores were not available during the three month period. India and Pakistan showed good density for moderately wider periods in round 1. United Kingdom showed the longest periods of survey responses in both rounds, which indicates that survey data including mental health

Each panel in a column shows percentages of categories/responses of a characteristic/question. Total respondents in each category were divided by observations shown at the beginning of the table and then multiplied by 100, to get the percentage.

scores were available for relatively more days in United Kingdom despite the fact that the survey was available for the same number of months at each site.

Daily cumulative COVID-19 cases (in million) have been plotted for each country, from April 1, 2020 to April 1, 2021 (Figure 2). As India had high COVID-19 cases, we have scaled down the COVID-19 cases by converting its unit into million, to raise the coefficients of cumulative COVID-19 case in regressions. United Kingdom also had high figures (reached nearly 10 million in March 2021). Ukraine and Canada reached relatively high figures. Other countries including Hong Kong had lower figures for cumulative COVID-19 cases. Therefore, the lines are relatively flat (near zero). Hong Kong had low figures at those periods as different countries had their spikes at different times. The figure shows downward movement of lines in India and United Kingdom, because COVID-19 cases were revised.

In survey data of the countries, scores of three mental health scales were available for several individuals in a day. They are reported as averages in a day. Country averages of those averages are taken to get single values in each day. Country average of cumulative COVID-19 cases are also taken. In Figure 3, scatter plots of average values of PHQ-9, GAD-7 and IES-R are shown in three different subplots. Average cumulative COVID-19 cases are plotted in line with three subplots. While left vertical axes measure the average cumulative COVID-19 cases, the right vertical axes measure three average values of mental health scores/indices. As mental health is an individual characteristic, average mental health scores fluctuated over time, and were not uniform like average cumulative COVID-19 cases. However, average mental health scores had less fluctuation/scatter at the beginning of each round (especially at the beginning of the second round). At that time, average mental health scores showed upward movement with average cumulative COVID-19 cases.

Table 2 Summary statistics of mental health scores by country and survey rounds

PHQ-9: Patient health questionnaire-9; IES-R: Impact of Events Scale-Revised; GAD-7: Generalized anxiety disorder-7.

In more scatter areas, such positive relation between average cumulative COVID-19 cases and average mental health scores is not seen. As less scatter zones showed a positive relation, we can expect an overall positive relation between them. To control for bias or contamination effect of lockdown, we added lockdown dummy, trend and their interaction

DOI: 10.5498/wjp.v13.i7.461 **Copyright** ©The Author(s) 2023.

Figure 1 Distribution of survey respondents over time, by country.

following the specification in RDD.

Table 3 shows lockdown and survey periods of participant countries in the study. In each round, we have made normalized trend by subtracting lockdown easing/withdraw dates of countries (as lockdown start dates do not fall in survey periods) from trend. Zero is a common cut-off date; based on that we made a discontinuity dummy (1 = above cut-off, 0 = below cut-off), that captured negative effects of lockdown or withdraw on mental health. To capture different slopes on either side of the cut-off, we took interaction of normalized trends and the discontinuity dummy.

Regression results

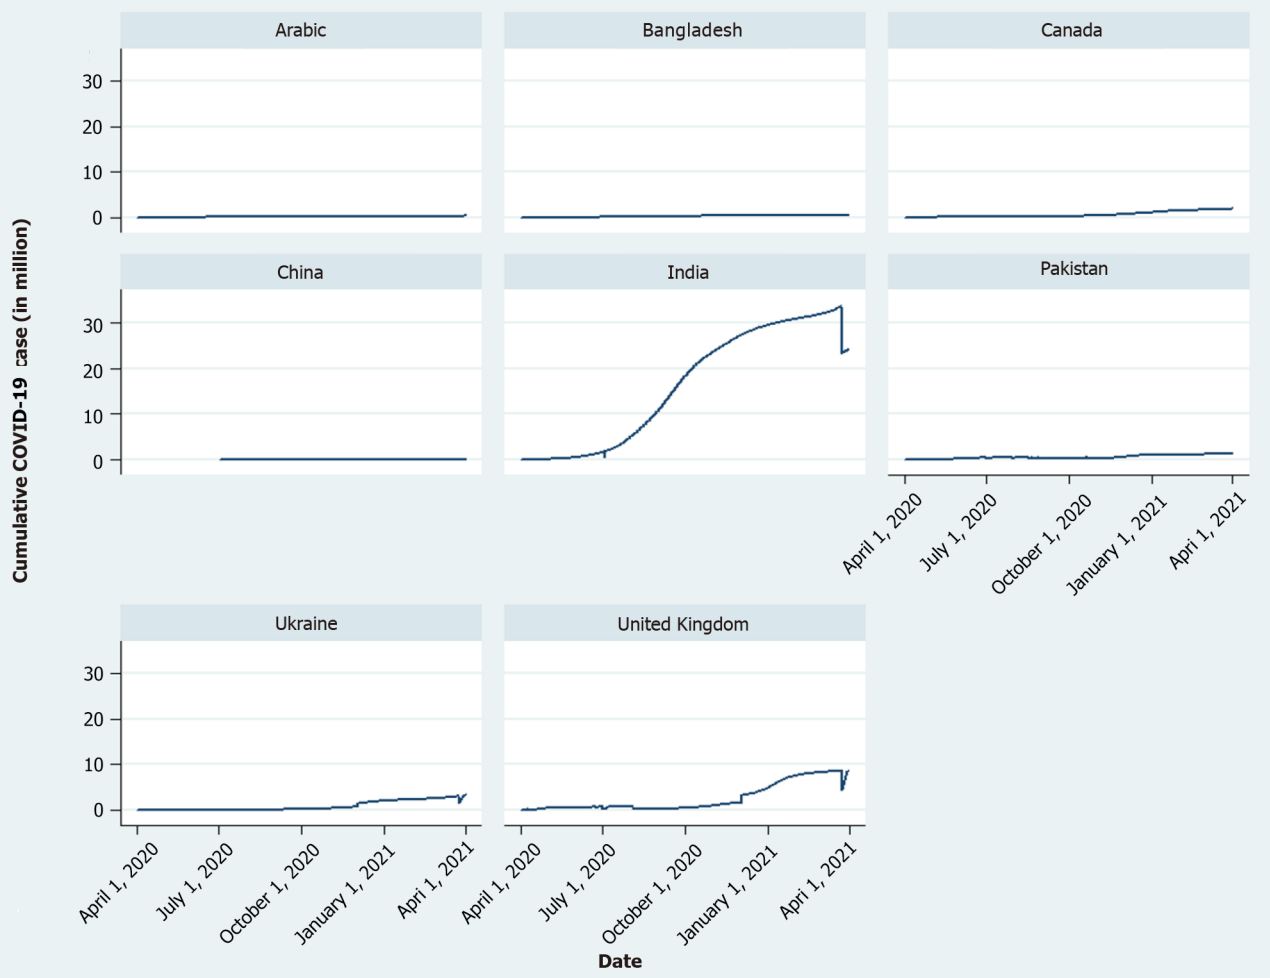

Table 4 shows regression results for round 1 and Table 5 for round 2. Both tables show two regression results for each mental health score/index, the dependent variable. The first one does not include RDD specification, while the second one does. When RDD specification is included, the results are for United Kingdom only.

In round 1, the cumulative COVID cases had statistically significant effect on all three mental health scores with RDD specification. For example, as United Kingdom had 7.70 average GAD-7, the increase size 1.75 in regression was nearly 23% (1.75 × 100/7.70). So, for a one million increase in cumulative daily COVID cases, GAD-7 increased by 23 percent.

In round 2 (Table 5), all three mental health indices increased statistically and significantly due to increase in cumulative COVID cases, with and without RDD specification. Without RDD specification, for a one million increase in cumulative COVID cases, the increase in PHQ-9 was 0.195 (2.38%), GAD-7 0.129 (2.14%), and IES-R 0.454 (2.37%). With RDD specification, for a one million increase in cumulative COVID cases, the increase in PHQ-9 was 0.433 (5.27%), GAD-7 0.577 (9.55%), and IES-R 1.265 (6.59%). Results with RDD specification implied that United Kingdom had higher effects than other countries.

Table 3 Lockdown and survey dates by country

Country	First lockdown		Second lockdown		Survey period		Can we capture lockdown effects?
	Start	End	Start	End	Round 1	Round 2	
Bangladesh	March 26, 2020	May 16, 2020	April 5, 2021	July 14, 2021	July 1, 2020-July 25, 2020	January 19, 2021-March 18, 2021	No
Canada	March 18, 2020	May 18, 2020	November 7, 2020	January 8, 2021	August 18, 2020-October 2, 2020	December 21, 2020-March 30, 2021	No
China	January 23, 2020	April 8, 2020			June 24, 2020-August 7, 2020		No
India	March 25, 2020	June 7, 2020	April 19, 2021	May 31, 2021	July 1, 2020-September 20, 2020	January 22, 2021-April 1, 2021	No
Pakistan	March 24, 2020	May 9, 2020	May 8, 2021	May 18, 2021	June 10, 2020-September 24, 2020	February 2, 2021-March 29, 2021	No
Saudi Arabia	March 29, 2020	June 21, 2020			June 3, 2020-October 7, 2020	January 16, 2021-April 1, 2021	Yes, in round 1
Ukraine	March 17, 2020	April 24, 2020			June 11, 2020-September 30, 2020	January 7, 2021-March 25, 2021	No
United Kingdom	March 23, 2020	July 4, 2020	November 5, 2020	December 2, 2020	April 28, 2020-August 6, 2020	November 12, 2020-February 18, 2021	Yes, in both rounds

95% confidence intervals are in brackets. PHQ-9: Patient health questionnaire-9; IES-R: Impact of Events Scale-Revised; GAD-7: Generalized anxiety disorder-7; COVID-19: Coronavirus disease 2019.

In both regression tables, lockdown withdraw dummy in RDD specification showed that lockdown withdraw had statistical and significant effects on mental health indices, which supported the findings of our previous paper that showed that lockdown increased participants mental health scores, or worsened participant's mental health[8].

In both regression tables, compared to the youngest age group (under 25), other age groups had lower scores on the mental health scales, meaning better mental health. Non-White participants reported better mental health than White participants, in most cases. Non-Christians reported better mental health than Christians in both rounds. In both rounds, higher educated participants had better mental health than the lowest educated group.

Heterogenous effects

To demonstrate heterogeneous effects of cumulative COVID cases on mental health scores for different countries, we ran regressions without RDD specification for each country separately, but we included all characteristics used in previous regressions. RDD specification was only applicable to United Kingdom data.

For China (Hong Kong), cumulative COVID cases was extremely low, and therefore, the coefficients of daily cumulative COVID cases were extremely high. Similarly high and low coefficients in different countries depended on scales of cumulative COVID cases in the relevant countries.

Most countries did not show any significant effects. United Kingdom had very good distribution of survey respondents over a long period of time. Therefore, regression results for United Kingdom are more reliable than others. The results are statistically positive in both rounds in the United Kingdom. The first round in the United Kingdom showed statistically and significantly higher positive results. As we have seen in Table 4, such significance vanishes with the inclusion of RDD specification.

DISCUSSION

Using repeated cross sectional survey data of eight country groups and cumulative COVID-19 cases of same countries from Microsoft AZURE, this study found that the daily cumulative COVID-19 cases had a statistically significant effect on

three mental health scale indices: Depression, anxiety, and trauma. Ordinary least squares regression results with RDD specification to control for lockdown effects confirms the results. The results are dominated by data in the United Kingdom, which has the largest number of respondents with wider distribution over time. The study findings imply that

participants' mental health worsened with high cumulative COVID-19 cases. Daily cases did not show any impact on mental health scores of participants. The study also highlights other important demographic information and differences due to impact of the COVID-19 pandemic on different countries' participants.

These findings are understandable, considering the significant impact of COVID-19 pandemic on the lives of people across the globe and similar results from other data. Evidence from the Centre for Disease Control and Prevention has shown that fear and stress related to the COVID-19 has led to symptomatology, including change in sleep and eating patterns, worsening of premorbid psychiatric conditions, and increased use of substances (*e.g.*, alcohol, tobacco, drugs), which add to the mental health burden[21]. Quadros *et al*[22] conducted a scoping review and concluded that females, younger adults, urban residents, divorcees, healthcare workers, those in quarantine settings, those in suspicion of being infected, and those with mental health problems, were found to be at an increased risk of COVID-19-related fear[22].

High cumulative COVID-19 cases not only presented a fear of infection and mortality, especially in vulnerable groups, but also impacted on education, jobs, ability to socialize, relationships, loneliness, and other socio-cultural and socioeconomic variables. Most studies have shown an impact on young people's mental health as does this study and the same study in United Kingdom participants has shown an increase in suicidal thoughts[23,24]. High cumulative cases additionally meant the implementation of public health interventions and lockdowns restricting activities. Our findings from the United Kingdom data of the same study demonstrate the positive association of lockdown relaxation and face covering policies on the mental health of participants evidencing the impact of these interventions on mental health of populations as also demonstrated by the international data in this study[9].

These results add to existing global evidence of the psychological impact of the COVID-19 pandemic and previous studies that have demonstrated the adverse impact of population shocks on population mental health[25-27]. A systematic review of data published between January 2020 to January 2021 during the COVID-19 pandemic found that daily SARS-CoV-2 infection rates and reductions in human mobility were associated with increased prevalence of major depressive disorder[28]. These findings have been confirmed by the WHO[3].

In our study, participants from Hong Kong, India and Ukraine had lower mental health scores than other countries' participants. It is not possible to make conclusions on these findings as the number of participants were small and there would be an element of time of participation in the survey.

Different countries had their case number surges and lockdowns at different times during the pandemic. Similarly different countries followed a different trajectory depending on their populations, readiness to respond, political, cultural, financial, and technical landscape. As an example, Ukraine underwent change in ministers three times during the pandemic. There were other determinants of response to the pandemic including levels of awareness, stigma, fear in the early phases of pandemic and attributions to the illness based on cultural explanations[11].

Since the COVID-19 pandemic, the need for mental health support services has increased significantly[29]. This has been particularly difficult due to isolation and distancing measures, causing a physical barrier to help-seeking and treatment implementation[29,30]. Mental health rehabilitation interventions aim to increase social skills and teach coping strategies through training and increased social interactions[29]. This can help individuals with various mental health conditions but is especially useful for those with anxiety or depression[30]. Social and peer support is an integral part of mental health rehabilitation, yet the isolating protection measures of the COVID-19 pandemic pose a barrier[30].

Measures, such as regular testing or online programmes, are some actions which help to overcome these unprecedented circumstances[30,31]. Many organisations and facilities moved their services online in order to provide continuous psychological support for their clients[30,31]. This will ensure that services can continue to operate whilst controlling the spread of the pandemic[31]. The United Kingdom government has published a COVID-19 Mental Health and Wellbeing Recovery Action Plan to accommodate for mental health interventions throughout and post-pandemic [32]. The plan outlines various measures including support for young people, assistance within the employment sector, and accessible and widely available support for frontline healthcare workers[32]. Whilst mental health has always been a pressing matter, the pandemic has amplified its prevalence and affects across all demographic groups[32]. As there were rigid isolation regulations in place, this made the imple-mentation of support difficult so organisations had to be innovative with the ways in which they would continue to assist clients[33]. Likewise, the pandemic also helped to highlight vulnerable groups, leading to the implementation of better support strategies and frameworks for these groups [33].

The results of this study should be interpreted considering its limitations. The timing of the study was such that most countries were in different phases of the pandemic. To conduct a study in that unusual environment meant that some may not consider this a cross sectional study in the epidemiological sense, and it could be difficult to judge the true population prevalence and make international comparisons. For this reason, we have explained the landscape of the different countries separately. This limitation could not have been avoided given the unpredictable nature of the spread of virus, even if confined parameters had been used. Additionally, where many cultural adaptations were made to account for the differences in the countries, it may still be difficult to draw conclusions about the differences in these populations which might be attributable to COVID as the measures are all taken after the onset of the pandemic. Another limitation concerning cumulative cases is that in many low and middle income countries, public health infrastructures and disease notification are very different to those used in high income countries, meaning that the potential for under-ascertainment of cases is much higher. The study has a high number of missing cases and non-random selection of participants are further limitations. In some participating centres the numbers are small. Many surveys were in circulation during this time in all the participating countries, especially during the second round, which may have affected the participation in the survey. Most studies of similar kind have reported small numbers.

CONCLUSION

The results from the current study add to developing evidence of the psychological impact of COVID-19, especially daily cumulative cases on three mental health indices. Building a database of evidence will allow for future planning of pandemics, particularly the impact on mental health of populations and the cultural differences.

ARTICLE HIGHLIGHTS

Research background

The coronavirus disease 2019 (COVID-19) pandemic had a huge effect on mental health across the globe. As the pandemic developed over time, international rates of mental health conditions increased. It would be insightful to explore how the increasing cases of COVID-19 impacted mental health throughout the pandemic.

Research motivation

Exploring the impacts of COVID-19 on mental health with help construct a better understanding of the current mental health situation across the globe. It will also help to inform pandemic preparedness policies around mental health services.

Research objectives

This study aimed to explore the psychological implications of the increasing COVID-19 case throughout the pandemic across various countries.

Research methods

A repeated, cross-sectional online international survey of adults was carried out in 10 countries. Five standardised psychological measures were included to explore the psychological impact of cumulative COVID-19 cases. This was carried out at two timepoints in all countries, aside from the United Kingdom which collected data at 3 timepoints.

Research results

There were two rounds of the online survey in eight country groups with 42866 participants recruited in Round 1 and 92260 recruited in Round 2. This study found that the daily cumulative COVID-19 cases had a statistically significant effect on three depression, anxiety, and trauma. Trauma scores were higher across all countries compared to those for anxiety and depression. All scores increased in Round 2 in all countries.

Research conclusions

Considering the significant impact of COVID-19, understanding the effects will enable for adequate services and support to be put in place. This evidence dataset will also help inform the policies and strategies for pandemic preparedness.

Research perspectives

COVID-19 has had enduring effects in all aspects of life including physical and mental health.

ACKNOWLEDGEMENTS

We would like to thank all the participants who gave their time to complete the survey. We also thank our collaborators–NHS and non-NHS organisations that disseminated the survey. We would specially like to thank Sana Sajid, for administrative support.

Abstract

BACKGROUND

The role of comprehensive geriatric assessment (CGA) in screening for mild cognitive disorders was not known.

AIM

To evaluate the role of CGA in screening for mild cognitive disorders.

METHODS

A total of 100 elderly people who underwent health examinations in our hospital and community between January 2020 and December 2021 were included for analysis. Using Petersen as the diagnostic gold standard, healthy individuals were included in the control group and patients with mild cognitive impairment were assigned to the study group. The correlation between the cognitive function of the patients and their baseline clinical profiles was analyzed. Patients' Montreal Cognitive Assessment (MoCA) and CGA screening results were compared, and the sensitivity and specificity were calculated to assess the screening role of CGA.

RESULTS

CGA assessment yielded higher diagnostic accuracy than MoCA. The results of the multivariate regression analysis showed no correlation of gender, age, body mass index and literacy with cognitive function. Patients with mild cognitive impairment obtained significantly lower MoCA scores than healthy individuals ($P < 0.05$). In the CGA scale, patients with mild cognitive impairment showed significantly lower Mini-mental State Examination, Miniature Nutritional Assessment and Berg Balance Scale scores, and higher Activity of Daily Living, Instrumental Activities of Daily Living Scale and Frailty Screening Inventory scores than healthy individuals ($P < 0.05$), whereas the other assessment scales showed no significant differences ($P > 0.05$). The CGA provides higher diagnostic sensitivity and specificity than the MoCA ($P < 0.05$).

CONCLUSION
CGA allows accurate identification of mild cognitive impairment with high sensitivity and specificity, facilitating timely and effective intervention, and is thus recommended for clinical use.

Key Words: Comprehensive geriatric assessment; Mild cognitive impairment; Screening; Montreal Cognitive Assessment; Sensitivity; Specificity

INTRODUCTION

Mild cognitive impairment (MCI) is the transitional state between normal aging and mild dementia and is an early stage of dementia[1,2]. People with MCI present with memory impairment that exceeds the allowable range for their age and culture. However, they experience normal social work or daily functioning and do not meet the diagnostic criteria for dementia. Evidence suggests that within the following 2-5 years, mild cognitive impairment is associated with a higher risk of developing dementia compared to age-appropriate non-mild cognitive impairment, which may be attributable to multiple diseases[3]. There is a prevalence of mild cognitive impairment of over 15% in people over 65 years of age, with 10%-15% of the population deteriorating to Alzheimer's disease within one year per year, whereas the prevalence in the normal population averages only 1%-2%. Therefore, enhanced detection, intervention, or delay of the onset of cognitive impairment in mild cognitive impairment at an early clinical stage is necessary[4,5]. Timely diagnosis of patients with mild cognitive impairment is a prerequisite for treatment and can efficiently mitigate the progression of the disease. Screening for mild cognitive impairment is normally performed using the Montreal cognitive assessment (MoCA)[6,7], a scale that references the cognitive elements and scores of the Mini-mental State Examination (MMSE) to assess mild cognitive impairment[8]. However, the results of studies related to the cut-off point, sensitivity and specificity of the scale vary considerably. Comprehensive geriatric assessment (CGA)[9] is a multidisciplinary approach that assesses the physical health, functional status, mental health and social-environmental status of older people[10]. CGA can facilitate timely treatment, slow down the disease process and reduce dementia through multidimensional analysis of MCI[11,12]. To this end, the current research was performed to evaluate the role of CGA in screening for mild cognitive disorders.

MATERIALS AND METHODS

Case selection

A total of 100 elderly people who underwent health examinations in our hospital and community between January 2020 and December 2021 were included for analysis. Written informed consent was obtained from all patients in this study.

Inclusion and exclusion criteria

Inclusion criteria: (1) Patients with objective signs of impairment in one or more areas of cognitive function; (2) patients met the relevant diagnostic criteria in the Diagnosis and Treatment of Mild Cognitive Impairment; and (3) clinical information was complete, with no restriction on gender, and age no less than 60 years.

Exclusion criteria: (1) Patients met the diagnostic criteria for clinical dementia; (2) physical organ disability, including vision and hearing; and (3) inability to cooperate with the completion of this study for psychiatric reasons.

Methods

Using Petersen as the diagnostic gold standard, healthy individuals were included in the control group and patients with mild cognitive impairment were assigned to the study group. The correlation between the cognitive function of the patients and their baseline clinical profiles was analyzed. Patients' MoCA and CGA screening results were compared, and the sensitivity and specificity were calculated to assess the screening role of CGA.

Outcome measures

Petersen diagnosis: The patient reported memory loss for no less than 3 mo, which was confirmed by others; age-incompatible objective memory decline, with overall normal cognitive function and a Geriatric Depression Scale (GDS) score of 2-3; patients had essentially normal activities of daily living and an Activity of Daily Living (ADL) score no higher than 18; patients did not meet the US NIA-AA dementia diagnostic criteria for dementia, with a CDR score = 0.5.

MoCA: The Chinese version of the MoCA scale developed by Peking Union Medical College Hospital and Professor Nasreddine was used for assessment. The scale has a total score of 30 and includes eight cognitive domains, namely time, positional orientation, language, calculation, memory and delayed memory, visuospatial ability, executive function, attention and abstract thinking. Scores are proportional to cognitive functioning, with scores below 26 indicating impaired cognitive functioning[13].

CGA: The CGA assesses the cognitive status of patients through the General Medical Assessment, Physical Functioning Assessment, Psychosocial Assessment, Social Health Assessment, Environmental Assessment, Quality of Life Assessment and Assessment of Common Symptoms or Problems in Older Adults. It includes the GDS, Geriatric Anxiety Inventory (GAI), MMSE, Miniature Nutritional Assessment (MNA), ADL, Instrumental Activities of Daily Living Scale (IADL), Frailty Screening Inventory (FRAIL), Berg Balance Scale (BBS), Falls Risk Factor Assessment (FRAF), and PAGAR. GDS, GAI, MMSE, MNA, BBS, FRAF, and PAGAR were proportional to the CGA score, and ADL, IADL, and FRAIL were inversely proportional to the CGA score.

Statistical analysis

SPSS 26.0 was used for data analyses. Measurement data were expressed as mean ± SD and tested using independent samples *t*-test. Count data were expressed as number of cases (%) and tested using χ^2 test. Pearson correlation analysis was applied for multiple regression analysis. Statistical significance was indicated by $P < 0.05$.

RESULTS

Screening results

Petersen diagnosed 62 healthy individuals as controls and 38 patients with mild cognitive impairment as the study group. The MoCA diagnosed 30 cases of healthy individuals and 38 cases of patients with mild cognitive impairment, while the CGA assessment showed 58 cases of healthy individuals and 36 cases of patients with mild cognitive impairment. CGA assessment yielded higher diagnostic accuracy than MoCA (Table 1 and Table 2).

Baseline patient profiles

The control group consisted of 41 males and 21 females, aged 62-80 (71.84 ± 7.21) years, with a body mass index (BMI) of 20-26 (24.18 ± 2.11) kg/m^2. There were 5 cases of illiteracy, 18 cases with an education level of primary school, 25 cases of junior high school, and 14 cases of high school and above. The study group consisted of 25 males and 13 females, aged 61-79 (71.52 ± 7.36) years, with a BMI of 20-26 (24.21 ± 2.07) kg/m^2. There were 2 cases of illiteracy, 11 cases with an education level of primary school, 16 cases of junior high school, and 9 cases of high school and above. The two arms were well-balanced in terms of baseline patient profiles ($P > 0.05$, Table 3).

Correlation

The results of the multivariate regression analysis showed no correlation of gender, age, body mass index and literacy with cognitive function ($P > 0.05$, Table 4).

MoCA scores

MoCA score in the control group was 26.88 ± 2.14 and the MoCA score in the study group was 20.86 ± 2.56. Patients with mild cognitive impairment obtained significantly lower MoCA scores than healthy individuals ($P < 0.05$, Table 5).

CGA scores

In the CGA scale, patients with mild cognitive impairment showed significantly lower MMSE, MNA and BBS scores, and higher ADL, IADL and FRAIL scores than healthy individuals ($P < 0.05$), whereas the other assessment scales showed no significant differences ($P > 0.05$) (Table 6).

Application value of CGA vs MoCA

The sensitivity and specificity of MoCA was 0.761 and 0.714, while the sensitivity and specificity of CGA was 0.882 and 0.964. The CGA provides higher diagnostic sensitivity and specificity than the MoCA ($P < 0.05$) (Table 7).

DISCUSSION

Cognitive impairment can affect learning, memory, social functioning, language, visuospatial function, and attention, and severe cognitive impairment can lead to dementia. Statistics show that 5%-10% of people with mild cognitive impairment

develop dementia each year, which is higher than the 1%-2% annual prevalence in the general population. Nearly 50 million people worldwide suffered from dementia in 2016, and its prevalence has been increasing[14]. The aging population and the increasing prevalence of dementia are the primary contributors to the expected increase in the cost of dementia. Few clinically effective medications are available for the treatment of cognitive impairment. However, studies have shown that 30%-50% of patients initially diagnosed with mild cognitive impairment recover to a normal cognitive

level during postoperative care. Therefore, timely screening and prevention will contribute to improving the standard of living of patients and reducing the family, social and economic burden[15,16]. Patients with mild cognitive impairment show no typical clinical manifestations in the early stages, which poses difficulties in the clinical diagnosis of the disease and is detrimental to the early identification and targeted treatment of the condition.

The MoCA is an assessment scale for mild cognitive impairment developed by Canadian scientists based on clinical experience and with reference to the cognitive elements and scores of the MMSE[17,18]. In the present study, patients with mild cognitive impairment showed significantly lower MMSE, MNA, and BBS scores, and higher ADL, IADL and FRAIL scores than healthy individuals, whereas the other assessment scales showed no significant differences, and the CGA provides higher diagnostic sensitivity and specificity than the MoCA, which was consistent with the findings of previous studies. It has been reported that the relative risk of conversion to dementia in those with cognitive abnormalities is 6.4 times higher than in those with normal cognition. Mild cognitive impairment is an early manifestation of dementia, and the MMSE is a scale that has been used to assess cognitive ability. It has been proposed that the dietary patterns of patients have implications for future perceptions in life, and that most older people require treatment for nutritional deficiencies to prevent cognitive decline. As a result, greater emphasis should be placed on screening for nutritional status in patients with mild cognitive impairment to ensure adequate nutritional support. In 2013, the International Academy of Nutrition and Aging and the International Association of Geriatrics introduced the concept of 'cognitive deprivation', linking cognition to deprivation. The present study also found that the results of the multiple regression analysis showed that gender, age, BMI and literacy were not correlated with cognitive function. However, this is inconsistent in previous studies and may be the result of the large variation in sample size from one study to another, with increased sample size contributing to the analysis of cognitive function factors.

The MoCA scale focuses on a single disease and fails to fully address the healthcare needs of older people. CGA was originally proposed by British scientists in 1946 as an intervention to comprehensively assess the illness, physical ability, cognitive, psychological, social and economic status of elderly patients at multiple levels, so as to comprehensively assess older people with a function-oriented approach during the recovery phase of chronic disease to guide treatment and health maintenance. Currently, it is widely used to determine the level of health functioning of older people and is recognized for its effectiveness in improving diagnosis, prognosis and quality of life of patients. Nevertheless, no consensus has been reached on the content of their specific assessments. Heterogeneity in the size of different research institutions precludes the comparison of different findings, for which the identification of standardized comprehensive CGA assessments for older people is an effective approach. However, a large body of evidence is required[19,20].

Limitations

Research suggests that all people over the age of 70 years ought to undergo annual subjective or objective cognitive testing with their healthcare provider. However, this has significantly increased the workload of medical staff, resulting in high human costs. This could be improved in the future through the development of a fee schedule for comprehensive assessments, including health insurance, changes to the writing of health records, the addition of a "comprehensive assessment and diagnosis for older people" and the conversion of different assessment scales into electronic health records. Limitations of the current study include the risk of bias due to insufficient sample size and lack of sample diversity. Future studies will expand the sample to further improve the protocol and provide more references for future relevant diagnostic treatments.

CONCLUSION

CGA allows accurate identification of mild cognitive impairment with high sensitivity and specificity, facilitating timely and effective intervention, and is thus recommended for clinical use.

ARTICLE HIGHLIGHTS

Research background

Comprehensive geriatric assessment (CGA) is a multidisciplinary approach that assesses the physical health, functional status, mental health and social-environmental status of older people. CGA can facilitate timely treatment, slow down the disease process and reduce dementia through multidimensional analysis of Mild cognitive impairment.

Research motivation

This study found that CGA allows accurate identification of mild cognitive impairment with high sensitivity and specificity, facilitating timely and effective intervention.

Research objectives

This study was conducted to evaluate the role of comprehensive geriatric assessment in screening for mild cognitive disorders.

Research methods

Using Petersen as the diagnostic gold standard, healthy individuals were included in the control group and patients with mild cognitive impairment were assigned to the study group. The correlation between the cognitive function of the patients and their baseline clinical profiles was analysed. Patients' Montreal Cognitive Assessment (MoCA) and CGA screening results were compared, and the sensitivity and specificity were calculated to assess the screening role of CGA.

Research results

CGA assessment yielded higher diagnostic accuracy than MoCA. The results of the multivariate regression analysis showed no correlation of gender, age, body mass index and literacy with cognitive function. Patients with mild cognitive impairment obtained significantly lower MoCA scores than healthy individuals. In the CGA scale, patients with mild cognitive impairment showed significantly lower Mini-mental State Examination, Miniature Nutritional Assessment and Berg Balance Scale scores, and higher Activity of Daily Living, Instrumental Activities of Daily Living Scale and FRAIL scores than healthy individuals. The CGA provides higher diagnostic sensitivity and specificity than the MoCA.

Research conclusions

CGA allows accurate identification of mild cognitive impairment with high sensitivity and specificity, facilitating timely and effective intervention, and is thus recommended for clinical use.

Research perspectives

Future studies will expand the sample to further improve the protocol and provide more references for future relevant diagnostic treatments.

Abstract

BACKGROUND

Differentiated thyroid cancer (DTC) often seriously impacts patients' lives. Radionuclide Iodine-131 (^{131}I) is widely used in treating patients with DTC. However, most patients know little about radionuclide therapy, and the treatment needs to be performed in a special isolation ward, which can cause anxiety and depression.

AIM

To explore anxiety and depression status and their influencing factors after ^{131}I treatment in patients with DTC.

METHODS

A questionnaire survey was conducted among postoperative patients with DTC who received ^{131}I treatment at our hospital from June 2020 to December 2022. General patient data were collected using a self-administered demographic characteristics questionnaire. The self-rating depression scale and self-rating anxiety scale were used to determine whether patients were worried about their symptoms and the degree of anxiety and depression. The patients were categorized into anxiety, non-anxiety, depression, and non-depression groups. Single-variable and multiple-variable analyses were used to determine the risk factors for anxiety and depression in patients with thyroid cancer after surgery.

RESULTS

A total of 144 patients were included in this study. The baseline mean score of self-rating anxiety and depression scales were 50.06 ± 16.10 and 50.96 ± 16.55, respectively. Notably, 48.62% (70/144) had anxiety and 47.22% (68/144) of the

patients had depression. Sex, age, education level, marital status, household income, underlying diseases, and medication compliance significantly differed among groups ($P < 0.05$). Furthermore, multivariate logistic regression analysis showed that education level, per capita monthly household income, and medication compliance level affected anxiety ($P = 0.015$, 0.001, and 0.001 respectively. Patient's sex, marital status, and underlying diseases affected depression ($P = 0.007$, 0.001, and 0.009, respectively).

CONCLUSION

Nursing interventions aiming at reducing the risk of anxiety and depression should target unmarried female patients with low education level, low family income, underlying diseases, and poor adherence to medications.

Key Words: Iodine-131; Thyroid gland; Neoplasms; Anxiety; Depression; Prognosis

Core Tip: Differentiated thyroid cancer (DTC) seriously impacts the patient's life and induces more adverse emotions. This study investigated anxiety and depression in 144 patients with DTC. Sex, education level, family factors, and basic diseases were the risk factors for anxiety and depression. Better intervention nursing measures can be proposed for clinical practice by observing and proposing indicators that affect patients' mood risk factors and by comparing them with previous studies, thereby reducing the risk of developing anxiety and depression and improving their prognosis.

INTRODUCTION

Thyroid cancer is a common malignant head and neck tumor, and its incidence has been annually increasing in recent years[1]. According to the International Agency for Research on Cancer, the worldwide incidence of thyroid cancer is approximately 6.7/100000, and the number of new cases in China is 190000 in 2022[2]. Among them, differentiated thyroid cancer (DTC) accounts for approximately 90%. Currently, DTC is treated with a three-step comprehensive treatment approach consisting of surgery, Iodine-131 (^{131}I) treatment and thyroid hormone suppression[3], which can significantly reduce the tumor recurrence rate and improve disease prognosis. However, the complications of tumor surgery and lack of understanding of ^{131}I treatment, especially the fact that ^{131}I treatment is a type of internal radiotherapy, may result in patients experiencing anxiety, fear, depression, and other negative emotions[4]. In clinical practice, several patients with DTC exhibit anxiety or poor mental state before radiotherapy, which leads to poor compliance with radiotherapy and ultimately affects the clinical treatment effect[5]. Therefore, it is crucial to analyze the anxiety status and related influencing factors of patients with thyroid cancer after surgery. This analysis can guide the formulation of clinical preventive nursing strategies and improve patient outcomes. Along those lines, this study aims to explore the anxiety states and associated risk factors in patients with DTC after ^{131}I treatment.

MATERIALS AND METHODS

Patient characteristics

A questionnaire survey was conducted among postoperative patients with DTC who received ^{131}I treatment at our hospital from June 2020 to December 2022.

Inclusion criteria were as follows: Pathological diagnosis of DTC; clinical indications for surgical treatment and completed surgical treatment; age ≥ 18 years; ability to read and independently complete the questionnaire, the patients were informed, cooperated well, and had complete clinical pathological data. Comply with medical advice, regular postoperative review at our hospital.

The exclusion criteria were as follows: Previous or concurrent malignant tumors combined with anxiety; depression; history of dementia; history of drug abuse; alcoholism; failure of the heart, liver, kidney, and other important organs; hearing and language dysfunction; and inability to cooperate.

A total of 144 patients met the inclusion standard. The patients were divided into anxiety, non-anxiety, depression, and non-depression groups based on their reported anxiety or depression status.

General information collection

General patient data, collected using a self-administered demographic characteristics questionnaire, mainly included age, sex, cultural background, marital status, family per capita monthly income, presence or absence of underlying diseases, and medication compliance. At the same time, the anxiety self-rating scales (SAS) and the self-rating depression scale (SDS) were used to evaluate the anxiety and depression of the patients one month after operation.

Anxiety status assessment

Trained healthcare professionals used SAS to assess anxiety in all patients. The SAS includes 20 items, of which 15 are scored positively, and 5 are scored negatively. Twenty entries add up to a total score of 20. The integer part of the total score was multiplied with 1.25 to obtain the standard score. The threshold was set to 50 points based on the Chinese scoring standard. The degree of anxiety was categorized as mild (50–60 points), moderate (60–80), and severe (80–100).

Depression status assessment

SDS was used to evaluate the depression status of the patients. All patients were evaluated by a professional medical staff member who had undergone systematic training. The SDS includes 20 items, and each item was evaluated using a 4-point Likert scale, with a score of 1–4 points. The rough score was obtained by adding the scores of each item (the reverse item is the reverse score); the coarse fraction was multiplied with 1.25 and the integer part was considered as the standard score. The threshold of the standard SDS score was 53 points, and the normal score was 53 points. Depression was classified as mild (53–60 points), moderate (53–60), or severe (90–100).

Statistical Methods

Descriptive analysis, and single-factor and multi-factor analyses were performed. Descriptive analysis was performed on the number of samples and their compositions. The histogram shows the basic characteristics of anxiety and depression. Univariate chi-square tests and single-factor logistic regression analyses were used to evaluate the influencing factors of anxiety and depression. Anxiety and depression (yes = 1; no = 0) were assigned as the dependent variables. All statistical tests were two-sided, with a statistically significant difference of $P < 0.05$. The data obtained were statistically analyzed using SPSS26.0 (IBM SPSS Inc., Chicago, United States).

RESULTS

Survey population

A total of 144 participants were included in this study, comprising 70 men (48.61%) and 74 women (51.39%). Their age was 18–60 (34.81 ± 4.92) years; and education level was 68 (47.22%) above high school, 76 (52.78%) below high school. Table 1 presents additional basic information collected in this study.

Anxiety and depression

The baseline mean scores of SAS and SDS were 50.06 ± 16.10 and 50.96 ± 16.55, respectively. Further, 51.38% (74/144) of the patients were in a non-anxiety state and 48.62% (70/144) were anxious. The proportions of mild, moderate, and severe anxiety were 21.52%, 24.30%, and 2.78%, respectively. Moreover, 52.78% (76/144) of the patients were non-depressive and 47.22% (68/144) experienced depression. The proportions of mild, moderate, and severe depressive loops were 20.83%, 22.92%, and 3.47%, respectively (Table 2).

Influencing factors of anxiety

Single-factor analysis of anxiety symptoms: The results of single factor showed that there were significant differences between the two groups in education level, family monthly average income and medication rule ($P < 0.05$) (Table 3).

Multivariate analysis of anxiety symptoms: Logistic regression analysis was performed with the dependent variable anxiety. Independent variables included age, sex, marital status, educational level, family income, basic diseases, and medication compliance. The detailed variables assignments are listed in Table 4.

Multivariate analysis showed that education level, monthly average family income, and medication compliance were factors influencing patients' possible anxiety ($P < 0.05$; Table 5). Patients with a high educational level were 0.28 times more likely to experience anxiety than that those with a low educational level. Patients with high family income were 0.09 times more likely to experience anxiety than those with low family income. Patients who took medications regularly were 0.03 times more likely to be anxious than those who missed medications occasionally.

Influencing factors of depression

Single-factor analysis of depression: The results of single factor showed that there were significant differences between the two groups in gender, marital status and basic diseases ($P < 0.05$) (Table 6).

Multivariate analysis of depression: Logistic regression analysis was performed with depression as the dependent variable. Independent variables included age, sex, marital status, educational level, family income, basic diseases, and medication compliance. The variables assignments are listed in Table 4.

Table 1 Characteristics of the survey population

Category	Variable	Number of samples	Percentage (%)
Age	< 30	66	45.83
	≥ 30	78	54.17
Sex	Male	70	48.61
	Female	74	51.39
Education	High school or above	68	47.22
	High school and below	76	52.78
Marital status	Have a spouse	69	47.92
	no spouse	75	52.08
Monthly household income	≥ 5000	70	48.61
	< 5000	74	51.39
Underlying medical conditions	Yes	71	49.31
	No	73	50.69
Medication adherence	Regular	67	46.53
	Irregular	77	53.47

Table 2 Overall status of anxiety and depression in patients undergoing ^{131}I treatment after surgery for differentiated thyroid cancer

Category	Normal	Mild	Moderate	Severe
Anxiety	74 (51.39)	31 (21.52)	35 (24.30)	4 (2.78)
Depression	76 (52.78)	30 (20.83)	33 (22.92)	5 (3.47)

Table 3 Single factor analysis of anxiety in survey participants

Category		Anxiety (n = 70)	Non-anxiety (n = 74)	χ^2	P value
Age	≤ 40	31 (44.29)	35 (47.30)	0.131	0.717
	> 40	39 (55.71)	39 (52.70)		
Sex	Male	33 (47.14)	41 (55.40)	0.983	0.321
	Female	37 (52.86)	33 (44.59)		
Education	High school or above	48 (68.57)	20 (27.03)	24.911	0.001
	High school and below	22 (31.43)	54 (72.97)		
Marital status	Have a spouse	38 (54.29)	35 (47.30)	0.703	0.402
	No spouse	32 (45.71)	39 (52.70)		
Monthly household income	≤ 5000	51 (72.86)	19 (25.68)	32.065	0.001
	> 5000	19 (27.14)	55 (74.32)		
Underlying medical conditions	Yes	37 (52.86)	34 (45.95)	0.687	0.407
	No	33 (47.14)	40 (54.05)		
Medication adherence	Irregular	56 (80.00)	11 (14.86)	61.342	0.001
	Regular	14 (20.00)	63 (85.14)		

Logistic multivariate regression analysis showed that the factors influencing depression were sex, marital status, and basic diseases (P < 0.05). Female patients were more likely to have depression than male patients. Patients without a spouse were more likely to experience depression than those with a spouse. Patients with underlying diseases were more likely to have depression than those without. Detailed data analysis is presented in Table 7.

DISCUSSION

DTC is a common thyroid gland malignancy that occurs in young and middle-aged women[6]. DTC has a serious impact on the lives of patients and also induces more adverse emotions. Radionuclide ^{131}I has been widely used to treat patients with DTC and has contributed to continuous progress in medical technology in China[7]. However, most patients know little about radionuclide therapy, and the treatment needs to be performed in a special isolation ward, which can easily cause anxiety and depression[8]. Thus, it is important to consider the mental health of patients, which is conducive to better recovery.

Table 7 Multivariate Logistic analysis of depression in differentiated thyroid cancer patients after ^{131}I treatment and surgery

Factors	β	SE	Wald χ^2 value	*P* value	OR	95%CI
Sex	-1.096	0.405	7.323	0.007	0.334	0.151–0.739

SE: Standard error; OR: Odds ratio.

The findings of this study showed that 48.61% of patients with DTC exhibited anxiety and 47.22% exhibited depression, one month following their ^{131}I treatment initiation. These elevated percentages could be attributed to patients having concerns about the problems associated with radiation involved in ^{131}I treatment during isolation, due to a limited understanding of ^{131}I treatment. These patients are prone to panic, anxiety, and other serious passive moods, which reduce their compliance with treatment and affect the overall treatment outcomes. Therefore, the assessment of anxiety and depression in patients undergoing ^{131}I treatment facilitates the provision of timely counseling intervention to alleviate these negative emotions, and improve patients' treatment compliance, prognosis, and quality of life[9]. Moreover, these negative emotions in patients with thyroid cancer are reported to be associated to age, educational level, and family income[4,10].

In the present study, the anxiety and depression symptom scores of postoperative patients after ^{131}I treatment were 50.06 ± 16.10 and 50.96 ± 16.55, respectively. It has been reported that the main reasons for the high scores of anxiety and depression were the lack of trust in the professional level of the medical staff, lack of understanding of treatment methods, and concerns regarding recurrence and adverse reactions during surgery, as well as the resulting economic burden[11,12]. The superposition of these factors inadvertently leads to high psychological pressure and stress responses in patients, thereby resulting in anxiety and depression[13].

Further multivariate logistic regression analysis showed that patient's education level, family income, and medication regularity were the independent influencing factors of anxiety. Therefore, our results suggest that patients with a low education level, low family income, and irregular adherence to medication were more prone to anxiety. These findings are consistent with those of Yang *et al*[14] and Tsartsalis *et al*[15]. Possible reasons for these results may include the limited knowledge levels among people with low education levels, less access to disease information, a lack of understanding of important stressors, and a difficulty in effectively reducing stress using corresponding methods. Such patients are sensitive to possible threats caused by diseases and operations and are prone to anxiety and depression[16]. Patients with higher education levels have a stronger learning ability and thorough understanding of medical staff's knowledge and educational status. Patients who are able to actively collect information about the disease and its treatment from books, networks, and other means, are better equipped to reduce the psychological burden and eliminate negative emotions. On the other hand, patients with low education levels require repeated explanations, even through the use audiovisual aids to increase their understanding of their diseases, thereby eliminating the uncertainty of the disease or treatment, and improving their confidence in the healing process[17].

Thyroid cancer requires long-term treatment, which is expensive and increases the economic burden of patients. Therefore, family income has also become an independent risk factor for patients ' concerns. Patients with thyroid cancer with a family monthly income ≤ 5000 yuan have often face financial difficulties. They experience significant psychological pressure because they worry about becoming a burden on their families, and they may feel anxious about being unable to afford the long-term medical expenses. The consequent uncertainty of follow-up treatment can easily lead to negative emotions, such as guilt and anxiety. Indeed, patients from low-income families can choose effective and low-cost drug treatment to reduce their families economic burden[18].

Occasionally missed medications are also a risk factor for anxiety in patients with DTC after surgery. Long-term and occasionally missed medication increases the fear of disease recurrence, resulting in anxiety symptoms. Therefore, family members should ensure that patients take their medications on time.

In the present study, sex, marital status, and underlying diseases were independent risk factors for depression. The incidence of depression was higher in women than that in men, which is consistent with previous studies[19]. This reason may be related to cyclical fluctuations in female endocrine hormone levels[20]. In addition, women now play multiple roles in social responsibility, leading to increased stress in life; they are relatively more sensitive, tend to have more physical and emotional pain, which may lead to a poor prognosis[21]. More attention should be paid to the feelings of female patients, and their symptoms should be actively improved to enhance their quality of life. Studies[19] have shown that marital status is an independent risk factor for depression. Although unmarried patients are accompanied by their parents, they lack active support from their spouses or children, and consequently experience greater loneliness than married patients. On the other hand, patients with spouses can receive family support to reduce their risk of anxiety and depression. Studies[22] have also reported that patients with cancer undergoing long-term treatments, such as radiotherapy and chemotherapy, are affected by irreversible damage to fertility and reproductive performance, resulting in depression, especially in unmarried and childless patients. In addition, ^{131}I treatment should be isolated in a separate closed ward for one week. This lack of social connection which has serious consequences, such as social isolation and interruption of important interpersonal relationships[23]. The present study shows that medical staff should pay more attention to such patients and mobilize social and family members to provide them with psychological support and emotional comfort. In addition, compared with patients without underlying diseases, patients with underlying diseases

tend to have higher levels of depression. First, patients with underlying diseases have higher medical costs than those without such conditions, and consequently exhibit a greater economic and psychological burden. Second, patients with underlying diseases often have severe physical pain and functional impairment, which can cause more severe depression than patients without such conditions[24]. In particular, this phenomenon is more common in patients with hypertension [25], cardiovascular disease[26], and brain edema[11]. Therefore, medical staff and family members should provide more care and companionship to such patients.

Notably, this was a single-center study with a small sample size and did not analyze the long-term concerns of the patients. The risk factors associated with anxiety in patients after DTC surgery must be further verified in large multicenter studies.

CONCLUSION

The anxiety scores of patients with DTC were higher after ^{131}I treatment. Among them, female sex, no spouse, low education level, low family income, basic underlying diseases, and irregularity in taking medicine were influencing factors of anxiety and depression in these patients. In clinical practice, providing patients with targeted nursing interventions according to the aforementioned factors could decrease the risk of anxiety and depression and eventually improve patient prognosis.

ARTICLE HIGHLIGHTS

Research background

Patients were investigated using the self-rating depression scale (SDS) and self-rating scales (SAS). Patients were grouped according to the presence and degree of anxiety and depression. The influencing factors were analyzed, and the appropriate intervention was suggested.

Research motivation

Patients with differentiated thyroid cancer (DTC) after ^{131}I treatment were more prone to anxiety and depression. Clinically, female patients with no spouse, low education level, and low family income, accompanied by basic diseases, and medication irregularity should receive intervention care, thereby reducing the risk of anxiety and depression and improving their prognosis.

Research objectives

The original mean score of SAS and SDS was 50.06 ± 16.10 and 50.96 ± 16.55, respectively; 48.62% (70/144) and 47.22% (68/144) of the patients experiences anxiety and depression, respectively. Educational level, average monthly family income, and medication compliance influenced anxiety. Sex, marital status, and underlying diseases influenced depression ($P < 0.05$).

Research methods

We analyzed 144 patients with thyroid cancer after surgery who received ^{131}I treatment in our hospital from June 2020 to December 2022. The patients were grouped according to their SDS and SAS scores. Single factor and multivariate analyses were used to determine the factors influencing anxiety and depression in patients with DTC after surgery.

Research results

It is crucial analyze the anxiety status and the related risk factors in patients with DTC after surgery, in order to formulate clinical preventive nursing strategies to improve the prognosis of patients.

Research conclusions

This study discussed the anxiety and depression status of patients with DTC after ^{131}I treatment and analyzed their influencing factors.

Research perspectives

Patients with DTC do not comprehend ^{131}I treatment, which is a type of internal radiotherapy, and they easily experience anxiety, fear, depression, and other negative emotions.

ABOUT COVER

Editorial board member of *World Journal Psychiatry*, Oleg V Tcheremissine, MD, Academic Fellow, Full Professor, Professor, Department of Psychiatry, Atrium Health, Charlotte, NC 28211, United States. oleg.tcheremissine@atriumhealth.org

AIMS AND SCOPE

The primary aim of *World Journal of Psychiatry* (*WJP*, *World J Psychiatry*) is to provide scholars and readers from various fields of psychiatry with a platform to publish high-quality basic and clinical research articles and communicate their research findings online.

WJP mainly publishes articles reporting research results and findings obtained in the field of psychiatry and covering a wide range of topics including adolescent psychiatry, biological psychiatry, child psychiatry, community psychiatry, ethnopsychology, psychoanalysis, psychosomatic medicine, *etc*.

INDEXING/ABSTRACTING

The *WJP* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Current Contents/Clinical Medicine, Journal Citation Reports/Science Edition, PubMed, PubMed Central, Reference Citation Analysis, China National Knowledge Infrastructure, China Science and Technology Journal Database, and Superstar Journals Database. The 2023 Edition of Journal Citation Reports® cites the 2022 impact factor (IF) for *WJP* as 3.1; IF without journal self cites: 2.9; 5-year IF: 4.2; Journal Citation Indicator: 0.52; Ranking: 91 among 155 journals in psychiatry; and Quartile category: Q3.

Abstract

Rapid-cycling bipolar disorder (RCBD) is a phase of bipolar disorder defined by the presence of ≥ 4 mood episodes in a year. It is a common phenomenon characterized by greater severity, a predominance of depression, higher levels of disability, and poorer overall outcomes. It is resistant to treatment by conventional pharmacotherapy. The existing literature underlines the scarcity of evidence and the gaps in knowledge about the optimal treatment strategies for RCBD. However, most reviews have considered only pharmacological treatment options for RCBD. Given the treatment-refractory nature of RCBD, nonpharmacological interventions could augment medications but have not been adequately examined. This review carried out an updated and comprehensive search for evidence regarding the role of nonpharmacological therapies as adjuncts to medications in RCBD. We identified 83 reviews and meta-analyses concerning the treatment of RCBD. Additionally, we found 42 reports on adjunctive nonpharmacological treatments in RCBD. Most of the evidence favoured concomitant electroconvulsive therapy as an acute and maintenance treatment. There was preliminary evidence to suggest that chronotherapeutic treatments can provide better outcomes when combined with medications. The research on adjunctive psychotherapy was particularly scarce but suggested that psychoeducation, cognitive behavioural therapy, family interventions, and supportive psychotherapy may be helpful. The overall quality of evidence was poor and suffered from several methodological shortcomings. There is a need for more methodologically sound research in this area, although clinicians can use the existing evidence to select and individualize nonpharmacological treatment options for better management of RCBD. Patient summaries are included to highlight some of the issues

concerning the implementation of adjunctive nonpharmacological treatments.

Key Words: Rapid-cycling bipolar disorder; Bipolar disorder; Adjunctive therapy; Nonpharmacological treatment

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: Rapid-cycling bipolar disorder (RCBD) is a common and highly disabling phase of bipolar disorder. The ineffectiveness of conventional pharmacological treatment for RCBD suggests that adjunctive nonpharmacological interventions could be useful. However, their role has not received much attention. This review carried out a comprehensive search to identify the existing evidence on the subject. We found that electroconvulsive therapy, chronotherapy, and psychotherapy could effectively augment medication treatment of RCBD. However, the evidence is limited and methodologically inadequate. Therefore, clinicians have to rely on general guidelines for the optimal use of the available nonpharmacological options while managing RCBD.

INTRODUCTION

Clinical features of rapid-cycling bipolar disorder

Rapid-cycling bipolar disorder (RCBD) is a phase in the longitudinal course of BD characterized by increased episode frequency. The Diagnostic and Statistical Manual of Mental Disorders (DSM) delineates rapid cycling as a specifier of the longitudinal course of BD rather than a distinct form of the disorder[1]. DSM-5 defines rapid cycling as a minimum of four episodes in the previous 12 mo that meet the diagnostic and duration criteria for hypomanic, manic, or major depressive episodes. Each episode is demarcated by either partial or full remission for at least 2 mo, or a switch to a new episode of the opposite polarity. A proportion of patients have shorter cycles of days to weeks (ultra-RCBD) and some have episodes lasting less than a day (ultradian-RCBD)[2-6]. However, DSM-5 does not include these categories.

The phenomenon of rapid cycling occurs among a significant proportion of patients with BD. The 12-mo prevalence of RCBD in patients from specialized mood disorder clinics is about 20% (range: 4%–27%)[4,6-9]. The prevalence is higher (range: 27%–56%) when ultrarapid and ultradian rapid cycling are included[6,7,10,11]. The rates are also higher in community settings (30%–40%) because these studies have included a wide spectrum of RCBD[9,12-14]. Reviews have estimated the annual prevalence rate of RCBD to be about 18% (range: 5%–33%) and lifetime rates of about 31% (range: 26%–43%)[9,15-18]. The rates obtained by different meta-analytic studies also vary from 15% to 24% (range: 12%–56%)[5,19-21].

Apart from its frequent occurrence, RCBD is characterized by clinical features that make it a severe and disabling phenomenon. Depressive episodes or symptoms appear to be the characteristic clinical presentation of RCBD[5,10,15,17,22]. Patients with BD who have depressive onsets are more likely to develop rapid cycling and patients with RCBD are more likely to present with depressive onsets. Episodes of depression are more frequent and severe in patients with RCBD. Depressive episodes are harder to treat compared with manic ones. As a result of this greater depressive burden, most reviews have also found a higher rate of suicidality in RCBD[5,16,21,23,24]. The frequent recurrence of treatment-resistant depression contributes to the treatment-refractory profile of RCBD. The distress and disability associated with unremitting depression are the main hurdles in effectively managing RCBD[10,13,14,22,25]. Although RCBD is a transient phenomenon that lasts about 2 years in most patients[2,6,16,22,24], many studies have found rapid cycling to persist in > 50% of patients[6,25-28]. A longer duration of rapid cycling, more frequent episodes, a depression-mania-free interval pattern, continuous cycling, agitated depression, temperamental disturbances, and poor response to treatment are associated with the persistence of RCBD[6,8,17,29,30]. Lastly, the consistent finding in the literature is that RCBD is associated with poorer outcomes in terms of severity, recurrence risk, chronicity, comorbidity, and treatment resistance [17-20,31]. Given all these adverse clinical features, it is not surprising that RCBD is associated with greater global functional impairment, poor socio-occupational outcomes, higher levels of disability, poorer quality of life, and greater family burden[2,6,9,16,24]. Thus, RCBD adds a great deal to the overall burden of BD[18].

Pharmacotherapy of RCBD

Since pharmacotherapy is the principal means of treating BD, the primary focus of research has been on the efficacy of medications in RCBD. Several reviews of the subject exist in the current literature. These include narrative reviews[4,24,27,30,32], systematic reviews[6,16,17,29,31], and meta-analyses[5,18,20,21,33] (Supplementary Material includes a complete list of all the reviews consulted).

The main finding of this research is that RCBD is resistant to treatment by conventional pharmacotherapy for BD[6,20,27,29,30]. RCBD comprises the largest group among patients with treatment-resistant BD[34]. Patients with RCBD have poorer treatment response and outcome compared to patients without rapid cycling[26,27,29,30,35]. Although initial studies suggested that RCBD responds poorly to lithium, it is now clear that rapid cycling is resistant to all mood-stabilizing treatments[6,20,36-38]. Treating depressive episodes in RCBD poses greater problems than treating mania/hypomania. The acute efficacy of medications is usually better than their long-term effects[8,11,18,29,32]. Recommendations regarding effective treatment options vary, but most of the evidence appears to favour second-generation antipsychotics, lithium, valproate, lamotrigine, thyroxine, and even antidepressants[17,18,24,31,39]. There is a considerable consensus that response to monotherapy is often inadequate. Therefore, combinations of mood stabilizers and antipsychotics are the more practical, if not the evidence-based options for treatment[17,40-43]. However, the prevailing concern about medication treatments for RCBD is the lack of research data and guidance on suitable evidence-based options, particularly for long-term treatment[17,18,24,29,31]. Not only is there a lack of randomized controlled trials (RCTs) on the subject, but there are also several methodological lacunae such as small sample sizes, uncertainties about the definition of RCBD, and inadequate study designs[6,11,18,20,44].

Nonpharmacological therapy for RCBD

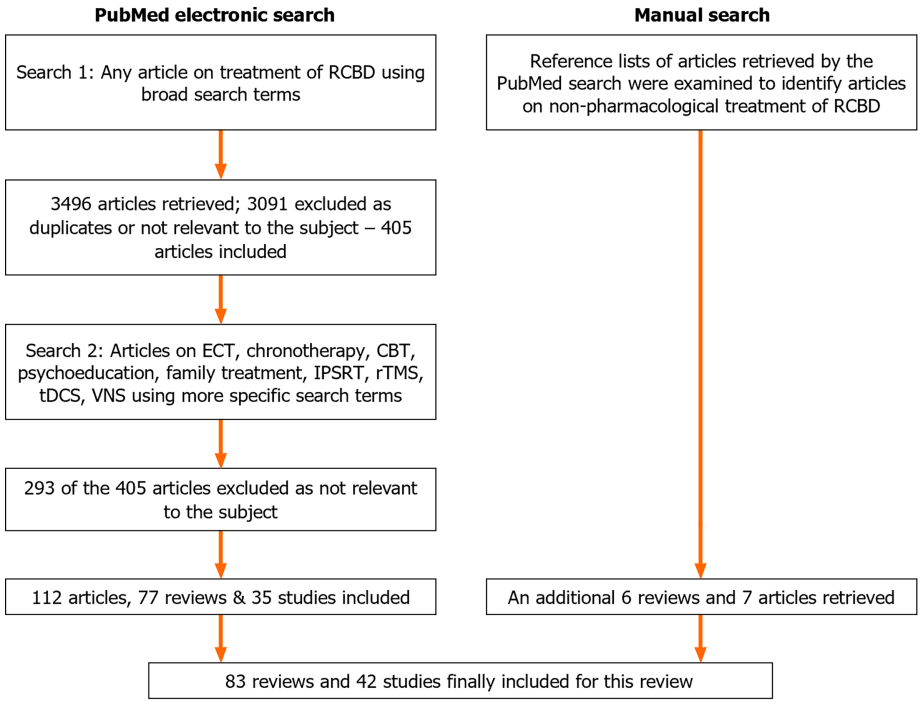
The shortcomings of pharmacological treatment indicate an unmet need for more effective management options for RCBD. Adjunctive nonpharmacological interventions could fill the existing gap in managing RCBD[18,36,45-47]. Treatments such as electroconvulsive therapy (ECT), chronotherapy, and psychotherapy can potentially augment the inadequate response obtained with medications. However, the role of adjunctive nonpharmacological treatments has not received much attention. A systematic review conducted in 2007 considered the different biological and psychotherapeutic options that could augment the pharmacological treatment of RCBD[45]. It found some evidence for the efficacy of ECT and sleep deprivation for acute and maintenance management of RCBD, especially in treatment-resistant patients. Light therapy was not efficacious and there was no data on recurrent transcranial magnetic stimulation (rTMS), vagus nerve stimulation (VNS), and psychotherapeutic treatments. The authors acknowledged that the evidence was based only on case reports and open trials and not RCTs. However, they concluded that adjunctive nonpharmacological treatments could be used to manage RCBD based on clinical experience and their usefulness in BD. They recommended the early institution of adjunctive treatments such as ECT in patients who were severely ill and needed immediate relief. Subsequent reviews of the treatment of RCBD have also noted the potential for concomitant use of nonpharmacological treatments and the lack of controlled trials in this area[17,18,32,46,47].

There are several reasons for examining the role of combined pharmacological and nonpharmacological therapy in RCBD. At present, there is no consensus or guidance on the optimal management of RCBD because pharmacological and nonpharmacological treatments have proved less effective[17,18,25,45]. Apart from the inadequate response to standard pharmacotherapy, many other factors make rapid cycling difficult to treat. These include its high prevalence, greater severity, depressive colouring, comorbidities, poorer outcomes, higher levels of disability, side-effect burden, and inadequate medication adherence[15,17,18,24,36]. Adjunctive nonpharmacological treatments can address some of these issues such as persistent depressive symptoms and risks of harm[45], comorbidities[2,10,40], psychosocial stressors, functional impairment[25,32,48-50], and treatment nonadherence[25,30,45,51,52].

Aims of this review

This review aimed to summarize the existing evidence on the role of nonpharmacological therapies as adjuncts to medications in RCBD. It attempted to expand on the previous review[45] by conducting a more comprehensive and updated search of this area.

LITERATURE REVIEW



Although this was not a systematic review, it relied on comprehensive electronic (PubMed) and manual searches to identify the existing literature on nonpharmacological treatments in RCBD from 1980 to April 2023. The accompanying figure depicts this search. Supplementary Material includes the details of the search terms used. The Reference Citation Analysis tool was used for searching articles and ranking them according to their impact (Figure 1).

This search identified 53 narrative reviews, 21 systematic reviews, and nine meta-analyses on the treatment of RCBD. These reviews were used to collate information regarding various nonpharmacological therapies in RCBD. A second round of electronic and manual searches identified 17 studies or reports of ECT, 16 of chronotherapy, six of psychotherapy, two of VNS, and one of rTMS. Patients consented to the presentation of their treatment histories. All patient details have been anonymized.

RESULTS

Adjunctive ECT in RCBD

ECT has proven efficacy in BD in treating acute episodes of both mania and depression. It is particularly useful in medication-resistant episodes that are severe, psychotic, or with a high risk of self-harm. The evidence also suggests that maintenance ECT in combination with medication is efficacious for patients with highly recurrent illnesses if they have

responded well to acute ECT[3,45,53-55]. Consequently, ECT has been used for similar indications in patients with RCBD. However, the evidence is limited and based on either case reports or naturalistic studies with small numbers of patients. These studies are included in Table 1[56-72].

Despite these limitations, acute ECT seems to be effective in patients with medication-resistant RCBD with complete or partial remission rates ranging from 70% to 100% in some studies[69,72]. Others have reported lower response rates[64,66,67,70]. Nevertheless, sustained periods of remission and better response to mood stabilizers are reported after acute ECT[64,65,67,70,72]. Acute ECT also reduces the number of episodes and the time spent ill. Though there are fewer studies, the combination of maintenance ECT and mood stabilizers appears to be effective with response rates ranging from 67% to 100%[68,70,71]. Adjunctive maintenance ECT prevents relapses, reduces the need for hospitalization and the length of hospital stay, decreases the time spent in episodes, and increases the duration of interepisodic intervals[68,70,71,73,74]. Patients with RCBD and ultra-RCBD may respond better to ECT than other patients with BD[41,45]. ECT is particularly helpful in patients with RCBD who have failed multiple medication trials, those who are intolerant to medication side effects, and those who are at high risk of self-harm[3,45,49]. ECT is effective in medication-resistant patients with mania[3,30,47,75,76], depression[32,41,68,72,75], or mixed states[49,72] as a part of RCBD. However, the best response is often obtained in patients with bipolar depression[32,41,67,68,72]. Other predictors of good response are depressive episodes with psychotic symptoms or catatonic features[41,68,72]. Minnai *et al*[71] carried out a multivariate analysis to identify the predictors of good response to maintenance ECT in RCBD. Young age, male sex, type II BD, and hyperthymic temperament emerged as factors associated with a higher chance of depression-free intervals with ECT. The better response in those with type II BD and hyperthymic temperament could be because a large proportion of these patients were included in their sample. However, hyperthymic temperament is often associated with antidepressant-induced rapid cycling[6], while ECT may be less likely to cause rapid cycling than antidepressants[4]. The use of ECT has shown to be safe with minimal side effects even when it is combined with mood stabilizers and used for long periods[62,63,68,71,72]. ECT is also less likely than antidepressants to cause manic/hypomanic switches or induce rapid cycling[4,48,49,64,76].

Thus, despite the scarcity of evidence, acute ECT is recommended for treating medication-refractory manic and depressive episodes in RCBD[30,32,45,49,76]. Maintenance ECT can be considered in those patients who improve with acute ECT or relapse on pharmacotherapy[45,73-77]. ECT is more effective if started early in the course of treatment because the outcome is likely to be worse if it is delayed[45,69].

Two of our patients (numbers 1 and 2) received acute ECT with varying degrees of success (Supplementary Material).

Adjunctive ECT in RCBD patient examples

A 72-year-old man with medication-resistant RCBD received two courses of acute ECT in 2017 for episodes of severe depression. The response to the first course was good with complete remission from depression. However, he did not respond as well with the second course a few months later. The depressive episodes did not remit and his rapid cycling continued. He had physical complications during ECT and was unwilling to try ECT further. Later, his rapid cycling

Table 1 Studies of adjunctive electroconvulsive therapy in rapid-cycling bipolar disorder

Ref.	Sample	Results
Case reports		
Berman and Wolpert[56], 1987	18-yr-old woman with medication-resistant RCBD	ECT during mania led to complete remission, which was maintained for 14 mo without medications
Mizukawa *et al* [57], 1991	81-yr-old woman with medication-resistant ultra-RCBD	ECT did not prevent the recurrence of episodes over a period of 35 yr of observation
Benjamin and Zohar[58], 1992	45-yr-old man with treatment-resistant RCBD	Depressive episodes responded transiently to total sleep deprivation and psychotherapy but complete remission was only achieved with acute ECT
Kho[59], 2002	79-yr-old woman with medication-resistant RCBD	ECT and lithium was used successfully during acute and maintenance treatment
Zavorotnyy *et al* [60], 2009	63-yr-old woman with medication-resistant bipolar disorder	The patient developed ultra-rapid cycling during acute ECT, which responded to the continuation of ECT and addition of lithium
Amino *et al*[61], 2011	63-yr-old woman with medication-resistant RCBD	Continuation-ECT for 12 mo prevented rehospitalization
Huber and Burke [62], 2015	67-year-old woman with medication-resistant ultra-RCBD	ECT was used to successfully treat depression and manic episodes that developed on discontinuation of lithium
Kranaster *et al*[63], 2017	21-yr-old woman with medication-resistant ultra-RCBD	ECT was used to successfully treat a treatment-resistant depressive episode
Observational studies		
Kukopulos *et al* [64], 1980	87 patients with RCBD	11 patients treated only with ECT for 7–35 yr remained in remission for long periods
Kukopulos *et al* [65], 1983	87 patients with RCBD	ECT was more effective than antidepressants in treating severe depression and when combined with lithium led to longer remissions
Wehr *et al*[66], 1988	24 patients with medication-resistant RCBD	None of the patients remitted with ECT
Mosolov and Moshchevitin[67], 1990	8 patients with mood stabilizer-resistant RCBD	Acute ECT lead to remission for 6 mo in 3 patients. The number of episodes and the time spent in mood episodes was reduced. Mood stabilizers were more effective following acute ECT treatment
Vanelle *et al*[68], 1994	Four patients with medication-resistant RCBD	Maintenance ECT for 18 mo led to full or partial remission in all 4 patients. Time spent in the hospital was reduced. Response was better in depressive episodes with psychotic symptoms
Wolpert *et al*[69], 2013	Six patients with continuous cycling	ECT started early in the course of cycling was effective in reducing recurrences
Koukopoulos *et al* [70], 2003	43 patients of RCBD who received ECT	11 patients remitted with ECT and mood stabilizer combinations and maintained in this state for 2–36 yr. Temporary improvement was noted in the others. Two out of 3 patients on maintenance ECT had good response
Minnai *et al*[71], 2011	14 patients with medication-resistant RCBD treated with maintenance ECT. Comparisons of 2-yr periods before and after ECT	All patients improved. Eight did not relapse over 2 yr and 6 had only one episode annually. Time spent ill was reduced and interepisodic periods were longer. Young males with type II BD and hyperthymic temperament had better outcome
Mosolov *et al*[72], 2021	1-year prospective study of 30 patients with RCBD and ultra RCBD with poor response to mood stabilizer treatment. Comparisons of 1-yr periods before and after acute ECT	40% achieved and maintained remission with ECT and lithium treatment; 30% showed partial response with the combination and 30% did not respond. Duration of mood episodes was significantly reduced with ECT. Mixed depression with/without catatonia had better response to acute ECT

ECT: Electroconvulsive therapy; RCBD: Rapid-cycling bipolar disorder; type II BD: Bipolar disorder type II; Ultra-RCBD: Ultra-rapid-cycling with shorter cycles of days to weeks; Ultradian-RCBD: Ultradian rapid-cycling with episodes lasting less than a day.

responded to repeated administration of partial sleep deprivation during depressive episodes and dark therapy during hypomanic episodes. A 42-year-old woman with medication-resistant, ultra-rapid, and ultradian cycling was administered ECT in 2005 during an episode of psychotic depression with high suicidal risk. She improved but her cycling did not stop. She was administered ECT again in 2015 for a mixed episode with psychosis and suicidal risk. Response to ECT was inadequate on this occasion and she had physical complications during ECT. Since then, her rapid-cycling pattern has shown a better response to intensive psychotherapy combined with medication. The detailed treatment histories of these patients (Supplementary Material) illustrate some of the disadvantages of ECT in RCBD including the variable response, greater acute than maintenance effects, and the higher risk of adverse effects in some patients[32,45,55,75]. Although ECT is used more commonly in RCBD than in the non-rapid-cycling group, it is still underutilized in RCBD because of these concerns[78,79].

Other neurostimulatory treatments in RCBD

There are few reports of rTMS and VNS treatment in RCBD. A case report described a 60-year-old woman with medication-resistant RCBD who improved after acute administration of rTMS and remained in remission for 6 mo with maintenance rTMS[80]. Another report of a 60-year-old woman with RCBD found that 12 mo of treatment with VNS reduced the severity of her depressive symptoms and the duration of her depressive episodes[81]. Finally, nine patients with treatment-resistant RCBD were treated with VNS for 1 year in a pilot study[82]. They had significant improvements in overall illness severity, the severity of depressive symptoms, and functioning. The VNS treatment was well-tolerated.

Adjunctive chronotherapy in RCBD

Chronotherapy refers to treatment based on controlled exposure to environmental stimuli such as light to alter circadian rhythms or manipulation of the sleep–wake cycle to benefit patients with psychiatric disorders[83-87]. Chronotherapy includes bright light therapy (BLT), wake therapy (total or partial sleep deprivation in the second half of the night), phase-advance of the sleep–wake cycle, triple chronotherapy (combinations of wake therapy, BLT, and sleep phase-advance) dark therapy, blue-light-blocking sunglasses, interpersonal and social rhythm therapy (IPSRT), cognitive behavioural therapy (CBT) for insomnia, and exogenously administered melatonin[84,86,88,89]. These treatments are effective among patients with BD.

Among the various options, BLT appears to be the one best supported by the evidence[86,89]. Several meta-analyses have shown medium to large effects of BLT during acute treatment of bipolar depression[89-93]. It is effective in seasonal and nonseasonal depression[94-98]. Adding BLT to antidepressants or sleep deprivation treatment yields a better response[90,99]. BLT is well tolerated and the risk of manic switches is not increased with it[93,100-103]. However, the efficacy of BLT is based on few RCTs and some meta-analyses have found no conclusive evidence for its efficacy[100,102,103].

The evidence for total or partial sleep deprivation is less convincing. Although 50%–60% of patients respond to a single session of wake therapy, the positive effects of wake therapy are usually transient[86,89,104,105]. The evidence base consists mainly of uncontrolled trials. Moreover, there may be a higher risk of manic switches. Nevertheless, several meta-analyses have concluded that wake therapy combined with medications causes significant reductions in symptoms of bipolar depression[106-109]. Combining sleep deprivation with antidepressants or mood stabilizers, BLT, or sleep phase-advance treatment also sustains its effects[107,110-112]. The treatment might be particularly effective for those with bipolar rather than unipolar depression[113-117]. There is no difference in efficacy between total and partial sleep deprivation[106,108,118,119]. Lastly, the rates of manic switches are low, except in patients with RCBD[104,107,112].

Triple chronotherapy is a treatment regimen designed to prevent the early relapse of symptoms with wake therapy [110,112,116]. It consists of one or more nights of wake therapy, followed by morning administration of BLT, and 3–5 d of sleep phase advance[84]. A systematic review[87] and a meta-analysis[120] showed that triple chronotherapy was effective in bipolar depression. Response rates ranged from 33% to 62% and the effects lasted several weeks. It was not associated with adverse effects and the rates of switching were low.

Dark therapy involves keeping patients with mania/hypomania in dark rooms for extended periods of rest and sleep [84]. This treatment can reduce manic symptoms but has not been examined in RCTs[84,86,117]. A more practical option is the use of glasses that block blue light. This treatment reduced manic and depressive symptoms and improved sleep efficiency in two RCTs[121,122].

A few RCTs of IPSRT have shown positive effects on bipolar depression during acute and maintenance treatment and a single RCT showed that CBT for insomnia improves sleep and decreases depressive symptoms[86,89].

RCBD is the prototypical example of the link between mood disorders and abnormalities of the circadian system and the sleep–wake cycle[28,123-126]. Compared to patients without rapid cycling, the circadian rhythm system in patients with RCBD is more vulnerable to the effects of environmental stimuli, for example, light and dark, irregular sleep patterns and sleep loss, and changes in the social environment such as stressful life circumstances[3,54,55,124,125]. Disturbances in circadian rhythms[3,28,124,126] and social rhythms[28,45,55,127], abnormalities of circadian genes[46,85,128,129], evening chronotypes[125,130], and hormonal abnormalities occur at a higher rate in RCBD[46,85]. However, despite this knowledge and the evidence for the efficacy of chronotherapy in BD, chronotherapy of RCBD is still an evolving area[86]. Since most of the RCTs of chronotherapy in BD usually exclude patients with RCBD, the current evidence is limited to case reports and observational studies with small sample sizes. Table 2 includes these studies and reports of chronotherapy of RCBD[58,70,127,131-143].

Despite the limited evidence, treatments such as wake therapy, BLT, dark therapy, and triple chronotherapy have been used successfully in the acute and maintenance treatment of patients with RCBD. Chronotherapy combined with medications is effective even in patients resistant to medications, ECT, or psychotherapy. There is some concern about the adverse effects of these treatments, particularly the risk of manic/hypomanic switches and exacerbation of rapid cycling with wake therapy. Early studies reported higher rates of switching with wake therapy in RCBD[110,113,114,118,119]. However, these studies mostly used total sleep deprivation. Recent studies of partial sleep deprivation have reported lower rates[115]. Moreover, the high rates are based on a small number of patients with RCBD and the rate of treatment-induced switches is probably no different from the rate of spontaneous switches in RCBD[86,115]. Lastly, such switches can be easily treated or prevented by combining sleep deprivation with medications, BLT, and phase-advance treatment [110,112,115].

Adjunctive chronotherapy in RCBD: patient examples

Four of our patients have been treated successfully with adjunctive chronotherapy. Triple chronotherapy, dark therapy, and blue-light-blocking glasses were used successfully in two inpatients: (1) A 69-year-old woman with a long history of ultra-rapid RCBD was hospitalized after 6 years of unsuccessful treatment with different combinations of medication.

Table 2 Studies of adjunctive chronotherapy in rapid-cycling bipolar disorder

Ref.	Sample	Results
Case reports		
Christodoulou *et al* [131], 1978	26-yr-old woman with rapid-cycling episodes of severe recurrent depression resistant to medications	Inpatient and outpatient total sleep deprivation every week for 36 wk led to remission for a period of 10 mo. The patient committed suicide after stopping the maintenance sleep deprivation treatments
Lovett Doust and Christie[132], 1980	48-yr-old woman with medication-resistant RCBD	Five nights of total sleep deprivation combined with medications during depressive episodes for 8 mo led to reduction in intensity and duration of depression. Switches into hypomania were recorded
Churchill and Dilsaver[133], 1990	47-yr-old woman with rapid-cycling episodes of severe recurrent depression	Partial sleep deprivation on alternate nights combined with an antidepressant led to complete remission from depression for 6 wk
Benjamin and Zohar[58], 1992	45-yr-old man with treatment-resistant RCBD resistant to antidepressants	One night of sleep deprivation was successful in aborting depressive episodes, but led to prolonged hypomania on one occasion and did not prevent the rapid-cycling pattern
Gann *et al*[134], 1993	64-yr-old man with ultradian-RCBD	Total sleep deprivation for 3 nights led to reduction of depressive symptoms for 2 wk. Further improvement occurred with carbamazepine
Eagles[135], 1994	50-yr-old man with medication-resistant ultradian-RCBD	Daily morning BLT for 2 mo produced sustained remission without hypomanic switches
Kusumi *et al*[136], 1995	2 patients with medication-resistant RCBD and nonseasonal depressions	Morning BLT led to improvement in sleep and mood. Withdrawal of BLT did not result in relapse. Remission was maintained for several months
Wehr *et al*[137], 1998	51-yr-old man with medication-resistant RCBD treated with 10–14 h of darkness, rest, and sleep over 1.5 yr	Dark therapy helped in stabilizing sleep, reducing hypomanic symptoms, and attenuating rapid cycling for the period of treatment. Lower doses of antipsychotics were required and hospital stay was shorter
Wirz-Justice *et al* [138], 1999	70-yr-old woman with medication-resistant ultra-RCBD	Rapid-cycling ceased on initiation of 10–14 h of darkness, rest, and sleep. Depression improved with mid-day BLT and remission was achieved with morning BLT. Patient remained on valproate and was stable for a year
Leibenluft and Suppes[127], 1999	42-yr-old woman with medication resistant ultra-RCBD	A lifestyle intervention that ensured a regular sleep–wake schedule in combination with medications led to decrease in rapid cycling
Observational studies		
Papadimitriou *et al* [139], 1981	5 patients with treatment-resistant RCBD	Weekly regimens of total sleep deprivation administered over several months reduced relapses and increased the duration of remissions
Wehr *et al*[140], 1982	9 patients with RCBD treated with 1 night of total sleep deprivation during depressive episodes	Depressive symptoms improved in 8 patients with sleep deprivation but 7 developed mania or hypomania
Papadimitriou *et al* [141], 1993	5 medication-free patients with RCBD treated with total sleep deprivation twice a week for 4 wk	All 5 patients responded to sleep deprivation treatment with > 50% improvement in depressive symptoms and remained in remission for a year with weekly sleep deprivation treatments. Rapid-cycling, young age, female sex, family history of mood disorder and illness duration < 10 yr predicted response. Hypomania was observed in 1 patient
Gill *et al*[142], 1993	3 patients with treatment-resistant RCBD treated with total sleep deprivation and mood stabilizers and antidepressants	Duration of response was significantly better when sleep deprivation treatment was administered late rather than early in the depressive episodes
Leibenluft *et al* [143], 1995	9 patients with RCBD treated with 3 mo of BLT and medications versus 3 mo of only medication treatment	Mid-day BLT was more effective in reducing depressive symptoms and days spent depressed than morning or evening BLT. Morning BLT precipitated hypomanic switches
Koukopoulos *et al* [70], 2003	2 women with RCBD	Sleep deprivation resulted in a temporary improvement of depression

BLT: Bright light therapy; RCBD: Rapid-cycling bipolar disorder; Ultra-RCBD: Ultra-rapid-cycling with shorter cycles of days to weeks; Ultradian-RCBD: Ultradian rapid-cycling with episodes lasting less than a day; Partial sleep deprivation: Sleep deprivation during the second half of the night; Total sleep deprivation: Sleep deprivation for 36 h.

Hypomania at admission responded well to dark therapy within 3–4 d and her antipsychotics could be stopped. She was started on triple chronotherapy when her depressive symptoms began to reappear 2 wk later. With two courses of this treatment, she remitted completely and remained symptom-free for 1 mo. Blue-light-blocking glasses also helped. Unfortunately, chronotherapy was not continued at home. Her rapid cycling resumed and 1 year later she dropped out of treatment; and (2) A 62-year-old woman with medication-resistant RCBD responded partially to morning bright light treatment combined with medication. Her depressive symptoms became less intense and the depressive episodes shorter. However, she was not able to carry out sleep deprivation treatment at home and her ultra-rapid cycling continued. She was hospitalized recently. Her depression responded to two cycles of triple chronotherapy and subsequent hypomanic symptoms responded to dark therapy and wearing blue-light-blocking glasses. She has achieved complete remission with

adjunctive chronotherapy after several years. Triple chronotherapy on an outpatient basis was planned for two more patients with treatment-resistant RCBD. It could not be implemented, but these patients responded to BLT, wake and dark therapy: (1) A 72-year-old man was able to undertake partial sleep deprivation for depression and dark therapy for hypomania at home with the help of his wife. He has achieved almost complete remission for the last 4 years with chronotherapy combined with medication, even though he had responded poorly to medications and ECT earlier; and (2) A 52-year-old woman with ultra-rapid RCBD could not undertake sleep deprivation at home. She has been undergoing morning bright light treatment for depression. Her response has been better since this treatment was added to her mood-stabilizer regimen. She has achieved almost complete remission after a long time. The treatment histories (Supplementary Material) of these patients illustrate the benefits and challenges of administering chronotherapy in RCBD[144]. Although wake therapy, BLT, triple chronotherapy, dark therapy, and blue-light-blocking glasses were successful, conducting these treatments at home was difficult because patients are unwilling to undertake sleep deprivation. Additionally, light boxes are expensive and few patients can afford them.

Adjunctive psychotherapy in RCBD

The existing literature on the treatment of BD indicates that the concomitant use of pharmacotherapy and psychotherapy significantly improves several patient outcomes[145-149]. The most effective forms of psychotherapy are psychoeducational treatments, CBT, and family-focused treatments. These are useful in decreasing symptom severity, reducing the duration of manic and depressive episodes, preventing recurrences, reducing residual depressive symptoms, and decreasing the number and duration of hospitalizations. Additionally, they improve medication adherence, illness management skills, coping abilities, and functional outcomes.

Despite the extensive evidence on the positive effects of adjunctive psychotherapy in BD, there are only a few reports of psychotherapy in RCBD. Table 3 shows these studies[51,58,150-153]. They provide some support for adjunctive psychoeducational treatments, CBT, family intervention, and supportive psychotherapy in RCBD. The outcomes obtained are similar to those shown by RCTs of adjunctive psychotherapy in BD.

The lack of studies on concomitant psychotherapies in RCBD is surprising because these treatments could yield better outcomes in RCBD. Moreover, this is contrary to the advice that psychoeducation, CBT, family interventions, and supportive psychotherapy should be used in RCBD because of the strong evidence base supporting the efficacy of adjunctive psychotherapy in BD[25,32,45,48,51].

Adjunctive psychotherapy in RCBD: patient example

One of our patients with treatment-resistant RCBD received adjunctive supportive therapy. A 42-year-old woman with ultra-rapid and ultradian cycling did not improve with medications and ECT. During the third period of hospitalization in 2015, she was started on regular sessions of structured psychotherapy. The strategies adopted included problem-solving to deal with day-to-day stresses and mood swings and supportive–expressive sessions to deal with more enduring problems such as interpersonal conflicts, and regrets about not working or marrying. She had her best period of mood stabilization for several months while she underwent psychotherapy. Unfortunately, she dropped out of the sessions and was following up irregularly till recently. Nevertheless, she remained free from any severe mood episodes with medications. She has had a recent relapse when medication doses were reduced to minimize side effects but improved with crisis intervention sessions. She has resumed supportive psychotherapy. Her treatment history (Supplementary Material) shows the usefulness of psychotherapy even in those who have not responded adequately to medications or ECT.

DISCUSSION

Treating RCBD remains a challenge for clinicians. Difficulties arise from its high prevalence, severity, poor outcomes, and high disability. The response to pharmacotherapy is often not adequate or complete. Therefore, nonpharmacological treatments are necessary for effectively managing RCBD[18,36,46-48]. However, research on adjunctive nonpharmacological treatments is still scarce[17,18,46,54]. This review shows that there has been limited progress in this area in the last 15 years[45]. A principal reason for the lack of data is the difficulty in conducting methodologically sound treatment trials in RCBD[18,44]. The treatment-resistant nature of RCBD creates further hurdles. Consequently, most RCTs of nonpharmacological treatments for BD usually exclude patients with RCBD.

Nevertheless, there are some promising developments. Not surprisingly, there have been more studies and reports since the 2007 review. Similar to the previous review, the current one also found that most of the evidence favours concomitant ECT as an acute and maintenance treatment in RCBD. Adjunctive acute ECT is effective for severe mood episodes in RCBD that are refractory to medication and have high risk of harm. Adjunctive maintenance ECT may prevent further rapid cycling, especially in those who respond favourably to acute ECT. There is an increasing interest in chronotherapy for BD, but the evidence concerning RCBD is still limited. However, unlike the earlier review, there appears to be preliminary evidence that wake therapy, BLT, dark therapy, and triple chronotherapy can provide better outcomes when combined with medication. Widespread use of these treatments has been hampered by a lack of funding for researchers and lack of awareness and expertise among clinicians[85,154]. Several other factors also hinder the use of chronotherapy, including the cost of equipment such as light boxes, the difficulty of conducting these treatments in outpatient settings or homes, and the problems in ensuring adherence to the treatment protocols[144,155-157]. Lastly, the scarcity of research on adjunctive psychotherapy in RCBD was particularly disappointing. Although psychotherapy appear to be commonly used in clinical settings, the lack of controlled evidence possibly reflects the difficulty in

Table 3 Studies of adjunctive psychotherapy in rapid-cycling bipolar disorder

Ref.	Type of study	Sample	Intervention	Results
Levy and Remick[51], 1986	Observational study	8 women with RCBD	Supportive psychotherapy with patients and family regarding treatment response and adherence	Complete remission in 5 patients and partial remission in 3 patients for 7–40 mo with combined psychotherapy and medications
Spurkland and Vandvik [150], 1989	Case report	13-yr-old girl with RCBD	Family therapy to reduce conflicts and improve adherence	Family therapy combined with medications led to lasting remission
Benjamin and Zohar[58], 1992	Case report	45-yr-old man with treatment-resistant RCBD	Supportive psychotherapy	Psychotherapy provided relief from the rapid-cycling pattern for 3 mo
Satterfield [151], 1999	Case report	33-yr-old man with medication-resistant RCBD	Pharmacotherapy and concomitant CBT	Significant reductions in the severity of manic, depressive, and anxiety symptoms with adjunctive CBT
Reilly-Harrington *et al*[152], 2007	Uncontrolled trial	10 patients with RCBD	CBT included psychoeducation, cognitive restructuring, and teaching illness-management skills	CBT over 5 mo led to significant improvements in depressive symptoms for 2 mo after the treatment in 6 patients who completed the trial
Lenz *et al* [153], 2016	Controlled trial	16 patients with RCBD; 14 wk of adjunctive psychotherapy and 12-mo follow-up	CPT *vs* BT. CPT included psychoeducation and CBT; BT consisted of reading and discussing a book on bipolar disorder	Significant effects of both treatments - reductions in illness severity, reductions in the number of all episodes with CPT and depressive episodes with BT, reductions in the number and duration of hospitalizations, reductions in disability, and improvement in medication adherence and illness concepts. CPT was better than BT

BT: Bibliotherapy; CBT: Cognitive behavioural therapy; CPT: Cognitive psychoeducational therapy; RCBD: Rapid-cycling bipolar disorder.

conducting psychotherapy trials for RCBD. Nevertheless, there is reason to believe that psychotherapy may be effective in RCBD because it can augment the response to medication, reduce acute and residual depression, improve functioning, promote recovery, and decrease family burden[45,48,51,158]. Studies show that childhood maltreatment, stressful life events, and disturbed family environments are more common in RCBD[2,9,25,48,50]. Adjunctive psychotherapy that addresses these factors and reduces psychosocial stress may be helpful in RCBD[45]. Medication nonadherence is a significant problem in BD. It is associated with adverse clinical and psychosocial outcomes among patients and their families. Although some studies show greater nonadherence in RCBD, the majority do not[159]. Nonadherence may be more common in those with more frequent episodes, higher disability, and in those with comorbid substance use disorders[10,40,160,161]. Rapid cycling with these features may contribute to nonadherence and inadequate adherence may worsen cycling[51]. Psychoeducational treatments help improve adherence and attitudes towards medication for BD [145,149]. Similarly, adjunctive psychosocial treatment can positively impact treatment adherence in RCBD by improving treatment attitudes, managing comorbid disorders, and minimizing disability[51,153]. Thus, despite the limited evidence many authors have recommended that adjunctive psychotherapy should form an essential part of the overall management of RCBD[26,32,45,49,158].

CONCLUSION

RCBD is a common phase in the course of BD characterized by greater severity, a predominance of depression, higher levels of disability, and poorer overall outcomes. It is resistant to treatment by conventional pharmacotherapy. The ineffectiveness of conventional pharmacological treatment for RCBD suggests that adjunctive nonpharmacological interventions could be useful but these have not been examined adequately.

According to this review, most of the evidence favoured concomitant ECT as an acute and maintenance treatment for medication-resistant RCBD. Although ECT is effective in refractory mania as a part of RCBD, a better response is obtained in depression with psychotic or catatonic symptoms. ECT is safe and the risk of inducing rapid cycling is low.

Among chronotherapeutic techniques, sleep deprivation or wake therapy has been the option most frequently investigated. Sleep deprivation is effective in relieving depressive symptoms but there is a high rate of relapse and the risk of inducing manic switches. Triple chronotherapy, which combines partial sleep deprivation, bright light treatment, and phase advance of the sleep cycle produces enduring effects and lowers the risk of manic switches. Although there are no studies of triple chronotherapy, examples of patients included in this review suggest that it can be successful in medication-resistant patients. Similarly, there are no studies of dark therapy or blue-light-blocking glasses, but these techniques have been successfully used to treat hypomania in individual patients. Case reports and studies also suggest that bright light treatment can be effective for patients with depression as a part of RCBD.

A few studies provide some support for adjunctive psychoeducational treatments, CBT, family intervention, and supportive therapy in medication-resistant RCBD. The overall quality of evidence for the usefulness of adjunctive nonpharmacological treatment in RCBD was poor and suffered from several methodological shortcomings.

It is apparent from this review that there are large gaps in the existing literature on the usefulness of adjunctive nonpharmacological treatments in RCBD. Therefore, examining the role of these treatments remains a priority for research. However, the current evidence regarding effective pharmacological and nonpharmacological treatment is inconclusive. Thus, clinicians may find treating RCBD a formidable task in the absence of specific guidelines. One option could be to select nonpharmacological treatments effective in BD[27,30,45,49]. Alternatively, treatment decisions can rely on the current evidence on nonpharmacological treatments in RCBD[18]. Clinicians can use this evidence to undertake the sequential or concurrent use of several pharmacological and nonpharmacological interventions[26,45]. Although this remains an exploratory exercise, such combinations are likely to succeed if individualized to meet the needs of patients with RCBD and their families. Table 4 includes principles derived from the existing recommendations that could guide clinicians in managing RCBD. As always, the key to successful treatment of RCBD requires patience, perseverance, and a strong collaborative relationship with patients and their families.

Table 4 Suggestions for the use of adjunctive nonpharmacological treatments in rapid-cycling bipolar disorder

	Suggestions
Goals of acute treatment[18,45]	The priority for acute treatment is to ensure that patients respond to treatment and no longer meet criteria for an acute mood episode
	A rapid response is necessary to provide relief for patients and their families and reduce the risks of self-harm, aggression, and physical complications
	The concurrent and early use of treatments such as ECT or wake therapy for depression, and dark therapy for mania may be considered if there is inadequate response to pharmacotherapy
	Treatments that are likely to be useful during long-term treatment should guide the use of treatments in the acute phases
Goals for long-term treatment[29,30,45,51,55]	Rather than focusing on acute treatment, the primary objective should be to prevent further episodes of rapid cycling
	The model for a chronic medical disorder with acute exacerbations should guide the long-term treatment plan for RCBD
	Adjunctive maintenance ECT, wake therapy, bright light treatment, dark therapy, and triple chronotherapy can be considered at this stage
	Education, support, and the involvement of the family is useful for all patients. Psychoeducational treatments, CBT, family treatment can be implemented if required
Improved functioning rather than complete remission should be the goal of long-term treatment[18,20,25,30]	Full remission and complete absence of recurrences is an unrealistic goal
	Clinicians should focus on an enduring response that consists of reduced frequency, intensity, and duration of mood episodes
	Clinicians should attempt to restore optimal functioning in the occupational, family, and social spheres
Basic tasks[2,4,54,55,162]	Careful diagnosis and comprehensive assessment of the patient including psychosocial factors
	Avoidance of precipitants such as stress, irregular sleep routines, and antidepressant medications when it worsens the course of RCBD
	Treatment of physical and psychiatric comorbidities especially hypothyroidism and substance use
Longitudinal approach and use of life charts [2,26,45,55,163]	Acute episodes should be viewed in the context of the long-term course of bipolar disorder/RCBD
	Life charts may be used to delineate the course of illness, possible precipitants, and treatment response. They might help patients and families understand the course of RCBD and the longitudinal approach to treatment
Use of treatments effective in bipolar disorder[27,30,45,49]	Options for adjunctive nonpharmacological treatment should be chosen based on the evidence for their efficacy in BD
Sequential trials of treatment for long durations[25-27,30,51]	Treatment of RCBD requires several trials of each treatment regimen lasting for about 3–4 mo before the acute-phase efficacy of the treatment regimen can be determined
	Frequent changes in treatment should be avoided since they might worsen rapid cycling
Combining pharmacological and nonpharmacological treatments[25,30,32,45,163]	One option is to add nonpharmacological treatments only in refractory patients in whom several medications have been tried and have failed
	An alternative option recommends the early use of adjunctive nonpharmacological patients even in those patients who are not medication resistant
Monitoring treatment response[17,18,25,35,	More intensive monitoring during acute phases which can be relaxed once the patient becomes more stable

51]	Mood charts can be used to assess response to treatment At least 12 mo of treatment is required to determine the efficacy of long-term treatment
Working with patients and families[4,32,45,51,127]	Education: explaining RCBD, its causes, and the treatment approach including lifestyle changes is necessary for ensuring the collaboration of patients and families. Psychoeducational treatments that reduce stress, improve attitudes to treatment, enhance treatment engagement, and reduce caregiver burden can be tried. CBT is another option Support: ongoing support for patients and families is essential. This can be provided by developing a strong collaborative relationship. Nonadherence can also be addressed by fostering a strong treatment alliance Patience: the protracted nature of the illness requires the clinician to accept that it will take a long time for the results to become apparent. Patience and perseverance on the part of patients and families has to be stressed repeatedly so that they learn to focus on long-term goals Sleep hygiene: regular sleep routines can be advised in all patients. Chronotherapeutic techniques can be tried when required and feasible

CBT: Cognitive behavioural therapy; ECT: Electroconvulsive therapy; RCBD: Rapid-cycling bipolar disorder.

Abstract

BACKGROUND

Alzheimer's disease (AD) is the most common neurodegenerative disorder, and there are currently no effective drugs to delay progression of the disease. Ferroptosis may play a vital part in AD, and is therefore receiving increasing attention by researchers.

AIM

To investigate the effects of dexmedetomidine (Dex) on ferroptosis in AD mouse hippocampus.

METHODS

Hippocampal neurons (HNs) HT22 were induced by amyloid β-protein (Aβ) and both *in vitro* and *in vivo* AD mouse models were prepared *via* injections. The cell-counting kit-8 assay and immunofluorescence technique were adopted to determine cell proliferation activity and intracellular Fe^{2+} levels, and the TBA method and microplate method were employed for malondialdehyde and glutathione measurements, respectively. Hippocampal tissue damage was determined using hematoxylin and eosin and Nissl staining. Mouse learning and memory ability in each group was assessed by the Morris water maze test, and the expression levels of mammalian target of rapamycin (mTOR) signal molecules and ferroptosis-related proteins transferrin receptor 1 (TFR1), SLC7A11 and glutathione peroxidase 4 were examined by western blotting.

RESULTS

Dex enhanced lipid peroxidation and iron influx in mouse HNs in both *in vitro* and *in vivo* experiments, while inhibition of the mTOR axis blocked this process. These findings demonstrate that Dex can inhibit ferroptosis-induced damage in mouse HNs by activating mTOR-TFR1 signaling to regulate ferroptosis-associated

proteins, thus alleviating cognitive dysfunction in AD mice.

CONCLUSION
Dex can activate the mTOR-TFR1 axis to inhibit ferroptosis in mouse HNs, thereby improving the learning and memory ability of mice.

Key Words: Dexmedetomidine; Ferroptosis; Alzheimer's disease; Mammalian target of rapamycin; Mice

Core Tip: Iron death of nerve cells caused by iron overload is an important factor in various neurodegenerative diseases, including Alzheimer's disease (AD). The classic mammalian target of rapamycin (mTOR) signaling pathway regulates the metabolism of iron ions by regulating transferrin receptor 1 (TFR1), thereby maintaining the intracellular iron balance. It has been shown that dexmedetomidine (Dex) inhibits the release of inflammatory factors and plays a neuroprotective role, thereby improving cognitive dysfunction in elderly rats. The Dex effectively improved hippocampal neuronal loss, cognitive dysfunction, learning and memory abilities in AD mice by regulating the mTOR-TFR1 signaling pathway to reduce iron death.

INTRODUCTION

With the current escalation in global aging, neurodegenerative disorders (NDDs), including Alzheimer's disease (AD), Parkinson's disease, and Huntington's disease, have attracted growing attention from researchers and have become a research hotspot[1]. Ferroptosis is a non-apoptotic programmed cell death associated with cytotoxicity caused by iron-dependent lipid peroxide accumulation, and iron overload is the key to triggering the occurrence of cell ferroptosis[2]. It is reported that iron deposition in brain tissue increases significantly with age, ultimately affecting nerve cell function[3-5]. Immunohistochemical tests confirmed that neuronal ferroptosis caused by iron overload in the cerebellum, cortex and hippocampus was an important factor leading to NDDs. The mammalian target of rapamycin (mTOR) is a classical autophagy-dependent regulatory protein that affects cell death pathways such as autophagy, apoptosis, and ferroptosis [6]. The classic mTOR axis influences iron ion metabolism by modulating transferrin receptor 1 (TFR1), thus maintaining the intracellular iron balance[7]. In addition, the high intracellular Fe^{2+} level leads to the inhibition of mTOR expression, resulting in intracellular iron homeostasis imbalance and consequently oxidative stress (OS)-induced ferroptosis[8]. Dexmedetomidine (Dex) is a highly selective α2 adrenergic receptor agonist that not only exerts analgesic and sedative effects by inhibiting sympathetic nerve activity, but is also neuroprotective against various brain injuries[9,10]. However, its underlying mechanism is unknown. Several studies have found that, by regulating ferroptosis, Dex can play a protective role in liver injury, myocarditis, cerebral ischemia-reperfusion, and craniocerebral injury[11-13]. In addition, Dex was shown to significantly improve neurocognitive function and effectively inhibit the abnormally high level of OS in NDDs and brain trauma, thus reducing inflammation[14]. Yet, it remains to be confirmed whether and how Dex can be neuroprotective by regulating ferroptosis in AD, a NDD. The experimental results of this study show that Dex can inhibit iron overload by activating the mTOR-TFR1 axis, thus maintaining iron homeostasis, protecting hippocampal neurons (HNs) from ferroptosis, and playing a neuroprotective role in AD mice, which can provide insights into ferroptosis-induced neuronal death.

MATERIALS AND METHODS

Experimental animals

Forty adult male specific pathogen free C57BL/6 mice, aged 8-10 wk and weighing (23 ± 2) g, were raised under constant temperature (25 ± 1 °C), humidity (60% ± 5%), and an alternating light/dark (12/12 h) cycle. The experiments were carried out after 7 d of adaptive feeding with rat chow and water available *ad libitum*. All animal experiments were carried out after obtaining approval from the Experimental Animal Ethics Committee of Peking University International Hospital.

Experimental reagents

Mouse HT22 HNs and dedicated cell culture medium (Procell Life Science & Technology, Wuhan, China); Dex (Chia Tai

Tianqing Pharmaceutical Group, Nanjing, China); BCA analysis kit (Boster, China); cell-counting kit-8 (CCK-8; Dojindo, Japan); Perls stain (Thermo Fisher Scientific; United States); Nissl stain (Jiangsu KeyGEN Biotech, Nanjing, China); polyvinylidene fluoride (PVDF) membrane (Millipore, United States); malondialdehyde (MDA) Colorimetric Assay Kit (Abcam, United States); Mito-FerroOrange (Dojindo Molecular Technologies, Tokyo, Japan); 2′,7′-dichlorodihydrofluorescein diacetate (DCFH-DA) fluorescence probe (Solarbio, Beijing); Lipofectamine 2000 (Invitrogen, United States); siRNA mTOR (Shanghai Sangon Biotech, China); specific primary antibodies (Abs) and HRP labeled anti-p-mTOR, TFR1, SLC7A11 and glutathione peroxidase 4 (GPX4), as well as the internal reference GAPDH secondary Ab (Abcam, United States) were used in this study.

Experimental instruments

The Morris water maze (MWM) system (Noldus, Netherlands); inverted fluorescence biomicroscope (Zeiss, Germany); E0970 Microtome Cryostat (Beyotime Biotech, Beijing, China); enhanced chemiluminescence (ECL) detection system (Bio-Rad, Hercules, CA, United States); Multiskan FC microplate reader (Thermo Scientific, United States); western blot Electrophoresis Instrument and Trans-Blot instrument (Bio-Rad, United States) were used in this study.

Animal grouping and model building

Forty C57BL/6 mice were randomized to the sham, amyloid β-protein (Aβ), Dex, and Dex + rapamycin (RAPA) groups, with 10 mice in each group. After anesthesia by intraperitoneal injection of 10% chloral hydrate (dosage: 0.1 mL/10 g body weight) in all C57BL/6 mice, 5 μL of condensed Aβ (80 pmol/μL) was injected as a single bolus into mouse bilateral ventricles using a micro-sampler, and the needle was left in place for 2 min before bandaging. The sham group was injected with an equal amount of normal saline into the bilateral ventricles. The Dex group was intraperitoneally injected with Dex (dosage: 20 μg/kg) dissolved in 0.9% sterile saline, once a day for 4 consecutive weeks; on this basis, the Dex + RAPA group was additionally injected with 2 mg/kg of RAPA dissolved in 2% dimethylsulfoxide. The sham and Aβ groups were given the same amount of 0.9% sodium chloride solution, and the remaining treatment was the same as above.

MWM test

After the above treatment, the mice underwent the MWM test for 5 d. During the training phase (the first 4 d), the mice were trained once a day at a fixed time, and the time they took to find the platform within 120 s (*i.e.*, escape latency) and the swimming trajectory map were recorded. On the fifth day, the platform was removed for spatial exploration experiments, and the running trajectory, escape latency, number of platform crossings, and target quadrant residence time were recorded.

Animal tissues

The mice were anesthetized with chloral hydrate after the MWM test. The right auricle was then cut open and the left ventricle was perfused with 4% paraformaldehyde solution. After sacrifice on ice by cervical dislocation, the mouse hippocampus tissues on both sides were quickly removed, some of which was stored in liquid nitrogen for later use. The remaining portion was fixed in 4% paraformaldehyde, and after gradient dehydration with ethanol, it was embedded in paraffin and sliced into sections (4 μm). The pathological changes of HNs were observed under a light microscope after conventional hematoxylin-eosin (HE) staining.

Nissl staining

Part of the hippocampus tissue was frozen in liquid nitrogen to prepare frozen sections (5 μm), which were degreased with a gradient concentration of ethanol solution and then washed three times with ddH_2O for 30 s each time. Cresyl violet (Nissl) dye solution (0.1%) was added dropwise and left at 56 °C for 1 h. After dyeing, the slices were washed with ddH_2O for a further three times. Next, color separation was carried out for 2 min with acid alcohol differentiation solution (0.5%), followed by immersion in 100% ethanol for 30 s and xylene permeation for 1 min. After mounting with neutral gum, each slice was observed microscopically (400 ×) with five visual fields randomly selected, and the number of nerve cells was recorded (n = 5).

Prussian blue staining

Paraffin slices were routinely dewaxed and rinsed with distilled water for 1 min. Perls staining solution, which was homogeneously formulated by mixing reagent A1 with reagent A2 in equal amounts, was used immediately after preparation. The sections were washed again with distilled water after 30 min of Perls staining. They were then nucleated with the nuclear fast red stain kit (reagent B) for 10 min and rinsed with distilled water, followed by conventional dehydration, vitrification, neutral-gum mounting, and air drying. The Prussian blue deposition in hippocampal tissue was observed under a light microscope. Five visual fields in each slice were randomly photographed, and the percentage of Prussian blue staining (PBS) positive area in the whole area was measured by image analysis.

Cell cultivation and treatment

Mouse HT22 HNs were immersed in HT22 dedicated culture medium and cultivated in a 37 °C, 5% CO_2 and 95% humidified cell incubator, and the well-grown cells were selected for the following experiment. All neuron cell lines used were within 20 passages. Grouping: (1) Blank control group: HT22 cells was cultured with HT22-dedicated medium without any other treatment; (2) Aβ model group: HT22 cells were treated with Aβ at a final concentration of 20 μmol/L and cultured for 24 h; (3) Dex group: Following 2 h of treatment with Dex at a final concentration of 5 μmol/L, HT22 cells

were cultured with Aβ at a final concentration of 20 μmol/L for 24 h; and (4) Dex + mTOR siRNA (si-mTOR) group: After transfection with si-mTOR using Lipofectamine 2000, HT22 cells were treated with 5 μmol/L Dex for 2 h and then cultured with 20 μmol/L Aβ for 24 h.

CCK-8 assay

HT22 cells (1×10^5/mL) were seeded with 100 μL of cell suspension per well on a 96-well culture plate and cultured for 24 h. After different treatments, the CCK-8 reagent was added at 10 μL/well for 1 h at 37 °C, after which the absorbance value at 450 nm was measured by a microplate reader to assess cell viability.

Intracellular Fe^{2+} level detection

Intracellular Fe^{2+} levels were measured with Mito-FerroOrange. After different cell treatments, the supernatant was discarded. Following three rinses with HBSS, 2 mL of cells were added to every 2 μL of Mito-FerroOrange working solution and incubated at 37 °C for 30 min. The cells were observed by confocal fluorescence microscopy and the fluorescence intensity level was determined.

OS determination

Cell lipid peroxidation (LPO) was detected by BODIPY-C11 labeled fluorescent staining. 5 μM BODIPY-C11 was added to the cells and incubated in the dark for 20-30 min. After staining, the cells were collected by centrifugation and the LPO level was calculated by measuring the fluorescence intensity. In addition, HT22 cells were stained with 10 μM DCFH-DA fluorescent dye for 30 min, and were then collected for fluorescence intensity measurement, which reflected the reactive oxygen species (ROS) level. According to the manufacturer's instructions, the level of MDA, the final product of LPO, was determined using the MDA colorimetric assay kit. The absorbance of reactants was calculated and determined according to the standard curve to evaluate the MDA concentration.

Western blot

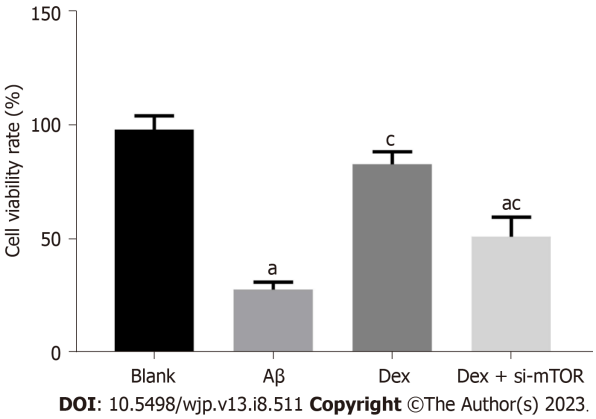
Following the standard protocol, HT22 cells in each group were lysed in RIPA buffer to extract the protein supernatant. In addition, the protein supernatants were isolated from the hippocampus following cryopreservation with liquid nitrogen and homogenized. The protein concentration was then quantitatively detected with a BCA assay kit. Following dilution and boiling, the protein samples were separated by 6%-10% polyacrylamide gel electrophoresis, after which semi-dry electroblotting was performed to transfer the protein bands to a PVDF membrane. The membrane was blocked in 5% defatted milk for 1 h, incubated with specific primary Abs at 4 °C overnight, washed with TBST twice, and incubated with HRP-labeled anti-p-mTOR, TFR1, SLC7A11 and GPX4 as well as the GAPDH specific secondary Ab (internal reference) for 1 h at ambient temperature. After dropwise addition of the ECL substrate to the protein bands, the grayscale values of the target protein bands were measured using the ECL detection system and the relative expression was calculated by the ratio of the grayscale values of the target protein to the reference protein.

Statistical analysis

Statistical processing and mapping of the data were performed using GraphPad Prism 7.0. Continuous variables that conformed to a normal distribution were described as the mean ± standard deviation (mean ± SD); statistical inter-group and multi-group differences, indicated by $P < 0.05$, were identified using the *t*-test and one-way variance analysis, respectively.

RESULTS

Dex blocks Aβ-induced cytotoxicity of mouse HNs by activating mTOR



In order to confirm whether Dex can alleviate the cytotoxicity of mouse HNs, we first measured the impact of Dex on the viability of Aβ-treated mouse HNs. As shown by the CCK-8 assay (Figure 1), Aβ-treated HNs showed notably weakened cell viability compared with HNs from blank control mice ($P < 0.05$), while Dex treatment significantly restored the viability of Aβ-treated HNs ($P < 0.05$); in addition, the viability of Dex + si-mTOR treated cells was significantly lower than that of Dex-treated cells ($P < 0.05$). These findings suggest that Dex can alleviate the cytotoxicity of Aβ-treated mouse HNs, while inhibiting mTOR can block the effect of Dex treatment on cytotoxicity.

Dex inhibits the increase of Fe^{2+} level in Aβ-treated mouse HNs by activating mTOR

To further examine whether ferroptosis was responsible for Aβ-induced inhibition of cell proliferation, we first measured the impact of Dex on Fe^{2+} levels in Aβ-treated mouse HNs. As shown in Figure 2, Aβ-treated mouse HNs showed markedly elevated Fe^{2+} levels ($P < 0.05$), which were significantly reduced by Dex treatment ($P < 0.05$); moreover, Dex and si-mTOR co-treatment led to statistically higher Fe^{2+} levels in Aβ-treated HNs compared with Dex treatment alone ($P < 0.05$). These results show that Dex can inhibit the Aβ-induced increase of Fe^{2+} level in mouse HNs, and this inhibition is achieved by activating mTOR.

Dex reduces Aβ-induced OS in mouse HNs by activating mTOR

The increase of intracellular OS level in mouse HNs is also an important feature of ferroptosis. Significantly elevated ROS, LPO and MDA levels were observed in Aβ-treated mouse HNs ($P < 0.05$), which were reduced after Dex treatment ($P <$

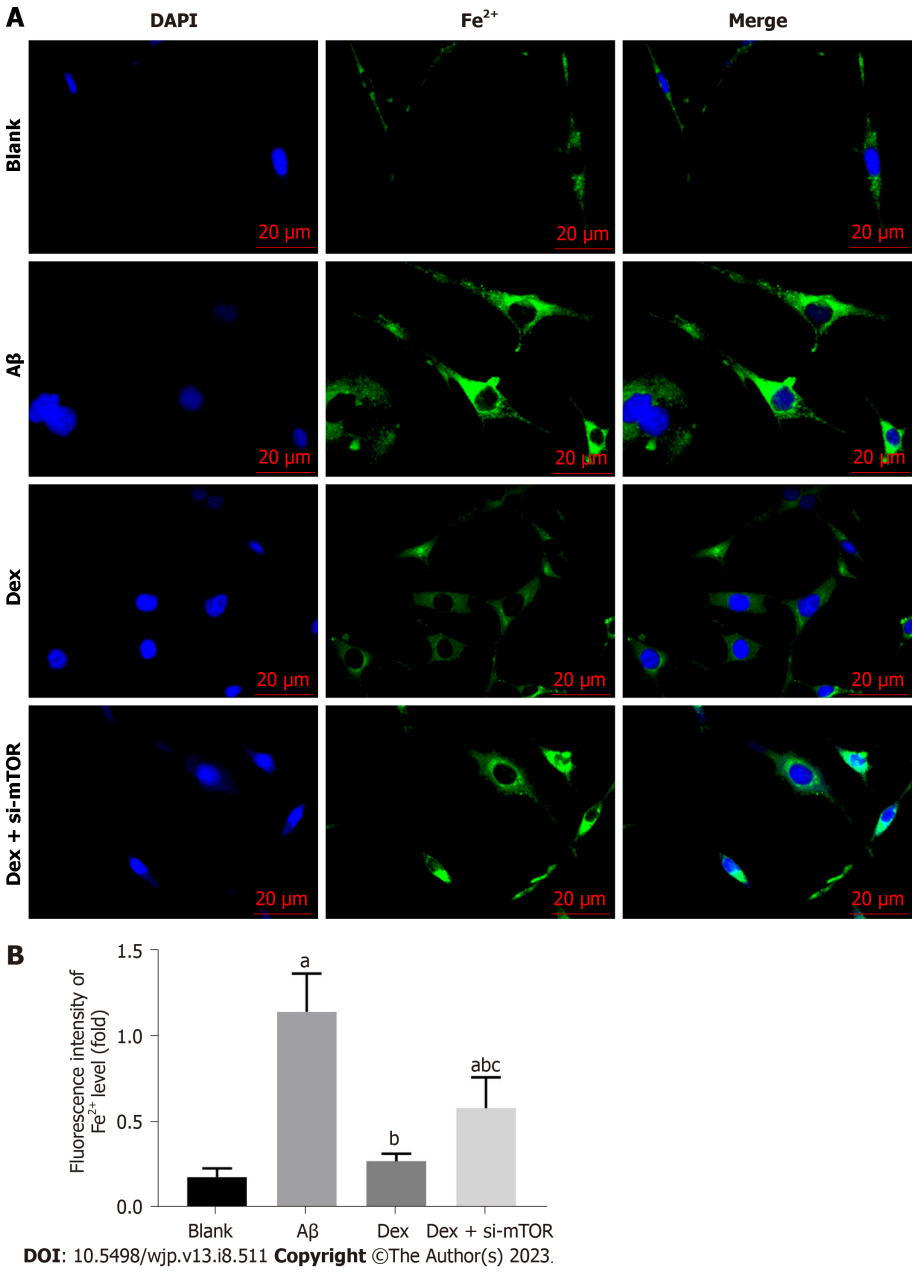
Figure 1 Comparison of the activity levels of hippocampal neurons in mice in the different treatment groups. $^{a}P < 0.05$, compared with the blank group; $^{c}P < 0.05$, compared with the dexmedetomidine group. Aβ: Amyloid β; Dex: Dexmedetomidine; si-mTOR: Mammalian target of rapamycin siRNA.

0.05); in addition, Dex and si-mTOR co-treated cells showed higher ROS, LPO and MDA levels than those treated with Dex alone ($P < 0.05$), as shown in Figure 3. These results suggest that Dex treatment can alleviate the increase in intracellular OS level induced by Aβ in mouse HNs, and inhibiting mTOR can block this process.

Dex blocks Aβ-induced ferroptosis in mouse HNs through regulation of the mTOR-TFR1 axis

In order to confirm whether the antioxidant protection and iron metabolism effects of Dex are related to ferroptosis in mouse HNs, we performed western blot to determine the expression levels of the mTOR signal molecular protein p-mTOR and ferroptosis-associated marker proteins TFR1, SLC7A11, and GPX4 in Aβ-treated mouse HNs. The results showed a marked reduction in p-mTOR, SLC7A11, and GPX4 protein expression in mouse HNs induced by Aβ, and an obvious increase in TFR1 protein expression ($P < 0.05$). Compared with the Aβ group, Dex-treated cells showed enhanced p-mTOR, SLC7A11 and GPX4 levels, and decreased TFR1 ($P < 0.05$). Simultaneous treatment with Dex and si-mTOR further reduced p-mTOR, SLC7A11 and GPX4 protein levels, and promoted TFR1 protein expression, and these changes were statistically significant ($P < 0.05$), as shown in Figure 4. Therefore, Dex can significantly activate mTOR signaling and reduce Aβ-induced ferroptosis in mouse HNs by modulating the mTOR-TFR1 axis.

Dex alleviates hippocampal tissue damage in AD mice by activating mTOR



According to HE staining results, the HNs in Sham mice were evenly distributed, with abundant cytoplasm, clear nuclei, and normal and intact cell morphology and structure; in the Aβ group, the HNs were sparsely arranged and disordered, with less cytoplasm, unclear cell morphology and atrophy; the HNs in the Dex group showed less neuronal atrophy, with uniform cell distribution, regular arrangement, and deep cytoplasmic staining; while HNs in the Dex + RAPA (mTOR inhibitor) group showed more atrophy, more irregular arrangement and less clear cell morphology than the Dex group. Nissl staining results demonstrated that Nissl bodies in the hippocampus of the sham group were closely arranged and in large numbers; a notably reduced number of Nissl bodies was observed in the hippocampus of the Aβ model group; following Dex treatment, the number of Nissl bodies in the hippocampus of the Aβ model mice increased significantly; while the Nissl body count in the hippocampus of the Dex + RAPA group decreased markedly compared with the Dex group (Figure 5). These findings indicate that Dex can mitigate Aβ-induced hippocampal tissue damage and increase the number of HNs in AD mice, and this process is realized through activation of mTOR signaling.

Dex mitigates OS and Fe^{2+} levels in AD mouse hippocampus by activating mTOR

To confirm whether the antioxidant protection of Dex is related to its regulation of iron metabolism, we further evaluated the influence of Dex treatment on OS and Fe^{2+} level in the mouse hippocampus. MDA in the hippocampus of AD model mice induced by Aβ was significantly increased compared with Sham mice, while glutathione (GSH) was markedly reduced ($P < 0.05$). The Dex group showed reduced MDA and elevated GSH compared with the Aβ group ($P < 0.05$); moreover, co-treatment with Dex and RAPA in AD mice showed enhanced MDA and decreased GSH in the hippocampus compared with Dex-treated AD mice ($P < 0.05$). In addition, based on PBS results, the level of Fe^{2+} in hippocampal tissue of Aβ-treated AD model mice was significantly increased ($P < 0.05$), and was markedly reduced after Dex treatment ($P < 0.05$); moreover, the Dex + RAPA group showed higher Fe^{2+} in hippocampal tissue than that in the Dex group ($P < 0.05$) (Figure 6). Thus, Dex can markedly alleviate iron deposition and OS in Aβ-treated AD mouse hippocampus by activating mTOR.

Dex reduces cognitive dysfunction in AD mice by activating mTOR

The MWM test was used to evaluate the learning and memory ability of mice in each group. AD mice in the Aβ group showed markedly prolonged escape latency, and a statistically significant reduced number of platform crossings and target quadrant residence time ($P < 0.05$). The escape latency, number of platform crossings and target quadrant residence time of AD mice in the Dex group and Dex + RAPA group were significantly improved compared with the Aβ group ($P < 0.05$), with improvement in cognitive dysfunction in the Dex group as compared with the Dex + RAPA group ($P < 0.05$),

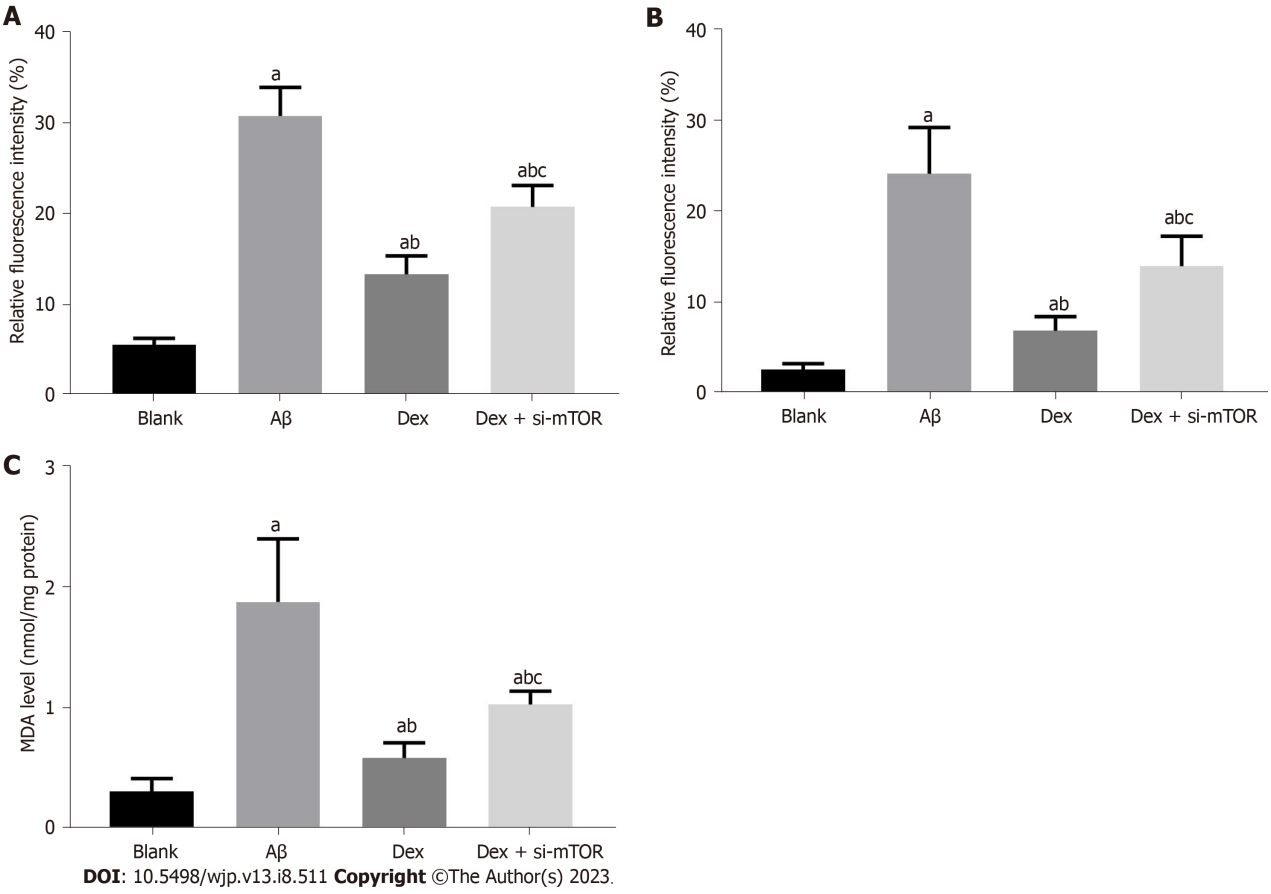
as shown in Table 1. These results suggest that Dex treatment improves the learning and memory ability of Aβ-treated AD mice, while RAPA exerts negative effects on this improvement.

Dex reduces ferroptosis in AD mice by modulating mTOR-TFR1

From the western blot analysis (Figure 7), it was found that the Aβ group had markedly reduced mTOR, SLC7A11 and GPX4 protein levels and elevated TFR1 protein expression in the hippocampus compared with the sham group ($P < 0.05$); Dex treatment enhanced mTOR, SLC7A11 and GPX4 protein expression in AD mice, and decreased TFR1 protein expression ($P < 0.05$); furthermore, the injection of RAPA effectively blocked the regulation of Dex on the expression of mTOR signaling molecules and ferroptosis markers TFR1, SLC7A11 and GPX4 in AD mouse hippocampus ($P < 0.05$). Therefore, Dex can mitigate ferroptosis in AD mouse hippocampus by activating the mTOR-TFR1 axis.



DISCUSSION

AD is the most common progressive NDD, and is mainly caused by synaptic loss of neurons in the cerebral cortex and

hippocampus, and the death of brain neurons[15]. In recent years, ferroptosis has been found[16-18] to be the underlying mechanism of neuron loss in many NDDs, and the "ferroptosis hypothesis" has been proposed for AD. GPX4 mRNA and protein levels are reported to be aberrantly down-regulated in the brains of patients and mice with AD[19,20]. GPX4 relies on reduced GSH to catalyze LPO reduction, which is considered the key regulator of ferroptosis, while the inhibition of GPX4 can lead to LPO accumulation, a hallmark feature of ferroptosis that is considered an early event in the pathological process of AD[21]. During the process of iron imbalance, free Fe^{2+} released by ferritin degradation reacts with lipids through the Fenton reaction, and eventually forms lipid peroxy radicals and hydroperoxides, leading to LPO accumulation, the prime reason for ferroptosis[22]. The present study demonstrated that there were significant iron deposits and increased ROS and lipid oxidation levels in Aβ-treated mouse HNs and AD mouse hippocampus tissues, and Aβ treatment promoted the expression of iron transfer-related protein TFR1 and decreased the expression levels of ferroptosis regulation associated proteins GPX4 and SLC7A11. Furthermore, *in vitro* and *in vitro* studies demonstrated the

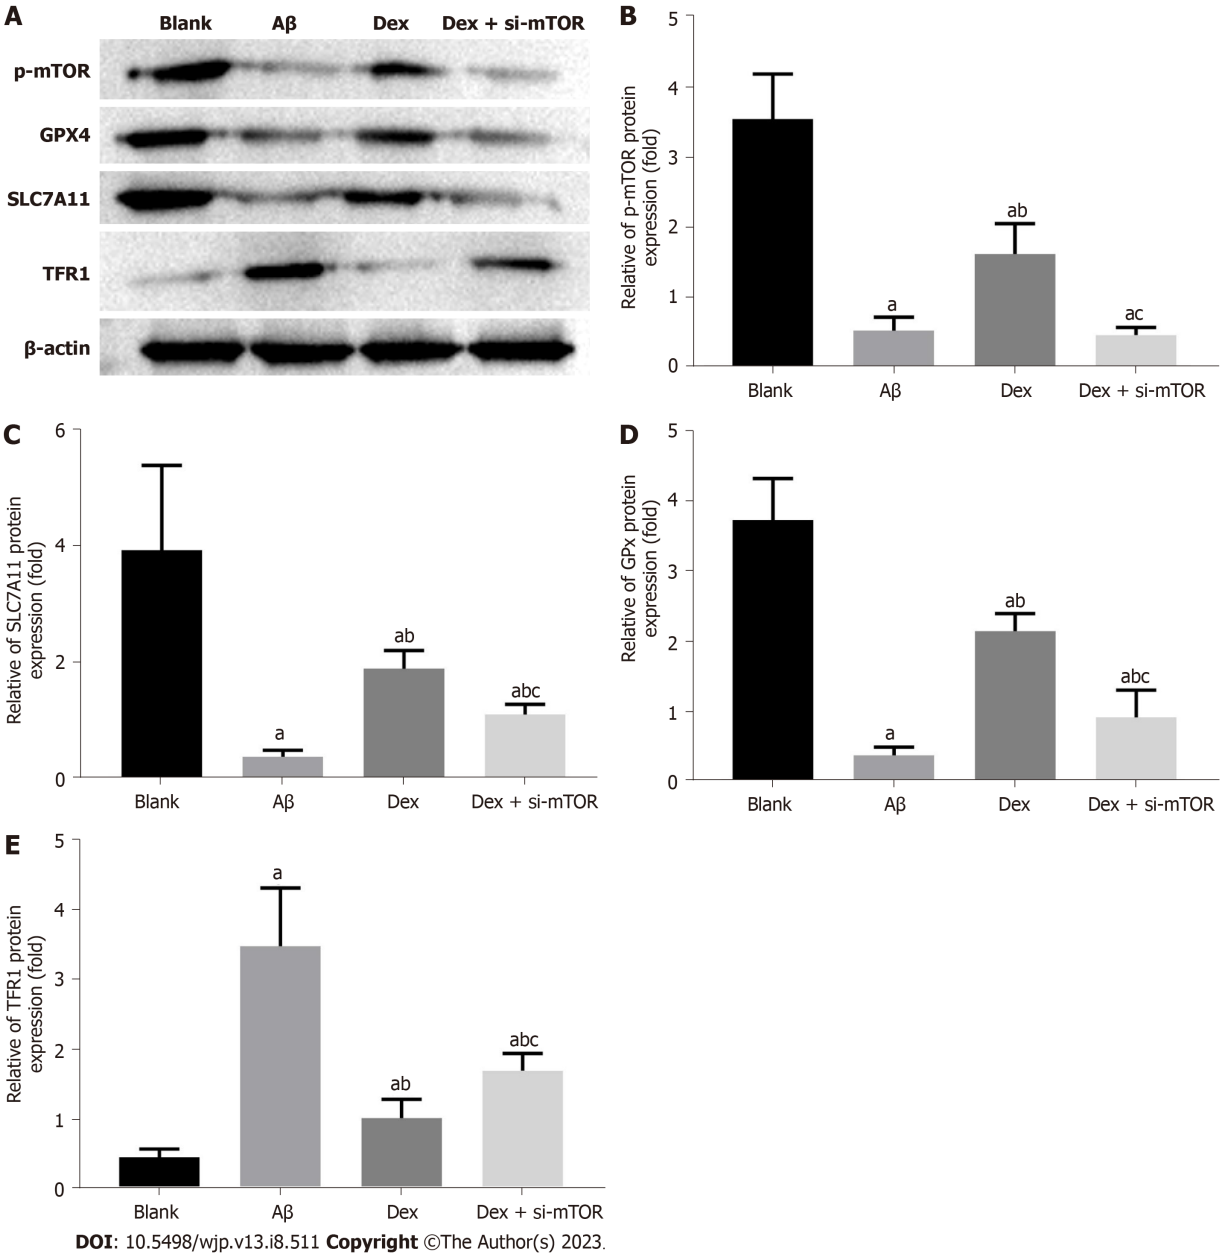

Figure 4 Comparison of iron death-related protein levels in hippocampal neurons of mice in the different treatment groups. occurrence of ferroptosis during AD. Thus, the above research suggests the important role of ferroptosis in AD.

Moreover, in the *in vivo* and *in vitro* experiments, it was found that Dex effectively reduced ferroptosis in HNs of AD mice. Previous studies have confirmed the neuroprotective effects of Dex, as it can inhibit the neuroinflammatory reaction and reduce OS, and has an anti-inflammatory and antioxidant role[23]. It has also been shown to prevent early cognitive dysfunction in senile mice after surgery[24]. Sun *et al*[25] also reported that Dex reduced Aβ1-induced HN apoptosis and OS responses in mice by modulation of the miR-129/YAP1/JAG1 axis, thus alleviating cognitive impairment and improving cognitive function in AD mice. In the present study, the number of Nissl bodies in the hippocampus of Aβ-treated AD mice decreased significantly compared with sham mice in the presence of neuronal atrophy, while intraperitoneal injection of Dex led to a marked elevation in Nissl body number in AD mouse hippocampus and an obvious reduction in neuronal atrophy. Moreover, the MWM test of mouse learning and memory ability in each group showed that the escape latency of AD mice in the Dex group was significantly shortened compared with the Aβ group, with a statistically significant higher number of platform crossings and target quadrant residence time, suggesting significantly reduced cognitive dysfunction in AD mice after Dex treatment. Considering the aforementioned inhibitory effect of Dex on ferroptosis of HNs in mice, it can be concluded that Dex can extend the survival of neurons by inhibiting HN ferroptosis, thus improving cognitive function in AD mice.

The mTOR axis has been reported to play a regulatory role in cell death and apoptosis in various diseases such as aging, NDDs, and brain injury[26]. Increasing attention has recently been paid to the mechanism of mTOR mediated ferroptosis. It has long been reported that mTOR plays a regulatory role in upstream targets of iron metabolism, and that the mTOR-TFR1 axis is essential in balancing iron homeostasis by regulating TFR1 expression[27]. Our experimental results revealed that inhibition of the mTOR pathway significantly promoted Fe^{2+}, OS and TFR1 levels in mouse HNs, and lowered GPX4 and SLC7A11 expression, indicating that the ability of Dex to protect HNs from Aβ-induced ferroptosis and mitigate cognitive dysfunction in AD mice is weakened following inhibition of mTOR expression. It is suggested that Dex can reduce ferroptosis of HNs and ease cognitive dysfunction in AD mice, possibly by activating the mTOR axis.

CONCLUSION

Both *in vitro* and *in vivo* experiments in this study confirmed that Dex can inhibit Aβ-induced ferroptosis of mouse HNs, and effectively reduce HN loss and cognitive dysfunction in AD mice. Furthermore, Dex improved learning and memory

in AD mice by modulating the mTOR-TFR1 axis to reduce ferroptosis.

ARTICLE HIGHLIGHTS

Research background

The main pathological feature of Alzheimer's disease (AD) is the formation of amyloid β-protein (Aβ) plaques in the brain, leading to loss of neuronal synapses, ultimately affecting the patient's learning and memory abilities. Research has shown that iron death caused by iron overload in nerve cells is an important factor leading to neurodegenerative diseases, and plays a crucial role in the progression of AD. Recently, reports have demonstrated the high selectivity of dexmedetomidine (Dex), an α adrenergic receptor agonist, that can exert neuroprotective effects by inhibiting the release of inflammatory factors, thereby improving cognitive dysfunction in elderly rats.

Research motivation

Currently, there are still no effective drugs to delay the progression of AD, and iron death which may play a crucial role in the progression of this disease is attracting increasing attention from researchers.

Research objectives

To investigate the effect of Dex on iron death in the hippocampus of AD mice by both *in vitro* and *in vivo* research.

Research methods

Construction and utilization of an AD model using Aβ. The mouse hippocampal neuronal cell line HT22 was induced, and the levels of cell proliferation activity and intracellular Fe^{2+} were measured by the cell-counting kit-8 assay and immunofluorescence. The contents of malondialdehyde and glutathione were measured by the TBA method and microplate method, respectively. In the AD mouse model Aβ was injected, and the pathological damage in the mouse hippocampus was detected by hematoxylin and eosin staining and Nissl staining. The Morris water maze was used to evaluate the learning and memory abilities of mice in each group, and protein immunoblotting was used to evaluate the expression levels of p-mammalian target of rapamycin (p-mTOR) and iron death-related proteins transferrin receptor 1 (TFR1), SLC7A11, and glutathione peroxidase 4.

Research results

Dex significantly improved lipid peroxidation and iron influx in mouse hippocampal neurons (HNs) both *in vivo* and *in vitro*, and inhibition of the mTOR signaling pathway blocked this process, demonstrating that Dex can inhibit the damage caused by iron death in mouse HNs by activating mTOR-TFR1 signaling regulation, thereby improving cognitive dysfunction in AD mice.

Research conclusions

Dex can significantly activate the mTOR-TFR1 signaling pathway and inhibit iron death in mouse HNs, thereby improving the learning and memory abilities of mice.

Research perspectives

From *in vitro* and *in vivo* molecular experimental research, it is possible to analyze the effect of Dex on iron death in AD related nerve cells.

Abstract

BACKGROUND

Antidepressants, particularly selective serotonin reuptake inhibitors, are currently considered the first-line treatment for panic disorder (PD). However, little is known about the relationship between the biomarkers that may predict better treatment.

AIM

To compare genome-wide methylation and gene expression patterns between responsive and non-responsive patients with PD after 4 wk of escitalopram treatment.

METHODS

Thirty patients with PD were enrolled in this study (responders = 13; non-responders = 17). All patients were assessed using the PD Severity Scale-Chinese version before and after treatment. The Illumina Infinium MethylationEPIC (850k) BeadChip for genome-wide methylation screening and mRNA sequencing was used in all patients with PD.

RESULTS

A total of 701 differentially methylated positions (DMPs) were found between responders and non-responders ($|\Delta\beta| \geq 0.06$, $q < 0.05$), and the hyper- and hypomethylated CpG sites were 511 (72.9%) and 190 (27.1%), respectively. Relative to non-responders, there were 59 differential transcripts, of which 20 were downregulated and 39 were upregulated ($q < 0.05$). However, no differen-

tially expressed genes were identified by mRNA sequencing after correcting for multiple testing (|log2(FC)| > 1, q > 0.05).

CONCLUSION

This preliminary study showed that DMPs might be associated with the treatment response to escitalopram in PD; however, these DMPs need to be verified in large samples.

Key Words: Panic disorder; Methylation; Expression profiling; Escitalopram

INTRODUCTION

Panic disorder (PD) is a common anxiety disorder characterized by recurrent and unexpected panic attacks. The estimated 12-month and lifetime prevalences of PD are 2.4% and 3.8%, respectively[1,2]. A cross-national epidemiological study reported that the lifetime prevalence of panic attacks was 13.2%[3]. Patients with PD experience symptoms such as tachycardia, chest pain, breathlessness, and dizziness. Consequently, they most frequently seek care in medical settings, such as emergency departments, and their condition is often undiagnosed[4]. PD causes substantial suffering and increases economic costs for both patients and society[5]. Hence, the availability of effective treatment may not only benefit individual patients but also provide economic returns to society.

Antidepressants, particularly selective serotonin reuptake inhibitors (SSRIs), are currently considered first-line treatments for PD. A meta-analysis suggested that SSRIs result in high remission rates with a minimal risk of adverse events in the treatment of PD[6,7]. However, not all patients benefit from the antidepressant therapy. For example, in a 12-week clinical trial of sertraline, citalopram, escitalopram, and paroxetine, 11.1%–18% of patients with PD did not respond to treatment[8,9]. Thus, predictive biomarkers of antidepressant response could greatly benefit clinical practice by decreasing the duration of drug efficacy evaluations.

Previous studies have found that common genetic variants could explain 42% of the individual differences in antidepressant response[10]. In addition, gene polymorphism studies focusing on *5-HTT*, *5-HTR1A*, *5-HTR2A*, *COMT*, *BDNF*, and *P450* (*CYP*) have been conducted in several large-scale studies on antidepressant drug responses in PD[11-14]. However, no consistent findings have been obtained from these studies. For example, with regard to treatment response to SSRIs in patients with PD, Zou *et al*[13] found that *5-HTTLPR* polymorphism, rather than *5-HTR1A*, may be an early predictor of response to sertraline in 2020, whereas Yevtushenko *et al*[11] indicated the importance of a *5-HT1A* receptor gene polymorphism in 2010. Therefore, genetic variation in a single gene cannot fully explain individual differences in the response to treatment.

Emerging evidence from human and animal studies suggests a key role of epigenetic markers, including DNA methylation and histone modifications, in the prediction of antidepressant response[15]. Methylation of some candidate genes, such as *SLC6A4*, *BDNF*, and *IL11*, has shown promising results as a biomarker for predicting antidepressant responses in major depressive disorder (MDD). However, the research methods and results have been heterogeneous [16]. Genome-wide methylation analysis can accurately determine the location of DNA methylation in the genome and screen for effect-related differentially methylated genes. Currently, 850k methylation BeadChip is a new generation of DNA methylation chips developed based on the original 450k methylation chip[17]. The newly developed Human Methylation 850 BeadChip covers over 850k CpG methylation sites and is the most useful tool for analyzing the DNA methylation profile of the human genome. In addition, DNA methylation is a key epigenetic mechanism involved in the developmental regulation of gene expression[18]. Nevertheless, no genome-wide methylation studies or mRNA sequencing have been conducted to identify early response biomarkers in patients with PD.

Hence, a pilot study of genome-wide DNA methylation and gene expression analysis was conducted in patients with PD using the Illumina 850k BeadChip and mRNA sequencing to identify possible predictors of treatment response to escitalopram.

MATERIALS AND METHODS

Study sample

All patients with PD were recruited from the inpatient and outpatient departments of Sichuan Provincial People's Hospital between March 2019 and December 2020. All patients satisfied the following inclusion criteria: (1) Primary diagnosis of PD in line with the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV) performed by a professional psychiatrist through a standardized structured clinical interview for DSM-IV Axis I disorders[19], with none of the patients having any other psychiatric disorders; (2) All PD patients were medication-naïve and had no history of any antidepressant or other psychotropic medication intake; (3) All subjects were without suicide ideations and attempts; (4) Subjects had no family history of psychiatric disorders in a first-degree relative; (5) All patients were Han Chinese aged 18 to 60 years; (6) All subjects were free of acute or chronic somatic disorders, head trauma, or neurological illnesses, and all subjects were free of alcohol consumption within 2 wk before their examination. Women were non-pregnant and non-nursing; and (7) All patients received escitalopram (10–20 mg qd) for 4 wk. The study was approved by the Sichuan Provincial People's Hospital ethics committee [reference number: (2021) Ethics Review (313)]. All individuals provided written informed consent prior to the initiation of study procedures.

Clinical assessment

Patients were assessed at baseline and after 4 wk of treatment using the PD Severity Scale (PDSS). The PDSS comprises seven items, and participants are instructed to rate each item from 0 (none) to 4 (extremely severe) based on the severity of each symptom[20]. The PDSS-Chinese version has good internal consistency (Cronbach's alpha) with an overall score of 0.83[21]. Treatment response for PD was defined as a reduction in the pretreatment PDSS score of at least 40% at 4 wk [22]. The PD samples were divided into responder and non-responder groups.

DNA and RNA extraction

A 4-mL ethylenediaminetetraacetic acid-anticoagulated peripheral blood sample was collected from all subjects in a fasting state *via* venipuncture between 7:00 a.m. and 8:30 a.m. DNA and RNA were extracted from whole blood samples from PD patients at baseline using DNeasy Blood and miRNeasy Mini kits (Qiagen, Hilden, Germany), respectively, according to the manufacturer's protocol.

Genome-wide DNA methylation analysis

DNA was subjected to sodium bisulfite conversion using the EZ DNA Methylation Kit (Zymo Research, Irvine, CA, United States). The Illumina Infinium Human Methylation 850K BeadChip (Illumina, San Diego, CA, United States) was used to assess genome-wide DNA methylation, with a genome-wide coverage of over 850k CpG methylation sites per sample according to the manufacturer's instructions. DNA quality control, bisulfite conversion, genome-wide methylation analysis, and initial methylation signal detection quality control were performed by Sinotech Genomics Co., Ltd. (Shanghai, China).

The raw intensity data were imported into R (v4.0.0; R Foundation for Statistical Computing, Vienna, Austria) and analyzed using the ChIP (ChAMP) package (v2.18.2) for data preprocessing, normalization, and comparison. β-values (ranging from 0 to 1) were used to determine the DNA methylation levels at each CpG site. Probes were filtered, including probes with a detection p-value of < 0.01, probes with less than three beads in at least 5% of the samples, non-CpG probes, and multi-hit probes. Beta-Mixture Quantile was used to normalize β-value matrices to adjust for type I and II probe biases[23]. In addition, we used singular value decomposition analysis to analyze the batch effect caused by the BeadChip Slide and Array and applied Combat to correct this batch effect[24]. Finally, all CpG sites were annotated using EPICanno software. ilm10b5. hg19.

Gene expression analysis

An Agilent 2100 Bioanalyzer (Agilent Technologies, Santa Clara, CA, United States) was used to assess RNA quality. A Qubit® 3.0 Fluorometer (Thermo Fisher Scientific, Waltham, MA, United States) and NanoDrop One spectrophotometer (Thermo Fisher Scientific) were used to quantify total RNA, after which the library was constructed. The library for polymerase chain reaction product purification by paired-end libraries was synthesized using the mRNA-seq Lib Prep Kit for Illumina (ABclonal, Wuhan, China) following the sample preparation guide. Libraries were quantified using a Qubit® 3.0 Fluorometer (Thermo Fisher Scientific) and validated using an Agilent 2100 Bioanalyzer (Agilent Technologies) to calculate the molar concentration and insert size. Clusters were generated using the cBot user guide and sequenced using an Illumina NovaSeq 6000 system (Illumina). Library construction and sequencing were performed by Sinotech Genomics Co. Ltd.

Hisat2 (2.1.0) was used to map the paired-end sequence files (fastq) to the reference genome (GRCh38.91). The output sequencing alignment/map files were converted into binary alignment/map files and sorted using SAM tools (v1.7). Gene abundance was expressed as fragments per kilobase of exons per million reads mapped (FPKM). StringTie software was used to count the fragments within each gene, and the TMM algorithm was used for normalization (https://www.ncbi.nlm.nih.gov/COG/). Finally, the FPKM value of each gene was calculated. EdgeR software was used to conduct differential expression analysis of the mRNA[25].

Statistical analysis

Data were analyzed using SPSS software (version 18.0; SPSS Inc., Chicago, IL, United States). Intergroup comparisons of continuous variables were conducted using Student's t-test, and categorical variables were analyzed using Pearson's chi-

square test. Differentially methylated CpG positions were identified using ChAMP. Δβ was calculated as the difference of mean β-values between responders and non-responders. We set the criteria for differential methylation positions (DMPs) as the calling significance of an absolute change in Δβ-value between groups ($|\Delta\beta| \geq 0.06$ and $q < 0.05$). Differentially expressed mRNAs were defined as $|\log2(FC)| > 1$ and $q < 0.05$. To identify genes with the same function and pathway in DNA methylation and gene expression profiling, we performed gene ontology (GO) (http://geneontology.org/) analysis for biological processes, cellular components, and molecular function, and Kyoto Encyclopedia of Genes and Genomes (KEGG) pathway analysis (http://www.kegg.jp/) for differentially methylated and expressed genes. For all statistical analyses, a two-tailed p-value < 0.05 indicated statistical significance. The q-value cut-off of 0.05 was corrected using the Benjamini–Hochberg method for multiple hypotheses[26].

RESULTS

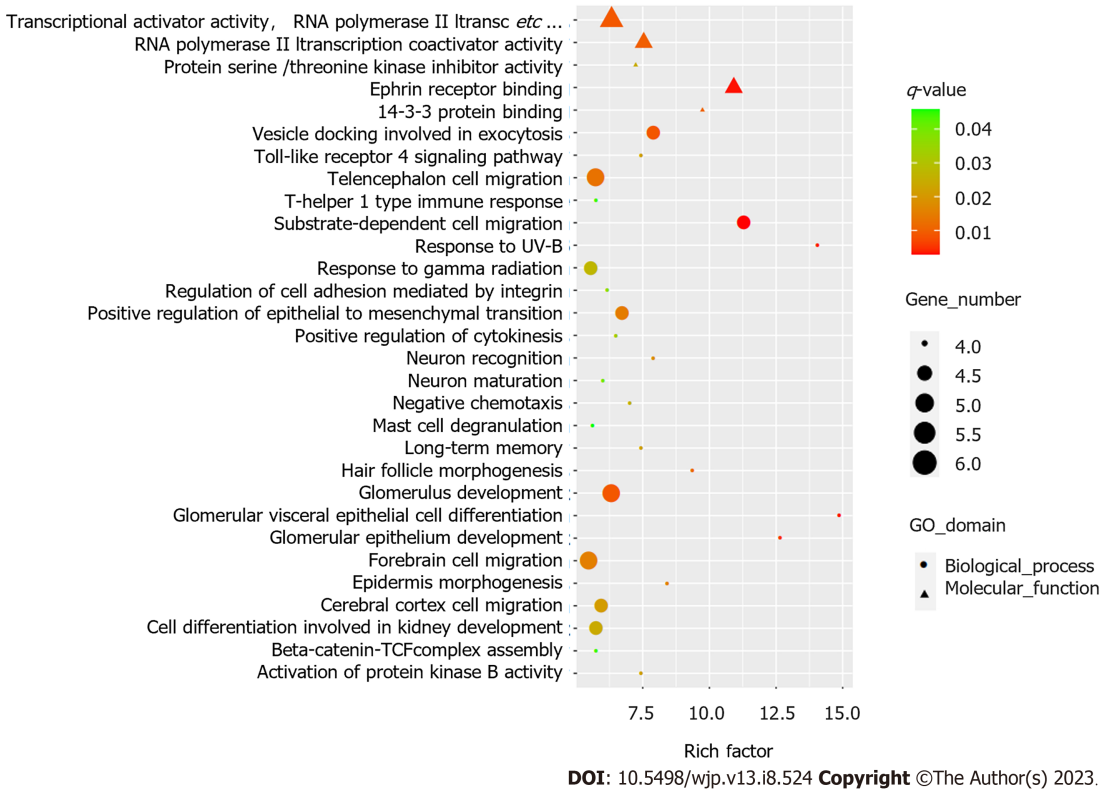
Demographic and clinical characteristics

PD samples were divided into 13 responders (6 men and 7 women; 33.54 ± 11.64 years old) and 17 non-responders (8 men and 9 women; 33.88 ±9.65 years old) at 4 wk. No statistically significant differences were found between the responders and non-responders in terms of sex ($\chi^2 = 0.002$, $p > 0.05$) or age ($t = -0.088$, $p > 0.05$). There were 4 smokers (30.8%) and 9 nonsmokers (69.2%) in the responder group, and 5 smokers and 12 nonsmokers in the non-responder group. The number of drinkers and nondrinkers among the responders was 3 (23.1%) and 10 (76.9%) in the responder group, and 5 drinkers and 12 nondrinkers in the non-responder group. No statistically significant group difference was observed in terms of smoking and drinking ($\chi^2 = 0.006$, 0.151; $p > 0.05$). In addition, the average PDSS total score was 13.08 ± 4.25 in responders and 14.94 ± 3.25 in non-responders at the start of treatment, and no statistically significant group difference was observed ($t = -1.363$, $p > 0.05$). The average PDSS total score for responders was 4.54 ± 2.11, which was significantly lower than that for non-responders 10.35 ± 2.00 after 4 wk of treatment ($p < 0.001$).

Differential methylation analysis

Compared with non-responders, there were 701 DMPs ($|\Delta\beta| \geq 0.06$, $q < 0.05$), and the hyper- and hypomethylated CpG sites were 511 (72.9%) and 190 (27.1%), respectively (Supplementary Table 1). The distribution of DMPs in the CpG islands was as follows: N-shore (34.6%), S-shore (24.5%), N-shelf (16.5%), island (14.4%), and S-shelf (10.1%). These DMPs in different regions of the gene were in the following order: Body region (64.4%), transcriptional start site (TSS) 1500 (15.3%), 5′-untranslated region (UTR) region (12.5%), 1st Exon (3.4%), TSS 200 (3.1%), and the 3′-UTR region (1.3%). According to the University of California Santa Cruz annotation, 437 unique genes were identified, including 311 hypermethylated and 122 hypomethylated genes; the coexistence of hyper- and hypomethylation sites was found in four genes (Supplementary Table 2).

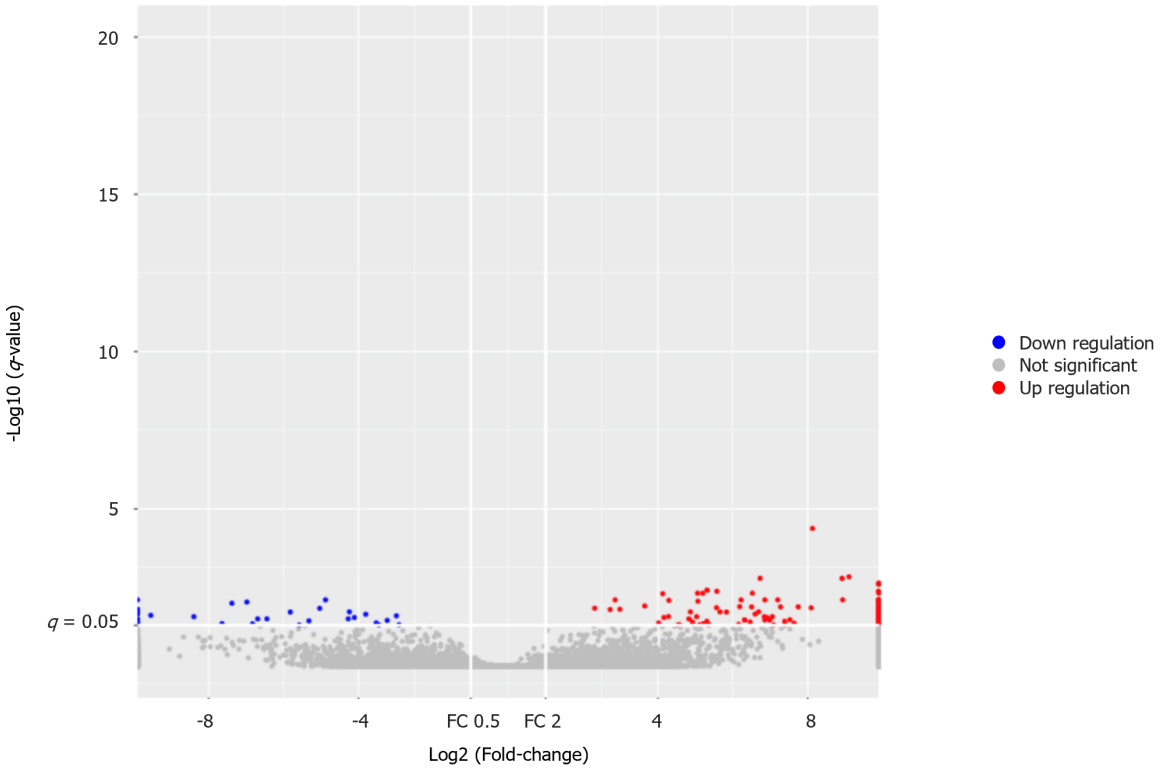
Enrichment analysis of differentially methylated genes



GO analysis revealed distinct functional categories for the associated genes, and approximately 226 biological processes, 14 cellular components, and 22 molecular functions were identified in differentially methylated genes ($q < 0.05$). Figure 1 shows the top 30 GO annotations for the differentially methylated genes. KEGG analysis showed that these differentially methylated genes were involved in 43 significant pathways ($p < 0.05$). However, no statistically significant pathways were found after adjusting using the Benjamini–Hochberg method ($q > 0.05$) (Supplementary Table 3).

Differential mRNA expression analysis

Compared with non-responders, there were 59 differential transcripts after adjusting using the Benjamini–Hochberg method, of which 20 were downregulated and 39 were upregulated ($q < 0.05$) (Figure 2). After the data were analyzed using the screening procedure, the results of mRNA sequencing showed that 132 differentially expressed genes were identified ($p < 0.05$). However, no statistically significant group differences between responders and non-responders were observed after adjusting using the Benjamini–Hochberg method ($q > 0.05$) (Supplementary Table 4).



DISCUSSION

DNA methylation plays an important role not only in the diagnosis of diseases but also in the prediction of efficacy[16, 27]. In this study, a pilot investigation of genome-wide DNA methylation in the early response to antidepressants in patients with PD was conducted using the Illumina 850k BeadChip. To our knowledge, this is the first genome-wide DNA methylation study of the treatment response to escitalopram in PD. According to the screening criteria for differential methylation sites, 701 DMPs were screened among responders and non-responders in patients with PD, and these DMPs were located within 437 unique genes. Similarly, one study assessed genome-wide DNA methylation using the Infinium MethylationEPIC BeadChip in patients with MDD for escitalopram treatment response. They identified 2571 significant DMPs, and 303 DMPs with an absolute change in Δβ-value between groups larger than 0.2[28]. These findings indicate that DMPs are potential peripheral predictors of antidepressant treatment response, and present an important opportunity to improve symptoms through prediction of medication response. Not only that, there is also some emerging evidence to suggest that PD patients have aberrant DNA methylations[29]. Psychiatry as a medical discipline, a diagnosis identifying a disorder should lead to an effective therapy[30]. Hence, epigenetic factors contributing to antidepressant

Figure 2 Differential transcripts between responders and non-responders.

response will be a unique and promising opportunity to implement personalized medicine in PD treatment. In addition, in the present study, most DMPs with an absolute change in value between groups were lower than 0.1. Furthermore, Ju *et al*[28] found that many DMPs showed very small differences in methylation (Δβ < 0.5%), making it difficult to fully

explain efficacy prediction from a single CpG site. The treatment efficacy may be largely determined by the combined effects of multiple loci.

Notably, the current study identified 10 DMPs with an absolute change in Δβ-value larger than 0.2 ($|\Delta\beta| \geq 0.2$) between groups, and these genes included *HLA-DPB1*, *HLA-DPA1*, *PDE1A*, *COL23A1*, *RUFY4*, *FRMD5*, and *SOHLH1*. For example, the *HLA-DPB1* site (cg12865025) is located in the TSS 1500 region. The major histocompatibility complex class II molecule consists of non-covalently associated alpha and beta chains, and this class II molecule is a heterodimer consisting of an alpha (DPA) and a beta chain (DPB)[31]. *HLA-DPA1* and *HLA-DPB1* are expressed on the surfaces of antigen-presenting cells; they play a central role in the adaptive immune system[32] and are associated with the pathophysiology of psychiatric disorders[17]. In recent years, increasing evidence has suggested that aberrations in immune-related pathways contribute to the pathophysiology and prediction of treatment responses in patients with PD [33,34]. Moreover, escitalopram led to a decrease in immune system activation[35], augmented tumor necrosis factor-peripheral secretion, induced faster kinetics of interleukin-1β secretion[36], and decreased Interleukin-17 levels[37]. Therefore, immune-related pathways may play an important role in the response to antidepressants in patients with PD. However, whether these DMPs can be used as molecular markers needs to be verified in larger samples.

In this study, functional enrichment analysis of differentially expressed genes was performed. GO analysis identified 262 GO terms in differentially methylated genes. Notably, the top 30 GO annotations, such as neuron recognition, neuron maturation, and cerebral cortex cell migration, may be associated with the treatment response. These enriched genes, including *DAB1*, *NRP1*, *DIXDC1*, *ROBO1*, *PEX5*, *APP*, *ANKS1A*, *EDNRB*, *BCL2*, and *NTM*, play central roles in brain development, neuronal remodeling, neurite outgrowth, and adhesion. For example, antidepressants such as citalopram increase *APP* secretion in primary rat neuronal cultures[38]. In addition, previous findings suggest that citalopram reduces mutant *APP*, Aβ, and mitochondrial toxicities and may have a protective role against mutant *APP* and Aβ-induced injuries in patients with depression, anxiety, and Alzheimer's disease[39]. In addition, these genes have a potential role in the development of many neuropsychiatric diseases. For example, a previous study found that *Dab1* knockout mice exhibited behavioral abnormalities, including hyperactivity, decreased anxiety-like behavior, and impaired working memory[40]. Hence, these differentially methylated genes in the GO terms may be involved in the pathophysiology and therapeutic response in PD, and the functions of these genes need further exploration. Further studies are needed to explore whether differential methylation in peripheral blood is similar to that in the brain.

Few studies have explored the association between gene expression and the prediction of therapeutic response in patients with PD. In this study, mRNA sequencing was compared between responders and non-responders among patients with PD. Unfortunately, no statistically significant group differences were found in differentially expressed genes. Furthermore, no candidate genes were identified based on integrative analysis of differential DNA methylation and expression. This may be due to the following reasons. First, the sample size was small. The different clinical features of patients with PD are closely related to the heterogeneity of heredity. Second, the use of whole blood, which is a mixed cell type sample, may limit the identification of mRNA expression changes. Finally, gene expression is affected by many factors, such as environmental and other epigenetic factors, especially non-coding RNA, which represents a promising source of peripheral biomarkers of antidepressant responses[41]. Ultimately, it is likely that combinations and not individual biomarkers will have the greatest utility in predicting antidepressant responses. In the future, researchers should integrate multiple types of information, including genetic, epigenetic, and gene expression data, to identify the most meaningful panel of biomarkers.

CONCLUSION

In conclusion, this preliminary study showed that DMPs may be associated with an early response to antidepressants in patients with PD. However, the results of our study should be considered in light of the following limitations. Since this is the first study to investigate genome-wide DNA methylation and gene expression in the prediction of early response to antidepressants in PD, it would be valuable to replicate our findings in a larger cohort. Furthermore, these DMPs must be verified using larger sample sizes. Lastly, it is necessary to test the association between treatment outcomes and changes in DNA methylation and gene expression from pre- to post-treatment with a long-term follow-up.

ARTICLE HIGHLIGHTS

Research background

Selective serotonin reuptake inhibitors are currently considered the first-line treatment for panic disorder (PD). However, not all patients benefit from the antidepressant therapy.

Research motivation

No genome-wide methylation studies or mRNA sequencing have been conducted to identify early response biomarkers in patients with PD.

Research objectives

To compare genome-wide methylation and gene expression patterns between responsive and non-responsive patients with PD after 4 wk of escitalopram treatment.

Research methods
Thirty patients with PD were enrolled in this study (responders = 13; non-responders = 17). All patients were assessed using the PD Severity Scale-Chinese version before and after treatment. The Illumina Infinium MethylationEPIC (850k) BeadChip for genome-wide methylation screening and mRNA sequencing was used in all patients with PD.

Research results
A total of 701 differentially methylated positions (DMPs) were found between responders and non-responders ($|\Delta\beta| \geq 0.06$, $q < 0.05$), and the hyper- and hypomethylated CpG sites were 511 (72.9%) and 190 (27.1%), respectively. Relative to non-responders, there were 59 differential transcripts, of which 20 were downregulated and 39 were upregulated ($q < 0.05$).

Research conclusions
This preliminary study showed that DMPs might be associated with the treatment response to escitalopram in PD, however, these DMPs need to be verified in large samples.

Research perspectives
DNA methylation contributing to antidepressant response will be a unique and promising opportunity to implement personalized medicine in PD treatment.

Abstract

BACKGROUND

As the perioperative risk of elderly patients with extremely unstable hip fractures (EUHFs) is relatively high and therapeutic effect is not satisfactory, new therapeutic strategies need to be proposed urgently to improve the efficacy and clinical outcomes of such patients.

AIM

To determine the influence of two surgical treatment modalities on postoperative cognitive function (CF) and delirium in elderly patients with EUHFs.

METHODS

A total of 60 elderly patients consecutively diagnosed with EUHF between September 2020 and January 2022 in the Chongqing University Three Gorges Hospital were included. Of them, 30 patients received conventional treatment (control group; general consultation + fracture type-guided internal fixation), and the other 30 received novel treatment (research group; perioperative multidisciplinary treatment diagnosis and treatment + individualized surgical plan + risk prediction). Information on hip function [Harris hip score (HHS)], perioperative risk of orthopedic surgery [Physiological and Operative Severity Score for the Enumeration of Mortality and Morbidity (POSSUM)], CF [Montreal cognitive assessment scale (MoCA)], postoperative delirium [mini-cognitive (Mini-Cog)],

adverse events (AEs; internal fixation failure, infection, nonunion, malunion, and postoperative delirium), and clinical indicators [operation time (OT), postoperative hospital length of stay (HLOS), ambulation time, and intraoperative blood loss (IBL)] were collected from both groups for comparative analyses.

RESULTS

The HHS scores were similar between both groups. The POSSUM score at 6 mo after surgery was significantly lower in the research group compared with the control group, and MoCA and Mini-Cog scores were statistically higher. In addition, the overall postoperative complication rate was significantly lower in the research than in the control group, including reduced OT, postoperative HLOS, ambulation time, and IBL.

CONCLUSION

The new treatment modality has more clinical advantages over the conventional treatment, such as less IBL, faster functional recovery, more effectively optimized perioperative quality control, improved postoperative CF, mitigated postoperative delirium, and reduced operation-related AEs.

Key Words: Extremely unstable hip fracture; Elderly; Multidisciplinary treatment; Cognitive function; Postoperative delirium

Core Tip: Characterized by severe fragmentation, extreme instability, and treatment-refractory, extremely unstable hip fractures (EUHFs) in the elderly population carry a higher perioperative risk. Given the unsatisfactory treatment outcomes of EUHFs in the elderly, there is an urgent need to develop new therapeutic strategies to improve the efficacy and clinical outcomes in these patients, thus providing a guarantee for their life, health, and quality of life.

INTRODUCTION

Extremely unstable hip fractures (EUHFs) account for approximately one-fourth of all hip fractures, mainly including Garden grade III and IV fractures of the femoral neck, A2 and A3 intertrochanteric femur fractures, and Seinsheimer type III and IV subtrochanteric femoral fractures, characterized by severe fragmentation, extreme instability, and treatment-refractory[1,2]. EUHF has a predilection for two groups of people: Young people who have suffered major trauma and elderly people with severe osteoporosis and minor trauma[3]. Elderly patients with EUHF have a higher perioperative risk due to their poorer physical conditions than young and middle-aged people and the high likelihood of comorbidities such as hyperlipidemia, hyperglycemia, hypertension, and other internal diseases[4]. Clinically, the surgical treatment modality for elderly patients with EUHF is selected mainly on the fracture type, which not only leads to unsatisfactory treatment outcome but may also cause postoperative cognitive dysfunction in > 40% and postoperative delirium in 5%-61% of patients, severely affecting their quality of life (QoL)[5,6]. Therefore, it is imperative to develop novel treatment strategies to improve the efficacy and clinical outcomes in elderly patients with EUHF and to provide a guarantee for their life, better health, and improved QoL.

Multidisciplinary treatment (MDT) is a diagnosis and treatment model that gathers the backbones of EUHF-related departments, such as geriatrics, critical medicine, anesthesiology, mental health, and rehabilitation medicine, to tailor personalized examination and treatment plans for patients to improve patient diagnosis and treatment experience and enhance treatment efficacy[7-9]. A randomized controlled trial including elderly patients with hip fractures also observed significant improvement in postoperative clinical outcomes using MDT, which suggested that MDT has great application potential in elderly patients with EUHF[10]. On the other hand, anatomic reduction, internal fixation, and effective control of postoperative adverse events (AEs) for EUHFs are the keys to successful surgery due to the vulnerability to fractures of the area involved and the complexity and involvement of the surrounding muscle groups[11,12]. We believe that individualized customization + fracture type co-determined internal fixation is a feasible and safe program, and risk prediction and advance treatment through Mini-Cog plus orthopedic Physiological and Operative Severity Score for the Enumeration of Mortality and Morbidity (POSSUM) scale assessment can further help minimize the surgical risks.

To test our conjecture and supplement the evidence-based new treatment model (MDT diagnosis and treatment + individualized surgical plan + risk prediction) still lacks, this study compared the clinical effects of the two surgical treatment modalities through a clinical cohort study to optimize and scientifically guide the clinical treatment.

MATERIALS AND METHODS

General data

This study comprised 60 elderly patients diagnosed consecutively with EUHF in the Chongqing University Three Gorges Hospital between September 2020 and January 2022. Of 60, 30 patients were treated using the conventional treatment model of general consultation plus fracture type-guided internal fixation (control group), and the other 30 patients received a new treatment model of perioperative MDT diagnosis and treatment + individualized surgical plan + risk prediction (research group). The two patient groups had similar baseline data ($P > 0.05$), which was clinically comparable.

Inclusion and exclusion criteria for patient enrollment

Patients diagnosed with extremely unstable femoral intertrochanteric fractures (Garden grade III or IV fractures of the femoral neck, A2 or A3 intertrochanteric femur fractures, or Seinsheimer type III or type IV subtrochanteric femoral fractures), but not old or pathological fractures, using computed tomography, magnetic resonance imaging, and other imaging examinations[13,14], with no severe osteoporosis, t value ≥ -2.5, normal communication and cognitive abilities, and active cooperation were included.

The exclusion criteria were as follows: Other hip diseases; serious nerve; vascular or muscle injuries; other joint diseases; femoral head necrosis; serious infections; diseases such as coagulation dysfunction, cardiopulmonary disease, and renal failure; drug and alcohol addiction; and history of severe trauma around the hip joint.

Treatment protocols

The control group received conventional treatment, with the following specific measures: Post-admission general consultation was provided to the patients and relevant examinations and treatment were further conducted according to the consultation. The patient's underlying diseases were stabilized preoperatively; however, another preoperative evaluation was conducted by the anesthesiologist. The surgical protocol was selected depending on the patient's fracture type. After surgery, the patient's vital signs, mental state, food intake, blood routine, biochemical indexes, drainage volume, and cardiopulmonary function were obtained, and bilateral lower limb vascular ultrasonography was performed. Prophylactic antibiotics were used within 24 h after surgery, and anticoagulant therapy composed of low molecular weight heparin and rivaroxaban was routinely given. Postoperatively, the affected limb was raised according to the patient's fracture type, surgical condition, and general condition. In addition, the patient was instructed to perform quadriceps isometric contraction and ankle pump exercises. Those with good wound healing, no hip pain, sound mind, good appetite, no serious complications, and no serious abnormalities in various laboratory indexes were discharged.

The research group adopted a new treatment model, perioperative MDT diagnosis and treatment + individualized surgical plan + risk prediction. Details of the treatment methods are described as follows: (1) After admission, an MDT team, which was led by orthopedic surgeons and composed of professional backbones with intermediate titles or above in geriatrics, critical medicine, anesthesiology, mental health, rehabilitation medicine, and other related departments, was set up. The MDT team evaluated the patients' specific conditions, formulated personalized examination and treatment plans, and opened green channels to shorten the waiting time for examinations. In addition, the mental state of the patients was adjusted to actively prepare them for surgery, and the time between admission and operation was shortened as much as possible; (2) A surgical protocol was jointly developed based on each patient's treatment and fracture type, as assessed by the MDT team. If the hemoglobin count was > 90 g/L after blood transfusion, with no hypertension, lower limb deep venous thrombosis (except for those undergoing inferior vena cava filter placement), preoperative delirium, and serious basic diseases, the internal fixation scheme was determined according to the fracture type. For those with preoperative hypoproteinemia, moderate-to-severe anemia that cannot be corrected, severe underlying diseases, and delirium, among others, the internal fixation method was comprehensively considered in combination with the fracture type, and proximal femoral locking plate (PFLP) fixation was performed when necessary; and (3) During the perioperative period, patients were assessed using the Mini-Cog and orthopedic POSSUM scales for delirium and risk prediction, respectively. Patients who were not eligible for surgery at the time were treated by relevant specialists and re-evaluated after their condition improved. The post-surgical patients were re-evaluated by the MDT team, and timely and effective treatment was given if necessary. Those with multiple medical diseases and more serious conditions were admitted to the intensive care unit after the operation. In addition, mental health practitioners assessed the patients' mental state before and after surgery to better guide the treatment. Moreover, rehabilitation physicians instructed patients to exercise to improve muscle strength and joint range of motion and assisted with early ambulation. Other routine diagnoses, treatments, and discharge standards after the operation were the same as in the control group.

Detection indicators

Hip function: Patients' hip function was assessed using the Harris Hip Score (HHS) before and 6 mo after surgery for pain (0-44 points), function (0-47 points), deformity (0-4 points), and range of motion (0-5 points) components, with a total score of 100 points. A higher score indicated a better hip functional recovery.

Preoperative risk assessment: The orthopedic POSSUM scoring system, which consists of 12 variables forming the physiological assessment (score range 12-96) and 6 variables forming the operative severity assessment (score range 6-48), was used to evaluate the surgical risk of patients. A higher score suggested a greater risk.

Cognitive function assessment: Using the Montreal Cognitive Assessment Scale (MoCA; score range 0-30), the patients' cognitive function (CF) was assessed from 11 items in 8 knowledge fields (memory, language, attention and concentration, executive functions, visuospatial skills, abstraction, calculations, and orientation). In addition, the patients'

Table 1 Analysis of comparability of general data between the two groups

Categories	Control group (*n* = 30)	Research group (*n* = 30)	χ^2 value	*P* value
Sex			0.067	0.796
Male	14 (46.67)	15 (50.00)		
Female	16 (53.33)	15 (50.00)		
Age (yr)	63.20 ± 5.32	62.40 ± 6.04	0.544	0.588
Fracture site			0.617	0.432
Left	11 (36.67)	14 (46.67)		
Right	19 (63.33)	16 (53.33)		
Hypertension			0.635	0.426
Yes	17 (56.67)	20 (66.67)		
No	13 (43.33)	10 (33.33)		
Diabetes			0.373	0.542

No	22 (73.33)	24 (80.00)		

intelligence was assessed using the Mini-Cognitive (Mini-Cog) scale (score range 0-5). Scores on both scales were proportional to CF.

Incidence rate of AEs: AEs that occurred during treatment, such as internal fixation failure, infection, nonunion, malunion, and postoperative delirium, were observed and recorded in all patients, and the incidence rate was calculated.

Clinical indicators: Clinical indicators, including operation time (OT), postoperative hospital length of stay (HLOS), ambulation time, and intraoperative blood loss (IBL), were recorded and compared.

Statistical analysis

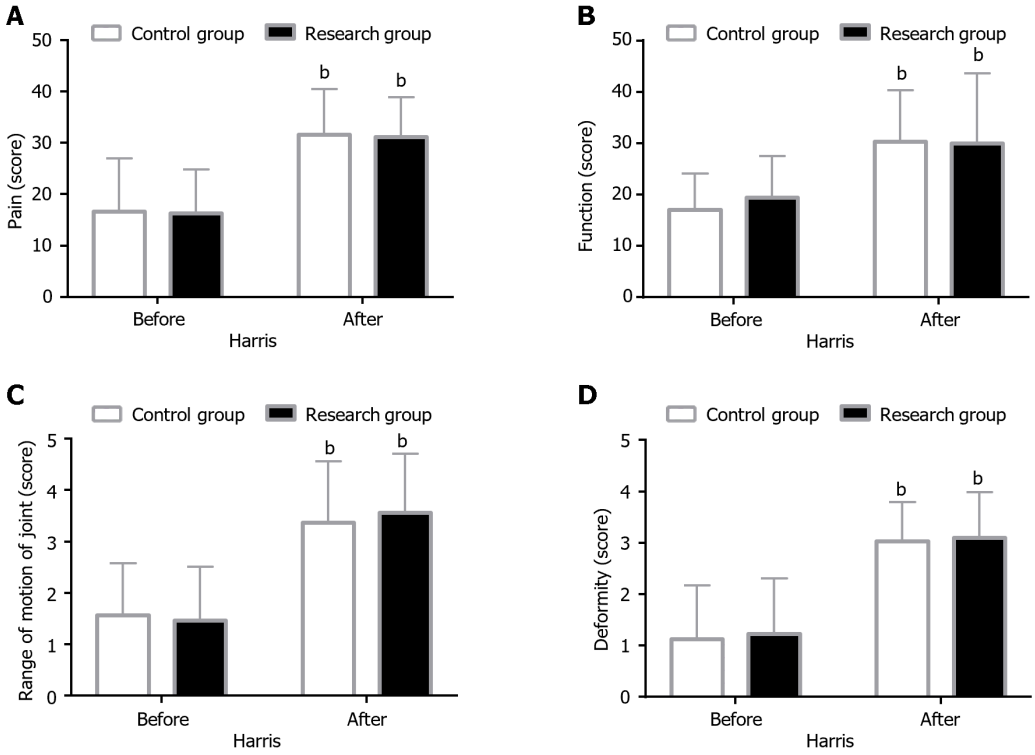
All statistical analyses were performed using SPSS 20.0. The mean ± SEM was used to describe continuous variables, and the *t*-test was used for comparison between groups. Categorical variables were expressed as percentages, and the χ^2 test was used for intergroup comparison. $P < 0.05$ was considered statistically significant.

RESULTS

General information

A comparative analysis of patient general data, such as sex, age, fracture site, hypertension, and diabetes, showed clinical comparability between both groups ($P > 0.05$; Table 1).

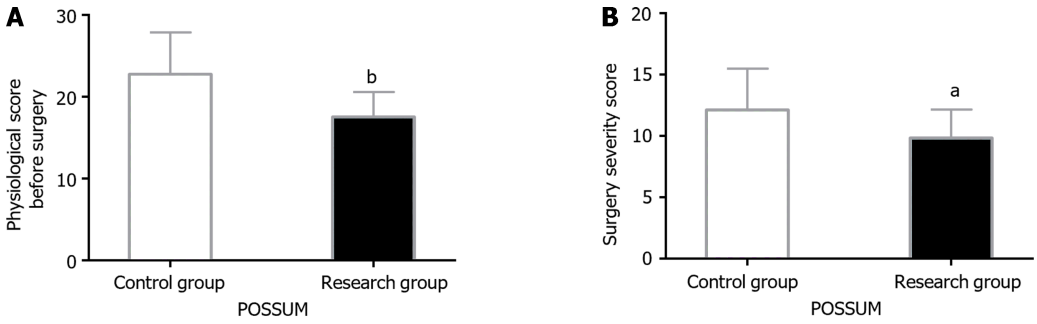
Hip joint function



The patients' hip joint function was evaluated by assessing the pain, function, range of motion, and deformity components of the HHS. The analysis showed no significant intergroup difference in HHS scores before and after intervention ($P > 0.05$). However, the intragroup comparison revealed markedly elevated HHS scores in both groups after intervention ($P < 0.05$) (Figure 1).

Orthopedic POSSUM scale scores

After the analysis using the orthopedic POSSUM scale, it was found that the preoperative physiological and operative severity scores of the research group were significantly reduced as compared to the control group ($P < 0.05$) (Figure 2).



CF

A comparative analysis of patients' CF using the MoCA and Mini-Cog showed no significant difference in both scores between groups prior to the intervention ($P > 0.05$). After the intervention, the MoCA score was significantly reduced in both groups ($P < 0.05$), with an even higher score in the research group ($P < 0.05$). In terms of the Mini-Cog score, a significant decrease was observed in the control group ($P < 0.05$) as opposed to a non-significant decrease in the research group after intervention ($P > 0.05$); however, comparatively, the score remained significantly higher in the research group ($P < 0.05$) (Figure 3).

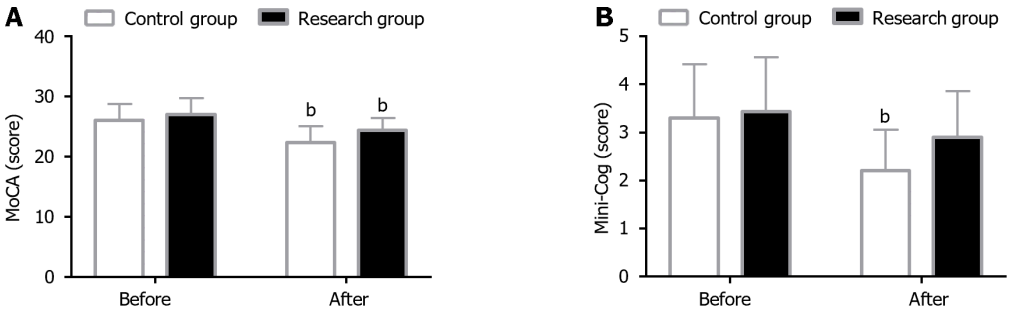
Figure 2 Orthopedic Physiological and Operative Severity Score for the Enumeration of Mortality and Morbidity scale scores. A: Preoperative physiological scores are significantly lower in the research group than in the control group; B: Surgical severity scores are lower in the research group than in the control group. $^{a}P < 0.05$ and $^{b}P < 0.01$ *vs* control group. POSSUM: Physiological and Operative Severity Score for the Enumeration of Mortality and Morbidity.

AEs



According to the statistics on internal fixation failure, infection, nonunion, malunion, and postoperative delirium, the total incidence of AEs was found to be significantly lower in the research than in the control group ($P < 0.05$; Table 2).

Clinical indexes

The measurement of clinical indexes revealed less OT, postoperative HLOS, and IBL and early ambulation in the research group than in the control group ($P < 0.05$) (Figure 4).

Table 2 Adverse events

Events	Control group (n = 30)	Research group (n = 30)	χ^2 value	P value
Internal fixation failure	1 (3.33)	1 (3.33)	-	-
Infection	2 (6.66)	1 (3.33)	-	-
Nonunion	2 (6.66)	1 (3.33)	-	-
Malunion	2 (6.66)	0 (0.00)	-	-
Postoperative delirium	3 (10.00)	0 (0.00)	-	-
Total	10 (33.33)	3 (10.00)	4.812	0.028

MoCA: Montreal cognitive assessment scale; Mini-Cog: Mini-Cognitive.

DISCUSSION

Conventional treatment is less effective in the treatment of elderly patients with EUHFs, and surgery is currently the treatment of choice to help patients regain their independence, including work ability, faster after injury[15]. In addition, the general consultation model adopted in conventional treatment has some shortcomings, such as delayed treatment time due to repeated preoperative consultation and examination, which leads to various complications in some patients waiting for surgery, including loss of the optimal timing for surgery[16]. Given the above problems, developing effective solutions to optimize the diagnosis and treatment experience of elderly patients with EUHF is imperative.

In this study, the new treatment model was based on MDT diagnosis and treatment + individualized surgical plan + risk prediction, with holistic sequential trauma treatment as the concept[17]. However, the conventional treatment model included general consultation + fracture type-guided internal fixation as the main program and local trauma theory as the main guidance[18]. Herein, significantly enhanced hip joint function, reflected in significantly elevated HHS scores in pain, function, range of motion, and deformity dimensions, was observed in both cohorts after surgery. However, no significant intergroup differences were observed, which suggested that the two surgical treatment modalities had similar effects in elderly patients with EUHF. This may be attributed to the guiding exercise for hip functional rehabilitation administered to patients in both treatment protocols. According to Wu *et al*[19], the application of MDT in combination with perioperative management in elderly patients with intertrochanteric fractures not only significantly reduced perioperative symptoms but also effectively facilitated postoperative rehabilitation and long-term improvement of hip function, similar to our findings. Surgical treatment of hip fractures is known to be extremely life-threatening for elderly patients, and the prediction and evaluation of surgical risk based on individual differences can be helpful to improve surgical outcomes[14,20]. Therefore, in this study, we used orthopedic POSSUM and Mini-Cog scales to predict the surgical risk and postoperative delirium in elderly patients with EUHF. The data from the orthopedic POSSUM scale showed that the research group had lower preoperative physiological and operative severity scores than the control group, indicating reduced surgical risk under the intervention of the new treatment model. This may be attributed to the preoperative prediction, accurate assessment, and advanced management of complications in patients under the new treatment model. Previous studies have shown that the POSSUM scale has a certain application value in the risk assessment of hip fracture surgery in elderly patients. Risk management based on this scale, combined with the cooperation of the MDT team, can help reduce the mortality and readmission rates of elderly patients with fractures in the perioperative period and improve their functional outcomes[21,22]. Regarding the MoCA and Mini-Cog scores, the post-interventional scores in the research group were notably higher than the post-interventional values in the control group, indicating that the new treatment model can help prevent postoperative cognitive impairment and delirium in such patients. Postoperative cognitive dysfunction and delirium, which are common postoperative complications in elderly patients with hip fractures, have been associated with a significant increase in postoperative serum S100A12 levels[23,24]. Similarly, Zhu *et al*[25] suggested that perioperative geriatric comprehensive assessment for elderly patients with hip fractures can not

Figure 4 Clinical indicators. A: Operation time is significantly shorter in the research group than in the control group; B: Postoperative hospital length of stay is significantly shorter in the research group than in the control group; C: Activity time is significantly longer in the research group than in the control group; D: Intraoperative blood loss is statistically less in the research group than in the control group. [a]$P < 0.05$ and [b]$P < 0.01$ *vs* control group.

only shorten the preoperative waiting time and total hospital stay compared with conventional consultation but also reduce the risk of postoperative delirium, in line with our findings.

Among various AEs, the incidence of internal fixation failure, infection, nonunion, malunion, and postoperative delirium was significantly lower in the research than in the control group, suggesting that it is safe for elderly patients with EUHF to receive the new treatment. The aforementioned prevention of postoperative cognitive impairment and delirium helps to avoid prolonged bed rest, subsequently reducing the risk of bedsores and pulmonary infection, including the incidence of postoperative AEs and mortality[26]. In addition, the orthopedic POSSUM scale was introduced in this study for preoperative comprehensive assessment, allowing for causative or symptomatic treatment of the problems found in the evaluation to significantly reduce postoperative AEs, which also explains the above results [27]. Finally, we found that patients in the research group had more clinical advantages than those in the control group in terms of OT, postoperative HLOS, ambulation time, and IBL, suggesting that the new treatment model can shorten treatment time, promote patients' rehabilitation, and improve surgical safety. This may be attributed to the emphasis on local trauma and the neglect of overall trauma in the conventional treatment model, which often leads to long OT, excessive bleeding, and more postoperative complications[28,29]. On the contrary, the new treatment model links the difficulty of anatomical reduction with the operation tolerance time and anesthesia mode and applies traditional PFLP fixation to a small number of patients with poor basic conditions. PFLP fixation, a simple clinical procedure, can not only reduce the interference to the blood supply at the fracture end but also increase the stability and strength of the nail-bone combination, which is conducive to shortening the OT while maintaining a certain therapeutic effect[30]. In a study by Rui *et al*[31], the new treatment model formulated by the MDT team for hip fractures in the elderly is beneficial to shorten the OT and postoperative HLOS, in line with our findings.

CONCLUSION

The new treatment model using MDT diagnosis and treatment + individualized surgical plan + risk prediction was superior to the conventional treatment model of general consultation + fracture type-guided internal fixation in clinical efficacy to a certain extent. The main clinical advantages of the novel treatment model were lower surgical risks, lower incidence of postoperative AEs, more effectively accelerated patient recovery, and prevention against postoperative cognitive dysfunction and delirium, which can improve the treatment efficacy and experience of elderly patients with EUHF and provide more accurate evidence to guide clinical application.

ARTICLE HIGHLIGHTS

Research background

Given the current high perioperative risk of extremely unstable hip fractures (EUHFs) in elderly patients and the unsatisfactory treatment outcomes, there is an urgent need to propose new treatment strategies to treat these patients.

Research motivation

To improve the efficacy and clinical outcome of EUHFs in the elderly, it is necessary to explore and optimize the relevant treatment strategies.

Research objectives

This study focuses on the clinical application effects of two surgical treatment modalities in older adults with EUHFs.

Research methods

First, 60 older adults consecutively diagnosed as EUHFs between September 2020 and January 2022 in the Chongqing University Three Gorges Hospital were selected as the research participants, among which 30 cases in the control group (Con) received conventional treatment (general consultation + fracture type-guided internal fixation) and the other 30 cases in the research group (Res) received novel treatment [perioperative multi-disciplinary treatment (MDT) diagnosis and treatment + individualized surgical plan + risk prediction]. Information on hip function (Harris hip score, HHS), perioperative risk of orthopedic surgery (Physiological and Operative Severity Score for the Enumeration of Mortality and Morbidity, POSSUM), CF (Montreal cognitive assessment scale, MoCA), postoperative delirium (mini-cognitive, Mini-Cog), AEs (internal fixation failure, infection, nonunion, malunion, and postoperative delirium), clinical indicators (OT; postoperative hospital length of stay, HLOS; ambulation time; intraoperative blood loss, IBL) were collected from both groups for comparative analyses.

Research results

The HHS scores were similar between both groups. The POSSUM score at 6 mo after surgery was significantly lower in the research group compared with the control group, and MoCA and Mini-Cog scores were statistically higher. In addition, the overall postoperative complication rate was significantly lower in the research than in the control group, including reduced OT, postoperative HLOS, ambulation time, and IBL.

Research conclusions

With comparable efficacy in fracture healing, the new treatment modality has some clinical advantages over the conventional treatment, such as less IBL, faster functional recovery, more effectively optimized perioperative quality control, improved postoperative cognitive function, mitigated postoperative delirium, and reduced operation-related adverse events.

Research perspectives

The novel treatment model of MDT diagnosis and treatment + individualized surgical plan + risk prediction can improve the therapeutic efficacy and experience of elderly patients with EUHFs, providing more accurate evidence to guide the management of EUHFs in clinical practice.

Abstract

BACKGROUND

Primiparas are usually at high risk of experiencing perinatal depression, which may cause prolonged labor, increased blood loss, and intensified pain, affecting maternal and fetal outcomes. Therefore, interventions are necessary to improve maternal and fetal outcomes and alleviate primiparas' negative emotions (NEs).

AIM

To discusses the impact of nursing responsibility in midwifery and postural and psychological interventions on maternal and fetal outcomes as well as primiparas' NEs.

METHODS

As participants, 115 primiparas admitted to Quanzhou Maternity and Child Healthcare Hospital between May 2020 and May 2022 were selected. Among them, 56 primiparas (control group, Con) were subjected to conventional midwifery and routine nursing. The remaining 59 (research group, Res) were subjected to the nursing model of midwifery and postural and psychological interventions. Both groups were comparatively analyzed from the perspectives of delivery mode (cesarean, natural, or forceps-assisted), maternal and fetal outcomes (uterine inertia, postpartum hemorrhage, placental abruption, neonatal pulmonary injury, and neonatal asphyxia), NEs (Hamilton Anxiety/Depression-rating Scale, HAMA/HAMD), labor duration, and nursing satisfaction.

RESULTS
The Res exhibited a markedly higher natural delivery rate and nursing satisfaction than the Con. Additionally, the Res indicated a lower incidence of adverse events (*e.g.*, uterine inertia, postpartum hemorrhage, placental abruption, neonatal lung injury, and neonatal asphyxia) and shortened duration of various stages of labor. It also showed statistically lower post-interventional HAMA and HAMD scores than the Con and pre-interventional values.

CONCLUSION
The nursing model of midwifery and postural and psychological interventions increase the natural delivery rate and reduce the duration of each labor stage. These are also conducive to improving maternal and fetal outcomes and mitigating primiparas' NEs and thus deserve popularity in clinical practice.

Key Words: Nursing model of midwifery; Postural intervention; Primipara; Maternal and fetal outcomes; Negative emotions

Core Tip: Primiparas are at high risk for depression during the perinatal period, which can lead to prolonged labor, increased blood loss, and intensified pain that can affect maternal and fetal outcomes. Therefore, it is necessary to give relevant interventions to improve maternal and fetal outcomes and alleviate negative emotions in primiparas.

INTRODUCTION

Primiparas and multiparas are often at a high risk of experiencing perinatal depression because of the significant physical and psychological burdens they encounter[1]. As reported, the incidence of depression is higher among primiparas than multiparas[2,3]. Clinically, primiparas often develop negative emotions (NEs), such as fear and anxiety, due to severe labor pain caused by inexperience during delivery[4]. Owing to this, mothers may suffer from a lack of strength or improper exertion, leading to prolonged labor, increased blood loss, and intensified pain[5,6]. The type of delivery can also affect maternal and fetal outcomes, with mothers undergoing cesarean section (CS) facing a higher risk of complications[7]. Thus, this study intends to mitigate the NEs of primiparas and improve maternal and fetal outcomes by combining the appropriate nursing model with certain interventions. This study also contributes toward the prevention of maternal complications as well as management optimization during clinical application.

Although routine midwifery and nursing aid primiparas, the quality across medical institutions may vary[8]. There is a need to improve the regulatory effect of routine nursing on maternal NEs[9]. Therefore, our research team adopted the care model of midwifery, a novel model of midwifery nurse practice that prioritizes the psychological and emotional state of mothers and is more humanized[10,11]. In the study on maternal care by Beecher *et al*[12], the improvement of maternal psychological quality under the midwifery responsibility system was demonstrated and its positive effect was affirmed. Besides, Wu *et al*[13] reported on the intervention of primary maternal care, pointing out that combining postural and breathing training under the original nursing model can effectively smoothen the delivery process and improve the outcomes of primiparas.

Currently, there are insufficient studies on the clinical application of the care model of midwifery as well as postural and psychological interventions in primipara nursing management, which is this study's focus. It explores and analyzes the same from the perspectives of delivery mode, maternal and fetal outcomes, NEs, labor duration, and nursing satisfaction. Its ultimate goal is to provide an effective clinical basis for the nursing management of primiparas and improve their delivery experience.

MATERIALS AND METHODS

Study participants

The study participants were 115 primiparas who visited the Quanzhou Maternity and Child Healthcare Hospital between May 2020 and May 2022. The control group (Con; n = 56) was subjected to conventional midwifery and routine nursing; the research group (Res; n = 59) was subjected to the nursing model of midwifery and postural and psychological interventions. Both groups had similar baseline (P > 0.05) and clinical comparability. The inclusion criteria were as follows: Primiparas with full-term pregnancy and normal pelvic diameter after measurement; single pregnancy, normal

fetal presentation, and priority for a vaginal birth; no high-risk maternal complications during pregnancy or pregnancy complications; and normal mental state and verbal communication ability. The exclusion criteria were as follows: Malignancies or organ dysfunction; conditions like nuchal cord, premature rupture of membranes, and amniotic fluid volume abnormality; history of uterine surgery; premature birth or post-term pregnancy; abnormal coagulation function; and autoimmune deficiency.

Methods

The Con was subjected to conventional midwifery and routine nursing. After admission, the midwives on duty provided services, such as routine fetal heart monitoring, maternal skin cleaning, labor process observation, and health guidance. There was no postural intervention during the labor period. The parturient was allowed to choose a comfortable posture, and the midwife delivered the baby after the cervix was fully dilated. Routine nursing measures were also provided.

The Res was subjected to the nursing model of midwifery and postural and psychological interventions. First, one-to-one nursing was provided to each primipara, and a private midwife was there to provide care and management throughout the process of labor preparation and delivery. This not only promoted mutual communication but also facilitated the collection of the primipara's information and the formulation and implementation of nursing strategies, thus improving the efficiency and experience of nursing. The main nursing and management provided by midwives included the following aspects: (1) Prenatal education: Midwives introduced perinatal knowledge to the parturients and informed them of the symptoms they may encounter during the perinatal period and the physiological process of delivery. Through videos and clinical demonstrations, mothers were instructed on pain relief in the first stage of labor through deep breathing, and proper force exertion in the second stage of labor to shorten the labor duration. Additionally, exchanges between multiparas and primiparas were arranged to impart childbirth experience to first-time mothers in order to strengthen their confidence; (2) Psychological intervention: By communicating with the parturients, the midwives evaluated the mothers' potential concerns, depression, fear, and other NEs; they encouraged the mothers to express their worries and provided one-on-one psychological counseling based on the mothers' personality traits and educational level. Furthermore, by enumerating the successful childbirth experiences of other parturients, the midwives enhanced the mothers' confidence in childbirth and relieved their unhealthy psychology; (3) Postural intervention: During the first stage of labor, the parturients were guided to take a free position, with their attention diverted. For mothers with half engagement of non-engagement of fetal presenting part, they were suggested to walk while supporting the belly to speed up the delivery. If the uterine orifice opening was 1-2 cm and the fetus was found to be in an occipital posterior position, the mother was instructed to assume the contralateral prone position during pregnancy, depending on the specific fixed position during pregnancy. During the second stage of labor when the fetal head descended slowly, the mother was instructed to squat according to the maternal situation; (4) Nursing during labor: During labor, the midwife paid close attention to the physical and mental condition of the mother and relieved contraction-induced pain by helping her wipe sweat, massaging the lower abdomen, and expressing encouragement. At the same time, the progress of labor was closely observed. In the case of increased maternal blood loss, uterine contraction weakness, prolonged second labor, fetal distress, and other conditions, the doctor was immediately reported to take timely corresponding measures; and (5) Postpartum care: After the fetus was delivered and processed, it was sent to the mother in time to guide and help early suckling. The newborn was observed in the infant room for two hours and was timely sent back to its mother if there was no abnormality. The midwives also closely observed the vital signs, uterine contraction, and mental state of the postpartum women, especially the amount of postpartum vaginal bleeding, and offered timely interventions when necessary.

Outcome measures

(1) Mode of delivery. The delivery modes of both groups, including CS, natural delivery, and forceps-assisted delivery (FAD), were observed and recorded; (2) Maternal and fetal outcomes. The maternal and fetal outcomes were compared, including uterine inertia, postpartum hemorrhage, placental abruption, neonatal lung injury, and neonatal asphyxia; (3) NEs. Maternal NEs were evaluated using the Hamilton Anxiety/Depression-rating Scale (HAMA/HAMD)[14]. HAMA has 14 assessment items, and HAMD has 24 assessment items; each item of both is graded from 0 to 4, with higher scores indicating more serious anxiety or depression symptoms; (4) Duration of labor. The duration of each stage of labor was recorded for comparative analysis; and (5) Nursing satisfaction. Patients were asked to fill in the self-made nursing satisfaction questionnaire of our hospital (0-100 points) to understand their satisfaction with the nursing services. Higher scores are indicative of better satisfaction, with a score of > 80 points, 60-80 points, and < 60 points representing satisfactory, basically satisfactory, and unsatisfactory, respectively.

Statistical processing and analysis

The number of cases/percentage (n, %) and the mean ± SEM were used to represent categorical and continuous variables, respectively. Among these, the χ^2 test was used to compare categorical data, and the independent sample t-test compared the continuous variables between the groups. In this study, the SPSS18.0 software package was used for statistical analysis, and a minimum significance level of $P < 0.05$ was used throughout.

RESULTS

General data of both groups

Both study groups were comparable in terms of age, gestational age, body mass index, smoking history, drinking history, educational level, and other general data ($P > 0.05$) (Table 1).

Delivery modes in both groups

According to the comparative analysis of the delivery modes (CS, natural delivery, and FAD), the Res had a higher natural delivery rate ($P < 0.05$), a lower CS rate ($P < 0.05$), and a comparable FAD rate than the Con ($P > 0.05$) (Table 2).

Maternal and fetal outcomes in both groups

Evaluating and comparing the maternal and fetal outcomes, such as uterine inertia, postpartum hemorrhage, placental abruption, neonatal lung injury, and neonatal asphyxia indicated that the incidence of adverse maternal and fetal outcomes described above was statistically lower in the Res ($P < 0.05$) (Table 3).

NEs of both groups

The assessment of maternal anxiety and depression using the HAMA and HAMD revealed that both scale scores were similar in the two groups before the interventions, but they significantly declined after corresponding interventions ($P < 0.05$), with even lower scores in the Res compared to the Con ($P < 0.05$) (Figure 1).

Labor duration in both groups

The time spent in the first, second, and third stages of labor was markedly shorter in the Res than the Con ($P < 0.05$) (Figure 2).

Patient satisfaction with nursing in both groups

Patient satisfaction with the care services was assessed using a self-developed nursing satisfaction questionnaire. The satisfaction of the Res was statistically higher compared to the Con (96.61% *vs* 82.14%, $P < 0.05$) (Table 4).

DISCUSSION

Labor is a physiological process a mother undergoes to deliver an infant, which is accompanied by pain and pressure [15]. Providing scientific and reasonable care management for primiparas is therefore of great value to improve their birthing experience and delivery outcomes. The mode of delivery affects not only maternal and infant health, but also the success rate of breastfeeding[16]. Specifically, although CS is devoid of childbirth pain, it is riskier for maternal and infant health compared to normal delivery; it is associated with a higher risk of maternal mortality and postoperative complications[17,18]. The analysis of delivery modes in this study revealed that the Res had a markedly higher natural delivery rate, a lower CS rate, and a comparable FAD rate than the Con, suggesting that the adoption of the nursing model of midwifery along with postural and psychological interventions can significantly improve the natural delivery rate in primiparas. This may be attributed to the postural guidance provided to the Res, which reduced the oppression of the uterus and the friction caused by the rotation of the carcass, thus ensuring natural delivery[19]. Furthermore, the statistics of maternal and fetal outcomes showed that the incidence of adverse events, such as uterine inertia, postpartum hemorrhage, placental abruption, neonatal lung injury, and neonatal asphyxia, was markedly lower in the Res than in the Con. Thus, the nursing model of midwifery along with postural and psychological interventions is conducive to reducing adverse maternal and fetal outcomes. Considering the potential occurrence of the aforementioned adverse events, this novel nursing model pays close attention to these events and entails timely treatment of such conditions throughout the labor process and postpartum care; this explains the low incidence of adverse events in the Res[20]. In the research of Zhang *et al*[21], continuous midwifery services, which also integrate health education, psychological interventions, and labor and postpartum care, not only elevate the natural delivery rate of primiparas but also significantly improve maternal and fetal outcomes, similar to our findings.

Primiparas are prone to anxiety, fear, and other NEs due to their lack of experience in childbirth; this can affect the progress of labor and the smooth delivery, making psychological interventions crucial[22]. In this study, the Res showed lower HAMA and HAMD scores than the Con after the interventions, indicating that the nursing model of midwifery along with postural and psychological interventions can significantly relieve anxiety, depression, and other NEs in primiparas. This may be related to the fact that the nursing model experienced by the Res included psychological interventions and the timely channelization of maternal NEs[23]. In terms of the labor process, the Con spent more time in the first, second, and third stages of labor than the Res, indicating that the labor process of primiparas is smoother when the nursing model of midwifery and postural and psychological interventions are adopted. In this study, the prenatal education in the nursing management model used in the Res provided primiparas with guidance on the possible problems and coping approaches during the labor process, which helps accelerate the progress of labor[24,25]. Finally, the evaluation of the nursing satisfaction questionnaire showed a satisfaction degree as high as 96.61% in the Res, demonstrating that the nursing model along with the interventions is more popular among first-time mothers and advantageous over the conventional model in clinical practice. Based on the one-to-one nursing model, this novel nursing model provides services, such as prenatal education, psychological and postural interventions, labor care, and

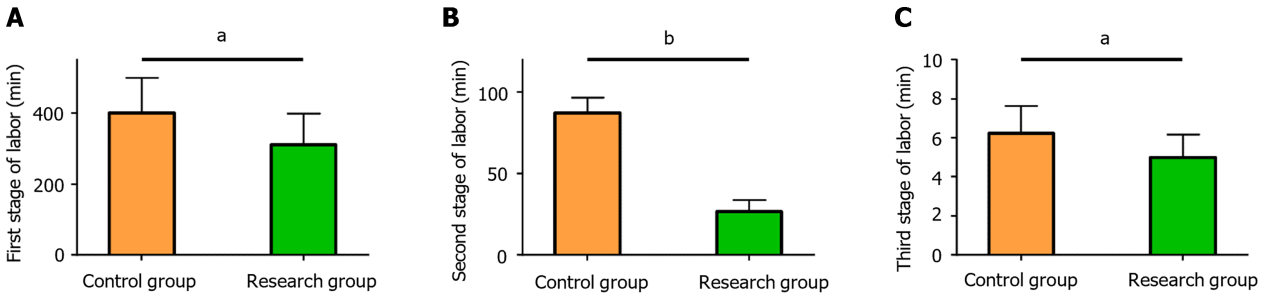
postpartum care for primiparas to improve their delivery experience, thus enhancing care quality and nursing satisfaction.



CONCLUSION

For primiparas, the nursing model of midwifery and postural and psychological interventions effectively improves maternal and fetal outcomes. Consequently, maternal anxiety and depression are alleviated, the natural delivery rate and nursing satisfaction increased, and the progress of labor is promoted. Therefore, this technique deserves clinical promotion.

ARTICLE HIGHLIGHTS

Research background

Parturients are physically and psychologically burdened during the perinatal period, so both primiparas and multiparas are at higher risk of depression. In addition, the mode of delivery of primiparas has an impact on maternal and infant outcomes, and those given birth by cesarean section (CS) are at a higher risk of complications.

Research motivation

To increase people's awareness of perinatal maternal management and provide reference for clinical care optimization of parturients during the perinatal period.

Research objectives

This study aims to analyze the effects of midwifery responsibility nursing plus postural interventions on maternal and fetal outcomes and negative emotions (NEs) of primiparas.

Research methods

In this study, 59 primiparas in the research group were treated by midwifery responsibility nursing plus posture interventions, and 56 primiparas in the control group were given conventional midwifery and routine nursing. The two groups were comparatively analyzed in terms of the mode of delivery, maternal and infant outcomes, NEs (Hamilton Anxiety/Depression-rating Scale, HAMA/HAMD), duration of labor, and nursing satisfaction.

Research results

Significantly higher natural delivery rate and nursing satisfaction, as well markedly lower CS and forceps delivery rates were determined in the research group compared with the control group; the research group also showed obviously lower incidence of uterine inertia, postpartum hemorrhage, placental abruption, neonatal lung injury, neonatal asphyxia and other events and shorter duration of each stage of labor than the control group; moreover, the HAMA and HAMD scores of the research group after intervention were significantly lower than those before treatment and in the control group.

Research conclusions

Midwifery responsibility nursing plus postural interventions is beneficial to improve maternal and infant outcomes, relieve maternal NEs, increase the rate of spontaneous labor, and shorten the duration of natural labor.

Research perspectives

This study mainly analyzes the application value of midwifery responsibility nursing plus postural intervention program in the care management of primiparas, focusing on the exploration and analysis of maternal and infant outcomes and NEs, in an attempt to provide an effective clinical basis for the care management of primiparas and contribute to improving their childbirth experience.

Abstract

BACKGROUND

Behavioral activation therapy (BA) is as effective as cognitive behavior therapy (CBT) in treating depression and can be delivered by practitioners with much less psychological training, making it particularly suitable for low resource settings. BA that is culturally adapted for Muslims (BA-M) is a culturally adapted form of BA that has been found acceptable and feasible for Muslims with depression in the United Kingdom and Turkey; however, this is the first time that its efficacy has been determined through a definitive randomized controlled trial.

AIM

To compare the effectiveness of BA-M with CBT for Muslim patients with depression in Pakistan.

METHODS

One hundred and eight patients were randomized 1:1 to treatment arms in a parallel-group randomized controlled trial in hospital or community sites in Lahore, Pakistan. Recruitment followed self-referral or referrals from clinicians, consultants or relevant professionals at each site. Four measures were recorded by blinded assessors: The patient health questionnaire-9 (PHQ-9); the BA for depression scale short form (BADS-SF); symptom checklist-revised and the World Health Organization Quality-of-Life Brief Scale. All measures were recorded at baseline and post treatment; PHQ-9 and BADS-SF were also recorded at each session and at three month follow up. The primary analysis was to regress the PHQ-9 score after therapy upon the PHQ-9 score before therapy (baseline) and the type of therapy given, that is, analysis of covariance. In addition, analysis using PHQ-9 scores collected at each therapy session was employed in a 2-level regression model.

RESULTS
Patients in the BA-M arm experienced greater improvement in PHQ-9 score of 1.95 units compared to the CBT arm after adjusting for baseline values (P = 0.006) The key reason behind this improvement was that patients were retained in therapy longer under BA-M, in which patients were retained for an average 0.75 sessions more than CBT patients (P = 0.013). Patients also showed significant differences on physical (P < 0.001), psychological (P = 0.004) and social (P = 0.047) domains of Quality of Life (QoL) at post treatment level, indicating an increased QoL in the BA-M group as compared to the treatment as usual group. Some baseline differences were noted in both groups for BA scores and two domains of QoL scale: Physical and environment, which might have influenced the results, though the BA-M group showed more improvement at completion of therapy.

CONCLUSION
Results proved the efficacy of BA-M in reducing symptoms for depressed patients in Pakistan, indicating BA-M is a promising treatment modality for depression in future, particularly in low resource settings.

Core Tip: Behavioral activation therapy that is culturally adapted for Muslims (BA-M) is a more effective treatment for depression in comparison to cognitive behavior therapy (CBT) for Muslim populations within the Pakistani cultural context. Increased engagement with the therapy appears to be the key reason for the significantly lower depression scores of patients receiving BA-M. As this treatment can be delivered by practitioners with much less psychological training than CBT, it is particularly suitable for Muslim patients in low resource settings.

INTRODUCTION

Depression is a mood disorder with widespread occurrence throughout the world[1,2], affecting more than 300 million people around the globe according to World Health Organization (WHO) estimates. It is ranked as the largest cause of disability worldwide, with more than 4% global prevalence and an upward trend in developing countries, with almost half of cases occurring in South-East Asia[3]. In Pakistan, the risk of developing depression is 10%-25% higher for women than for men and this can be further increased by infertility[4], having a disabled child, emotional setbacks or family issues and disputes[5]. Depression can have a strong impact on family members as well as on the individual with depression[6]. Recorded rates of prevalence for maternal depression in Pakistan are among the highest globally at 28%–36%[7,8] and children of depressed mothers in this context are at an increased risk of being underweight, having poor health with more frequent episodes of diarrhea compared to the children of non-depressed mothers[8,9]. A strong relationship between infertility and psychological comorbidities has also been found[10] and evidence suggests that poverty is strongly linked with depression with almost 50% of low income mothers likely to be depressed[11]. This evidence highlights the need for a cost-effective treatment for depression in Pakistan. Interventions are needed to increase access to treatment and reduce the personal as well as social costs of depression, including impact on daily life, upbringing of children and loss in productivity, such as time taken off from work[12].

Despite the availability of a number of evidence-based therapies for depression, such as cognitive behavioral therapy (CBT), behavioral activation (BA), acceptance and commitment therapy (ACT) and exposure-based therapy[13-15], there is a growing body of empirical evidence about the need for, and effectiveness of, culturally adapted and religion-sensitive therapies[16]. Literature in this area shows that interventions that focus on culture and faith can effectively reduce depression and improve quality of life (QoL)[17,18]. Sensitivity to religious beliefs as a resource for health has been integrated into therapies such as CBT[17,19,20]; counseling[21,22]; ACT[23]; and trauma related therapies[24]. Integrating religious coping in adapted versions of such therapies has proved as effective as existing treatments and faith-adapted therapies have shown more positive results in the management of depressive symptoms in Muslim clients[25,26].

BA that is culturally adapted for Muslims (BA-M), developed for United Kingdom-based Muslim communities, is a successful faith-sensitive adaptation of an existing psychological treatment[27,28]. BA-M therapy is based on BA, an existing evidence-based psychosocial treatment for depression that focuses on clients' values and links these with behavioral goals[29-31]. Piloting of this adapted version has shown that BA-M was feasible within a United Kingdom healthcare setting and was very positively received by Muslim clients[28]. The inclusion of 'client values' in therapy makes BA a particularly suitable treatment for adaptation to diverse cultural needs and it has been successfully adapted and tailored to multiple cultural contexts across the globe[32-34]. The present research is the first study globally to assess

the efficacy of BA-M through a randomized controlled trial with adult depressed patients. The trial was conducted in Pakistan, a low income setting in which the approach was considered relevant for the majority of the population.

MATERIALS AND METHODS

A three-center two-arm parallel block-randomized controlled trial was conducted to estimate the effectiveness of BA-M to treat depression in Pakistan compared to treatment as usual (TAU) using a 1:1 allocation ratio. Patients were allocated at each center in blocks of two with one being randomized to TAU and the other allocated to treatment by BA-M (BA culturally adapted to Muslim faith). There were no changes to the recruitment procedure or methods during the trial. The trial was registered with ISRCTN. Ethical approval was granted by the Faculty of Medicine and Health Ethics Committee at the University of Leeds and the National Bioethics Committee, Pakistan.

Participants

Patients with depression were recruited from outpatient departments of three targeted data sites in Lahore, Pakistan: Mayo Hospital (Mayo), Punjab Institute of Mental Health (PIMH) and the Centre for Clinical Psychology, University of the Punjab, Lahore (CCP). Recruitment followed self-referral or referrals from clinicians, consultants or relevant professionals at each site. All patients were over 18 years of age.

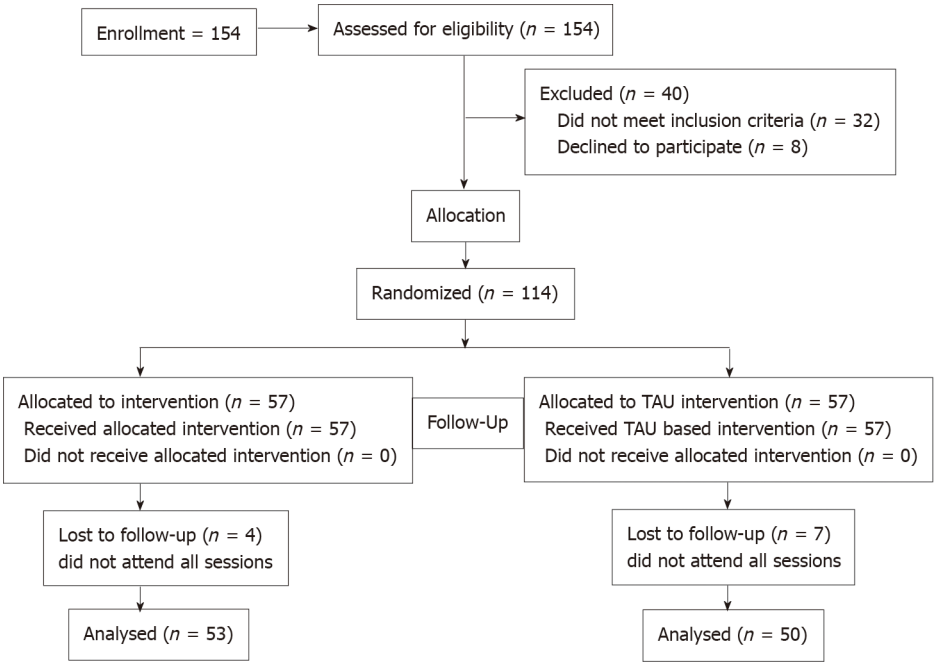
Assessment measures

An Urdu version of the patient health questionnaire (PHQ-9) was used to screen for depression[35] alongside the symptom checklist-revised (SCL-R) - an indigenous screening tool for which psychometric properties are well established [36]. Patients were invited to take part in the trial if their depression score on PHQ-9 was at least 10 and if they had no comorbid psychological disorders, such as bipolar disorder or schizophrenia, could understand the study measures and could give informed consent.

Intervention

Patients were randomized to receive either TAU, which was CBT at each site, or BA, adapted to meet the needs of Muslims patients (BA-M). TAU comprised of 8 sessions of CBT.

BA-M is a culturally tailored version of BA, an existing evidence-based psychosocial treatment for depression, which is as effective as CBT but requires less practitioner training[37]. BA-M comprises 6–12 sessions of treatment involving a values assessment. Muslim clients who select religion as a personal value during this assessment are offered the choice of using a self-help booklet designed to help their recovery[27]. The booklet draws on Islamic religious teachings to promote therapeutic goals and 'positive religious coping' that supports resilience, hopefulness and self-esteem[38]. Patients were treated in outpatient clinics at the three sites following referrals to clinical psychologists involved in delivering the intervention for the trial.



Outcomes

A demographic information sheet with details of age, gender, education, birth order, family income and type, psychological illness, physical illness, current diagnosis and history of treatment related to psychological issues was administered to each recruited patient. The primary outcome, on which the trial was powered, was the change in PHQ-9 score following therapy, that is, the difference between the PHQ-9 score after therapy and that recorded before therapy commenced. The PHQ-9 measure was used to assess depression and determined the extent to which patients had experienced depressive symptoms over the previous two weeks. The nine items were rated on a 0-3 scale ranging from 'not at all' to 'nearly every day'. The PHQ-9 has adequate construct validity and sensitivity to change[39]. In the present study, the Urdu translated version of PHQ-9 was used[7].

There were several secondary outcomes collected to provide greater understanding of the performance of BA-M as a therapy. PHQ-9 was collected not just at baseline and at the end of treatment but at the start of every therapy session. Two other measures were collected before and after therapy. The 9-item BA for depression scale short form (BADS-SF) was used to track activation, including when and how clients became activated during the course of treatment. This measure was developed to improve the original BADS measure and has stronger psychometric properties[40]. The SCL-R [36] is an indigenous checklist which assesses six psychopathologies: Depression, anxiety, obsessive compulsive disorder, somatization, schizophrenia and low frustration tolerance. In the present study, the subscale of depression with 24 items was used to assess the degree of depression in depressed patients. The items are rated on a 4-point Likert scale and psychometric properties are well established for all subscales of SCL-R. A fourth measure, the WHO QoL Brief Scale (WHOQOL-BREF)[41], developed by the WHO with 26 items, was used to assess QoL in depressed patients. This covers 4 major domains: physical health, psychological health, social relationships and environment. One item from each of the 24 facets contained in the WHOQOL-100 was included along with two items from the overall QoL and the general health facets. A further outcome measure was the number of sessions attended by each patient to assess patient engagement with therapy.

Sample size

Power calculations for the sample were based on change in PHQ-9 from baseline (PHQ-9-0) to 3 mo after therapy (PHQ-9-3). Drawing on earlier research, we anticipated that PHQ-9 would have a standard deviation of 5 units and that the

DOI: 10.5498/wjp.v13.i8.511 **Copyright** ©The Author(s) 2023.

Figure 1 Flow diagram representing process of the study. TAU: Treatment as usual.

correlation between before and after measurements would be 0.75. Consequently, we anticipated that the difference between PHQ-9-3 and PHQ-9-0 would have a standard deviation of 3.54 units[42]. A minimal clinically important difference in PHQ scores was considered to be 2 units on PHQ-9. Using a two-sample *t*-test to assess the difference between the groups, with 5% significance level, the number required to achieve 80% power is 50 patients per group. It was anticipated that around 15% patients would drop out of the trial before the completion of therapy. Adjusting for drop out thus yielded a sample size of 59 patients per group.

Randomization

At each site, patients were recruited in pairs by a blind assessor who screened for depression and assigned individuals from each pair at random (using a Microsoft Excel random number generator value below 0.5) to TAU or BA-M. This ensured a random sample balanced for each site and for therapy. It was not possible to conceal the randomization from either the patient or those delivering therapy.

Statistical methods

The primary analysis was to regress the PHQ-9 score after therapy upon the PHQ-9 score before therapy (baseline) and the type of therapy given. This analysis of covariance approach was considered to be the optimum statistical method for the analysis of continuous outcomes of randomized control trials (RCTs) where baseline measurements are available[43].

Analysis was undertaken on a complete case basis and the implication for bias due to drop out was considered through analysis of the secondary outcomes. It was not appropriate to assume that data was missing at random since patients may have withdrawn from the trial or from therapy because they were either dissatisfied with their progress through therapy or improved so much that they considered that therapy was no longer required. Hence imputation methods which are valid under the assumption of missing at random were not appropriate here.

As a secondary analysis of PHQ-9, all of the measurements made were considered in a two- level regression analysis with measurements nested within patients by the inclusion of a random intercept for patient. This provided the average change in score per session for each of the two therapies. A Wald test for the interaction term made it possible to formally test if there was a difference in therapy per session.

The average number of sessions attended for each arm was compared with a two-sample *t*-test to explore the duration of the therapy in each arm. Other secondary outcomes, namely BADS-SF, the total SCL-R score, and the four domains of WHOQOL-BREF were compared with analysis of covariance, as for the primary analysis of PHQ-9.

RESULTS

Participant flow

For each group, TAU and BA-M, the numbers of participants who were randomly assigned, received intended treatment and were analyzed for the primary outcome, namely change in PHQ-9 after treatment, is shown in Figure 1.

Table 1 Baseline characteristics of patients stratified by therapy arm

Recruitment

The first patient was recruited in March 2020 and recruitment continued until at least 59 patients completed their therapy in each arm. Recruitment was then closed in August 2021, having established that at least 50 patients had been recruited and retained until the end of therapy.

Baseline data

Characteristics between the two groups were similar (Table 1) apart from the initial BADS-SF score and the initial values of the D2 (psychological health) and D4 (environment) domains of WHOQOL-BREF. Analysis methods were designed to adjust for these baseline imbalances.

Drop out

Seven of 57 patients assigned to TAU and 4 of 57 patients assigned to BA-M withdrew from the trial. Data after baseline collection was not available for analysis for these patients. Table 2 shows the characteristics of patients who were lost to follow up compared to those who were retained.

SES: Socioeconomic status; FA/A: Upper secondary level education; PHQ: Patient health questionnaire; BADS: Behavioral activation for depression scale short form; SCL-R: Symptom checklist-revised; D: Domain; Dep: Depression

Male patients and those in nuclear families were seen to be more susceptible to drop out. Feedback from therapists indicated that therapy sessions during working hours were more likely to adversely affect attendance by men and the average baseline SCL-R value was also lower among drop outs, indicating less severe depressive symptoms in this group. Data for 50 TAU patients and 53 BA-M patients was available for analysis.

Outcomes and estimation

A summary of the outcome variables after therapy is provided in Table 3. This provides unadjusted *t*-test comparisons of the outcomes between groups. Significant post treatment differences in depression ($P = 0.006$) and QoL scores were found in the BA group compared to TAU following completion of treatment.

The primary outcome (PHQ-9) was also regressed upon baseline values and therapy arm and the table of regression coefficients is given in Table 4.

From the coefficients in Table 4, it is seen that generally those in the TAU arm have higher PHQ-9 scores after therapy and that an adjustment for baseline values of PHQ-9 is important since the coefficient is statistically significant at the 5% level. Plots of residuals (not shown due to space limitations) were seen as satisfactory. The interpretation for this trial based on the primary analysis is that BA-M is associated with a greater reduction in depression symptoms as measured by PHQ-9 after completion of therapy.

Further analyses

The analysis of secondary outcomes BADS-SF and SCL-R are summarized in Table 5.

Table 3 Summary of outcome after therapy

Characteristics	BA-M	TAU	*P* value
n	57	57	
Drop Out	4 (7%)	7 (12%)	0.526
Retained	53 (93%)	50 (88%)	
PHQ (Post), mean (SD)	4.19 (3.42)	6.18 (3.85)	0.006

Table 4 Coefficients for the regression of the patient health questionnaire-9 post-therapy measurement on baseline and therapy arm

Characteristics	Estimate	95%CI	*P* value
Intercept	1.205	(-1.887, 4.298)	0.441
TAU Arm	1.946	(0.545, 3.347)	0.007
Baseline PHQ	0.152	(0.002, 0.301)	0.046

TAU: Treatment as usual; PHQ: Patient health questionnaire.

As the PHQ-9 tool was used at every therapy session, more detailed longitudinal data was available. Values are plotted in Figure 2.

Figure 2 shows that the PHQ-9 trajectories might be simply modeled with a linear decrease by session. This was undertaken with a linear mixed effects model with a random intercept for patient. The coefficients are shown in Table 6.

The results revealed that the interpretation of the coefficients in Table 6 showed a decline in PHQ-9 of 2.26 points on average for every session attended and there is little evidence of BA-M being superior to TAU on this basis. The reason behind the statistically significant improvement due to BA-M therapy rather than TAU, as seen in the analysis of primary outcome, is that patients under BA-M are retained in therapy longer. Table 3 also shows that the mean number of sessions attended increases from 8.25 under TAU to 9.00 under BA-M ($P = 0.013$).

DISCUSSION

This is the first trial evaluation of the BA-M culturally adapted therapy for depression globally. Previous evaluations have shown feasibility and acceptability to therapists and patients in both United Kingdom[27] and Turkish settings[44]. Findings confirm the importance of culturally adapted approaches when delivering mental health therapies developed in Western contexts to non-Western populations[16] and the benefits of faith-sensitive approaches in general[25]. The results of the current study support the efficacy of BA-M therapy in line with the wider literature on BA as a cost-effective and efficacious alternative to CBT[45]. Patients in the BA-M group showed lower levels of depression (PHQ-9 and SCL-R) and higher scores of BA (BADS-SF) post treatment, indicating the effectiveness of BA-M therapy in reducing depression and increasing helpful activity in patients. Patients also showed significant differences on physical ($P < 0.001$), psychological ($P = 0.004$) and social ($P = 0.047$) domains of QoL at post treatment level, indicating an increased QoL in the BA-M group as compared to the TAU group.

Retention in BA-M therapy

Fewer patients dropped out of the BA-M group than from the TAU group and this was seen to lead to greater benefit since the improvement in symptoms per session was consistent throughout the usual therapy period of 8 wk. Patients who dropped out tended to have low scores on the depression scale as compared to those who were retained. The results

also showed that men and those who were living in nuclear families were found to be more susceptible to drop out.

The particular benefits of BA-M appear to have been achieved as a result of patient retention in therapy and this is an important factor in recovery from depression. As in the United Kingdom study for BA-M[27], the faith-sensitive approach appears to have a motivating influence on patients. Qualitative findings from the United Kingdom study indicated that most patients were enthusiastic about and motivated by the engagement with religious identity in this approach. This was designed to support 'positive religious coping' that increased resilience, hope and self-esteem[38]. The findings confirm previous research, both on value-based practice that takes account of cultural context and on BA, which partic-

Figure 2 Plot of patient health questionnaire-9 values observed at every therapy session. BA: Behavioral activation therapy; TAU: Treatment as usual; PHQ: Patient health questionnaire.

ularly focuses on increasing activities that are linked to an individual's values and reward systems, consequently enhancing their behavioral patterns and reducing depressive symptoms[46,47].

We note there were important baseline differences in both groups for BA scores and two domains of QoL scale: Physical and Environment. The BA-M group showed more BA and QoL related to physical health and environment as compared to the TAU group. These may have influenced findings although it is clear that there was greater improvement in physical, psychological and social QoL domains for the BA-M group at completion of treatment.

There were also gender differences in retained and dropped out patients as 82% of dropped out patients were men. Differences in the family system of patients were also apparent as 91% of dropped out patients were from nuclear families.

CONCLUSION

In conclusion, this RCT demonstrated the benefit of BA-M, a culturally adapted form of BA, over usual treatment (CBT) at the end of therapy. It is clear that both CBT and BA-M are successful therapies for reducing depression, however, findings suggest that the additional benefit of BA-M is due to greater retention of participants in therapy that is likely to be due to the cultural adaptation. The trial confirms existing evidence on the benefits of therapy that supports activation of religious behaviors as a resource for health and fulfills the need for rigorous research in a population sample that has hitherto been underrepresented and for whom such behaviors may be critical to treatment outcomes[48].

ARTICLE HIGHLIGHTS

Research background

Depression is the largest cause of disability worldwide and can strongly impact on families and society as well as individuals. Culturally appropriate, accessible and cost-effective treatments are needed in low resource settings such as Pakistan. This study is the first randomized control trial globally of behavioral activation (BA) therapy that is culturally adapted for Muslim patients (BA-M).

Research motivation

The main focus was to explore whether BA-M, as a culturally adapted therapy, would achieve better results than

cognitive behavior therapy (CBT), a standard treatment developed in a Western context. BA can be delivered by practitioners with much less psychological training than CBT, making it particularly suitable for low resource settings. This research has great significance for future studies on how to reduce depression and increase access to treatment for Muslim communities worldwide.

Research objectives

The purpose of the study was to compare the effectiveness of BA-M with CBT for Muslim patients in Pakistan.

Research methods

Clinical data were analyzed for 108 patients in a parallel-group randomized controlled trial in hospital or community sites in Lahore, Pakistan. Four measures were recorded by blinded assessors: The patient health questionnaire-9 (PHQ-9); the BA for depression scale short form (BADS-SF); symptom checklist-revised and the WHOQOL-BREF quality of life (QoL) scale. All measures were recorded at baseline and post treatment; PHQ-9 and BADS-SF were also recorded at each session and at three month follow up. The primary analysis was to regress the PHQ-9 score after therapy upon the PHQ-9 score before therapy (baseline) and the type of therapy given. In addition, analysis using PHQ-9 scores collected at each therapy session was employed in a 2-level regression model.

Research results

Patients in the BA-M arm experienced greater improvement in PHQ-9 score compared to the CBT arm and were retained in therapy longer than those receiving CBT after adjusting for baseline values. BA-M patients also showed significant differences on physical, psychological and social domains of QoL at post treatment level, indicating an increased QoL in the BA-M group as compared to the CBT group.

Research conclusions

BA-M is a culturally appropriate treatment for depression that achieves better results than CBT, which is current standard treatment in Pakistan. BA-M can be delivered by practitioners with much less psychological training than CBT and is a promising treatment modality for depression in Muslim communities, particularly in low resource settings.

Research perspectives

Future research should evaluate acceptability and effectiveness of BA-M in other Muslim populations, including where these constitute minorities, and issues related to implementation and scale-up.

ACKNOWLEDGEMENTS

The researchers gratefully acknowledge the contribution of participants, blind reviewers and therapists at data sites.

Abstract

BACKGROUND

Sport help promote healthy physical and mental development of high school students. To date, there have been few studies on the effect of sport on school adaptability, resilience and cell phone addiction tendency of high school students.

AIM

To explore the effects of sports on school adaptability, resilience and cell phone addiction of high school students.

METHODS

A stratified random sampling method was used to select 600 students from two high schools in Lhasa, and Physical Activity Rating Scale, School Adjustment Scale for High School Students, Chinese Adolescents Resilience Scale, and Mobile Phone Addiction Index were used for field questionnaire survey.

RESULTS

Sport was positively correlated with school adaptability and resilience ($P < 0.01$), school adaptability was positively correlated with resilience ($P < 0.01$) and cell phone addiction was negatively correlated with sports, school adaptability and resilience ($P < 0.01$). The direct effect of sport on cell phone addiction was significant ($P < 0.001$), accounting for 20.51% of the total effect. The mediating effect of school adaptability on sport and cell phone addiction was significant ($P < 0.001$), accounting for 17.38% and 35.36% of the total effect value, respectively. School adjustment and resilience had a significant chain-mediated effect on sport and cell phone addiction ($P < 0.001$), accounting for 26.75% of the total effect.

CONCLUSION
Sport affected the cell phone addiction tendency of senior high school students through the mediating effect of school adaptability and resilience, and through the chain mediation effect of both.

Key Words: Sport; High school students; School adaptability; Resilience; Cell phone addiction

Core Tip: Sport is beneficial to the development of heart and lung function and motor system, and can develop physical strength and promote mental health. This study analyzed the questionnaire data of 560 high school students' sporting activity, school adaptability, resilience and cell phone addiction tendency. By constructing a chain mediation model, the relationship between sport and school adaptability, resilience and cell phone addiction tendency was obtained, providing a theoretical basis for the physical and mental health development of high school students.

INTRODUCTION

High school students are in a stage of growth and development, and sport plays a particularly important role in promoting their physical and mental health[1]. However, many high school students neglect sport because they study all day under academic pressure or are addicted to their cell phones[2,3]. The decline in sport could have a negative effect on physical and mental health of high school students[4]. Sport can improve high school students' adaptability to school, which can promote interpersonal relations and enthusiasm for learning[5]. Sport can enhance the resilience of high school students, and help them to face the pressure and difficulties brought by school life with a more positive and optimistic attitude[6]. Sport is also linked to lower levels of cell phone addiction among senior high school students[7]. Although many studies have shown that sport has an impact on school adaptability, resilience and cell phone addiction of adolescent students[8-11], few studies have combined sport with these other aspects in high school students. Therefore, by establishing the amount of sport of high school students, we analyzed the relationship between sport and senior high school students' school adaptability, resilience and cell phone addiction tendency. We also discussed the influence of sport on high school students' school adaptability, resilience and cell phone addiction tendency.

MATERIALS AND METHODS

Research object

From March to June 2022, a questionnaire survey was conducted among students from two high schools in Lhasa using stratified random sampling. A total of 600 students were selected according to different grades, and 200 in each grade were selected. The mean age was 16.56 years ± 1.01 years. There were 320 male students (53.33%) with an average age of 16.58 years ± 1.0 years. There were 280 female students (46.67%) with an average age of 16.53 years ± 1.04 years. We included senior grade one, two and three students, and students gave informed consent to complete the questionnaire. We excluded students with poor physical and mental health, and those who were unable to cooperate with the questionnaire. This study is in accordance with the Declaration of Helsinki.

Questionnaire

The questionnaire was conducted with the consent of the students, their parents and the school. Before the test, a mental health professional instructed the students to fill in the questionnaire according to their own situation. After filling in the questionnaire, it was recovered immediately. Six hundred questionnaires were sent out, and 560 (93.33%) were collected.

Research tools

Physical activity rating scale: The Physical Activity scale modified by Liang *et al*[12] was adopted, which measured sport from three dimensions of participation; namely time, intensity and frequency. Score = sport intensity score "(sport time score-1)" sport frequency score. Each dimension was divided into five grades, scoring 1-5 points. Scores ranged from 0 to 100: Low level of sport ≤ 19 points; level 20-42 points, and high level ≥ 43 points. Cronbach's α was 0.82.

School adjustment scale: We used Hou *et al*[13] School Adjustment Scale for Senior High School Students. The scale consisted of 82 items, including seven dimensions of academic adjustment, peer relationship, school attitude, class

activity adjustment, emotional adjustment, conflict in teacher-student relationship, and intimacy of teacher-student relationship. A 5-point Likert 5 scale was used. Scores ranged from 1 to 5. All dimensions were added together to obtain the School Adaptation Score. A higher total score indicated better school adaptability. Cronbach's α was 0.964.

Resilience scale for Chinese adolescents: Hu *et al*[14] compiled the Resilience Scale for Chinese adolescents. The scale consisted of 27 items, including five dimensions: Goal focus, positive cognition, emotional control, family support, and interpersonal assistance. The scale used a 5-point Likert scoring method. Scores ranged from 1 to 5, and a higher total score indicated greater resilience. Cronbach's α was 0.86.

Mobile phone addiction index: The Mobile Phone Addiction Index was compiled by Leung[15]. There were 17 items, including four dimensions: Loss of control, withdrawal, inefficiency and escape. A 5-point Likert scoring method was used. Scores ranged from 1 to 5, and a score < 34 was considered to show no cell phone addiction, 34-51 mild addiction, 52-68 addiction, and 68-85 severe addiction. Cronbach's α was 0.90.

Statistical analysis

SPSS 26.0 statistical software was used for data analysis. Descriptive statistics, *t* test, analysis of variance, and correlation analysis were conducted on the collected data, and PROCESS was used to test the mediating effect. The statistical significance was $P < 0.05$.

RESULTS

Essential features of senior high school sport

The total score for level of sport in high school students was 16 (6, 30) points (Table 1). The level of sport of high school students was mostly in the low sport level, accounting for 59.29% of the total number.

The level of sport among high school students was significantly higher in male than female students ($P < 0.05$) (Table 2). Sport intensity, time and frequency and total score were also significantly higher in male students ($P < 0.05$), indicating that male students had a greater need of sport.

There were no significant differences in sport intensity, time and frequency in senior grade one, two and three students ($P > 0.05$) (Figure 1).

Among the 560 high school students participating in the survey 332 (59.29%) had a low level of sport, 144 (25.71%) had a medium level, and 84 (15%) had a high level (Table 1). Among the 300 male students, 157 (52.33%) had a low level of sport, 82 (27.33%) had a medium level, and 61 (20.34%) had a high level. Among the 260 female students, 175 (67.31%) had a low level of sport, 62 (23.85%) had a medium level, and 23 (8.84%) had a high level. Among the 184 senior grade 1 high school students, 107 (58.15%) had a low level of sport, 53 (24.81%) had a medium level, and 24 (13.04%) had a high level. Among the 192 senior grade two students, 115 (59.90%) had a low level of sport, 46 (23.96%) had a medium level, and 31 (16.14%) had a high level. Among the 184 senior grade 3 students, 110 (59.78%) had a low level of sport, 45 (24.46%) had a medium level, and 29 (15.76%) had a high level.

Specific analysis of different levels of sports in senior high school sports

As shown in Tables 3-5, there was no significant difference in gender and grade among high school students of low, medium and high sports levels ($P > 0.05$), indicating that there was no gender and grade difference between high school students at the same sports level. Therefore, the following analysis was performed in three groups of high school students at low, medium and high sports levels to analyze resilience, school adaptability and cell phone addiction tendency.

Effect of level of sport on school adaptability of high school students

There were significant differences in the scores for academic adjustment, peer relationship, school attitude, class activity adjustment, emotional adjustment, conflict in teacher-student relationship, intimacy of teacher-student relationship when comparing low, medium and high levels of sport ($P < 0.05$) (Figure 2A). There were significant differences in the seven dimensions of school adaptability between students with low and medium levels of sport, low and high levels of sport, and medium and high levels of sport ($P < 0.05$).

Effect of level of sport on resilience of high school students

The total scores for goal focus, positive cognition, emotional control, family support, and interpersonal assistance were significantly different between students with low, medium and high levels of sport ($P < 0.05$) (Figure 2B). There were significant differences between these five dimensions when comparing students with low and medium levels of sport, low and high levels of sport, and medium and high levels of sport ($P < 0.05$).

Effect of level of sport on cell phone addiction tendency of high school students

There were significant differences in loss of control, withdrawal, escape, and inefficiency among students with low, medium and high levels of sport ($P < 0.05$) (Figure 2C). There were significant differences in these four dimensions of cell phone addiction tendency between students with low and medium levels of sport, low and high levels of sport, and medium and high levels of sport ($P < 0.05$).

Table 1 Analysis of characteristics of different levels of sport

	Low level (≤ 19 points)	Medium level (20-42 points)	High level (≥ 43 points)	Total
Score (point)				
Intensity	3 (2, 3)	3 (3, 4)	4 (3, 5)	3 (2, 4)

Correlation analysis of level of sport with school adaptability, resilience and cell phone addiction tendency among high school students

Level of sport was positively correlated with school adaptability and resilience ($P < 0.01$); school adaptability was positively correlated with resilience ($P < 0.01$); and cell phone addiction was negatively correlated with sports, school adaptability and resilience ($P < 0.01$) (Table 6).

Table 4 Effect of gender and grade among high school students with medium level of sport

	Intensity	Time	Frequency	Total score
Male	3 (3, 5)	4 (3, 5)	3 (3, 4)	30 (24, 32)
Female	3 (2, 4)	3 (3, 4)	3.5 (3, 4)	24 (24, 36)

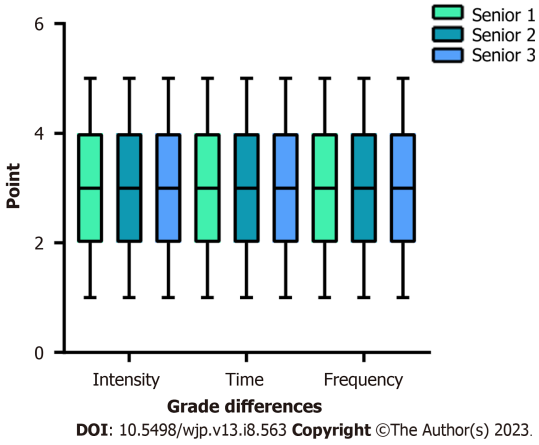
[b]$P < 0.01$ (two-tailed).

Analysis of the mediating effects of sport and school adaptability, resilience and cell phone addiction among senior high school students

The Bootstrap method was used to test for mediation effect, so as to prove the degree of influence among dependent, independent and mediating variables. The direct effect of sport on cell phone addiction was significant ($P < 0.001$), accounting for 20.51% of the total effect (Figure 3; Table 7). The mediating effect of school adaptability on sport and cell phone addiction was significant ($P < 0.001$), accounting for 17.38% and 35.36% of the total effect value, respectively. School adjustment and resilience had a significant chain-mediated effect between sport and cell phone addiction ($P < 0.001$), accounting for 26.75% of the total effect.



DISCUSSION

We used a field questionnaire survey to collect data on the level of sport, school adaptability, resilience and cell phone

Table 7 Test results of mediating effect

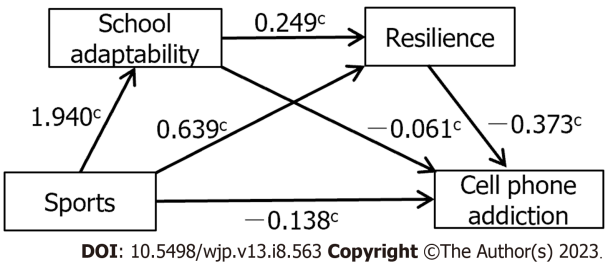
Figure 1 Differences in level of sport of high school students according to grade.



addiction tendency of senior high school students. Through correlation analysis, a chain mediation effect model was constructed to deeply analyze the influence of sports on school adaptability, resilience and cell phone addiction tendency of senior high school students.

The overall level of sport of high school students reached the medium level, and the level of sport differed significantly by gender, but not by grade. In terms of school adaptability, resilience and cell phone addiction tendency, there were significant differences among low, medium and high levels of sport. There was a positive correlation between level of sport, school adaptability and resilience, and a negative correlation between cell phone addiction and level of sport, school adaptability and resilience. Level of sport had a significant direct effect on cell phone addiction, and school adaptability had a significant mediating effect on level of sport and cell phone addiction. There was a significant mediating effect of resilience between level of sport and cell phone addiction. School adjustment and resilience had significant chain-mediated effects between level of sport and cell phone addiction. Previous studies have shown a significant positive correlation between level of sport and school adaptability[16]. This shows that sports can enhance high school students' adaptability to school, help them establish good interpersonal relationships in school, promote their physical and mental health, and better adapt to the school environment. Similarly, other results show that there is a significant positive correlation between sport and resilience[17], indicating that increasing level of sport is the key to improving the resilience of senior high school students[18]. There was also a significant positive correlation between school adaptability and resilience, indicating that high school students with stronger school adaptability had greater resilience. This is conducive for high school students to cope with various difficulties and setbacks encountered in school or life, and to better complete their studies and develop their social ability in the future[19]. A previous study has shown that sports have a significant negative correlation with cell phone addiction tendency of college students[20], and the results of this study show that sports have a significant negative correlation with cell phone addiction tendency of high school students, which is similar to the results of the present study, indicating that sports can indeed improve the extent of cell phone addiction of senior high school students[21]. Sport can enhance the interpersonal interaction between high school students and their peers, teachers and parents, thus enriching their emotional and social needs, so as to reduce the need to use cell phones for social interaction, thereby preventing cell phone addiction[22]. Analysis of the chain mediation effect model of sport, school adaptability, resilience and cell phone addiction showed that the increase in level of sport improved school adaptability of high school students, and their level of resilience, and reduced their cell phone addiction tendency. Increased level of sport also improved high school students' adaptability or resilience, and reduced their cell phone addiction tendency. Improvement of school adaptability is accompanied by improvement of resilience, which can ultimately reduce cell phone addiction tendency of high school students. Therefore, in order to better develop

Figure 3 Chain mediation effect model. $^{c}P < 0.001$.

the mental and physical health of high school students, schools should raise awareness of the importance of sport. Schools should strengthen sports facilities, provide professional guidance and management of sporting activities, and formulate relevant policies to ensure participation in sport, to help high school students participate in school life in a positive manner, eliminate negative emotions, and enhance ability to withstand pressure. Meanwhile, high school students can reduce their dependence on cell phones and improve their physical and mental development[23].

This study had some limitations. The study sample was not comprehensive enough to represent all high school students, so the results have some limitations. The questionnaire survey was a cross-sectional study, which lacked longit-

udinal data and follow-up survey. The longitudinal data and follow-up survey can be combined to further study the relationship between high school students' level of sport, school adaptability, resilience and cell phone addiction tendency, so as to research on the influence of enriching sports on high school students' school adaptability, resilience and cell phone addiction tendency[24,25].

CONCLUSION

Sport can directly affect school adaptability, resilience and cell phone addiction tendency of senior high school students. Sport can affect cell phone addiction tendency through the mediating effect of school adaptability and resilience, and through the chain mediation effect of both.

ARTICLE HIGHLIGHTS

Research background

High school students are in an important stage of physical development. Sport can promote the healthy physical and mental development of high school students, help them adapt to the school environment, relieve study pressure, reduce the level of stress, and reduce cell phone addiction, which are important for healthy physical and mental development.

Research motivation

This study investigated the influence of sport on school adaptability, resilience and cell phone addiction, to establish whether their relationship had a positive impact on the physical and mental development of high school students.

Research objectives

We investigated the relationship between sport and school adaptability, resilience and cell phone addiction tendency in high school students, and the mediating effect of sport was tested. We hope that this study can strengthen high school students' participation in sport, and indicate new ways for improving school adaptability and resilience and reducing cell phone addiction tendency.

Research methods

We collected data using a field questionnaire survey and SPSS was used to analyze the collected data on the effect of sport, school adaptability, resilience and cell phone addiction tendency in senior high school students. Through correlation analysis, a chain mediation effect model was constructed to analyze the influence of sport on school adaptability, resilience and cell phone addiction tendency of high school students.

Research results

Sport, school adaptability and resilience were positively correlated, while cell phone addiction was negatively correlated with sport, school adaptability and resilience, and sport affected the other three through the chain mediation model. The results provide a theoretical basis for further research combined with longitudinal research.

Research conclusions

We conclude that sport has an impact on school adaptability, cell phone addiction tendency and resilience of high school students.

Research perspectives

We analyzed the effect of sport on school adaptability, resilience and cell phone addiction tendency in high school students. In future research, longitudinal research and follow-up can be combined to analyze the relationship among level of sport, school adaptability, resilience and cell phone addiction tendency.

Abstract

BACKGROUND

Due to academic pressure, social relations, and the change of adapting to independent life, college students are under high levels of pressure. Therefore, it is very important to study the mental health problems of college students. Developing a predictive model that can detect early warning signals of college students' mental health risks can help support early intervention and improve overall well-being.

AIM

To investigate college students' present psychological well-being, identify the contributing factors to its decline, and construct a predictive nomogram model.

METHODS

We analyzed the psychological health status of 40874 university students in selected universities in Hubei Province, China from March 1 to 15, 2022, using online questionnaires and random sampling. Factors influencing their mental health were also analyzed using the logistic regression approach, and R4.2.3 software was employed to develop a nomogram model for risk prediction.

RESULTS

We randomly selected 918 valid data and found that 11.3% of college students had psychological problems. The results of the general data survey showed that the mental health problems of doctoral students were more prominent than those of junior college students, and the mental health of students from rural areas was more likely to be abnormal than that of urban students. In addition, students who had experienced significant life events and divorced parents were more likely to have an abnormal status. The abnormal group exhibited significantly higher Patient Health Questionnaire-9 (PHQ-9) and Generalized Anxiety Disorder-7 scores than the healthy group, with these differences being statistically significant ($P < 0.05$). The nomogram prediction model drawn by multivariate analysis includ -ed six predictors: The place of origin, whether they were single children, whether

there were significant life events, parents' marital status, regular exercise, intimate friends, and the PHQ-9 score. The training set demonstrated an area under the receiver operating characteristic (ROC) curve (AUC) of 0.972 [95% confidence interval (CI): 0.947-0.997], a specificity of 0.888 and a sensitivity of 0.972. Similarly, the validation set had a ROC AUC of 0.979 (95%CI: 0.955-1.000), with a specificity of 0.942 and a sensitivity of 0.939. The H-L deviation test result was $\chi^2 = 32.476$, $P = 0.000007$, suggesting that the model calibration was good.

CONCLUSION
In this study, nearly 11.3% of contemporary college students had psychological problems, the risk factors include students from rural areas, divorced parents, non-single children, infrequent exercise, and significant life events.

Core Tip: Mental health problems in college students have a marked impact on their physical and mental health, and learning capacity, and are also one of the key issues of concern to educators and society. This study analyzed the mental health status of 40874 college students in selected colleges and universities in Hubei Province, China. A logistic regression model was used to explore the factors affecting the mental health of college students. A risk prediction nomogram model was constructed by R software, which improved the visualization and comprehensibility of the research.

INTRODUCTION

Mental health refers to all aspects and activities of the psyche that are balanced and harmonious, and is manifested in the individual's correct cognition, good mood, and appropriate behavior[1,2]. Research has demonstrated an annual yearly increase in the detection of psychological health issues among college students over the last three years[3], indicating that this problem has attracted more and more attention. In 2017-2018, a white paper study on the mental health of Chinese urban residents showed that 73.6% of the college students surveyed had sub-health status. This problem requires attention in order to be resolved. College students are the backbone of the future of society[4]; with the development of the social economy, competition is becoming increasingly fierce, and the mental health of these students has attracted extensive attention from society and schools[5]. University students are in the transition stage between school and society, and their mental health is highly susceptible to pressure from all sides. Most of the studies on the mental health of college students have mainly focused on the main influencing factors, and there are few studies on risk prediction analysis[6,7]. However, the diversity, complexity, variability, contingency, and uncertainty of college students' mental health problems pose challenges in mental health risk prediction. Therefore, constructing a risk prediction model is conducive to screening mental health problems, preventing and treating risk factors for disease occurrence, and reducing morbidity. This study determined the mental health of current college students using a questionnaire survey. Based on an analysis of influencing factors, a mental health risk prediction model for college students was constructed using logistic regression, which provided a reference for counseling college students' mental health problems in the future, which was conducive for providing better mental health care for college students.

MATERIALS AND METHODS

General information

All college students in some of the universities in Hubei Province were selected as research subjects. An online questionnaire survey was conducted from March 1 to 15, 2022, and the questionnaires were distributed using QQ and WeChat. Based on the principle of voluntariness, the respondents completed the questionnaire after scanning the QR code. Each IP address can only be registered to answer once to ensure the quality of the questionnaire. After the investigation, a total of 41610 survey forms were acquired, of which 40874 data were used, and the effective response rate was 98.2%. In these valid data, girls accounted for 45.4% (18547) and boys accounted for 54.6% (22327). A random sampling method selected 2% of valid questionnaires from 40874 valid data.

Research methods

The general questionnaire included data on age, grade, gender, family situation, academic performance, major life events, and other social demographic data. Using the symptom self-rating scale (SCL-90)[8,9], a total of 90 items were scored at 5 levels (0-4), with scores ranging from 0 (none) to 4 (severe); the scale is divided into physical status, interpersonal sensitivity, obsessive-compulsive symptoms, anxiety, depression, hostility, paranoia, terror, psychosis and another 10 symptoms. This scale is commonly used in mental health screening tools due to its comprehensiveness and ease of understanding. The Patient Health Questionnaire (PHQ-9)[10,11] was used to evaluate depression in college students. There were 9 criteria in total and the scoring ranged from 0 (never) to 3 (almost every day). The total score was the sum of the scores of each item (0-27 points). The score was divided into 5 levels (no depression to severe depression): 0-4, 5-9, 10-14, 15-19, and 20-27. Assessment of generalized anxiety symptoms was carried out using The Generalized Anxiety Disorder score[5], with a total of 7 items (0-3 points: From none to almost always), 4 levels of the total score 0-21 points (no anxiety to severe anxiety: 0-4, 5-9, 10-14, 15-21), and the higher the score, the more pronounced the anxiety state.

Statistical analysis

Statistical analysis was conducted using SPSS23.0 software. The experimental data obeyed normal distribution, expressed as mean ± SD in terms of homogeneity of variance, and were compared by independent samples *t*-test. Count data were expressed as n (%) using the χ^2 test; data with a value of $P < 0.05$ were considered statistically significantly different. Single-factor analysis was performed with SPSS23.0, and logistic regression was used for multivariate analysis of statistically significant variables. The prediction model was then constructed, and a nomogram model was constructed using R4.2.3. This research used the receiver operating characteristic (ROC) curve to predict the model performance and used the H-L to test the goodness of fit of the model.

RESULTS

Sample characteristics

We randomly selected 918 cases consisting of 2% of the valid data, including 814 cases in the mental health group and 104 cases in the abnormal mental health group. The incidence of mental health abnormalities was 11.3%. Educational background, place of origin, parent's marital status, whether they were single children, whether they had significant life events, and whether they had intimate friends showed statistical significance ($P < 0.05$) (Table 1).

Logistic regression analysis

Logistic regression analysis was performed to determine whether mental health was abnormal as the dependent variable (mental health = 0, mental health abnormality = 1) and independent variables comprising factors with a significant statistical correlation or association in single-factor analysis (Table 2). The results showed that parents who were divorced/widowed, non-single children, major life events, infrequent exercise, and no close friends were independent risk factors for mental health abnormalities in college students ($P < 0.05$) (Table 3).

Construction of the nomogram model and validation of its predictive performance

Based on the independent factors in the regression model (education, place of origin, exercise, parents' marital status, close friends, and whether major life events occurred), variables with significant differences ($P < 0.05$) were included and a nomogram model was constructed (Figure 1). The Bootstrap method was used to verify the model. The results of the H-L deviation test were $\chi^2 = 32.476$, $P = 0.000007$, suggesting that the model exhibited favorable calibration. According to the training set, the area under the ROC curve was 0.972 [95% confidence interval (CI): 0.947-0.997], and the specificity and sensitivity were 0.888 and 0.972, respectively. The validation set ROC area under the (AUC) was 0.979 (95%CI: 0.955-1.000), with a specificity of 0.942 and a sensitivity of 0.939. In the training set, the nomogram-based prediction model yielded a mean absolute error (MAE) of 0.01, and the mean square error (MMSE) was 0.00022. The MAE of the validation set was 0.007, and the MMSE was 0.00026. The smaller the statistics, the higher the calibration of the prediction model (Figures 2 and 3).

DISCUSSION

University is an important stage in the life of college students and a crucial period for personality completion and self-improvement[12]. College students are active and accept a wide range of information but do not have complete psychological defense abilities. They are easily disturbed by external factors, causing anxiety, panic, and other negative emotions, resulting in blind conformity and impulsive behavior. For college students, entering university means they are about to enter society. At this crossroad, they face pressure and confusion due to learning, love, employment, and family. These aspects of stress, to a certain extent, affect the psychological health of college students[13]. Due to the increased risk of mental health problems, mental health research has become a priority for many scholars[14]. Studies have found that different nationalities, genders, grades, only children, different subjects, and different school types are all related to the mental health of college students[15]. In addition, some studies have found that only children, parental relationships, and domestic violence directly affect the mental health of college students[16]. These results are not entirely consistent with those of this study. This phenomenon can be explained by the vulnerability of mental health to environmental/social

PHQ: Patient Health Questionnaire; GAD: Generalized Anxiety Disorder.

conditions. A survey conducted in the United States found that more than one-third of students suffered from depression, while between 2007 and 2008, approximately 10 percent of college students were found to have considered suicide[17]. According to a study conducted in China in 2010, approximately 10% to 30% of university students were affected by mental health issues, which aligns with the findings of this research. According to the National Mental Health Development Report of China (2019-2020), 18.5% of college students tend towards depression, 4.2% have a high risk of depression, and 8.4% have an anxiety tendency. A sample survey by the former State Education Commission found that 20.3% of college students have psychological problems. The above research results are not entirely different to the results in this study.

Our findings show that parental' divorce/widowhood is a risk factor affecting college students' mental health [odds ratio (OR) = 5.628, (95%CI: 2.450-12.927)]. Family is the crucial environment for personal growth. The family atmosphere

PHQ: Patient Health Questionnaire; GAD: Generalized Anxiety Disorder; OR: Odds ratio; CI: Confidence interval.

significantly relates to the formation of a person's personality[18] and impacts personal psychological development. A large number of research surveys have shown that family has a significant impact on students' mental health[19,20]. A good family environment is conducive to college students' physical and mental health[21], which can reduce the risk of abnormal mental health. An unhealthy family environment (*e.g.*, parental divorce or widowhood, family conflicts) can

Figure 2 Column chart prediction model receiver operating characteristic curve. A: Receiver operating characteristic (ROC) curve of the training set; B: ROC curve of the validation set. AUC: Area under the curve; CI: Confidence interval.

easily lead to abnormal mental health in college students and even result in students forming bad personalities[22].

Similarly, studies have shown that parental separation is a risk factor for college students' mental health issues[23]. Domestic and foreign research shows that parental relationships affect children's growth and mental health. Paying attention to the influence of parental relationships on college students' mental health and providing improvement strategies can enable parents to play a role in promoting their mental health.

The present study showed that students from rural areas had an increased risk of mental health issues (OR = 3.099, 95%CI: 1.363-7.043). These results are consistent with those of Zhang and Qi[24]: In terms of psychological stress, college students from rural areas have a significantly higher risk than those from urban areas. These results were related to the rural family's economic environment and cultural atmosphere. Due to differences in resources, the economic conditions of college students from rural areas are worse than those from urban areas. In particular, students from rural areas studying in large cities, have higher living expenses. Some families do not have stable economic sources, and their economic deficiencies and life pressure make them prone to inferiority[25].

Figure 3 Column chart prediction model calibration curve. A: Calibration curve of the training set; B: Calibration curve of the validation set.

A significant correlation exists between critical life events and the psychological health of university students. In this study, major life events were a risk factor for mental health problems in college students (OR = 40.709, 95%CI: 15.329-108.111). Due to their limited exposure to social and real-life situations, college students are often confined within a sheltered campus environment, lacking sufficient life experience, exhibiting immature cognition, and having insufficient capacity to effectively cope with psychological stressors. When faced with adverse events or unforeseeable circumstances, such as natural disasters or family tragedies, their psychological resilience will be significantly challenged, potentially leading to psychological distress and impediments.

This study showed that regular exercise was a protective factor for mental health (OR = 0.093, 95%CI: 0.031-0.274). Relevant studies have found that moderate physical exercise has a more significant impact on mental health than non-exercise[26]. Fossati *et al*[27] found that participating in sports and exercise benefits an individual's mental state and can improve mood and quality of life. Herbert[28] found that physical activity and exercise help to promote the mental health of emerging adults such as college students. Huang[29] used the intelligent health system to assess the health status of college students before and after dance exercises. The results showed that the mental health of college students participating in dance exercises increased by 7.8%, indicating that sports and dance can promote physical and mental health. Thus, regular exercise can not only promote physical health but also help to improve mental health.

According to the findings of this investigation, a single child has a good mental health status, and being a non-single child is a risk factor for college students' mental health (OR = 37.175, 95%CI: 11.862-116.500). These results are quite different from existing research. Cheng *et al*[30] and others found that the incidence of emotional distress characterized by feelings of unease, apprehension, and low mood in non-single children was higher than that in single children in college and university students from Jinan, Shandong. The reason for this may be that the survey areas were different, and the results do not represent the mental health status of all college students. This may be because most of the single children come from cities, their parents have relatively high educational levels, and their family economic situations are better than those of non-single children. In the one-child family, parents will meet their wishes as much as possible, pay more attention to their education, and get help when they encounter problems. Most of the non-single children were from rural areas, with relatively poor economic conditions and a sense of inferiority[31]; because there are other siblings in the family, parents pay less attention to each child and do not pay attention to communication with their children, resulting in some non-single children encountering problems that cannot be solved and thus affects their mental health.

The findings from this investigation indicated a higher likelihood of psychological problems among college students who lack close friends compared to those who have intimate companions, and was a risk factor for college students' mental health (OR = 4.773, 95%CI: 2.002-11.384). The results by Li *et al*[32] proved this view. Research also shows that good friendships can help people alleviate negative psychology and provide emotional support[33]. The survey by Abraham and Sher[34], it was found that a solid interpersonal relationship was a protective factor against adolescent suicide, which was in line with the findings obtained from the current research: The existence of intimate friends was a protective factor for college students' mental health. In the face of difficulties and pressure, good friends will help and care about each other, which can reduce psychological pressure and is conducive to good mental health. Therefore, getting along with or having close friends is necessary.

The individual is central in resolving their psychological issues. First, they need to develop a scientific understanding of health, proactively foster positive psychological traits, gain accurate comprehension and acceptance of themselves, sustain a favorable emotional outlook, engage with loved ones and acquaintances as support systems when confronting challenges, and cultivate a fully-rounded and harmonious state of health. Secondly, strive to actively acquire and master the techniques for recognizing psychological issues and practicing self-regulation. Individuals should actively exercise, participate in social activities, enrich life experiences, increase social experience, and improve their ability to resist pressure.

Universities and colleges should integrate mental health education into their talent development paradigm by designing courses, organizing psychological quality training sessions, and establishing psychological counseling rooms, among other methods. This would enable college students to acquire knowledge on mental health, enhance their psychological adjustment abilities, and effectively address various psychological issues. In so doing, college students can access timely and effective assistance and guidance during any psychological crises that they may encounter.

Parents ought to lead by example by creating a favorable family environment that fosters effective communication and mutual respect while prioritizing the emotional well-being of their offspring. To achieve this, parents should eagerly listen to their children's emotional needs, encourage them to express themselves fully, and form a close-knit bond with them. They should also aim to foster home-school cooperation towards safeguarding the mental health of college-going students.

CONCLUSION

According to the results of this study, the current college students show a good state in mental health. By using the sample set data of the mental health risk prediction model and modeling and processing it, we provide an important reference for the prevention and intervention of college students' mental health problems. The data obtained from this research is singular, and sourced from a specific region with a limited sample size. As mental health depends on the environment, the representativeness of the sample may have specific limitations. Therefore, it is essential to enhance the model through prospective, multi-center studies with a sufficient sample size.

ARTICLE HIGHLIGHTS

Research background

Mental health problems in college students have become the focus of academic and social attention. The main reason is that college students are facing many pressures and challenges, such as academic pressure, social pressure, career planning pressure, and so on. In addition, the rapid development of modern society and the competitive environment have also brought new challenges and threats to the mental health of college students. Therefore, the study of college students' mental health has profound practical significance and theoretical value.

Research motivation

With the increasing pressure and challenges faced by college students, their mental health problems are becoming more and more serious, and the detection rate is increasing yearly.

Research objectives

Research on the mental health status of current college students and the construction of a risk prediction model can not only help us to understand the mental health problems faced by college students more comprehensively, but also provide a valuable reference for prevention strategies. It can also identify and intervene in mental health problems at an earlier time point to avoid further deterioration of the problem. In addition, future research in this field can also explore the relationship between mental health status and college students' learning, life, and interpersonal communication, and provide useful support for improving the overall quality and development of college students.

Research methods

The objective of the current research was to examine the mental well-being of 40874 undergraduate and graduate students enrolled in various higher education institutions within a particular geographical area. Additionally, using logistic regression analysis, the determinants that exert a substantial influence on the psychological health of university students were investigated. This model has high accuracy and interpretability. This study used R software to construct a risk prediction nomogram model, which enabled researchers to understand the influence and relationship of different variables more intuitively and improved the visualization and comprehensibility of the research. In summary, this study adopted a variety of advanced research methods, which had a wide range of reference values and application prospects.

Research results

The survey found that 11.3% of college students had psychological problems. The risk factors for college students' mental health include being from rural areas, non-single children, major life events, parents' marital divorce, infrequent exercise, and no close friends. The area under the receiver operating characteristic (ROC) curve in the training set was 0.972, the specificity was 0.888, and the sensitivity was 0.972. The area under the ROC curve in the validation set was 0.979, the specificity was 0.942, and the sensitivity was 0.939. These findings reflect the current mental health status of college students and is of great significance for the public to raise attention and awareness of mental health problems. It provides a basis for the government and schools to formulate mental health policies and help to formulate effective mental health management measures. At present, there are still some problems in the design and application of college students' mental health questionnaires, as some students could not understand or answer the questions in the questionnaire. More comprehensive and in-depth analysis and research are still needed to ensure the accuracy and reliability of the analysis

and statistical results.

Research conclusions

From this research, we conclude that the current mental health status of college students is good. New methods used in this study include the use of a logistic regression model and the use of R software to construct a risk prediction nomogram model to explore the related factors affecting the mental health of college students. These methods can predict the risk factors related to college students' mental health more accurately and provide more effective intervention measures and prevention methods.

Research perspectives

Assessing and monitoring the mental health of college students can help schools and other institutions to better understand the needs of college students and take timely measures to prevent the emergence of mental health problems. Future research should focus on developing more effective assessment tools and establishing tracking and monitoring systems.

Abstract

BACKGROUND

The efficacy of cognitive behavioral group therapy (CBGT) for cognitive dysfunction and negative symptoms of schizophrenia is established, but more evidence is required.

AIM

To assess the effectiveness of CBGT combined with mental health education as a treatment for schizophrenia compared with mental health education alone.

METHODS

In all, 120 schizophrenia out-patients were randomized into CBGT combined with mental health education or single mental health education. The primary outcomes were positive and negative symptoms, cognitive function, excitatory factor, anxiety and depression symptom improvements on the positive and negative syndrome scale score. Secondary outcome measures included social function and drug compliance.

RESULTS

There were significant differences between CBGT combined with mental health education and single mental health education on measures of positive and negative symptoms, cognitive functions, excitatory factor, anxiety and depression symptoms, and social functions. No other significant difference in outcomes was

observed.

CONCLUSION
CBGT combined with mental health education may be relevant beneficial treatment method in reducing symptoms, cognitive and social functions of patients with schizophrenia.

Core Tip: Psychological therapies for schizophrenia still deserves to be explored due to its advantages of having comparatively fewer side effects. As one of the different psychological approaches, cognitive behavioral therapy has been proven to be effective in the treatment of schizophrenia with sound evidence. This study provides new insights by adding cognitive behavioral group therapy to the conventional pharmaceutical therapy plus mental health education for the treatment of schizophrenia. It also provides some guidance on developing community rehabilitation models in patients with mental illness.

INTRODUCTION

Schizophrenia is a serious mental disorder, which can lead to loss of personality, decline in social function and the state of mental disability in various levels. Negative symptoms and cognitive impairment have been found to have a profound impact on long-term outcomes of schizophrenia, but current treatment options are limited. Recent studies have shown that the combination of cognitive behavioral group therapy (CBGT) can improve patient compliance with drug therapy, alleviate psychotic symptoms, reduce recurrence and rehospitalization rates, and improve social function and quality of life in schizophrenia.

This study aims to evaluate the impact of CBGT combined with mental health education on the clinical symptoms, cognitive and social functions and psychological status in patients with schizophrenia on the basis of conventional drug treatment, so as to provide evidence for its application to community rehabilitation for patients with schizophrenia.

MATERIALS AND METHODS

Participants

This was a randomized control trial approved by the Biomedical Ethics Review Committee of Longhua District Chronic Disease Prevention and Treatment Center (Mental Health Center), and obtained the informed consent of family members of the research patients. Participants were recruited from outpatients with schizophrenia. The inclusion criteria included diagnosis of schizophrenia (ICD-10 codes F20.0 to F20.9); 1 to 5 years of disease course with a stable condition; presence of dangerous behavior involving verbal threats; no obvious vandalism; partial recovery of self-knowledge; positive score for positive and negative symptom scale (PANSS) ≤ 49 or negative scale score ≤ 49; social function deficiency screening scale (SDSS) score ≥ 2; aged 19 to 60 years old; higher levels of education than primary school; with at least one guardian; taking second-generation antipsychotics for ≥ 1 year. Inclusion criteria for family members was those who have no mental history. Patients with co-morbidities, other psychiatric disorders (*e.g.*, organic disorders, psychoactive substance-induced psychiatric disorders) or serious physical disorders affecting cognitive functions and family members with speech impairment were excluded from this trial.

Study design

Randomization was conducted using computer-generated random numbers with 120 participants allocated in blocks. These patients were randomly allocated to an intervention group and a control group with 60 patients in each group. The intervention group was subdivided into four groups with 15 patients and their family members in each group receiving CBGT combined with mental health education for 8 wk. The interventions in each group were led by an experienced psychiatrist or psychotherapist trained in CBGT. The control group was only given mental health education courses for 8 wk. The study was reviewed and approved by the Biomedical Ethics Review Committee of the Shenzhen Longhua District Chronic Disease Control Centre (Mental Health Centre) and informed consent was obtained from patients'

families.

Intervention programs

CBGT intervention is divided into four stages: (1) Stage 1 (the first time): The initial stage. The basic task is acceptance and commitment. Members and team leaders get to know each other, understand the troubles in each other's life and communicate with each other, normalize problems, introduce CBGT to group members, set group contracts, set group goals and enhance group cohesiveness; (2) Stage 2 (2nd-3rd): *i.e.*, transition stage. Assist group members to deal with their emotional reactions and conflicts, and promote trust and relationship building. Identify the situations that induce stress and emotional conflicts, and perceive the related assumptions of situations, ideas, emotions and behaviors constructed under the stress situation; Identify and evaluate symptoms and negative cognitions; Examine the evidence to repair negative cognitions, core beliefs and dysfunctional assumptions. In addition, this stage also includes relaxation training, role play, imitation demonstration, resolving emotional conflicts such as anxiety and depression, seeking resource support and increasing self-confidence; (3) Stage 3 (4th-7th): *i.e.*, working stage. Further explore problems and take effective actions to promote the change of members' behaviors. Through psychological education and social skill training, encourage members to observe and imitate, consolidate self-monitoring and self-guidance training during rehabilitation, change distorted thinking patterns and improve self-esteem; and (4) Stage 4 (8th): The end stage. Summarize group experiences, consolidate achievements, encourage team members to use learning experiences in life, solve problems and emotional conflicts, enhance self-confidence, inject hope, and deal with parting emotions.

Outcome measures

The participants were randomly divided into an intervention group (60 cases) and a control group (60 cases). Each patient had his/her one family member to participate in the trial. In addition to antipsychotics and mental health education implemented in the community, patients in the intervention group received CBGT together with their guardians for 8 wk. Patients in the control group only received antipsychotic drugs and mental health. Patient social functions, symptoms of schizophrenia and activities of daily living (ADL) were evaluated by SDSS, PANSS and ADL scale before CBGT treatment, 8 wk and 4 wk after the treatment (*i.e.*, before the intervention, after the intervention and 4 wk after the intervention, respectively). According to the evaluation results of the scale at three time points, the intervention effects of CBGT on patient symptoms and social functions were analyzed.

Primary outcome measures

Primary outcome measures include improvements in symptoms measured by the scale of the PANSS. Using the positive and negative symptom scale, five-factor dimensions of Chinese norm were evaluated: Positive factor, negative factor, cognitive factor, excitatory factor, anxiety and depression factor. Social function is evaluated by SDSS scale.

Two psychiatrists scored 10 patients using PANSS scale, and calculated kappa coefficient = 0.822 through SPSS 22.0. The evaluation of the two doctors is in good agreement and has high consistency.

Secondary outcome measures

The ability to live was assessed by the ability of daily living scale. Medication compliance was evaluated from three types: (1) Complete compliance: Completely follow the doctor's advice for one month; (2) part compliance: Taking medicine for more than 33% course of treatment in a month; and (3) non-compliance: 33% course of treatment in a month with no medication.

Statistical analysis

Statistical analysis was conducted using the SPSS 22.0 software. The rank-sum test and sample independent *t*-test were used for the variable data, and the chi square test was used for the categorical data. Repeated measures ANOVA was used to determine the effects of different intervention modalities on patients' clinical symptoms, social functioning, abilities to perform daily living activities and medication adherence at three different time points: Pre-intervention, post-intervention and 4 wk post-intervention. By analysis of studentized residuals, the data in each group had no outliers (≥ ± 3SD) and followed a normal distribution ($P > 0.05$) according to the Kolmogorov-Smirnov test. The conditions for the sphericity test must be satisfied so that the data could be tested for normality and symmetry with sphericity, and in case the assumption for sphericity was not met, the method of Greenhouse-Geisser (G-G) for correction was used. The test level of $P < 0.05$ was considered statistically significant. It was then determined whether there was an interaction between factors (groups and time points) in the intervention group and the control group. If there was an interaction, *t*-test and one-way ANOVA were required to determine whether there was a separate effect. When a separate effect test was required, test level of $P < 0.05$ was considered statistically significant. If there was no interaction, a main effect test was required to determine whether there was a main effect, with a test level of $P < 0.05$ being statistically significant. A two-by-two comparison was carried out. We used Bonferroni correction for multiple repeated ANOVA testing.

RESULTS

After the treatment and at 4-wk follow-up, none of the 120 patients dropped out.

Participant characteristics

Patients with schizophrenia in both groups had a disease course of 1 to 5 years and were in stable condition. They were treated with second-generation antipsychotics in the community. General data show that the average age of them is 38 years old. There were slightly more women (53.33%) than men (46.67%) in the intervention group, and there were more men (61.67%) than women (38.33%) in the control group. The educational background for the participants is mainly below junior high school. There was no significant difference in age, gender, education level, medical burden and family income between the intervention group and the control group. The baseline characteristics of the participants are presented in Table 1.

The general data (age, gender, education level, medical burden, annual family income) of the family members were analyzed and compared in the two groups. There was no significant difference in general data between the two groups ($P > 0.05$). The baseline characteristics of the sample are presented in Table 2.

Primary outcomes

The overall PANSS score, positive factor score, cognitive factor score, excitatory factor score, anxiety and depression factor score and SDSS score decreased successively in the two groups at three time points. After the intervention and at four weeks after the intervention, the overall PANSS score ($P < 0.05$ and $P < 0.001$, respectively), positive factor score ($P > 0.05$ and $P < 0.001$, respectively), cognitive factor score ($P < 0.05$ and $P < 0.001$, respectively), excitatory factor score ($P > 0.05$ and $P < 0.001$, respectively), the scores of anxiety and depression factors ($P > 0.05$ and $P < 0.001$, respectively) and the overall score of SDSS ($P < 0.01$ and $P < 0.01$, respectively) were significantly different from those before the intervention. After repeated measurement analysis of variance, there was interaction between group and time points in the total overall score of SDSS ($P < 0.05$). After the intervention, there were significant differences between the intervention group and the control group in PANSS total score ($P < 0.05$), positive factor score ($P < 0.05$), cognitive factor score ($P < 0.05$) and SDSS total score ($P < 0.01$). At four weeks after the intervention, there were significant differences between the intervention group and the control group in PANSS total score ($P < 0.01$), excitation factor score ($P < 0.05$), cognitive factor score ($P < 0.01$), anxiety and depression factor score ($P < 0.01$) and SDSS total score ($P < 0.01$). Outcomes are shown in Table 3 and Figure 1.

Secondary outcomes

χ^2-test was performed for medication compliance in the two groups at three time points. The results showed that there was no significant difference between the intervention group and the control group before the intervention ($P > 0.05$). There was no significant difference in medication compliance between the two groups after the intervention and at 4 wk after the intervention ($P > 0.05$). Compared with the control group, the proportion of complete compliance in the intervention group increased slightly (8.34%) after the intervention (83.33%) and at 4 wk after the intervention (91.67%) as presented in Table 4.

DISCUSSION

This is a study to evaluate the effect of CBGT combined with mental health education on community-based rehabilitation of patients with schizophrenia. The main results showed that: (1) Compared with the control group, patients in the intervention group had significantly lower PANSS total scores and five factor scores post-intervention, with negative factor and cognitive factor scores still showing reduction at 4 wk post-intervention; (2) SDSS scores in the intervention group significantly decreased; (3) ADL scores decreased in both groups after the intervention and at 4 wk after the intervention, and the difference was not significant; and (4) there was no significant difference in medication adherence between the intervention group and the control group.

Our findings confirm the ameliorative effect of CBGT on the psychotic symptoms of patients with schizophrenia. Combined with the current situation of community psychiatric rehabilitation management in Shenzhen, the participants of this study are migrant workers in Shenzhen, and as general information shows, this group of population has a low level of education, and nearly half of them do not purse education beyond junior high school with a household income of around 40000 CNY. The migrant workers have medical and social resources availability is restricted and have received relatively little social support. Therefore, the aim of this study is to explore a feasible community-based rehabilitation model for migrant workers. In this study, a comparative analysis of psychiatric symptoms using the five-factor dimension of the PANSS scale Chinese normative model found that 8 wk of CBGT combined with mental health education significantly improved the patients' clinicopathological symptoms and remained effective in improving negative symptoms and cognitive dysfunction after 4 wk of follow-up.

Previous studies have reported inconsistent results on the effectiveness of CBGT in improving positive and negative symptoms of schizophrenia, possibly because different studies have used different evaluation criteria and intervention cycles[1-11]. This study was completed using a modified short-term CBGT format in patients with schizophrenia and their family members, and explored together with patients the reasons for their laziness and reluctance to think and communicate, which were often related to their automatic thoughts such as "I am a useless person", "I will not be welcomed by anyone", "things outside are not interesting", *etc*. Behavioral tests are used, *e.g*. developing a behavioral plan to test the validity of one's beliefs, *e.g*. encouraging one to recall his/her pre-morbid state, self-affirming exceptions and increase self-confidence. When distressing experiences such as hallucinations and delusions of "if I go out, I'll get hurt", coping strategies such as self-symptom monitoring logs and problem solving support are used to alleviate patient feelings of unease and surveillance towards the external environment. Patients are encouraged to think about how they

perceive the attitudes and behaviors of others in a situation, and how their performance respond to the patient's behaviors. Patients are encouraged to be friendly to group members (behavioral activation: Greeting, asking for help, *etc*.) and then to observe if the group members are interested in them. Friendly feedback from others encourages patients to be more positive in their interpersonal interactions. When prejudicial attributions and negative self-evaluations such as "I can't do it", "I'm useless", "No one wants to help me", "I'm not the same as others" occur, self-focus is enhanced through family companionship, empathic psychological support, imitative learning among group members, focusing on solving difficult problems, improving self-awareness and insight, and strengthening social skills training. Through positive and effective communication, expressing one's real emotional needs, accessing resource support (family support, peer support and social support), coping with crisis, testing hypotheses in practice and feeling trusted. Recent research has also demonstrated the effectiveness of social skills training in improving negative symptoms[1,12]. Cognitive remediation has a small to moderate beneficial effect on negative symptoms enhancing a positive outcome for cognitive impairment [13,14].

The results showed that combined CBGT and mental health education significantly improved social functioning in patients with schizophrenia, but did not have a significant advantage over single mental health education in improving daily living skills[15]. Related studies found that there were more factors influencing daily living skills, such as executive function (21%), memory and abstract thinking (13.5%), negative symptoms (13%), age of onset and years of education

(8%)[16]. This shows that the improvement in cognitive function facilitates the improvement of patient independent living in their communities and issue management in their daily lives. We also saw that the short duration of the intervention and the influence of other related factors, among others, suggest that further research is needed to reveal the effect of CBGT on other factors related to the abilities of schizophrenia patients in their everyday lives.

Furthermore, the results suggest that CBGT combined with mental health education did not have a significant impact on medication adherence in schizophrenia patients, and only slightly increased the proportion of patients who were fully adherent. We can see that outpatients' medication adherence (duration of medication) was more stable under family medication supervision, but we speculate that this may be related to a number of factors influencing adherence, including severity of illness, level of awareness of illness, duration and dosage of medication, family factors, environmental factors, and doctor-patient relationship[17-19]. In future studies, we may need to optimize adherence assessment criteria and will further explore the correlation between adherence and other factors.

We know that treatment with CBGT can have a positive impact on the pathophysiology and cognitive control networks in functional areas of the brain such as the anterior cingulate cortex, dorsolateral striatum, dorsolateral prefrontal cortex, amygdala, basal ganglia, and thalamus, and this evidence provides the basis for a neurobiological brain mechanism for CBGT treatment to relieve negative symptoms and cognitive impairments[20-29]. This study has demonstrated that

Table 4 Medication compliance in the two groups using χ^2 test, *n* (%)

CBGT combined with mental health education intervention improved social functioning, enhanced work drive, interpersonal interactions and cognitive functioning (verbal communication), and reduced positive symptoms, and negative symptoms better than single mental health education in community-rehabilitated schizophrenia patients.

There are some limitations to this study. Firstly, the sample size of this study is relatively small and our findings are preliminary and need to be further validated in an expanded patient sample. Secondly, although the PANSS scale is a screening tool to assess psychopathological symptoms, it cannot further assess quantitative cognitive functions such as executive function, reasoning, attention, verbal-visual learning, and working memory. In future studies, we should select corresponding assessment tools to test the relationship between research CBGT and cognitive impairment. Thirdly, only

the duration of medication was considered when evaluating medication adherence. We need to include other relevant factors (such as disease severity, medication duration and dosing) as measurements to effectively evaluate adherence in patients taking medication regularly in outpatient clinics. Fourthly, this study is a cross-sectional study and suffers from the general limitation of clinician and patient blinding settings that cannot be overcome by CBGT studies, which may lead to a high risk of bias in the assessment results. Further measurements of cognitive function, duration of illness, dosing of medication and other relevant factors are needed in the future to help support the clinical evidence.

CONCLUSION

In conclusion, our data support the view that CBGT combined with mental health education improves clinical symptoms and psychosocial rehabilitation outcomes in people with schizophrenia in the community. Good medication adherence lays the foundation for psychosocial recovery. The degree of family involvement in patient medication supervision has a significant impact on patient psychiatric recovery. Support systems such as family support, peer support and social support are important positive factors for community rehabilitation. Patients can gain social experiences in group-based activity exchanges, gain emotional support and recognition through mutual imitation and learning exchanges, enhance resilience and thus rebuild rational beliefs and strategies, and it also provides some guidance on the development of community rehabilitation models in patients with mental illness.

ARTICLE HIGHLIGHTS

Research background

Cognitive behavioral therapy is an evidence-based adjunctive intervention for schizophrenia and has shown benefits.

Research motivation

Whether the combination therapy of cognitive behavioral group therapy (CBGT) and mental health education shows superior benefits to mental health education alone in the management of schizophrenia?

Research objectives

This study aimed to compare the efficacy of CBGT combined with mental health single mental health education and mental health education alone for schizophrenia.

Research methods

A total of 120 patients with schizophrenia were enrolled and allocated to an intervention group (n = 60) and a control group (n = 60). Patients in the intervention group received CBGT therapy which was added as an adjunctive intervention to antipsychotics and mental health education. Patients in the control group only received antipsychotic drugs and mental health. The cycle of treatment is 8 wk. After a follow-up of four weeks, score for positive and negative symptom scale, social function, activities of daily living and medication compliance were measured.

Research results

It showed that 8 wk of CBGT combined with mental health education significantly alleviated symptoms and cognitive dysfunction and improved social functioning although it did not have a significant impact on medication adherence in patients with schizophrenia after 4 wk of follow-up.

Research conclusions

The results of this study indicate that the combination therapy of CBGT and mental health education is a promising addition to antipsychotics.

Research perspectives

To attain robust results, further large-scale studies should be conducted with the measurements of cognitive function, duration of illness, dosing of medication and other relevant factors are considered to support the clinical evidence.

Abstract

BACKGROUND

Depression is one of the most common and important psychological issues faced by dialysis patients. It can make it more difficult for them to adhere to their treatment regimen, which, in turn, can worsen their physical symptoms and lead to poorer health outcomes.

AIM

To examine the evolution and growth of publications related to dialysis and depression. The objectives were to identify the number of publications, the top active countries, the contributed institutions, funding agencies and journals, as well as to perform citation and research theme analysis.

METHODS

The search was conducted using the Scopus database for publications related to dialysis and depression between 1970 and 2022. Subsequently, bibliometric analysis was carried out on the data obtained using VOSviewer software, version 1.6.9. This analysis included visualization analysis, co-occurrence analysis and examination of publication trends in dialysis and depression.

RESULTS

We identified 800 publications that met the search criteria. The number of publications related to dialysis and depression has increased significantly in the past two decades. The USA led the way with 144 publications, which is 18% of all publications on this topic. Turkey came second with 88 publications (11%), followed by China with 55 publications (6.88%) and Iran with 52 publications (6.5%). Analysis of the research theme identified three main clusters related to gender differences in prevalence, identification of depression as a risk factor, and effective interventions to relieve depression. Future research direction analysis shows a shift toward effective interventions to relieve depression in dialysis patients.

CONCLUSION
This study provides a comprehensive overview of growth, trends and research themes related to dialysis and depression that could help researchers identify gaps in the literature and develop future research.

Key Words: Dialysis; Depression; Bibliometric; Hot issues; Scopus

Core tip: Depression is a prevalent psychological problem among dialysis patients, and it can negatively impact their adherence to treatment and health outcomes. A total of 800 publications were identified through a bibliometric analysis of dialysis- and depression-related publications between 1970 and 2022. In the last two decades, there has been a significant increase in the number of publications, and the USA led the way. The identified research themes were gender differences in depression prevalence, the identification of depression as a risk factor, and effective interventions to treat depression. Effective interventions to ameliorate depression in dialysis patients will be the focus of future research endeavors.

INTRODUCTION

Dialysis is life-sustaining management for patients who have lost renal function due to kidney failure[1,2]. Although it can be an effective treatment for many, it is a complex and demanding procedure that can have significant effects on patients' physical, mental and emotional well-being[3,4]. Depression is a prevalent mental health issue that dialysis users regularly experience[5]. A sensation of despair, hopelessness and helplessness characterizes this syndrome[6]. The stress and ambiguity of treating a chronic illness such as renal failure, as well as the other lifestyle changes that occur alongside dialysis therapy, such as changes to one's diet and daily routine, may all contribute to the onset of depression[7].

According to one study, depression can dramatically affect dialysis patients' quality of life[8]. This can result in psychological and physical symptoms such as weariness, sleeplessness, lack of appetite and loss of interest in previously rewarding activities[9]. Furthermore, depression might make it more difficult for patients to stick to their treatment plan, exacerbating physical symptoms and resulting in poorer health outcomes[10-12]. Several studies have been conducted in recent years to investigate the link between dialysis and depression[13-17]. According to several studies[18-21], depression is more prevalent among dialysis patients than among the general population. Additionally, another study suggests that certain characteristics, such as dialysis duration or changes in dialysis, may increase the incidence of depression[22,23].

A research methodology that studies the organization of academic literature to indicate research trends, patterns and areas of competence is bibliometric and visualization mapping. We may acquire a clearer grasp of the field's structure and geography, identify gaps in knowledge and highlight key contributions by using this methodology to study dialysis and depression[24-27]. This paper reviews the current state of dialysis and depression research, identifies the most influential research publications and institutions and outlines prospective future research directions. It also seeks to provide a complete overview of dialysis and depression research, highlight major research trends and knowledge gaps, and make recommendations for future research. In addition, this study can help researchers to identify voids in the current literature and guide future efforts to advance our understanding of the complex relationship between dialysis and depression.

MATERIALS AND METHODS

Data acquisition

Scopus was chosen to retrieve the publication sources. To avoid potential bias from the daily updates in Scopus, the documents for this study were retrieved and saved on April 12, 2023. The majority of bibliometric studies use Scopus[28-32] and Web of Knowledge[33-35]. Scopus is regarded as the most advantageous database for such analyses due to its numerous benefits[36-40]. Its bibliometric indicators are simple and straightforward. In addition, Scopus includes publications from Medline. Scopus has a number of benefits over Google Scholar and Web of Science. It has a more comprehensive database for bibliometric analysis and covers social sciences and humanities. Its unique characteristics, such as author identification, improve the tracking and evaluation of academics' influence on a particular topic. By offering filtering and sorting options, Scopus facilitates the discovery of relevant research.

Search strategy

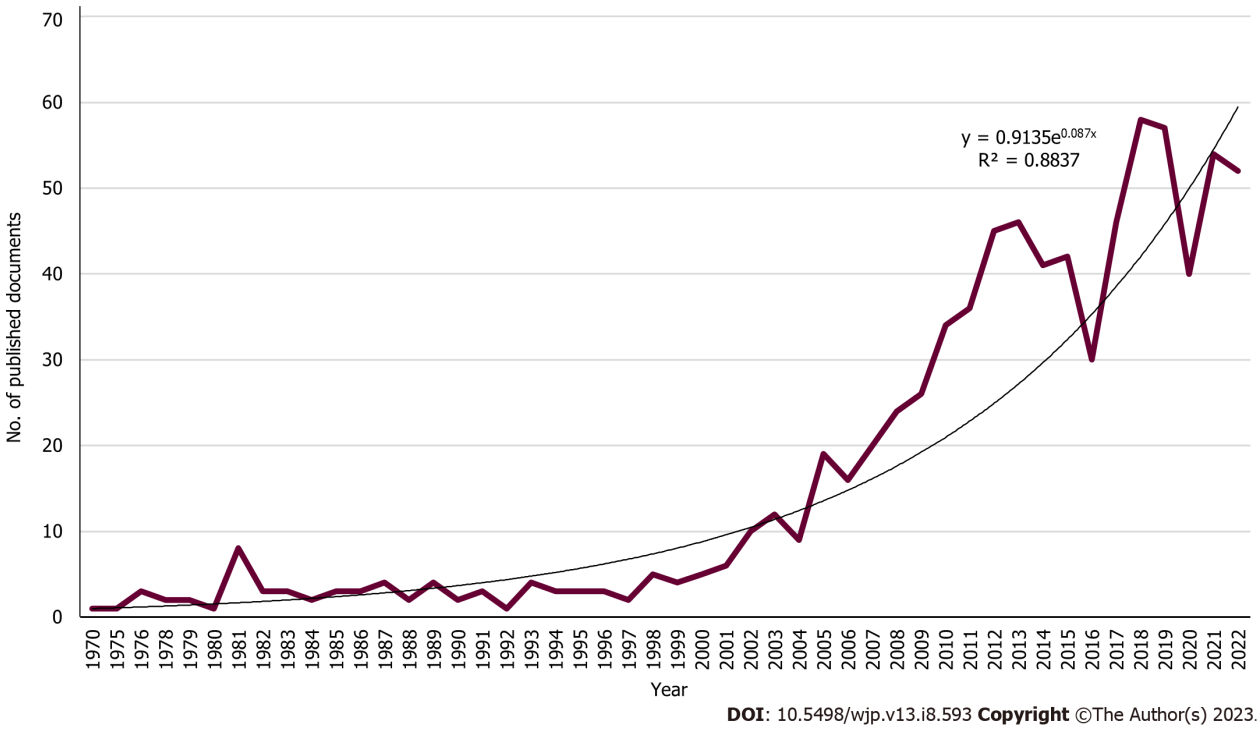
A detailed review of the systematic and meta-analysis research on the topic was undertaken to establish the search approach, as referenced in the sources[18-21]. Scopus Engine was used to integrate relevant words connected with dialysis and depression, including Medical Subject Headings from PubMed and prior systematic reviews and meta-analyses. There were four steps in the research strategy. (1) The initial step involved using specific terms and phrases related to dialysis to conduct a title search, which included the following. TITLE ("artificial kidney therapy") OR TITLE (*dialysis*) OR TITLE (extracorporeal therapy) OR TITLE (Hemofiltration) OR TITLE (hemodiafiltration) OR TITLE (hemoperfusion) OR TITLE ("continuous renal replacement therapy"). (2) The second step used specific terms and phrases that are related to depression to conduct a title search that included the following: (TITLE (depress*) OR TITLE (dysthym*) OR TITLE ("seasonal affective") OR TITLE ("bipolar disorder") OR TITLE ("mood disorder*") OR TITLE ("affective disorder")). (3) In the third step, the first two steps were merged and filtered by implementing exclusions and limitations. The search was conducted in Scopus, including articles published up to December 31, 2022, without language restrictions. The research methodology employed the wildcard symbol (*) and quotation marks ("") to refine the search for particular terms or phrases. Errata and retracted documents were excluded from the analysis. (4) The search query resulted was as follows: ((TITLE(depress*) OR TITLE("seasonal affective") OR TITLE(dysthym*) OR TITLE("affective disorder") OR TITLE("mood disorder*") OR TITLE("bipolar disorder")) AND ((TITLE ("Artificial kidney therapy") OR TITLE (*dialysis*) OR TITLE (Extracorporeal therapy) OR TITLE (Hemofiltration) OR TITLE (Hemodiafiltration) OR TITLE (Hemoperfusion) OR TITLE ("Continuous renal replacement therapy")) AND PUBYEAR < 2023)) AND (EXCLUDE (DOCTYPE,"er")).

The search strategy used involved searching for the title using specific keywords rather than searching for both the title and the abstract simultaneously. This approach is considered reliable because it yields minimal false-positive results[41-45]. In contrast, searching for both titles and abstracts may result in a large number of false positives, as the studies' primary focus is on topics other than dialysis and depression.

Validation of the search strategy

The author has taken several steps to ensure the accuracy and reliability of the search query. Firstly, the author improved the query to eliminate false positives. Then, we examined the top 50 most cited papers for relevance to the search subject. Two bibliometric specialists evaluated the title and abstract of these papers and ensured that there were no false positives. The search query was declared complete once it was completed. To confirm that there were no false negatives, the author ran a correlation test between the collected data and the real findings of the field's 20 most active researchers. This test found a strong correlation (r = 0.960) and a significant result (P = 0.001), showing that the search query was precise. This validation method has already been employed in bibliometric studies[46-48]. The rigorous approach and cooperation of two bibliometric specialists enhanced the findings' trustworthiness, and the correlation test gave additional support.

Indices of research productivity



The data collected served as the basis for generating the following information[32,49,50]: (1) Comprehensive analysis and trends of global contributions in publications regarding dialysis and depression from 1970 to 2022; (2) examination of scientific research productivity and collaboration patterns by country; (3) evaluation of research productivity among the most prolific institutions; (4) identification of funding agencies involved; (5) determination of the journals in which international researchers published their work; and (6) assessment of the citations received by these publications.

Bibliometric indicators were utilized to rank the data using the standard competition ranking methodology. Only the top 10 rankings were considered and if two ranking numbers were the same, a gap was left in the subsequent ranking numbers (*e.g.*, 1, 2, 3, 3 and 5)[51]. The quality of research productivity was assessed using the h-index, which represents the number of articles (h) that have received at least h citations[52]. For example, if a researcher has 50 published journal articles, they would have an h-index of 10 if 10 of those papers have received at least 10 citations each and the remaining 40 papers have fewer than 10 citations each. The impact factor was used as an indicator to gauge the importance of the journals, evaluated using the Journal Citation Report (Clarivate Analytics) for the year 2022.

The presented Impact Index per Article refers to the top 10 highly cited papers obtained from the Reference Citation Analysis (RCA) database, which is an open, multidisciplinary citation analysis database owned by Baishideng Publishing Group, located in Pleasanton, CA, USA[53-55].

Visualization analysis

VOSviewer software (version 1.6.9, Leiden University, Leiden, The Netherlands) was used to create network maps depicting the relationships between terms identified in titles or abstracts, as well as cross-national cooperation[56-58]. VOSviewer allows the establishment of knowledge networks by utilizing co-occurrence analysis, which provides a scientific foundation for projecting future research hotspots and following the advancement of various research disciplines[56-58]. By clustering terms based on their co-occurrence, VOSviewer assigns a unique color to each cluster, which can be used to identify and analyze research hotspots more effectively. This approach allows for the visualization and detection of developing trends. Terms are represented as nodes and the associations between them are depicted as lines or links. The thickness of the lines represents the strength of the association between the terms.

Figure 1 Number of articles analyzed in a bibliometric study on global dialysis and depression-related publications between 1970 and 2022.

RESULTS

Evolution and growth of publications

We identified 800 publications that met the search criteria between 1970 and 2022. Of these, 707 (88.38%) were original research articles, 33 (4.13%) were reviews, 29 (3.63%) were letters to the editor and 31 (3.88%) fell under other categories, such as notes or editorials. The number of publications related to dialysis and depression has increased significantly in the last two decades, with fewer than three articles published annually before 2002. However, since 2013, the number of publications related to dialysis and depression has grown much more rapidly, with more than 46 articles published annually (Figure 1).

Top active countries

In fact, 93 countries have contributed to the literature on dialysis and depression, according to Scopus. The USA led the way with 144 publications, which was 18% of all publications on this topic; Turkey came second with 88 publications (11%), followed by China with 55 publications (6.88%) and Iran with 52 publications (6.5%) (Table 1). Figure 2 depicts the countries with > 10 publications on dialysis and depression, highlighting their collaborative network. The larger the circle, the more publications from that country will be published; and the thicker the line, the stronger the collaboration. The width and number of lines on the map reflect the intensity and degree of interaction between the countries represented. We focused on five VOSviewer clusters to assess their centrality and linkages with other countries. The data are based on a study of 21 countries (as seen in Figure 2), with the USA and Turkey contributing the most publications to the purple cluster.

Contributing institutions

According to Table 2, the top 10 institutions in the study generated a total of 89 publications, representing 11.13% of all the analyzed publications. On examining the papers related to dialysis and depression, the Leids Universitair Medisch Centrum came out on top, producing 18 publications, followed by the Onze Lieve Vrouwe Gasthuis with 14 publications, the VA Medical Center with 13 publications and the University of Hertfordshire with 13 publications.

Contributed funding agencies

Table 3 shows the leading funding agencies according to their production. The National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK), the National Institutes of Health (NIH) and the Japan Society for the Promotion of Science (JSPS) emerged as the most productive funding agencies, the NIDDK leading with 26 (3.25%), followed by the NIH with 15 (1.88%) and the JSPS with 11 (1.38%).

Table 1 Top 10 countries ranked by article output on dialysis and depression from 1970 to 2022

Ranking	Country	No. of documents	%
1	USA	144	18.00
2	Turkey	88	11.00
3	China	55	6.88
4	Iran	52	6.50
5	Brazil	42	5.25
5	United Kingdom	42	5.25
7	Japan	38	4.75
8	South Korea	37	4.63
9	Taiwan	35	4.38
10	Canada	25	3.13

Table 2 Top 10 institutions with the highest frequency of article publications on dialysis and depression worldwide, ranked by productivity

Ranking	Institute	Country	No. of documents	%
1	Leids Universitair Medisch Centrum	Netherlands	18	2.25
2	Onze Lieve Vrouwe Gasthuis	Netherlands	14	1.75
3	VA Medical Center	USA	13	1.63
3	University of Hertfordshire	UK	13	1.63
5	Amsterdam UMC	Netherlands	12	1.50
5	The Lister Hospital	UK	12	1.50
5	The University of Jordan	Jordan	12	1.50
8	University of Toronto	Canada	11	1.38
9	The George Washington University	USA	10	1.25
9	King's College London	UK	10	1.25
9	Başkent Üniversitesi	Turkey	10	1.25

Contributing journals

Table 4 lists the top 10 journals ranked by number of publications, which together make up approximately 21.16% of all publications. *International Urology and Nephrology* had the highest number of publications, with 24, followed by *Renal Failure* with 20 publications and *Kidney International* with 16 publications.

Citation analysis

In total, the top 10 articles received 2715 citations, with an average of 271.5 citations per article. The number of citations ranged from 206 to 446[59-68]. Table 5 displays the publications that garnered > 205 citations and were among the top 10. The impact index per article of the 10 most cited articles ranged from 4.9 to 16.6 (Table 5).

Research themes in the literature on dialysis and depression

Figure 3 presents the most commonly used terms in the titles and abstracts of the articles related to dialysis and depression. The size of the circle indicates the frequency of the term, while the distance between two circles or terms indicates their co-occurrence. The terms are grouped based on their close relationship and are represented by different colors. Cluster analysis identified three main clusters, displayed in green, blue and red. The green cluster relates to "gender differences in the prevalence of depression and anxiety among dialysis patients", the red cluster to "identification of depression as a potential risk factor for poor outcomes in dialysis patients", and the blue cluster to "effective interventions to alleviate depression in dialysis patients". The blue cluster was significantly associated with terms from other clusters. Overall, the three clusters are presented in Figure 3.

Table 3 The top ten funding agencies that have the most publications in research related to dialysis and depression from 1970 to 2022

Ranking	Funding agencies	Country	No. of publication	%
1	National Institute of Diabetes and Digestive and Kidney Diseases	USA	26	3.25
2	National Institutes of Health	USA	15	1.88

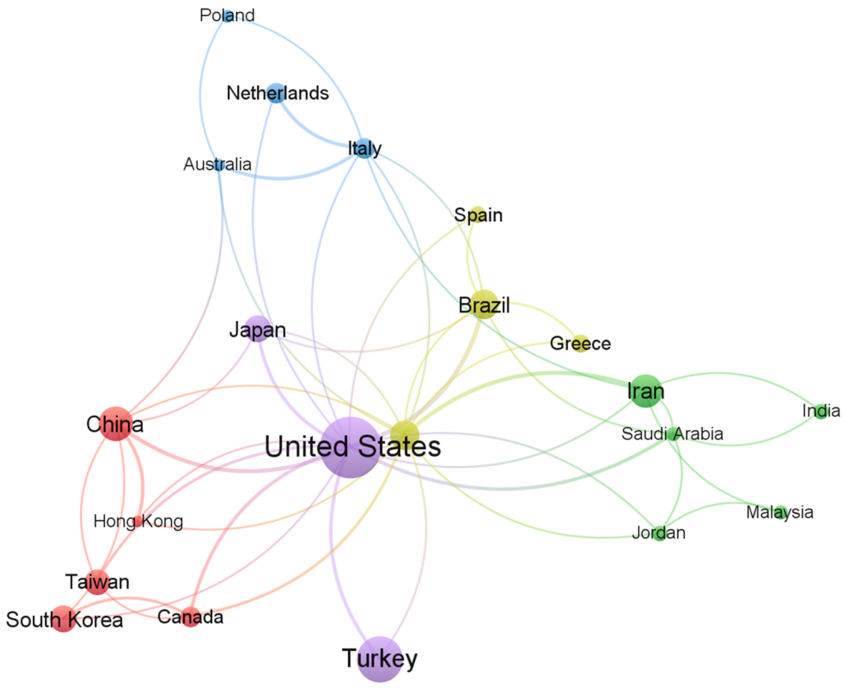
IF: Impact factor.

Future research direction analysis

In Figure 4, VOSviewer assigned distinct colors to each term based on the frequency of its appearance in all retrieved publications. Blue was assigned to the terms that first emerged in the literature, whereas yellow was assigned to those that were recently discovered. Before 2014, research in this field focused on the connection between "gender differences in the prevalence of depression and anxiety among dialysis patients" and "identification of depression as a possible risk factor for poor outcomes in dialysis patients". However, the latest research trends, discovered after 2014, revolved around "effective interventions to alleviate depression in dialysis patients".



DISCUSSION

Bibliometric analysis is a useful method for evaluating the global research landscape of a specific field. This work's analysis provides insights into the research on depression and dialysis, demonstrating that it has been a topic of interest to scientists worldwide. The prominence of the USA, Turkey and China suggests that these nations may have made distinctive contributions to the discipline. This analysis also yields the identification of notable contributors, such as institutions, journals and funding agencies. These contributors may serve as valuable resources for future researchers seeking collaboration or funding. Identified trends and concentrations in the field of research can help to guide future investigations and inform policy decisions regarding depression and dialysis. Forecasting future developments is also

beneficial for researchers, clinicians and policymakers who wish to anticipate future requirements and plan accordingly.

This study reveals that the amount of research evaluating the literature on dialysis and depression has increased consistently over the past two decades. In the foreseeable future, the amount of research into the connection between

VOSviewer software version 1.6.19 was used to generate the map.

dialysis and depression is likely to increase. This is due to the increasing prevalence of chronic kidney disease (CKD) and the fact that depression is a common comorbidity among patients with CKD, especially those who require dialysis[69,70]. Furthermore, there is growing awareness among healthcare professionals of the impact that depression can have on the overall health and well-being of dialysis patients, as well as a greater emphasis on addressing mental health issues as part of comprehensive care[71,72]. As a result, it is reasonable to anticipate that research on this subject will continue to grow in the coming years.

Research studies to identify nations with a significant presence in a specific research discipline. In this case, the USA was determined to have the most influential research on depression and dialysis. This conclusion was likely reached by analyzing the number of publications and citations in these disciplines from various countries. It is not uncommon for countries to excel in particular areas of research while lagging behind in others[73-76]. Variables such as financial resources, government support, academic infrastructure, and cultural attitudes toward research contribute to scientific productivity. Countries such as Turkey, Iran and Brazil may have devoted more resources to depression and dialysis research, resulting in an increase in the number of publications. Additionally, these countries may have research questions or perspectives that have not been investigated as extensively in other regions. Notably, the connection between economic development and scientific productivity is intricate. Although it is true that countries with larger economies typically have more resources for research, there are numerous instances in which smaller or developing countries make significant scientific contributions. However, it is essential to note that research output does not necessarily equate to quality or influence. Other factors, such as funding, collaboration, and the caliber of research institutions, can also affect a country's research influence[77]. It is also possible that other countries conduct high-quality research in these fields but are not recognized due to language barriers or lack of visibility[78].

The main themes of a research paper are usually reflected in the title and abstracts. When the terms depression and dialysis occur together frequently in a research field, it indicates current trends and progress in that area. Based on this cooccurrence, research on depression and dialysis can be categorized into three aspects: (1) "Prevalence of depression and anxiety among dialysis patients and gender differences"; (2) "Identification of depression as a potential risk factor for poor outcomes in dialysis patients"; and (3) "Effective interventions for alleviating depression in dialysis patients".

The prevalence of depression and anxiety among dialysis patients, as well as gender differences, was one of the most important aspects of the study. There are gender differences in the prevalence and presentation of depression and anxiety in this population[79,80]. According to previous studies, women on dialysis are more likely to experience depression and anxiety than men[79-81]. Several factors, including fluctuations in hormones, social roles and cultural norms, might contribute to this[4,82].

DOI: 10.5498/wjp.v13.i8.593 **Copyright** ©The Author(s) 2023.

Figure 4 Map of a network visualization analysis of terms in titles and abstracts based on their frequency of appearance. Blue indicates earlier occurrences of the terms, whereas yellow indicates later occurrences. VOSviewer software version 1.6.19 was utilized to create the map.

The second hot topic was the "identification of depression as a potential risk factor for poor outcomes in dialysis patients". According to previous findings, depression in hemodynamic patients is associated with a decline in the quality of life, an increase in mortality and an increase in healthcare costs[11,83-86]. Depression may also be linked to poor adherence to medicine and diet plans, a higher number of hospitalizations and a lack of social support[87]. Healthcare practitioners must be aware of the likelihood of depression in hemodynamic patients and perform routine screenings. Antidepressant drugs, psychotherapy and lifestyle changes can all be used to treat depression in patients[88,89]. Correctly diagnosing and treating depression in these patients can improve both their mental and physical health[88].

The third hot topic was "effective therapies to relieve depression in dialysis patients". Enhancing the quality of life and health outcomes of dialysis patients involves the deployment of depression-fighting therapies[90,91]. Various therapies have been found to be useful for lowering depression in dialysis patients experiencing hemodynamic lysis[19,92,93]. One of the most widely utilized therapies is antidepressant medication. Antidepressant medication has been proven in various studies to be beneficial for reducing depressive symptoms in dialysis patients, as well as for improving other aspects of their health, such as sleep quality and pain management[94,95]. Cognitive behavioral therapy (CBT) is a successful treatment for depression in dialysis patients. CBT is a type of therapy that aims to change negative thought and behavior patterns[96-98]. Several studies have indicated that CBT can considerably reduce depressive symptoms and enhance dialysis patients' quality of life[96,97]. In addition to CBT, exercise, music therapy and mindfulness-based therapies have been demonstrated to be helpful for treating depression in patients[92,99,100]. It has been shown that exercise enhances mood and reduces depressive symptoms in dialysis patients, whereas music therapy and mindfulness-based interventions may be helpful in the management of stress and anxiety.

Most research publications that involved dialysis patients before 2014 focused on the prevalence and gender differences of depression and anxiety and the identification of depression as a risk factor for negative outcomes in those patients. However, a marked change in research trends has been undertaken since 2014. The emphasis has shifted to focus on effective interventions that improve depression in dialysis patients. Thus, the research has acknowledged the value of addressing the practical elements in managing depression and improving the well-being of patients undergoing dialysis. The following future directions in this field are based on these findings. Although this issue to explore gender differences in the prevalence of depression and anxiety among patients undergoing dialysis was prevalent before 2014, further research may be needed for a deeper understanding of the factors that contribute to gender differences and their effects on treatment and outcome. Previous research has focused mainly on studying the correlation between depression and adverse outcomes, but it is necessary to continue to evaluate the relationship and understand the underlying mechanism of depression's impact on the well-being of patients treated with dialysis. Recent articles focus primarily on methods to help people with depression. In the future, researchers should study various treatments such as medication therapies and social support to determine the most effective methods for alleviating depression in these patients.

Research is needed to investigate the psychological and social factors causing depression and anxiety in patients who require dialysis. This involves assessing factors such as economic difficulties, stress management strategies, the presence of strong support systems and other relevant factors that can influence the development and deterioration of depression in this particular patient group. It is essential to acknowledge the lasting effects of therapeutic interventions on the mental and overall health of dialysis patients. By conducting long-term studies and follow-up evaluations, we can gain valuable information regarding the long-term efficacy and sustainability of various treatment approaches.

By utilizing bibliometrics, this study took a novel approach to understanding the academic literature on the relationship between dialysis and depression. Researchers could easily identify study participants, focal areas of interest and emerging patterns within this specific domain by utilizing visual analysis. Although these methods were useful in identifying research trends and knowledge gaps, they did have some limitations. Firstly, there was a potential risk of bias in the selection of publications and the inability to capture the full complexity of research topics. This was mainly due to our search being limited to Scopus, which, although comprehensive and reputable for numerous academic fields, might have omitted papers from alternative sources such as PubMed and Web of Science. Secondly, the list of keywords used in the study was derived from previous literature reviews and it is possible that some keywords were omitted, resulting in false-negative findings. Thirdly, as the citation searches were time dependent, older articles were more likely to be cited, which may have influenced the study findings. Fourthly, the scope of the investigation was limited to the search for the title and specific search phrases related to dialysis and depression, which may have led to the omission of relevant articles that used different terms. Lastly, the limitations of the Scopus database resulted in the dispersion of research output from active institutions with multiple Scopus profiles and the omission of funding agency names due to variations in publication naming conventions. Therefore, it is essential to refrain from manipulating or merging the Scopus output and to restrict data analysis to the specified method.

CONCLUSION

This study investigated the growth, trends and research topics associated with depression in dialysis patients. Analysis of 800 documents published between 1970 and 2022 revealed a significant increase in research activity over the past two decades, emphasizing the significance of addressing this common psychological condition in dialysis patients. In addition to the USA as the main contributor, Turkey, China and Iran have also made substantial contributions to the field. The study identifies key research areas and three major clusters of findings: gender differences in depression distribution; depression as a risk factor; and effective depression treatments. These findings contribute to the knowledge concerning gender-specific depression in dialysis patients and the development of effective strategies to improve their mental health. In addition, this report proposes future research directions, given the increasing emphasis on effective treatments for depression in dialysis patients. The study highlighted the growing awareness of the influence of depression on treatment adherence and health outcomes in this population. This study contributed to the advancement of knowledge in its field by indicating the way forward for future research on depression treatments for dialysis patients.

ACKNOWLEDGMENTS

The author thanks An-Najah National University for all its administrative assistance during the implementation of the project. In addition, the author thanks Drs. Waleed Sweileh and Sa'ed H. Zyoud for helping and validating the research strategy.

ARTICLE HIGHLIGHTS

Research background

Depression is a prevalent psychiatric disorder among patients with end-stage renal disease. Hemodialysis patients have a significantly higher occurrence of depression than the general population. Similar to other chronic illnesses and the overall population, research indicates that depression in hemodialysis patients is linked to a diminished quality of life and heightened mortality.

Research motivation

To identify knowledge gaps and guide future research directions, it is crucial to comprehend the present status of research and areas of focus within the domains of depression and hemodialysis.

Research objectives

The objective of the research was to offer a comprehensive analysis of the existing research in the area of depression and hemodialysis through bibliometric analysis.

Research methods

A search was performed in the Scopus database to find publications on the topic of dialysis and depression from 1970 to

2022. The acquired data underwent bibliometric analysis utilizing VOSviewer software version 1.6.9. This analysis encompassed visualization, co-occurrence, and examination of publication patterns in the field of dialysis and depression.

Research results

The number of publications addressing the correlation between dialysis and depression has increased substantially over the past 20 years. Prior to 2002, the yearly publication count was below three. Nonetheless, starting from 2013, there has been a remarkable acceleration in the publication rate, surpassing 46 articles per year, specifically focusing on dialysis and depression.

Research conclusions

Three significant research topics have emerged, focusing on the varying occurrence of depression and anxiety based on gender, recognizing depression as a contributing factor to negative consequences, and assessing the effectiveness of therapies in reducing depression among individuals undergoing dialysis.

Research perspectives

The objective of this study was to determine present patterns and focal points in the domain of dialysis and depression. This will aid in directing future research and updating clinical practices. Through the utilization of bibliometric analysis, the study offers a thorough summary of the literature concerning this subject matter. Consequently, it facilitates researchers and clinicians in keeping abreast of the most recent advancements in the field.

ABOUT COVER

Editorial Board Member of *World Journal Psychiatry*, Thomas Sobanski, MD, Chief Doctor, Senior Research Fellow, Department of Psychiatry, Psychotherapy, and Psychosomatic Medicine, THUERINGEN-Kliniken GmbH, Saalfeld D-07318, Germany. tsobanski@thueringen-kliniken.de

AIMS AND SCOPE

The primary aim of *World Journal of Psychiatry* (*WJP*, *World J Psychiatry*) is to provide scholars and readers from various fields of psychiatry with a platform to publish high-quality basic and clinical research articles and communicate their research findings online.

WJP mainly publishes articles reporting research results and findings obtained in the field of psychiatry and covering a wide range of topics including adolescent psychiatry, biological psychiatry, child psychiatry, community psychiatry, ethnopsychology, psychoanalysis, psychosomatic medicine, *etc.*

INDEXING/ABSTRACTING

The *WJP* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Current Contents/Clinical Medicine, Journal Citation Reports/Science Edition, PubMed, PubMed Central, Reference Citation Analysis, China National Knowledge Infrastructure, China Science and Technology Journal Database, and Superstar Journals Database. The 2023 Edition of Journal Citation Reports® cites the 2022 impact factor (IF) for *WJP* as 3.1; IF without journal self cites: 2.9; 5-year IF: 4.2; Journal Citation Indicator: 0.52; Ranking: 91 among 155 journals in psychiatry; and Quartile category: Q3.

Abstract

Deep transcranial magnetic stimulation (DTMS) is a new non-invasive neuromodulation technique based on repetitive transcranial magnetic stimulation technology. The new H-coil has significant advantages in the treatment and mechanism research of psychiatric and neurological disorders. This is due to its deep stimulation site and wide range of action. This paper reviews the clinical progress of DTMS in psychiatric and neurological disorders such as Parkinson's disease, Alzheimer's disease, post-stroke motor dysfunction, aphasia, and other neurological disorders, as well as anxiety, depression, and schizophrenia.

Key Words: Deep transcranial magnetic stimulation; Neurological disorders; Psychiatric disorders; Minireview

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Deep transcranial magnetic stimulation as a novel non-invasive neuromodulation technique has been reported to be applied in clinical psychiatric and neurological disorders. The potential clinical efficacy and safety of this technique in each disorder and the mechanisms behind them need to be further summarized and sorted out, and the direction of future development needs to be more clearly defined.

INTRODUCTION

Transcranial magnetic stimulation (TMS) is a magnetic stimulation technique that acts on the cerebral cortex, using electromagnetic principles to deliver an electric field to the cerebral cortex to alter the action potential of cortical nerve cells, thereby regulating metabolism and neural activity in the brain[1]. Repetitive transcranial magnetic stimulation (rTMS) is another form of TMS, which modulates cortical excitability. At high frequencies (> 5 Hz), cortical excitability increases, whereas at low frequencies (1 Hz), a long-term depression effect is produced and cortical excitability decreases [2]. TMS has been widely used to treat several neurological and psychiatric disorders, such as Parkinson's disease (PD), post-stroke limb movement disorders, and depression, with few adverse events. However, conventional TMS has some limitations[3,4], such as limited and imprecise localization of the stimulation site, which has led to the development of deep TMS (DTMS).

DTMS has the advantages of deeper and wider stimulation, more precise localization, and less damage to the superficial cortex than conventional TMS[5,6]. The depth of stimulation can be controlled by adjusting the intensity of the stimulation or the distance between the skull and the coil element. In recent years, this technique has been used to study and treat a variety of neuropsychiatric and psychiatric disorders and has been approved by the Food and Drug Administration (FDA) for the treatment of refractory depression. There has been an increase in national and international research on the use of DTMS in neurological and psychiatric disorders, but there has not been a systematic review of DTMS in the treatment of neurological and psychiatric disorders to evaluate its specific efficacy. This article presents a comprehensive review of the current state of research on DTMS in neurological disorders, such as PD and AD, and psychiatric disorders, such as schizophrenia (SZ) and depression, to provide a reference for future studies.

DTMS IN PSYCHIATRIC DISORDERS

Treatment-resistant depressive

Major depressive disorder (MDD) is one of the most common and disabling psychiatric disorders, with a prevalence of 5%-15% in the general population[7]. Approximately 30% of patients with MDD who do not respond to two or more trials of first-line antidepressants are considered to have treatment-resistant depression (TRD)[8]. TRD is a debilitating chronic mental illness that is associated with increased morbidity and mortality, reduced quality of life, impaired occupational, social, and offspring development, and increased costs on the healthcare system[9]. Currently, depression is mainly treated with medication, but antidepressants tend to be slow-acting and some of the active ingredients in depressants, such as neuropeptides, can be affected by the blood-brain barrier and cause some adverse effects[10].

Studies have shown that an active state of the left dorsolateral prefrontal cortex (PFC) is associated with depressed mood, and improvement of activity levels in the PFC may reduce depressive symptoms. Although TMS is effective in treating depression after stimulation of the dorsolateral PFC[11], there are limitations to this technique, such as the inability to produce some effect in areas such as deeper cortical and limbic areas, where deeper stimulation may be useful. DTMS is an effective new therapy and the FAD has approved the use of DTMS with H1 coils for the treatment of major depression[12]. So far, great results have been achieved with DTMS in the treatment of TRD. The development of DTMS applied to TRD is shown in Table 1.

Levkovitz *et al*[13] conducted a study to examine the impact of high frequency (20 Hz) repeat DTMS on the PFC in 65 patients with non-medicated depression. The researchers discovered that the use of high stimulus intensity resulted in significant improvements in both Hamilton depression rating scale (HDRS) scores and cognitive performance. Notably, no serious adverse events related to the treatment were observed. This study represents a pioneering exploration of the potential of DTMS in addressing psychiatric and neurological disorders[14]. Levkovitz *et al*[15] conducted a pioneering double-blind controlled randomized multicentre study aimed at validating the safety and efficacy of DTMS for the treatment of MDD. The study enrolled a total of 212 outpatients with MDD who had previously experienced treatment failure with antidepressants. The findings revealed a significant improvement in the HDRS-21 score, with a mean increase of 6.39 points in the DTMS group compared to only 3.28 points in the sham control group. Furthermore, the group that underwent DTMS stimulation demonstrated significantly higher rates of response and remission in comparison to the group that received sham stimulation. Moreover, the therapeutic impact of DTMS persisted throughout the 16-wk maintenance phase, proving to be advantageous for patients who had previously shown no response to alternative treatments[15]. The study findings revealed a remission rate of 60% [95% confidence interval (95%CI): 48%-71%] in the DTMS group, whereas the remission rate for rTMS with conventional figure-of-eight coils was 43% (95%CI: 31%-55%) (Table 1)[16-22]. In a meta-analysis conducted in 2019, it was observed that the DTMS group exhibited a response rate of 47.8%, whereas the sham group demonstrated a response rate of 25.6%. Additionally, the remission rate in the DTMS group was found to be 36.6%, while the sham group exhibited a remission rate of 14.8%. The criteria for response were defined as a 50% or greater improvement from baseline, as determined by the primary depression scale used in the study.

Table 1 Development of deep transcranial magnetic stimulation in treatment-resistant depression

Ref.	Method	Result	Adverse events	Significance
Levkovitz *et al*[13], 2009	20 Hz DTMS stimulates FPC	Significant improvement in HDRS scores	Headaches	This is the first time that TRD has been treated with the new H-coil
McGirr *et al* [14], 2014	20 Hz stimulates DLFPC	Reduction in HAMD-21 scores	Unreported	Five-factor personality assessment may have prognostic value in DTMS for resistant MDD
Levkovitz *et al*[15], 2015	20 Hz DTMS stimulates PFC	HDRS-21 score was improved by 6.39 points	Unreported	It is efficacious and safe in patients not responding to antidepressant medications, and the effect remains stable
Feffer *et al* [16], 2017	18 HZ DTMS stimulation; right abductor pollicis brevis muscle	Depressive symptoms (HDRS-21 total score) decreased significantly	Headaches	The severity of the depressive episode is associated with a positive therapeutic effect of dTMS
Kaster *et al* [17], 2018	18 HZ DTMS stimulates DLPFC and VLPFC	Remission rate was significantly higher with active than sham rTMS (40.0% *vs* 14.8%)	Pain and discomfort from stimulus	High-dose DTMS appears to be safe, well tolerated, and efficacious in the treatment of LLD
Tendler *et al* [18], 2018	10 HZ DTMS combined with SSRIs	The remission rate was 35.3%	Headaches	DTMS can augment formerly ineffective SSRI treatment
Filipčić *et al* [19], 2019	18 HZ DTMS stimulates LDLPFC	The response was significantly better in H1-coil than in 8-coil group (OR = 2.33; 95%CI: 1.04-5.21; P = 0.040)	Unreported	DTMS had better response rate than rTMS
Matsuda *et al* [20], 2020	18 Hz DTMS stimulates LDLPFC	HDRS-21 was more significantly improved	Unreported	DTMS might be effective and safe for office workers with treatment-resistant depression
Bahun *et al* [21], 2022	18 Hz stimulates DLFPC	Cognitive function all showed mild to moderate improvement	Unreported	Can improve MDD symptoms

DLFPC: Dorsolateral prefrontal cortex; HDRS-21: Hamilton Depression Rating Scale-21; DTMS: Deep transcranial magnetic stimulation; HAMD-21: 21-item Hamilton Depression Rating Scale; VLPFC: Ventrolateral prefrontal cortex; MDD: Major depressive disorder.

Remission, on the other hand, was defined as a HDRS-17 score of 7 or less, or a HDRS-24 score of 10 or less. Based on these findings, it can be concluded that DTMS is a safe and effective intervention for patients suffering from TRD. Studies combining DTMS and antidepressant medications seemed to show greater therapeutic effects[23].

From the above studies, it is clear that DTMS is an effective treatment for MDD and is well tolerated by patients without major adverse events, and may be a good option for patients who are antidepressant-resistant or ineffective.

Obsessive-compulsive disorder

Obsessive-compulsive disorder (OCD) is a common and disabling psychiatric disorder characterised by the presence of intrusive thoughts and repetitive behaviors[24], with a lifetime prevalence of 2% to 23%[25]. It is characterised by early onset, which places a heavy burden on patients and their families. Currently, only 40% to 60% of patients can improve certain symptoms with treatment[26]. Studies have shown that the cortico-striatal-thalamic-cortical circuit is dysfunctional in patients with OCD[27], including the orbitofrontal cortex, anterior cingulate cortex (ACC), cingulate cortex, and ventral striatum[28]. A meta-analysis published in 2023 suggested that the average treatment response rate (percentage reduction in total Y-BOCS score) across studies was 39.5% for rTMS and 8.8% for sham conditions. rTMS showed a moderate therapeutic effect (g = 0.65) on OCD symptom severity and a threefold increased likelihood of treatment response (relative risk = 3.15) compared with sham conditions. Greater improvements in comorbid depression severity were associated with greater treatment effects of rTMS on OCD symptom severity. In addition, longer rTMS sessions and fewer total sessions predicted greater clinical improvement[29].

The development of DTMS applied to OCD is shown in Table 2. DTMS was first applied in 2015, when Modirrousta *et al*[30] found that 1-Hz frequency DTMS applied to Brodmann areas 24 and 32 improved OCD symptoms and Yale-Brown-Obsessive-Compulsive Scale (Y-BOCS) scores. In 2018, Carmi *et al*[27] noted a significant increase in Y-BOCS scores with high-frequency (20 Hz) deep magnetic stimulation and the ability to safely and effectively reduce OCD symptoms. They then conducted a prospective multicentre, randomized, double-blind, placebo-controlled trial[31], the results of which showed that patients treated with DTMS had a more significant reduction in OCD symptom scale scores, with an efficacy rate of 38.1%. At the 1-mo follow-up, the efficacy rate increased in both the treatment and sham-stimulation groups, to 45.2% in the treatment group and 17.8% in the sham-stimulation group. In 2018, the United States FDA approved DTMS with the "H7 coil" for the treatment of OCD, potentially for patients for whom medication and psychological interventions have not been effective. Based on previous studies, the response of patients with OCD to DTMS treatment was determined by whether the total score on the Y-BOCS decreased by 30% or more from baseline[32]. We summarised the available studies and found that the remission rate of OCD treated with DTMS was 29.22%-53.90% [31,33,34].

Table 2 Development of deep transcranial magnetic stimulation in obsessive-compulsive disorder

Ref.	Method	Result	Adverse events	Significance
Modirrousta *et al* [30], 2015	1 Hz DTMS stimulates PFC	Improvement in Y-BOCS	Electric shocking sensation	Low frequency deep rTMS was effective in OCD symptom reduction
Carmi *et al*[27], 2018	20 Hz or 1 Hz DTMS stimulates mPFC and ACC	Improvement in Y-BOCS	Slight headache	DTMS has the ability to directly modify ACC activity
Carmi *et al*[31], 2019	20 Hz DTMS stimulates mPFC and ACC	Improvement in Y-BOCS	Slight headache	High-frequency DTMS in special region can significantly improve OCD symptoms
Ikawa *et al*[33], 2022	20 Hz DTMS stimulates mPFC and ACC	Improvement in Y-BOCS	Slight headache	DTMS treatment of OCD had a favorable therapeutic effect
Ikawa *et al*[33], 2022	20 Hz DTMS stimulates mPFC and ACC	Improvement in Y-BOCS	Electric shocking sensation	DTMS was found to be a safe and effective intervention for OCD symptoms in adolescents

Y-BOCS: Yale-Brown obsessive compulsive scale; mPFC: Medial prefrontal cortex; ACC: Anterior cingulate cortex; DTMS: Deep transcranial magnetic stimulation; PFC: Prefrontal cortex; OCD: Obsessive-compulsive disorder.

Although DTMS is effective in improving OCD symptoms and Y-BOCS scores, the biological basis for the efficacy of DTMS is not yet clear, and more randomised, double-blind, placebo-controlled trials (using dummy coils, at different parameter frequencies) and larger-sample clinical trials are needed to explore this further.

Schizophrenia

SZ, a chronic illness of unknown etiology, is a psychiatric disorder that affects 1% of the world's population[35,36] and may be associated with genetic and environmental risk factors. SZ is often associated with severe impairments in emotions, thinking, and behaviour. A common symptom in people with SZ is hallucinations, which can cause mental debilitation in schizophrenics. Although antipsychotic medications are effective for this symptom, they are still less effective in about 25% of patients. Some studies have shown that hallucinations are associated with increased activity in areas such as the temporal cortex and prefrontal cortex[37], so inhibitory DTMS could be considered to reduce abnormal activity in these areas.

The development of DTMS in SZ is shown in Table 3. DTMS treatment may improve positive symptoms. Rosenberg *et al*[38] conducted an open-label study in which the investigators treated eight patients with SZ diagnosed with persistent hallucinations (hallucinations that had persisted for an average of 11 years) with low-frequency DTMS using an H1 coil, using the Auditory Hallucinations Rating Scale (AHRS) and the Positive Symptom Rating Scale (SAPS) to assess the patients. Five of the patients' AHRS scores decreased by 34.5% and the SAPS score improved by 23.1%. Three patients were subsequently treated with 20 sessions of DTMS, resulting in a 27.8% improvement in AHRS and a 13.75% improvement in SAPS at the end of treatment, and these improvements were maintained over the subsequent 1-mo follow-up period[38]. They then conducted a double-blind study in 2012, in which a total of ten patients completed the treatment and both groups showed an increase in phantom hearing scores, but the difference between the treatment and sham stimulation groups was not statistically significant on either scale[39]. Negative symptoms and cognitive deficits are central to SZ, but current treatments for this condition are underdeveloped. Levkovitz *et al*[40] used DTMS to stimulate the prefrontal cortex of 15 patients with SZ in 2011, and the results obtained 2 wk after treatment showed improvements in both negative symptoms and cognitive function. Some previous studies have suggested that the temporal and parietal cortices are central parts of the language system, that verbal hallucinations may be related to abnormal activity in these regions, and that it may be possible to reduce the hallucination symptoms by suppressing pathological hyperactivity in this region through the use of low-frequency magnetic stimulation[41], but more in-depth studies are needed in the future. In patients with SZ, negative symptoms are often associated with social dysfunction, so it is important to improve negative symptom-based treatment. In 2022, a study of bilateral DTMS of the insula and prefrontal cortex using special H4 coils demonstrated the therapeutic effects of DTMS on psychotic symptoms. In functional magnetic resonance imaging (fMRI) analyses, resting-state connectivity between the insula and the default mode network showed a numerically greater change from baseline in the active DTMS group than in the sham group, consistent with a functional change in insular circuitry[42-44].

Although the current findings on the treatment of negative symptoms with DTMS have shown to be effective, the sample size of the studies is small, and more clinical studies are needed to confirm this in the future. DTMS was also compared to other brain stimulation techniques such as electroconvulsive therapy, transcranial direct current stimulation, vagus nerve stimulation, or standard TMS.

Substance use disorders

Substance use disorders (SUDs) are a group of disorders in which brain damage is caused by chronic use of alcohol and drugs. Substance use disorders are currently difficult to treat, medications are less effective, and the disease has a high relapse rate of 40%-60%[45]. Non-invasive brain stimulation can affect neuroplasticity in the cerebral cortex and throughout the brain, potentially reducing and controlling the compulsive craving for psychoactive substances by rewiring the brain's nerves[46]. Different substance use disorders are affected by similar neural circuits, and because the

Table 3 Development of deep transcranial magnetic stimulation in Schizophrenia

Ref.	Method	Result	Adverse events	Significance
Birdi *et al*[36], 2023	1 Hz DTMS stimulates LTPC	Significant improvement in AHRS score	Transient headache	DTMS treatment was effective for chronic auditory hallucinations in schizophrenic patients
Rosenberg *et al* [38], 2011	20 Hz DTMS stimulates PFC	Cognition and negative symptoms are improved	Transient headache and fatigue	DTMS can improve negative symptoms and cognitive deficits for schizophrenia patients
Rosenberg *et al* [38], 2011	1 Hz DTMS stimulates LTPC	Significant improvement in AHRS score	Mild and self-limiting headaches	DTMS had no significant effect on auditory hallucinations
Rabany *et al*[43], 2014	20 Hz DTMS stimulates PFC	SANS was significantly reduced	Unreported	DTMS was effective for negative symptoms, but the effect was moderate
Linsambarth *et al* [44], 2019	18 Hz DTMS stimulates bilateral PFC	SANS was significantly reduced		DTMS contributed to negative symptoms in schizophrenia
Moeller *et al*[42], 2022	10 HZ DTMS stimulates the insular and prefrontal cortices	The DTMS group had a more pronounced decrease in insula blood flow than the sham operation group	Unreported	DTMS in smoking patients with schizophrenia was effective

AHRS: Auditory Hallucinations Rating Scale; DTMS: Deep transcranial magnetic stimulation; PFC: Prefrontal cortex; SANS: Scale for the Assessment of Negative Symptoms; TPC: Temporoparietal cortex.

use of H-coils can alter the electrical field activity in deep subcortical brain regions, DTMS may be recommended for the treatment of different SUDs.

The evolution of DTMS applied to SUDs is shown in Table 4. Harel *et al*[47] intervened in patients with alcohol use disorders using high-frequency (10 Hz) DTMS and showed that the results were similar to sham. The results showed that the DTMS group had significantly lower levels of alcohol craving and relapse rates of alcohol use disorders compared to the sham-stimulation treatment group. In addition, resting-state network connectivity between the ACC and medial frontal cortex was reduced in the DTMS group during the 3 wk of treatment, and this altered connectivity may be related to substance-induced craving and relapse[47]. Dinur-Klein *et al*[48] evaluated the effects of bilateral prefrontal and insula cortical stimulation using DTMS in patients with nicotine use disorder. The investigators recruited 115 patients with nicotine use disorder (for whom prior treatment had been ineffective), randomizing patients to high-frequency and sham stimulation groups, and showed that high-frequency DTMS treatment significantly reduced patients' nicotine dependence, resulting in a 44% abstinence rate at the end of treatment and a 33% abstinence rate at the 6-mo follow-up, in contrast to the low-frequency DTMS (1 Hz) group, which was less effective[48-50].

In summary, it is clear from the few available studies that high-frequency DTMS may be effective in the acute phase of treatment for some SUD symptoms.

APPLICATION OF DTMS IN NEUROLOGICAL DISEASES

Alzheimer's disease

Alzheimer's disease (AD) is a common and persistent neurological disorder whose prevalence is increasing with the world's aging population. The pathological mechanism of AD may be the structural changes in the brain, abnormal protein deposition, and loss of cholinergic neurotransmission[51]. The functional networks closely related to memory in the brain of AD patients show large-scale disruptions and their plasticity is impaired, as confirmed by neurophysiological and fMRI studies[52]. Currently, there are several disease-modifying therapies such as monoclonal antibodies developed [53]. However, these therapies are specific to early AD stages and amyloid-related imaging abnormalities[54], and there is no effective treatment for AD patients[55]. Gamma oscillations function in information processing by modulating neuronal and glial cell responses to ameliorate AD[56], and pathological increases in gamma band power may be due to the disruption of GABAergic interneuronal networks, resulting in an imbalance between excitation and inhibition in the central nervous system[57]. Brain modulation techniques such as TMS can regulate this unbalanced state of excitation. Recently, brain stimulation to improve cognitive function has received much attention. Chang *et al*[58] first introduced TMS to the motor cortex, and it has now been suggested to be useful in improving cognitive function in AD patients, and the basic principle is that rTMS induces long-term potentiation to enable patients to have enhanced neuronal signaling and increased synaptic plasticity. High-frequency rTMS applied to the dorsolateral prefrontal cortex[59-61] or multiple brain regions[62,63] improves cognition in randomised controlled trials (RCTs) in AD, while functional performance and mood are unaffected[64]. DTMS is still in the early stages of investigation for the treatment of patients with AD.

The evolution of DTMS applied to AD is shown in Table 5. In 2016, Avirame *et al*[65] first applied DTMS to patients with moderate to severe AD, where the researchers used H2 coils to administer 20 DTMS sessions to the PFC of 11 patients with moderate to severe AD, and found that cognitive function improved in 60% to 77% of patients after

Table 4 Development of deep transcranial magnetic stimulation in substance use disorders

Ref.	Method	Result	Adverse events	Significance
Girardi *et al* [49], 2015	20 Hz DTMS stimulates DLFPC	Craving scores dropped significantly	Unreported	DTMS was well tolerated and found to be effective in AUD
Harel *et al* [50], 2022	10 Hz DTMS stimulates mPFC and ACC	A lower percentage of heavy drinking days	Moderate to severe headaches	DTMS was a safe and well-tolerated intervention, with promising initial evidence for efficacy in alcohol addiction

DLFPC: Dorsolateral prefrontal cortex; DTMS: Deep transcranial magnetic stimulation; SUD: Substance use disorders; mPFC: Medial prefrontal; ACC: Anterior cingulate cortices; AUD: Alcohol use disorder.

Table 5 Development of deep transcranial magnetic stimulation in Alzheimer's disease

Ref.	Method	Result	Adverse events	Study design	Significance
Avirame *et al* [65], 2016	10 Hz DTMS for PF stimulation	60%-70% of AD patients' cognitive function was improved	Light headache and occasional tiredness	Case series study	DTMS led to preservation and even improvement of cognitive functions
Leocani *et al* [66], 2020	10 Hz DTMS	ADAS-cog at 4 and 8 wk compared with baseline was improved	Temporary headaches	Double-blind, placebo-controlled pilot study	DTMS was feasible and safe in patients with probable AD

ADAS-cog: Alzheimer's disease assessment scale-cognitive; AD: Alzheimer's disease; DTMS: Deep transcranial magnetic stimulation; PF: Bilateral prefrontal regions.

treatment[65]. A randomized double-blind placebo-controlled trial by Leocani *et al*[66] showed that the DTMS group showed an improvement in AD Assessment Scale-Cognitive (ADAS-cog) scores compared with the sham-stimulation group at weeks 4 and 8 compared with baseline, but this effect diminished after 2 mo of treatment, suggesting that DTMS is effective in AD patients in a short period. However, most of the subjects included in the above two studies were patients with moderate to severe AD for whom DTMS was ineffective in improving cognitive function, and this may be related to the reduced neuroplasticity of the brain in patients with advanced AD. Patients with early AD respond better to DTMS.

Although DTMS is effective in improving cognitive function in AD patients, we need to further validate the efficacy of DTMS combined with cognitive training in early AD patients and conduct more relevant large-scale multicenter RCTs.

Aphasia

Approximately 1/3 of stroke patients are diagnosed with aphasia[67]. Aphasia is an acquired language disorder that has phonological, morphological, semantic, and syntactic deficits that negatively affect patients' functioning, emotions, quality of life, and social participation. Language deficits after stroke aphasia are heterogeneous, and each subtype of aphasia is associated with damage to specific cortical areas, with some extension to subcortical areas[68,69]. Studies have shown that TMS can significantly improve language outcomes in patients with aphasia[70]. H-coil stimulation of a large number of neural networks involved in language function may be more effective than conventional focal coils because of the extensive and non-selective stimulation of language areas in the brain, where aphasia is often due to damage to areas involved in language function[71].

The development of DTMS applied to aphasia is shown in Table 6. First, Spagnolo *et al*[72] utilized repetitive DTMS on a patient diagnosed with progressive supranuclear paralysis accompanied by aphasia. The patient exhibited enhancements across all cognitive domains, particularly in language function. Furthermore, 18-FDG-PET scans revealed notable clinical, neuropsychological, and metabolic improvements when compared to the pre-treatment phase. These findings suggest that DTMS elicits excitation in pertinent functional circuits beyond the intended area of stimulation. Moreover, the observed improvements endured for a minimum of 1 mo post-stimulation, as confirmed through telephone follow-up. In the same year, Trebbastoni *et al*[73] treated a patient with primary progressive aphasia with high-frequency DTMS in the left dorsolateral PFC and showed that the patient also showed transient but significant improvements in verbal fluency and writing ability. Chieffo *et al*[71] suggested that high-frequency DTMS can significantly improve naming ability in patients with chronic post-stroke aphasia.

Although the sample sizes of all the above studies are small and subject to some error, they provide new insights into the use of DTMS in aphasia.

Post-stroke motor dysfunction

Limb motor dysfunction is one of the most common sequelae after stroke. rTMS has been studied to improve motor dysfunction in stroke patients, but the results are somewhat mixed. Some scholars have suggested that an interhemispheric competition model is a basis for rTMS to promote motor recovery after stroke, in which the healthy hemisphere inhibits the diseased hemisphere, resulting in reduced dominance of the hemiplegic limb[74]. In recent years, some of the

Table 6 Development of deep transcranial magnetic stimulation in aphasia

Ref.	Method	Result	Adverse events	Significance
Spagnolo *et al*[72], 2013	10 Hz DTMS stimulates Broca's area and DLPFC	Improvement of language function	Unreported	This observation opens new possibilities for treatment of drug-unresponsive neurodegenerative disorders
Trebbastoni *et al*[73], 2013	hf-rTMS stimulates DLPFC	Improved language in LPPA	Unreported	DTMS improved the linguistic skills
Chieffo *et al*[71], 2014	10 Hz DTMS stimulates Broca's area	Significant improvement in the naming power	Unreported	Deep brain rTMS improved naming in right-handed chronic poststroke aphasic patients

LPPA: Primary progressive aphasia logopenic variant; DLPFC: Dorsolateral prefrontal cortex; DTMS: Deep transcranial magnetic stimulation; hf-rTMS: High frequency-repetitive transcranial magnetic stimulation; rTMS: Repetitive transcranial magnetic stimulation.

above-mentioned scientists have critically proposed a bimodal balance-recovery model, suggesting that the residual structural reserve of the corticospinal tract on the affected side also influences both the hemispheric balance and the degree of functional recovery. Diffusion tensor imaging studies have shown that the integrity of nerve fiber connections between primary and secondary motor areas is positively correlated with recovery of motor function after stroke[75]. DTMS helps to improve motor dysfunction after a stroke.

The development of DTMS applied to post-stroke motor dysfunction is shown in Table 7. Chieffo *et al*[76] applied DTMS to patients with lower limb motor dysfunction after chronic stroke, showing improved lower limb function in patients receiving treatment, and high-frequency DTMS has long-term effects on lower limb motor function in patients with chronic stroke. In 2018, this team again applied DTMS to the rehabilitation of upper limb motor dysfunction after chronic stroke and found that the recovery of upper limb function in patients treated with DTMS combined with exercise training was significantly better than that in patients treated with exercise training combined with sham stimulation, and this effect was more pronounced in patients with severe upper limb motor dysfunction, without serious adverse effects [77].

DTMS is effective in restoring motor function in the limbs after stroke, but the exact mechanism of action remains to be explored. Does DTMS somehow improve the language of patients with aphasia? At this time, we have not found any studies to provide a reference. Existing studies show clinically beneficial effects of TMS with or without combined speech and language therapy on overall language function and expressive language (including naming, repetition, writing, and comprehension) in patients with post-stroke aphasia[70]. In the assessment of aphasia and why not in aphasia therapy, spontaneous and semi-spontaneous speech analysis may be useful[78]. We recommend that future DTMS research on aphasia could be more involved in this gap area.

PD

PD is the second most common neurodegenerative disease in the world, and patients most commonly suffer from abnormal motor symptoms due to the loss of dopaminergic neurons in the substantia nigra[79]. The gold standard treatment for PD is oral levodopa, but the long-term efficacy of levodopa is mostly not maintained[80]. Some reports suggest that the excitability of cortical-mediated pathways may be altered in PD patients, resulting in dyskinesia[81]. Several studies have shown that stimulation of the motor cortex with high-frequency rTMS can improve dyskinesia in PD patients and that the effects can be sustained for a longer period of time[82]. However, some studies suggest that cortical inhibition is impaired in PD patients[83] and perhaps low-frequency stimulation may be more beneficial for PD patients, whereas DTMS is used to act on a wider range of cortical and deeper brain areas.

The development of DTMS applied to PD is shown in Table 8. In 2013, by treating 27 PD patients with movement and high-frequency rDTMS to the prefrontal cortex, Spagnolo *et al*[84] found that the Unified PD Scale (UPDRS) score of PD patients improved significantly after treatment compared to before treatment. Spagnolo *et al*[85] conducted a randomized, sham-controlled trial to evaluate whether high-frequency TMS with an H5 coil is safe and effective for PD patients, and the results showed that patients who received rTMS (M1-PFC and M1 combination) had better results in tremor and hemilateral scores than those in the sham stimulation group. There was no significant difference in safety and efficacy between the two groups, suggesting that gh-frequency rTMS with the H-coil is a safe and effective intervention. It has been suggested that high-frequency rTMS acting on the M1 or PFC may, on the one hand, induce the release of endogenous dopamine in the ipsilateral dorsal striatum[86]. On the other hand, it may promote the production of dopaminergic neurons[87-90].

Studies today have shown that PD patients tolerate DTMS well and no serious adverse effects have been reported in these patients, but there are still some side effects such as transient headache, dizziness, and involuntary movements. However, DTMS can be used to improve the symptoms of dyskinesia in PD patients, and high-frequency stimulation may be more effective than low-frequency stimulation. In the future, RCTs with larger sample sizes and long-term follow-up are needed to determine the optimal treatment parameters and duration of the effect of DTMS.

Table 7 Development of deep transcranial magnetic stimulation in post-stroke motor dysfunction

Ref.	Method	Result	Adverse events	Significance
Chieffo *et al* [76], 2014	20 Hz DTMS	Significant improvement in lower limb motor function	Unreported	DTMS could induce improvements in lower limb functions in the chronic post-stroke period
Chieffo *et al* [77], 2018	20 Hz DTMS	Upper limb motor function improved significantly	Transitory dizziness, toothache, and muscle twitches	DTMS combined with exercise training is more effective (upper limb motor function)

DTMS: Deep transcranial magnetic stimulation.

Table 8 Development of deep transcranial magnetic stimulation in Parkinson's disease

Ref.	Method	Result	Adverse events	Significance
Spagnolo *et al* [84], 2014	10 Hz DTMS for PF stimulation	UPDRS was improved	Slight and transitory hypotension and headache	DTMS might be a safe treatment for PD motor symptoms
Cohen *et al*[87], 2018	M1 + PFC or M1	M1 + PFC OR M1 group was improved in T-UPDRS and M-UPDRS	Mild and transient head discomfort, transient fatigue, and rare mild visual transient hallucinations during stimulation	DTMS improved PD motor symptoms but the effect was moderate
Torres *et al*[80], 2015	M1 + PFC	UPDRS was improved	Sleepiness, headaches, and nausea	DTMS improved motor, postural, and motivational symptoms of PD patients
Cohen *et al*[88], 2016	1 Hz DTMS M1 and 10 Hz DTMS PFC	UPDRS was improved	Headache, dizziness, pain in the head or neck during treatment; nausea, general weakness, and transient aggravation of gait disturbance	DTMS improved motor, but no advantage compared to sham treatment
Spagnolo *et al* [85], 2020	M1 + PFC or M1	UPDRS was improved	Mild, not-distressing, and transient dyskinesias	DTMS was a safe and potentially effective procedure
Cohen *et al*[87], 2018	1 Hz M1 or 10 Hz PFC	UPDRS was improved	Headache, nausea, and discomfort of the eye region or tearing of the eyes during stimulation	DTMS can decrease the subjective motor symptom severity and depression

PF: Bilateral prefrontal regions; M1 + PFC: Sequential stimulation of low frequency over the primary motor cortex and then high frequency over the prefrontal cortex; M1: Low-frequency stimulation over the primary motor cortex alone; UPDRS: Unified Parkinson's Disease Rating Scale; M-UPDRS: Motor UPDRS; T-UPDRS: Total UPDRS; DTMS: Deep transcranial magnetic stimulation; PFC: Prefrontal cortex; PD: Parkinson's disease.

DISCUSSION

The results of our review suggest that the DTMS technique is safe and effective when applied to various neurological and psychiatric disorders, with no serious adverse effects identified other than transient headache and fatigue. However, the biology of the efficacy of DTMS is not yet clear, so its efficacy is mostly assessed by psychometric scales such as the UPDRS and HDRS-24[13], and biological indicators are lacking. A comparison of DTMS with other brain stimulation techniques[90] such as magnetic shock therapy, electroconvulsive therapy[91], transcranial direct current stimulation, vagus nerve stimulation, or deep brain stimulation would provide better clinical evidence for patients.

The advantage of DTMS over conventional TMS is that the H-coil can stimulate deeper areas of the brain without increasing the intensity of the stimulation[92], thus ensuring the continuous stimulating effect of DTMS. There are currently more than 20 H-coils available, of which the H1/H2 coil is FDA cleared for bilateral PFC stimulation. DTMS can stimulate deeper and wider areas of the brain and modulate neurological function through the H-coil, which is effective and safe in the treatment of PD, AD, SZ, and depression. Based on the above tables, it can be seen that DTMS is currently most commonly used in PD, OCD, and depression, with high levels of patient acceptance and efficacy. Some of the other neurological and psychiatric disorders treated with DTMS are still in the early stages of research, and although some have shown significant efficacy, more research is needed to validate them in the future. It is believed that with the continued optimization of the DTMS coil device and further understanding of the etiology of neurological and psychiatric disorders, as well as the resolution of some ethical and legal issues related to these disorders, the use of DTMS with different coils and parameters for different disorders can be explored in the future, thus creating a standardized treatment plan for patients with different disorders, which will facilitate the treatment of patients who have failed or cannot take medication for a long time. This will facilitate the use of DTMS for patients who have been on medication for a long time or are unable to take medication.

CONCLUSION

A large number of studies have shown that DTMS technology is generally safe and tolerable, with mild side effects, and can be used to rehabilitate mental and nervous system disorders. DTMS regulates neural function by directly stimulating deeper and wider brain regions, and currently the evidence for DTMS in the treatment of depression and OCD should be strong. However, for other neurological disorders (particularly neurodegenerative disorders), there are very preliminary results and small sample sizes. RCTs with larger sample sizes should be warranted.

However, DTMS research is still in the exploratory stage, and several issues need to be addressed and determined: (1) Consistency of efficacy: Although some studies have shown that DTMS is effective in certain diseases, the results of these studies are variable and the effects are unpredictable. Further studies are needed to determine the consistency of efficacy and to identify patients who are best suited for this treatment modality; (2) Long-term safety and side effects: The long-term safety and potential side effects of DTMS are not fully understood, and although some studies have shown that the technique is relatively safe and well tolerated in the short term, the potential for adverse effects and potential risks associated with long-term use needs to be further evaluated; (3) Determining optimal stimulation parameters: DTMS involves the selection of stimulation site, stimulation frequency, stimulation intensity, and other parameters; it is unclear which stimulation parameters are most effective, and further research is needed to determine the optimal stimulation parameters and to ensure their consistency and reproducibility in clinical applications; (4) Disease-specific mechanism of action: The mechanism of action of DTMS on various diseases is not fully understood. A deeper understanding of its mechanism of action may help us to better understand and optimize its clinical application; and (5) Development of individualized therapeutic strategies: Since each patient's situation is unique, there is a need to develop methods for individualized therapeutic strategies that can better guide treatment and improve treatment efficacy by combining information from brain imaging technology and biomarkers. Addressing and identifying these issues will advance the use of DTMS in clinical practice and provide more effective options for the treatment of psychiatric and neurological disorders.

Abstract

BACKGROUND

Autophagy is associated with hippocampal injury following status epilepticus (SE) and is considered a potential therapeutic mechanism. Baicalin, an emerging multitherapeutic drug, has shown neuroprotective effects in patients with nervous system diseases due to its antioxidant properties.

AIM

To investigate the potential role of autophagy in LiCl-pilocarpine-induced SE.

METHODS

The drugs were administered 30 min before SE. Nissl staining showed that Baicalin attenuated hippocampal injury and reduced neuronal death in the hippocampus. Western blotting and terminal deoxynucleotidyl transferase dUTP nick end labeling assay confirmed that Baicalin reversed the expression intensity of cleaved caspase-3 and apoptosis in hippocampal CA1 following SE. Furthermore, western blotting and immunofluorescence staining were used to measure the expression of autophagy markers (p62/SQSTM1, Beclin 1, and LC3) and apoptotic pathway markers (cleaved caspase-3 and Bcl-2).

RESULTS

Baicalin significantly upregulated autophagic activity and downregulated mitochondrial apoptotic pathway markers. Conversely, 3-methyladenine, a

commonly used autophagy inhibitor, was simultaneously administered to inhibit the Baicalin-induced autophagy, abrogating the protective effect of Baicalin on the mitochondrial apoptotic level.

CONCLUSION
We illustrated that Baicalin-induced activation of autophagy alleviates apoptotic death and protects the hippocampus of SE rats.

Key Words: Baicalin; Status epilepticus; Autophagy; Mitochondrial apoptosis

Core Tip: This study established the rat model of status epilepticus by intraperitoneally injecting LiCl-pilocarpine. Then, Baicalin was administered to the rats for treatment. The pathological changes of hippocampal were observed. Western blotting and terminal deoxynucleotidyl transferase dUTP nick end labeling assays were used to verify the inhibitory effect of Baicalin on apoptosis of rat hippocampal neuronal cells. We have drawn the conclusion that Baicalin protects the hippocampus from apoptosis.

INTRODUCTION

It has been reported that 1% of the global population is affected by epilepsy, which has diverse etiologies and is characterized by recurrent and spontaneous seizures[1,2]. The most notable kind of epilepsy is temporal lobe epilepsy, characterized by a typical seizure that originates from the hippocampus-a structure located in the mesial temporal lobe[3-5]. Hippocampal injury following status epilepticus (SE) is due to oxidant damage. The accumulation of reactive oxygen species can harm hippocampal neurons, inducing cell death through an apoptotic or necrotic pathway, as hippocampal cells are highly sensitive to oxidative stress[6].

Autophagy is a highly conserved intracellular process that can be categorized into three classes: Macroautophagy, chaperone-mediated autophagy, and microautophagy. As the major type of autophagy, macroautophagy (hereinafter referred to as "autophagy") is crucial for eliminating cytoplasmic materials and maintaining intracellular homeostasis under pathological conditions[7,8]. This process of degrading long-lived proteins and cytoplasmic organelles is associated with SE, PD, and other neurodegenerative diseases[9]. Indications of autophagy variation have been observed in several neuroprotective drugs (*e.g.*, 17-allylamino-demethoxygeldanamycin and Tanshinone IIA), which simultaneously confirmed their ability to ameliorate SE-induced hippocampal neuronal death by upregulating autophagy[10,11]. Baicalin, as a natural extract, undergoes a safe and established preparation process and offers several significant advantages, including minimal side effects.

Baicalin-a traditional Chinese medicine-is among the main flavonoid compounds isolated from *Scutellaria baicalensis* Georgi and possesses multiple pharmacological properties, including neuroprotective[12], anti-inflammatory[13], antiapoptotic[14], and antioxidant[15] effects. Baicalin can freely cross the blood-brain barrier[14,16]; thus, it has been used to treat many nervous system diseases. Several studies have explored the relationship between autophagy and Baicalin. For example, Baicalin has been found to induce autophagy in tubercle bacillus-infected macrophages through the PI3K/Akt/mTOR signaling pathway, indicating its potential to alter disease progression by regulating autophagy activity[17]. Baicalin has also been shown to exert anticancer and anti-inflammatory effects by activating autophagy in pathogenic cells, such as human bladder cancer T24 cells, human hepatocellular carcinoma SMMC-7721 cells[18], and *Mycobacterium tuberculosis*-infected macrophages. A much-debated issue is whether Baicalin exerts neuroprotective effects while regulating autophagy. However, the mechanism by which Baicalin activates autophagy in the hippocampus following SE remains unclear. Thus, we aim to investigate the emerging role of autophagy in the hippocampus during SE and elucidate the precise mechanism underlying the neuroprotective effects of Baicalin.

MATERIALS AND METHODS

Animal preparation

Ninety-six pathogen-free Wistar rats (male, 180-220 g) were purchased from Shanghai Laboratory Animal Center. The rats were raised under controlled conditions with a 24 °C ± 1 °C temperature and a 12-h light/dark cycle. All rats had free access to water and food.

Rat model of SE and experimental groups

The rat model of SE was induced by intraperitoneally injecting adult Wistar rats with LiCl-pilocarpine[19]. The rats were lightly anesthetized through isoflurane inhalation and then intraperitoneally injected with 0.2 mL (127 mg/kg) of lithium chloride; Pilocarpine (30 mg/kg) was injected 16 h after LiCl administration. Rats that did not develop SE after the injection were excluded. The rats were randomly divided into four groups: Control, SE, SE + B100, and SE + B200 (Figure 1).

For the SE group, pilocarpine (25 mg/kg) was injected intraperitoneally 30 min after intraperitoneal injection of atropine methyl nitrate (2 mg/kg) to ameliorate peripheral cholinergic signs. The control group received a physiological salt solution instead of pilocarpine. The SE + B100 and SE + B200 groups were intraperitoneally injected with 100 mg/kg and 200 mg/kg of Baicalin, respectively, after the pilocarpine injection. The drug dosages used in this study were based on previous reports[20].

3-Methyladenine (3-MA) was used to inhibit autophagy. Subsequently, the rats were randomly divided into the following groups: Control, SE, SE + Baicalin, and SE + Baicalin + 3-MA. In the SE + Baicalin + 3-MA group, rats were injected with 400 nmoL 3-MA (2 μL) through an intracerebroventricular injection to the right lateral ventricle 1 h before SE induction, according to a previous study[21]. The SE + Baicalin and SE + Baicalin + 3-MA received a dose of 200 mg/kg of Baicalin. Isoflurane inhalation was used for anesthesia after SE induction. All rat brains were harvested for subsequent histological and biochemical studies.

Nissl staining

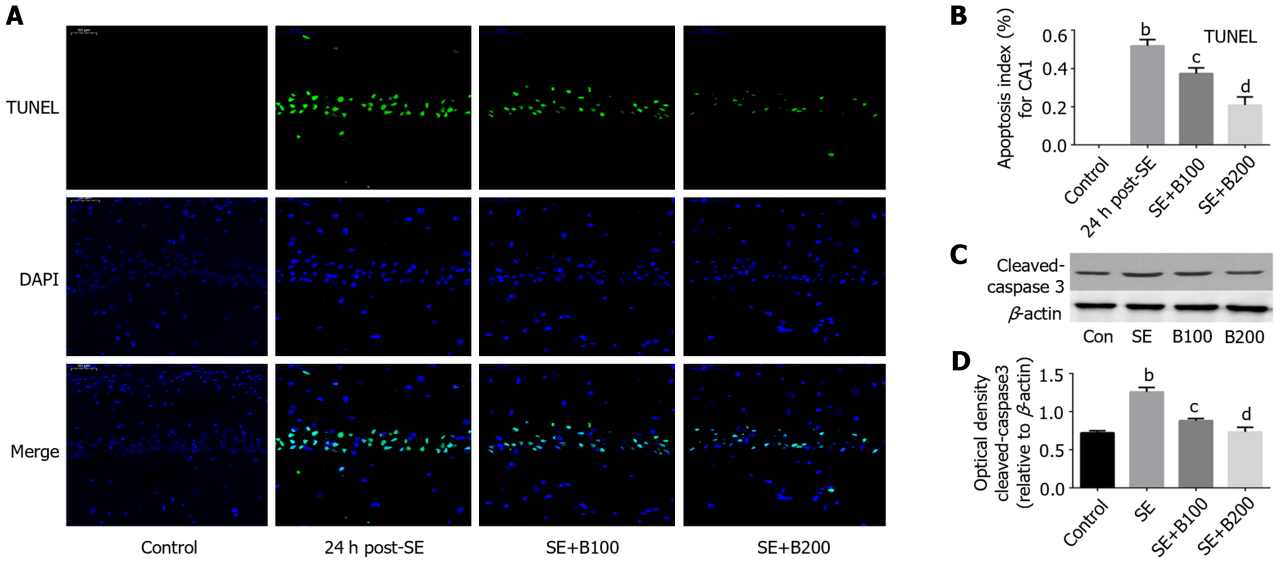
Twenty-four rats were executed 24 h after the onset of SE. HE staining was performed to detect damaged neurons in the hippocampus (six per group) based on a previous study[22]. Damaged neurons were characterized by an abnormal neuronal morphology, a dried-up cytoplasm with vacuoles, and a shrunken- hyperchromatic nucleus, as reported in a previous study[23].

Transferase dUTP nick end labeling staining

Terminal deoxynucleotidyl transferase dUTP nick end labeling (TUNEL) staining was conducted using an *in situ* cell death detection kit (Promega) to detect the cell apoptosis index. Briefly, rats were executed 24 h after the onset of SE, and 4-μm-thick coronal slices of the brain tissue were prepared using a paraffin slicer. Proteinase K (Nanjing Jianchen Co., Ltd.) was used to digest the coronal sections for 15 min. After deparaffinization, rehydration, and washing (with PBS), the sections were cultivated with a TdT reaction mix (Promega) containing TUNEL reaction fluid for 50 min at 37 °C (avoiding exposure to light from hereon). To stop the reaction, plastic coverslips were removed, and coronal slides were immersed in 2XSSC (Nanjing Jianchen Co., Ltd.) for 15 min. After three washes with 0.02 M TBS (5 min/wash), the liquid around the sections was dried, and the tablets were sealed with a seal containing DAPI fluorescent dye. Under a fluorescence microscope, localized apoptotic cells appeared green, and DAPI-stained nuclei appeared blue. Five slides per rat and five random fields per slide (scale bar = 50 μm) were selected to calculate the final average percentage and apoptosis index.

Western blotting

Hippocampal tissues were isolated, and hippocampus protein was extracted. The protein content was calculated using the BCA assay. Each quantity of protein per lane (30 μg) was separated on a 12% SDS-PAGE gel. The proteins were then electrotransferred onto a PVDF membrane (Millipore, United States). The membrane was blocked with 5% skim-fat milk prepared with TBST for 3 h. Primary antibody incubation was conducted with the following antibodies: LC3B (1:1000, Cell Signaling Technology), Beclin 1 (1:2000, Cell Signaling Technology), p62/SQSTM1 (1:500, Cell Signaling Technology), cleaved caspase-3 (1:500 dilution, Cell Signaling Technology), Bcl-2 (1:500 dilution, Cell Signaling Technology), and β-actin (1:2000, Bioworld Technology). Subsequently, secondary antibody incubation was conducted for 3 h at room temperature. The signals were visualized using an ECL reagent (Millipore), and band density was quantitatively analyzed using Quantity One software. The expression intensity was normalized to the loading control (β-actin).



Immunofluorescent labeling

Immunofluorescence staining was performed to localize LC3 in the hippocampal cells. Brain sections from 24 rats (six per group) were prepared as described for the TUNEL staining procedure.

The slides were blocked with 5% normal donkey serum containing 0.01% Triton X-100 for 2 h. Primary antibody incubation was conducted with antibodies against LC3B (1:1000, Cell Signaling Technology) for 12 h at 4 °C. After washing three times with PBST, the sections were incubated with the secondary antibody (1:200, Alexa Fluor 594) for 2 h. DAPI treatment was applied for 1 min, and the sections were analyzed under a fluorescence microscope. We counted the cells with LC3 puncta, which appear as a result of LC3-II aggregation around the nucleus, and positive cells in the same field of view were quantified. In each coronal section, six fields (scale bar = 50 μm) around the hippocampus were randomly chosen to determine the average.

Statistical analysis

All results were represented as mean ± SD. The GraphPad Prism 6 software was used to analyze the data. Analysis of variance was used to compare data among multiple groups. Inspection level $\alpha = 0.05$ and $P < 0.05$ was considered a statistical difference.

Figure 1 Baicalin ameliorated status epilepticus-induced neuronal apoptosis. A: Transferase dUTP nick end labeling staining was performed; B: Neuronal apoptosis was analyzed; C: Western blotting was performed; D: Semi-quantitative analysis of cleaved caspase-3 (n = 6). $^{b}P < 0.01$ compared to the control group; $^{c}P < 0.05$ and $^{d}P < 0.01$ compared to the status epilepticus group. Scale bar = 50 μm. SE: Status epilepticus; TUNEL: Transferase dUTP nick end labeling.

RESULTS

Baicalin exerted neuroprotective effects on the hippocampus following SE

Because the neurons in hippocampal CA1 are sensitive to SE stress, toluidine blue staining was performed to detect neuronal loss. The number of surviving neurons was significantly lower in the SE group than in the control group. However, Baicalin significantly increased the number of surviving neurons after SE (Table 1). To further confirm whether Baicalin provides neuroprotection to the hippocampus in SE rats, we monitored the latency of seizures following pilocarpine administration. The latent period (the time from pilocarpine administration to the onset of a seizure above the grade of Racine IV) was 29.60 ± 6.603 min in the SE group, whereas it was 41.70 ± 10.93 min and 63.80 ± 11.73 min in the Baicalin intervention groups (SE + B100 and SE + B200 groups, respectively). Treatment with different doses of Baicalin significantly prolonged the latency, and these differences were statistically significant ($P < 0.01$). The seizure latency in the SE + B200 group exceeded that in the SE + B100 group (Table 2). These results indicate that both concentrations of Baicalin exerted neuroprotective effects on the hippocampus dose-dependently. Therefore, the dosage of Baicalin (200 mg/kg) that produced superior effects was selected and employed for the subsequent experiments.

Baicalin reduced neuronal apoptosis in the hippocampus of SE rats

SE induced significant apoptosis of neurons in hippocampal CA1 ($P < 0.01$; Figure 1A and B). However, after 24 h, the apoptosis percentage was considerably lower in the SE + B100 and SE + B200 groups than in the SE group, with the SE + B200 group showing a more significant decrease (Figure 1B).

The level of pro-apoptotic cleaved caspase-3 in the SE + B200 group was significantly lower than in the SE group ($P < 0.01$; Figure 1C and D). These findings confirmed that Baicalin has neuroprotective effects against SE-induced apoptosis in an SE rat (Figure 2).

Baicalin upregulated autophagy in hippocampal neurons

To further investigate the potential relationship between autophagy and the neuroprotective effect of Baicalin, we measured three highly related autophagy proteins (p62/SQSTM1, Beclin 1, and LC3) as markers of autophagy using western blotting[24]. Under normal conditions, LC3 exists in a cytosolic form (LC3-I), whereas during autophagy activation, LC3-I is cleaved, lipidated, and inserted into autophagosome membranes as LC3-II. Beclin 1, located in the trans-Golgi network, contributes to autophagosome formation and localizes autophagy-related proteins in the pre-autophagosome membrane. p62, an important factor in cytoplasmic material delivery, is also degraded by autophagy and thus frequently serves as an autophagy marker.

As shown in Figure 3A-D, Beclin 1 and LC3-II levels were lower in the SE group than in the control group, whereas the level of p62 was significantly higher in the SE group. These results indicate that SE insults can partially inhibit autophagy activity. However, Baicalin treatment significantly upregulated the levels of Beclin 1 and LC3-II and downregulated the level of SQSTM1/p62 compared with the SE group, indicating that Baicalin activates autophagy in the pilocarpine-induced SE rat model. The results of immunofluorescence staining are consistent with those of western blotting (Figure 3). The SE group exhibited a slight decrease in the number of cells with LC3 puncta (Figure 4A). Moreover, Baicalin significantly enhanced the number of LC3-positive cells compared to the group SE (Figure 4B).

Table 1 Protective effect of Baicalin against neuron death in the hippocampal CA1 area following status epilepticus

Group	Neuron numbers (mean ± SD)
Control	129.0 ± 11.0
24 h post-SE	29.60 ± 6.603[a]
24 h post-SE + B100	41.70 ± 10.93[b]
24 h post-SE + B200	63.80 ± 11.73[c]

[a]$P < 0.01$ compared with the control group.
[b]$P < 0.01$ compared with the 24 h post-SE group.
[c]$P < 0.001$ compared with the 24 h post-SE group.
Data are represented as mean ± SD ($n = 6$). Under a light microscope, the surviving neurons showed regular cell morphology and round nuclei. Neuron number is expressed as the number of surviving neurons/0.5-mm-long hippocampal CA1 subfield. SE: Status epilepticus.

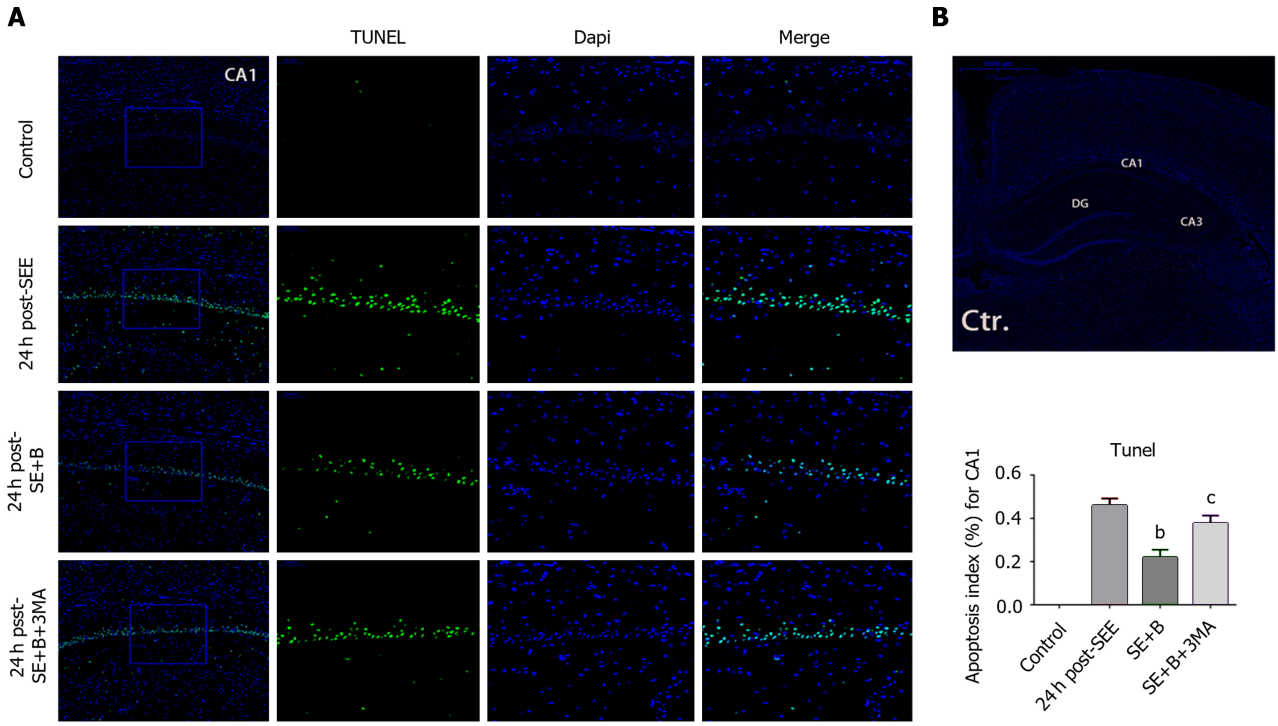
Table 2 Neuroprotective effect of Baicalin on seizure latency

Group	Seizure latency (mean ± SD), min
Control	
24 h post-SE	29.60 ± 6.603
24 h post-SE + B100	41.70 ± 10.93[a]
24 h post-SE + B200	63.80 ± 11.73[b]

[a]$P < 0.01$ compared with the 24 h post-status epilepticus (SE) group.
[b]$P < 0.001$ compared with the 24 h post-SE group.
Data are represented as mean ± SD ($n = 6$). SE: Status epilepticus.

Methyladenine inhibited the autophagy activated by Baicalin and abrogated its protective effect against the apoptotic pathway

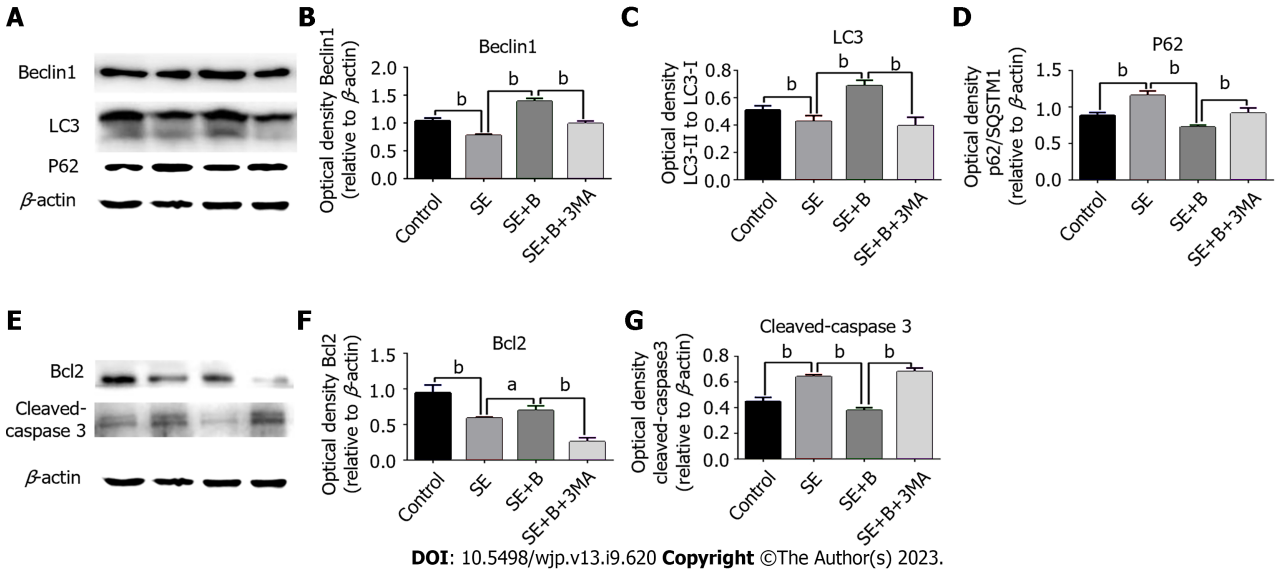
To further explore the correlation between Baicalin-induced autophagy and apoptosis following SE, we applied 3-MA to detect alterations in autophagy proteins through western blotting. LC3-II and Beclin 1 levels were significantly lower in the SE + B + 3-MA group than in the SE + B group (Figure 3B and C). Conversely, the level of p62 was higher in the SE + B + 3-MA group than in the SE + B group (Figure 3D). These results indicate that normal baseline autophagy is possibly inhibited by SE and that Baicalin-induced autophagy is abolished by 3-MA.



Activated caspase-3 degrades the substrate, and the degradation products enhance mitochondrial permeability, ultimately resulting in apoptosis. Bcl-2 can reportedly suppress apoptosis by inhibiting the activation of caspase-3, which is released in the upstream and downstream apoptotic pathways. To further investigate the mechanism underlying the neuroprotective effect of Baicalin following SE, we evaluated mitochondrial apoptosis–related proteins using western blotting (Figure 3E-G).

The level of Bcl-2 was lower in the SE group than in the control group, whereas the level of cleaved caspase-3 was significantly higher in the SE group than in the control group ($P < 0.01$; Figure 3E-G). Therefore, SE stress could induce neuronal apoptosis in the hippocampus, possibly through the regulation of mitochondrial apoptosis-related proteins. Furthermore, Baicalin restored Bcl-2 levels and reduced the level of cleaved caspase-3 compared with the SE group, suggesting that Baicalin ameliorated SE-induced mitochondrial apoptosis. In addition, 3-MA significantly increased mitochondrial apoptosis by enhancing cleaved caspase-3 and abrogating the restoration of Bcl-2 induced by Baicalin. Overall, these results illustrate that 3-MA exacerbated mitochondrial apoptosis in SE and abrogated the neuroprotective effect of Baicalin against the apoptotic pathway.

DISCUSSION



SE is a complex pathophysiological process involving multiple mechanisms. Baicalin is a traditional herbal medicine with multitarget protective effects against seizures[25]. A previous study in our laboratory found that Baicalin has a neuroprotective effect on the hippocampus following SE through the antiapoptotic pathway. However, the correlation between autophagy and the effects of Baicalin remained unclear.

To further investigate the function of Baicalin after SE, we monitored seizure latency and apoptosis in this study. The most significant finding (using western blotting and immunofluorescence) was that Baicalin promoted autophagy activity and inhibited mitochondrial apoptosis following SE. Furthermore, the intervention of 3-MA inhibited Baicalin-induced autophagy and even abolished its neuroprotective effects against mitochondrial apoptosis. These findings have

theoretical implications for the treatment of epilepsy by regulating autophagy.

In recent decades, the focus on alterations in autophagy after SE has increased due to the close relationship between autophagy activity and hippocampal injury. Different theories regarding the role of autophagy in nervous system diseases exist in the literature. The prevailing view is that activated autophagy has a protective role in rat models of ischemia-reperfusion[26-29], but there is still some ambiguity. A previous study focusing on autophagy has noted that autophagy dynamics in a rat's hippocampus act as determinants for epileptogenesis, suggesting that applying autophagy

Figure 4 The number of LC3-II-positive neurons was partially decreased by SE and increased by Baicalin. 3-Methyladenine **reversed the Baicalin-induced alteration.** A: Representative immunofluorescence staining; B: Positive neuronal cells were analyzed. $n = 6$. $^{a}P < 0.05$ and $^{b}P < 0.01$ *vs* the relevant group. The number of LC3-II-positive cells/0.5-mm-long subfield of the hippocampus under a light microscope was regarded as the numerical value (scale bar = 50 μm). SE: Status epilepticus; 3-MA: 3-Methyladenine.

inducers such as rapamycin, an mTOR inhibitor, to activate autophagy has an unambiguous effect on severe epileptic seizures[30,31]. Similarly, several studies have supported the view that activating autophagy through specific factors could provide neuroprotection in rat models of epilepsy[32], suggesting that autophagy induction plays a positive role in cell survival.

One significant finding is the activation of autophagy using recombinant human erythropoietin, which has been recently confirmed to exert neuroprotective effects and help ameliorate apoptosis in hippocampal neurons after SE[33]. In our study, we showed that Baicalin treatment significantly upregulated autophagy activity based on alterations in autophagy-related proteins and immunofluorescence staining of LC3-II puncta. In addition, decreased neuronal apoptosis and prolonged seizure latency were observed in Baicalin-treated groups, consistent with the findings of previous studies that support the neuroprotective effect of autophagy on the hippocampus in patients with seizures. A prior report concluded that impaired autophagy possibly contributes to epileptogenesis, which may be interesting as a potential therapeutic target for treating and preventing epilepsy[34]. Nevertheless, we could not elucidate whether autophagy inhibition promotes the occurrence of epilepsy, which is a limitation of our study.

There are possible situations where autophagy plays a dual role in epilepsy. The practical effect of autophagy depends on the degree of its activation due to the release of various deleterious factors following SE. The possible situations are as follows: (1) Inhibited autophagy potentially contributing to epileptogenesis, although a definitive causal relationship between autophagy and epileptogenesis in rat models has not been established; (2) Proper activation of autophagy benefiting the survival of hippocampal neurons by generating adenosine triphosphate; and (3) SE causing autophagic death and apoptosis in hippocampal neurons due to excessive autophagy[35].

It has not been determined whether administering neuroprotective drugs increases or decreases autophagic flow. For instance, we can only detect signs of decreased autophagy because the activation of autophagy promotes the clearance of autophagosome accumulation[36]. However, the amelioration of apoptosis by autophagy activation in epilepsy is complex and has not been fully elucidated.

Pro-apoptotic materials, such as damaged mitochondria and Bax accumulation induced by traumatic brain injury, can be eliminated by increased autophagy flux[37].

A previous study reported another possible mechanism involving autophagy activation and sequestration of abnormal proteins that trigger endoplasmic reticulum (ER) stress[38]. Hence, autophagy activation may inhibit ER stress in response to external stimuli and ameliorate apoptosis[39]. However, the role of autophagy in apoptosis after SE remains

unknown.

In this study, we discovered that Baicalin induces autophagy activation and alleviates apoptosis in hippocampal neurons following SE. Significantly, the abolition of Baicalin-induced autophagy and its neuroprotective effects against the mitochondrial apoptotic pathway by 3-MA administration suggest that autophagy activation may reduce neuronal apoptosis by removing damaged mitochondria after SE.

These results further support previous studies that have linked mitophagy, apoptosis, and neuron survival[34] and reported that mitophagy exerts anti-apoptosis effects, which promote cell survival. In this research, only male rats were used to reduce the impact of gender differences on research results. However, further experiments need to be validated with female animals.

CONCLUSION

In conclusion, we demonstrated that Baicalin prolongs seizure latency, ameliorates hippocampal injury, increases the survival rate of hippocampal neurons, and reduces mitochondrial apoptosis following SE in rats through autophagy activation. This study contributes to the pharmacological effects of traditional Chinese herbs such as Baicalin. Furthermore, it provides a new way of regulating autophagy for treating SE.

ARTICLE HIGHLIGHTS

Research background

Autophagy is associated with hippocampal injury after status epilepticus (SE), and is considered a potential mechanism with curative value. Baicalin, an emerging multi-therapeutic drug that has been demonstrated to exert neuroprotective effects in patients with nervous system diseases because of its antioxidant property.

Research motivation

We investigate the influence of Baicalin on the improvement of LiCl-Pilocarpine-induced rat SE.

Research objectives

We intended to investigate the potential role of autophagy in LiCl-pilocarpine-induced SE.

Research methods

Nissl staining showed that Baicalin attenuates hippocampal injury and reduces the number of neuronal deaths in the hippocampus. Besides, the expression intensity of cleaved caspase-3 and apoptosis in hippocampal CA1 following SE were reversed by Baicalin, as proven by western blotting and terminal deoxynucleotidyl transferase dUTP nick end labelling assay. Furthermore, western blotting and immunofluorescence staining were used to measure the expression of autophagy markers (p62/SQSTM1, Beclin 1, and LC3) and apoptotic pathway markers (cleaved caspase-3 and Bcl-2).

Research results

Baicalin significantly upregulated autophagic activity and downregulated mitochondrial apoptotic pathway markers. Conversely, 3-methyladenine, a commonly used inhibitor of autophagy, was simultaneously administered to inhibit the autophagy induced by Baicalin, abrogating the latter's protection on the mitochondria apoptotic level.

Research conclusions

We illustrated that Baicalin induced activation of autophagy alleviates apoptotic death and protects the hippocampus of SE rats.

Research perspectives

The improvement of LiCl-Pilocarpine-induced rat SE by Baicalin was validated.

Abstract

BACKGROUND

Exosomal miRNAs play crucial roles in many central nervous system diseases. Cerebral small vessel disease (CVSD) is a small vessel disease that is affected by various factors. This study aimed to investigate the role of exosomal miR-320e in the Wnt/β-catenin pathway stimulated by oxidative stress and assess its clinical correlation with psychiatric symptoms in patients with CVSD.

AIM

To explore whether exosomal miR-320e could suppress the Wnt/β-catenin pathway and play a protective role in CVSD progression, as well as examine its potential correlation with cognitive impairment and depression in patients with CVSD.

METHODS

Differentially expressed exosomal miRNAs were filtered by sequencing plasma exosomes from patients with CVSD and healthy controls. Bioinformatics and dual luciferase analyses were used to confirm the binding of miR-320e to Wnt2, and the mRNA and protein levels of downstream components in the Wnt/β-catenin pathway were evaluated when overexpressed or with knockdown of miR-320e under H_2O_2-induced oxidative stress. In addition, Wnt2-targeting siRNA was used to confirm the role of miR-320e in the Wnt2-mediated inhibition of the Wnt/β-catenin pathway. A retrospective analysis was conducted among patients with CVSD to confirm the correlation between miR-320e expression and the severity of cognitive impairment and depression, which were quantified using the Montreal

Cognitive Assessment (MoCA)/Executive Function Assessment (EFA), and the Hamilton Depression Scale (HAMD)/Beck Depression Inventory (BDI), respectively.

RESULTS

High-throughput sequencing revealed that exosomal miR-320e was downregulated in patients with CVSD. Bioinformatics analysis and dual-luciferase reporter gene experiments showed that exosomal miR-320e inhibited the Wnt/β-catenin pathway in response to oxidative stress by targeting the 3' noncoding region of Wnt2. Uptake of exosomes carrying miR-320e into endothelial cells could also target Wnt2 and inhibit the Wnt2/β-catenin pathway. Elevated miR-320e expression may protect patients with CVSD from relatively severe cognitive impairment and depression, as it was found to have a positive correlation with the MoCA/EFA and HAMD/BDI scores.

CONCLUSION

Our results suggest that exosomal miR-320e suppresses the Wnt/β-catenin pathway and may play a protective role in CVSD progression.

Key Words: Exosome; Cerebral small vessel disease; miRNA-320e; Wnt2; Wnt/β-catenin pathway; Depressed

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Exosomal miR-320e is downregulated in patients with cerebral small vessel disease (CVSD), and it inhibits the Wnt/β-catenin pathway by targeting Wnt2 in response to oxidative stress. Uptake of exosomes carrying miR-320e can also target Wnt2 and inhibit the Wnt2/β-catenin pathway. Elevated miR-320e expression may protect patients with CVSD from severe cognitive impairment and depression, as it correlates positively with Montreal Cognitive Assessment/Executive Function Assessment and Hamilton Depression Scale/Beck Depression Inventory scores. Therefore, exosomal miR-320e may play a protective role in CVSD progression by suppressing the Wnt/β-catenin pathway, indicating its potential as a therapeutic target for CVSD.

INTRODUCTION

Stroke is the deadliest disease in China and the second most disabling disease worldwide, and its socioeconomic burden has increased dramatically in the last three decades[1]. Cerebral small vessel disease (CVSD) accounts for 20%–30% of ischemic stroke cases. CVSD is a series of clinical, imaging, and pathological syndromes caused by various etiologies that affect the small arteries, microarteries, capillaries, microvenules, and small veins in the brain[2]. White matter and deep gray matter damage caused by CVSD is also considered a major cause of cognitive impairment due to damaged crosstalk between the arteries, capillaries, and small veins[3]. Currently, conventional anti-hypertensive, lipid regulatory, and antiplatelet aggregation treatments are not effective in improving cognitive and motor function impairments in patients [4,5]. Thus, new therapeutic targets or mechanisms for CVSD are warranted.

Exosomes, presenting as 30-150 nm extracellular vesicles in diameter, carry rich contents to exert their bioinformatics function near or distantly[6-8] and have been demonstrated to play important roles in vascular diseases, such as atherosclerosis, diabetic vasculopathy, and stroke[9-11]. Moreover, miRNAs (a class of 17–24 nt small, noncoding RNAs) have been identified in exosomes and are involved in the biogenesis, release, and uptake of relevant proteins by mediating post-transcriptional gene silencing by binding to target mRNAs[12]. Exosomal miRNAs participate in numerous biological processes during nerve injuries. Exosomal miR-451a plays a protective role against cerebral ischemia/reperfusion injury[13]. Exosomal miR-124a can be transported to glioblastomas to play a tumor-suppressive role[14]. Therefore, in this study we performed high-throughput sequencing analysis of plasma exosomal miRNAs between patients with CVSD and healthy controls and found that exosomal miR-320e, with the most significant difference, was speculated to be a highly promising target relevant to CVSD pathogenesis.

With aging and the presence of other risk factors, the integrity of the vasculature is gradually lost. This affects various cellular pathways, including the Wnt/β-catenin pathway, which is known to regulate vascular neogenesis, vascular remodeling, and blood-brain barrier maturation in response to harmful stimuli[15,16]. The Wnt family of proteins has been reported to play essential roles in the development of the nervous system[17]. miRNAs have been found to regulate vascular function by targeting the Wnt pathway, as evidenced by the involvement of miR-29b in vascular smooth muscle calcification[18] and the regulation of miR-330 in the process of unstable atherosclerotic plaque formation and vascular endothelial cell proliferation[19]. These studies indicate that the inhibition of the Wnt/β-catenin pathway may delay the progression of some diseases, such as cancer[20], axonal degeneration[21], and chronic kidney disease[22]. However, the

mechanism by which exosomal miR-320e regulates the Wnt/β-catenin pathway in cerebrovascular disease has not yet been explored.

Among the secretory glycoproteins belonging to the Wnt family, Wnt2 shows potent antidepressant effects and can inhibit the development of depressive disorders, suggesting the direct binding of miR320e to Wnt2[23]. In this study, we assessed the regulatory effects of miRNA-320e on the Wnt/β-catenin pathway by targeting Wnt2 in endothelial cells under oxidative stress. Furthermore, the predictive value of decreased exosomal-derived miR-320e for the clinical deterioration of depression and impaired cognition in CVSD was analyzed in a retrospective study.

MATERIALS AND METHODS

Sequencing of exosomal microRNAs from patients with CVSD

In total, 120 blood samples were collected from patients with CVSD and healthy subjects at the Qingdao University Affiliated Hospital between January 2017 and January 2019 (80 patients with CVSD and 40 controls). Baseline information of the patients with CVSD and controls was shown in the Supplementary Material. The inclusion criteria were based on the STRIVE diagnostic criteria, with the following: (1) Magnetic resonance imaging (MRI) manifestations, including lacunar infarctions, white matter lesions, cerebral microbleeds, and perivascular space enlargement > 2 mm and brain atrophy; (2) Clinical symptoms such as dizziness, fatigue, and cognitive changes; and (3) Age > 18 years. Patients with a definite diagnosis of cardiovascular or cerebrovascular diseases, severe head and neck artery stenosis, arteriosclerosis, incomplete brain MRI, blood system diseases or tumors, or severe liver and kidney insufficiencies were excluded. This study was approved by the Ethics Committee of the Affiliated Hospital of Qingdao University. All specimens were collected after obtaining authorization from the patients and their families and signing a consent form.

Isolation and extraction of exosomes

Thermo Fisher Scientific's Total Exosome Precipitation Reagent (from plasma) kit (REF4484451; Waltham, Massachusetts, United States Thermo Fisher Scientific) was used to extract the exosomes. Although ultracentrifugation was often noted for the ability to produce highly purified exosome, filtration could more conveniently generate a higher yield. However, both filtration and ultracentrifugation methods had their unique advantages and were well accepted in the area of exosome extraction.

The frozen plasma was thawed at room temperature, and 200 μL was placed in an EP tube and centrifuged at 2000 × g for 20 min at room temperature. The supernatant was collected in a new EP tube at room temperature and centrifuged again at 10000 × g for 20 min. Then, 100 μL of Phosphate-buffered saline (PBS) was added to the resulting supernatant and vortexed. Then, 10 microliters of proteinase K (Thermo Fisher Scientific 4485229) was added, shaken well and incubated at 37 °C for 10 min. Then, 60 microliters of extraction reagent was added to the incubated liquid, fully vortexed until turbid, and incubated at 4 °C for 30 min. Next, the sample was removed from the 4 °C environment and centrifuged it at 10000 × g for 5 min at room temperature. A pale yellow or colorless precipitate was observed, and the supernatant was discarded. Finally, we resuspended the sample in 100 μL of PBS to obtain an exosome solution and proceeded to the next step immediately or stored it at -80 °C.

Identification of exosomes

The morphology of the exosomes was observed by transmission electron microscopy, and the quality of the isolated exosomes was determined by nanoparticle tracking analysis. Exosome surface proteins were examined using western blotting.

Extraction of exosomal RNA

Total RNA was extracted using the miRNeasy Serum/Plasma Kit (50) (Cat. No. 217184). Immediately or after thawing the cryopreserved exosome solution, we took 100 microliters for lysis with 500 microliters of TRIzol and incubated at room temperature for 5 min. After addition of 100 μL of chloroform, the sample was vortexed and incubated at room temperature for 3 min. The samples were centrifuged at 12000 × g for 15 min at 4 °C. We transferred the upper part of the aqueous phase after centrifugation into a new EP tube, added absolute ethanol, mixed well, transferred to a spin column, centrifuged at 8000 × g for 15 s, and discarded the filtrate. Then, we added 700 microliters of RWT to the spin column at room temperature, centrifuged at 8000 × g for 15 s, and discarded the filtrate; added 500 microliters of RPE to the spin column at room temperature, centrifuged at 8000xg for 15 s, and discarded the filtrate; added 500 microliters of 80% ethanol, centrifuged the spin column at room temperature at 8000 × g for 2 min, changed the spin column into a new EP tube, and centrifuged at 12000 × g for 5 min for drying. Finally, 14 μL of enzyme-free water was added, and approximately 14 μL of total RNA was obtained by centrifugation at 12000 × g for 1 min after 1 min.

Cell culture

Human umbilical vein endothelial cells (HUVECs), cell models with stem cell potential commonly used for vascular endothelial cell experiments, were cultured in 90% dulbecco's modified eagle medium (DMEM) containing 10% FBS and 1.5% penicillin-streptomycin. All cells were cultured in 5% CO_2 at 37 °C in a humidified atmosphere. DMEM, FBS, and penicillin-streptomycin were purchased from BI (BI, United States), and trypsin was purchased from Thermo Scientific. Oxidative stress stimulation was induced using a 1 mmol/L solution of DEME prepared with hydrogen peroxide for 30 min. R-Spondin-1 (the Wnt pathway agonist) and WIF1 (the Wnt pathway inhibitor) were procured from MCE (MCE,

United States) using complete medium diluted to 60 and 20 ng/mL, respectively, for 24 h of cell culture before subsequent treatment as needed. The plasmids of wild-type and mutated Wnt2 3'-UTR and Wnt2-targeting siRNA, as well as the miR-320e mimic and inhibitor required for the transfection of HUVECs, were constructed by Gikai Gene (Shanghai Genechem Co, Ltd.).

Plasma membrane staining

We used a DiI (DiI perchlorate, C59H97CIN2O4) cell membrane orange-red fluorescent probe to stain the cell and exosome membranes (Yeasen; 40726ES10, China), and absorbance was detected at 550/567 nm.

Western-Blot analysis for protein expression detection

Cell lysis buffer (Elabscience Biotechnology Co., Ltd., China) for western blotting was used for total protein extraction. Following centrifugation at 4 °C (12000 × g, 15 min), a BCA kit (Elabscience, China) was used to quantify the protein concentrations. Protein samples were separated using polyacrylamide gel electrophoresis and transferred onto membranes (ACE Biotechnology, China). Freshly prepared Tris-buffered saline (TBS) containing 5% nonfat milk was used to block the membranes for 2 h at room temperature. The blots were probed with primary antibodies at 4 °C overnight at a dilution ratio of 1:1000. The primary antibodies used for the detection of Wnt/β-catenin pathway by western blotting were as follows: Wnt2, FZD2, Axin2, GSK3β, and β-catenin (Proteintech Group, Inc, United States). Membranes coated with primary antibodies were washed three times with TBS-0.05% Tween 20, followed by incubation at room temperature with the corresponding secondary antibodies for 1 h. The blots were then incubated in the dark with ECL and visualized by exposure to enhanced chemiluminescence reagents (GE Healthcare, United States). ImageJ software 1.4.3.67 (National Institutes of Health, United States) was used to analyze the grey scale values of the blots.

Detection of gene expression with real-time PCR

Total RNA was isolated from the cells using TRIzol Reagent (Invitrogen, United States). Goldenstar RT6 cDNA Synthesis Kit Ver. 2 (TSINGKE, China) was used to synthesize cDNA from the RNA. Wnt2, FZD2, Axin2, GSK3β, and β-catenin were detected by a 2xT5 Fast real-time polymerase chain reaction (PCR) Mix (SYBR Green I) kit (TSINGKE, China). Primer design and synthesis were performed by the Sangon Corporation (Shanghai, China), and the primer sequences were listed in the Supplementary Material. The results of RT-PCR analysis were calculated by the − ΔΔCt method.

Retrospective clinical study in patients with CVSD

Patients and Ethics: Using a retrospective analysis, relevant information on patients with CVSD who met the inclusion criteria was collected between January 2022 and December 2022 at the Department of Neurology of Qingdao University Affiliated Hospital. The inclusion criteria were as follows: (1) Aged–50-80 years; (2) Meeting the diagnostic criteria for CVSD according to the Expert Consensus on Diagnosis and Treatment of CVSD in China (2021); and (3) Agreement to participate in this study and signed an informed consent form. The exclusion criteria were as follows: (1) Other neurological or psychiatric diseases affecting cognitive function; (2) Other systemic diseases or medication history affecting vascular function; and (3) Other factors affecting exosome isolation or detection. Healthy volunteers who underwent physical examinations at the health examination center during the same period were enrolled as controls after obtaining informed consent and met the following conditions: (1) No clinical symptoms or signs; (2) No abnormal laboratory or imaging examinations; and (3) No history of chronic diseases or medication use. This study was approved by the ethics committee of our hospital. This study was conducted in accordance with the principles of the Declaration of Helsinki.

Treatments: Standard therapies were provided to patients with CVSD after a comprehensive assessment of their condition. Doctors developed a personalized treatment plan targeting the risk factors for CSVD in each patient, including anti-hypertensive drugs (such as angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, calcium channel blockers, diuretics, or β-receptor blockers), antiplatelet drugs (such as aspirin, clopidogrel, or ticagrelor), anticoagulation drugs (such as warfarin, dabigatran etexilate, or rivaroxaban), lipid-lowering therapy (such as simvastatin and atorvastatin), and diabetes controlling drugs (such as insulin and metformin). In addition, lifestyle improvements, such as quitting smoking, limiting alcohol intake, maintaining a healthy diet, and engaging in appropriate exercise, were recommended. For cognitive dysfunction related to CVSD, cholinesterase inhibitors and memantine were chosen to improve depression, anxiety, apathy, and psychiatric symptoms.

Psychiatric Assessments: The following assessment scores of patients were collected: (1) Cognitive function assessment, including the Montreal Cognitive Assessment (MoCA) and the Executive Function Assessment (EFA); and (2) Depression symptom assessment, including the Hamilton Depression Scale (HAMD) and the Beck Depression Inventory (BDI). Utilizing the average scores that patients received as the cutoff point, the CVSD population in this study was divided into two groups: Relatively more severe and relatively better disease.

Statistical analysis

Statistical analysis was performed using SPSS 26.0. Quantitative data were presented as the mean ± SD and were compared using the Wilcoxon test between the two groups, while categorical data were expressed as frequencies (percentages). For western blotting, the mean normalized gray level in the control group was defined as a relative FC of 1. For qRT-PCR, all data were normalized to the FC of the control group. Correlation analysis was performed using the Spearman's rank correlation coefficient. Statistical significance was set at $P < 0.05$. The statistical method of this study was reviewed by Ai-Jun Ma from Qingdao University Affiliated Hospital.

RESULTS

Identification of the miRNA expression profiles in CVSD patients

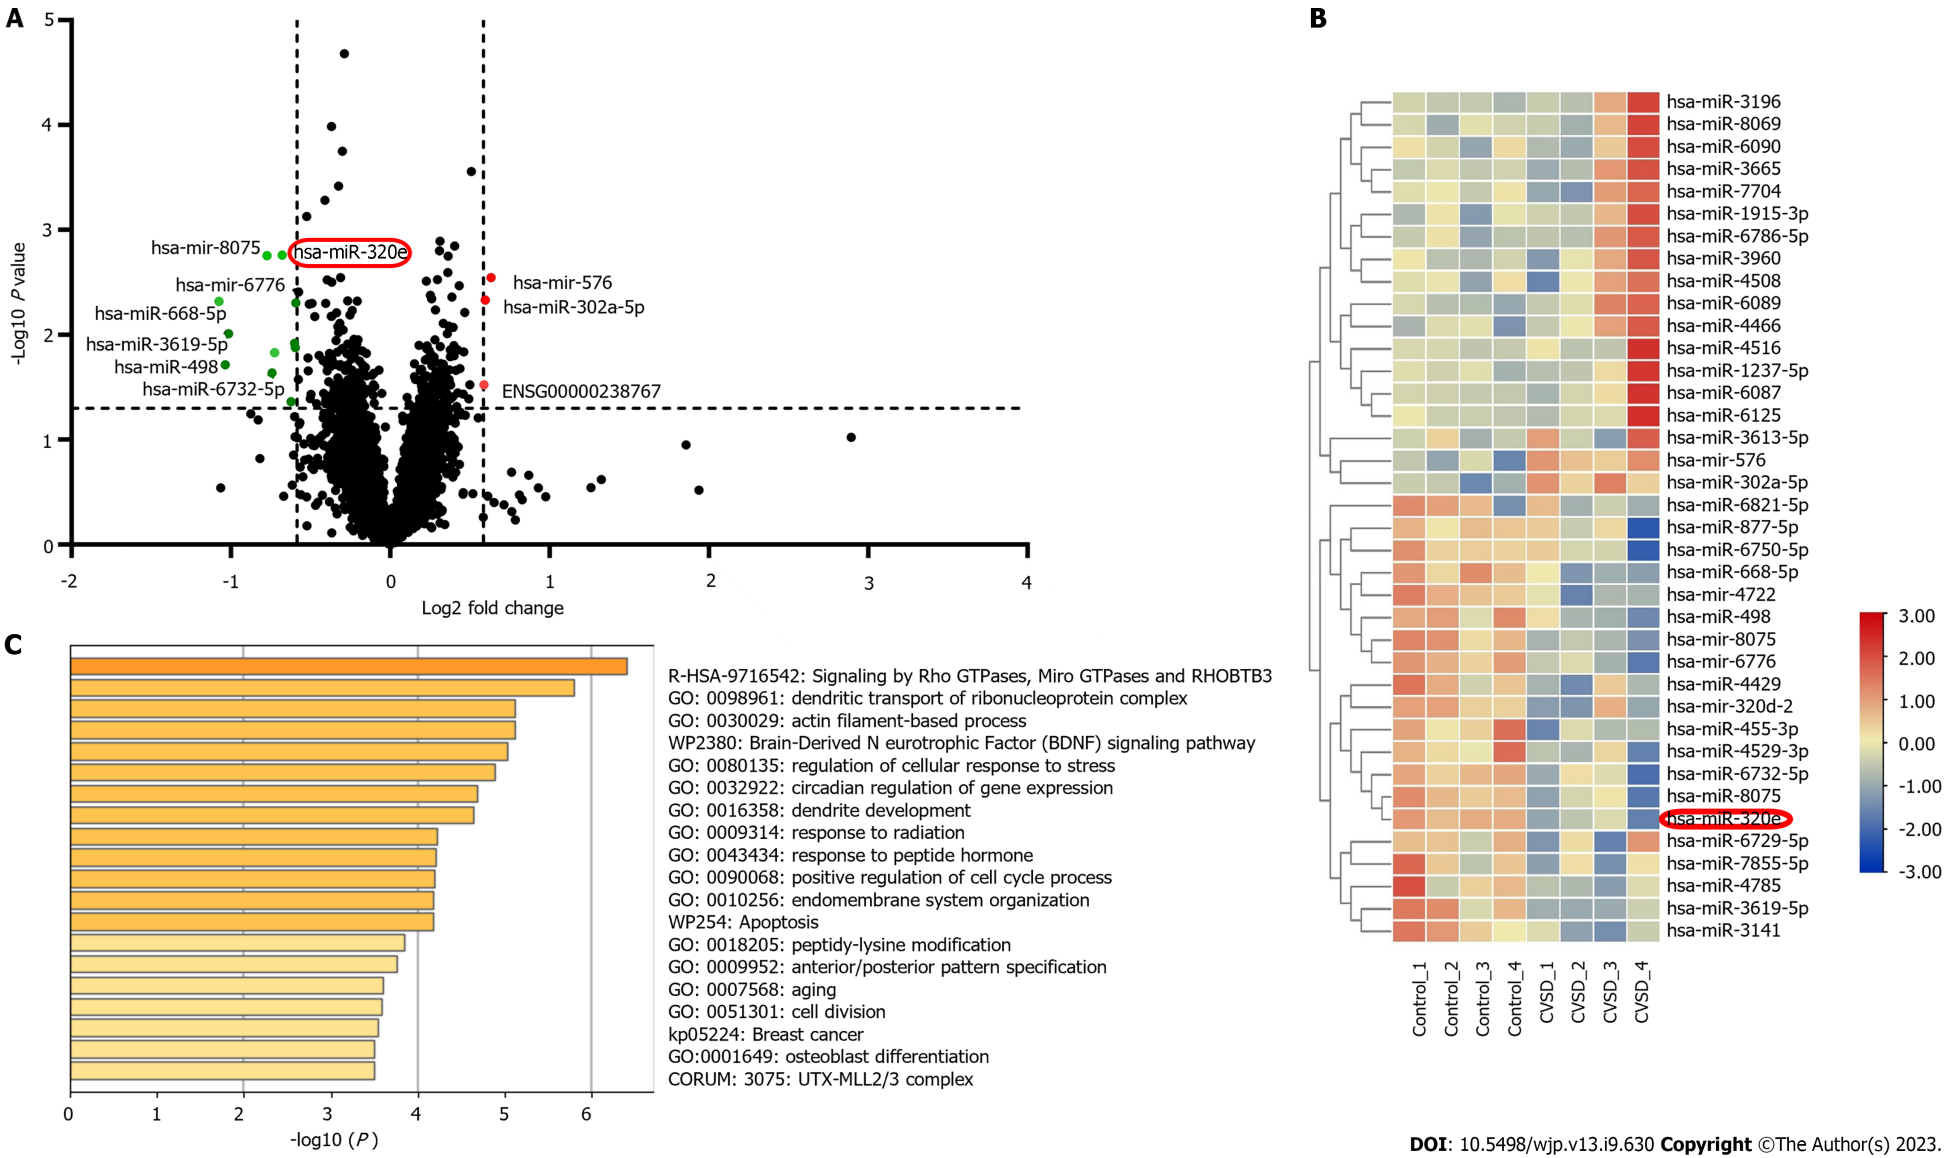
The results of the identification of the extracted exosomes were shown in Supplementary Material. In total, 120 blood samples were collected from 80 patients with CVSD and 40 healthy controls. The expression of miRNAs in plasma exosomes from patients with CVSD and healthy controls was detected by high-throughput detection. As shown in Figure 1A, the results showed that the expression of 38 miRNAs was significantly different in the plasma exosomes of patients with CVSD compared with the controls. Among these differentially expressed miRNAs, 18 miRNAs were significantly upregulated and 20 miRNAs were downregulated. A heatmap of the miRNAs with significant differential expression was shown in Figure 1B. Next, miR320e, miR-498, miR-6776, and miR-455 were verified using real-time PCR. This trend in the real-time PCR results was consistent with that of the miRNA sequencing results. Previous studies have shown that miR-320 regulates the biological behavior of ischemic neurons and changes the state of tissue inflammation and oxidative stress through drug regulation[24,25]. miR-320e was significantly downregulated compared with that in the healthy control group (16.8478, 95%CI = 7.4456–26.2501), and the difference was statistically significant ($P < 0.001$) (Supplementary Material), indicating that this molecule might play an important role in the pathophysiological process of CVSD.

MiR-320e targets the Wnt2 gene and exerts post-transcriptional regulation

According to the RNACentral and TargetScan human databases, Wnt2 was one of the target mRNAs of miR-320e. In addition, functional enrichment analysis showed that miR-320e was involved in the regulation of cellular responses to stress, mRNA metabolic processes, cell division, and apoptosis (Figure 1C), which was associated with vascular endothelial structural integrity. In contrast to other differentially expressed miRNAs, miR-320e and its target gene Wnt2 were associated with both leukocyte transendothelial function and vascular structural integrity, leading us to speculate that miR-320e may play an important role in the progression of CVSD development.

To verify the binding relationship between miR-320e and Wnt2, we performed a dual-luciferase reporter assay. The plasmids of wild-type and mutated Wnt2 3′-UTR were constructed and cotransfected with overexpressed miR-320e and control mimics. The results showed that the fluorescence intensity in the WT-Wnt2/miR320e-overexpressed group was significantly reduced (Figure 2A and B), indicating that miR320e specifically bound to Wnt2. A two-factor recovery experiment was conducted to prevent off-target effects. The results showed that the protein expression of Wnt2, Axin2, β-catenin, FZD2, and GSK3β was downregulated in the group that was transfected with the miR-320e mimic. In contrast, the endothelial cells transfected with the inhibitors targeting miR-320e showed higher expression of Wnt2, Axin2, β-catenin, FZD and GSK3β than those in the control group (Figure 2C and D). The fluorescence photos observed after transfection of miR-320e mimic and inhibitor were shown in Figure 2E. These results indicated that miR-320e inhibited the expression of Wnt2 at the post-transcriptional level as well as the activation of downstream β-catenin pathways.

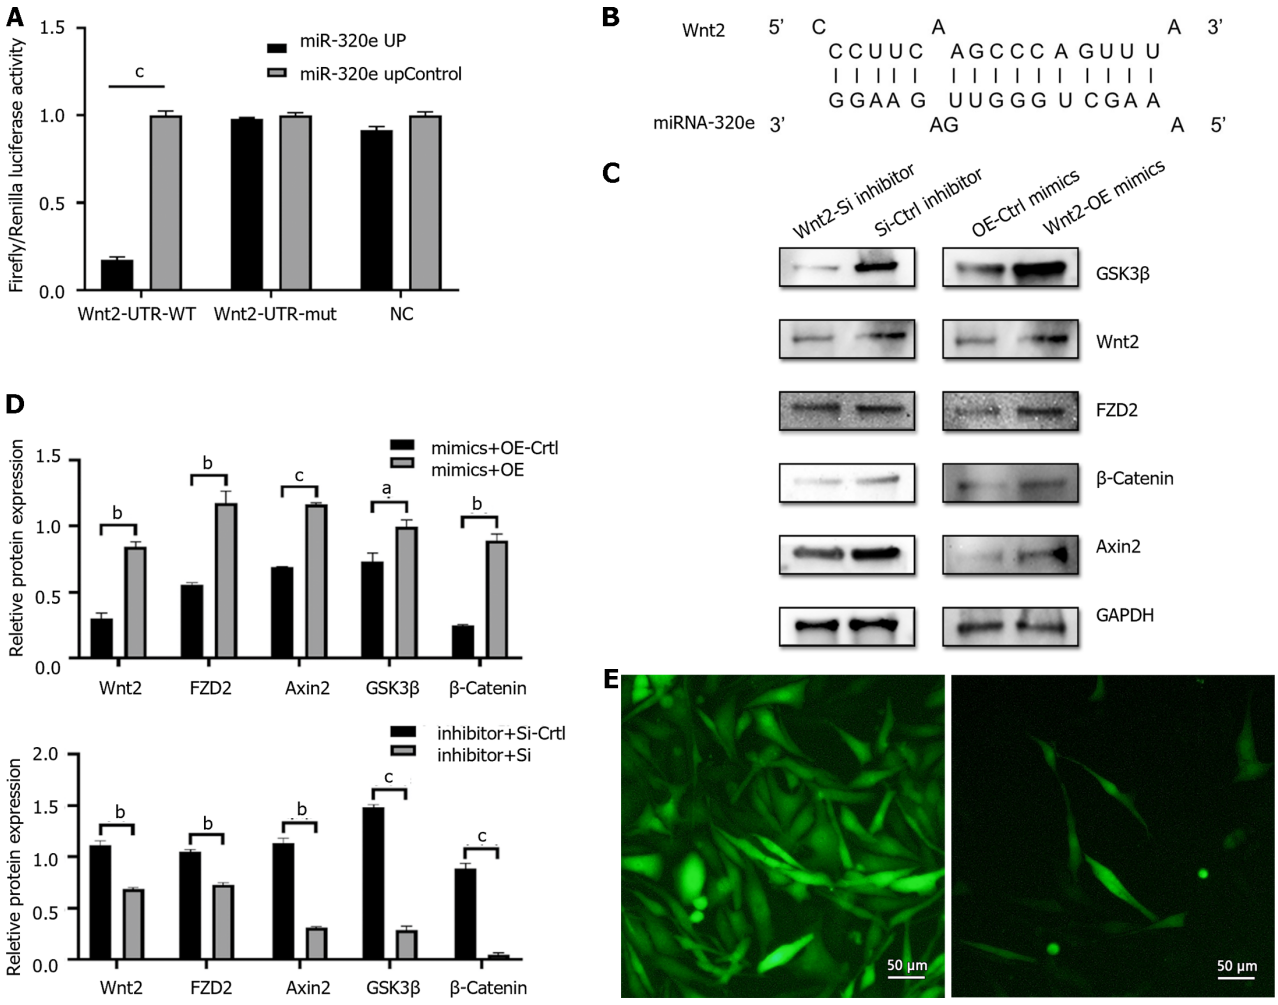
The Wnt/β-catenin pathway was involved in the H_2O_2-induced oxidative stress response



HUVECs were treated by adding H_2O_2 to the medium to create oxidative stress in the cell culture environment. The expression levels of Wnt2, FZD2, Axin2, GSK3β and total β-catenin in the Wnt/β-catenin pathway were all increased (Figure 3A-C). Oxidized HUVECs were further stimulated with the Wnt pathway inhibitor WIF1 or the agonist R-spondin in parallel with the mock control. We found that the protein expression of Wnt2, FZD2, Axin2, GSK3β and total β-catenin in the WIF1 + H_2O_2-treated group was similar to that in the WIF1-treated group without oxidative stress, meaning the Wnt2 inhibitor effectively alleviated the H_2O_2-induced Wnt/β-catenin pathway (Figure 3D-G). Meanwhile, R-spondin activated the Wnt2-mediated β-catenin pathway, and the expression of downstream components in the R-spondin + H_2O_2 group was enhanced compared to that in the group treated with R-spondin alone (Figure 3D and F-H). The above data indicate that the Wnt/βcatenin pathway and its relevant components were upregulated under H_2O_2-induced oxidative stress.

miR-320e inhibited the H_2O_2-induced Wnt/β-catenin pathway through targeting Wnt2

To demonstrate the effects of transfection, we used plasmids or siRNAs with green fluorescent labels and puromycin resistance. The fluorescence images observed after transfection of miR-320e mimics, mimic control, Wnt2-targeting siRNA, and siRNA control were shown in Figure 4A and B. Utilizing H_2O_2–treated HUVECs, when signaling in the Wnt/β-catenin pathway including Wnt2 was obviously inhibited by miR-320e mimics compared with control mimics, Wnt2-targeting silencing but not the siRNA control reversed the inhibition of the Wnt/β-catenin pathway (Figure 4C). Protein and mRNA expression detected by western blotting and real-time PCR showed similar results under H_2O_2-induced oxidative stress (Figure 4D-G). These data show that miR-320e inhibited the H_2O_2–induced Wnt/β-catenin pathway by targeting Wnt2.



Exosomes could be taken up by endothelial cells and release their loaded miR-320e into the endothelium to bind to Wnt2 for inhibitory effects

HUVECs were cultured using miR-320e mimics (Figure 5A), and the lipid membranes in the system were stained with DiI, a lipophilic stain with red fluorescence. We collected fresh culture medium and extracted the exosomes secreted by HUVECs to treat another group of HUVECs, and then tested the expression of Wnt2 and β-catenin in the exosome-treated and control groups. The results showed that HUVECs could be stained with DiI (Figure 5B), and we detected the collected exosome suspension in a microplate reader. We observed an increase in the absorbance at 550 and 567 nm

(Figure 5C). Using the collected exosomes secreted by DiI-stained endothelial cells to treat unstained and treated endothelial cells, we observed red fluorescence in the unstained cells after exosome treatment. In addition, we used these exosomes to treat human aortic vascular smooth muscle cells (HASMCs) and observed red fluorescence in these HASMCs (Figure 5D), indicating that HUVEC-derived exosomes could be secreted into the extracellular environment and taken up by other cells. In the Exo/miR-320e-mimic group, Wnt2 mRNA and β-catenin protein and mRNA levels were lower than those in the control group (Figure 5E-G). The above information proves that exosomes can be taken up by other cells, and miR-320e loaded into exosomes enters the cells and exerts an inhibitory effect on Wnt/β-catenin pathway activation by targeting Wnt2.

Retrospective analysis in patients with CVSD

In the same population for exosome extraction, 80 patients with CVSD (42 men and 38 women) with an average age of 66.3 years were included. The average educational level was 9.2 years. Among these patients, 60 patients had hypertension, 24 patients had diabetes, and 36 patients had hyperlipidemia, while the remaining patients did not have respective diseases. Additionally, 28 patients had a history of smoking and 16 patients had a history of alcohol consumption. At the baseline of disease characteristics, 40 patients (50%) had lacunar infarctions, 20 (25%) had cerebral microbleeds, and 20 (25%) had mixed-type CSVD. The white matter hyperintensity burden of the CVSD patient group at enrollment was 12.5 ± 4.2 cm^3, and the total CSVD burden score was 3.2 ± 1.1 points.

The correlation between exosomal miR-320e levels and psychiatric symptoms in patients with CVSD was characterized by Pearson's correlation analysis, which suggested that miR-320e was positively correlated with both cognitive impairmentrelated MoCA/EFA scores and depression-related HAMD/BDI scores (all $P < 0.05$), as shown in Table 1. Based on the scores for cognitive function and depressive symptoms of patients, we found that patients with relatively severe cognitive impairment and depression had statistically lower expression levels of miR-320e in the extracted exosomes than patients in relatively good condition (all *P*-values < 0.05), as shown in Table 2.

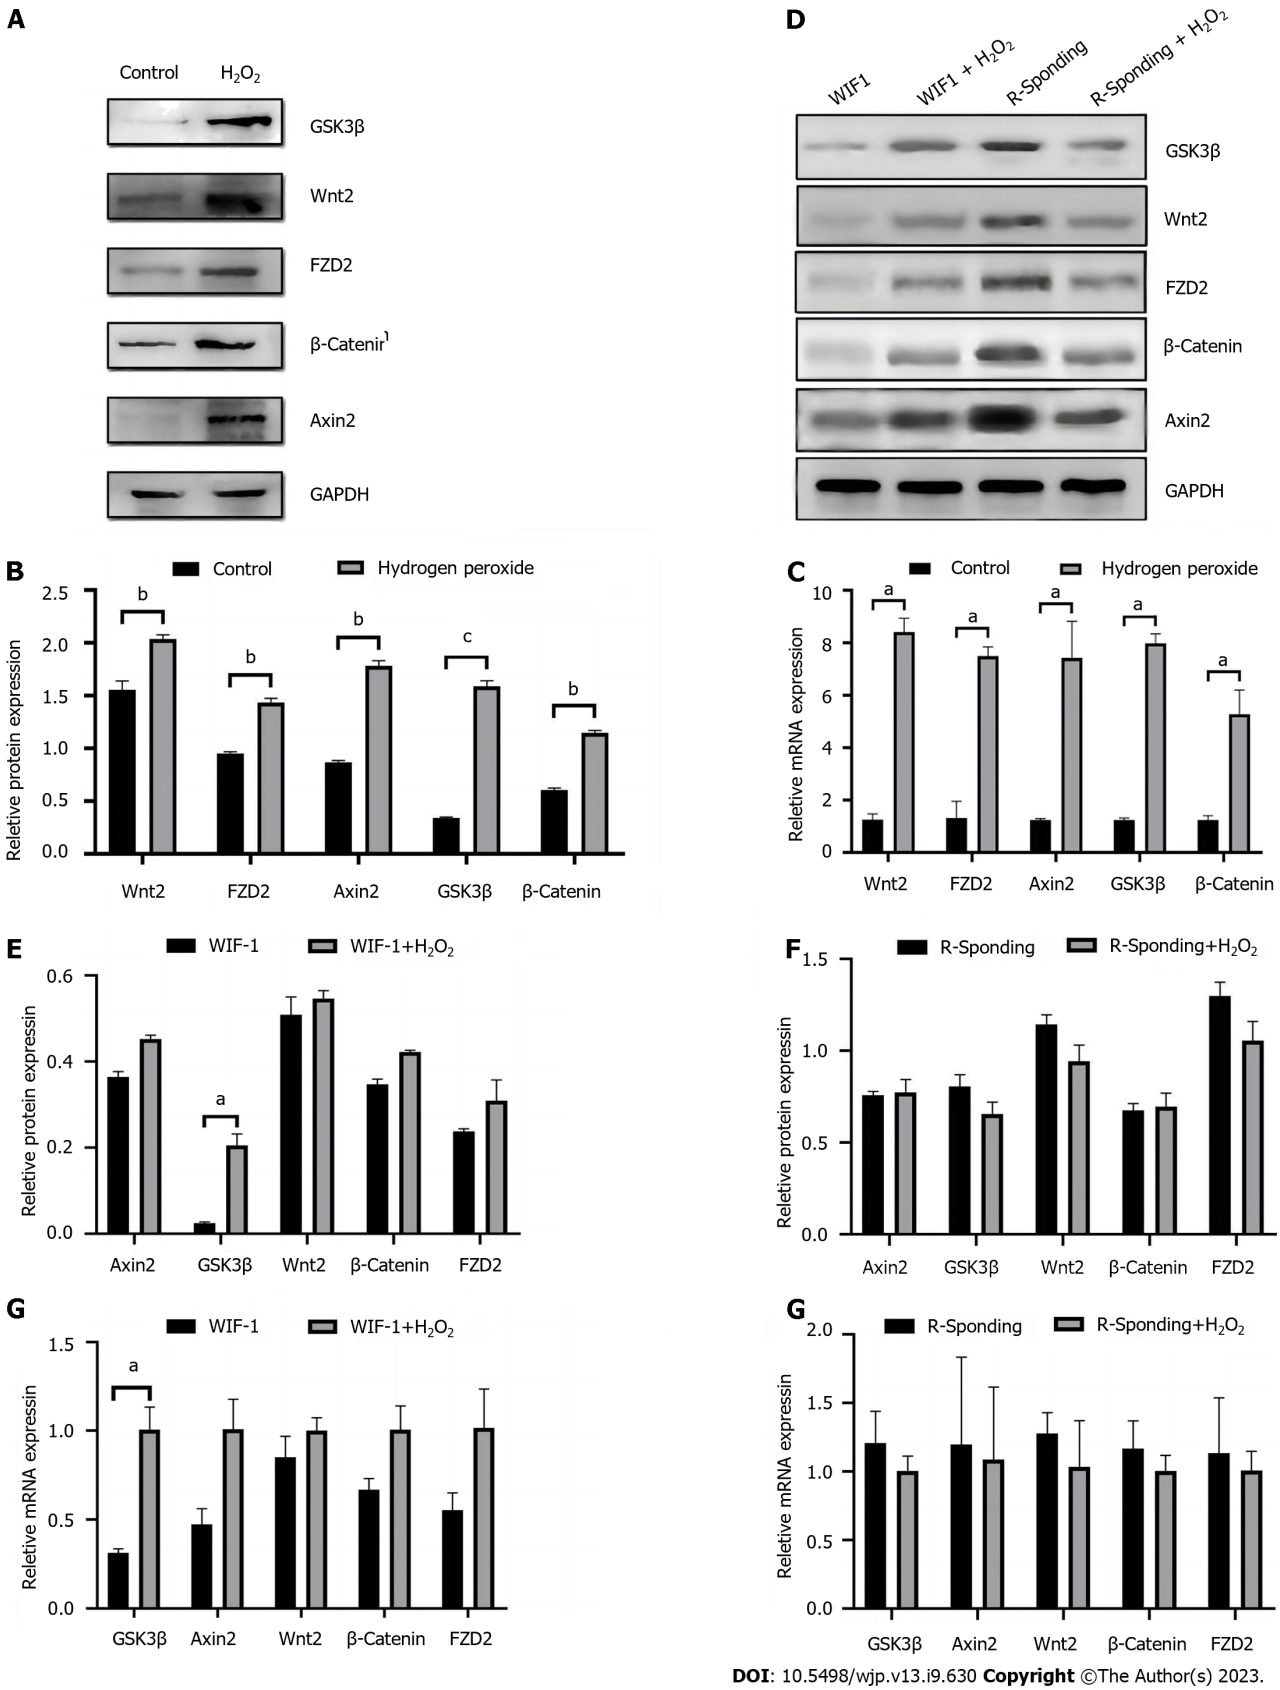
Table 1 Correlation analysis of exosomal miR-320e levels with clinical assessment results in cerebral small vessel disease patients

Variable	Spearman correlation coefficient	*P* value
MoCA score	0.328	0.003
EFA score	0.301	0.006
HAMD score	-0.296	0.007
BDI score	-0.283	0.010

MoCA: Montreal Cognitive Assessment; EFA: Executive Function Assessment; HAMD: Hamilton Depression Scale; BDI: Beck Depression Inventory.

Table 2 miRNA levels by groups of more and less severe symptoms of cognitive impairment or depress in cerebral small vessel disease patients, *n* (%)

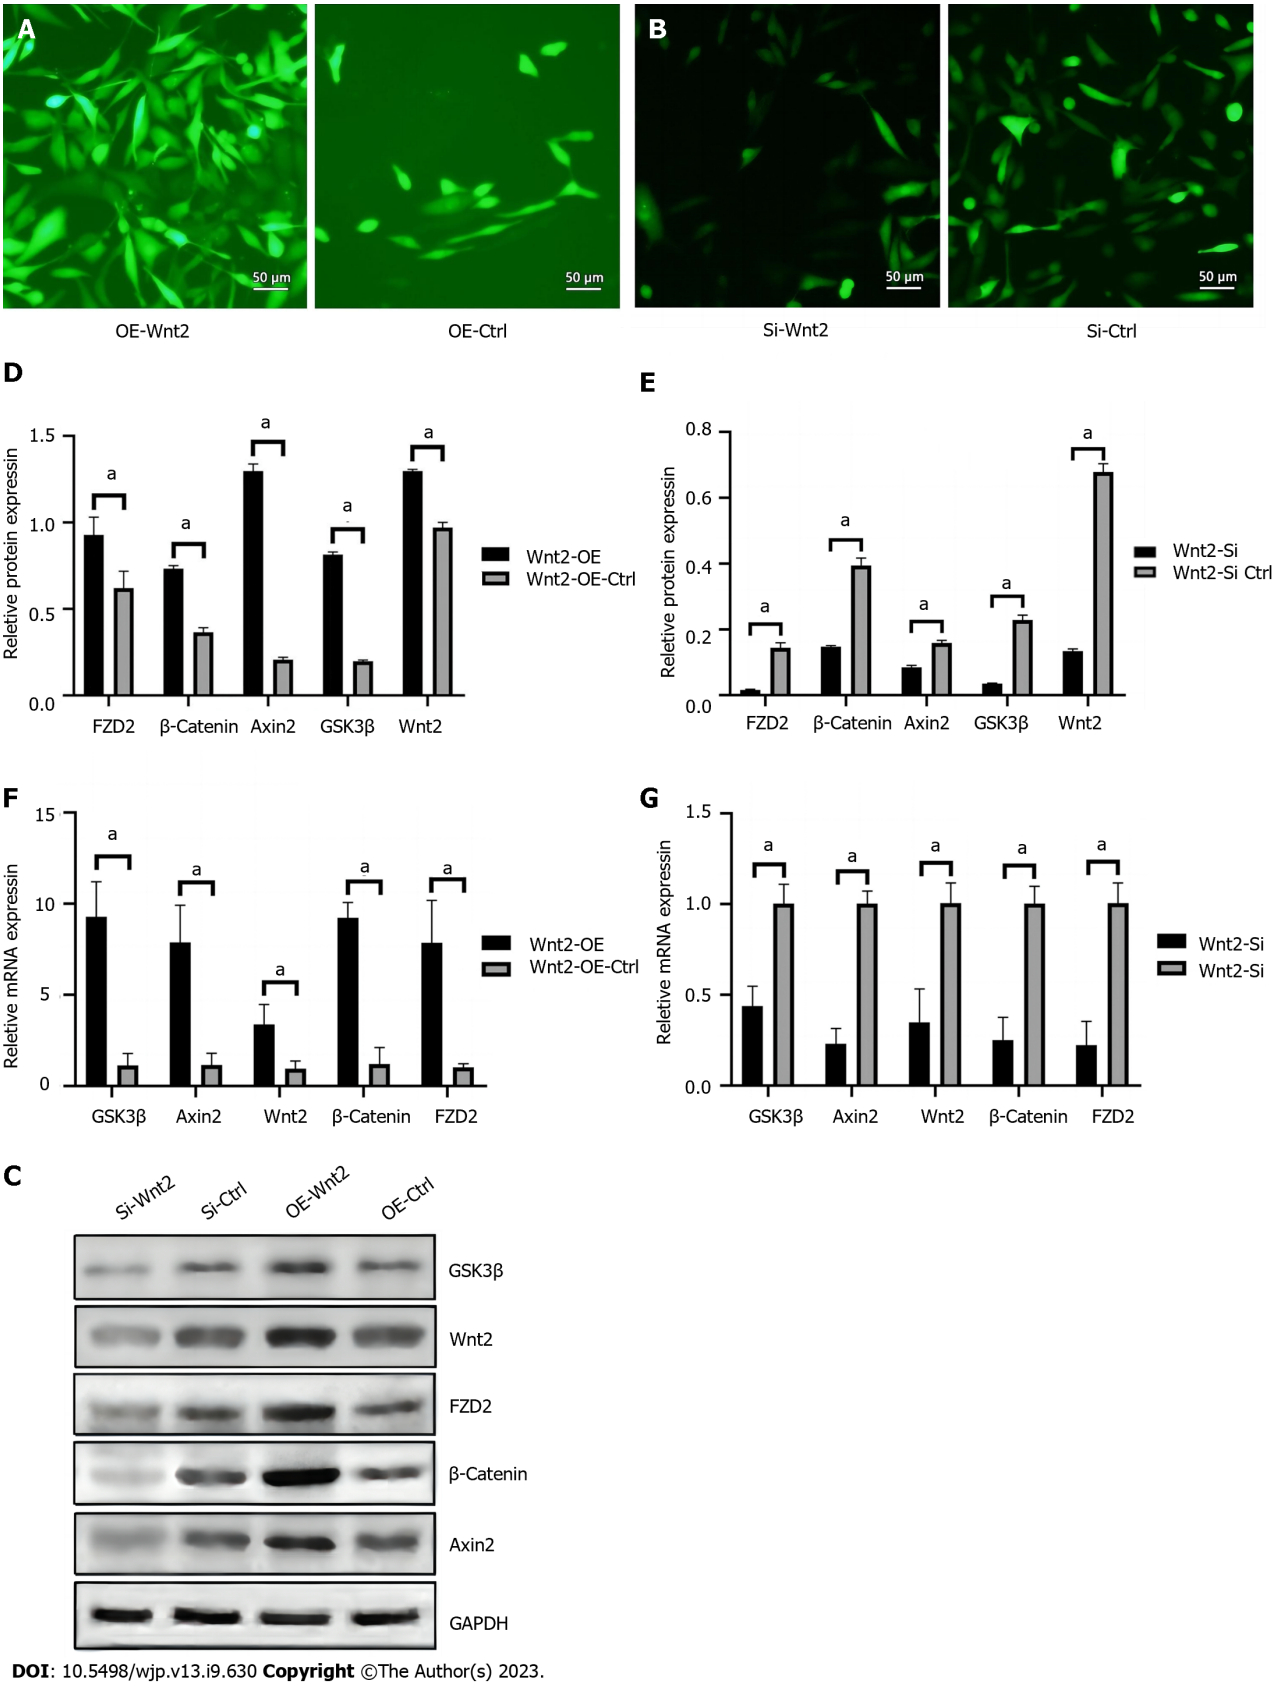
Assessment Scale	More severe disease (below the average score)		Less severe disease (beyond the average score)		*P* value of miRNA-levels
	Patients	miRNA level	Patients	miRNA level	
MoCA	45 (56.25)	1.18 ± 0.32	35 (43.75)	2.15 ± 0.45	0.010
EFA	40 (50)	1.25 ± 0.40	40 (50)	2.30 ± 0.50	0.0092
HAMD	50 (62.5)	1.10 ± 0.35	30 (37.5)	2.20 ± 0.55	0.030
BDI	38 (47.5)	1.15 ± 0.38	42 (52.5)	2.25 ± 0.48	0.0012



MoCA: Montreal Cognitive Assessment; EFA: Executive Function Assessment; HAMD: Hamilton Depression Scale; BDI: Beck Depression Inventory.

DISCUSSION

The Wnt/β-catenin pathway is involved in the response to oxidative stress stimuli and leads to white matter lesions and central nervous system inflammation and injury[26-28]. Inhibition of the abnormal activation of the Wnt/β-catenin pathway was shown to delay coronary artery disease in the myocardial tissue of rats[29] and the process of renal ischaemia-reperfusion injury involving oxidative stress in the kidney[30]. Inhibition of the Wnt/β-catenin pathway also inhibited the progression of neuroblastoma and attenuated axonal degeneration in Parkinson's disease models[20,21,31]. However, studies on the involvement of the Wnt/β-catenin pathway in CVSD are lacking. Based on the widespreadly applied model of HUVECs in the study of cerebral vasculature, our study showed that miR-320e inhibited the oxidative stress-induced Wnt/β-catenin pathway by targeting Wnt2 in endothelial cells to facilitate a protective role in CVSD. The miR320e expression in patients with CVSD was significantly lower in those with relatively severe cognitive impairment and depression, with a positive correlation with both MoCA/EFA and HAMD/BDI scores. Thus, we speculated that miR-320e could be a potential predictive and therapeutic target for CVSD. However, it was important to note that while HUVECs serve as a useful preliminary model, future investigations employing more directly relevant cell types could potentially further reinforce and expand upon our findings.



Due to the scarcity or absence of smooth muscle content in small arteries, smallvessel diastolic function and substance screening are dependent on endothelial cells to perform normal physiological functions, which are influenced by a combination of factors[32-35]. Recent studies have shown that exosomes transport complex substances that freely reach and cross the blood-brain barrier (BBB), and the miRNAs carried are protected by the exosome membrane from degradation by RNA enzymes so that they can effectively act on target cells. Thus, exosomal miRNAs are considered to affect cerebrovascular disorders by affecting the microenvironment of intracranial vessels[36,37]. Previous studies have found that neuronal-secreted exosomal miR-132 can regulate cerebrovascular integrity[38], exosomal miR-451a may play a protective role in ischemia-reperfusion injury[13], and exosomal miR-124a from mesenchymal stem cells can target and inhibit FOX A2 to suppress glioblastoma[14]. Our study showed that exosomes could carry miR-320e into HUVECs, allowing miR-320e to target Wnt2 to exert inhibition of the Wnt/β-catenin pathway during oxidative stress.

To verify the inhibitory effect of miR-320e on the Wnt/β-catenin pathway, we detected the binding target of Wnt2 and the downstream components of FZD2, Axin2, GSK3β and total cellular β-catenin. Our experiment showed that the oxidative stressinduced enhanced Wnt/β-catenin pathway was significantly inhibited by miR320e, as evidenced by the significant suppression in the above genes. In addition, exosomes carrying miR-320e exerted a similar inhibitory effect on the Wnt/β-catenin pathway. Furthermore, we found that GSK3β was inhibited by miR-320e to a much lesser extent than the other genes in the Wnt/β-catenin pathway. GSK3β is involved in multiple pathways, in addition to its role in the Wnt/β-catenin pathway, representing a class of components that exert pathway interactions during cell signaling[39], which suggests that other miRNAs carried by the experimental exosomes from patients with CVSD may contribute to disease deterioration through other mechanisms.

Figure 5 The expression of miR-320e in the exosomes secreted by the miR-320e mimic-transfected cells was significantly higher than that in the mimic NC group and the blank control. A: HUVECs were transfected using miR-320e mimics and the expression of miR-320e was detected. B: Lipid membrane of HUVECs marked by DiI; C: Microplate reader analysis showed that exosomes were also marked by DiI; D: As shown by using marked exosomes harvested from HUVECs and cocultured with HASMCs, HUVECs also showed red fluorescence; E-G: Western blotting and PCR showed that Wnt2 and β-catenin expression in the Exo-mimic group decreased compared to that of the control group. HUVECs: Human umbilical vein endothelial cells; HASMCs: Human aortic vascular smooth muscle cells; PCR: Polymerase chain reaction. $^{a}P < 0.05$, $^{b}P < 0.01$.

The Wnt pathway has been suggested to exhibit different responses when subjected to different time frames of oxidative stress, with transiently activated Wnt pathways generally inducing neovascularization and protecting vascular structure and cellular function[40,41], and continuously activated Wnt pathways leading to senescence and basement membrane disruption[42]. In CVSD, when the small vessels that develop lesions are not in critical areas of the white matter or cortex or when CVSD is masked by more severe ischemia and hemorrhage, small vessel lesions can be detected at a more advanced stage, while various aggressive factors may allow sustained activation of Wnt/β-catenin, thus promoting CVSD progression. Because of the ability of exosomal miR-320e to target Wnt2 and thereby inhibit abnormal activation of the Wnt/β-catenin pathway, the significantly lower expression of miR-320e in the plasma exosomes of patients with CVSD may lead to a lack of protection. Moreover, other miRNAs with different expression profiles may exert protective effects when combined with miR-320e, which may guide further investigation and validation.

Normal brain function depends on the integrity of the cerebrovascular system, and several underlying pathophysiological mechanisms have been shown to be involved in CSVD, such as BBB damage, small-vessel stiffness, venous collagen proliferation, inflammation, and myelin damage[43,44]. Endothelial cells are the cornerstone of small vessel function; with the natural onset of aging and the onslaught of various risk factors, intracranial vascular function

gradually declines and structural integrity is gradually lost, which has long been seen as a vital process in CSVD[36,45,46]. Currently, there are only a few studies on the mechanisms of action of exosomal miRNAs in CVSD. In summary, using bioinformatics and clinical retrospective analyses, this study predicted and confirmed that the inhibitory role of Wnt2-targeting miR-320e on the Wnt/β-catenin pathway may protect patients with CVSD from relatively severe cognitive impairment and depression, providing a potential novel predictive and therapeutic target for CVSD.

CONCLUSION

Our study demonstrates that exosomal miR-320e plays a significant role in the pathogenesis of CVSD by regulating the Wnt/β-catenin pathway under oxidative stress. Our findings suggest that exosomal miR-320e may be a potential therapeutic target in CVSD based on its ability to inhibit the Wnt/β-catenin pathway and protect against cognitive impairment and depression. The uptake of exosomes carrying miR-320e can also target Wnt2 and suppress the Wnt2/β-catenin pathway, highlighting the significance of exosomal miRNAs as novel therapeutic agents for CVSD. Further studies are needed to investigate the underlying mechanisms of exosomal miR-320e in CVSD progression and to explore its clinical applications. Overall, this study provides new insights into the complex pathophysiology of CVSD and suggests a promising avenue for developing effective therapies for this devastating disease.

ARTICLE HIGHLIGHTS

Research background

Cerebral small vessel disease (CVSD) is a common neurodegenerative disorder characterized by cognitive impairment and depression. Exosomal miRNAs play an essential role in the pathophysiology of CVSD, and their dysregulation contributes to disease progression. This study aimed to investigate the potential role of exosomal miR-320e in the Wnt/β-catenin pathway stimulated by oxidative stress and its clinical correlation with cognitive impairment and depression in patients with CVSD. The study utilized high-throughput sequencing, bioinformatics analysis, dual-luciferase reporter gene experiments, and retrospective analysis among patients with CVSD. The aim was to explore whether exosomal miR-320e could suppress the Wnt/β-catenin pathway and play a protective role in CVSD progression, as well as examine its potential correlation with cognitive impairment and depression in patients with CVSD. The findings suggest that exosomal miR-320e targets Wnt2 and inhibits the Wnt/β-catenin pathway in response to oxidative stress, potentially playing a protective role in CVSD progression. Elevated miR-320e expression may also correlate with less severe cognitive impairment and depression in patients with CVSD.

Research motivation

CVSD is a complex neurodegenerative disorder that affects cognitive function and mental health, but currently lacks effective treatments. Exosomal miRNAs are emerging as important regulators of physiological and pathological processes in the brain, including CVSD. This study aimed to investigate the potential role of exosomal miR-320e in the Wnt/β-catenin pathway stimulated by oxidative stress and its clinical correlation with cognitive impairment and depression in patients with CVSD. The study utilized high-throughput sequencing, bioinformatics analysis, dual-luciferase reporter gene experiments, and retrospective analysis among patients with CVSD. The aim was to explore whether exosomal miR-320e could suppress the Wnt/β-catenin pathway and play a protective role in CVSD progression, as well as examine its potential correlation with cognitive impairment and depression in patients with CVSD. The findings suggest that exosomal miR-320e has a potentially protective role in CVSD progression and may be a novel therapeutic target. The study provides further insights into the complex pathophysiology of CVSD and highlights the importance of exosomal miRNAs in neurological diseases.

Research objectives

The research objectives of this study were to explore the potential role of exosomal miR-320e in the Wnt/β-catenin pathway stimulated by oxidative stress and its clinical correlation with cognitive impairment and depression in patients with cerebral small vessel disease (CVSD). The study aimed to identify differentially expressed exosomal miRNAs by sequencing plasma exosomes from patients with CVSD and healthy controls, confirm the binding of miR-320e to Wnt2 through bioinformatics and dual luciferase analyses, evaluate the mRNA and protein levels of downstream components in the Wnt/β-catenin pathway when overexpressed or knocked down miR-320e under H_2O_2-induced oxidative stress, and conduct a retrospective analysis among patients with CVSD to confirm the relationship between miR-320e expression and the severity of cognitive impairment and depression. The study also aimed to investigate whether exosomal miR-320e could inhibit the Wnt/β-catenin pathway and play a protective role in CVSD progression, potentially leading to the development of novel therapeutic targets for this complex neurodegenerative disorder.

Research methods

The study utilized various methods to investigate the role of exosomal miR-320e in CVSD. Differentially expressed exosomal miRNAs were identified by sequencing plasma exosomes from patients with CVSD and healthy controls. Bioinformatics analysis and dual-luciferase reporter gene experiments were conducted to confirm the binding of miR-

320e to Wnt2. The mRNA and protein levels of downstream components in the Wnt/β-catenin pathway were evaluated through overexpression or knockdown of miR-320e under H_2O_2-induced oxidative stress. Wnt2-targeting siRNA was used to confirm the role of miR-320e in the Wnt2-mediated inhibition of the Wnt/β-catenin pathway. A retrospective analysis was conducted among patients with CVSD to assess the correlation between miR-320e expression and cognitive impairment and depression, which were quantified using the Montreal Cognitive Assessment (MoCA)/Executive Function Assessment (EFA) and the Hamilton Depression Scale (HAMD)/Beck Depression Inventory (BDI), respectively. Overall, these methods provided valuable insights into the potential role of exosomal miR-320e in the pathophysiology of CVSD and its potential clinical significance.

Research results

The results of the study indicate that exosomal miR-320e is downregulated in patients with CVSD. Exosomal miR-320e was found to inhibit the Wnt/β-catenin pathway in response to oxidative stress by targeting the 3' noncoding region of Wnt2. Uptake of exosomes carrying miR-320e could also target Wnt2 and inhibit the Wnt2/β-catenin pathway in endothelial cells. The study also found that elevated miR-320e expression may protect patients with CVSD from relatively severe cognitive impairment and depression, as it had a positive correlation with the MoCA/EFA and HAMD/BDI scores. These findings suggest that exosomal miR-320e may have a potentially protective role in CVSD progression and could be a novel therapeutic target for this complex neurodegenerative disorder. Overall, the results provide important insights into the pathophysiology of CVSD and highlight the importance of exosomal miRNAs in neurological diseases.

Research conclusions

The study found that exosomal miR-320e is downregulated in patients with CVSD and may play a crucial role in the progression of the disease. Exosomal miR-320e was found to inhibit the Wnt/β-catenin pathway by targeting the 3' noncoding region of Wnt2 in response to oxidative stress. The uptake of exosomes carrying miR-320e could also target Wnt2 and inhibit the Wnt2/β-catenin pathway in endothelial cells. Furthermore, elevated miR-320e expression was found to have a positive correlation with cognitive function and depression scores, suggesting it may protect patients from severe cognitive impairment and depression. The study provides new insights into the pathophysiology of CVSD and highlights the potential clinical significance of exosomal miRNAs in neurological diseases. These findings have implications for the development of novel therapeutic targets for CVSD and may provide hope for patients with this complex neurodegenerative disorder.

Research perspectives

The study provides valuable insights into the potential role of exosomal miR-320e in the pathophysiology of CVSD. Future research could investigate the use of exosomal miR-320e as a therapeutic target to prevent or delay the progression of CVSD. Further studies could also investigate the underlying mechanisms by which miR-320e regulates the Wnt/β-catenin pathway and how it affects cognitive function and depression. In addition, the use of animal models could provide further insight into the potential clinical significance of exosomal miRNAs in neurological diseases. Further research could also explore the potential diagnostic and prognostic value of miR-320e in patients with CVSD. Overall, the findings of this study pave the way for future research on the role of exosomal miRNAs in CVSD and other neurodegenerative disorders.

Abstract

BACKGROUND

Few relevant literature reports on applying acupoint press-needle embedding combined with emotional nursing in patients with a gynecological malignant tumor.

AIM

To explore the effect of traditional Chinese medicine acupoint needle embedding combined with emotional nursing on chemotherapy-related nausea and vomiting (CINV), cancer-related fatigue (CRF) and psychological state in patients with gynecological malignant tumors.

METHODS

Retrospective analysis of the clinical information of 84 patients with gynecological malignant tumors treated in our hospital from August 2020 to December 2022 Led to the development of an observation group (n = 42) and a control group (n = 42) based on various nursing approaches. Ondansetron hydrochloride injection was administered to the individuals in the control group. However, the observation group received emotional nursing based on the control group and acupoint press-needle embedding of traditional Chinese medicine. Patients in both groups received the chemotherapy regimen of paclitaxel liposome + carbo-platin/cisplatin. For four weeks, both groups intervened. The CINV grade, quality of life, CRF, psychological status and sleep quality scores of the two groups before and

after intervention were compared.

RESULTS

After intervention, the degree of CINV in the observation group was significantly better than that in the control group. After intervention, the scores of each dimension and total score of FLIE scale were significantly higher than those in the control group. After intervention, the scores of each dimension and total score of Piper Fatigue Scale were significantly lower than those in the control group ($P < 0.05$). After intervention, the scores of avoidance and yield dimensions in the observation group were significantly lower than those in the control group, and the scores of confrontation dimension were significantly higher than those in the control group ($P < 0.05$). After intervention, the sleep quality score of the observation group was significantly lower than that of the control group, and the Karnofsky Performance Status scale score was significantly higher than that of the control group ($P < 0.05$).

CONCLUSION

The acupuncture point needle embedding of traditional Chinese medicine combined with emotional nursing can further reduce the incidence of chemotherapy-related nausea and vomiting in patients with gynecological malignant tumors, improve the quality of life and the degree of CRF, alleviate the bad psychological state, adopt a positive way to face the disease and treatment, and improve the quality of sleep and quality of life.

Key Words: Press-needle; Acupoint; Emotional nursing; Gynecologic malignant tumor; Sleep quality; Chemotherapy-induced nausea and vomiting; Cancer-related fatigue; Mental state

Core Tip: Nausea, vomiting and cancer-related fatigue (CRF) are the most common symptoms during chemotherapy in patients with gynecological malignant tumors. If timely and effective nursing intervention is not given, it is easy to affect the quality of life of patients. Acupressure needle has the advantages of simple operation, safety and convenience, while emotional nursing can effectively alleviate the negative emotions of patients with malignant tumors during chemotherapy. The combination of the two can effectively reduce the incidence of nausea and vomiting, improve the quality of life and the degree of CRF in patients with gynecological malignant tumors.

INTRODUCTION

Cervical, ovarian, and endometrial cancer are the three most prevalent gynecological malignancies, accounting for approximately 18% of all tumors worldwide[1]. The incidence rate has been rising recently, significantly negatively affecting women's physical and emotional health. Chemotherapy, which can efficiently eliminate cancerous cells and increase patients' overall survival times, is currently the preferred clinical treatment technique. However, while treating diseases, chemotherapy can also suppress normal cells, resulting in the suppression of the immune function of patients and negative responses, such as vomiting and nausea, peripheral neurotoxicity, a decrease in hematopoietic stem cell level, *etc*[2], as well as cancer-related fatigue (CRF), thus affecting patients' chemotherapy compliance. Chemotherapy-induced nausea and vomiting (CINV), which can occur in up to 70% of patients with gynecological malignant tumors during chemotherapy, is the most common adverse response. If not prevented and treated promptly and effectively, it can easily lead to eating difficulties in patients and even an imbalance of water, electrolyte, and acid-base balance in severe cases[3]. CRF is a term used to describe severe, continuous, psychological fatigue in physical, emotional, or cognitive aspects unrelated to recent activities caused by a tumor or tumor treatment and interferes with everyday activities. According to incomplete statistics[4], about 57.84% of patients with gynecological malignant tumors will have CRF during chemotherapy, which is easy to increase the pain of patients and affect the quality of sleep and life. Western medicine mainly uses 5-HT3 receptor antagonists, NK-1 receptor blockers, glucocorticoids and other drugs to treat CINV, which can effectively prevent patients from developing CINV. Still, some patients are prone to constipation, headache and other adverse reactions after Western medicine treatment[5].

Traditional Chinese medicine (TCM) has an extensive history of treating gastrointestinal side effects brought on by chemotherapy and offers the benefits of safe use, ease of use, cheap cost, and lack of side effects, *etc.* The external treatment of traditional Chinese medicine has formed a systematic theory and specific methods in developing traditional Chinese medicine for thousands of years, mainly including press-needle embedding, acupoint application, acupuncture, emotional therapy, *etc.* Acupoint press-needle embedding is a type of external treatment of TCM, which can induce continuous weak stimulation at the acupoint by penetrating the needle into the subcutaneous area of a specific acupoint

[6]. It has the advantages of simple operation, safety and convenience. Emotional nursing is a type of TCM nursing technology that consists of the language guidance method, emotion inter-resistance treatment, and emotional desire adjustment. It can easily relieve the negative emotions of cancer patients undergoing chemotherapy[7]. Few relevant literature reports on applying acupoint press-needle embedding combined with emotional nursing in patients with a gynecological malignant tumor. The clinical effectiveness of acupoint press-needle embedding and emotional nursing in individuals with gynecological cancer is examined in this study using a retrospective analysis method.

MATERIALS AND METHODS

Clinical data

A retrospective analysis was done on the clinical data of 84 patients who received chemotherapy for gynecological malignant tumors at our institution between August 2020 and December 2022. (1) Inclusion criteria: Aged 18-80 years old; the patient was diagnosed with a gynecological malignant tumor by postoperative pathological and cytological examination. Patients who needed chemotherapy; Karnofsky Performance Status scale (KPS) score ≥ 70 points; No other antiemetic drugs were taken 48 h before chemotherapy; Complete clinical data; and (2) Exclusion criteria: Patients with liver and kidney insufficiency; Nausea and vomiting caused by intracranial hypertension, vestibular dysfunction and digestive system diseases; Those with contraindications to press-needle; Mental disorders and cognitive disorders; incomplete case data. The 84 patients were grouped into a control group (n = 42) and an observation group (n = 42) using various nursing techniques.

Methods

Liposome + carboplatin/cisplatin. The control group was given an injection of 0.9% sodium chloride (Sichuan Kelun Pharmaceutical Co., Ltd., Approval No. H20056626), a 100 mL injection of ondansetron hydrochloride [Qilu Pharmaceutical Co., Ltd., (No. H10970065)], and 8 mg intravenously 15 min before chemotherapy. Based on the control group, the observation group received acupoint press-needle embedding treatment and emotional nursing. The acupoints of Guanyuan, Dazhui, bilateral Geshu, Zusanli and Shenshu were selected for press-needle treatment, used alcohol to disinfect the patient's skin at the corresponding acupoint, used tweezers to remove the disposable press-needle, quickly attached the press-needle to the acupoint, pressed and smoothed. The operation was performed at the beginning of chemotherapy, the patient was instructed to press intermittently during treatment, the needle could be removed after 2 d, and the press-needle embedding therapy was performed once every 3 d. Emotional nursing: Chinese medical nursing staff carried out emotional nursing, kept the indoor environment in a calm and bright state, and adopted emotional nursing methods such as language guidance method, emotion inter-resistance therapy, emotional transference method, calming mind method, and emotional desire adjustment: (1) Language guidance method: Following the start of chemotherapy, the responsible nurse assessed the patient's mental health and identified the root reasons for their depression, 30 min for each time; (2) Emotion inter-resistance therapy: After chemotherapy, music therapy was used to help patients relieve negative emotions, guided patients to watch skits, cross talk and other programs, and helped patients increase joy to reduce the sadness of patients; and (3) Emotional transference method: Guided patients to find their interests and hobbies, and transfer their attention to chemotherapy through painting, calligraphy, walking and other ways to alleviate bad emotions. The responsible nurse selected 2-3 emotional nursing methods daily and operated once daily. Both groups were treated for 4 wk.

Observation indicators

Between the two groups, comparisons were made of the basic information, CINV grade, quality of life, CRF, coping style, and sleep quality scores: (1) General data questionnaire: including age, education level, primary tumor site, initial chemotherapy, KPS score and other clinical data; (2) CINV grade classification: Grade 0: No nausea or vomiting; Grade I: Nausea but no vomiting; Grade II: Intermittent vomiting with nausea; Grade III: Vomiting Needs Treatment; Grade IV: Excessive vomiting; CINV grades were assigned on the basis of patient's nausea and vomiting[8]; (3) Quality of life (QoL): The QoL of both groups before and after the intervention was evaluated by the Functional Living Index-Emesis (FLIE)[9], which was divided into two dimensions: nausea and vomiting. Each dimension had 9 items, each scoring according to 1 to 7 levels. The higher the score, the smaller the impact of CINV on functional living; (4) CRF: The Chinese version of the Revised Piper Fatigue Scale (PFS-R)[10] was employed to examine the level of fatigue in the two groups before and following the intervention. It consists of 22 questions and is categorized as follows: Behavior, emotion, perception, and cognition; (5) Mental state: The medical coping style scale[11] was applied to determine the coping style of both groups before and after the intervention, which was divided into three dimensions: Avoidance, yield and facing, with 20 items. The higher the score of each dimension, the more likely the patient was to adopt the coping style; and (6) Sleep quality: The Pittsburgh Sleep Quality Index (PSQI)[12] was utilized to examine 18 items, including seven aspects of sleep latency, sleep duration, sleep efficiency, sleep disorders, hypnotic drugs, and daily dysfunction. The scale ranged from 0 to 21, and the overall score was the average for each item. A total score of ≤ 7 suggested normal sleep quality and sleep disorders by a total score of ≥ 8. The lower the patient's sleep quality, the higher the overall score.

Data collection

Nursing staff who had been trained in a unified manner distributed the general information questionnaire and scales of quality of life, CRF, coping style, and sleep quality to the patients, explained the purpose of this study and the

precautions for filling in the patients before filling in, and checked whether the questionnaire and scale were missing after filling in to ensure the integrity of the questionnaire and scale.

Statistical analysis

In this study, EpiData 3.0 software was used to input data by two people. The data obtained were analyzed and processed with SPSS25.0 software. The counting data is presented as "n (%)", and the comparison was made using the chi-square test. The measurement data following the normal distribution were presented as mean ± SD, and the t-test was employed for comparison. A P value < 0.05 was deemed as statistically significant for all analyses.

RESULTS

General data comparison between the two groups

Table 1 demonstrates no statistically considerable variation in the basic data of both groups (P > 0.05).

The CINV score comparison in both groups following treatment

Following the intervention, the observation group's CINV grade was considerably higher as compared to the control group (P < 0.05; Table 2).

Comparison of pre-and post-intervention QoL values in both groups

The scores for each dimension and the FLIE scale's overall score before intervention did not significantly vary (P > 0.05) in both groups. With statistical significance (P < 0.05), the scores for each component and the overall FLIE scale score in the two groups were higher after the intervention. Following the intervention, the observation group's scores on each component and overall FLIE scale score were significantly higher than those of the control group (P < 0.05; Table 3).

Comparison of CRF scores before and after intervention for both groups

Before the intervention, there was no statistically significant difference (P > 0.05) between the scores of each dimension and the total score on the PFS-R scale in both groups. After the intervention, the scores of each dimension and the total score of the PFS-R scale in the observation group were considerably lower than before the intervention (P < 0.05). In contrast, the scores of each dimension and the total score of the PFS-R scale of the control group pre- and post-the intervention did not demonstrate statistical significance (P > 0.05). Table 4 shows that after the intervention, the score of each dimension and the overall score of the PFS-R scale in the observation group were significantly lower compared to the control group (P < 0.05).

Comparison of coping style ratings before and after intervention in both groups

Before the intervention, no significant difference (P > 0.05) in the scores of medical coping strategies in both groups was observed. Both groups' avoidance and yield dimensions dropped after the intervention compared to before. The scores on the facing dimension improved (P < 0.05) compared to those before the intervention. Following the intervention, the observation group's scores for the avoidance and yield dimensions were significantly lower than those of the control group. The face dimension score was significantly higher compared to the control group (P < 0.05; Table 5).

Evaluation of both groups' KPS scores and sleep quality pre- and post-intervention

Both groups had no significant change (P > 0.05) before the intervention in sleep quality or KPS score. Both groups' sleep quality and KPS scores dropped significantly (P < 0.05) after the intervention compared to before. As shown in Table 6, the observation group's sleep quality score was considerably lower than the control group's after the intervention, while the control group's KPS score was significantly higher (P < 0.05).

DISCUSSION

Epidemiological research shows that[13] the number of patients diagnosed with gynecological malignancies and the number of deaths from such diseases are increasing yearly and have obvious characteristics such as low age and high malignancy, which seriously affect the physical and social psychological health of contemporary women. There are many treatments for gynecological malignant tumors. Adjuvant chemotherapy is an important measure to improve the postoperative survival rate. Since vomiting and nausea are frequent side effects of chemotherapy, therapeutic attention has turned to preventing and treating CINV. Previous clinical studies have suggested that the vomiting mechanism is complex, mainly because the neurotransmitter receptors on the gastrointestinal pheochromocytoma combine with chemotherapy drugs to stimulate the brain centre and send signals to the organs and tissues of the upper digestive tract to complete the vomiting reflex. Among them, important neurotransmitters such as 5-HT and substance P participate in the reaction and bind to the 5-HT_3 receptor and NK-1 receptor, respectively[14].

Therefore, Western medicine often uses 5-HT3 receptor antagonists and NK-1 receptor blockers to prevent nausea and vomiting[15], but long-term use is prone to adverse reactions. Compared with traditional acupuncture, the diameter of the press needle is generally about 0.20 mm, and the length of the needle body varies from 0.30 to 5.00 mm. After the

needle is inserted into the human body, there is almost no sense of acupuncture. After the needle is applied, it is buried in the body with glue and can be retained for a long time. It has the advantages of simple operation and low price. Traditional Chinese medicine acupoint press needles can achieve a sustained therapeutic effect by continuously stimulating the body and then prolonging the effect of acupuncture[15]. Previous studies have found that[16] applying an acupoint press needle in patients with dermatitis helps promote the blood circulation of patients and has a good analgesic effect. Emotional nursing affects patients' emotions through the words and behaviors of medical staff, thus improving patients' negative emotions, eliminating patients' worries and anxieties, and improving patients' anti-cancer concepts.

This study applied acupoint press needle and emotional nursing to gynecological malignant tumor patients receiving chemotherapy. The results showed that the observation group's post-intervention FLIE scale scores on each dimension and overall were considerably higher compared to the control group and that the observation group's post-intervention CINV grade was higher than that of the control group. The findings indicated that emotional nursing and acupoint press-needle embedding could further lower the prevalence of CINV in patients with gynecological malignant tumors and lessen the negative effects of nausea and vomiting on quality of life. CRF is a subjective feeling often associated with cancer patients. Unlike other common symptoms, CRF does not have obvious physiological changes or measurable physiological indicators[17].

Meanwhile, Chinese women are more tolerant and often hide their fatigue performance to avoid burdening their families, mistakenly believing that fatigue is only temporary. However, studies have shown[18] that persistent CRF leads to a higher risk of death. The findings of this research demonstrated that after the intervention, the observation group's PFS-R scale scores on each dimension and overall were lower than the control group. The statistical significance of the difference suggests that acupoint press-needle embedding combined with emotional caregiving can help reduce the severity of CRF in patients with gynecological cancerous tumors. The study's findings also revealed that the observation group's avoidance and yield dimension scores were significantly lower after the intervention than those of the control group.

Compared to the control group, their face dimension scores were significantly higher, their sleep quality scores were significantly lower, and their KPS scores were higher, indicating that the acupoint press-needle embedding combined therapy had an effect. The acupoint press-needle embedding may produce constant stimulation on particular acupoints, which can have the effect of antiemesis and lessen the negative effects of CINV on quality of life. With emotional nursing measures, the language guidance method, emotion inter-resistance therapy, emotional transference method, calming mind method and other methods were used to relieve the bad mood of patients. Music therapy was used to improve the cerebral cortex excitability to regulate the human body's mood, thus eliminating the tension, anxiety and other feelings of the human body, improving fatigue degree and sleep quality, and establishing confidence in treating disease.

CONCLUSION

In conclusion, Chinese medicine acupoint needle embedding combined with emotional nursing can further reduce the incidence of chemotherapy-related nausea and vomiting in patients with gynecological malignant tumors, improve the quality of life and the degree of CRF, alleviate the bad psychological state, and adopt a positive way to face the disease and treatment, improve sleep quality and quality of life, which is worthy of clinical application.

ARTICLE HIGHLIGHTS

Research background

The number of patients diagnosed with gynecological malignant tumors and the number of deaths from such diseases are increasing year by year. At the same time, it has obvious characteristics such as low age and high malignancy, which seriously affects the physical and social mental health of contemporary women. Nausea and vomiting are common adverse reactions after chemotherapy. Therefore, preventing and improving chemotherapy-related nausea and vomiting has become a hot topic in clinical research. In the past, 5-HT3 receptor antagonists, NK-1 receptor blockers and other drugs were used to prevent nausea and vomiting, but long-term use was prone to adverse reactions. The use of traditional Chinese medicine nursing measures has the advantages of simple operation and good safety.

Research motivation

To observe the application value of traditional Chinese medicine acupoint needle embedding combined with emotional nursing in improving the adverse reactions of gynecological malignant tumor chemotherapy, which can effectively reduce the incidence of nausea and vomiting and cancer-related fatigue (CRF) caused by chemotherapy, improve the treatment confidence and improve the prognosis of patients.

Research objectives

By observing the effect of traditional Chinese medicine acupoint needle embedding combined with emotional nursing on chemotherapy-related nausea and vomiting, CRF and psychological state in patients with gynecological malignant tumors, it is helpful to reduce the incidence of chemotherapy-related nausea and vomiting in patients with gynecological malignant tumors, improve the quality of life and the degree of CRF, alleviate the bad psychological state, adopt a positive and positive way to face the disease and treatment, and improve the quality of sleep and quality of life.

Research methods

By observing the effect of traditional Chinese medicine acupoint needle embedding combined with emotional nursing on chemotherapy-related nausea and vomiting, CRF and psychological state in patients with gynecological malignant tumors, it is helpful to reduce the incidence of chemotherapy-related nausea and vomiting in patients with gynecological malignant tumors, improve the quality of life and the degree of CRF, alleviate the bad psychological state, adopt a positive and positive way to face the disease and treatment, and improve the quality of sleep and quality of life.

Research results

By observing the application value of traditional Chinese medicine acupoint needle embedding combined with emotional nursing in patients with gynecological malignant tumors, it was found that acupoint needle embedding combined with emotional nursing had significant effects on reducing the incidence of adverse reactions to chemotherapy, improving CRF and quality of life of patients. The effect of this program on the long-term prognosis of patients with gynecological tumors still needs to be further verified.

Research conclusions

Traditional Chinese medicine nursing program is of great significance to reduce the incidence of adverse reactions of chemotherapy in patients with gynecological malignant tumors and improve their quality of life.

Research perspectives

In the future, it is necessary to further observe the effect of traditional Chinese medicine nursing technology on improving the long-term prognosis of patients with gynecological malignant tumors.

Abstract

BACKGROUND

It is positive to integrate and evaluate the risk factors for postpartum depression in patients with pregnancy-induced hypertension syndrome and to detect high-risk patients as early as possible, which has application value for the clinical development of personalized prevention programs and prognosis of patients.

AIM

To analyze factors related to postpartum depression in patients with pregnancy-induced hypertension and construct and evaluate a nomogram model.

METHODS

The clinical data of 276 patients with pregnancy-induced hypertension admitted to Huzhou Maternity and Child Health Care Hospital between January 2017 and April 2022 were retrospectively analyzed. We evaluated the depression incidence at 6 wk postpartum. The depression group included patients with postpartum depression, and the remainder were in the non-depression group. Multivariate logistic regression analysis and the LASSO regression model were applied to analyze the factors related to postpartum depression in patients with pregnancy-induced hypertension. After that, a risk prediction model nomogram was constructed and evaluated.

RESULTS

Multivariate logistic regression analysis showed that vitamin A deficiency (VAD) during pregnancy and puerperium, family history of hypertension, maternal intestinal flora imbalance, eicosapentaenoic acid (EPA), and docosahexaenoic acid (DHA) were independent risk factors for postpartum depression in patients with pregnancy-induced hypertension ($P < 0.05$). We constructed the nomogram model based on these five risk factors. The area under the curve, specificity, and

sensitivity of the model in predicting postpartum depression in patients with pregnancy-induced hypertension was 0.867 (95% confidence interval: 0.828–0.935), 0.676, and 0.889, respectively. The average absolute error was 0.037 (Hosmer-Lemeshow test χ^2 = 10.739, P = 0.217).

CONCLUSION
VAD during pregnancy and puerperium, family history of hypertension, maternal intestinal flora imbalance, EPA, and DHA affect postpartum depression in patients with pregnancy-induced hypertension.

Key Words: Pregnancy-induced hypertension syndrome; Postpartum depression; Unhealthy emotions; Related factors; Nomograms; Evaluation

Core Tip: Pregnancy-induced hypertension usually manifests as an elevation of blood pressure, oedema, multiple organ damage, eclampsia, and even coma. Here, we analyzed the factors related to postpartum depression in patients with pregnancy-induced hypertension. We used vitamin A deficiency during pregnancy and puerperium, family history of hypertension, maternal intestinal flora imbalance, eicosapentaenoic acid, and docosahexaenoic acid to construct a nomogram evaluated and confirmed to have good predictive performance. It is a breakthrough in the prediction of postpartum depression in pregnancy-induced hypertension.

INTRODUCTION

Pregnancy-induced hypertension is a syndrome caused by elevated blood pressure, with a prevalence of 12%[1]. Elevation of blood pressure, oedema, multiple organ damage, eclampsia, and even coma are common clinical symptoms in patients with pregnancy-induced hypertension, which can increase the risk of maternal and perinatal death. Postpartum depression includes negative emotions such as pessimism, anxiety, loss, and ease of fright after childbirth. In severe cases, there may be suicidal tendencies and dangerous events such as harming infants or others[2]. The incidence of postpartum depression in patients with pregnancy-induced hypertension is about 9.4%, significantly higher than in non-depressed pregnant women[3]. Women can have both hypertension and depression during pregnancy and puerperium, which are a threat to maternal and infant health. The pathogenesis of postpartum depression is still unknown, and it may be related to genetic, mental, biochemical, social, and other factors. Therefore, it is practical to integrate and evaluate the risk factors for postpartum depression in patients with pregnancy-induced hypertension and to detect high-risk patients as early as possible, which is of guiding effects for the clinical development of personalized prevention programs and prognosis of patients. In this study, by analyzing the risk factors for postpartum depression in patients with pregnancy-induced hypertension, we constructed a personalized nomogram model to provide reference data for reducing the occurrence of clinical postpartum depression.

MATERIALS AND METHODS

Patient data

We conducted a retrospective study on 276 patients with pregnancy-induced hypertension in Huzhou Maternity and Child Health Care Hospital between January 2017 and April 2022. The enrolled patients met the following criteria: Diagnosis of pregnancy-induced hypertension[4]; age ≥ 18 years; and complete clinical data, laboratory examination data, and 5-HT1A receptor gene C (-1019)G [5-HTR1AC(-1019)G] detection data. The exclusion criteria were: Abnormal cognitive function; malignant tumours, myocardial infarction, stroke, or other serious diseases; inability to communicate smoothly with language; or prenatal history of mental illness or family history.

Clinical data collection

We collected the clinical data by consulting the electronic medical records of patients, including gestational weeks of pregnancy-induced hypertension, adverse delivery outcomes, adverse delivery history, family support status, vitamin A deficiency (VAD) during pregnancy and puerperium, complications, family history of hypertension, delivery mode, delivery times, education level, planned pregnancy, occupational status during pregnancy and puerperium, feeding mode, 5-HTR1AC(-1019)G, intestinal flora imbalance during pregnancy and puerperium, weight gain during late

pregnancy, age, family monthly income during pregnancy and puerperium, eicosapentaenoic acid (EPA), docosahexaenoic acid (DHA), arachidonic acid (AA), hypersensitive C-reactive protein (Hs-CRP), and procalcitonin (PCT).

Definition and detection methods of related indicators

Adverse birth outcomes included premature birth (gestational age < 37 wk), birth defects, low weight, asphyxia, and infection. The family member support score was measured using the social support rating scale developed by Xiao Shuiyuan to evaluate the support of family members (parents, spouses, compatriots, children, and one other). The total score was 4–16 points, divided into four levels: Full strength, general, very little, and no support. The higher the score, the higher the level of family support[5]. In smears of faecal samples taken from patients during pregnancy and puerperium, a large number of suppressed proto-flora, a decrease in the total number of bacteria, an increase in Gram-negative bacteria, or a decrease/increase in Gram-positive bacteria indicated intestinal flora imbalance.

Weight gain in the third trimester was weight in the third trimester minus the initial weight. The boundaries for the classification of pregnant women with normal and overweight initial weight were an insufficient increase, < 11.5 and < 7 kg; sufficient increase, 11.5-16 and 7-11.5 kg; and excess increase, > 16 and > 11.5 kg[6]. At 16 wk of gestation and 6 wk after delivery, the venous peripheral blood serum VA content was determined by HPLC. Serum VA concentration < 0.7 μmol/L was determined as VAD[7]. Complications included thyroid disease, kidney disease, heart disease, and diabetes. The concentration of EPA, DHA, and AA in venous blood serum was determined by the double antibody sandwich method on day 3 after delivery. Hs-CRP and PCT were measured by Roche Cobas 8000C701 biochemical analyzer and Roche E411 Luminescence analyzer, respectively.

Grouping

At 6 wk postpartum, the Edinburgh Postpartum Depression Scale (EPDS)[8] was used to assess depression status. The total score was 0-30 points. The higher the score, the more serious the depression. Patients with EPDS scores ≥ 13 were diagnosed with postpartum depression. Women who met the criteria for postpartum depression fell into the depression group, and the remainder into the non-depression group.

Statistical methods

We analyzed and processed the data using R version 4.0.3 and performed LASSO regression analysis with the glmnet package. We used the rms package to draw the nomogram and calibration curve and the predictive receiver operating characteristic curve (ROC) package to draw the ROC. We verified the resulting nomogram model by bootstrap self-sampling 500 times and evaluated its efficacy by the area under the ROC curve (AUC). The test level was $\alpha = 0.05$.

RESULTS

Comparison of clinical data of patients

Among the 276 patients with pregnancy-induced hypertension, 54 were in the depression group and 222 in the non-depression group. The incidence of postpartum depression in patients with pregnancy-induced hypertension was 19.57% (54/276). We compared the number of gestational weeks, adverse delivery outcomes, family support status, VAD during pregnancy and puerperium, complications, family history of hypertension, maternal intestinal flora imbalance, weight gain in the third trimester, EPA and DHA between the two groups (Table 1).

Multivariate analysis of postpartum depression in pregnancy-induced hypertension

We put independent variables ($P < 0.05$) and dependent variables (grouping, 0 = non-depression group, 1 = depression group) into a multivariate logistic regression analysis model (Table 2). VAD during pregnancy and puerperium, family history of hypertension, intestinal flora imbalance during pregnancy and puerperium, EPA, and DHA were independent risk factors for postpartum depression ($P < 0.05$) (Table 3). The AUC of VAD during pregnancy and puerperium, family history of hypertension, intestinal flora imbalance during pregnancy and puerperium, EPA, and DHA in predicting postpartum depression in patients with pregnancy-induced hypertension were 0.612, 0.584, 0.603, 0.293, and 0.281, respectively. The best cut-off values of EPA and DHA were 1.82 pg/mL and 2.18 pg/mL, respectively. Figure 1A shows the ROC curve of each index to predict postpartum depression in patients with pregnancy-induced hypertension.

Construction of nomogram model

The independent risk factors for postpartum depression in patients with pregnancy-induced hypertension were used as predictors to construct a nomogram model (Figure 2). The internal verification was carried out by bootstrap self-sampling 500 times. The slope of the calibration curve was similar to that of the diagonal line, suggesting that the degree of fitting between the calibration curve and the ideal curve was high, indicating that there was no significant difference between the predicted and measured values. The average absolute error (0.037) was small, which suggested that the nomogram model had a predictive effect (Figure 3).

ROC curve analysis of nomogram model prediction

The AUC predicted by the nomogram for each index was 0.867 greater than the AUC of each index in Figure 1A. The specificity and sensitivity were 0.676 and 0.889, respectively. The Hosmer–Lemeshow test statistic was 10.739, and there was no significant difference between the predicted value and actual ($P = 0.217$) (Figure 1B).

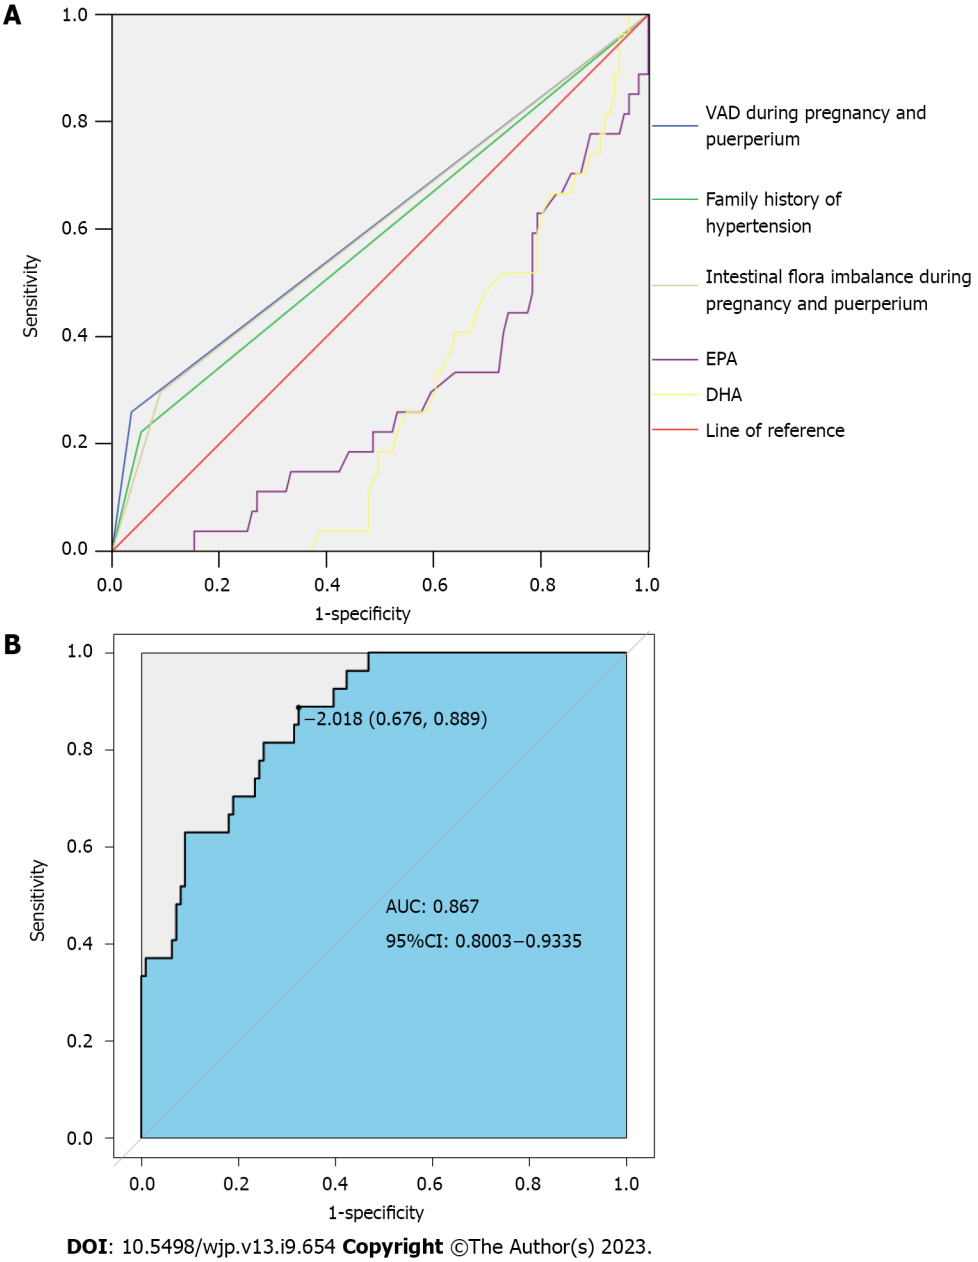
DISCUSSION

Postpartum depression in patients with pregnancy-induced hypertension can cause neurological and endocrine system disorders, often making them lose their ability to care for themselves and their infants, which is not conducive to them and their infant's health[9]. Other studies have shown that for infants aged 1.5-2 mo, maternal postpartum depression may lead to developmental delays in gross motor, fine motor, and communication areas. Research has suggested that postpartum depression harms mothers and adversely affects children's cognition, behaviour, temperament, and physical development[10]. The risk of postpartum depression in patients with pregnancy-induced hypertension is higher than that in normal pregnant, which may be related to many factors such as VAD during pregnancy and puerperium, family history of hypertension, and intestinal flora imbalance during pregnancy and puerperium. Therefore, integrating the risk factors for postpartum depression in patients with pregnancy-induced hypertension is of clinical significance for identifying high-risk patients.

Table 2 Assignment

Variable	Assignment
Gestational weeks of pregnancy-induced hypertension	0 > 34; 1, 28–34; 2 < 28.
Adverse birth outcomes	0 = No, 1 = Yes
Family support status	0 = full support, 1 = general support, 2 = little or no support
VAD during pregnancy and puerperium	0 = No, 1 = Yes
Complications	0 = none, 1 = have
Family history of hypertension	0 = none, 1 = have
Intestinal flora imbalance during pregnancy and childbirth	0 = none, 1 = have
Weight gain in late pregnancy	0 = increase sufficient, 1 = increase insufficient, 2 = increase excessive
EPA	Actual value
DHA	Actual value



VAD: Vitamin A deficiency; EPA: Eicosapentaenoic acid; DHA: Docosahexaenoic acid.

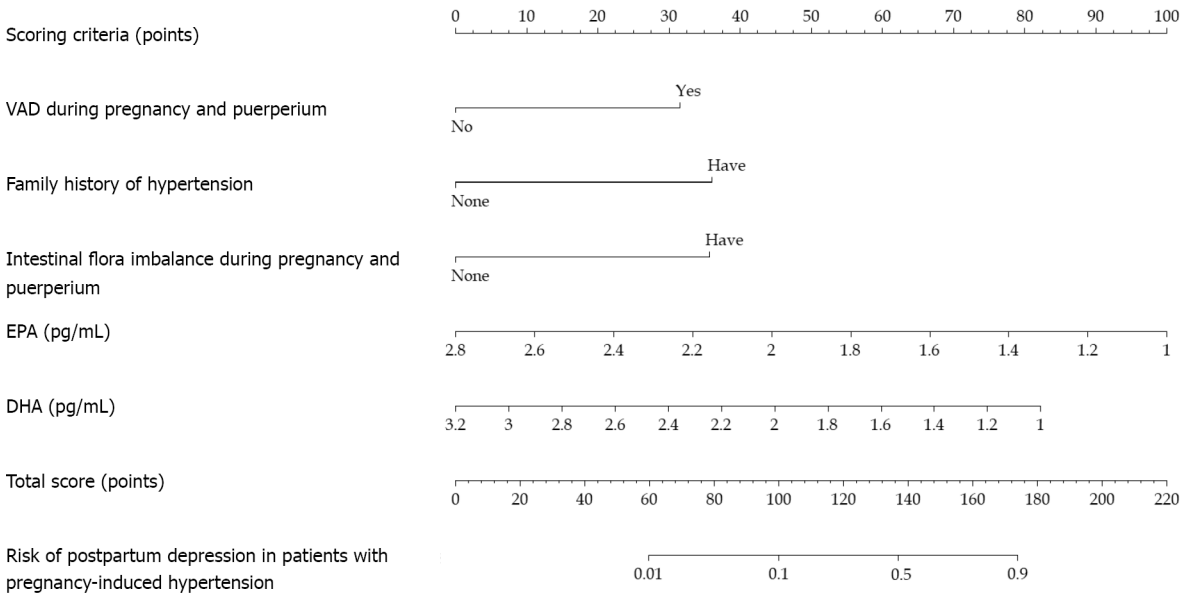
VAD: Vitamin A deficiency; EPA: Eicosapentaenoic acid; DHA: Docosahexaenoic acid.



The postpartum depression incidence in 138 patients with pregnancy-induced hypertension was 19.57%, similar to previous studies[11]. Multivariate logistic regression analysis showed that patients with pregnancy-induced hypertension and VAD during pregnancy and puerperium, family history of hypertension, maternal intestinal flora imbalance, low EPA level, or low DHA level had an increased risk of postpartum depression. We speculated that progesterone level in pregnant women in early pregnancy decreases. Because progesterone can promote the release of VA stored in the liver and adipose tissue into blood, this function of progesterone is weakened after progesterone deficiency, resulting in a decrease in serum VA concentration and the development of VAD. VAD during puerperium may also be related to insufficient progesterone secretion. Long-term continuous VAD during pregnancy and puerperium can promote postpartum depression[12]. In the present study, the proportion of VAD during pregnancy and puerperium in depressed patients was higher than in non-depressed patients, indicating that perinatal VAD also increased the risk of postpartum depression in patients with pregnancy-induced hypertension. There is no consensus on the mechanism of VAD in

postpartum depression development. Some scholars believe that VA can affect the proliferation and differentiation of nerve cells, synapse formation, and axon growth. Studies have also found that VAD may be the basis of the pathogenesis of Alzheimer's disease, which can increase hippocampal Aβ deposition, resulting in hippocampal plasticity and memory function[13]. Therefore, VA is involved in related activities of cranial nerves. These activities may be factors that maintain a good mood. Once the body has continuous VAD, it may increase the incidence of depression. For pregnancy-induced hypertension patients with a family history of hypertension, the psychological burden may be aggravated by similar diseases in their relatives, resulting in anxiety, such as poor pregnancy and poor fetal birth due to unsatisfactory blood pressure control, so it is more likely to induce postpartum depression. Research has also shown a significant difference in the family history of hypertension between the postpartum depression group and the non-depression group of pregnant women with gestational hypertension[14], which is consistent with the results of our study. In recent years, more studies on the mechanism of postpartum depression have shifted from social environmental factors to biological factors (such as gene polymorphism). Abnormal intestinal flora structure can cause abnormal fluctuations in the central nervous system, thus promoting the occurrence of mental diseases such as depression. Intestinal flora imbalance can induce an immune response, and then the hypothalamus-pituitary-adrenal (HPA) axis is abnormally active, and depression occurs. Relevant studies have also shown that after bifidobacteria supplementation to people with intestinal flora imbalance, the HPA axis activity weakens. Also, the concentration of neurotrophic factors in the brain that regulate neuronal development increases, and the HPA axis improves[15]. Therefore, intestinal flora imbalance is a risk factor for postpartum depression in patients with pregnancy-induced hypertension. Clinically, we can reduce the occurrence of postpartum depression by

Figure 3 Correction curve.

improving the composition of intestinal flora in patients with pregnancy-induced hypertension. EPA and DHA are fatty acids with multiple double bonds and are chief components of phospholipids in the human brain. Phospholipids ensure the integrity and fluidity of nerve cell membranes and participate in the signal transduction of various substances in nerve cells. Therefore, EPA and DHA are closely related to the brain's nervous system. The lack of both may cause neurological and psychological disorders and damage the cerebellum, vision, and cognition. The lower the level of EPA or DHA, the more prone patients are to depression. Serum EPA and DHA levels affect the formation of postpartum depression and negative correlation[16,17]. These show that ensuring adequate EPA or DHA intake during pregnancy may be a protective factor for postpartum depression in patients with pregnancy-induced hypertension. This study also analyzed the 5-HTR1AC (-1019) G genotype and allele in patients with pregnancy-induced hypertension. The results showed that there was no difference in the gene polymorphism of this locus between patients with postpartum depression and non-depressed patients, which was inconsistent with relevant research[18]. It may be related to the

different sample sizes and inclusion/exclusion criteria of the two studies. Therefore, we speculated that the occurrence of postpartum depression in patients with pregnancy-induced hypertension may be slightly influenced by biological factors.

This study summarized the risk factors related to postpartum depression in patients with pregnancy-induced hypertension and applied these five risk factors as predictive variables to construct a predictive nomogram model. After the model verification, we found that the degree of fitting between the calibration and the ideal curve was high. The AUC predicted by the nomogram model was higher, indicating that the model had better discriminant ability. The Hosmer–Lemeshow test showed that the predictive data of the model were not much different from the actual data, suggesting that the model had high calibration or predictive accuracy. The nomogram model showed the relationship between the five variables of VAD during pregnancy and puerperium, family history of hypertension, intestinal flora imbalance during pregnancy and puerperium, EPA, and DHA with the calibrated lines, which was readable and easy to evaluate. This study explored the nomogram model of postpartum depression in post-inflammatory hyperpigmentation (PIH) patients, which can help clinicians quickly and accurately identify patients with PIH who are at risk of depression after high production, help guide them to take targeted intervention measures, and thus reduce the possibility of postpartum depression in patients. It has high clinical application value.

There were some limitations to this study. All the women were from a single centre, and there may have been potential selection bias. The risk prediction nomogram model for postpartum depression in patients with pregnancy-induced hypertension was only internally validated, and there was a lack of external validation from other central data. Therefore, we need sufficient external evidence before the practical application of the model.

CONCLUSION

Postpartum depression in patients with pregnancy-induced hypertension is affected by VAD during pregnancy and puerperium, family history of hypertension, intestinal flora imbalance during pregnancy, and puerperium, EPA, and DHA. The established nomogram model can effectively assess its risk.

ARTICLE HIGHLIGHTS

Research background

The clinical prediction of postpartum depression in patients with pregnancy-induced hypertension is still insufficient, and the application of the nomogram model in predicting postpartum depression in patients with pregnancy-induced hypertension is rarely reported.

Research motivation

Compared with normal pregnant, pregnancy-induced hypertension patients have a higher risk of postpartum depression, which is related to several factors. By integrating risk factors of postpartum depression in pregnancy-induced hypertension and constructing predictive models, this study guides identifying high-risk patients and early clinical intervention.

Research objectives

The study's purpose was to integrate the risk factors of postpartum depression in patients with pregnancy-induced hypertension, construct a graph prediction model, and evaluate the predictive effect of the model.

Research methods

Multivariate logistic regression analysis and LASSO regression were used to analyze the factors related to postpartum depression in pregnancy-induced hypertension. R version 4.0.3 was used to construct a line graph risk predictive model. The area under the receiver operating curve was used to evaluate effectiveness.

Research results

Vitamin A deficiency (VAD) during pregnancy and puerperium, eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) are independent risk factors for postpartum depression in pregnancy-induced hypertension. The histogram model established by this method had good predictive efficacy and could guide clinical prevention and intervention.

Research conclusions

Postpartum depression in pregnancy-induced hypertension is related to VAD during pregnancy and puerperium, family history of hypertension, intestinal flora disorders during pregnancy and perinatal period, EPA, and DHA. The predictive efficacy of the risk model established by this method has clinical application value.

Research perspectives

Future research directions should increase the sample size or multicenter study to verify the results, enhance the reliability of the conclusions, and better carry out clinical prevention interventions.

Abstract

BACKGROUND

Gastric ulcer (GU) is a common digestive tract disease, and medical records of GU combined with depression are increasingly common. Currently, the risk factors and pathogenesis of GU complicated with depression remain unclear. Low immune function and gastrointestinal hormone levels may also be significant risk factors. Therefore, this study explored the immune function and gastrointestinal hormone levels in patients with GU combined with depression.

AIM

To explore the immune function, gastrointestinal hormone level, and clinical significance of patients with GU combined with depression.

METHODS

A retrospective analysis was conducted on 300 patients with GU combined with depression admitted to Guizhou Provincial People's Hospital from January 2021 to June 2022 as the study subjects. According to the Hamilton Depression Scale (HAMD) score, patients were divided into mild-to-moderate (n = 210) and heavy (n = 90) groups. Basic data, immune function indices [immunoglobulin A (IgA), IgM, IgG, serum $CD4^+$ and $CD8^+$ percentage, and $CD4^+/CD8^+$ ratio], and gastrointestinal hormone indices [serum gastrin (GAS), cholecystokinin (CCK), and motilin (MTL) levels] were collected. The basic data of the two groups were compared, and the immune function and gastrointestinal hormone indices were analyzed. Multivariate logistic regression was used to analyze the factors influen-

cing the severity of GU complicated with depression. The receiver operating characteristic (ROC) curve and area under the ROC curve (AUC) were used to analyze the value of the immune function index, gastrointestinal hormone index, and combined index in predicting the severity of GU complicated with depression.

RESULTS

There were no marked differences in sex, age, body mass index, abdominal distension, abdominal pain, belching, nausea, vomiting, or sleep disorders between the heavy and mild-to-moderate groups ($P > 0.05$). There was a marked difference in the family history of depression between the heavy and mild-to-moderate groups ($P < 0.05$). There were significant differences in serum IgA and IgM levels and serum $CD4^+$, $CD8^+$, and $CD4^+/CD8^+$ ratios between the heavy and mild-to-moderate groups ($P < 0.05$). Multivariate analysis showed that IgA, IgM, GAS, and CCK serum levels influenced the severity of GU with depression ($P < 0.05$). The AUC of the ROC curve for serum IgA level predicting GU with depression severity was 0.808 [95% confidence interval (CI): 0.760-0.857], the AUC of the serum IgM level was 0.757 (95%CI: 0.700-0.814), the AUC of the serum GAS level was 0.853 (95%CI: 0.810-0.897), the AUC of the serum CCK level was 0.762 (95%CI: 0.709-0.822), the AUC of immune function (IgA, IgM) and gastrointestinal hormone levels (GAS, CCK) for the prediction of GU with depression severity was 0.958 (95%CI: 0.933-0.976).

CONCLUSION

Important factors influencing GU complicated with depression are serum IgA, IgM, GAS, and CCK indicators. They can be used as indicators to predict the severity of GU complicated with depression.

Key Words: Gastric ulcer combined with depression; Immune function; Gastrointestinal hormones

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: The occurrence and severity of gastric ulcer (GU) combined with depression may be related to autoimmune dysfunction and gastrointestinal hormone levels. In this study, multivariate logistic regression analysis was used to influence the severity of concurrent depression in GU. The results suggest that impaired T cell function and gastrointestinal hormone disorders may directly affect the development and development of depression. In addition, the immune function indicators combined with gastrointestinal hormone levels predict high AUC, specificity and sensitivity, which has a very good reference value.

INTRODUCTION

With the continuous development of living standards, people's eating and living habits have changed to varying degrees; however, poor living habits have had a greater impact on people's health. Gastric ulcers (GU) are common digestive system diseases. The occurrence and continuous progression of the disease are related to the dynamic balance between gastric mucosal defense and invasion factors. *Helicobacter pylori* (*H. pylori*) infection, excessive gastric acid secretion, and adverse drug factors are all influencing factors that cause GU[1,2]. Gastric juice concentration in patients with GU stimulates the gastric mucosa, promotes changes in the gastric structure and environment, causes serious damage to the gastric mucosa, and causes long-term stay of pathogenic factors, resulting in the long-term treatment of the disease[3]. Clinical manifestations of GU include stomach and abdominal pain, heartburn, acid reflux, among others. The symptoms worsen after eating irritating foods or foods that are hard to digest. Smoking and alcohol consumption can also cause GU. Patients with severe GU often experience gastric perforation and gastric bleeding[4].

Recently, psychophysiological factors have been significant in the pathogenesis of gastrointestinal illnesses. GU are characterized by repeated attacks that can easily cause adverse severe psychological states. Some patients also experience anxiety and depression due to a lack of timely and effective treatment for physical illness, which makes depression increasingly prominent in GU patients[5]. Anti-*H. pylori* therapy, drugs controlling excessive gastric acid secretion, and protecting gastric mucosa are primarily used for the clinical treatment of GU. The impact of psychological factors on disease occurrence and progression in clinical practice is often overlooked, which makes it difficult to treat patients comprehensively[6]. Relevant data show that poor psychological status may increase the risk of digestive disorders[7]; however, there are few studies on patients with GU associated with depression. Exploring the factors influencing GU combined with depression is important for clinical treatment and the improvement of patients' quality of life. Studies have shown that the occurrence of GU combined with depression may be related to abnormal autoimmune function and disorders of gastrointestinal hormone levels[8]; however, the specific mechanism is not clear. Due to the decrease in gas-

trointestinal function and food intake, GU complicated with depression is often accompanied by a decline in immune function, and the adverse psychological state aggravates the risk of malnutrition. The intestinal mucosal barrier and immune function are extremely poor, which increases the risk of depression. Therefore, 300 patients with GU and depression were included in this study to explore their immune function, gastrointestinal hormone levels, and clinical significance, to provide a reference for reducing the incidence of GU complicated by depression.

MATERIALS AND METHODS

Patient characteristics

A retrospective analysis was conducted to select 300 patients with GU complicated with depression admitted to Guizhou Provincial People's Hospital from January 2021 to June 2022 as the study subjects. Inclusion criteria: (1) Age ≥ 18 years old; (2) All patients have nausea, stomach pain, and acid reflux symptoms; and (3) The basic information and laboratory indicators of all patients are complete. The exclusion criteria were as follows: (1) Patients with malignant tumors or chronic atrophic gastritis and other gastrointestinal illnesses; (2) Patients who had undergone gastrointestinal surgery in the past 3 mo; (3) Patients with organic disorders; and (4) Patients with autoimmune diseases and systemic inflammatory diseases.

Diagnostic criteria for GU[9]: GU was confirmed by endoscopy, and the pathological diagnosis of *H. pylori* infection was positive. Diagnostic criteria for depression[10]: Diagnostic criteria for depression in the Diagnostic and Statistical Manual of Mental Disorders were employed. The diagnosis was based on the patient's low mood, slow thinking, reduced language, movements, suspected illness, insomnia, loss of interest, and related symptoms lasting more than 2 wk. The severity of the disease and the degree of social function impairment increase with the number of symptoms.

Grouping method

All patients on the day of admission, patients were routinely assessed using the Hamilton Depression Scale (HAMD)[11], And were graded according to the HAMD scale: A score of 7 points indicates no depression, > 8-19 points indicates depression, > 20-34 points indicates mild to moderate depression, and > 35 points indicates major depression. All enrolled patients with GU and depression were divided into mild-to-moderate (n = 210) and heavy (n = 90) groups.

Clinical data collection

Clinical data collection: (1) Basic information: Sex, age, body mass index (BMI), abdominal distension, abdominal pain, belching, nausea, vomiting, sleep disorders, and family history of depression; (2) Immune function index: The levels of serum immunoglobulin A (IgA), IgM, and IgG were detected by immunoturbidimetry (the kit was purchased from Lifotronic Technology Co., Ltd.). The percentages of serum $CD4^+$ and $CD8^+$ cells were detected using a Beckman CytoFLEX flow cytometer and a supporting kit (Beckman Coulter), and the ratio of $CD4^+/CD8^+$ cells was calculated; and (3) Gastrointestinal hormone indices: The levels of serum gastrin (GAS), cholecystokinin (CCK), and motilin (MTL) were detected by ELISA (the kit was purchased from MLBIO Enzyme Linked Biology).

Statistical analysis

Data analysis was performed using SPSS statistical software 24.0. The measurement data conforming to the normal distribution were expressed as mean ± SD and analyzed by t-test. Count data is expressed as frequency percentage (n%) by the χ^2 test. Multivariate logistic regression analysis was used to explore factors influencing the severity of GU complicated with depression. The receiver operating characteristic curve (ROC) and area under the ROC curve (AUC) were used to analyze the value of the immune function index, gastrointestinal hormone index, and combined index in predicting the severity of GU complicated with depression, and the specificity and sensitivity were calculated. Test level: α = 0.05.

RESULTS

Basic data analysis

Figure 1 shows the number of patients, the number of patient inclusion, and the flow chart of the analysis method. There was no significant difference in gender, age, BMI, abdominal distension, abdominal pain, belching, nausea, vomiting, and sleep disorders between the heavy group and the mild to moderate group (P > 0.05). There was statistically significant difference in family history of depression between severe group and mild to moderate group (P < 0.05) (Table 1).

Comparison of the immune function indicators between the two groups

There were significant differences in serum IgA and IgM levels and serum $CD4^+$, $CD8^+$, and $CD4^+/CD8^+$ ratios between the heavy and mild-to-moderate groups (P < 0.05). There was no significant difference in serum IgG level between the two groups (P > 0.05) (Table 2).

Comparison of the gastrointestinal hormone indexes

Serum GAS and CCK levels were compared between the severe and mild-to-moderate groups (P < 0.05), and there was no difference in serum MTL levels between the two groups (P > 0.05) (Table 3).

Multivariate analysis affecting the severity of GU combined with depression

The above statistically significant indicators (family history of depression, IgA, IgM, $CD4^+$, $CD8^+$, $CD4^+/CD8^+$ ratio, GAS, and CCK) were used as independent variables, and GU combined with depression severity as the dependent variable (see Table 4). Multivariate analysis showed that serum IgA, IgM, GAS, and CCK levels influenced the severity of GU complicated with depression ($P < 0.05$) (Table 5).

ROC curve of immune function predicting GU with depression severity

The AUC of the ROC curve of serum IgA level for predicting GU with depression severity was 0.808 [95% confidence interval (CI): 0.760-0.857], sensitivity was 0.738, and specificity was 0.778, The AUC of the serum IgM level was 0.757 (95%CI: 0.700-0.814), with a sensitivity of 0.748 and a specificity of 0.700 (Figure 2A).

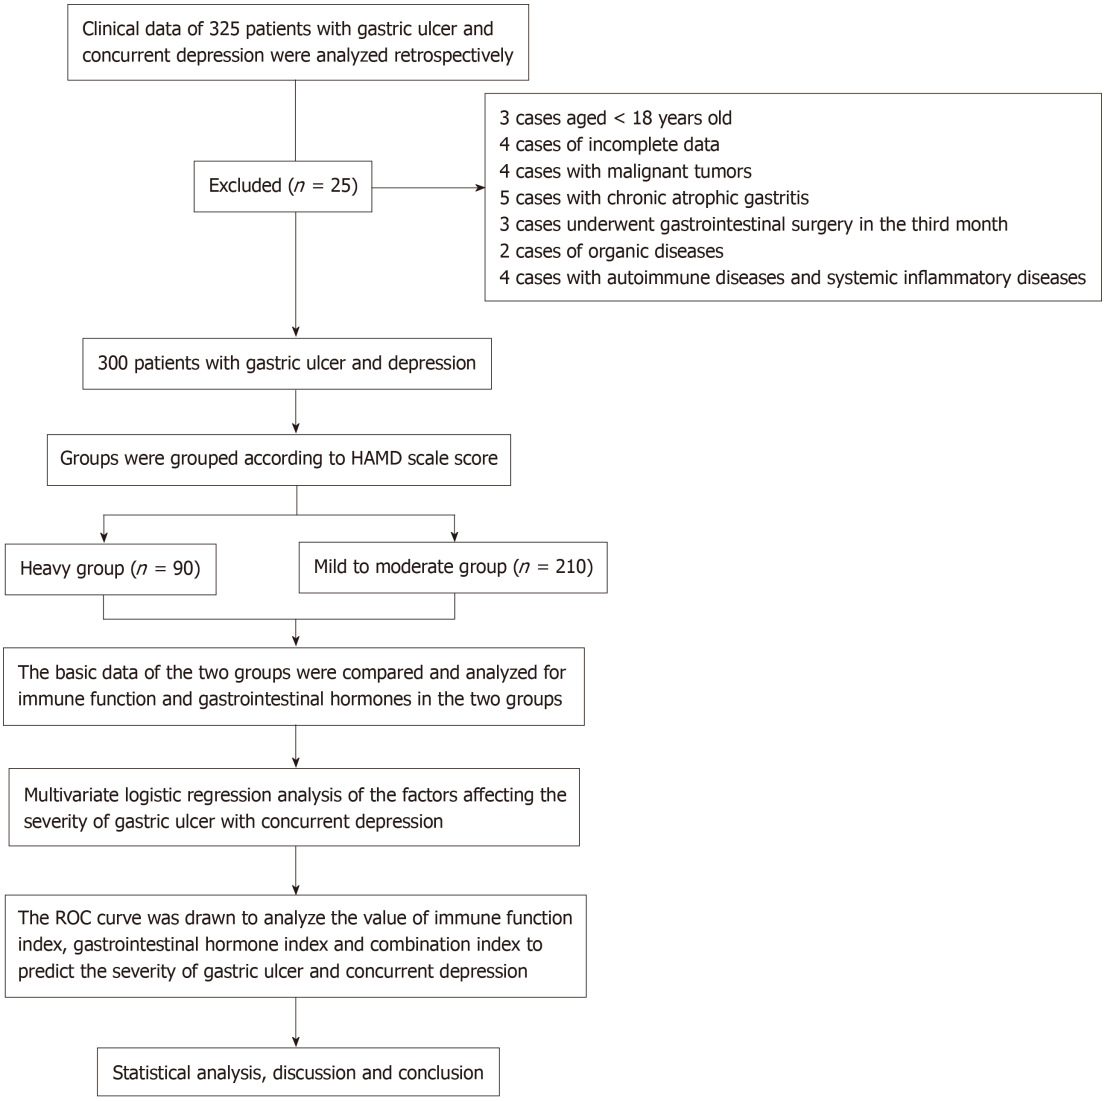
The ROC curve of gastrointestinal hormones in predicting GU combined with depression severity



The AUC of the ROC curve of serum GAS level predicting GU with depression severity was 0.853 (95%CI: 0.810-0.897), sensitivity was 0.814, and specificity was 0.767, The AUC of serum CCK level was 0.762 (95%CI: 0.709-0.822), with a sensitivity of 0.590 and a specificity of 0.844 (Figure 2B).

ROC curve of immune function combined with gastrointestinal hormone levels in predicting GU combined with depression severity

The AUC of immune function (IgA, IgM) combined with gastrointestinal hormone levels (GAS, CCK) predicting GU with depression severity was 0.958 (95%CI: 0.933-0.976), sensitivity was 0.967, and specificity was 0.829 (Figure 2C).

DISCUSSION

GU refers to the ulcer formed in the gastric angle, gastric antrum, cardia, and hiatal hernia. It is a gastric mucosal injury that is caused by various factors. It can be caused by *H. pylori* infection, drugs, heredity, diet, and other factors and is often accompanied by acid reflux, belching, abdominal distension, and upper abdominal pain symptoms[12]. The related study showed that the occurrence of GU is caused by the process of 'attack factor' or the weakening of 'defense factor'; the "attack factor" includes gastric acid, pepsin, *H. pylori*, among others, and the "defense factor" includes gastric mucosa, gastric mucus, bicarbonate, among others[13]. It has been found that *H. pylori* infection is the most common cause of GU. *H. pylori* can damage the protective layer of the gastric mucosa, thus accelerating the occurrence of gastric mucosal lesions, easily causing various complications, and threatening the physical and mental health of patients[14]. GU combined with depression is a typical digestive tract illness in clinical medicine, and gastric acid secretion in the human body is associated with psychological pressure. Patients are affected by psychological and physiological factors, and inner

Figure 1 The number of patients, the number of patients included, and the flow chart of the analysis method. HAMD: Hamilton Depression Scale; ROC: Receiver operating characteristic.

tension and nervous system pressure can cause GUs. The incidence of psychosocial abnormalities has increased in recent years and exists as a comorbidity of other basic and chronic diseases, with these two factors influencing each other[15].

Depression is a primary emotional and common mood disorder. Its incidence ranks second in the incidence of various diseases worldwide. Furthermore, it is found that patients with various chronic diseases have anxiety and depression, and the mortality rate of patients with heart disease complicated with depression is higher than that of patients with simple depression, so the treatment of patients with depression is necessary[16]. The National Institute of Mental Health showed that the prevalence of mental disorders in patients with somatic diseases is as high as 41%[17]. Therefore, while paying clinical attention to the diagnosis and treatment of physical diseases, we should also pay attention to mental and psychological interventions, as the number of patients with GU complicated with depression in China has increased annually[18]. Several factors affect the pathogenesis of GU, which is complicated with depression. Autoimmune dysfunction and gastrointestinal hormone disorders may be important factors affecting disease severity; however, this hypothesis remains controversial. Therefore, it is necessary to explore the importance of immune function and gastrointestinal hormone indices in patients with GU or depression.

In this study, all selected patients were scored using the HAMD. Among them, 210 patients with mild to moderate GU complicated with depression, accounting for 70%, and 90 patients in the heavy group, accounting for 30%. Studies have shown that disease characteristics and severity of depression are influenced by a family history of affective disorder[19]. In this study, the mild-to-moderate and heavy groups had a family history of depression. This indicates that patients with a family history of depression may have more severe anhedonia and anxiety symptoms and that these mood disorders can potentially affect immune function and gastrointestinal hormone levels. The pathogenesis of GU is closely associated with immune deficiency[20]. Depression and anxiety can cause digestive system diseases. Long-term mental disorders overstretch the nervous system, leading to gastrointestinal hormone secretion disorders and excessive sensitivity to food stimulation. Patients with GU and depression have weakened gastrointestinal motility, delayed gastric emptying, and

IgA: Immunoglobulin A; IgM: Immunoglobulin M; GAS: Gastrin; CCK: Cholecystokinin.

uncoordinated gastrointestinal motility, causing a series of complex syndromes such as fullness, belching, and abdominal pain[21]. There was no significant difference in gender, age, BMI, abdominal distension, abdominal pain, belching, nausea, vomiting and sleep disorders between the moderate-to-severe group and the mild-to-moderate group in this study, this result may be related to the sample size included in this study. However, these syndromes must be considered clinically.

Immunoglobulin is produced by B lymphocytes as long as it is a specific binding antigen. Serum IgA, IgM, and IgG are important components of the body's immune cell molecules, which can be consumed in large amounts in consumptive diseases, acute inflammation, and malignant tumors, resulting in a decline in immune function[22]. In this study, serum IgA and IgM levels in the moderate and heavy groups were lower than those in the mild and moderate groups, indicating that impaired B cell function and low immune function could aggravate the risk of infection, GU progression, and depression status. According to modern immunology, the clinical manifestations and prognosis of diseases are closely related to the functional status of T lymphocytes[23]. The percentage of serum $CD4^+$ and $CD8^+$ cells and the $CD4^+/CD8^+$ ratio reflect the cellular immune function of the body. The percentage of serum $CD4^+$ cells are helper T lymphocytes, the percentage of serum $CD8^+$ cells are inhibitory T lymphocytes, and the $CD4^+/CD8^+$ ratio is an index to assess immunity, which can reflect the immune status of the body. When the body is stimulated or damaged by stress, the percentage of $CD4^+$ cells decreased rapidly, the percentage of $CD8^+$ cells increased rapidly, the $CD4^+/CD8^+$ cell ratio increased significantly, and the immune function of the body decreases[24]. In this study, serum $CD4^+$ and $CD4^+/CD8^+$ ratios were significantly decreased in the moderate-to-heavy group, and serum $CD8^+$ levels were markedly increased. This indicates that impaired T-cell function may directly lead to the development of depression. Therefore, enhancing immune cell function is of great clinical value for controlling illness progression in patients with GU and depression.

The gastrointestinal hormone level is a sensitive index that reflects the function of the gastric mucosa. It plays an important role in regulating the function of the digestive system and is closely related to digestive system dysfunction [25]. GAS is the main hormone of the digestive tract that affects gastrointestinal transitional compound movement, prolongs gastric emptying time, stimulates the vagus nerve inhibitory fiber, promotes gastric fundus relaxation, and inhibits reflux of bile discharge[26]. When patients with GU are complicated with depression, the patient's body is in an emergency state, and the levels of stress hormones, such as hypothalamus-pituitary-adrenaline, increase, which affects the interaction between the gastrointestinal flora and gastrointestinal mucosa and the shedding of mucosal mast cells, resulting in dyspepsia[27]. In this study, the levels of serum GAS and CCK were markedly increased in the severe group. This shows that increased secretion or synthesis of gastrointestinal hormones occurs in GU patients with severe depression, leading to an imbalance in the gastrointestinal hormone balance. The low levels of GAS and CCK in plasma

affect the normal functioning of their physiological functions and slow down gastrointestinal motility, thus affecting the digestive tract symptoms of patients with depression. CCK is an important hormone that regulates the gallbladder function. Its main functions include promoting bile secretion, destroying the mucosa lining of the digestive tract, preventing gastrointestinal peristalsis, and prolonging gastric emptying[28]. The increase in CCK levels stimulates the hypothalamus and acts on the central nervous system to inhibit appetite, which is also the reason for the loss of appetite in patients with GU and depression.

In this study, the ROC curves of immune function, gastrointestinal hormone levels, and the combined prediction curve of GU and depression severity were drawn. The results showed that the immune function and gastrointestinal hormone indices alone predicted low AUC, specificity, and sensitivity, and the combined prediction had the highest efficacy, indicating that the immune function indices (IgA and IgM) combined with gastrointestinal hormone levels (GAS and CCK) have good efficacy and significance in predicting the severity of GU and depression. Serum IgA, IgM, GAS, and CCK indicators are simple, convenient, economical, effective, and have strong applicability and operability, which is conducive to the development of primary medical institutions.

Limitations of this study: All the selected participants were admitted to our hospital, the reliability may be affected by the limitation of sample size. In the later stages, the sample size can be expanded clinically, a multicenter study can be conducted, and the mechanism of immune function and gastrointestinal hormone levels in GU complicated with depression can be analyzed in depth.

CONCLUSION

In summary, the important influencing factors of GU with depression were serum IgA, IgM, GAS, and CCK indices. Immune function and gastrointestinal hormone levels can be used as effective indicators to predict the severity of GU combined with depression. Clinically, targeted measures should be taken to address these causes and reduce the risk of GU concomitant with depression.

ARTICLE HIGHLIGHTS

Research background

Psychophysiological factors play a significant role in the pathogenesis of gastrointestinal illnesses. Gastric ulcers (GU) are characterized by repeated attacks that can cause adverse severe psychological states. Some patients also experience anxiety and depression due to a lack of timely and effective treatment for physical diseases, which makes depression increasingly prominent in patients with GU.

Research motivation

The relevant risk factors and pathogenesis of GU concomitant with depression have not yet been fully elucidated. The occurrence and severity of GU complicated with depression may be related to autoimmune dysfunction and gastrointestinal hormonal disorders.

Research objectives

This study aimed to investigate the immune function, gastrointestinal hormone levels, and clinical significance of patients with GU combined with depression and to control disease progression in patients with GU complicated with depression.

Research methods

This study used a retrospective approach to analyze two indexes of immune function and gastrointestinal hormones. Furthermore, it explored the factors influencing the severity of GU concurrent depression using multivariate logistic regression analysis.

Research results

Serum immunoglobulin A (IgA), IgM, gastrin (GAS), and cholecystokinin (CCK) levels were the influencing factors affecting the severity of GU combined with depression; the area under the receiver operating characteristic curve of immune function (IgA, IgM) and gastrointestinal hormone levels (GAS, CCK) for the prediction of GU with depression severity was 0.958 (95% confidence interval: 0.933-0.976).

Research conclusions

The occurrence of GU complicated with depression is related to autoimmune dysfunction and disorders of gastrointestinal hormone levels. Immune function and gastrointestinal hormone levels can be used as effective indicators to predict the severity of GU complicated with depression.

Research perspectives

Using a retrospective analysis approach, patients were divided into severe and mild-moderate groups according to the Hamilton Depression Scale. Basic data from both groups, including immune function and gastrointestinal hormone

markers, were used to analyze the factors affecting the severity of GU and concurrent depression. To explore the value of immune function indices, gastrointestinal hormone indices and a combination of indices were used to predict the severity of GU and depression.

Abstract

BACKGROUND

Spiritual wellbeing emphasizes optimistic and positive attitudes while self-regulating negative emotions when coping with stress. However, there have only been a few small studies of spiritual wellbeing of pancreatic ductal adenocarcinoma (PDAC) patients undergoing chemotherapy. The core factors influencing spiritual wellbeing in this clinical population are still unclear.

AIM

To identify factors influencing spiritual wellbeing among patients with PDAC receiving chemotherapy.

METHODS

A total of 143 PDAC patients receiving chemotherapy were enrolled from January to December 2022. Patients completed general information questionnaires including: Functional Assessment of Chronic Illness Therapy-Spiritual Well-Being 12 Item Scale (FACIT-Sp-12), European Organization for Research and Treatment of Cancer Quality of Life Questionnaire Core 30 (EORTC QLQ-C30) and Zung's Self-rating Anxiety Scale (SAS). Independent sample *t*-test, one-way analysis of variance, Pearson's correlation analysis, and multiple linear regression analysis were adopted for statistical analyses. $P < 0.05$ (two-tailed) was considered statistically significant for all tests.

RESULTS

Total spiritual wellbeing (FACIT-Sp-12) score was 32.16 ± 10.06 points, while dimension sub-scores were 10.85 ± 3.76 for faith, 10.55 ± 3.42 for meaning, and 10.76 ± 4.00 for peace. Total spiritual wellbeing score was negatively correlated with SAS score for anxiety and with the symptom domain of EORTC QLC-C30. Conversely, spiritual wellbeing score was positively correlated with global health status and EORTC QLQ-C30 role functioning domain score. Multivariate

regression analysis identified educational level, health insurance category, symptom domain, functional role domain, and global health status as significant independent factors influencing spiritual wellbeing among PDAC patients undergoing chemotherapy (R^2 = 0.502, P < 0.05).

CONCLUSION
Individualized spiritual support is needed for PDAC patients. Health, daily functioning, emotional, cognitive, and social function status should be taken into account to promote implementation of spirituality in nursing practice.

Key Words: Pancreatic ductal adenocarcinoma; Chemotherapy; Spiritual wellbeing; Quality of life; Anxiety

Core Tip: Identifying the core factors influencing spiritual wellbeing of pancreatic ductal adenocarcinoma (PDAC) patients undergoing chemotherapy and formulating individualized spiritual care regimens can improve quality of life. However, there have only been a few small studies on spiritual wellbeing of PDAC patients undergoing chemotherapy. The core factors influencing spiritual wellbeing in this clinical population are still unclear. In this study, we analyzed factors influencing the spiritual wellbeing of PDAC patients undergoing chemotherapy, the newest study of PDAC patients undergoing chemotherapy in Mainland China.

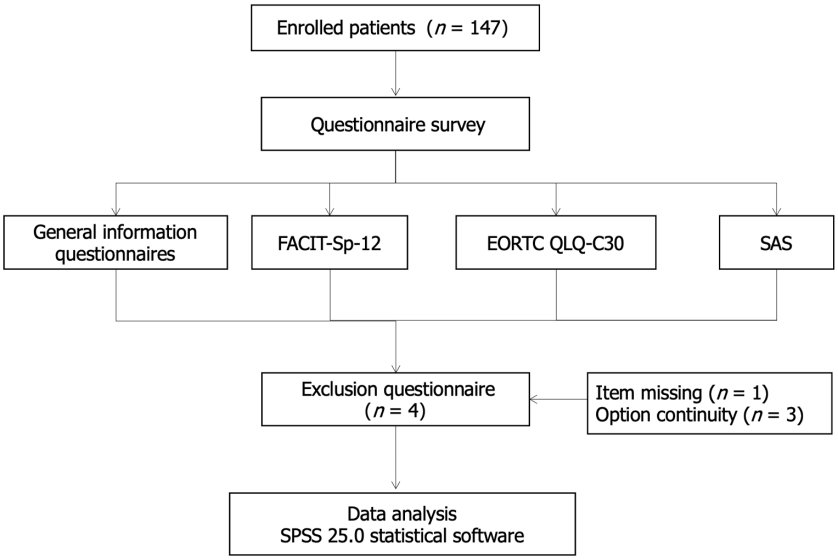
INTRODUCTION

Pancreatic ductal adenocarcinoma (PDAC) is a tumor of the digestive tract with a high degree of malignancy, poor prognosis, and high mortality rate[1]. In recent years, the application of surgery combined with neoadjuvant chemotherapy has prolonged the survival of PDAC patients. However, PDAC patients undergoing chemotherapy experience surgical and chemotherapy-induced adverse events, negative emotions, changes in family and social relationships, and high treatment expenses; all of which can negatively influence health outcomes[2]. As an important part of human health, spiritual wellbeing emphasizes the role of maintaining optimistic and positive attitudes while self-regulating negative emotions when coping with stressful events. Studies have shown that spiritual wellbeing is positively correlated with health and contributes to better prognosis and quality of life[3,4]. Therefore, identifying the core factors influencing spiritual wellbeing of PDAC patients undergoing chemotherapy and formulating individualized spiritual care regimens can improve quality of life among this patient group. However, there have only been a few small studies of the spiritual wellbeing of PDAC patients undergoing chemotherapy. The core factors influencing spiritual wellbeing in this clinical population are still unclear[5,6]. Therefore, this study was designed to identify factors influencing the spiritual wellbeing of PDAC patients undergoing chemotherapy to provide a theoretical basis for formulating individualized spiritual care regimens.



MATERIALS AND METHODS

Sample size calculation

According to the sample size estimation method in *Nursing Research Methods*[7], sample size should be 5–10 times the number of independent variables. Twenty-two independent variables were included in this study, and a nonresponse rate of 10% was considered as the upper limit. According to the formula, n = 22 × (5-10) × (1+10%), the sample size should range from 121 to 242.

Patient characteristics

PDAC patients receiving cyclic adjuvant chemotherapy in our department from January 2022 to December 2022 were recruited, and 147 questionnaires were distributed and collected with a recovery rate of 100%. After four invalid questionnaires were excluded, 143 were finally included in this study with an effective recovery rate of 97.28% (Figure 1). Inclusion criteria were: (1) Diagnosis of PDAC; (2) classified as locally progressive stage disease; (3) age 18–75 years; (4) requiring cyclic chemotherapy; and (5) clearly expressed willingness to participate in the study. Exclusion criteria were: (1) Mental illness or cognitive dysfunction; and (2) insufficient energy or physical strength to complete the questionnaire.

Figure 1 Flowchart of the study design. FACIT-Sp-12: Functional Assessment of Chronic Illness Therapy-Spiritual Well-Being 12 Item Scale; SAS: Zung's Self-rating Anxiety Scale; EORTC QLQ-C30: European Organization for Research and Treatment of Cancer Quality of Life Questionnaire Core 30.

Study tools

General information questionnaire: A self-designed questionnaire was distributed with items on gender, age, educational level, occupation, family income, marital status, religious beliefs, number of children, medical expenses, date of disease diagnosis, and recurrence of the disease.

Functional Assessment of Chronic Illness Therapy-Spiritual Well-Being 12 Item Scale (FACIT-Sp-12): Spiritual well-being was measured by the FACIT-Sp-12 originally formulated by Brady *et al*[8] and translated into Mandarin by Liu *et al* [9]. Each item was scored on a 5-point Likert scale and assessed on three dimensions: faith, meaning, and peace, with higher scores indicating greater spiritual wellbeing. The Cronbach's α coefficient ranged from 0.711 to 0.920 with high validity, indicating that the FACIT-Sp-12 can be widely applied among cancer patients for the assessment of spiritual wellbeing.

European Organization for Research and Treatment of Cancer Quality of Life Questionnaire Core 30 (EORTC QLQ-C30): The EORTC QLQ-C30 was a standard questionnaire designed for cancer patients by EORTC. It consisted of 30 items assessing eight quality of life dimensions. Items 29 and 30 were divided into seven levels, and scores ranged from 1 to 7 points, while all other items were scored on a 4-point Likert scale. For the functional and global health status domains, higher scores were indicative of better quality of life. For the symptom domain, a higher score indicated worse quality of life. The reliability of EORTC QLQ-C30 was 0.988 and validity was 0.989[10].

Zung's Self-rating Anxiety Scale (SAS): The SAS was designed by William W.K. Zung to reflect the degree of anxiety among patients. All items were graded on a 4-point Likert scale. A score < 50 was considered indicative of little or no anxiety, 50–60 of mild anxiety, 61–70 of moderate anxiety, and > 70 of severe anxiety[11].

Data collection methods

Prior to the survey, all investigators received standardized training to guarantee the objectivity and accuracy of data collection. All scales were completed by scanning QR codes. During the survey, investigators explained the response method and precautions for each scale by unified instructions. Each section of the questionnaire was completed by the patients independently or with the assistance of investigators. Investigators addressed any questions from patients to ensure the efficiency of questionnaire completion. After the survey, investigators examined whether any item was missing and instructed the patients to supply the missing response. Each scale required < 10 min to complete.

Statistical analysis

All data were analyzed using SPSS version 25.0 software. Quantitative data were expressed as frequency and percentage, and qualitative data as mean ± SD if it was under normal distribution. Total questionnaire scores and domain scores were compared among subgroups using the independent samples *t*-test or one-way analysis of variance (ANOVA) as indicated. Associations among total scores and domain were first assessed using Pearson's correlation analysis. Potential factors influencing spiritual wellbeing were then included in a multiple logistic regression model. A $P < 0.05$ (two-tailed) was considered statistically significant for all tests.

RESULTS

Questionnaire results

The total score of FACIT-Sp-12 of PDAC patients treated with chemotherapy was (32.16 ± 10.06), (10.85 ± 3.76) for the dimension of faith, (10.55 ± 3.42) for meaning and (10.76 ± 4.00) for peace, respectively. The SAS score was calculated as (45.59 ± 6.44). The EORTC QLQ-C30 score was (83.74 ± 2.85), (74.01 ± 21.41) for global health status and (8.88 ± 1.79) for the symptom domain. The results of all questionnaires are summarized in Table 1.

Differences in spiritual wellbeing among demographic and clinical subgroups

Significant differences were observed in the spiritual wellbeing regarding sex, education level, household monthly income, type of health insurance and recurrence of PDAC patients treated with chemotherapy. Spiritual wellbeing scores were higher in males than females, in higher-educated compared to less-educated patients, and in patients at first diagnosis (without recurrence) (all $P < 0.05$), but showed no significant difference among age group, duration of illness, or occupational group (Table 2). Further, scores also differed by household monthly income and type of health insurance (both $P < 0.05$). The spiritual wellbeing score of patients with a household monthly income of 3000–5000 Yuan was the highest up to (35.00 ± 8.64), and the lowest score was (29.37 ± 10.65) in their counterparts with income of 1000–3000 Yuan. Patients with workers' medical insurance had the highest spiritual wellbeing score of 35.68 ± 7.80, and those with other types of health insurance obtained the lowest score of 19.42 ± 11.87.

Associations of spiritual wellbeing with anxiety and quality of life

The correlation coefficients between spiritual wellbeing and anxiety, and symptom domain of EORTC QLQ-C30 were calculated as -0.357 and -0.322, and those between spiritual wellbeing and global health status, and function domain were 0.464 and 0.421 ($P < 0.05$). These findings suggested that spiritual wellbeing was negatively correlated with anxiety level as measured by the SAS score and with the quality of life symptom domain according to EORTC QLQ-C30. The high spiritual wellbeing was predictive of lower anxiety and better symptom-related quality of life. Conversely, heightened anxiety and severity of symptoms were associated with lower spiritual wellbeing. In addition, spiritual wellbeing was positively correlated with global health status and the functional role domain of quality of life (all $P < 0.05$) (Table 3).

Independent factors predictive of spiritual wellbeing

In multivariate regression analysis, FACIT-Sp-12 total score was considered the dependent variable and all variables significantly associated with the wellbeing score in ANOVA (anxiety, functional role domain of EORTC QLQ-C30, global health status, and symptom domain) were included as independent variables (default values are shown in Table 4). Educational level, type of health insurance, functional role domain of the EORTC QLQ-C30, symptom domain of the EORTC QLQ-30, and global health status of the EORTC QLQ-30 were identified as independent factors influencing spiritual wellbeing (overall $R^2 = 0.502$, $P < 0.05$) (Table 5).

DISCUSSION

Spiritual wellbeing of PDAC patients treated with chemotherapy needs to be enhanced. The total spiritual wellbeing score for patients with PDAC undergoing chemotherapy was in the mid-range (32.16 ± 10.06), consistent with other patient populations described by Xue *et al*[12] and Liu *et al*[13], and indicating the need for improvement through spiritual care regimens. The diagnosis of PDAC places heavy emotional and financial burdens on patients[14]. Although surgery combined with neoadjuvant chemotherapy can prolong survival[15], the overall survival rate is still low[16], which increases uncertainty about life and reduces patient confidence in treatment outcome. Cyclic chemotherapy is a substantial imposition, disrupting lifestyle and social participation, with side effects including physical pain and other discomforts that further increase the psychological burden[13], which may eventually lower spiritual wellbeing. Therefore, medical staff should actively provide spiritual support, identify patients' negative emotions, strengthen health education, emphasize the importance of companionship, and create a positive atmosphere. Potential strategies included sharing treatment success stories, encouraging patients to reflect on the meaning of life, and alleviating negative emotion to help the patient achieve harmony of body, heart, and spirit.

Individual differences in spiritual wellbeing were related to demographics and clinical status. Although PDAC incidence was lower in females than males, the former reported significantly lower spiritual wellbeing, possibly due to a greater propensity for negative emotions in response to stressful events[17,18]. However, at present, the causes of gender difference on spiritual wellbeing are still unclear and warrant further investigation to formulate gender-specific spiritual care regimens for PDAC patients undergoing chemotherapy. Patients with higher educational level reported greater spiritual wellbeing. Many of these patients also reported a heavy economic burden (76%), which may explain why spiritual wellbeing was higher among PDAC patients in households with a monthly income of 3000–5000 Yuan compared to those with income of 1000–3000 Yuan. However, several studies[19-21] have found that household income was not an influencing factor on the spiritual wellbeing of cancer patients. Patients with higher household monthly incomes and urban medical insurance experience less pressure from medical expenses and were able to afford better chemotherapy; therefore, this group of patients could maintain a better quality of life. Nonetheless, the subgroup of patients with monthly income > 5000 Yuan did not have significant additional benefits, possibly due to the small sample size. Recurrence of PDAC was also an influencing factor for spiritual wellbeing as recurrence can intensify uncertainty and

reduce individual capacity to resolve difficulties, thereby lowering spiritual wellbeing. Medical staff should act to address issues such as economic pressure, negative emotions, and poor knowledge of treatment benefits and challenges, especially among female patients, to improve spiritual wellbeing.

In this study, the mean SAS score was in the very low range, albeit higher than reported previously[5] and was negatively correlated with spiritual wellbeing. Symptoms such as dyspnea (83.91%), irritation (78.32%), fatigue (51.05%), poor sleep (48.25%), and gastrointestinal reactions (46.15%) can induce anxiety. Long-term anxiety among these patients may evoke hypersensitivity to negative events, causing loss of faith in the treatment process, reducing optimism, and even leading to suicide[22,23]. Therefore, medical staff should closely monitor and attempt to mitigate anxiety by regulating respiratory and gastrointestinal functions, improving sleep and psychological state, encouraging patients to express their true emotions, mentally preparing patients to face negative events with a peaceful attitude, and strengthening their optimism.

High quality of life related to functional role and global health status can enhance spiritual wellbeing. In contrast, the functional role domain score and global health status score were predictive of greater spiritual wellbeing. More than 60% of these patient were unable to perform persistent physical activities due to advanced stage disease[24], which can interfere with family life and social activities, thereby provoking negative emotions. The difficulties in long cycles of treatment and the unpredictable health outcome may cause substantial anxiety, leading to negative emotions, reluctance to communicate with others, and ultimately loss of faith and meaning in life. Patients with high social support were more inclined to welcome alternative opinions and enjoy the companionship of others to relieve stress, find peace of mind, and

better adapt to life challenges. Therefore, medical staff should provide comprehensive and individualized spiritual care aiming to assist and encourage patients to positively accept and face negative events through disease cognition, psychological counseling, and life review.

The symptom domain of quality of life negatively affects spiritual wellbeing, suggesting that severe symptoms and concomitant poor quality of life can degrade spiritual wellbeing. This was consistent with the findings of Du *et al*[25], who also found that most PDAC patients treated with chemotherapy developed symptoms such as fatigue (68%) and insomnia (52%), which may have persisted during the course of treatment[26]. Patients with chronic fatigue were prone to express negative emotions, while discomfort from cyclic chemotherapy and chronic disease pain aggravated insomnia and lowered life expectations[27,28]. Consequently, medical staff should closely monitor adverse symptoms such as

fatigue and insomnia to alleviate discomfort and improve life expectations, possibly *via* family guidance and mindfulness meditation.

This study had several limitations. Most patients were from southwestern China (Chongqing) and so this may not be a nationally representative sample. Future studies will expand the sample size and evaluate the effects of specific religious beliefs on the spiritual wellbeing of PDAC patients receiving chemotherapy.

CONCLUSION

Education level, health insurance category, symptom domain, functional role domain and global health status were the main factors influencing spiritual wellbeing among PDAC patients undergoing chemotherapy. Individualized spiritual care regimens can be formulated through life care, behavioral therapy, mindfulness meditation, cognitive interview, and life review among other strategies.

ARTICLE HIGHLIGHTS

Research background

Identifying the core factors influencing spiritual wellbeing of pancreatic ductal adenocarcinoma (PDAC) patients undergoing chemotherapy and formulating individualized spiritual care regimens can improve quality of life among this patient group. However, there have only been a few small studies of the spiritual wellbeing of PDAC patients undergoing chemotherapy. The core factors influencing spiritual wellbeing in this clinical population are still unclear. Therefore, this study was designed to identify factors influencing the spiritual wellbeing of PDAC patients undergoing chemotherapy.

Research motivation

This study was designed to investigated the spiritual wellbeing status and identify factors influencing the spiritual wellbeing of PDAC patients undergoing chemotherapy. To draw attention to the spiritual health of patients with pancreatic cancer undergoing chemotherapy and formulate individualized spiritual care regimens.

Research objectives

This study was designed to investigated the spiritual wellbeing status and identify factors influencing the spiritual wellbeing of PDAC patients undergoing chemotherapy. This study found that effective measures to mitigate anxiety and increase quality-of-life-related role functioning, emotional guidance, cognition of disease, social function, and life education may enhance spiritual wellbeing. Individualized spiritual care regimens can be formulated through life care, behavioral therapy, mindfulness meditation, cognitive interview, and life review among other strategies.

Research methods

The research method of this study was a questionnaire survey. Prior to the questionnaire survey, all investigators received standardized training to guarantee the objectivity and accuracy of data collection. The questionnaire included a

general information questionnaire, Functional Assessment of Chronic Illness Therapy-Spiritual Well-Being 12 Item Scale, European Organization for Research and Treatment of Cancer Quality of Life Questionnaire Core 30 and Zung's Self-rating Anxiety Scale. All data were analyzed using SPSS version 25.0. $P < 0.05$ (two-tailed) was considered statistically significant for all tests.

Research results

This study investigated the spiritual wellbeing of Chinese patients with PDAC undergoing chemotherapy and analyzed its influencing factors for the first time. This study found that individualized spiritual care regimens can be formulated through life care, behavioral therapy, mindfulness meditation, cognitive interview, and life review among other strategies. This study had limitations. Most patients were from southwestern China (Chongqing), so this may not be a nationally representative sample. Future studies will expand the sample size and evaluate the effects of specific religious beliefs on the spiritual wellbeing of PDAC patients receiving chemotherapy.

Research conclusions

Spiritual wellbeing of PDAC patients treated with chemotherapy was in the mid-range, and individual differences in spiritual wellbeing related to demographics and clinical status. Anxiety and symptom severity markedly disrupted the spiritual wellbeing of PDAC patients undergoing chemotherapy, whereas a sustained functional role and good global health status related to quality of life promoted spiritual wellbeing. This study provides a theoretical basis for formulating individualized spiritual care regimens.

Research perspectives

Future studies will expand the sample size and evaluate the effects of specific religious beliefs on the spiritual wellbeing of PDAC patients receiving chemotherapy.

Abstract

BACKGROUND

There is little data on physical activity (PA), organized PA (OPA), and sedentary behaviors in autism spectrum disorders (ASD) and other neurodevelopmental disorders in developing countries.

AIM

To examine OPA, non-OPA, and sedentary behaviors and their associated factors in children and adolescents with ASD, cerebral palsy (CP), and intellectual disability (ID).

METHODS

A total of 1020 children and adolescents with ASD, CP, and ID were assessed regarding the child and family information as well as the Children's Leisure Activities Study Survey.

RESULTS

The results showed that the OPA level was significantly lower than non-OPA in all groups. Furthermore, the OPA level was significantly lower in the CP group compared to ASD and ID groups ($P < 0.001$). Also, moderate ($P < 0.001$), vigorous ($P < 0.05$), and total ($P < 0.001$) physical activity levels were significantly different between all three groups, with the values being higher in the ASD group

compared to the other two. The mean of the total sedentary behavior duration in the ASD group (1819.4 min/week, SD: 1680) was significantly lower than in the CP group (2687 min/week, SD: 2673) (P = 0.007) but not ID group (2176 min/week, SD: 2168.9) (P = 0.525).

CONCLUSION

Our findings remark on the participation rate of PA, OPA, and sedentary behaviors of children and adolescents with ASD, CP, and ID in a developing country. In contrast, the need for developing standards of PA/OPA participation in neurodevelopmental disorders is discussed.

Key Words: Neurodevelopmental disorders; Physical disability; Mental disability; Active lifestyle

INTRODUCTION

Sedentary behavior has been defined as any waking behavior with an energy expenditure ≤ 1.5 metabolic equivalents while in a sitting, reclining, or lying posture and is associated with chronic underlying diseases such as diabetes and cardiovascular diseases[1-3]. On the other hand, non-organized physical activity (PA) is defined as any bodily movement that requires energy expenditure higher than sedentary behavior level, and organized PA (OPA) is defined as involving in regular and structured health and leisure activities with peers, coaches, and group leaders such as tennis, football, etc [4].

Plenty of literature points to the importance of PA in children; however, levels of PA are insufficient for different groups of children, particularly those with disabilities[5]. The optimal level of PA can increase health status and decrease the incidence of chronic disorders such as cancer, diabetes, cardiovascular disorders, and mood disorders[6]. Mental, intellectual, and motor disabilities negatively impact the opportunities to participate in an optimal level of PA to gain health benefits and limit sedentary behaviors consequences[7]. In other words, children with particular disabilities, such as neurodevelopmental disorders, may be limited regarding motor disabilities and social skills[8]. For example, children with autism spectrum disorders (ASD) participate in less PA[9] and more sedentary behaviors than their peers leading to greater body mass index (BMI) in comparison to typically developing (TD) children[10-12]. In addition, according to estimates of developed countries, children with neurodevelopmental disorders such as ASD, cerebral palsy (CP), and intellectual disability (ID) also participated less in a regular and OPA than those children without a neurodevelopment disability[13-17]. Studies have also shown children with neurodevelopmental disabilities encounter additional personal and environmental barriers that hinder their participation in physical activities compared to TD children[10,18].

Although the disability characteristics should be considered[8], participation in PA, benefiting from its psychosocial and motor advantages, is of paramount importance for children with neurodevelopmental disorders[8,19]. PA could also enhance cognitive and meta-cognitive function and improve educational performance[20-22]. Moreover, OPA provides additional benefits, including promoting inclusion, facilitating social connection, improving social and emotional well-being, and reducing functional decline[23]. For example, Sun *et al*[24], in a clinical trial, assessed the effects of an adapted PA consisting of moderate-intensity aerobic and resistance exercises on health-related physical fitness in adolescents with ID. The authors declared significant changes were observed in cardiorespiratory fitness, running/walking tests, and flexibility in the intervention group compared to the control group. In addition, in a recent systematic review and meta-analysis, Howells *et al*[23] represented that group-based OPA participation improves overall social functioning in children with ASD. Moreover, Mak *et al*[25] reported the positive effect of a regular 8-wk mindfulness yoga program on attention outcomes of children with CP. However, due to motor skill limitations, such a positive impact was not observed in their physical skills outcomes. Given the above, OPA is a constructive and helpful context in which children and adolescents with neurodevelopmental disorders could benefit from opportunities, including social engagement, promoting social skills, enhancing mental health, and improving quality of life[26,27].

Despite valuable research in terms of the effect of PA and OPA on different aspects of neurodevelopmental disorders, there are few studies assessing the rate of OPA participation in children with ASD in comparison to other neurodevelop-

mental groups and not TD children. Arim *et al*[8] assessed the PA/OPA participation rate in 4-9 years old Canadian children with neurodevelopmental disorders (including epilepsy, CP, ID, and learning disability) compared to TD children. Their results represented that although the frequency of OPA participation in this population varied depending on the child's health condition, there was no significant difference in general PA participation among different neurodevelopmental groups.

Thus, the current study aimed to assess and compare sedentary behavior, OPA, and non-OPA levels, as primary outcomes in children and adolescents with ASD, ID, and CP. We also aimed to determine the personal and familial factors associated with PA and sedentary behavior among these children. This is one of the few studies on PA levels among children with neurodevelopmental disorders in the context of a developing country, utilizing a large sample size. The findings of this study may help to identify the groups which benefit the most from the interventions to improve PA levels and can be a basis for future studies in the context of developing countries.

MATERIALS AND METHODS

Study design and setting

The data for the current cross-sectional study were drawn from a longitudinal survey of "Quality of life and psycho-physical function in children and adolescents with developmental disabilities; evaluating risk factors and developmental trend", which was conducted from 2011 to 2021 with a sample size of 1850 participants (1040 boys and 810 girls) aged 6-18 years from special schools in Tehran, Iran. Participants were included in the study by stratified random sampling. The population was stratified into different strata by disorders; each stratum was divided into different clusters (schools), respectively. Then five schools were included for each stratum (disorder). Afterward, children's parents/caregivers responded to the Children's Leisure Activities Study Survey (CLASS questionnaire) to examine the children's non-OPA (*i.e.*, general routine PA), OPA, and sedentary behavior activities. The study was approved by the ethics committee of Tehran University of medical sciences (ethics code: IR.TUMS.NI.REC.1401.031), and written consent was obtained from participants' parents/caregivers before entering the study.

Participants

Children and adolescents with neurodevelopmental disorders were included in the current study. The diagnosis of ASD was confirmed by DSM-IV, and the autism diagnostic inventory-revised by a professional child psychiatrist. The participants were excluded if they had two or three of the conditions (*i.e.*, ASD, CP, or ID) together and being less than six years of age.

Measurements

Basic and sociodemographic data: Parents/caregivers of the participants were asked to fill the items of a questionnaire containing child and family basic and sociodemographic information, including the child's age, gender, childcare status (two parents, single parent, and other), household status (owner, tenant, and other), parents' age, and parents' educational level. Physical therapists also conducted a physical examination to measure participants' height, weight, waist circumference, and hip circumference. Moreover, the existence of any musculoskeletal disorder preventing physical movements was assessed based on physical examination as well as the participants' medical history by a physical therapist.

Non-OPA/OPA and sedentary behavior data: We used the Persian version of the CLASS to assess non-OPA/OPA and sedentary behavior. This survey measures the type, frequency, and duration of different types of PA, including non-OPA and OPA as well as sedentary behavior among children. The CLASS checklist contains items for both non-OPA (such as playing indoors with toys, walking the dog, *etc.*) and OPA (such as football, basketball, aerobics, *etc.*), as well as items for sedentary behaviors (such as sitting, talking, listening to music, and reading). Previous studies have demonstrated test-retest reliability (ICC > 0.58 across different domains) and criterion validity CLASS[28].

Statistical methods

First, descriptive statistics for basic, demographic, and sociodemographic variables, PA/OPA, and sedentary behavior data were calculated for each group. We used the chi-square test to compare the categorical variables between groups. We also used the Kolmogorov-Smirnov test to test if the continuous variables are distributed normally. As none of the continuous variables had normal distribution, we used non-parametric tests, such as the Kruskal-Wallis test, to compare them between groups. Moreover, the Mann-Whitney *U* test was also conducted to compare two individual groups whenever the difference between the three groups was significant. Finally, the Wilcoxon test was used to compare OPA and non-OPA levels in all groups. All analyses were conducted using SPSS version 26, while a *P* value of less than 0.05 was considered significant.

RESULTS

Descriptive statistics

In the current study, 1020 participants (ASD: 248, CP: 306, ID: 466) were included in the final analysis (Table 1 shows the

Table 1 Basic and demographic data of participants in autism spectrum disorders, intellectual disability, and cerebral palsy groups, *n* (%)

ASD: Autism spectrum disorders; CP: Cerebral palsy; HC: Hip circumference; ID: Intellectual disability; SD: Standard deviation; WC: Waist circumference; WHR: Waist to hip ratio.

descriptive statistics). In the ASD group, 3.6% of participants were female, which is significantly lower than the ID and CP groups (53% and 52.3%, respectively; $P < 0.001$). In pairwise comparison, there were significant differences between groups regarding their ages ($P < 0.05$), with the ASD group being the youngest (mean = 11.15, SD = 2.66) and the ID group being the oldest (mean = 12.69, SD = 3.15). Similarly, height was significantly different between all three groups ($P < 0.05$). Also, children with CP had lower weights ($P < 0.01$), smaller waist circumferences ($P < 0.01$), and smaller hip circumferences ($P \leq 0.001$) than the other groups. In addition, the prevalence of musculoskeletal disorders was significantly higher in the CP group compared to both ASD and ID groups ($P < 0.001$). The parents in the ASD group were more educated than both CP and ID groups ($P < 0.001$). Parents of children with ID were significantly older than the parents of the other two groups ($P \leq 0.001$).

Non-OPA/OPA and sedentary behavior results

Table 2 presents and compares the physical activity levels of children with ASD, ID, and CP. Our results showed that the level of OPA is significantly lower in comparison to non-OPA in ASD ($P < 0.001$), CP ($P < 0.001$), and ID ($P < 0.001$) groups (Table 2). Furthermore, the OPA level was significantly lower in the CP group compared to ASD and ID groups ($P < 0.001$). Also, non-OPA levels were significantly different between the three groups ($P < 0.001$). Also, in pairwise comparisons, moderate ($P < 0.001$), vigorous ($P < 0.05$), and total ($P < 0.001$) physical activity levels were significantly different between all three groups, with the values being higher in the ASD group compared to the other two.

Travel by car/bus	154.7 (357.6)	105.7 (296.1)	160.3 (372.4)	**0.032**
Total sedentary behavior	1819.4 (1680.0)	2176.5 (2168.9)	2687.0 (2673.5)	0.008

ASD: Autism spectrum disorders; CP: Cerebral palsy; ID: Intellectual disability; SD: Standard deviation.

Table 3 represents the sedentary behaviors of participants. The mean of the total sedentary behavior duration in the ASD group (1819.4 mins/week, SD: 1680) was significantly lower than in the CP group (2687 mins/week, SD: 2673; P = 0.007) but not ID group (2176 mins/week, SD: 2168.9; P = 0.525). There was also no significant difference between children with CP and ID concerning the time spent on sedentary behavior (P = 0.106).

Sociodemographic contributing factors

Tables 4-6 show the details of contributing factors for moderate to vigorous physical activities (MVPA) and sedentary behaviors in the ASD, ID, and CP groups, respectively. OPA was significantly lower in females (mean = 5.6, SD = 11.1) than males (mean = 61.6, SD = 136) in children with ASD (P = 0.045). Also, in the ASD group, non-OPA (P = 0.032) and sedentary behavior (P = 0.02) levels were significantly different in children of mothers with various educational levels (Table 4). Males in the ID group had higher MVPA (P < 0.001), OPA (P < 0.001), and non-OPA (P = 0.001) levels than the females. Household status (P = 0.018) and age (P = 0.004) were associated with OPA, while the presence of musculoskeletal disorders (P = 0.041) and household status (P = 0.008) were associated with sedentary behavior in the ID group (Table 5). Additionally, in this group, childcare status was associated with MVPA (P = 0.021) and non-OPA (P = 0.023). Gender was associated with MVPA (P = 0.091), OPA (P = 0.045), and sedentary behavior (P = 0.002) in children with CP. Also, household status (P = 0.018) and father's education (P = 0.029) were associated with sedentary behavior and OPA, respectively (Table 6).

DISCUSSION

Regular OPA and general PA help enhance psychosocial and health outcomes[29]. On the other hand, sedentary behaviors can indirectly increase the risk of various health conditions. It is worth noting that children and adolescents with disabilities have a lower participation rate in PA, putting them at higher risk for complications[30], which can cause significant challenges for the child, their families, and society[30]. Thus, we aimed to examine the participation rate of OPA, PA, and sedentary behaviors among children with neurodevelopmental disorders in a new sample from a developing country.

Interestingly, our findings showed that the amount of OPA is lower than non-OPA in all ASD, CP, and ID groups. Despite the known positive effects of group-based OPA in overall social functioning in children[23], it seems that the parents/caregivers of children with neurodevelopmental disorders still do not take advantage of regular OPA as a non-medical treatment for their children. Papadopoulos *et al*[31] examined parent-reported barriers to OPA, reported a lack of children's happiness and motivation during OPA as the main existing barriers to OPA among individuals with neurodevelopmental disorders. However, it seems that other hypothetical major barriers, such as the lack of appropriately adapted OPA programs and parents' unawareness of OPA's benefits, are also playing a role in developing

OPA: Organized physical activity; SB: Sedentary behaviors MVPA: Moderate to vigorous physical activities

societies.

In addition, our study showed that among our participants, children with ASD had the highest level of OPA, non-OPA, and total PA, followed by children with ID and then CP. Besides, our study showed that although the pattern and specific type of sedentary behaviors were different among the three groups, children with ASD were similar to ID and better than the CP group. Moreover, regarding the intensity of PA, children with ASD demonstrated the highest levels of moderate and vigorous PA compared to CP and ID groups. Although previous investigations reported a lesser amount of MVPA in children with ASD compared to their TD peers[29,32], our study showed that among two other neurodevelopmental disorders, such as CP and ID, children with ASD would report better results. According to the world health organization (WHO), it is recommended 60 min per day (300 min per week) of MVPA to gain health benefits of PA for children[33]; thus, our study showed that all three groups of participants, on average, participated in less MVPA than what is recommended for children. However, due to the lack of a developed standard of PA or OPA participation for children and adolescents with neurodevelopmental disorders, such interpretation should be made with caution.

To our knowledge, this is one of the first reports representing the amount of OPA/non-OPA as well as sedentary behaviors in children and adolescents with ASD in comparison to other neurodevelopmental disorders such as ID and CP. This finding highlights the importance of considering the health conditions (*e.g.*, motor *vs* non-motor limitation) of children with neurodevelopmental disorders in OPA participating. For example, children with CP might have more motor limitations than children with ASD and ID. Designing adapted OPA specific for each neurodevelopment disorder is of paramount importance for increasing the rate of OPA participation in these populations. As an important limitation, previous studies only examined the general PA participation in ASD and similar disorders. For example, examining ASD with TD peers, data showed an association between lower levels of PA participation and an increase in medical complications such as obesity and chronic illness[11,34]. Recent studies have shown that the issue has worsened because of the COVID-19 pandemic, quarantine, and social distancing[35,36].

Although, according to evidence, the level of PA in children and adolescents with ASD is lower than TD ones, our study showed that, at least in part, the PA status of children and adolescents with ASD is better than other children with neurodevelopmental disorders such as children with CP and ID. It highlights the urgent need to design and develop strategies to enhance the PA and OPA levels for all children and adolescents with neurodevelopmental disorders, which might be challenging due to the lack of studies and the inefficacy of current interventions[37]. This issue warrants much more attention in developing countries which need both increase the general awareness of people and design novel strategies for enhancing adapted PA behavior in individuals with neurodevelopmental disorders. According to theories and frameworks[31], the opportunities for adapted PA/OPA must be intrinsically rewarding to encourage acquiring life skills and reassure peer relationships, parental involvement, and the sense of belonging to a bigger community[38].

Children with CP had the least PA time compared to ASD and ID, possibly related to the higher number of physical and movement incapacities. On the other side, we recruited children and adolescents with ASD from special schools; usually, children who attend these schools are high functioning and consequently do not have the limitations of children with low-functioning ASDs (comorbid with ID and other disabilities). Consequently, they may also have the potential to do more deliberate and regular activities, improving their PA level than more physically and mentally disabling disorders such as CP and ID. Given the above, it seems necessary to develop standards for PA/OPA participation rate in children and adolescents with neurodevelopmental disorders generally and specifically for each group based on the amount of physical and cognitive limitations.

In addition, regarding the contributing factors, our results suggest that gender, parent's education, and childcare status might be related to PA and sedentary behaviors. Factors contributing to enhancing the amount of PA may have an adverse effect on sedentary behaviors and vice versa[39,40]. In the general population, individuals with older age, female gender, comorbidities, the need for movement equipment, or higher BMI are more prone to engage in less PA and more sedentary behaviors[39]. In previous investigations, factors such as symptom severity, gender, having other comorbidities, using mobility equipment, and household status have been reported to contribute to PA participation rate in children with ID and CP[13,14].

The current study is unique in its sample and measures; however, it is not without limitations. The recall bias and the selection of the participants from special schools were from study limitations. In addition, we had to use cross-sectional data for physical activity behavior, and we could not scrutinize the potential effects of data changes over time. Nevertheless, the relatively sizable number of participants could be accounted as one of the important strengths of the current study. This might authenticate and increase the validity of the result in the study despite its limitation.

CONCLUSION

The current study showed that PA behavior in ASD, ID, or CP groups was lower than expected, highlighting the need to support PA/OPA opportunities by designing targeted and adapted programs to decrease unhealthy sedentary behaviors in these groups.

ARTICLE HIGHLIGHTS

Research background

There is little data on physical activity (PA), organized PA (OPA), and sedentary behaviors in children with neurodevel-

opmental disorders in developing countries.

Research motivation

In this large-scale study, we evaluated PA levels among children with neurodevelopmental disorders in the context of a developing country to help identify the groups which benefit the most from the interventions to improve PA levels, which can be a basis for future studies.

Research objectives

To examine OPA, non-OPA, and sedentary behaviors and their associated factors in children and adolescents with autism spectrum disorders (ASD), cerebral palsy (CP), and intellectual disability (ID).

Research methods

A total of 1020 children and adolescents with ASD, CP, and ID living in Tehran between 2011 and 2021 were assessed regarding the child and family information as well as the Children's Leisure Activities Study Survey.

Research results

The results showed that the OPA level was significantly lower than non-OPA in all groups. Moderate to vigorous PA levels were higher among children with ASD compared to children with CP and ID.

Research conclusions

The PA levels are lower than the recommended levels in children with neurodevelopmental disabilities living in a developing country, and there is a need for interventions to improve PA levels, especially OPA, in this group.

Research perspectives

Future studies should focus on evaluating PA levels in children with neurodevelopmental disabilities in other developing countries, and aim to design intervention to improve OPA and total PA in this group.

Abstract

BACKGROUND

A clean operating room is an important part of surgical and critical treatment in hospitals. The workload is substantial, the pace is rapid, and the working environment is intense; therefore, nurses who work in clean operating rooms are constantly challenged, which can lead to anxiety, depression, and other mental health issues. Life satisfaction and resilience are important factors that ensure mental health. Therefore, exploring the mediating role of life satisfaction in the influence of resilience on depression among nurses in clean operating rooms can help improve nursing services and teamwork.

AIM

To explore the mediating effect of satisfaction on the influence of resilience on depression among nurses in a clean operating department.

METHODS

From April to November 2022, 196 nurses from the Department of Clean Operating at Harbin Medical University Cancer Hospital participated in this study. Participants were selected using convenience sampling. Participants' gender, age, marital status, position, length of service, personal monthly income, daily working hours, employment status, and professional title were collected, and the Connor-Davidson resilience scale, satisfaction with life scale, and self-rating depression scale were used to evaluate resilience, life satisfaction, and depression. The researchers conducted professional training in advance, introduced the research methods to the participants before the investigation, and explained the study's significance and purpose. Surveys were distributed and collected on-site. Each questionnaire took 30 min to complete.

RESULTS

The average scores for life satisfaction, resilience, and depression were 3.13 (±

0.28), 4.09 (± 0.78), and 56.21 (± 8.70), respectively. The correlation between resilience and depression was negative (r = -0.829, P < 0.01). Life satisfaction was positively related to resilience (r = 0.855, P < 0.01) and negatively related to depression (r = -0.778, P < 0.01). The relationship between resilience and depression was partially mediated by life satisfaction. The value of the mediating effect was -6.853 (26.68% of the total effect).

CONCLUSION

Life satisfaction partially mediates the link between resilience and depression among nurses in clean operating departments.

Key Words: Psychological resilience; Depression; Life satisfaction; Clean operation department; Nurses; Mediating effect

Core Tip: The professional and psychological qualities of clean operating department nurses affect their operation success. Clinical practice emphasizes the importance of the mental health of nurses in operating rooms. This study found that, for nurses working in clean operating departments, resilience was positively correlated with life satisfaction and negatively correlated with depression, indicating that resilience can increase life satisfaction and decrease depression. Life satisfaction mediated the relationship between resilience and depression. This suggests that nurses in clean operating departments should improve their life satisfaction and resilience to adversity to improve their mental health.

INTRODUCTION

The psychological health of nursing staff has received increasing attention in recent years[1,2]. Relevant studies have shown that heavy, harsh, and demanding working conditions; medical requirements of patients and their families; public opinion; difficulty balancing work and family; salary; and other factors affect the psychological well-being of nursing personnel[3,4]. A clean operating department is necessary for hospitals to provide surgical procedures and treat critically ill patients, and the workload is closely related to the number and difficulty of operations[5,6]. Especially in tertiary hospitals, all types of difficult and complicated diseases are more complex, and new surgical techniques are rapidly being developed. In addition, in clean operating departments, the workload is large, rhythm is fast, and intensity is high□ constantly challenges nurses in clean operating departments, and can easily result in negative emotional states, such as depression and anxiety, and ultimately, psychological problems.

Life satisfaction is the overall cognitive appraisal of a person's level of satisfaction in their life[7]. Life satisfaction is a crucial factor in achieving good mental health and directly associated with various psychological, behavioral, interpersonal, and social factors such as reduced stress, externalized behavior, and internalized problems[8,9]. Therefore, life satisfaction is one of the most important indicators used to gauge an individual's level of happiness and overall quality of life. Further, resilience plays a significant role in positive psychology[10]. Resilience is a psychological quality that allows individuals to cope well with adversity and a protective factor for individual mental health[11,12]. Previous research has reported that life satisfaction is positively associated with individual psychological health and negatively correlated with depression[13,14]. The results of studies conducted with different groups have shown that individual life satisfaction is positively correlated with resilience[15-17].

However, few studies have examined the correlations among resilience, depression, and life satisfaction in nurses in clean operating departments. This study aims to explore the mediating role of life satisfaction in the effects of resilience on depression and to provide a scientific basis for improving resilience, increasing life satisfaction, and reducing the occurrence of depression among nursing staff in clean operating departments.

MATERIALS AND METHODS

Participants

From April to November 2022, 196 nurses from the Department of Clean Operating at Harbin Medical University Cancer Hospital took part in this study. Participants were selected using convenience sampling. The inclusion criteria were as follows: (1) Currently employed on the nursing staff with at least one year of job experience; (2) no personal or family history of mental illness; and (3) no psychotropic drugs use in the last year. The exclusion criteria were as follows: (1) Non-frontline nurses; (2) nurses who took long-term personal, sick, or maternity leave during the study period; (3) nurses

from other departments; (4) nurses participating in other clinical studies; and (5) nurses who were working on an internship or in training.

Basic information survey

The general demographic variables questionnaire designed by this research team was used to collect basic information on the participants, including gender, age, marital status, position, length of service, personal monthly income, daily working hours, employment, and professional title.

Life satisfaction survey

The satisfaction with life scale (SWLS) by Diener *et al*[18] was used to measure life satisfaction. The SWLS includes five items, each rated on a Likert scale ranging from 1 (strongly disagree) to 7 (strongly agree). In this study, average scores across the five life satisfaction questions ranged from 1 to 7 points. The SWLS has been shown to be trustworthy and is often utilized in quality-of-life research conducted in Chinese populations[19].

Resilience survey

Resilience was evaluated using the Chinese version of the Connor-Davidson resilience scale (CD-RISC)[20], which has 25 items. Responses were rated on a five-point Likert scale ranging from 0 (never) to 4 (always). The overall scale's average value ranged from 0 to 4, and higher scores indicated greater resilience.

Depression survey

The Self-Rating Depression Scale (SDS), compiled by Zung[21], was used to assess depressive symptoms among the participants in the current or previous week. The scale has 20 questions, 10 positive and negative, rated on a four-point Likert scale (no, sometimes, often, and continuously, rated between 1-4 points respectively). The original score was multiplied by 1.25 to take the integer as the standardized score, and a standardized score > 53 was considered to indicate the presence of depressive symptoms.

Quality control

Prior to beginning the study, the researchers conducted a professional training session in which they introduced the research methods to the participants with unified guidance language and explained the study's significance and purpose. Questionnaires were distributed in person and collected immediately after participants completed them. Participants took approximately 30 min to complete the survey. After eliminating invalid questionnaires, the effective questionnaire recovery rate was 90.8% (178 out of 196). Questionnaire review and score entry was completed by two researchers.

Statistical analysis

Data collected in this study were analyzed using IBM SPSS version 26.0. The significance threshold for each two-sided statistical test was set at $P < 0.05$. The mean, standard deviation (SD), number (n), and percentage (%) were used for descriptive statistics of participant demographics and other factors. A t-test and single-factor analysis of variance were used to compare the variations among classification crowds. Pearson correlation analysis was used to examine the relationship between continuous variables. The mediating effects were examined using Hayes' Process Macro Model 4. To determine whether the regression coefficient of the mediating effect of the estimated chain of 5000 samples in the initial data was significant by employing repeated random sampling, it was determined using a bootstrap 95% confidence interval (CI). If the 95%CI did not contain zero, the indirect effect was considered statistically significant.

RESULTS

Participant characteristics

A total of 196 surveys were distributed, and 178 valid surveys were returned, for a response rate of 90.8%. The participants' ages ranged between 22-52 years, with a mean age of 33.69 years (SD = 6.99). Employment duration ranged between 1-30 years, with a mean of 10.80 years (SD = 7.12). Descriptive statistics are shown in Table 1.

Correlations among resilience, life satisfaction, and depression

Resilience was negatively correlated with depression ($r = -0.829$, $P < 0.01$) and positively correlated with life satisfaction ($r = 0.855$, $P < 0.01$). Life satisfaction was negatively correlated with depression ($r = -0.778$, $P < 0.01$) (Table 2).

Analysis of influencing factors of mental resilience, life satisfaction and depression

As shown in Table 3, the results of multi-factor analysis show that gender, age, working time and employment status are the main factors affecting the level of mental resilience; gender, age and working time are the main factors affecting life satisfaction; gender, age, working time and employment status are the main factors affecting depression score.

Mediating effects of life satisfaction between resilience and depression

In testing the mediating effects, resilience was the independent variable, life satisfaction the mediating variable, and depression the dependent variable. Figure 1 depicts the mediation model established in this study. The regression results

Figure 1 The model of the mediating role of life satisfaction in the relationship between resilience and depression.

are presented in Table 4. Resilience had a negative and considerable direct predictive effect on depression (β = -0.608, *P* < 0.001). Further, resilience was found to significantly and positively predict life satisfaction (β = 0.855, *P* < 0.001) and negatively predict depression (β = -0.829, *P* < 0.001). Finally, life satisfaction was found to significantly negatively predict depression (β = -0.258, *P* = 0.001).

As shown in Table 5, the 95%CI of the direct effect of resilience-depression was (-23.636, -14.104), excluding 0, indicating that the direct effect was significant (the value of the effect was -18.832, accounting for 73.32% of the total effect). The 95%CI of the indirect effect of resilience-life satisfaction-depression was (-10.546, -3.120), excluding 0, indicating that life satisfaction mediated the relationship between resiliency and depression (the value of the effect was -

6.853, accounting for 26.68% of the total effect).

DISCUSSION

The professional and psychological qualities of nurses working in clean operating departments are important factors that affect the success of an operation[22,23]. Maintaining the mental health of nurses in operating departments has become a focus of clinical practice. that the nurses who participated in this study had a mean depression score of 56.21 (± 8.70) points, which exceeded the critical value for the norm score on the Chinese SDS, which is consistent with previous research[24,25]. Clean operating room nurses not only face fast work rhythms and heavy workloads but also need to constantly improve their professional skills[26,27]. In addition, the operating room is an important place to rescue critically ill patients, and surgical nurses often need to complete emergency rescue tasks, which can impact on their mental health.

This study found that, compared with female nurses in clean operating departments, male nurses had higher resilience and life satisfaction scores and lower depression scores, which may be related to gender differences in personality traits. The results also showed that older respondents had lower resilience and life satisfaction scores, and higher depression scores, compared with younger respondents. This may be due to older nurses often being required to deal with more complex work because of their rich work experience, resulting in increased work pressure and, subsequently, more psychological difficulties. Regarding marital status, the findings showed that, compared with unmarried nurses, nurses whose marital status was married, divorced, or other had lower resilience scores and higher depression scores. This may be because married nurses tend to receive family support and help, and can often obtain psychological comfort in their marriage. This study further found that, compared with nurses with intermediate and senior professional titles, those with junior professional title had lower resilience and life satisfaction scores and higher depression scores. This may be related to the fact that pressure to receive a promotion often negatively affects the mental health of those with low-level professional titles. In this study, compared to nurses with less than ten years of work experience, those in the groups with 10-19 or 20-38 years of work experience had lower resilience and life satisfaction scores and higher depression scores. This may be because nurses with extensive work experience have experienced more problems that can arise in emergency surgery, high-risk patients, medical problems, and job promotions, resulting in greater psychological pressure. Compared with those with a personal monthly income < 3000 yuan, nurses with a personal monthly income of 3000-5000 yuan or 5001-10000 yuan had lower resilience and life satisfaction scores and higher depression scores, which may be related to higher income indicating more job requirements, promotion pressure, and family expectations. In addition, compared with contract nurses, formal nurses had lower resilience and life satisfaction scores and higher depression scores. This may be because formal nurses must deal with administrative work while also completing nursing work and face a more stringent assessment mechanism.

This study found that resilience among the participants was positively correlated with life satisfaction scores and negatively associated depression scores. This indicates that, among nurses working in clean operating departments, the better the resilience, the greater the life satisfaction and lower the depression, which is in accordance with the findings of previous studies[28,29]. Good resilience and life satisfaction are indicators of less psychological difficulty. As a protective factor for adversity, resilience can mobilize individuals to use their own strengths and resources, mitigate the negative impact of risk factors, and ultimately reduce the probability of negative consequences while increasing that of positive

outcomes. These positive outcomes will increase life satisfaction, so that the individual's cognition of people and things related to it is more positive. In addition, nurses will have more positive experiences in life, work, and study, resulting in a decreased risk for psychological problems[30,31].

This study's findings indicate that the connection between resilience and depression is partially mediated by life satisfaction among nurses working in a clean operating department. The value of the effect was -6.853, accounting for 26.68% of the total effect. Related studies have shown that the higher an individual's resilience, the higher their life satisfaction, and high life satisfaction indicates good mental health and low depressive symptoms[32,33]. One characteristic of highly resilient individuals is that they can maintain a high level of life satisfaction in a complex environment, and the positive emotional experience generated by high life satisfaction reduces depression[34,35]. In view of the psychological status of nurses in the operating room, hospitals should regularly carry out psychological and physiological assessment activities for nurses in the operating room, understand the source of stimuli and the causes of nurses' depression, and carry out targeted intervention measures to help nurses decompress psychologically, relieve fatigue and boredom, and improve their life satisfaction and psychological resilience. At the same time, the hospital should further deepen the reform of management mode, establish the professional ethics of medical staff, stimulate the enthusiasm and standardization of nurses' work, and create a good working atmosphere. In addition, we suggest that the hospital actively take targeted intervention measures to optimize the working state of nurses by improving their psychological quality and mental resilience, and finally improve their life satisfaction. For example, experts are invited to hold lectures regularly, and nurses are trained to endure hardships and overcome setbacks through practical experience or typical cases. Psychological lectures, cognitive behavior intervention, relaxation training and other activities were carried out for nurses to help them improve their physical and mental state, psychological resilience and life satisfaction.

However, several factors can affect the mental health of nurses in clean operating departments, such as work boredom, work pressure, job burnout, and lack of social support. This study selected only one direction for in-depth discussion, which is a limitation. In future studies, we hope to further analyze other factors. To improve the mental health of nurses in clean operating departments to provide a more reliable theoretical basis.

CONCLUSION

Depression scores were negatively correlated with resilience. Life satisfaction was positively related to resilience and negatively related to depression. The connection between resilience and depression was partially mediated by life satisfaction among nurses working in a clean operating department.

ARTICLE HIGHLIGHTS

Research background

A clean operating department is important for hospitals to implement surgical treatments and attend to critically ill patients. These departments have a large workload, fast rhythm, and high intensity. The working environment in clean operating departments constantly challenges nurses and can easily lead to negative mental states, such as despair and anxiety, and ultimately, psychological problems. However, ensuring the mental health of nurses in clean operating departments is key to the normal functioning of hospital operating rooms.

Research motivation

A crucial determinant of a person's subjective well-being and quality of life is their level of life satisfaction. Resilience is a protective factor for individual mental health. Both are important factors in ensuring mental health. Therefore, exploring the mediating role of life satisfaction in the effects of resilience on depression among nurses in clean operating departments can provide a reference for promoting harmonious development among nursing teams in operating rooms and improving the quality of nursing services.

Research objectives

To investigate how depression and resilience are related and the possible mediating role of life satisfaction in this association among nurses in clean operating departments and provide a scientific basis for increasing their resilience and life satisfaction, and reducing the occurrence of depression.

Research methods

A total of 196 nurses from three clean operating departments in one hospital were selected using convenience sampling. The Connor-Davidson resilience scale, satisfaction with life scale, and self-rating depression scale (SDS) were used to evaluate resilience, life satisfaction, and depression.

Research results

The mean depression score for nurses in the clean operating department was 56.21 (± 8.70), which exceeded the critical value of the norm score for the Chinese SDS. Nurses' resilience was positively correlated with life satisfaction and negatively correlated with depression. Life satisfaction served as a partial mediator between resilience and depression in

the nurses in the clean operating department, with a mediation effect value of -6.853, accounting for 26.68% of the total effect.

Research conclusions

Life satisfaction had a partial mediating role between resilience and depression among nurses in a clean operating department, suggesting that hospitals should not only increase the resilience of medical staff in the face of adversity but also promote the mental health level of this group by improving their life satisfaction.

Research perspectives

Depression is not the only psychological problem that nurses in clean operating departments face. In the future, we will further study psychological distress and its influencing factors among nurses in clean operating departments to provide a more reliable theoretical basis for ensuring their mental health.

Abstract

BACKGROUND

Post-intensive care syndrome (PICS) is a term used to describe a constellation of new or worsened dysfunctions in the physical, cognitive, or mental health status of critically ill patients after their discharge from the intensive care unit (ICU). These dysfunctions persist beyond the acute phase of illness and have a significant impact on both the patient and their family. Connect, Introduce, Communicate, Ask, Respond, Exit (CICARE) communication advocates that patients should be respected and accepted when receiving medical services. Clinicians should attach importance to the communication mode of feelings, including connection, introduction, communication, ask, response, and exit 6 steps.

AIM

To assess the impact of CICARE communication on the reduction of anxiety, depression, and post-traumatic stress disorder (PTSD) symptoms in patients transitioning from the ICU to other care settings.

METHODS

This prospective, randomized, controlled study was performed between October 2021 and March 2023. Intensive Care Unit Memory Tool was used to evaluate patients' ICU memory. The Hospital Anxiety and Depression Scale was employed to determine the presence of anxiety or depression symptoms. Impact of Event Scale-Revised was utilized to assess the presence of PTSD. All data were processed and analyzed using R language software version 4.1.0. The measurement data were expressed as mean ± SD, and the *t* test was used. The count data were analyzed by the χ^2 test and expressed as [*n* (%)].

RESULTS
In total, 248 subjects were included in this study. Among them, 206 were successfully followed up for three months after transfer from the ICU, and 42 cases were lost to follow-up. There was no significant difference in the composition of ICU memory between the two groups. The application of the CICARE communication nursing model combined with the motivational psychological intervention nursing model, as well as the adoption of only the motivational psychological intervention nursing model, demonstrated favorable effects on PICS. Both groups of patients showed a reduction in anxiety scores, depression scores, and PTSD scores following the implementation of these two nursing models. However, it is noteworthy that the experimental group exhibited greater improvements compared to the control group.

CONCLUSION
Our findings suggest that CICARE communication nursing mode may have good influence on relieving PICS.

Key Words: Connect, Introduce, Communicate, Ask, Respond, Exit; Post-intensive care syndrome; Motivational psychological intervention

INTRODUCTION

Connect, Introduce, Communicate, Ask, Respond, Exit (CICARE) communication is an approach that emphasizes the respect, acceptance, and acknowledgement of patients during the delivery of medical services. It places importance on the effective communication of emotions, encompassing six key steps: Connect, introduce, communicate, ask, respond, and exit. Research has shown that under the clear guidance of these steps, patients' satisfaction with health care has been improving[1]. For example, the application value of CICARE communication mode nursing intervention in patients with coronary artery disease after percutaneous coronary intervention has demonstrated notable value. It has shown great potential in reducing disease uncertainty, improving treatment adherence, enhancing patients' self-care abilities, and promoting both quality of life and nursing satisfaction[2].

With the development of modern technology and medical technology, intensive care unit (ICU) treatment technology has rapid development, including advanced respiratory and circulation acquired immunodeficiency syndrome, a variety of standard diagnosis and treatment guidelines, the implementation of health education programs, so that the short-term results of ICU patients, including mortality rates and 28-d survival rates, there has been a significant increase[3]. However, the long-term prognosis and quality of life of sepsis patients remains poor, and there are many studies showings that some patients transferred out of ICU may be suffer from cognitive, mental, and physical impairments are common in patients transferred out of ICU, which can last for months or even years, or remission over time and this syndrome is called post-intensive care syndrome (PICS) which is a range of cognitive, mental, and physical impairments that are new or increased in critically ill patients after transfer from ICU and continue to affect the patient after discharge; or because of the patients admitted to ICU for treatment and late care, the family members brought a variety of pressure, resulting in psychological and physical disorders[4-7].

Numerous studies have focused on developing strategies to reduce the risk of PICS, and caregivers of PICS. High levels of education and early active mobilization are considered potential risk factors for PICS[8-11]. The impact of nursing interventions on PICS is an area that has been inadequately explored in the existing literature. Specifically, the influence of CICARE communication on PICS remains largely understudied. In light of this knowledge gap, our study aimed to evaluate the potential effects of CICARE communication on the duration of post-ICU stay, as well as its impact on anxiety, depression, and post-traumatic stress disorder (PTSD) symptoms among patients transitioning from the ICU to other care settings.

MATERIALS AND METHODS

Research contents

This prospective, randomized, controlled study was performed between October 2021 and March 2023 in Department of Neurosurgery, Dushu Lake Hospital Affiliated to Soochow University. The study was registered at the Clinical Trial Center (www.researchregistry.com) with registration number (researchregistry9376). All subjects have signed the consent form before participating in the study. Patients were divided into two groups, experiment group and controlled group. The patients of experiment group received the CICARE communication nursing model combined with motivational psychological intervention nursing model, and the patients of controlled group received the motivational psychological intervention nursing model. The main study objective was to investigate differences in the occurrence of symptoms of anxiety, depression and PTSD at 3 mo after ICU transfer between two groups of patients receiving different modes of nursing care.

Patient selection

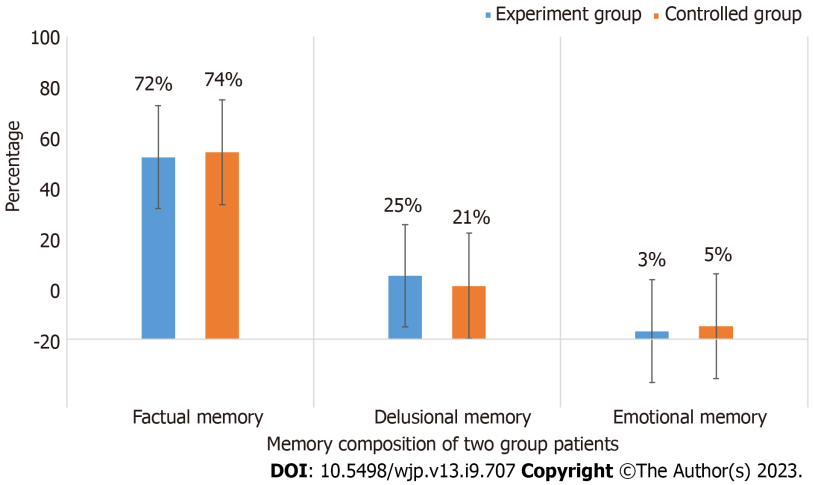
Patients hospitalized and successfully transferred out of comprehensive ICU were selected as subjects by convenience sampling. All patients seen by the investigators in their clinical practices or who responded to requests for volunteers were screened for participation in the study. Those who met the screening criteria and gave their consent were sequentially admitted. Inclusion criteria: (1) At least 18 years old; (2) ICU stay longer than 24 h; (3) Patients transferred to the general ward after ICU treatment; and (4) Informed consent and voluntary participation in the study. Exclusion criteria: (1) Patients with severe brain injury or brain disease; (2) Patients with cognitive dysfunction; (3) Patients with language dysfunction and inability to communicate effectively; (4) Patients transferred to ICU twice or more; (5) Patients with mental disorders; and (6) Patients with malignant diseases receiving palliative care.

Materials

General information questionnaire: The general information questionnaire included gender, age, education, length of stay in ICU, diagnosis of ICU admission, presence of sepsis during ICU treatment, presence of hormones, and presence of analgesics. Intensive Care Unit Memory Tool (ICUMT): The ICUMT, assessment of patients' ICU memory, consists of a total of 14 questions: 5 open-ended questions and 9 closed questions. It mainly includes three parts: (1) The memory of admission and ICU transfer; (2) The memory during ICU care was divided into three dimensions, a total of 21 items: Factual memory (family, face, darkness, alarm sound, breathing tube, clock, sound, sputum aspiration, nasal cannula, light, medical rounds); delusional memories (others wanting to harm themselves, hallucinations, nightmares, dreams); emotional memory (discomfort, confusion, low mood, anxiety and panic, panic, pain); and (3) Memory after transfer out of ICU and ICU[12].

The Hospital Anxiety and Depression Scale (HADS): HADS was divided into two subscales of anxiety and depression, with a total of 14 items, among which 7 items (A) assessed anxiety and 7 items (D) assessed depression, and each item was scored at four levels of 0-3. The subscale was divided into critical value with 8 points, 0-7 points indicated no symptoms, and 8-10 points indicated possible anxiety or depression. A score of 11 to 21 indicates the presence of anxiety or depression symptoms, and the higher the score, the more severe the anxiety or depression symptoms[13,14].

Impact of Event Scale-Revised (IES-R): IES-R consists of 22 entries, including the three core symptoms of PTSD: Intrusion, avoidance and increased alertness were scored on five levels ranging from 0 (never) to 4 (always), with a total score ranging from 0 to 88, and a critical value of 35. The total score ≥ 35 was classified as positive PTSD symptoms, and the higher the score, the more serious the PTSD symptoms[15].



Within one week after the patients were transferred from ICU to the general ward (with appropriate extension to two weeks for special patients), the researchers visited the ward for follow-up, and reported. After knowing the purpose and significance of the study, the informed consent was signed after obtaining the informed consent of the patients, and the general information questionnaire and ICU memory assessment scale were distributed. For the patients who could not complete the questionnaire independently, the questionnaire contents were read aloud word by word, and the patients provided oral answers, and the researchers filled in the answers for them. HADS and IES-Rs were collected by telephone interview at 3 mo after patients were transferred out of the ICU. The questionnaire was read aloud, word for word, and the patients responded verbally, while the researchers wrote the answers for them. Limit each phone interview to 15 to 20 min.

Statistical analyses

The integrity of all questionnaires was checked before input, and invalid questionnaires with obvious logical contradictions or too many missing items were eliminated. All data were processed and analyzed using R language software version 4.1.0. The measurement data were expressed as mean ± SD, and the t test was used. The count data were expressed as [n (%)], and the χ^2 test was used. $P < 0.05$ was considered statistically significant.

RESULTS

There were 248 subjects were included in this study, and 206 patients were successfully followed up three months after being transferred out of ICU, and 42 cases were lost to follow-up from October 2021 and March 2023. The reasons for the loss of follow-up included death, refusal to participate in the investigation, loss of contact, and failure to cooperate with

DOI: 10.5498/wjp.v13.i9.707 **Copyright** ©The Author(s) 2023.

Figure 1 Intensive care unit memory composition of two group patients.

the investigation in critical condition. Among 206 patients successfully followed up, 125 (60.7%) were male and female in 81 cases (39.3%); most of the patients were over 45 years old, with 112 cases (54.4%), which were presented in Table 1.

There was no statistical difference in the composition of ICU memory between the two groups, and 72% of patients in the experimental group had factual memory. Delusional memory was present in 25% of patients and emotional memory was present in 3%; in the control group, 74% of patients had factual memories, 21% had delusional memories, and 5% had emotional memories (see Figure 1). There was no statistic difference in ICU memory composition of two group patients.

HADS and IES-R score change of two group patients were presented in Table 2. Adopting CICARE communication nursing model combined with motivational psychological intervention nursing model and only adopting motivational psychological intervention nursing model both had good influence on PICS. Anxiety score, depression score and PTSD score of both group patients decreased after using these two nursing modes, but experiment group was better than the control group.

DISCUSSION

Annually, a staggering number of over 20 million patients worldwide necessitate ICU treatment due to severe illness, injury, or the worsening of chronic conditions. Advances in medical technology have increased the survival of critical illness, increasing the number of patients transferred out of the ICU, and increasing attention to their long-term outcomes [16,17]. Patients may experience both physiological and psychological stressors during their stay in the ICU, including critical illness, sedation, pain, sleep deprivation, noise, delirium, lack of privacy, and fear. These experiences can significantly impede the recovery process and may even contribute to the development of psychological disorders, including anxiety, depression, and PTSD, following the patient's discharge from the ICU. Among these, anxiety, depression, and PTSD are the most prevalent psychological conditions observed in such cases[18]. According to the above facts, The American Academy of Critical Care Medicine Put forward the concept of PICS that it is a series of new or aggravated dysfunction in the physical, cognitive or mental health status of a critically ill patient after discharge, which continues to affect the patient or his or her family. There are many studies on the influencing factors of psychological disorders in patients transferred out of ICU, mainly focusing on demographic factors (such as gender, age, education level, family income, *etc.*), disease factors (such as chronic history, severity of disease, sepsis, *etc.*), and factors related to ICU treatment (such as the use of glucocorticoids, the use of analgesics, the use of sedatives, *etc.*). It is a great challenge for intensive care to improve long-term mental health and health-related quality of life of patients transferred out of ICU.

CICARE communication mode is a process-oriented communication approach advocated by American medical institutions. It integrates psychological and medical knowledge along with humanistic values to enhance the effectiveness of communication between healthcare providers and patients in outpatient settings. The implementation of CICARE communication mode aims to improve patients' medical experience and enhance the overall quality of care delivery. In our study, 14 nurses were trained in CICARE communication mode for 1 mo and passed the examination. CICARE mode was fully applied in the experiment group patients who accepted the motivational psychological intervention at same time. After study and observation, the experiment patients more willing to speak out their demand and worries. Other studies have found the same thing[2,19-21]. CICARE communication is a mode of communication that advocates good communication that attends to the patients feelings of being respected, accepted and valued during the provision of medical services for patients, including connect, introduce, communication, ask, response and exit. Patients feel respected and are more likely to trust their doctors, talk about their problems, and give feedback. A major limitation of this study is that we enrolled a small sample size from a single-center study. Therefore, our results may not be generalized.

Table 1 Baseline characteristics of subjects

	Indicator	Number	Percentage
Gender	Male	125	60.7
	Female	81	39.3
Age (yr)	< 30	27	13.1
	30-45	67	32.5
	> 45	112	54.4
Operation situation	Non-operation	38	18.4
	Elective operation	102	49.5
	Emergency	66	32.1
Length of ICU stay	1-5	123	59.7
	5-10	55	26.7
	10-20	14	6.8
	> 20	14	6.8
Tranquilizer	Yes	181	87.9
	No	25	12.1
Sedative	Yes	166	80.6
	No	40	19.4

ICU: Intensive care unit.

Table 2 Hospital Anxiety and Depression Scale and Impact of Event Scale-Revised score change of two group patients

	Experiment group	Controlled group
Samples	103	103
Anxiety score	12	11
Depression score	10	9
PTSD score	52	52
ICU transfer anxiety score at three months	3	6
Depression score at three months after ICU transfer	2	5
PTSD score at three months after ICU transfer	16	38

PTSD: Post-traumatic stress disorder; ICU: Intensive care unit.

CONCLUSION

CICARE communication nursing mode may have good influence on relieving PICS. Patients transferred from ICU can be adopted CICARE communication nursing model combined with motivational psychological intervention nursing model, rather than only motivational psychological intervention nursing model.

ARTICLE HIGHLIGHTS

Research background

Connect, Introduce, Communicate, Ask, Respond, Exit (CICARE) communication is a kind of advocating that patients should be respected, accepted and accepted when providing medical services attach importance to the communication mode of feelings. Post-intensive care syndrome (PICS) is a series of new or aggravated dysfunction in the physical, cognitive or mental health status of a critically ill patient after discharge, which continues to affect the patient or his or her family.

Research motivation

The aim of this study was to evaluate CICARE communication whether shorten post-intensive care (ICU), affecting anxiety, depression, and post-traumatic stress disorder (PTSD) in patients transferred out of the ICU.

Research objectives

The object of this study as follows: (1) Assess the impact of CICARE communication combined with motivational intervention on anxiety, depression, and PTSD symptoms in PICS patients; (2) Compare outcomes between CICARE + motivational intervention and motivational intervention alone; and (3) Determine feasibility and acceptability of implementing CICARE communication in PICS care.

Research methods

The study employed a prospective, randomized, controlled design. Data collection occurred from October 2021 to March 2023. ICU memory was evaluated using the Intensive Care Unit Memory Tool. Anxiety and depression symptoms were assessed using Hospital Anxiety and Depression Scale, while PTSD was measured with Impact of Event Scale-Revised. Statistical analysis utilized R software (version 4.1.0). Follow-up was conducted for three months after ICU transfer.

Research results

There was no statistical difference in the composition of ICU memory between the two groups. Adopting CICARE communication nursing model combined with motivational psychological intervention nursing model and only adopting motivational psychological intervention nursing model both had good influence on PICS. Anxiety score, depression score and PTSD score of both group patients decreased after using these two nursing modes, but experiment group was better than the control group.

Research conclusions

CICARE communication nursing mode may have good influence on relieving PICS.

Research perspectives

Patients transferred from ICU can be adopted CICARE communication nursing model combined with motivational psychological intervention nursing model, rather than only motivational psychological intervention nursing model.

AIMS AND SCOPE

The primary aim of *World Journal of Psychiatry* (*WJP*, *World J Psychiatry*) is to provide scholars and readers from various fields of psychiatry with a platform to publish high-quality basic and clinical research articles and communicate their research findings online.

WJP mainly publishes articles reporting research results and findings obtained in the field of psychiatry and covering a wide range of topics including adolescent psychiatry, biological psychiatry, child psychiatry, community psychiatry, ethnopsychology, psychoanalysis, psychosomatic medicine, *etc.*

INDEXING/ABSTRACTING

The *WJP* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Current Contents/Clinical Medicine, Journal Citation Reports/Science Edition, PubMed, PubMed Central, Reference Citation Analysis, China National Knowledge Infrastructure, China Science and Technology Journal Database, and Superstar Journals Database. The 2023 Edition of Journal Citation Reports® cites the 2022 impact factor (IF) for *WJP* as 3.1; IF without journal self cites: 2.9; 5-year IF: 4.2; Journal Citation Indicator: 0.52; Ranking: 91 among 155 journals in psychiatry; and Quartile category: Q3.

Abstract

BACKGROUND

Cognitive dysfunction in epileptic patients is a high-incidence complication. Its mechanism is related to nervous system damage during seizures, but there is no effective diagnostic biomarker. Neuronal pentraxin 2 (NPTX2) is thought to play a vital role in neurotransmission and the maintenance of synaptic plasticity. This study explored how serum NPTX2 and electroencephalogram (EEG) slow wave/fast wave frequency ratio relate to cognitive dysfunction in patients with epilepsy.

AIM

To determine if serum NPTX2 could serve as a potential biomarker for diagnosing cognitive impairment in epilepsy patients.

METHODS

The participants of this study, conducted from January 2020 to December 2021, comprised 74 epilepsy patients with normal cognitive function (normal group), 37 epilepsy patients with cognitive dysfunction [epilepsy patients with cognitive dysfunction (ECD) group] and 30 healthy people (control group). The mini-mental state examination (MMSE) scale was used to evaluate cognitive function. We determined serum NPTX2 levels using an enzyme-linked immunosorbent kit and calculated the signal value of EEG regions according to the EEG recording. Pearson correlation coefficient was used to analyze the correlation between serum NPTX2 and the MMSE score.

RESULTS

The serum NPTX2 level in the control group, normal group and ECD group were 240.00 ± 35.06 pg/mL, 235.80 ± 38.01 pg/mL and 193.80 ± 42.72 pg/mL, respectively. The MMSE score was lowest in the ECD group among the three, while no significant difference was observed between the control and normal groups. In epilepsy patients with cognitive dysfunction, NPTX2 level had a positive correlation with the MMSE score (r = 0.367, P = 0.0253) and a negative correlation with epilepsy duration (r = −0.443, P = 0.0061) and the EEG slow wave/fast wave frequency ratio value in the temporal region (r = −0.339, P = 0.039).

CONCLUSION

Serum NPTX2 was found to be related to cognitive dysfunction and the EEG slow wave/fast wave frequency ratio in patients with epilepsy. It is thus a potential biomarker for the diagnosis of cognitive impairment in patients with epilepsy.

Key Words: Serum neuronal pentraxin 2; Cognitive dysfunction; Epilepsy; Electroencephalogram slow wave/fast wave frequency ratio; Biomarker

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Here, we found serum neuronal pentraxin 2 (NPTX2) levels were found to be significantly higher in the normal group than in the cognitive dysfunction group. Additionally, NPTX2 levels showed a positive correlation with cognitive function scores and a negative correlation with epilepsy duration and electroencephalogram (EEG) slow wave/fast wave frequency ratio values in the temporal region. Serum NPTX2 level and the EEG slow wave/fast wave frequency ratio value had good sensitivity and specificity for evaluating cognitive dysfunction. These findings suggest that serum NPTX2 could be a valuable biomarker for diagnosing cognitive impairment in patients with epilepsy, providing important insights for clinical practice.

INTRODUCTION

Epilepsy is a common neurological disorder characterized by abnormal synchronous firing of neurons in the brain[1]. The causes of epilepsy are sometimes known and sometimes unknown (idiopathic epilepsy). Epidemiological studies have shown that approximately 70% of adults with epilepsy have cognitive dysfunction[2,3]. However, there are no effective cognitive assessment criteria for patients with epilepsy. Cognitive dysfunction in epilepsy patients occurs on multiple levels, including executive ability, attention, language, and memory ability. Various epilepsy-related factors are closely related to cognitive dysfunction, including epilepsy course, lesion location, underlying neuropathology, and antiepileptic seizure drugs[2]. Cognitive impairment is common in epileptic patients and is characterized by impairment in neurological function. Due to the lack of early diagnostic methods for cognitive impairment in epilepsy patients, unavoidable neurological damage is present in epilepsy patients[3,4].

Neuronal pentraxin 2 (NPTX2), also named "neuronal activity-regulated pentraxin", is first find in in 1995[5]. NPTX2 is being found to take part in neurotransmission, the maintenance of synaptic plasticity, and the formation of excitatory synapses at presynaptic and postsynaptic sites[6,7]. NPTX2 is also being found to take part in Parkinson's disease[8,9], ischemic diseases[10,11], and Alzheimer's disease[12,13]. A recent study reported that NPTX2 was a novel biomarker for Alzheimer's disease[14]. In addition, researchers have explored the role of NPTX2 in vascular dementia. A recent study reported significantly higher serum levels of NPTX2 in patients with vascular dementia than in healthy controls. Furthermore, NPTX2 serum levels were found to be significantly correlated with cognitive function scores in patients with vascular dementia[15]. However, we still known nothing about NPTX2 in epilepsy.

This study evaluated NPTX2 serum levels in epilepsy patients, and future study their relationship with the patients' cognitive function.

MATERIALS AND METHODS

Patients and ethical statement

This study enrolled 111 patients diagnosed with epilepsy at the First Affiliated Hospital of Fujian Medical University between January 2020 and December 2021. In addition, 30 healthy volunteers were recruited as a control group. The

inclusion criteria were as follows: (1) Clinically confirmed epilepsy [electroencephalogram (EEG) with or without epileptiform discharge]; (2) No seizures 24 h before enrollment; (3) Age between 18 and 60 years; (4) Clear consciousness and cooperative during the examinations; (5) Normal vision, hearing, and speech functions; (6) An education level of at least primary school and an ability to understand the scale content sufficiently to answer the questions; (7) Signed an informed consent form; and (8) Asymptomatic epilepsy (head computed tomography or magnetic resonance imaging does not show intracranial lesions). The exclusion criteria were as follows: (1) Liver dysfunction (alanine transaminase or aspartate aminotransferase > 50 U/L) or renal impairment (serum creatinine > 135 μmol/L); (2) In the acute stage of the disease course; (3) A long-term history of alcoholism or psychoactive substance abuse or recent use of drugs that could affect cognitive function such as antidepressants, antipsychotics, baclofen, and benzodiazepines; or (4) Uncooperative behavior. The study was conducted in accordance with the Declaration of Helsinki (revised in 2013) and was approved by the ethics board of the First Affiliated Hospital of Fujian Medical University (No. [2019]274). Informed consent was obtained from all participants.

Cognitive function assessment

The mini-mental state examination (MMSE) scale was used to evaluate cognitive function in all participants. The MMSE scale consists of 30 questions related to cognitive function; each correct answer receives one point. An MMSE scale score of less than 27 indicates cognitive dysfunction in persons with at least a junior high school education[16].

Serum NPTX2 assay

Fasting venous blood was drawn from all participants. The peripheral blood was centrifuged at room temperature to obtain serum, which was then frozen in liquid nitrogen, awaiting further tests. Serum NPTX2 was detected using a Human Neuronal pentraxin-2 (NPTX2) enzyme-linked immunosorbent assay kit (CSB-EL016030HU; CUSABIO, Houston, TX, United States).

EEG test

All patients with epilepsy were subjected to an EEG test. The test was conducted in a quiet room, and the patients were told to relax and stay awake with closed eyes. The patients were also subjected to induction tests such as opening their eyes and hyperventilation. The EEG detection parameter settings were as follows: Filter channel 0.5–30 Hz, time constant 0.3, paper feed speed 3 cm/s, gain 100 μV = 1 cm, and scalp resistance of each electrode not exceeding 5,000 Ω. After selecting monopolar lead tracing for 1 min and once the EEG signal was stable, the EEG signal sampling without artifacts and representing EEG background activity was selected. Each patient took 8 s for one sampling unit, with 10 sampling units selected intermittently. The EEG slow wave/fast wave frequency ratio (EEGs value) was calculated using the fast Fourier transform method: EEGs value = (δ+θ)/(α1+α2+β1+β2). δ (1.0–3.9 Hz), θ (4.0–7.9 Hz), α1 (8.0–10.0 Hz), α2 (10.1–13.9 Hz), β1 (14.0–19.9 Hz), and β2 (20.0–30.0 Hz).

Statistical analysis

Data were recorded in an Excel sheet and were analyzed using SPSS 25.0 (IBM, Corp., Armonk, NY, United States). Count data were expressed as percentages, while continuous data were expressed as mean ± SD. The Kolmogorov–Smirnov test was used to test whether the quantitative data were normally distributed. Normally distributed data were presented as (mean ± SD), and differences between groups were analyzed using unpaired Student's *t*-test. Non-normally distributed quantitative data were presented as the median (interquartile range), and differences between groups were analyzed using the Mann–Whitney U-test. The Pearson correlation coefficient was used to analyze the correlation between two variables of measurement data. Furthermore, the receiver operating characteristic curves were constructed, and the area under the curve (AUC) was calculated to assess the performance of NPTX2 serum levels and EEGs values in diagnosing cognitive dysfunction in patients with epilepsy. A P value < 0.05 was considered statistically significant.

RESULTS

Cognitive function and baseline data of patients with epilepsy

Cognitive function was assessed using the MMSE scale. The epilepsy patients with cognitive dysfunction (ECD) group recorded the lowest MMSE score among the three groups. Furthermore, no significant difference in MMSE scores was observed between the control and normal groups (P > 0.05, Figure 1). In addition, the age, gender, education and something related to epilepsy between normal group and ECD group are omparable (P > 0.05, Table 1).

Relationship between NPTX2 serum levels and clinical features

No statistically significant difference was observed in NPTX2 serum levels between the control and normal groups (P > 0.05). However, serum NPTX2 levels in normal group were significantly higher than that in the ECD group (P < 0.05, Figure 2). The serum level of NPTX2 was positively related to MMSE score (r = 0.367, P = 0.0253), not to age (r = 0.115, P = 0.497), and negatively related to epilepsy duration (r = -0.443, P = 0.0061, Figure 3) in the ECD group. In addition, no significant differences were found in gender, education level, epilepsy type, epilepsy drug types, or treatment protocol between the ECD and normal groups (Figure 4).

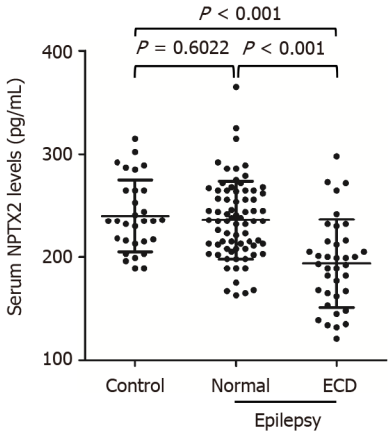
ECD: Epilepsy patients with cognitive dysfunction; ECG: Electrocardiogram.

Ratio of EEG slow wave/fast wave frequency in epilepsy patients

Patients in the normal and ECD groups showed different EEG slow wave/fast wave frequency ratios (EEG value). Patients in the normal group recorded lower EEGs values in the frontal, central, top, temporal, and occipital regions than patients in the ECD group. However, significant differences in EEG values were observed only in the frontal, central, and temporal regions ($P < 0.05$, Table 2).



Relationship between NPTX2 serum levels and EEG values

The correlation analysis showed that NPTX2 serum levels in the group were not correlated with EEG values in the frontal or central region ($P > 0.05$). However, NPTX2 serum levels in the group were negatively correlated with the EEG values

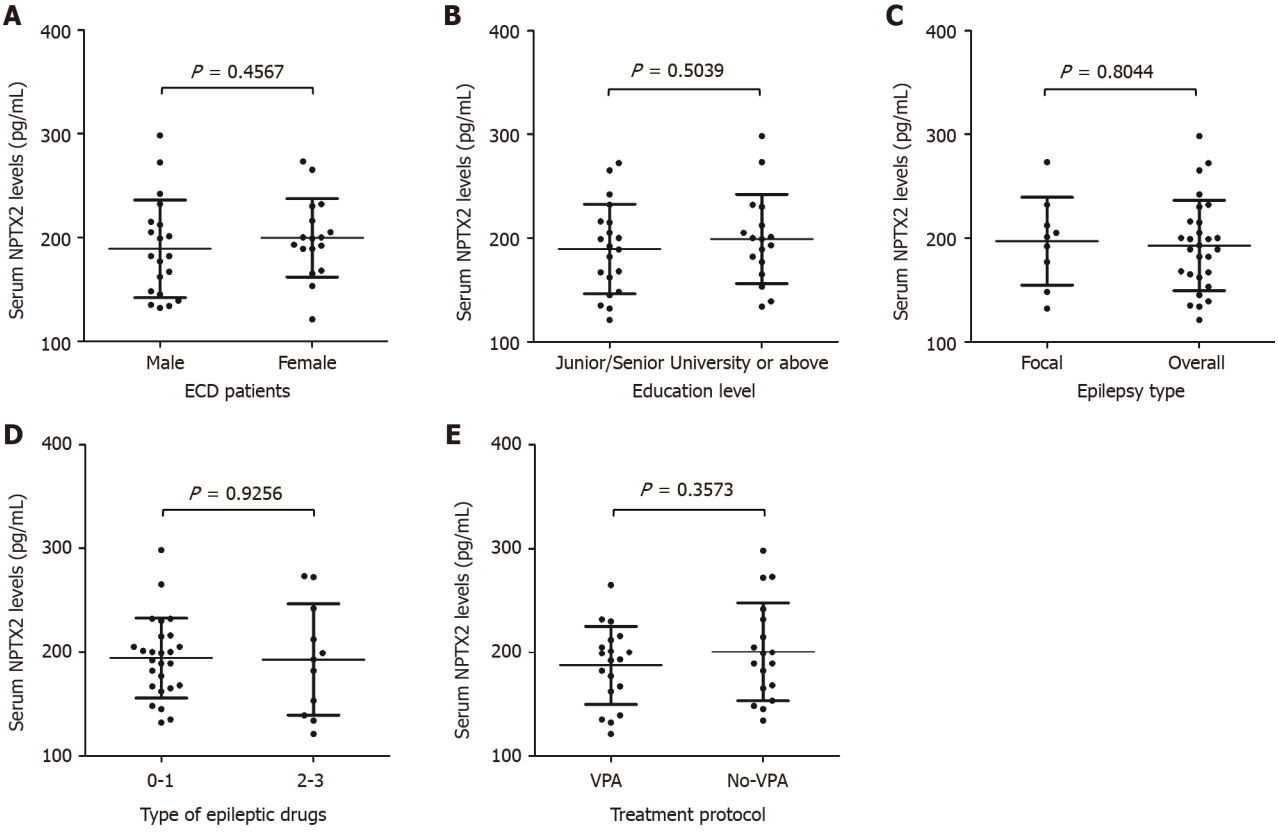
in the temporal region ($P < 0.05$, Figure 5).

Predictive analysis of NPTX2 serum levels and EEG values of the temporal region in cognitive dysfunction



The AUC value of NPTX2 for diagnosing cognitive impairment in epilepsy patients is 0.777, and the 95%confidence interval (95%CI) is 0.679-0.876 (Figure 6). When the cutoff NPTX2 serum level for distinguishing cognitive function in patients with epilepsy was 206.50 pg/mL, the sensitivity and the specificity was 91.89% and 85.14%, respectively (Figure 6).

Moreover, the AUC value of electrocardiogram (ECG) for diagnosing cognitive impairment in epilepsy patients is 0.815, and the 95%CI is 0.739–0.892 (Figure 6). When the cutoff EEG value for distinguishing cognitive function in patients with epilepsy in the temporal region was set at 0.455, the sensitivity and the specificity was 91.89% and 68.92%, respectively (Figure 6).

DISCUSSION

Epilepsy is a disease that damages the nervous system, causing damage to the patient's nervous system and subsequently leading to cognitive impairment[17,18]. Epilepsy patients with cognitive impairment are affected in various aspects of their lives. However, it can be confirmed that if diagnosed in the early stages of neu-rological damage, existing medicine has the ability to mitigate cognitive impairment caused by epilepsy. Due to the lack of biomarkers for diagnosing neurological damage in epilepsy patients, it is very difficult to diagnose early neurological damage in epilepsy patients, which also leads to varying degrees of cognitive impairment in epilepsy patients as adults. Therefore, there is a need to develop novel biomarkers for the early detection of cognitive impairment in epilepsy patients.

In this study, we first found that the serum NPTX2 in epilepsy were strongly higher than that in healthy people, and is related to the cognitive function score of epilepsy patients. However, previous studies have shown that NPTX2 is associated with neurological damage, such as significantly accelerating the onset time of Parkinson's mice by upregulating NPTX2 blood levels, and NPTX2 has been identified as associated with neurological damage in Parkinson's patients. In addition, previous studies have also found that the level of NPTX2 in the hippocampus of mice decreases due to cognitive decline caused by neuropathic pain, and it is related to cognitive function in mice after cerebral ischemia[19].

In 1995, NPTX2, a secreted protein, was first discovered[20]. Subsequently, research on NPTX2 was reported, and its main function was mainly studied in synapses, indicating that NPTX2 plays an important role in the nervous system[21, 22]. This function makes NPTX2 associated with the occurrence and development of many neurological diseases, such as stroke, Huntington's disease, and Amyotropic lateral sclerosis[23]. The development and damage of the nervous system are closely related to cognitive function, especially in the hippocampus, and has been reported to have significant expression levels in the cerebrospinal fluid of Alzheimer's disease patients, and it is related to the patient's cognitive function score[24]. In this study, we not only found that the levels of serum NPTX2 in ECD group were lowest, but also found that NPTX2 levels was strongly related to the the patient's cognitive function score. Therefore, these data indicate that NPTX2 is associated with nerve injury and cognitive impairment caused by nerve injury, making it a potential biomarker for diagnosing cognitive impairment in epilepsy patients.

EEG is widely used for diagnosis, identification, prognosis evaluation, and treatment efficacy assessment for neurological diseases, including epilepsy[25]. Quantitative EEG transforms the brain wave signals from the time domain in the ordinary EEG into the frequency domain[26]. Due to the inability to effectively control the onset time and pattern of epilepsy patients, it is very difficult for us to detect the EEG during the seizure period of epilepsy patients. Therefore, researchers usually study the EEG during the interval between seizures[27]. Therefore, we selected EEG in the

background of the interseizure period. This study found lower EEG values in the frontal, central, top, temporal, and occipital regions of patients with epilepsy and normal cognitive function than in those with epilepsy and cognitive dysfunction. Importantly, this study also found that NPTX2 serum levels were negatively correlated with EEG values in the temporal region of patients with epilepsy and cognitive dysfunction. These findings suggest that NPTX2 serum levels and temporal region's EEG values is related to cognitive impairment in epilepsy patients.

This study has several limitations. First, this study was conducted in a single center, and had a low sample size. Second, we did not monitor NPTX2 serum levels dynamically. Third, several factors that could affect NPTX2 serum levels—such as smoking, alcohol use, and drug use history—were not considered. Finally, our patient follow-up period was short.

CONCLUSION

In this study, we found that NPTX2 levels in epilepsy patients were lower than those in the healthy population and were associated with cognitive function scores, seizure duration, and ECG values in epilepsy patients. All in all, these results indicate that serum NPTX2 levels are potential biomarkers for diagnosing cognitive dysfunction in epilepsy patients.

ARTICLE HIGHLIGHTS

Research background

Cognitive dysfunction is a common complication in epileptic patients, but there is a lack of effective diagnostic biomarkers. This study investigated the relationship between serum levels of neuronal pentraxin 2 (NPTX2), an important molecule involved in neurotransmission and synaptic plasticity, and cognitive dysfunction in epilepsy patients. The study also explored the association between electroencephalogram (EEG) slow wave/fast wave frequency ratio and cognitive impairment. The aim was to determine if serum NPTX2 could serve as a potential biomarker for diagnosing cognitive impairment in epilepsy patients, addressing the need for reliable diagnostic tools in this population.

Research motivation

The high incidence of cognitive dysfunction in epileptic patients highlights the need for effective diagnostic biomarkers. Currently, there is a lack of reliable tools to identify cognitive impairment in this population. This study aimed to investigate the correlation between serum NPTX2 levels and EEG slow wave/fast wave frequency ratios with cognitive dysfunction in epilepsy patients. By exploring these potential biomarkers, the study aimed to contribute to the development of a diagnostic tool for identifying cognitive impairment in epilepsy patients, facilitating early intervention and improved patient care.

Research objectives

The main objectives of this study were to investigate the relationship between serum levels of NPTX2 and EEG with cognitive dysfunction in epilepsy patients. The study aimed to determine if serum NPTX2 could serve as a potential biomarker for diagnosing cognitive impairment in patients with epilepsy. Additionally, the study aimed to assess the correlation between serum NPTX2 levels, EEG patterns, and cognitive function using the mini-mental state examination (MMSE) scale. The ultimate goal was to contribute to the development of effective diagnostic tools for identifying cognitive impairment in epilepsy patients.

Research methods

The study enrolled three groups of participants: Normal group, 74 epilepsy patients without cognitive dysfunction; epilepsy patients with cognitive dysfunction group, 37 epilepsy patients with cognitive dysfunction; Control group, 30 healthy individuals. Cognitive function was evaluated using the MMSE scale. Serum levels of NPTX2 were measured using an enzyme-linked immunosorbent kit, and EEG recordings were used to calculate the slow wave/fast wave frequency ratio in different EEG regions. Statistical analyses were performed to compare variables among the groups and assess correlations between biomarkers and cognitive function. Receiver operating characteristic (ROC) curve analysis was conducted to evaluate the diagnostic performance of serum NPTX2 and EEG patterns for cognitive dysfunction in epilepsy patients.

Research results

The study found no significant differences in age, gender, or education level among the three groups. There were also no significant differences in epilepsy-related factors between the normal group and the cognitive dysfunction group. Serum levels of NPTX2 were significantly higher in the normal group compared to the cognitive dysfunction group, while the control group showed no significant difference from the normal group. The cognitive dysfunction group had the lowest MMSE scores. The EEG slow wave/fast wave frequency ratio values were significantly higher in the cognitive dysfunction group compared to the normal group in various EEG regions. In epilepsy patients with cognitive dysfunction, NPTX2 levels correlated positively with the MMSE score and negatively with epilepsy duration and the EEG slow wave/fast wave frequency ratio value in the temporal region. ROC curve analysis demonstrated that serum NPTX2

level and EEG patterns had diagnostic potential for evaluating cognitive dysfunction in epilepsy patients.

Research conclusions

The study concluded that serum NPTX2 levels are associated with cognitive dysfunction and the EEG slow wave/fast wave frequency ratio in epilepsy patients. Serum NPTX2 shows potential as a diagnostic biomarker for cognitive impairment in epilepsy. The study found no significant differences in demographic and epilepsy-related factors between the normal and cognitive dysfunction groups. However, serum NPTX2 levels were significantly higher in the normal group compared to the cognitive dysfunction group. The EEG slow wave/fast wave frequency ratios were also higher in the cognitive dysfunction group. These findings suggest that serum NPTX2 and EEG patterns may serve as valuable indicators for diagnosing cognitive impairment in epilepsy patients.

Research perspectives

The findings of this study highlight the potential of serum NPTX2 as a diagnostic biomarker for cognitive impairment in epilepsy patients. Further research is needed to validate and expand upon these results. Future studies could explore the underlying mechanisms linking NPTX2 levels and cognitive dysfunction, investigating the role of NPTX2 in neurotransmission and synaptic plasticity. Additionally, larger sample sizes and longitudinal studies could provide more robust evidence regarding the relationship between serum NPTX2, EEG patterns, and cognitive dysfunction. Ultimately, establishing reliable biomarkers could aid in early detection and intervention for cognitive impairments in epilepsy, improving patient outcomes and quality of life.

Abstract

BACKGROUND

The gut microbiome interacts with the central nervous system through the gut-brain axis, and this interaction involves neuronal, endocrine, and immune mechanisms, among others, which allow the microbiota to influence and respond to a variety of behavioral and mental conditions.

AIM

To explore the correlation between cognitive impairment and gut microbiota imbalance in patients with schizophrenia.

METHODS

A total of 498 untreated patients with schizophrenia admitted to our hospital from July 2020 to July 2022 were selected as the case group, while 498 healthy volunteers who underwent physical examinations at our hospital during the same period were selected as a control group. Fluorescence *in situ* hybridization was employed to determine the total number of bacteria in the feces of the two groups. The cognitive function test package was used to assess the score of cognitive function in each dimension. Then, the relationship between gut microbiota and cognitive function was analyzed.

RESULTS

There were statistically significant differences in the relative abundance of gut microbiota at both phylum and class levels between the case group and the control group. In addition, the scores of cognitive function, such as attention/alertness and learning ability, were significantly lower in the case group than in the control group (all $P < 0.05$). The cognitive function was positively correlated with Actinomycetota, Bacteroidota, Euryarchaeota, Fusobacteria, Pseudo-

monadota, and Saccharibacteria, while negatively correlated with Bacillota, Tenericutes, and Verrucomicrobia at the phylum level. While at the class level, the cognitive function was positively correlated with Class Actinobacteria, Bacteroidia, Betaproteobacteria, Proteobacteria, Blastomycetes, and Gammaproteobacteria, while negatively correlated with Bacilli, Clostridia, Coriobacteriia, and Verrucomicrobiae.

CONCLUSION

There is a relationship between the metabolic results of gut microbiota and cognitive function in patients with schizophrenia. When imbalances occur in the gut microbiota of patients, it leads to more severe cognitive impairment.

Key Words: Schizophrenia; Cognitive function; Gut microbiota; Metabolic imbalance; Bacteria

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: The highlights of this study are as follows. First, individuals with schizophrenia have imbalanced intestinal microbiota compared to healthy individuals. Second, patients with schizophrenia exhibit cognitive impairments in various areas such as attention, memory, social cognition, and executive function. Additionally, specific microbial groups such as Actinomycetes, Bacteroides, and Proteobacteria have shown a positive correlation with cognitive function in patients with schizophrenia. Furthermore, there is a close relationship between metabolic imbalance of intestinal flora and cognitive impairment in individuals with schizophrenia. Lastly, further clinical trials are necessary to gather more data and insights for the development of effective treatments for schizophrenia.

INTRODUCTION

Schizophrenia is a severe mental disorder with unknown etiology. Most of the patients are young and middle-aged. Frequently, the patients may encounter various obstacles in thinking, perception, emotion, and behavior, leading to a lack of coordination between mental activities and the surroundings[1]. Patients with schizophrenia exhibit characteristics such as a high disability rate, substantial burden, and an increased tendency of suicide. This disorder also causes hallucinations, delusions, language, and behavior abnormalities, with a long course and heterogeneous clinical manifestations. Schizophrenia has an impact on the physical and mental health, as well as social quality of life for patients, resulting in economic pressure and social burden. With the continuous advancement of biological technology, the understanding of schizophrenia is gradually deepening[2,3]. As one of the primary symptoms of schizophrenia, cognitive dysfunction includes two aspects, mental cognition and social cognition. Generally, it manifests before other psychotic symptoms of schizophrenia and persists throughout the course of the disease[4]. In recent years, there has been an increasing focus on the cognitive impairment of patients. Cognitive impairment can impede patients' social and occupational rehabilitation, and assessing cognitive function can predict the disease progression and treatment response[5]. Gut microbiota constitutes a complex and vast ecosystem. Scholars have proposed that gut microbiota can regulate the immune and inflammatory responses within the human body and influence neural development. However, the understanding of the relationship between gut microbiota and schizophrenia is still limited[6,7].

In this study, cognitive function and gut microbiota were examined to explore the potential correlation between cognitive impairment and metabolic imbalance of gut microbiota in patients with schizophrenia.

MATERIALS AND METHODS

Materials

A total of 498 patients with schizophrenia admitted to The First Affiliated Hospital of Zhengzhou University from July 2020 to July 2021 were selected as the case group, and 498 healthy volunteers who underwent physical examination at the same hospital were randomly chosen as the control group.

Inclusion criteria were: patients who met the diagnostic criteria for schizophrenia in the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition[8], patients with no abnormality in routine blood tests, and patients who were 18-years-old to 50-years-old.

Exclusion criteria were: patients with diabetes, thyroid disease, hypertension, heart disease, or other diseases that may affect the stability of gut microbiota; patients who suffered from diarrhea in the past 3 mo; or patients who were pregnant or lactating.

Determination of bacterial counts

The bacterial counts in patients were determined using fluorescence *in situ* hybridization. We utilized fluorescent tags as a substitute for isotope labeling. First, biotin labeling was carried out, followed by DNA probe hybridization. Next, fluorescein avidin was used to bind with the probe hybridization to the target DNA on the chromosomes to form a hybrid. Qualitative and quantitative analyses were then performed after detecting the fluorescence under a microscope.

Cognitive function scores

The first step was to determine whether the patient was conscious. Generally, the Glasgow scale was employed to assess the degree of consciousness disturbance. If the patient was conscious, the Short Form Mental State Examination was used to screen for cognitive dysfunction. Based on the results, the presence of cognitive impairment could be identified, and further assessment of cognitive function was conducted accordingly.

Statistical processing

SPSS21.0 software was used for the data analyses. The independent *t*-test was used for comparisons between the two groups. For multivariate regression analysis, the multiple linear regression model was employed when the dependent variable was continuous, whereas the logistic regression model was used when the dependent variable was dichotomous. $P < 0.05$ was considered statistically significant.

RESULTS

Distribution of gut microbiota at the phylum level in the two groups

As shown in Table 1, the case group exhibited a significantly higher relative abundance of Actinomycetota, Bacteroidota, Euryarchaeota, Fusobacteria, Pseudomonadota, and lower abundance of Bacillota, Tenericutes, and Verrucomicrobia when compared with the control group ($P < 0.05$).

Distribution of gut microbiota at the class level in the two groups

As shown in Table 2, compared with the control group, the case group exhibited a significantly higher relative abundance of Class Actinobacteria, Bacteroidia, Betaproteobacteria, Proteobacteria, Blastomycetes, and Gammaproteobacteria, and lower relative abundance of Bacilli, Clostridia, Coriobacteriia, and Verrucomicrobiae ($P < 0.05$).

Comparison of cognitive scores between the two groups

As shown in Table 3, the scores of attention or alertness, learning, memory, fine motors, social cognition, executive function, conversion, inhibition, planning, working memory, category fluency, information processing, and total cognitive score were all significantly lower in the case group than in the control group ($P < 0.05$).

Correlation analysis between cognitive function and gut microbiota at the phylum level

As shown in Table 4, cognitive function was positively correlated with Actinomycetota ($r = 6.591$, $P = 0.001$), Bacteroidota ($r = 5.625$, $P = 0.016$), Euryarchaeota ($r = 6.281$, $P = 0.183$), Fusobacteria ($r = 2.190$, $P = 0.026$), Pseudomonadota ($r = 6.364$, $P = 0.018$), and Saccharibacteria ($r = 5.196$, $P = 0.037$), while negatively correlated with Bacillota ($r = -0.976$, $P = 0.281$), Tenericutes ($r = -0.623$, $P = 0.001$), and Verrucomicrobia ($r = -0.191$, $P = 0.006$).

Correlation analysis of between cognitive function and gut microbiota at the class level

As shown in Table 5, cognitive function was positively correlated with Class Actinobacteria ($r = 3.257$, $P = 0.001$), Bacteroidia ($r = 6.294$, $P = 0.001$), Betaproteobacteria ($r = 6.281$, $P = 0.016$), Proteobacteria ($r = 6.270$, $P = 0.008$), Blastomycetes ($r = 5.671$, $P = 0.006$), and Gammaproteobacteria ($r = 4.195$, $P = 0.005$), while negatively correlated with Bacilli ($r = -0.981$, $P = 0.001$), Clostridia ($r = -0.124$, $P = 0.015$), Coriobacteriia ($r = -0.293$, $P = 0.019$), and Verrucomicrobiae ($r = -0.549$, $P = 0.010$).

DISCUSSION

Schizophrenia is a chronic and severe mental disorder characterized by disturbances in an individual's sensory, emotional, and behavioral functions[9]. Patients with schizophrenia have difficulties distinguishing between reality and the imaginary. They may exhibit slow reactions, and show a phenomenon of behavioral withdrawal, significantly affecting their ability to engage in normal social behavior. In medical terms, schizophrenia is classified as a disorder rather than a disease. This disorder often typically occurs during the young or prime stages of life. It encompasses disturbances in the body, mind, emotions, and behaviors, but the patients do not have a coma or mentally retarded imagination[10,11]. Some studies have found that genetic factors, brain structure, and environment factors contribute

significantly to the development of this disorder. Therefore, comprehensive medical and psychological treatments are necessary to address the multifaceted nature of the condition.

Cognitive impairment is commonly observed in patients with schizophrenia, impacting various aspects such as information integration, memory, and attention. Symptoms of cognitive dysfunction are prominently manifested through memory decline in the general population[12,13]. In addition to memory decline, schizophrenia can result in impairments in executive function, visuospatial ability, comprehension, and numeracy. People's general cognition and social cognition are also closely associated with age. As the aging population continues to grow, the incidence of cognitive dysfunction is increasing[14,15]. A large number of clinical studies have demonstrated a certain correlation between schizophrenia and cognitive function. Effective interventions targeting overall cognition, emotions, and society aspects have shown promising results. In this study, patients with schizophrenia exhibited considerable declines in various cognitive aspects, including learning, memory, fine motor skills, social cognition, working memory, category fluency, information processing, and kinetic energy, when compared to healthy individuals. These results suggest association between cognitive function and schizophrenia, which is similar to the results of the above research.

Schizophrenia has profoundly impacted numerous families. Consequently, there is a paramount need to pursue effective treatment options and improve the patient prognosis[16]. Gut microbiota is a central regulator of metabolism in the human body and has been found to be associated with various mental diseases[17,18]. In modern society, there is a growing awareness of the diversity, complexity, and dynamics of gut microbiota. Differences in the structure and diversity of gut microbiota have been observed in patients with schizophrenia, with the control of the disorder having a great impact on the distribution of gut microbiota structure[19,20]. Some scholars have noted that alterations in the gut microbial community can affect the cytokine levels in the body, subsequently impacting the brain function and behaviors,

Table 3 Comparative analysis of cognitive scores between the two groups

Cognitive domain	Case group, *n* = 498	Control group, *n* = 498	*T* value	*P* value
Attention/alertness	40.27 ± 6.29	51.98 ± 9.92	22.250	0.001
Learning	36.27 ± 10.01	50.69 ± 10.08	22.650	0.001
Memory	40.31 ± 11.26	54.27 ± 7.19	23.320	0.001

Information processing	33.43 ± 9.14	48.45 ± 7.39	28.520	0.001
Total score	40.64 ± 7.17	51.14 ± 5.29	26.300	0.001

Data are presented as mean ± SD of points.

Table 4 Correlation analysis between the total cognitive score and gut microbiota at the phylum level

Name of bacteria	Total cognitive score	
	R value	*P* value
Actinomycetota	6.591	0.001
Bacteroidota	5.625	0.016
Euryarchaeota	6.281	0.183
Bacillota	0.976	0.281
Fusobacteria	2.190	0.026
Pseudomonadota	6.364	0.018
Saccharibacteria	5.196	0.037
Tenericutes	0.623	0.001
Verrucomicrobia	0.191	0.006

and greatly affecting the prognosis of patients. In this study, we found that the relative abundance of gut microbiota in patients with schizophrenia differed significantly from that in healthy individuals, indicating an imbalance in the gut microbiota in patients with schizophrenia, which is consistent with the previous results. This article examined gut microbiota at a phylum level (Actinomycetota, Bacteroidota, Euryarchaeota, Fusobacteria, Pseudomonadota, *etc*) and a class level (Class Actinobacteria, Bacteroidia, Betaproteobacteria, Proteobacteria, Blastomycetes, and Gammaproteobacteria, *etc*). The results suggest that there is a certain correlation between gut microbiota and schizophrenia.

In this study, a correlation was identified between cognitive impairment and metabolic imbalance of gut microbiota. However, it is essential to acknowledge that the small sample size in this study may introduce some bias in the data. In the future, clinical trials with larger sample size should be conducted to provide more reliable data to guide the clinical treatment for patients with schizophrenia.

CONCLUSION

To summarize, this study revealed the presence of gut microbiota imbalance in schizophrenia patients and found the correlation between cognitive impairment and metabolic imbalance of gut microbiota in these patients. of intestinal flora, providing insights into the link between changes in gut microbiota and cognitive function, as well as the pathogenesis of schizophrenia. This research presents a novel approach that may pave the way for future treatments targeting schizo-

phrenia.

ARTICLE HIGHLIGHTS

Research background

Schizophrenia is a severe mental disorder characterized by impaired thinking, perception, emotion, and behavior. It affects the physical and mental health of the patients, leading to a high disability rate, burden, and suicide tendency. Cognitive dysfunction is a primary symptom of schizophrenia and includes mental cognition and social cognition. It can significantly impact the overall functioning and quality of life of individuals with schizophrenia. In recent years, there has been increasing recognition of the importance of cognitive function in schizophrenia. Cognitive impairment can not only predict the progression of the disease but also affect the treatment response and functional outcomes. Therefore, understanding the factors that contribute to cognitive impairment in schizophrenia is crucial for improving patient outcomes. Gut microbiota, a complex ecosystem of microorganisms residing in the gastrointestinal tract, has been found to play a role in regulating immune and inflammatory responses, as well as influencing neural development. Emerging evidence has suggested a potential connection between gut microbiota and psychiatric disorders, including schizophrenia. However, the specific relationship between gut microbiota and cognitive impairment in schizophrenia patients remains limited and requires further exploration.

Research motivation

Recent research has suggested a potential link between gut microbiota and psychiatric disorders, including schizophrenia. However, the specific relationship between gut microbiota and cognitive impairment in schizophrenia remains poorly understood. This knowledge gap necessitates further investigation to explore the potential role of gut microbiota in the cognitive dysfunction observed in schizophrenia.

The motivation behind this study is to bridge this gap by investigating the correlation between cognitive impairment and gut microbiota imbalance in patients with schizophrenia. By examining the composition of gut microbiota and evaluating cognitive function in a large sample of untreated schizophrenia patients, we aimed to shed light on the potential mechanisms underlying cognitive dysfunction in this population.

The findings of this study provide significant clinical implications and contribute to the development of novel therapeutic strategies targeting the gut microbiota to improve cognitive outcomes of patients with schizophrenia. Ultimately, this research aims to enhance the understanding of the complex interplay between gut microbiota and cognitive impairment in schizophrenia, leading to improved diagnosis, treatment, and overall management of this mental disorder.

Research objectives

The objective of this research was to explore the correlation between cognitive impairment and gut microbiota imbalance in patients with schizophrenia. The study compared the composition and abundance of gut microbiota in untreated schizophrenia patients and healthy controls, evaluated cognitive function using a consensus version of the cognitive function test package, and examined the relationship between specific microbial groups and cognitive function.

Research methods

The research employed a case-control study design. A total of 498 untreated schizophrenia patients admitted to the

hospital from July 2020 to July 2022 were selected as the case group, while 498 healthy volunteers who underwent physical examinations at the same hospital during the same period served as the control group. The composition and abundance of gut microbiota were assessed using fluorescence *in situ* hybridization to determine the total number of bacteria in fecal samples from both groups. Cognitive function was evaluated using a cognitive function test package consensus version, which assesses various dimensions of cognitive function. Statistical analysis was performed to compare the relative abundance of actinomycetes and other microbial groups between the case and control groups, as well as to examine the relationship between specific gut microbiota and cognitive function. The statistical significance level was set at $P < 0.05$.

Research results

The research findings revealed the correlation between gut microbiota and cognitive function in patients with schizophrenia. There was a statistically significant difference in the relative abundance of Actinomycetota between the case group and the control group, indicating an imbalance in the gut microbiota of schizophrenia patients. Moreover, compared to the control group, the schizophrenia patients demonstrated statistically significant differences in scores related to attention/alertness, and learning ability, suggesting impaired cognitive function in these areas. Furthermore, specific microbial groups showed correlations with cognitive function: Actinomycetota, Bacteroidota, Fusobacteria, and Proteobacteria were found to be positively associated with cognitive function, while the Coriobacteriia showed a negative correlation. These findings provide evidence of the influence of gut microbiota on cognitive impairment in schizophrenia patients and underscore the importance of addressing gut microbiota imbalance as a potential therapeutic target for improving cognitive outcomes in this population.

Research conclusions

In conclusion, this research confirmed a relationship between gut microbiota metabolic imbalance and cognitive function in patients with schizophrenia. The study findings indicate that when there is an imbalance in the composition of gut microbiota, the cognitive function of schizophrenia patients is more severely affected. The relative abundance of Actinomycetota was found to significantly differ between the case group and the control group, suggesting an imbalance in gut microbiota in schizophrenia patients. Additionally, specific microbial groups, including Actinomycetota, Bacteroidota, Fusobacteria, and Proteobacteria, were positively correlated with cognitive function, while the Coriobacteriia showed a negative correlation. These results emphasize the importance of addressing gut microbiota imbalances as a potential target for improving cognitive impairment in schizophrenia patients. Further research and interventions focused on modulating gut microbial composition and promoting gut health may lead to improved cognitive outcomes in this population.

Research perspectives

In future research, it is recommended to conduct longitudinal studies to observe changes in gut microbiota and cognitive function over time in schizophrenia patients, as well as intervention studies to investigate the effects of modulating gut microbiota on cognitive outcomes. Mechanistic studies can provide insights into the underlying mechanisms of the gut-brain axis in schizophrenia. The identification of specific gut microbiota markers as diagnostic or prognostic biomarkers for cognitive impairment, exploring individual differences, and developing personalized therapeutic strategies are also important areas for further investigation. By pursuing these research perspectives, we can advance our understanding of the role of gut microbiota in schizophrenia-related cognitive impairment and potentially develop targeted interventions to improve cognitive outcomes in this population.

Abstract

BACKGROUND

Studies have shown that sleep disorders are closely related to anxiety and depression, and the quality of life (QoL) of patients with sleep disorders is generally poor.

AIM

To examine the occurrence of sleep disorders in people with coronary heart disease (CHD) and their relationships with QoL, depression, and anxiety.

METHODS

As per the sleep condition, 240 CHD individuals were separated into two groups: non-sleep disorder group (n = 128) and sleep disorder group (n = 112). The self-rating anxiety scale (SAS), self-rating depression scale (SDS), and World Health Organization criteria for the Quality of Life Brief scale (WHOQOL-BREF) scores of the two groups were compared. Logistic regression method was used to analyze the independent risk factors of CHD patients with sleep disorders. Multivariate logistic regression analysis was employed to develop the risk prediction model. The association among the Pittsburgh Sleep Quality Index, SAS, and SDS was examined using Spearman's correlation analysis.

RESULTS

The incidence of sleep disorder was 46.67% in 240 patients. The scores of SAS and SDS in the sleep disorder group were higher than those in the non-sleep disorder group, and the WHOQOL-BREF scores were lower than those in the non-sleep disorder group ($P < 0.05$). The risk prediction model of sleep disturbances in CHD patients was constructed using the outcomes of multivariate logistic regression analysis, $P = 1/[1 + e (-2.160 + 0.989 \times (\text{female}) + 0.001 \times (\text{new rural cooperative medical insurance}) + 2.219 \times (\text{anxiety}) + 2.157 \times \text{depression})]$. The results of a Spearman's correlation study revealed that sleep quality was strongly adversely connected with the physiological field, psychological field, and social relation scores in QoL, and was considerably positively correlated with SAS and SDS ($P < 0.05$).

CONCLUSION

A multivariate logistic regression model can better predict the occurrence of sleep disorders in CHD patients. Sleep disorders in CHD patients are significantly correlated with QoL, depression, and anxiety.

Key Words: Coronary heart disease; Sleep disorder; Quality of life; Depression; Anxiety

Core Tip: Sleep disorder is a common clinical problem, and the correlation between sleep disorder and anxiety and depression has been widely discussed in clinical practice. This study explored the problem of sleep disorder in patients with coronary heart disease (CHD) and its correlation with anxiety, depression, and quality of life (QoL). The results showed that the incidence of sleep disorder is higher in patients with CHD, and is positively correlated with anxiety and depression, and negatively correlated with QoL.

INTRODUCTION

Coronary heart disease (CHD) can damage people's health and lead to death. Sleep disorders are a prevalent aspect of CHD that can have a negative effect on a patient's quality of life (QoL), cause coronary events, increase disease progression, and influence patients' survival[1,2]. As a result, treating patients' sleep disorders will enable them to have a longer life expectancy. Exploring the influencing factors of sleep disorders is conducive to further research and evaluation of sleep disorders in CHD patients. Patients with CHD are more likely to experience negative feelings, depression, and anxiety as a result of the disease, which affects their QoL. The reason may be that CHD is critical and difficult to treat and may be accompanied by symptoms such as angina pectoris or arrhythmia, and excessive worry may lead to anxiety and depression[3,4]. There is currently little research on the influence of anxiety and depression on the sleep quality of CHD patients, and there are also few studies on the influence of demographic and clinical factors on sleep problems in CHD patients.

Our present research aimed to study and explore the current status of sleep disorders in CHD patients and its correlation with QoL, depression, and anxiety to establish a standard for therapeutic prevention and management of sleep disturbances in individuals with CHD.

MATERIALS AND METHODS

Data sources

Clinical data were gathered from 240 CHD patients (114 females and 126 males) with an age range of 48-79 years (average age = 61.58 ± 6.93) referred to our facility between January 2020 and September 2022. The study inclusion criteria: (1) All patients met the Diagnostic Criteria for Coronary atherosclerotic Heart Disease[5]; (2) the vital signs were stable after treatment; (3) no history of drug abuse; and (4) patients with normal communication ability. Exclusion criteria were: (1) Patients with depression, schizophrenia, or other mental diseases; (2) patients with cognitive impairment; (3) patients with cerebrovascular disease or central nervous system disease; (4) patients with malignant tumor disease; and (5) patients with heart failure. This study was approved by the ethics committee.

Data collection

General data such as sex, age, disease type, smoking, marital status, hypertension, diabetes, family history of CHD, dyslipidemia, education level, working status, and type of medical insurance of all patients were collected.

Observation indexes

(1) The Pittsburgh Sleep Quality Index (PSQI)[6] score of 240 CHD patients was collected. Each of the seven evaluation items on the scale received a score between 0 and 3, for a range of 0 to 21 points. A score > 7 points denotes poor sleep quality and a sleep disorder, whereas a score of 7 points shows good sleep quality and no sleep disorders. The lower the score, the poorer the sleep quality. Then 240 patients with CHD were divided into the sleep disorder group and non-sleep disorder group according to the PSQI score, and the incidence of sleep disorder in 240 patients with CHD was calculated; (2) The self-rating anxiety scale (SAS)[7] and self-rating depression scale (SDS)[7] scores of CHD patients with and without sleep disturbances were collected and compared. There are 20 items in SAS scale; ≥ 50 is classified as anxiety, and the higher the score, the more serious the anxiety. The SDS scale consists of 20 items; ≥ 53 points indicates depression, and the higher the score, the more serious the degree of depression; (3) The World Health Organization criteria for the Quality of Life Brief scale[8] score of CHD patients with and without sleep disturbances were collected and compared. The scale includes four dimensions, namely physiology, psychology, environment, and social relation, and each dimension scores 0-100 points; (4) A comparison of the general data for the sleep disorder group and the non-sleep disorder group was done; (5) To examine independent risk factors of sleep problems in CHD patients, components with statistically significant variations in basic information were considered in the multivariate logistic regression analysis; (6) The logistic regression analysis findings were used to develop the risk prediction model. The area under the curve (AUC), receiver operating characteristic (ROC), and Hosmer-Lemeshow analyses were employed to examine the model's degree of correlation, and the ROC curve was constructed to demonstrate how effectively the model predicts results. The closer the AUC is to 1.0, the higher the prediction efficiency; and (7) The association among PSQI, SAS, and SDS was investigated using Spearman's correlation analysis.

Statistical analyses

Two individuals working independently entered the study data into Excel tables, and SPSS 24.0 statistical software was employed to examine and interpret the data. The experimental data are expressed as the mean ± SD, and the *t*-test was used to compare homogeneous and normally distributed data. Numbers "*n*" and percentages "%" were employed to characterize the counting data, and the χ^2 test was performed to compare groups. For multivariate analyses, a logistic regression model was utilized, and Spearman's correlation analysis was performed for correlation analyses. The threshold for statistical significance was set at $P < 0.05$ for all bilateral tests.

RESULTS

Comparison of the incidence of sleep disorders in CHD patients

Among the 240 patients, 112 CHD patients had PSQI scores > 7 points and had a sleep disorder, with an incidence of 46.67%.

Comparison of QoL, depression, and anxiety scores of CHD individuals with sleep disorder and without sleep disorders

As can be seen in Table 1, the difference between the SDS and SAS scores in both groups was statistically significant ($P < 0.05$; Figure 1).

Comparison of QoL scores of CHD patients in both groups

The sleep disorder group scored lower on the social relation, psychological field, and physiological field compared to the non-sleep disorder group ($P < 0.05$). Environmental field scores between the two groups were not significantly different ($P > 0.05$) (Figure 2, Table 2).

Single-factor analysis of sleep disorders in CHD patients

No significant difference was observed in both groups in terms of disease type, smoking, marital status, hypertension, diabetes, family history of CHD, dyslipidemia, educational level, and working status. In the group of people with sleep disorders, there were more female patients ($P < 0.05$), patients under the age of 60, individuals in new rural cooperative medical systems, and patients with anxiety and depression (Table 3).

Multivariate logistic regression investigation of sleep disorders in individuals with CHD

The parameters with significant differences in the univariate study of sleep quality disorders in CHD patients were subjected to multivariate logistic regression analysis. The sleep disorder of patients was taken as dependent variables, and sex, age, medical insurance type, anxiety and depression were taken as independent variables (Table 4). Multivariate logistic regression analyses showed that females, new rural cooperative medical insurance, depression, and anxiety were independent risk factors for sleep disorders in individuals with CHD ($P < 0.05$; Table 5).

Establishment and calibration of the multivariate logistic regression model

The risk prediction model of sleep disturbances in CHD patients was established using the results of a multivariate logistic regression study, $P = 1/[1 + e (-2.160 + 0.989 \times (\text{female}) + 0.001 \times (\text{new rural cooperative medical insurance}) + 2.219 \times (\text{anxiety}) + 2.157 \times \text{depression})]$, and the Hosmer-Lemeshow test was used, $\chi^2 = 7.284$, $P = 0.506$, indicating a good

fit between the model and the observed values, as shown in Figure 3.

Prediction efficiency of the logistic regression model

Figure 4 illustrates the outcomes of ROC analysis, which revealed that the model had a good predictive effect ($P < 0.05$). Moreover, the AUC of the risk prediction model for sleep disorders in CHD patients was 0.851 with a 95% confidence interval (CI) of 0.803-0.900.

Correlation between sleep disorders and anxiety, depression, and QoL

As indicated in Table 6, Spearman's correlation analysis revealed that sleep quality exhibited a strong negative association with the physiological field, psychological field, and social relations of QoL, and was positively associated with SAS and SDS ($P < 0.05$; Figures 5 and 6).

DISCUSSION

Sleep disturbances have been linked to an increased risk of CHD and the development of CHD, according to several studies conducted both domestically and internationally[2,9,10]. Disease factors, psychological factors, and environ-

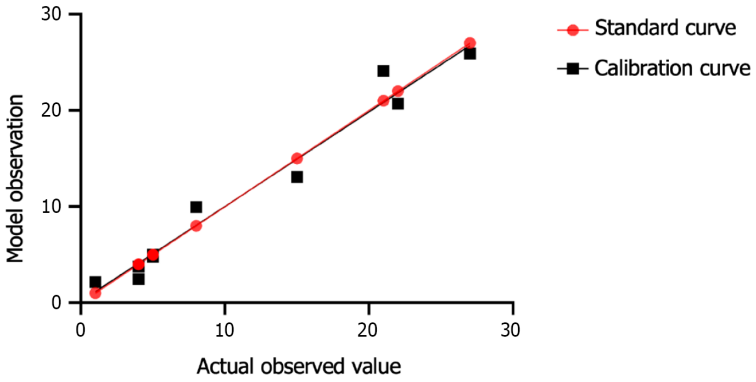
SAS: Self-rating anxiety scale; SDS: Self-rating depression scale.



mental factors can affect the sleep quality of CHD patients. In this study, 46.67% of 240 CHD patients had sleep disorders, accounting for a relatively high proportion. Sleep disorders in CHD patients are very serious and should be paid attention to. In this study, CHD patients with sleep disorders had higher SAS and SDS scores than CHD patients without sleep disorders, and their QoL scores were substantially lower than those of patients without sleep disorders, showing that sleep disorders can have an impact on a patient's psychological health and QoL.

Multivariate logistic regression analyses showed that females, new rural cooperative medical insurance, depression, and anxiety were independent risk factors for sleep disorders in individuals with CHD ($P < 0.05$). According to research by Ulander *et al*[11], women are more prone than men to experience sleep disorders. According to Wang *et al*[12], female cancer patients have an increased incidence of sleep disorders. In line with the aforementioned study, these findings

support the previous study by showing that sex is a definite risk factor for anxiety problems in patients with CHD. It is speculated that the reason may be that female patients are more sensitive, their mood is easy to fluctuate, and their sleep quality is easy to be affected. The specific reason needs to be further explored. Most patients with the new rural cooperative medical insurance are rural patients. They are not as economically secure as patients in metropolitan areas, and there are disparities in the payment rates between the employee medical insurance and the new rural cooperative medical insurance, which adds to the financial strain on patients and their families and impairs patient sleep. The new

rural cooperative medical insurance is thus a significant risk factor for sleep problems in CHD patients in this study.

Sejbuk *et al*[9] reported that anxiety is a negative factor affecting sleep quality. Bonanni *et al*[13] also believe that depression and anxiety are related to menopause insomnia. Anxiety and depression were found to be independently associated risk factors for sleep disorders in this investigation, which was similar to previous research findings. CHD patients have serious physical discomfort and reduced QoL, and their strong concern for prognosis is easy to affect sleep quality. Long-term sleep disorders can lead to increased blood pressure, cardiovascular system dysfunction and neurological dysfunction, and further, aggravate psychological stress[14,15]. By contrast, anxiety, depression, and other adverse emotions can seriously affect the endocrine of patients, causing body discomfort symptoms such as palpitation and chest tightness, further affecting sleep and leading to sleep disorders[16-18]. To increase the quality of their sleep, patients with depression and anxiety should receive psychological treatment, while female CHD patients and CHD patients with new rural cooperative medical insurance should receive clinical attention. A sleep disorder prediction model was developed using multivariate logistic regression, and its prediction performance was assessed using the ROC curve. This prediction model's AUC value was 0.851 (95%CI = 0.803-0.900), showing that it has a strong predictive value for sleep problems in CHD patients.

Sleep disorder is a process of dual physiological and psychological disorders[19], and some anxiety and depression patients tend to shift more attention to sleep problems, trying to improve physiological and psychological disorders by adjusting sleep, but they are more likely to be nervous, and further aggravate sleep disorders, forming a vicious cycle. Long-term anxiety, depression and sleep disorders cause and affect each other, seriously affecting patients' work and life, and in severe cases, it may lead to functional disorders and further reduce the QoL. In addition, sleep disorders are one of the main characteristics of depression, mainly manifested by early waking, difficulty in maintaining sleep, and waking dysthymic tendencies. Serious anxiety and depression can cause psychological stress and lead to autonomic nervous disorder, and the wake-up system of the brain related to sleep and the hypnotic system is in an unbalanced state, and the excitation of the wake-up system will further lead to sleep disorders[20-22].

Adverse emotions such as anxiety and depression before bedtime can promote the activity of the reticuloendothelial system, promote the release of norepinephrine, enhance the activity of the body, and cause sleep disorders. In this study, the Spearman's correlation study showed that sleep quality was inversely correlated with the physiological field, psychological field, and social relations in QoL and positively associated with SAS and SDS. This finding implies that patients with sleep disorders should focus on enhancing their poor mood and QoL to prevent an unnecessary vicious cycle that negatively affects their prognosis. The shortcoming of the present work is that it included too few influencing factors and could not identify the reason for the high incidence of sleep disorders. Besides, it only used SAS and SDS scales to conduct a simple psychological assessment of patients, and in-depth structured psychological interviews are not conducted, which may lead to bias in survey results. Therefore, it is necessary to increase the analysis of influencing factors for further and in-depth exploration.

CONCLUSION

In summary, risk variables for sleep disturbances in CHD patients include sex, new rural cooperative medical insurance, depression, and anxiety. The risk factor prediction model established by multivariate logistic regression has good predictive efficacy. The considerable inverse relationship between sleep disorders and QoL and the substantial positive relationship between sleep disorders and depression and anxiety suggests that individuals may be able to improve their depressive moods through psychological counselling and break the vicious cycle of mutual influence between a bad mood and sleep quality. In terms of economic pressure, cost-effective treatment programs can be selected for patients as far as possible to reduce the economic pressure on patients' families, which is conducive to improving their bad mood, improving their sleep quality and QoL, and improving their prognosis.

ARTICLE HIGHLIGHTS

Research background

Studies have shown that sleep disorders are closely related to anxiety and depression, and the quality of life (QoL) of patients with sleep disorders is generally poor. The significance of this study is to explore the status quo and risk factors of sleep disorders in patients with coronary heart disease (CHD) and their correlation with anxiety, depression and QoL. To provide reference for the prevention and treatment of sleep disorders in clinical CHD.

Research motivation

The current status of sleep disorders in patients with CHD is the main topic of this study. At present, it is clinically necessary to explore the current status of sleep disorders in patients with CHD and its correlation with anxiety, depression and QoL, so as to provide reference for the prevention and treatment of patients with CHD sleep disorders. The significance of this study is to explore the risk factors of patients with CHD sleep disorders and their correlation with anxiety, depression and QoL, encourage clinical teams to continue to explore CHD sleep disorders, and promote the continuous progress of sleep disorder prevention and treatment technology.

Research objectives

The incidence of sleep disorders in patients with CHD was 46.67%. Sex, female, new rural cooperative medical insurance, anxiety and depression were independent risk factors for CHD sleep disorders. It was confirmed that CHD sleep disorders were closely related to anxiety, depression and QoL, providing a new reference for clinical prevention and treatment of CHD sleep disorders in the future.

Research methods

The clinical data of patients were retrospectively analyzed, and the patients were divided into the sleep disorder group and the non-sleep disorder group according to their sleep conditions. The general data of the two groups were statistically analyzed by independent sample *t*-test and χ^2 test. The risk factors of sleep disorders in patients with CHD were analyzed by the logistic multivariate regression method and a risk prediction model was built. Receiver operating characteristic was used to analyze the effectiveness of the risk prediction model, and Spearman's correlation was used to analyze the correlation between sleep disorders and anxiety, depression, and QoL.

Research results

Patients with CHD sleep disorder are closely related to anxiety, depression and QoL, and sex, female, new rural medical insurance, anxiety and depression are risk factors for patients with CHD sleep disorder, providing a new reference for the prevention and treatment of patients with CHD sleep disorder. It is necessary to further expand the sample size to explore the influencing factors of patients with CHD sleep disorder.

Research conclusions

Patients with CHD sleep disorders can interact with anxiety and depression, forming a vicious circle, so clinical attention should be paid to psychological intervention for patients with CHD sleep disorders.

Research perspectives

Sleep disorders in patients with CHD are closely related to anxiety and depression, which can have a negative impact on QoL. Emotional intervention methods can be used to improve sleep disorders and QoL in patients with CHD.

Abstract

BACKGROUND

Considering the limited effectiveness of clinical interventions for knee osteoarthritis (KOA), it is necessary to continue to explore appropriate and effective treatment strategies to improve the condition of KOA patients.

AIM

To clarify the influence of ankle flexion and extension exercises combined with a psychological intervention on the psychological status and activities of daily living (ADLs) of patients with KOA.

METHODS

The research participants were 116 KOA patients admitted to The First Affiliated Hospital of Guizhou University of Traditional Chinese Medicine between May 2019 and May 2022, including 54 patients receiving routine treatment, care and psychological intervention (control group) and 62 patients additionally treated

with ankle flexion and extension exercises (research group). The two groups were comparatively analyzed in terms of psychological status (Self-rating Anxiety/Depression Scale, SDS/SAS), ADLs, knee joint function (Lysholm Knee Scoring Scale), pain (Visual Analog Scale, VAS), fatigue (Multidimensional Fatigue Inventory, MFI), and quality of life (QoL; Short-Form 36 Item Health Survey, SF-36).

RESULTS

After evaluation, it was found that the postinterventional SDS, SAS, VAS, and MFI scores in the research group were significantly reduced compared with the baseline (before the intervention) values and those of the control group, while the postinterventional Lysholm, ADL and SF-36 scores were markedly elevated.

CONCLUSION

Therefore, ankle flexion and extension exercises are highly effective in easing negative psychological status, enhancing ADLs, daily living ability, knee joint function and QoL, and relieving pain and fatigue in KOA patients, thus warranting clinical promotion.

Key Words: Ankle flexion and extension exercises; Knee osteoarthritis; Psychology; Negative emotions; Activities of daily living; Quality of life

INTRODUCTION

Knee osteoarthritis (KOA) is a chronic, inflammatory and degenerative joint disease that predominates in middle-aged and elderly women and is pathologically characterized by cartilage degeneration and bone overgrowth (osteophyte and subchondral thickening)[1-3]. KOA patients suffer from joint pain, swelling, stiffness, deformity, and dysfunction, which not only negatively affect patients' activities of daily living (ADLs) to varying degrees but also cause psychological distress to patients, affecting their quality of life (QoL); hence, it is also paramount to intervene in patients psychologically[4,5]. An in-depth analysis of the causes of KOA revealed that abnormal joint loads such as excessive exercise and past sprains, mechanical injuries, age, obesity, diet and genetic factors are factors that increase the risk of developing KOA[6]. According to epidemiological data, KOA is one of the important causes of lower-limb disability in the elderly population and may affect 40% of men and 47% of women, with an incidence of 60% among middle-aged and elderly individuals[7,8]. The pathogenesis of KOA is complicated. Although many attempts have been made to suppress the course of KOA, it is still necessary to continue to explore suitable and effective treatment strategies to improve the condition of KOA patients.

There are many clinical treatment options for KOA, including weight loss, exercise, painkillers, intra-articular hyaluronic acid, and joint replacement surgery[9]. Weight loss is mainly applicable to obese patients, while analgesics, intra-articular hyaluronic acid, and joint replacement surgery carry certain medication or surgical risks, especially for elderly patients with serious diseases[10]. Therefore, this study included an in-depth exploration of therapeutic strategies for KOA patients from the perspective of exercise. Exercise therapy, as a lifestyle intervention, mainly strengthens blood circulation by regulating venous reflux and congestion, thus increasing joint range of motion and muscle strength while positively influencing joint stability[11,12]. Ankle flexion and extension exercise is an exercise mode mainly based on ankle plantar flexion and ankle dorsiflexion, which has a positive effect on lower-limb blood circulation and muscle strength[13]. A report suggests that passive ankle flexion and extension exercises in elderly KOA patients can significantly resolve symptoms and pain with a certain degree of safety, suggesting the clinical application potential of this exercise program.

Considering that there are few studies on the clinical application of ankle flexion and extension exercises combined with a psychological intervention in KOA, this study evaluated the potential clinical value of these interventions from the aspects of psychology and ADLs.

MATERIALS AND METHODS

Patient source

The study population comprised 116 KOA patients admitted to The First Affiliated Hospital of Guizhou University of Traditional Chinese Medicine between May 2019 and May 2022, including 54 patients receiving routine treatment and nursing (control group) and 62 patients additionally given ankle flexion and extension exercises (research group). The two patient groups did not differ much in baseline data and had clinical comparability ($P > 0.05$).

Criteria for patient enrollment and exclusion

Inclusion criteria were as follows: in accordance with the diagnostic criteria for KOA[14]; primary disease; intermittent joint narrowing, subchondral osteosclerosis, or cystic degeneration shown by radiographs; complete medical records; normal comprehension and expression ability; and high compliance.

The exclusion criteria were as follows: history of knee joint trauma or surgery; knee joint redness, swelling, heat pain, and obvious limitation of motion; complications with other serious chronic diseases that are not suitable for routine functional exercise; and cardio-cerebrovascular diseases, malignant tumors, or coagulation dysfunction.

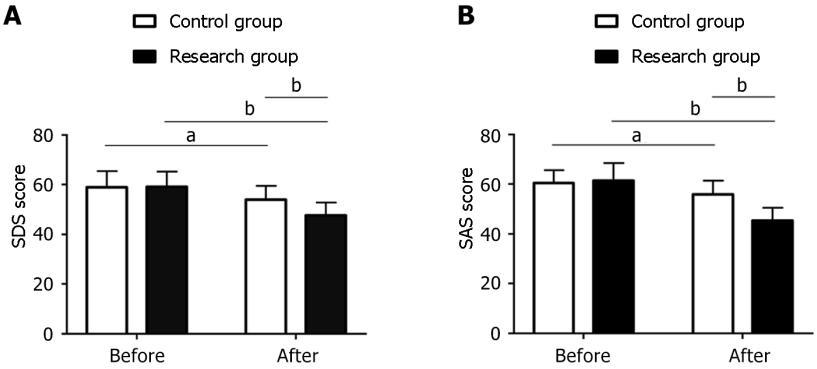
Methods

The control group received routine therapy. A comfortable hospitalization environment was provided for patients. Meanwhile, nursing staff patiently addressed the doubts and concerns of patients and their families and provided vital sign monitoring, dietary guidance, psychological care, health education, nursing-patient interaction, and local massage. In addition, patients were informed of matters to be noted during the convalescence period to prevent and control the occurrence of complications and were assisted in relieving limb symptoms and reducing the pain of the primary lesion as much as possible. The psychological intervention is described below. First, relevant health education was carried out, and the etiology of KOA and the mechanism and purpose of the treatment were explained to patients in plain language to enhance their disease awareness and better understand the treatment methods, thus improving their cooperation as much as possible. Second, by enumerating patients who experienced positive outcomes (patients who experienced an ideal curative effect after following the doctor's advice) and patients who experienced negative outcomes (patients who experienced unsatisfactory curative effects due to noncompliance with the doctor's advice), the patients developed a greater realization of the importance and necessity of following the doctor's advice. Third, during the treatment, medical staff actively asked patients about their treatment feelings to optimize patients' treatment experience and find potential problems in time to give reasonable suggestions. Patients' psychological status was also considered, and psychological counseling was given in a timely manner. Moreover, the hospital provided a quiet and comfortable environment for patients so that they could take the initiative to receive diagnosis and treatment.

In addition to the measures implemented in the control group, the research group was also treated with cognitive education and ankle flexion and extension exercises. The cognitive education intervention is described below. Health and KOA-related cognitive education was conducted through multimedia lectures, mainly teaching the characteristics, functions, pathological mechanisms, risk factors and treatment methods of KOA, so that patients could understand the therapeutic value and mechanism of exercise therapy in KOA. Ankle flexion and extension exercise methods were as follows: (1) Supine ankle flexion and extension: The patient took the supine position with toes pointing to the ceiling as the starting position; the ankles were flexed and kept in that position for 10 s, followed by ankle dorsolateral extension that was maintained for 10 s before returning to the initial posture. The above exercises were performed for 20 repetitions per set with 5 sets per session and a 1-min break between sets; (2) Ankle flexion and extension in the seated position: The patient sat on the chair, with feet flat on the ground and toes pointing straight ahead; ankle plantar flexion of both feet was performed for 10 s, followed by ankle dorsiflexion for 10 s; finally, the patient returned to the initial posture. The above exercises were performed for 20 repetitions per set with 5 sets per session and a 1-minute rest between sets; and (3) Ankle flexion and extension in the standing position: The patient took a comfortable standing posture with one or both hands placed on the table or wall for support; foot plantar flexion followed by ankle dorsiflexion was performed; finally, the patient returned to the initial posture. The above exercises were performed for 10 repetitions per set with 5 sets per session and a 1-min break between sets. The ankle flexion and extension exercises in these three positions were performed in turn, that is, supine ankle flexion and extension on the first day, seated ankle flexion and extension on the second day, and standing ankle flexion and extension on the third day. Both groups were treated for three months.

Outcome measures

Psychological state. We used the Self-rating Depression/Anxiety Scale (SDS/SAS)[15] to evaluate patients' depression and anxiety before and after the intervention. Both scales have 20 items and a score range of 0-80 points, with the scores in direct proportion to the patient's depressive and anxious symptoms.



ADLs. Patients were evaluated before and after the intervention using the ADL Scale[16] for feeding, bathing, dressing, decorating, continence, and toileting domains, with a maximum score of 100. A higher score suggests a more significant improvement in patients' ADLs.

Knee joint function. Knee joint function assessment was made before and after treatment using the Lysholm Knee Scoring Scale[17], with the evaluation contents including pain, swelling, limping, blocking, instability, crouching, and climbing stairs. On a 100-point scale, higher scores are associated with better recovery of knee function.

Degree of pain. Before and after the intervention, patients were also assessed by the Visual Analog Scale (VAS; score range: 0-10)[18] to determine the degree of pain. The score is directly proportional to the degree of pain.

Table 1 Analysis of baseline data of knee osteoarthritis patients in the two groups

Factors	Control group (n = 54)	Research group (n = 62)	χ^2/t value	P value
Age (yr)	59.46 ± 6.95	58.55 ± 6.82	0.711	0.479
Sex (male/female)	25/29	27/35	0.894	0.466
Disease course (yr)	5.20 ± 2.55	5.37 ± 2.67	0.349	0.728
Single knee disease (yes/no)	38/16	41/21	0.813	0.269
Cause of illness (excessive exercise/sprain/others)	25/19/10	29/21/12	0.406	0.705
Education level (junior high school and below/senior high school and above)	34/20	38/24	0.404	0.725

DOI: 10.5498/wjp.v13.i10.743 **Copyright** ©The Author(s) 2023.

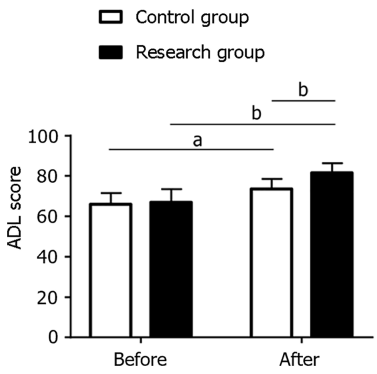
Figure 1 Analysis of the influence of ankle flexion and extension exercises on knee osteoarthritis patients' psychological state. A: The research group had a postinterventional Self-Rating Depression Scale score that was lower than the preinterventional value and that of the control group; B: The research group had a postinterventional Self-Rating Anxiety Scale score that was lower than the preinterventional value and that of the control group. Note: $^aP < 0.05$; $^bP < 0.01$. SDS: Self-Rating Depression Scale; SAS: Self-Rating Anxiety Scale.

Fatigue. The fatigue of patients before and after the intervention was evaluated by the Multidimensional Fatigue Inventory (MFI)[19], a tool with a score ranging from 20 to 100 that is positively related to fatigue.

QoL. Finally, we assessed patients' QoL from eight dimensions [physical functioning (PF); role-physical (RP); bodily pain (BP); social functioning (SF); general health (GH); mental health (MH); role-emotional (RE), and vitality (VT) by referring to the Short-Form 36 Item Health Survey (SF-36)]. Each dimension has a score of 0-10 that is positively correlated with QoL.

Statistical methods

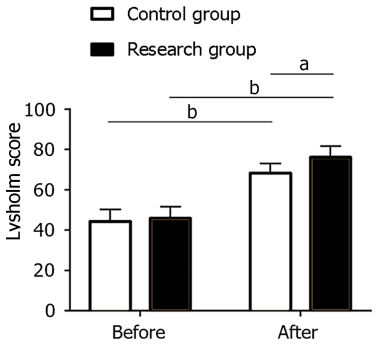
The mean ± SEM was used to describe the measurement data, and the independent-samples t-test was used to compare two sets of measurement data. The intergroup comparison of count data expressed by percentages (%) was made by the χ^2 test. Data analysis was performed using SPSS 19.0, and the significance threshold was $\alpha = 0.05$.



RESULTS

Analysis of baseline data of KOA patients in the two groups

Baseline data such as age, sex, course of disease, single knee disease, cause of disease and education level of KOA patients in the two groups were compared and analyzed, and no significant differences were found ($P > 0.05$). See Table 1.



Analysis of the influence of ankle flexion and extension exercises on KOA patients' psychological state

We evaluated patients' negative psychological state by using the SDS and SAS. The results showed no significant difference in the two scale scores between the research and control groups prior to intervention [SDS: (59.15 ± 6.05) score *vs* (58.91 ± 6.44) score, SAS: (61.34 ± 7.13) score *vs* (60.37 ± 5.31) score, $P > 0.05$]. An obvious reduction in both scales was found in the two groups after the intervention [SDS: (47.60 ± 5.21) score *vs* (54.02 ± 5.51) score, SAS: (45.32 ± 5.16) score *vs* (55.83 ± 5.62) score, $P < 0.05$], especially in the research group ($P < 0.05$). See Figure 1.

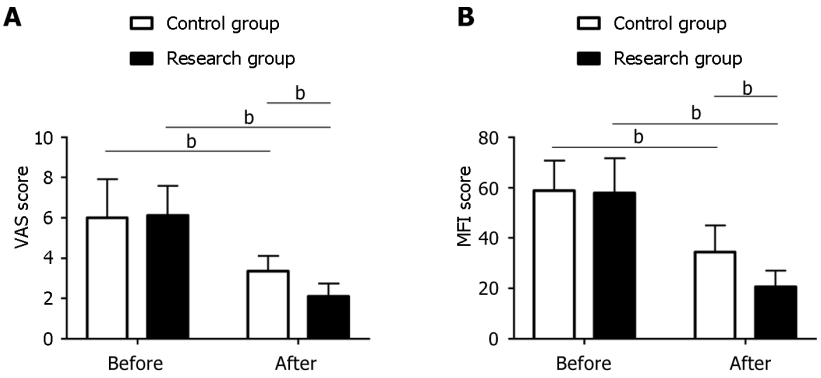
Figure 3 Analysis of the influence of ankle flexion and extension exercises on knee osteoarthritis patients' knee joint function. The research group had a postinterventional Lysholm score that was higher than the preinterventional value and that of the control group. [a]*P* < 0.05; [b]*P* < 0.01.

Analysis of the impact of ankle flexion and extension exercises on KOA patients' ADLs

KOA patients' ADLs were assessed by the ADL scale. The ADL score did not differ markedly between the groups prior to intervention (66.97 ± 6.53) score *vs* (65.98 ± 5.65) score, $P > 0.05$), but it was elevated in both groups after the intervention (81.44 ± 4.95) score *vs* (73.50 ± 5.13) score, $P < 0.05$), with a higher postinterventional score in the research group ($P < 0.05$). See Figure 2.

Analysis of the influence of ankle flexion and extension exercises on KOA patients' knee joint function



Knee function was assessed in both groups of KOA patients using the Lysholm Knee Scoring Scale. The two groups also showed similar Lysholm scores before the intervention (45.89 ± 5.69) score *vs* (44.43 ± 5.79) score, $P > 0.05$. An evident elevation in the Lysholm score was found in both arms after the intervention, with an even higher score in the research group (76.40 ± 5.25) score *vs* (68.39 ± 4.74) score, $P < 0.05$. See Figure 3.

Analysis of the impact of ankle flexion and extension exercises on pain and fatigue in KOA patients

By evaluating the VAS and MFI scores of both groups, the pain and fatigue status of KOA patients were determined. VAS and MFI scores were found to be similar in the two groups before the intervention [VAS: (6.11 ± 1.47) score *vs* (6.00 ± 1.91) score, MFI: (57.87 ± 13.85) score *vs* (58.81 ± 11.94) score, $P > 0.05$], but they were significantly reduced after the intervention, with even lower scores in the research group [VAS: (2.11 ± 0.63) score *vs* (3.35 ± 0.76) score, MFI: (20.55 ± 6.61) score *vs* (34.48 ± 10.50) score, $P < 0.05$]. See Figure 4.

Analysis of the impact of ankle flexion and extension exercises on KOA patients' QoL

The QoL of KOA patients in both groups was evaluated using the SF-36 scale. The data revealed no significant difference in SF-36 scores between the research and control groups before the intervention ($P > 0.05$). The SF-36 scores of both arms showed a significant upward trend after the intervention ($P < 0.05$), with a more significant increase in the research group ($P < 0.05$). See Figure 5.

Figure 4 Analysis of the impact of ankle flexion and extension exercises on knee osteoarthritis patients' pain and fatigue. A: The research group had a postinterventional Visual Analog Scale score that was lower than the preinterventional value and that of the control group; B: The research group had a postinterventional MFI score that was lower than the preinterventional value and that of the control group. $^{a}P < 0.05$; $^{b}P < 0.01$. VAS: Visual Analog Scale; MFI: Multidimensional Fatigue Inventory.

DISCUSSION

KOA, with complex pathological mechanisms and triggers that are not fully understood, has no effective treatment at present[20]. Ankle flexion and extension exercises, as a type of exercise rehabilitation therapy, integrate and apply the knowledge of sports medicine, rehabilitation medicine, biomechanics and modern functional anatomy to provide KOA patients with an evidence-based exercise intervention[21]. In the research of Abbott *et al*[22], exercise therapy was proven to be beneficial to physical function recovery in KOA patients, suggesting the potential value of ankle flexion and extension exercises in KOA. In another study, exercise therapy was more effective in treating KOA than conventional therapy, contributing to more significant pain reduction and improved function and QoL[23]. Psychological intervention is a measure centered on patients' psychological state and emotional experience, which can improve patients' functional outcomes by eliminating or alleviating their psychological distress[24]. Previous studies have shown that psychological intervention can play a positive role in reducing the severity of KOA symptoms and improving life satisfaction by establishing a positive attitude toward illness[25].

According to the negative psychological state investigation in this study, the research group had markedly reduced SDS and SAS scores after the intervention, which were lower than those of the control group, suggesting that ankle flexion and extension exercises combined with a psychological intervention have a good regulatory effect on the negative psychological state of KOA patients. Song *et al*[26] reported that modified Tai Chi exercises, as a kind of kinesitherapy, can significantly relieve anxiety and depression in elderly female patients with KOA, similar to our findings. Negative emotions such as anxiety and depression in KOA patients have been shown to be related to factors such as high pain levels[27]. In this study, the research group who received ankle flexion and extension exercises experienced a significant reduction in pain levels after the intervention, which may help explain its relieving effect on negative emotions. Furthermore, in the investigation of ADLs, the research group showed a postinterventional ADL score that was evidently higher than the baseline and that of the control group, indicating that ankle flexion and extension exercises combined with a psychological intervention are beneficial to significantly improve the ADLs of KOA patients. This may be attributed to the improvement in muscle strength and range of motion in patients after ankle flexion and extension exercises, thus reducing activity limitations in such patients[28]. Subsequently, knee function analysis revealed markedly increased Lysholm scores in the research group that were higher than those in the control group after the intervention, which indicates that ankle flexion and extension exercises combined with a psychological intervention are conducive to enhancing the knee joint function of KOA patients. Exercise therapy, such as ankle flexion and extension exercises, has also been reported to alleviate KOA by enhancing muscle strength, restoring neuromotor control and improving the range of joint motion[29]. Later, the analysis of pain and fatigue showed marked reductions in VAS and MFI scores in the research group that were significantly lower than those in the control group, demonstrating that ankle flexion and extension exercises combined with a psychological intervention are significantly effective in mitigating pain and fatigue in KOA patients. Peeler *et al*[30] noted in their study that low-load exercise for KOA patients has significant advantages in improving ADLs and knee joint function, with a potent pain-relieving effect, which can support our research results. In addition, the fatigue of KOA patients is primarily associated with pathological pain and decreased physical function[31]. The alleviation of fatigue in KOA patients may be related to the reduction of pain and improvement of body function by ankle flexion and extension exercises, which agrees with the research results reported by Casilda-López *et al*[32]. Finally, the QoL assessment showed that the SF-36 scores of the research group increased significantly after the intervention and were markedly higher than those of the control group, indicating that ankle flexion and extension exercises combined with a psychological intervention can significantly boost QoL in KOA patients.

CONCLUSION

Taken together, while resulting in psychological relief and improvement of ADLs, ankle flexion and extension exercises combined with a psychological intervention can effectively restore knee joint function and mitigate pain and fatigue in KOA patients, thus playing a positive role in improving the quality of life of patients and warranting clinical promotion.

ARTICLE HIGHLIGHTS

Research background

Given the limited efficacy of clinical intervention in knee osteoarthritis (KOA), it is necessary to continue to explore appropriate and effective treatment strategies to improve the condition of KOA patients.

Research motivation

The pathogenesis of KOA is complex, and exploring effective treatment strategies is of great significance for the prevention and treatment of this disease.

Research objectives

The aim of this study is to clarify the influence of ankle flexion and extension exercises combined with psychological intervention on the psychology and activities of daily living (ADLs) of patients with KOA.

Research methods

The research participants were 116 KOA patients admitted between May 2019 and May 2022, including 54 cases receiving routine treatment, care and psychological intervention (control group) and 62 cases additionally treated with ankle flexion and extension exercises (research group) on the basis of the control group. The two groups were comparatively analyzed in terms of psychological status (Self-rating Anxiety/Depression Scale, SDS/SAS), ADLs (ADL scale), knee joint function (Lysholm Knee Scoring Scale), pain (Visual Analogue Scale, VAS), fatigue (Multidimensional Fatigue Inventory, MFI), and quality of life (QoL; Short-Form 36 Item Health Survey, SF-36).

Research results

After evaluation, it was found that the postinterventional SDS, SAS, VAS, and MFI scores in the research group were significantly reduced compared with the baseline (before the intervention) values and those of the control group, while the postinterventional Lysholm, ADL, and SF-36 scores were markedly elevated.

Research conclusions

Ankle flexion and extension exercises are highly effective in easing negative psychology, enhancing ADLs, knee joint function and QoL, and relieving pain and fatigue in KOA patients, which is worthy of clinical promotion.

Research perspectives

In addition to the positive effect on the negative psychological relief and improvement of ADLs of KOA patients, ankle flexion and extension exercises combined with a psychological intervention can also effectively restore knee joint function, alleviate pain and fatigue, and enhance patients' quality of life, providing an effective treatment option for KOA patients.

Abstract

BACKGROUND

Patients with chronic hepatitis B (CHB) experience various problems, including low psychological flexibility, negative emotions, and poor sleep quality. Therefore, effective nursing interventions are required to reduce adverse events. Acceptance and commitment therapy (ACT) combined with enabling cognitive-behavioral education (ECBE) can improve patients' psychological and sleep. Therefore, we speculate that this may also be effective in patients with CHB.

AIM

To investigate the effects of different intervention methods on psychological flexibility, negative emotions, and sleep quality in patients with CHB.

METHODS

This retrospective study examined clinical and evaluation data of 129 patients with CHB. Intervention methods were divided into a conventional group (routine nursing, $n = 69$) and a combination group (ACT combined with ECBE, $n = 60$). We observed changes in psychological flexibility, negative emotions, sleep quality, and self-care ability in both groups. Observation items were evaluated using the Acceptance and Action Questionnaire-2nd Edition (AAQ-II), Self-Rating Anxiety Scale (SAS), Self-Rating Depression Scale (SDS), Pittsburgh Sleep Quality Index (PSQI), and Exercise of Self-Care Agency Scale (ESCA).

RESULTS

Compared with the conventional group, the AAQ-II score of the combined group was lower ($F_{\text{between-group effect}} = 8.548$; $F_{\text{time effects}} = 25.020$; $F_{\text{interaction effects}} = 52.930$; all $P < 0.001$), the SAS score ($t = 5.445$) and SDS score ($t = 7.076$) were lower (all $P < 0.001$), as were the PSQI dimensions ($t_{\text{sleep quality}} = 4.581$, $t_{\text{fall sleep time}} = 2.826$, $t_{\text{sleep time}} = 2.436$, $t_{\text{sleep efficiency}} = 5.787$, $t_{\text{sleep disorder}} = 5.008$, $t_{\text{hypnotic drugs}} = 3.786$, $t_{\text{daytime dysfunction}} = 4.812$); all $P < 0.05$). The ESCA scores for all dimensions were higher ($t_{\text{health knowledge level}} = 6.994$, $t_{\text{self-concept}} = 5.902$, $t_{\text{self-responsibility}} = 19.820$, $t_{\text{self-care skills}} = 8.470$; all $P < 0.001$).

CONCLUSION
ACT combined with ECBE in patients with CHB can improve psychological flexibility and sleep quality, alleviate negative emotions, and improve self-care.

Key Words: Acceptance and commitment therapy; Empowerment cognitive-behavioral education; Chronic hepatitis B; Psychological flexibility; Negative emotion; Sleep quality

Core Tip: Chronic hepatitis B (CHB) is an infectious and progressive disease requiring basic treatment supplemented with effective nursing interventions. We analyzed the clinical data of 129 patients with CHB. Acceptance and commitment therapy combined with cognitive-behavioral education improved the psychological flexibility and sleep quality of patients with CHB, relieve negative emotions, and improve self-care ability, making a breakthrough in the problem of insufficient routine care.

INTRODUCTION

Chronic hepatitis B (CHB) is a frequent chronic infectious disease. According to the World Health Organization in 2017 [1], the number of CHB infections worldwide reached 257 million. Approximately 900000 people worldwide die each year from hepatitis B virus (HBV) infection or its complications[1]. Due to the mutual influence of physiological, psychological, and social factors, patients with CHB often have various sleep disorders, thus reducing the therapeutic effect[2]. Drug therapies such as conventional antiviral therapy combined with effective nursing interventions can control disease progression[3].

Bedside delivery of health education to the patient improves understanding and self-management[4]. However, after receiving education, patients still have an insufficient sense of participation, low mastery of disease knowledge, and no change in incorrect understandings. Additionally, their psychological and behavioural adaptation to the disease is not obvious, and most patients have unresolved problems such as anxiety, depression, and poor sleep. This is related to the lack of conventional health education and targeted psychological counselling[5]. Moreover, the lack of routine CHB care is a clinical problem that needs to be resolved.

Acceptance and commitment therapy (ACT) is a new type of cognitive behavioral therapy based on functional contextualism and relational reference theory, which promotes individual acceptance of the present and self, and increases psychological flexibility[6]. Additionally, enabling cognitive-behavioral education (ECBE) is a psychological behavior therapy that aims to explore individual-centered problems; help individuals reconstruct cognitive processes; solve emotional, cognitive, and behavioral disorders; and promote the development of skills and positive beliefs that enable the individual to effectively deal with problems associated with their disease[7]. ACT and ECBE have been applied to the nursing care of patients with diabetes[8], cancer[9], and other diseases[10] and have achieved good results. However, the combination of these two therapies has not been previous investigated in the treatment of CHB. This study explored the effects ACT combined with ECBE on psychological flexibility, negative emotions, and sleep quality in patients with CHB.

MATERIALS AND METHODS

Research object

A total of 129 patients with CHB treated at The First People's Hospital of Wenling between January 2021 and June 2022 were retrospectively selected. Patients were divided into two groups, depending on whether they received routine care or ACT combined with ECBE intervention.

The inclusion criteria were as follows: (1) Diagnosis of CHB according to the criteria; (2) normal vision and hearing function; (3) a complete record of baseline data (sex, age, disease course, and liver function); and (4) assessment of psychological flexibility, negative emotions, and sleep quality.

The diagnostic criteria for CHB included a positive results for both serum surface antigen and HBV DNA[11]. Additionally, liver function index alanine aminotransferase continually increased and liver histological examination showed hepatitis lesions.

The following exclusion criteria was applied: (1) Severe sleep disorders or insomnia caused by other diseases; (2) Combined heart, liver, kidney, and other organ lesions; (3) Viral hepatitis other than CHB; and (4) Malignant tumors.

According to the different nursing intervention methods applied, the patients were classified into a conventional group (routine nursing care, n = 69) and a combination group (ACT combined with ECBE, n = 60). The research concepts used are presented in Figure 1.

Related research data collection

We collected baseline patient data from the electronic medical records, including sex, age, disease course, and evaluation data of psychological flexibility, negative emotions, sleep quality, and self-care agency.

Detailed intervention methods

Routine nursing: Based on principles of nursing practice, nursing staff provided nutritional interventions, medication guidance and safety nursing, early rehabilitation training, and relevant health education. Health education for patients with CHB was delivered through one-to-one communication or distribution of educational manuals to disseminate knowledge on the causes of CHB, treatment methods, risk factors, and other aspects of the disease. Relevant psychological counseling; daily personal self-care skills in a home setting and life guidance were discussed with patients on discharge from hospital.

ACT: Acceptance perception: Medical staff provided health education using graphic publicity pages or short videos to inform patients of the pathogenesis, routine treatment options, and precautions of CHB, to help increase understanding of CHB and the ramifications of the disease.

Cognitive disengagement: Family members were guided to encourage patients to actively cooperate with drug treatment or psychotherapy and strengthen family awareness of CHB to reduce the impact of adverse events or negative emotions. Under the guidance of nutritionists, dietary management and stress reduction training was also strengthened to adjust patients' negative emotions.

Experience life: Patients were encouraged to exchange experiences with their friends to can share the burden of disease and integrate into surrounding life and work. The encouragement and support of family and patient friends enabled patients to develop a good understanding of their disease and alleviate negative emotions such as fear, anxiety, and depression. Patients were also encouraged to share their experiences and empathize with life experiences, diverting patients' attention.

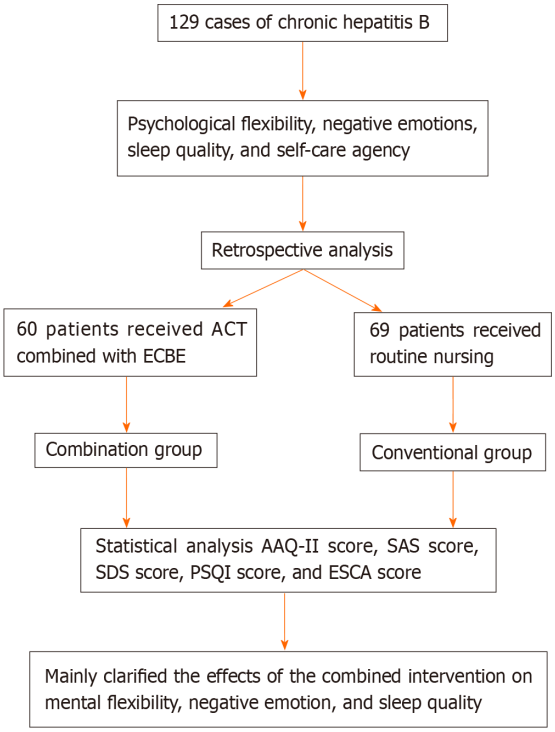
Self-awareness: Through patient communication and doctor-patient communication, patient awareness of the disease was strengthened, establishing confidence in treating the disease to establish correct cognition and attitude and understanding the disease.

Values: With the support of family members and medical staff, patients established social values, adjusted their mentality, returned to society and work, and developed positive attitudes towards life.

Positive coping: Through drug treatment, psychological intervention, and moderate exercise, patients strengthened their confidence, modified negative emotions, and actively cooperated with treatment.

ECBE: Clarify themes and processes: To understand the most harmful, extensive, and high-incidence problems and in CHB care, the nursing content included identifying problem(s), expressing feelings, setting goals, and making plans.

Clarify patient needs (problem establishment): Patient's thoughts and educational needs, such as changes during illness, daily mood and reasons, family support and care, disease knowledge, support, and help were identified.



Scale assessments: Acceptance and Action Questionnaire-2nd Edition (AAQ-II), Self-Rating Anxiety Scale (SAS), Self-Rating Depression Scale (SDS), Pittsburgh Sleep Quality Index (PSQI), Exercise of Self-Care Agency Scale (ESCA), and Master of psychological flexibility, negative emotions, sleep quality, and self-care abilities scores were observed.

Goal setting Cognitive aspects: (1) CHB Education. By playing videos, issuing manuals or one-on-one communication, and conducting collective lectures, patients could fully understand the harm caused by CHB, importance of a good mentality, importance of drug treatment, and side effects; and (2) diet education. Based on the health belief model[12], a reasonable diet knowledge education plan was developed for patients to understand the importance of nutritional balance and related information. Specific information about nutritional balance for example, dietary calcium supplements (China's recommended amount of calcium is 800 mg per day), and increased fresh fruits and vegetable and protein-rich food (such as milk, poultry, fish) intake was provided. Education was delivered through videos, pictures, animations, and text.

Behavior: (1) Improved family support. Family members or spouses were included in the synchronous education program to develop basic knowledge of CHB nursing and psychological and physiological support. Family members were also instructed to create a good family atmosphere and environment, pay attention to the patients' psychological state, and provide timely counseling to reduce the negative emotions caused by loneliness and family apathy; and (2) Improve self-care. Help was provided to patients to understand the importance of self-care and prevention and treatment of common health problems in CHB. Nursing staff focused on the mental health of patients, teaching them physical and mental adjustment methods to prevent anxiety and depression.

Observation target

Psychological flexibility: Before the intervention, 3 mo after intervention, and 6 mo after, the psychological flexibility of the patients was evaluated using the AAQ-II scale[13]. The seven items were scored from 1 (never) to 7 (always) with a total score of 7-49 points. Higher scores indicated higher empirical avoidance and psychological flexibility. Cronbach's α coefficient of the scale was 0.880, indicating good reliability.

Figure 1 Research ideas. ACT: Acceptance and commitment therapy; ECBE: Enabling cognitive-behavioral education; AAQ-II: Action Questionnaire-2nd Edition; SAS: Self-Rating Anxiety Scale; SDS: Self-Rating Depression Scale; PSQI: Pittsburgh Sleep Quality Index; ESCA: Exercise of Self-Care Agency Scale.

Negative emotions: The SAS and SDS[14] were used to evaluate the degree of anxiety and depression before and 6 mo after the intervention. The two scales were composed of 20 items scored according to a four-level scoring method (score 1-4 points). Higher scores indicated more severe anxiety and depression.

Sleep quality: The PSQI[15] was used to evaluate sleep quality before and after the intervention. This scale included the following seven dimensions: sleep quality, sleep time, sleep time, sleep efficiency, sleep disorders, use of hypnotic drugs, and daytime dysfunction. Each dimension was scored on a scale of 0-3 points. Higher scores indicated worse sleep quality.

Self-care ability: Before and 6 mo after the intervention[16], self-care abilities, including health knowledge (14 items), self-concept (nine items), self-responsibility (eight items), self-care skills (12 items) and four other dimensions (health knowledge level, self-concept, self-responsibility, and self-care skills). The 43 items were scored using the five-level scoring method (0-4 points). Higher scores indicated better self-care ability. Cronbach's α coefficient was 0.76-0.87, indicating good internal consistency.

Statistical analysis

SPSS 20.0 [IBM SPSS Statistics software, IBM Corp (version 20.0), NY, United States] was used to analyze the data. The data are presented as mean ± SD. The *t*-test was used to compare the difference between two sets of data. One-way analysis of variance was used to compare the two groups. The Bonferroni *t*-test was used for multiple comparisons between multiple samples. Repeated-measures analysis of variance was used to compare data at different time points between groups. The number of cases and chi-square test were used to analyze the count data. A test value = 0.05 was used. $P < 0.05$ was considered statistically significant.

RESULTS

Clinical characteristics

Baseline data such as sex, age, and course of disease were compared between the two groups. No significant differences were observed (all $P > 0.05$), indicating comparability (Table 1).

AAQ-II score

The AAQ-II score in the combination group was significantly lower than that in the conventional group. The AAQ-II scores of both groups decreased with time, with an interaction effect between group and time ($F_{\text{between-group effect}} = 8.548$; $F_{\text{time effects}} = 25.020$; $F_{\text{interaction effects}} = 52.930$; all $P < 0.001$) (Table 2).

Table 1 Basic data

Group	Gender (*n*, male/female)	Age (mean ± SD, yr)	Number of units(*n*, first visit/return visit)	Course of disease (mean ± SD, yr)		Educational level (*n*)			Child-Pugh grade	
				Course of CHB	Course of insomnia	Junior high school and below	High school	Bachelor's degree and above	Grade A	Grade B
Combination group (*n* = 60)	38/22	48.36 ± 10.25	19/41	12.25 ± 3.17	2.51 ± 0.86	15	28	17	39	21

CHB: Chronic hepatitis B.

Table 2 Action Questionnaire-2nd Edition scores

Time	Combination group (*n* = 60)	Conventional group (*n* = 69)	*t*	*P*
Before intervention	39.27 ± 6.22	38.72 ± 5.69	0.524	0.601
3 mo after intervention	31.26 ± 7.15	36.28 ± 6.67	4.123	< 0.001
6 mo after intervention	28.11 ± 6.32	33.51 ± 6.63	4.715	< 0.001
F	45.920	11.640	–	–
P	< 0.001	< 0.001	–	–

Multiple comparison results of PSQI scores at each time point between the conventional and combination groups showed significant differences in AAQ-II scores between the two time points in each group (all $P < 0.05$) (Table 3).

SAS and SDS score

The SAS scores of the combination group were 49.25 ± 5.35 and 37.56 ± 6.11, before and after intervention, respectively; $t = 11.150$, $P < 0.001$. The SDS scores were 53.58 ± 7.12 and 41.56 ± 5.38, before and after intervention, respectively; $t = 10.430$, $P < 0.001$.

The SAS scores of the conventional group were as follows: before intervention (48.68 ± 5.52), and after intervention (43.27 ± 5.79), $t = 5.618$, $P < 0.001$. The SDS scores were, before intervention (54.03 ± 6.69), after intervention (49.20 ± 6.69), $t = 4.241$, $P < 0.001$.

In comparison with the conventional group, the SAS ($t = 5.445$) and SDS ($t = 7.076$) scores of the combination group were lower after the intervention (both $P < 0.001$) (Figure 2).

PSQI score

The post-intervention scores for sleep quality, fall sleep time, sleep time, sleep efficiency, sleep disorders, use of hypnotic drugs, daytime dysfunction, and other dimensions in the combination group and the conventional group were lower than the corresponding pre-intervention scores (all $P < 0.001$). The scores for each dimension in the combination group were lower than those in the conventional group ($P < 0.05$) (Table 4).

ESCA score

The pre-intervention scores of health knowledge level, self-concept, self-responsibility, and self-care skills in the combination group were: 33.48 ± 5.36, 20.16 ± 3.25, 21.58 ± 4.39, and 31.25 ± 5.54 points. The same pre-intervention scores in the conventional group were: 34.02 ± 4.54, 20.67 ± 3.51, 21.24 ± 4.13, and 30.86 ± 6.62 points.

After the intervention, the scores of the above dimensions in the combination group were 51.27 ± 3.39, 31.25 ± 4.42, 29.17 ± 3.08, and 43.12 ± 4.24 points. The scores in the conventional group were 45.36 ± 5.73, 26.17 ± 5.24, 25.68 ± 4.42, and 35.56 ± 5.67 points.

Scores in both groups were higher after the interventions (all $P < 0.001$). The scores for each dimension in the combined group were higher than those in the conventional group (*t*: 6.994, 5.902, 5.128, and 8.470; all $P < 0.001$) (Figure 3).

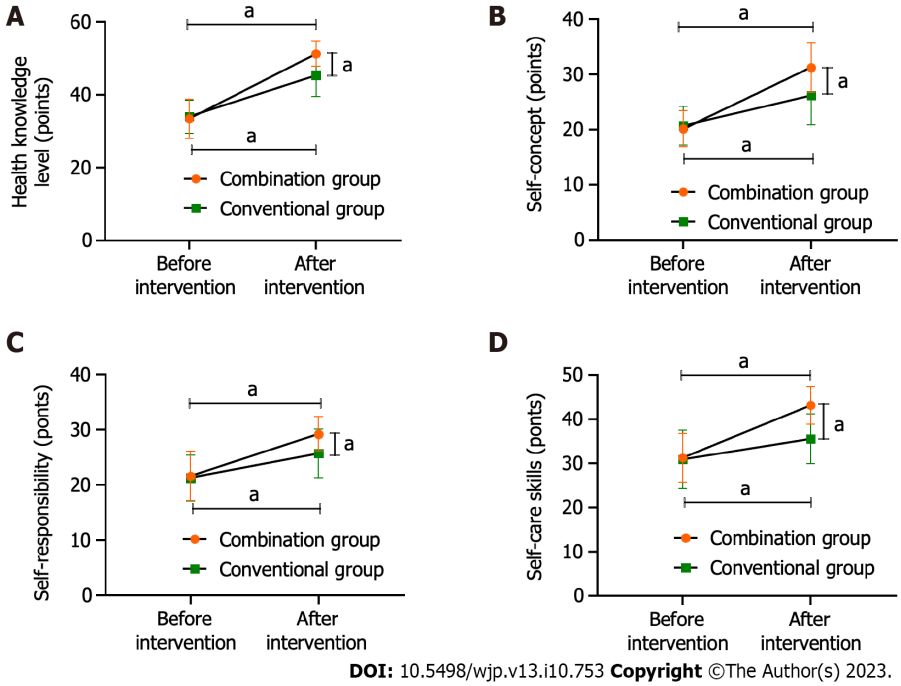
DISCUSSION



As CHB easily progresses to cirrhosis or liver cancer[17], there are considerable changes in the psychological, emotional, and living conditions of patients; effective nursing interventions are needed. Insomnia, a decline in sleep quality, is a common symptom in patients with CHB. primarily caused by an increase in endotoxin levels, unbalanced hormone secretion, and increased psychological burden which negatively impacts quality of life.

We found that the AAQ-II scores of both groups were lower after the intervention, and the combined group scores were lower, indicating that ACT combined with ECBE could reduce patient empirical avoidance behavior and enhance psychological flexibility. This is consistent with previous studies on adult patients with chronic pain [18]. Psychological

flexibility refers to psychological and behavioral adaptations to changing situations during interactions between individuals and the environment[19], a protective factor for mental health[20].

CHB is characterized by progression to cirrhosis or liver cancer and a heavy economic burden, which can easily cause negative emotions and need for patients to escape and control their worries. ACT guides and encourages patients to accept all negative and positive experiences with an open and optimistic attitude. After ACT intervention, patients may no longer resist, control, or evade CHB but observe and accept it objectively. Additionally, patients with CHB can cope more effectively with the stimulation of surrounding environmental factors and take positive actions to reduce psychological pressure, anxiety and depression.

ECBE focuses on four aspects: Establishing problems, expressing emotions, setting goals, and formulating plans. It focuses on patients' psychological changes, unhealthy emotions, and sleep quality and adopts targeted interventions and supervision. ECBE also encourages patients to gradually reduce avoidance behaviours, anxiety, depression, insomnia, and other problems, improves psychological flexibility, and relieves negative emotions. Previous research[21] has demonstrated that psychological flexibility is closely related to anxiety and depression. According to the results of this study, the SAS and SDS scores of patients receiving ACT combined with ECBE nursing were significantly reduced, indicating that anxiety and depression were significantly alleviated, highlighting the effectiveness of the combined

intervention in relieving negative emotions in patients with CHB.

In this study, the scores of the PSQI were lower and ESCA scores were higher in the combination group, demonstrating that ACT combined with ECBE also played a significant role in regulating sleep quality and patient self-care ability. The sleep quality of patients with CHB is typically much lower[22]. For ACT combined with ECBE, nursing staff developed patient knowledge of CHB and helped to correct misunderstandings about the disease, reducing excessive worrying and negative emotions, and improving sleep quality.

Moreover, the low self-care ability of patients with CHB has been demonstrated[23]. Improving self-care ability is the final step in the implementation of ECBE. Nursing staff guide patients to understand the importance of self-care and the prevention and treatment of common health problems associated with CHB. They also promote patient self-care ability, an important component that is lacking in routine nursing. Furthermore, providing effective relief from negative emotions encourages patients to actively cooperate with treatment and related auxiliary interventions, accept guidance and transmission of nursing knowledge; it also enhances patient understanding of the disease and nursing measures, indirectly improving self-care abilities[24,25].

Some limitations should be noted. First, this was a single-center study; therefore, the application of these findings to those in different centers needs to be approached with caution and the results need to be corroborated in future studies. Second, this was a retrospective study, and the data may be subject to selection, information, and confounding biases. Therefore, prospective randomized controlled studies are required to obtain more accurate clinical data and generate more robust evidence.

CONCLUSION

The combination of ACT and ECBE in patients with CHB can improve psychological flexibility and sleep quality, alleviate negative emotions, and improve self-care abilities.

ARTICLE HIGHLIGHTS

Research background

Chronic hepatitis B (CHB) is an infectious, progressive disease. Patients experience a heavy psychological burden and severe insomnia symptoms.

Research motivation

Patients with CHB urgently require effective nursing interventions to alleviate mental flexibility, negative emotions, and sleep quality problems.

Research objectives

To analyze the effects of acceptance and commitment therapy (ACT) combined with enabling cognitive-behavioral education (ECBE) on mental flexibility, negative emotions, and sleep quality in CHB patients.

Research methods

We retrospectively analyzed the clinical data of 129 patients with CHB and observed changes and differences in Acceptance and Action Questionnaire-2nd edition (AAQ-II), Self-Rating Anxiety Scale (SAS), Self-Rating Depression Scale (SDS), Pittsburgh Sleep Quality Index (PSQI), and Exercise of Self-Case Agency Scale (ESCA) scores after routine nursing and ACT combined with ECBE intervention.

Research results

Compared to patients receiving conventional care, the AAQ-II, SAS, SDS, and PSQI scores in patients receiving ACT combined with ECBE were lower and ESCA scores were higher.

Research conclusions

ACT combined with ECBE is effective for CHB patients in China and overcomes the problem of nursing defects in CHB.

Research perspectives

We observed the mental flexibility, negative emotions, and sleep quality of patients with CHB according to two different nursing interventions: routine nursing and ACT combined with ECBE.

Abstract

BACKGROUND

Preeclampsia is a pregnancy-specific multi-system disease with multi-factor and multi-mechanism characteristics. The cure for preeclampsia is to terminate the pregnancy and deliver the placenta. However, it will reduce the perinatal survival rate, prolong the pregnancy cycle, and increase the incidence of maternal complications. With relaxation of the birth policy, the number of elderly pregnant women has increased significantly, and the prevalence rate of preeclampsia has increased. Inappropriate treatment can seriously affect the normal postpartum life of pregnant women. Studies have shown that postpartum anxiety in women with preeclampsia can affect physical and mental health, as well as infant growth and development.

AIM

To analyze the factors influencing preeclampsia in pregnant women complicated with postpartum anxiety, and to construct a personalized predictive model.

METHODS

We retrospectively studied 528 pregnant women with preeclampsia who delivered in Wenzhou Hospital of Integrated Traditional Chinese and Western Medicine between January 2018 and December 2021. Their basic data were collected, and various physiological and biochemical indicators were obtained by laboratory examination. The self-rating anxiety scale was used to determine whether the women had postpartum anxiety 42 d after delivery. The independent factors influ-encing postpartum anxiety in early pregnant women with eclampsia were analyzed with multifactor logistic regression and a predictive model was constructed. The Hosmer-Lemeshow test and receiver operating characteristic (ROC) curve

were used to evaluate the calibration and discrimination of the predictive model. Eighty pregnant women with preeclampsia admitted to our hospital from January 2022 to May 2022 were retrospectively selected to verify the prediction model.

RESULTS

We excluded 46 of the 528 pregnant women with preeclampsia because of loss to follow-up and adverse outcomes. A total of 482 cases completed the assessment of postpartum anxiety 42 d after delivery, and 126 (26.14%) had postpartum anxiety. Bad marital relationship, gender discrimination in family members, hematocrit (Hct), estradiol (E2) hormone and interleukin (IL)-6 were independent risk factors for postpartum anxiety in pregnant women with preeclampsia ($P < 0.05$). Prediction model: Logit (P) = 0.880 × marital relationship + 0.870 × gender discrimination of family members + 0.130 × Hct - 0.044 × E2 + 0.286 × IL-6 - 21.420. The area under the ROC curve of the model was 0.943 (95% confidence interval: 0.919-0.966). The threshold of the model was -1.507 according to the maximum Youden index (0.757), the corresponding sensitivity was 84.90%, and the specificity was 90.70%. Hosmer-Lemeshow $\chi^2 = 5.900$, $P = 0.658$. The sensitivity, specificity and accuracy of the model were 81.82%, 84.48% and 83.75%, respectively.

CONCLUSION

Poor marital relationship, family gender discrimination, Hct, IL-6 and E2 are the influencing factors of postpartum anxiety in preeclampsia women. The constructed prediction model has high sensitivity and specificity.

Key Words: Preeclampsia; Postpartum anxiety; Risk factors; Predictive model

Core Tip: Preeclampsia is a progressive multisystem disease during pregnancy, characterized by new hypertension and proteinuria after 20 wk of pregnancy, and the condition develops continuously, which has a serious effect on the health of the mother and child. We analyzed the biochemical indicators of 528 pregnant women with preeclampsia and the independent factors influencing postpartum anxiety, and constructed a predictive model, with high clinical value.

INTRODUCTION

The incidence of preeclampsia can reach 8%[1], and studies have found that women with preeclampsia are more likely to suffer from postpartum anxiety[2-4], with an incidence of up to 20%[5]. Postpartum anxiety can aggravate maternal comorbidities, resulting in poor treatment compliance. Postpartum anxiety has short- or long-term adverse effects on maternal physical and mental health, as well as infant growth and development, and may lead to adverse events such as maternal drug abuse, suicide, and even infant injury[6,7]. Therefore, if we can predict the risk of postpartum anxiety in women with preeclampsia, targeted management and early intervention could avoid postpartum anxiety or improve postpartum psychological status. Current research focuses on the pregnancy outcome of women with preeclampsia, and few studies involve postpartum anxiety. In this study, we retrospectively studied 528 pregnant women with preeclampsia who delivered at our hospital between January 1, 2018 and December 31, 2021. The risk factors for preeclampsia in pregnant women complicated with postpartum anxiety were analyzed, and a predictive model was constructed to provide clinicians with an effective and practical risk assessment tool.

MATERIALS AND METHODS

General data

A total of 528 pregnant women with preeclampsia who delivered at Wenzhou Hospital of Integrated Traditional Chinese and Western Medicine Jianka between January 2018 and December 2021 were retrospectively selected. Inclusion criteria were: (1) Pre-eclampsia was diagnosed according to the relevant standards of obstetrics and gynecology[8]; (2) Conception occurred naturally, the fetus was normal, and the pregnancy was singleton; (3) No cognitive impairment or history of mental illness, and normal communication; and (4) Age > 18 years and living in the local area. Exclusion criteria were: (1) Prenatal anxiety; (2) Medical history of encephalopathy; (3) Severe heart, liver, kidney and other organ diseases; (4) Concurrent diseases of the immune system, nervous system, severe cardiovascular disease and malignant

tumors; (5) Adverse pregnancy outcomes (including arrhythmia, fetal growth restriction, intrauterine fetal death, neonatal death, severe neonatal asphyxia, neonatal defects and serious postpartum complications); and (6) Patients who had to withdraw from the study due to an emergency.

The predictive model was clinically verified by retrospectively selecting 80 pregnant women with preeclampsia who met the above criteria in Wenzhou Hospital of Integrated Traditional Chinese and Western Medicine between January and May 2022. Sample size calculation: (1) According to references, preeclampsia and the incidence of postpartum anxiety at about 20%, this study is expected to end in the multi-factor regression model analysis of 10 variables, according to the average number of events per predictor variable (EPV) sample size calculation, take EPV = 10, sample size = into variables × EPV/incidence rate = 10 × 10/20% = 500 cases, according to the inclusion and exclusion criteria and considering adverse outcomes, the sample size was 528; and (2) The sample size of the external validation was generally 1/4 to 1/2 of the modeling set, and the sample size = 1/4 of the modeling set, 120 cases (482/4) should be included. However, due to the influence of the external environment such as the epidemic situation and the actual situation of our hospital, 80 cases of preeclampsia pregnant women were finally included.

Data collection

General information: Age, educational level and occupation of pregnant women; occupation and educational level of spouse; family economic status; emotional status of husband and wife (self-rated as good or bad); whether pregnancy was planned; whether there was experience of raising children; whether there was gender discrimination on the part of oneself or family members (expecting to have male or female baby); whether there was regular maternity examination; and history of adverse pregnancy outcomes. Laboratory indicators included: Routine blood tests [including hematocrit (Hct), hemoglobin, and platelet count]; estrogen [including estradiol (E2)]; liver function (including alanine aminotransferase and aspartate aminotransferase); renal function (including creatinine and urea nitrogen); coagulation indicators (including fibrinogen and prothrombin time); and other biochemical indicators [including triglycerides and interleukin (IL)-6].

Postpartum anxiety criteria

The self-rating anxiety scale (SAS) was used to determine whether the parturients who completed the study had postpartum anxiety at 42 d postpartum. The SAS consisted of 20 items, with each item scoring 1 (none or few), 2 (sometimes yes), 3 (most of the time yes), and 4 (most of the time yes). In accordance with the Chinese standard, SAS score ≥ 50 indicated the presence of postpartum anxiety; a score of 50-59 indicated mild anxiety, 60-69 moderate anxiety, and ≥ 70 severe anxiety.

Statistical analysis

The data obtained were processed by SPSS 27.0. Measurement data and numerical data were expressed as mean ± SD and percentage, respectively, using t and χ^2 tests, respectively. The independent factors influencing postpartum anxiety in pregnant women with preeclampsia were analyzed using multifactor logistic regression and a predictive model was constructed. The Hosmer-Lemeshow test and receiver operating characteristic (ROC) curve were used to evaluate the calibration and discrimination of the predictive model. $P < 0.05$ indicated a significant difference.

RESULTS

Comparison of baseline data of pregnant women with preeclampsia

We excluded 46 of 528 pregnant women with preeclampsia because of loss to follow-up and adverse outcomes, and 482 women completed the anxiety assessment 42 d after delivery. Among them, 126 women (26.14%) experienced postpartum anxiety. The analysis of baseline data of 482 pregnant women with preeclampsia showed that marital relationship, gender discrimination of family members, Hct, E2 and serum IL-6 levels were factors potentially influencing postpartum anxiety in pregnant women with preeclampsia ($P < 0.05$) (Table 1).

Multifactor logistics regression analysis of pregnant women with preeclampsia complicated with postpartum anxiety

The significant factors above were used as covariates marital relationship (0 = good, 1 = bad), gender discrimination among family members (0 = none, 1 = yes). Concurrent postpartum anxiety was used as the dependent variable (0 = none, 1 = yes), and multifactor logistic regression analysis was performed. Bad marital relationship, gender discrimination among family members, Hct, E2 and IL-6 were independent risk factors for postpartum anxiety in pregnant women with preeclampsia ($P < 0.05$) (Table 2).

Construction and validation of predictive model for pregnant women with preeclampsia complicated with postpartum anxiety

According to the multivariate logistic regression model, a predictive model of postpartum anxiety in pregnant women with preeclampsia was constructed: Logit(P) = 0.880 × conjugal affection + 0.871 × gender discrimination in family members + 0.130 × Hct - 0.044 × E2 + 0.286 × IL-6 - 21.420. The ROC curve was drawn to evaluate the discrimination of the predictive model. The area under the ROC curve was 0.943 (95% confidence interval: 0.919-0.966). The threshold of the model was -1.507 according to the most approximate maximum Youden index (0.757), and the corresponding sensitivity and specificity were 0.849 and 0.907, respectively (Figure 1). The goodness-of-fit test was used to evaluate the

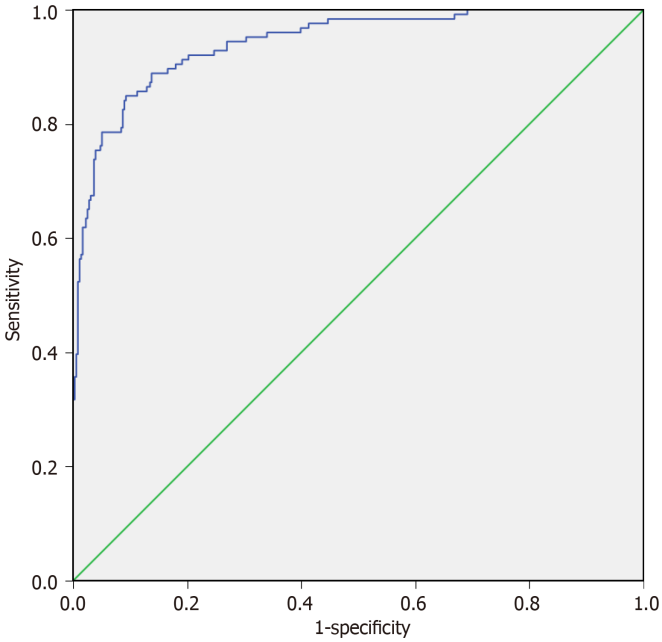
calibration of the predictive model, which showed Hosmer-Lemeshow χ^2 = 5.900, and P = 0.658 (Figure 2).

Clinical verification of predictive model for pregnant women with preeclampsia complicated with postpartum anxiety



We retrospectively selected 80 pregnant women with preeclampsia in our hospital between January and May 2022 to clinically verify the predictive model. The sensitivity was 81.82%, specificity 84.48%, and accuracy 83.75% (Table 3).

DISCUSSION

The results of this study showed that serum transaminase levels, blood pressure, platelet levels, and coagulation indicators in pregnant women with preeclampsia with postpartum anxiety did not differ significantly from those in women without postpartum, which was consistent with previous studies[4]. We found that bad marital relationship, gender discrimination among family members, Hct, IL-6 and E2 were all independent factors influencing postpartum anxiety in pregnant women with preeclampsia. The care and support of husbands play a key role in improving the psychological status of pregnant women[9,10]. Therefore, strengthening the health education of the spouses of pregnant and lying-in

Figure 2 Goodness of fit test of a predictive model for postpartum anxiety in women with preeclampsia.

women and guiding them to attach importance to psychological care and support are important to reduce the risk of postpartum anxiety. The feudal thought of "son preference" is deeply rooted in China. Family members and even the pregnant women themselves care about the gender of the newborn[11]. When pregnant women with preeclampsia excessively consider the views of family members on the gender of their newborn, it can easily exert psychological pressure, leading to postpartum anxiety. Therefore, for pregnant women with preeclampsia, health education should be strengthened during prenatal examination, the idea of gender equality should be advocated, and possible gender discrim-

ination should be corrected in time to reduce the risk of postpartum anxiety of pregnant women.

There is a biological basis for postpartum anxiety in pregnant women with preeclampsia. Postpartum estrogen deficiency is an important reason for the significantly increased incidence of mental illness at 30 d postpartum[12], and E2 level is negatively correlated with the severity of female anxiety[13], which is similar to our study. The possible causes are that E2 can play an antianxiety role by improving the binding rate of serotonin reuptake transporter and the reuptake capacity of cells for serotonin. However, postpartum estrogen secretion from the uterus is stopped, the recovery of ovarian estrogen secretion function is slow, and the level of E2 is low, thus the antianxiety effect is weakened. If the level of E2 is low in pregnant women with preeclampsia, it may further decrease the level of postpartum estrogen, so anxiety is more likely to occur[14,15]. Ramiro-Cortijo *et al*[16] confirmed that the Hct in patients with preeclampsia was significantly higher than that of healthy people, and increased with aggravation of preeclampsia. Noori *et al*[17] showed that the prenatal Hct accurately predicted severity of depression and anxiety 6 wk after delivery. The results of this study showed that Hct was an independent factor influencing postpartum anxiety in pregnant women with preeclampsia, which was consistent with the above conclusions. Pregnant women with preeclampsia usually have overactivation of inflammation and immunity, and a large number of inflammatory factors are released into the blood, resulting in increased serum IL-6 level, which is positively correlated with the severity of preeclampsia[18]. Immune activation caused by inflammatory factors can lead to dysfunction of the neuroendocrine and immune systems[19,20]. Therefore, elevated serum IL-6 levels may cause postpartum anxiety in women with preeclampsia. Therefore, clinical attention should be paid to patients with abnormal indicators, and follow-up observation should be strengthened, or appropriate treatment should be given to adjust the level of related indicators.

In this study, a risk predictive model for pregnant women with preeclampsia complicated with postpartum anxiety was constructed based on the above independent influencing factors (bad marital relationship, gender discrimination of family members, Hct, IL-6 and E2). The ROC curve analysis results showed that the predictive model had good discrimination, and the goodness-of-fit test showed that the model had good calibration. The prospective clinical validation showed that the model had high sensitivity (81.82%), specificity (84.48%) and accuracy (83.75%), indicating that the predictive model had clinical practicability. The model was simple to use and had high accuracy. However, the number of cases in the time period selected for clinical verification is small, and the results may have certain errors. In the future will be incorporated into various validation.

CONCLUSION

Bad marital relationship, gender discrimination of family members, Hct, IL-6 and E2 are independent factors influencing postpartum anxiety in pregnant women with preeclampsia. The predictive model established based on these factors has high sensitivity, specificity and accuracy, strong operability, and high clinical value. However, this study was a single-center study, the clinical validation of the model was only conducted in our hospital, and the sample size was insufficient, so the results were inevitably biased. In the future, multi-center research and multi-center clinical verification will be carried out, and multi-factor, multi-sample and multi-time span will be adopted to explore, so as to enhance the reliability of the research results.

ARTICLE HIGHLIGHTS

Research background

Relaxation of the maternity policy has resulted in an increase in the number of elderly pregnant and lying-in women, and the prevalence of preeclampsia. Preeclampsia can lead to organ damage and system dysfunction.

Research motivation

To explore the factors influencing postpartum anxiety in pregnant women with preeclampsia and construct a predictive model, to provide an effective and practical risk assessment tool for clinical practice.

Research objectives

The object of this study is to explore the factors influencing postpartum anxiety in pregnant women with preeclampsia and construct a personalized model for predicting postpartum anxiety, to provide a reference for clinical trials.

Research methods

We retrospectively analyzed 528 pregnant women with preeclampsia who delivered in our hospital between 2018 and 2021. Various physiological and biochemical indicators were obtained through laboratory tests. Multivariate logistic regression, receiver operating characteristic curve, Hosmer-Lemeshow and other methods were used to analyze the factors influencing postpartum anxiety in pregnant women with preeclampsia and to construct a predictive model.

Research results

A total of 126 pregnant women with preeclampsia experienced postpartum anxiety. Bad marital relationship, gender discrimination among family members, hematocrit, estradiol hormone and interleukin-6 were independent risk factors

for postpartum anxiety in pregnant women with preeclampsia, and the predictive model constructed based on these factors had high accuracy.

Research conclusions

We analyzed the factors influencing postpartum anxiety in pregnant women with preeclampsia and constructed a predictive model with high sensitivity and accuracy, which provided a reference value for clinical practice.

Research perspectives

Firstly, multi-sample, multi-factor, multi-center and multi-time span clinical studies will be carried out in the future to enhance the reliability of the research results. In addition, different models were constructed for clinical application in pregnant women with preeclampsia and postpartum anxiety.

Abstract

BACKGROUND

Medical school is known for its lengthy process, which is both physically and emotionally draining. Students' mental balance would shrink as they progress in their medical training. A systematic review and meta-analysis reported that the prevalence of depressive symptoms among medical students remained relatively constant at 27.2%.

AIM

To assess the prevalence of depressive symptoms among Tunisian medical students and evaluate its associated factors.

METHODS

This is a descriptive cross-sectional study that was carried out in the second semester of the academic year 2017/2018, between April 2018 and July 2018 among 1138 medical students. Data were collected using a socio-demographic questionnaire and the Beck Depression Inventory-II (BDI-II).

RESULTS

Sixty-four percent (n = 728) of the participants had depressive symptoms, of which 266 (23.4%) met the criteria for mild, 271 (23.8%) for moderate, and 191 (16.8%) for severe depressive symptoms. Female gender, low socio-economic level, smoking habits and history of mental disorder, performing leisure and physical activities, satisfaction toward a career choice, and happiness perception were the main prognostic factors for depression among medical students. Although academic grades may not be considered a prognostic factor, final-year

students appeared to be less depressive than their colleagues.

CONCLUSION

These findings give insight into mental health issues and comorbidities among Tunisian medical students. It is a hopeful request for decision-makers and academic authorities to set serious measures and draw effective interventions to minimize the currency of psychological distress among this subpopulation.

INTRODUCTION

The Global Burden of Diseases, Injuries, and Risk Factors Study 2017 (GBD 2017), conducted between 1990 and 2017 in 195 countries and territories, concluded that more than 264 million people of all ages were depressed[1].

Depression can be long-lasting or recurrent, and standing still impairs an individual's ability to function in his daily life[2].

Psychological distress among university students has witnessed a considerable rise, becoming a concern for public health authorities around the globe. And among university students, medical students are particularly more vulnerable to psychological distress and morbidity since medical education is reputed for its long process and it is physically and emotionally consuming[3,4].

Rotenstein *et al*[5] reported in a systematic review and meta-analysis conducted in 2016 that between 1982 and 2015, depressive symptom prevalence remained relatively constant at 27.2% for medical students with no significant difference between preclinical and clinical students.

Even though it is crucial for an educational institution to assess the mental status of its students, only a few Tunisian studies surveyed the currency of depression among medical students.

Within this framework, this study aimed to assess the prevalence of depressive symptoms among medical students in Tunisia and to evaluate its associated factors.

MATERIALS AND METHODS

Study design and participants

The present study is a descriptive cross-sectional study that was carried out in the second semester of the academic year 2017/2018, between April 2018 and July 2018 (away from exams). We recruited students from the four medical faculties in Tunisia [Faculty of Medicine of Monastir (FMM), Sousse, Tunis, and Sfax].

The minimal sample size required for the study was 322694. It was calculated using the formula: $n = \mu\alpha 2\ p\ (1\text{-}p)/\delta 2$, where "μα" is the one-sided magnitude of the confidence level (μα = 1.96) and "p" is the expected proportion of the outcome of interest with an assumption of 30% depression among medical students.

Only enrolled medical students from the first year to the fifth year were invited to complete an online survey as a main tool of the study.

To retrieve an adequate sample for the present study, all candidates were invited to complete an anonymous nationwide web-based questionnaire *via* their student delegate who published the questionnaire in their Facebook group, mentioning the purpose of the study and assuring the confidentiality and anonymity of each answer. The questionnaire was sent with a description of the study. Every person could only answer the questionnaire once.

As the response rate is the number of completed and sent survey responses divided by the number of people who viewed the survey, the present study response rate was measured to be 16.45%, considering students who reached the link and viewed the survey content (Figure 1).

Study instruments

The self-report questionnaire employed in the French language (the second language and official language for medical studies in Tunisia) took approximately 15 min to answer and collected data on.

Students' general characteristics: It consists of personal (age, gender, origin, personal medical history, tobacco use, alcoholism, marital status, self-assessment of their financial status, and current residence) and academic characteristics: Faculty, academic level, satisfaction toward career choice, and dropping out thoughts, leisure and sporting activities, participation in a stress management workshop, and a precedent visit to a psychiatrist/psychologist.

Beck Depression Inventory-II (BDI-II): It is a self-administrated tool, used to screen for the presence of depressive symptoms[6,7]. The BDI-II timeframe extends for 2 wk to correspond with the DSM-IV criteria for diagnosing depressive disorders and includes items measuring cognitive, affective, somatic, and vegetative symptoms of depression. With a sensitivity of 87% and specificity of 79%, the BDI-II was validated using adult and adolescent psychiatric outpatients.

Each participant is asked to answer 21 items rated on a 4-point Linkert scale indicating the degree of severity from 0 (not at all) to 3 (extreme form of each symptom). Cumulative score is calculated. The provisional diagnosis of depression is made if the BDI-II score is greater than 13 and the presence of severe depressive symptoms if the score is greater than or equal to 29. The severity of depression was classified into three categories: Mild, moderate, and severe depression[7,8].

Statistical analysis

The data collected were keyed into Excel for Windows and statistical analyses were carried out using the software package SPSS version 24 (SPSS Inc.). Descriptive analysis (frequencies, prevalence, mean, and standard deviation) was applied to evaluate the characteristics of the samples. The Chi-square (χ^2) test was carried out to compare the prevalence of depression between different groups, while the Student's *t*-test was used to analyze quantitative data (age) with the presence of depression. Variables whose *P* value was < 0.2 were entered as independent variables in regression analysis. The 95% confidence intervals (95%CI) were calculated for prevalence rates. Binary logistic regression models were used to show the predictive model of BDI based on the values of the independent variables (predictors). The level of significance was set at $P < 0.05$.

Ethical considerations

We explained the purpose of the study to all participants. The confidentiality and anonymity of each answer were guaranteed. A completed questionnaire was considered as consent to participate in the study. The present study was approved by the ethics committee of the FMM (No. 3067).

RESULTS

Description of general characteristics

The sample consisted of 1138 medical students, including 888 (78%) females and 250 (22%) males, with ages ranging from 18 to 37 years (mean, 22.0 years ± 2.3 years). There were 423 students (37.2%) who were enrolled in the Faculty of Medicine of Tunis (FMT), while 304 (26.7%), 248 (21.8%), and 163 (14.3%) were registered, respectively, in the FMM, Sousse (FMS) and Sfax (FMSF). Of the sample, there were 448 pre-clinical students (Year 1 and Year 2) (39.3%) and 690 clinical students (Year 3, Year 4, and Year 5) (60.6%).

Based on their financial status self-assessment, most of the students (921, 80.9%) were at a moderate socio-economic level while 146 (12.8%) were at a high level and 71 (6.2%) were at a low level. Fourteen percent of the participants were smokers and 16% revealed drinking habits. Almost 70% of the sample did not practice either leisure or physical activities. Only 158 (13.9%) had participated in a stress management workshop and 228 (20%) had sought psychiatric help.

Half of the sample were unsatisfied with their career choice and have thought, at least once, of dropping out of medical studies. Sixty-one percent of participants (699) admitted feeling unhappy. More personal and academically related details are illustrated in Table 1.

Depressive symptoms

The BDI-II total scores of participants ranged from 0 to 63 with a mean score of 18.73 ± 10.60 as shown in Table 2. Sixty-four percent (n = 728) of the participants had depressive symptoms, of which 266 (23.4%) met the criteria for mild, 271 (23.8%) for moderate, and 191 (16.8%) for severe depressive symptoms. Among 728 depressive students, only 177 (24.3%) had sought psychiatric help.

Students' general characteristics as determinants of depression

Personal characteristics: Female students were more depressed than males. Neither students' residency nor marital status showed a significant effect on depressive symptoms. Depression was more prevalent among smokers and students with low socio-economic levels.

Figure 1 Flowchart of the study.

Depressive symptoms were associated with age ($P = 0.048$; the age difference was not meaningful), gender ($P = 0.038$), socio-economic level ($P < 10^{-3}$), history of medical illness ($P = 0.034$), history of mental illness ($P < 10^{-3}$), and smoking habits ($P = 0.025$).

Academic characteristics: With 70% depressed students, Sousse Faculty of Medicine was ranked as the most depressed faculty. There was no difference between pre-clinical and clinical students. The lack of leisure and physical activities was significantly associated with the presence of depressive symptoms.

The presence of depression was associated with faculty ($P = 0.042$), leisure activities ($P < 10^{-3}$), physical activities ($P < 10^{-3}$), satisfaction toward career choices ($P < 10^{-3}$), dropping out thoughts ($P < 10^{-3}$), a precedent visit of a psychiatrist/psychologist ($P < 10^{-3}$), and happiness perception ($P < 10^{-3}$). Different correlations are illustrated in Table 3.

Association between depressive symptoms and sample characteristics: Regression analysis

Female gender, low socio-economic level, smoking habits, and history of mental disorders were identified to be the main prognostic factors for depression among medical students (Table 4).

Although academic grade and participation in a stress management workshop did not show a significant correlation in the univariate analysis, we added these two variables in the regression analysis as they were mentioned in the literature. Academic grade may not be considered a prognostic factor. However, as detailed in Table 4, final-year students seemed

to be less depressed than their colleagues.

Performing leisure and physical activities, satisfaction toward a career choice, happiness perception, and participation in a stress management workshop were considered prognostic factors for depression among participants.

DISCUSSION

Prevalence of depression among students

Sixty-four percent (n = 728) of the participants had depressive symptoms. These results seem to be higher than the aggregate prevalence of 27.2% (range, 9.3%-55.9%) reported by Rotenstein *et al*[5] in their systematic review and meta-analysis that covered 195 studies in 47 different countries, involving 129123 medical students. In a medical education journal, a meta-analysis that concerned a total of 62728 medical students pooled across 77 studies was published in March 2016[9], which reported similar results (28%).

The magnitude of depression found in our study closely resembled the findings from some neighboring countries: Egypt 60.2%[10], Bahrain 65.6%[11], *etc*. Lower prevalence were found in India[12] (18%), Thailand[13] (12.6%), Germany [14] (10.3%), *etc*.

Nationally, the proportion of depressed medical students was higher than what was reported in a previous Tunisian study[15] that was conducted at the University of Sfax and showed that out of 80 medical students, 31% were depressed. Similar results were found in another study that included Tunisian medical residents (30.5%)[16]. Both studies used the same screening tool (Hospital Anxiety and Depression scale)[15,16].

This variation worldwide can be explained to be due to sample size and data collection tools. Besides, diversity in cultural, religious, and spiritual peculiarities[17] in addition to dissimilarity in the healthcare system might also elucidate the disparity of findings between countries.

Association between characteristics of participants and symptoms of depression

Female gender: Globally, there were controverted issues given the impact of gender on depression symptoms. The significant correlation of poor mental health with female students found in the current study is supported by previous studies in Sweden[18], Nepal[19], Australia[20], *etc*. In contrast, no difference in depression between genders was disclosed in previous studies in Tunisia[16], Greece[21], Ethiopia[22], *etc*. Furthermore, regression analysis yielded mixed findings with some considering female gender as a risk factor for depression: South Africa[23], Turkey[24], South Korea [25], *etc*. Studies took a multitude of tracks to elucidate why female students were more prone to depression than their male peers, and they suggested social stigma, gender inequity, and cultural constraints as the main reasons[9,26,27].

Financial status: Based on their financial status self-assessment, students at a low socioeconomic level were more likely to get depressed than their peers. These outcomes are in harmony with those run in neighboring and foreign countries[3,10, 14,25,28]. The impact of financial status on the occurrence of depression was documented in numerous studies among general populations[29-32]. A large four-year study (The PATH Through Life Survey) was conducted by Butterworth and colleagues in the city of Canberra and the surrounding regions in south-east Australia, and it included 6715 participants from different cohorts (1975-1979; 1956-1960; and 1937-1941). The study proclaimed that the lack of financial resources was strongly associated with depression[33,34].

Mental problems: Out of 1138 participants, 79 (6.9%) reported having a history of mental illness. These results seem to be akin to those found in other studies[26,35]. Nineteen Saudi Arabian medical students (out of 398) reported having a psychological illness. Eighty-four percent of them met the BDI criteria for depression. The chi-square test detected a significant correlation ($P < 0.001$) and multiple linear regression inferred that the presence of psychological problems makes students 1.435 times more likely to get depressed [$P = 0.03$, exp(B) 4.200, 95%CI: 1.150-15.338][35]. These findings are congruous with those reported earlier by Asal *et al*[36], Pagnin *et al*[37], and Pillay *et al*[38], who found that depressive and anxiety features were related to students' history of poor mental health[36-38].

Smoking, drinking, and substance use: Out of 1138 participants, 160 (14.1%) had smoking habits while 183 (16.1%) had drinking habits. Smokers (115, 71.9%) and drinkers (120, 65.6%) met the BDI-II criteria for depression. The regression analysis considered smoking as a risk factor for depression. Many studies have looked for the link between substance use and the occurrence of depression[39]. On the other hand, Palestinian and Saudi Arabian studies that explored the impact of smoking only (but not drinking for cultural limitations) found no significant correlation with depression ($P = 0.08$)[26, 35]. Moreover, O. Coskun and colleagues[24] perceived no significant relationship between alcohol and the magnitude of depression. Correspondingly, studies among Ethiopian, Nepali, and Australian medical students found, also, no significant link between substance use and the development of depression[19,20,22]. Strikingly, a similar study was performed in the Netherlands. Authors noticed that first-year students who had drinking habits tended to be more balanced in their mental wellness than non-drinking students. Hence, drinking seems to be a coping tool wielded to ease the pressure but also to inflate social interactions and activities[40,41]. Even though drinking can be regarded as a relief from stress or a coping strategy, immoderate drinking may ruin liver and pancreas functioning, alter the cardiovascular system, and lead to tumoral issues as well as numerous psychiatric disorders[41-44].

Association between academic characteristics of participants and depression symptoms

Physical activities: Almost 70% of the sample did not practice any physical activity. Among them, 551 (67.5%) met the BDI-II criteria for depression. The regression analysis considered physical activity as a protective factor against depression[45].

A tiny number of studies had explored physical behavior among medical students. Abdelwahed and colleagues, for instance, observed that 210 out of 442 were performing physical activity at least three times a week. Yet, statistical analysis did not show any significant correlation between physical activity and depression ($P = 0.647$), anxiety ($P = 0.78$), or stress ($P = 0.76$)[10].

Worldwide, the impact of physical exercises was exemplified in numerous studies. A systematic review on the effects of physical activity on brain structure and function in youth related that physical activity can redesign white matter integrity and arousal of regions key to cognitive tasks[46]. Identically, Rebar and colleagues performed a meta-analysis of the impact of physical activity on depression and anxiety among the non-clinical population[47]. Authors concluded that physical activity was shown to decrease depression by a medium effect [standardized mean difference (SMD) = -0.50; 95%CI: -0.93 to -0.06] and anxiety by a small effect (SMD = -0.38; 95%CI: -0.66 to -0.11)[47].

Leisure activities and extracurricular involvement: More than half of the participants (69.3%) were not performing any leisure activity. Fifty hundred and fifty-one (69.8%) among them were found depressed. Statistical analysis proved a significant association between spare time ventures and the occurrence of depression: The odds of developing depression was reduced to half among socially active participants. These findings seem in line with a Nepalian study where 34% of students (221/651) were involved in extracurricular activities. While those who answered "Always" and "Often" as the frequency of their extra activities were 28.6% and 21.7% depressed, respectively, those who answered "Rarely" and "Never" were 42.4% and 41.7% depressed, respectively. Even though a strong correlation ($P < 10^{-3}$) was found in the chi-square test, having a spare schedule tends to be a protective factor against anxiety ($P = 0.012$, OR = 0.367, 95%CI: 0.165-0.799) but not depression[19]. The part taken by social life and social relationships turns out to be a key strand in the fight against depression and lessen stressful life pressures[22,40,48,49]. Dyrbye *et al*[28], who drove a longitudinal study among 3743 United States medical students from 2010 to 2014, noticed that students who avowed having low social support were more likely to manifest depressive features ($P < 10^{-3}$). Similarly, Turkish and Palestinian studies substantiated the strong correlation ($P < 10^{-3}$) that relates social interaction and social stand with the contingency of depression[24,35].

Satisfaction and dropping out ideas: Statistical analysis showed a strong correlation between students' dissatisfaction and depression ($P < 10^{-3}$). Unsatisfaction is, then, considered a risk factor for developing depression. These data closely resemble findings from other studies. Pokhrel *et al*[19] demonstrated that satisfied students in Nepal were less prone to depression (OR = 0.51, 95%CI: 0.33-0.80). Similarly, discontented KSA medical students tend to be more depressed than their peers ($P = 0.03$)[35]. Studies conducted in New Zealand[50] and Palestine[26] reported results in line with our study. The influence that satisfaction toward career choice has on students' mental health did not come out of anywhere. It arises from the reluctance to study medicine: Whether to please parents' desire to become a doctor or to go along with friends aiming to get higher social status. All of it ends by being hushed, knowing the reality of medicine[51].

Recommendations

As disclosed above, medical students are without a doubt prone to several mental afflictions. Therefore, preventing such distress among students should be a priority and a must.

Primary prevention is possible by supplying learners with seminars on time management, relaxation exercises, and mindfulness activities through counseling services such as the listening unit that has been established in our faculty. Finally, prioritizing students' welfare starts by providing space and needed materials to enhance students' physical exercises and group activities, delivering variable and healthy meals in university restaurants, and revising students' schedules to suit their academic, physical, and psychological needs.

Limitations

Overall, the authors acknowledge some limitations to this study. Being a descriptive cross-sectional study, causal links between the correlations could not be inaugurated. Preferably, further studies should be surveyed in longitudinal, prospective, and multicenter designs aiming to yield a greater overview of the circumstances. Even though the number of students who participated in this survey is much higher than those carried out in Tunisian and neighboring studies, a larger sample size would have risen the diligence and exactness of our study.

As our study was based on self-administrated questionnaires and all data employed were self-reported, it is possible that students could have understated or overstated their depressive symptoms. The choice, itself, of participating in the online survey may mirror some level of bias related to the personal traits and characteristics of the students. We have estimated the occurrence of depression among medical students using a self-reported inventory (BDI-II), there were no clinical assessments supervised by psychiatrists. Consequently, the diagnostic value may be restricted, and further psychiatric interviews are required to validate our results. Other students' characteristics that were correlated to the development of depressive symptoms were not explored among participants, such as emotional intelligence, coping skills, social support, religious beliefs, personality characteristics, and substance use disorders.

CONCLUSION

These findings give insight into Tunisian medical students' mental health issues and comorbidities. It is a hopeful request for decision-makers and academic authorities to take serious measures and offer effective interventions to minimize the currency of psychological distress among this subpopulation. To date, this is the largest study on depression among Tunisian and Maghrebian medical students. Yet, further research is recommended to explore other correlated factors and to evaluate the effectiveness of these measures on depression levels among medical students.

ARTICLE HIGHLIGHTS

Research background

Most medical schools in the world (including Tunisia) still recruit their students based solely on the university entrance exam score. Students' motivation, though being a crucial conjecture in their academic performance and well-being, has never been conventionally and structurally assessed in Tunisia. As a result, many students simply choose the medical field due to social codes, family influences, and cultural norms.

Research motivation

It is crucial for an educational institution to assess the mental status of students and its associated factors.

Research objectives

To assess the prevalence of depressive symptoms among Tunisian medical students and to evaluate its associated factors.

Research methods

This is an online survey of students from the four Tunisian medical faculties using Beck's depression questionnaire.

Research results

Sixty-four percent ($n = 728$) of the participants had depressive symptoms. Female gender, low socioeconomic level,

smoking habits and history of mental disorder, performing leisure and physical activities, satisfaction toward a career choice, and happiness perception were the main prognostic factors for depression among medical students.

Research conclusions

These findings give insight into mental health issues and comorbidity among Tunisian medical students. It is a hopeful request for decision-makers and academic authorities to take serious measures and offer effective interventions to minimize the currency of psychological distress among this subpopulation.

Research perspectives

Further studies are needed to explore other correlated factors (such as emotional intelligence, coping skills, social support, religious beliefs, and personality characteristics) and to evaluate the effectiveness of these measures on depression levels among Tunisian medical students.

Abstract

BACKGROUND

Depression is a common mental disorder among college students. The main symptoms include being persistent low mood, sad emotional experiences, lack of pleasure, listlessness, and impaired cognitive function accompanied by tendencies of self-harm and suicide.

AIM

To clarify the pathways and effects of the behavioral activation system between physical activity and depressive symptoms in college students with depressive symptoms.

METHODS

This cross-sectional research screened 3047 college students. Of these, 472 had depressive symptoms, with a depression detection rate of 15.49%. Furthermore, 442 college students with depressive symptoms were analyzed. A one-way analysis of variance and Pearson's correlation, linear regression, and structural equation modeling analyses were used to explore the correlations and pathways of the interactions between the variables.

RESULTS

Depressive symptoms were significantly negatively correlated with physical activity (r = -0.175, $P < 0.001$), the behavioral activation system (r = -0.197, $P < 0.001$), and drive (r = -0.113, $P = 0.017$). Furthermore, it was negatively correlated with fun-seeking (FS) (r = -0.055, $P = 0.251$); however, it was not significant. Physical activity was significantly positively correlated with reward respons-

iveness (RR) (r = 0.141, *P* = 0.003) and drive (r = 0.124, *P* = 0.009) and not significantly positively correlated with FS (r = 0.090, *P* = 0.058). The mediating effect of RR between physical activity and depressive symptoms was significant [B = -0.025, 95% confidence interval (95%CI): -0.051 to -0.008, *P* = 0.001]. The direct and total effects of physical activity on depressive symptoms and were significant (B = -0.150, 95%CI: -0.233 to -0.073, *P* < 0.001; B = -0.175, 95%CI: -0.260 to -0.099, *P* < 0.001), respectively.

CONCLUSION

As physical activity levels increased, depression scores among college students decreased. The mediating effect of RR between physical activity and depressive symptoms was significant. Therefore, colleges and universities should encourage college students with depression to increase their physical activity and improve their behavioral activation system. Particular attention should be paid to RR, which may reduce the prevalence of depressive symptoms.

Key Words: College students; Physical activity; Depressive symptoms; Behavioral activation system; Mediating role

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: This study explored the specificity of the behavioral activation system for physical activity and reward motivation in college students with different depressive symptom scores. Furthermore, the inter-relationships among the three variables were examined *via* a cross-sectional research design. Pathways of the behavioral activation system that mediated the effect of physical activity level on depressive symptoms in college students with depressive symptoms were clarified.

INTRODUCTION

Depression, a disabling mental disorder, seriously endangers the lives and health of people and ranks the 13th highest in the number of disability-adjusted life-years among all illnesses and injuries worldwide[1]. It is a common mental disorder among college students, with a detection rate of over 30%[2,3]. The main symptoms include persistent low mood, sad emotional experiences, lack of pleasure, listlessness, and impaired cognitive function, with tendencies of self-harm and suicide. The World Health Organization predicted that depression would rank first in the disease burden worldwide by 2030[4].

The behavioral activation system, also known as reward motivation, is located in the midbrain dopamine loop and refers to the convergent motivation for reward, promoting goal-directed behavior to obtain the reward, and producing positive emotions or hedonic pleasure experiences[5]. It is divided into three factors: Reward responsiveness (RR), drive, and fun-seeking (FS)[6]. Impaired reward function, or anhedonia, is a core symptom of depression, and deficits in the behavioral activation system can serve as functional deficits in depressive symptoms[7,8].

An inter-relationship between physical activity, depressive symptoms, and behavioral activation system exists. Appropriate physical activity significantly alleviates clinical symptoms in people with depressive symptoms[9-11] and reduces anxiety and depression levels in college students[12]. In addition, exercise is also strongly associated with behavioral activation system, such as enhancing the midbrain-striatal dopamine (DA) system and improving the brain reward function in adolescents[13]. Physical activity also positively affects the behavioral activation system, and thereby alleviates depressive symptoms.

Previous studies[7-11,13] examined the two-sided relationship between physical activity, behavioral activation system, and depressive symptoms. Physical activity enhanced the behavioral activation system and reduced depressive symptoms. Furthermore, the behavioral activation system acted as an influencing factor for depressive symptoms. However, whether the behavioral activation system intervened in the relationship between physical activity and depressive symptoms remains unclear. Furthermore, its pathways of actions, how it intervened through the three subdimensions of the behavioral activation system, and whether the effects were consistent also remain unclear. Therefore, this study conducted a cross-sectional research that aimed to provide a theoretical basis for a deeper understanding of the relationship between human behavior, emotion, and the nervous system. Furthermore, we aimed to provide a reference for researchers and college administrators. This study proposed the following research hypotheses: (1) Physical activity and the behavioral activation system would have specificity among college students with different depressive symptom scores; (2) Physical activity, the behavioral activation system, and depressive symptoms would be closely related; and (3) Behavioral activation system would mediate the relationship between physical activity and depressive symptoms with different effects of the sub-dimensions.

Figure 1 Flow chart of the participants recruitment.

MATERIALS AND METHODS

Participants

This study used a cross-sectional research design. In total, 3047 college students were recruited online based on voluntary participation to complete a questionnaire. College students with depressive symptoms were screened *via* the Beck Depression Inventory (BDI)-II, and 472 students had depressive symptoms, with a depression detection rate of 15.49% (Figure 1). Inclusion criteria were participants who were college students, aged 18-26 years, had a score of ≥ 14 on the BDI-II, with a scores of 14-19, 20-28, and 29-63 indicating mild, moderate, and severe depression, respectively, and had no other psychiatric disorders and no brain injury. The exclusion criteria were participants who took drugs, such as barbiturates, benzodiazepines, and chloral hydrate, majored in sports, and had contraindications for exercise. After 30 invalid questionnaires with regular responses, a short response time (< 3 min), or outliers that exceeded the standard deviation ± 3 were excluded, 442 valid questionnaires (93.64%) were obtained. This study was approved by the Ethics Committee of the Shanghai University of Sport (102772021RT007).

Measures

General information questionnaire: Participants' basic information, such as age, sex, height, weight, and family status were obtained.

International physical activity questionnaire short form: This 7-item questionnaire has been widely used to measure physical activity among Chinese university students. Of these, six questions enquired regarding individuals' physical activity, which included high-intensity and moderate-intensity physical activity, and walking, and the frequency of different intensity activities for one week and the cumulative time per day. The weekly physical activity levels were calculated and divided into high, medium, and low groups according to the relevant criteria. The higher the group level, the greater the intensity of daily physical activity. This scale's retest reliability coefficient was 0.718[14].

Behavioral inhibition/activation system scale: A revised Chinese version by Li *et al*[15] was adopted with 18 items, which included two dimensions: Behavioral inhibition and activation. The behavioral activation dimension, also known as the behavioral activation system, was selected and contained three subfactors: RR, drive, and FS. Each item was scored on a scale from 1 (fully agree) to 4 (fully disagree). Cronbach's alpha was 0.759[15].

BDI-II: This widely used 21-item self-assessment scale assessed depressive symptoms. Responses were rated on a 4-point Likert scale that ranged from 0 (no symptoms) to 3 (severe symptoms). Total scores of 0-13, 14-19, 20-28, and 29-63 indicated no, mild, moderate, and severe depression, respectively. The internal consistency coefficient was 0.948[16].

Statistical analysis

Measures were expressed as mean ± SD, and the results were retained to three decimal places. For questionnaire data that were not missing at random, interpolation of the means of the same category was performed to avoid biased estimated coefficients *via* the simple deletion method. One-way analysis of variance and least significant difference post-hoc multiple tests were applied to compare the specificity of physical activity and behavioral activation system among college students with different depressive symptom scores. Pearson's correlation and linear regression analyses were performed to explore the relationships among physical activity, depressive symptoms, and behavioral activation system. Two-tailed tests were adopted for statistical inference of all parameters, and the test level α was set at 0.05. $P < 0.05$, $P < 0.01$, and $P < 0.001$ all indicated statistical significance.

Table 1 Differences in physical activity and behavioral activation system in college students with different depressive symptom scores

Variables	Whole (442)	Levels of depressive symptoms			F-value	*P* value	Post hoc multiple comparisons		
		Severe (*n* = 58)	Moderate (*n* = 190)	Mild (*n* = 194)			Severe *vs* Moderate	Severe *vs* Mild	Moderate *vs* Mild

Table 2 Regression analysis of each variable

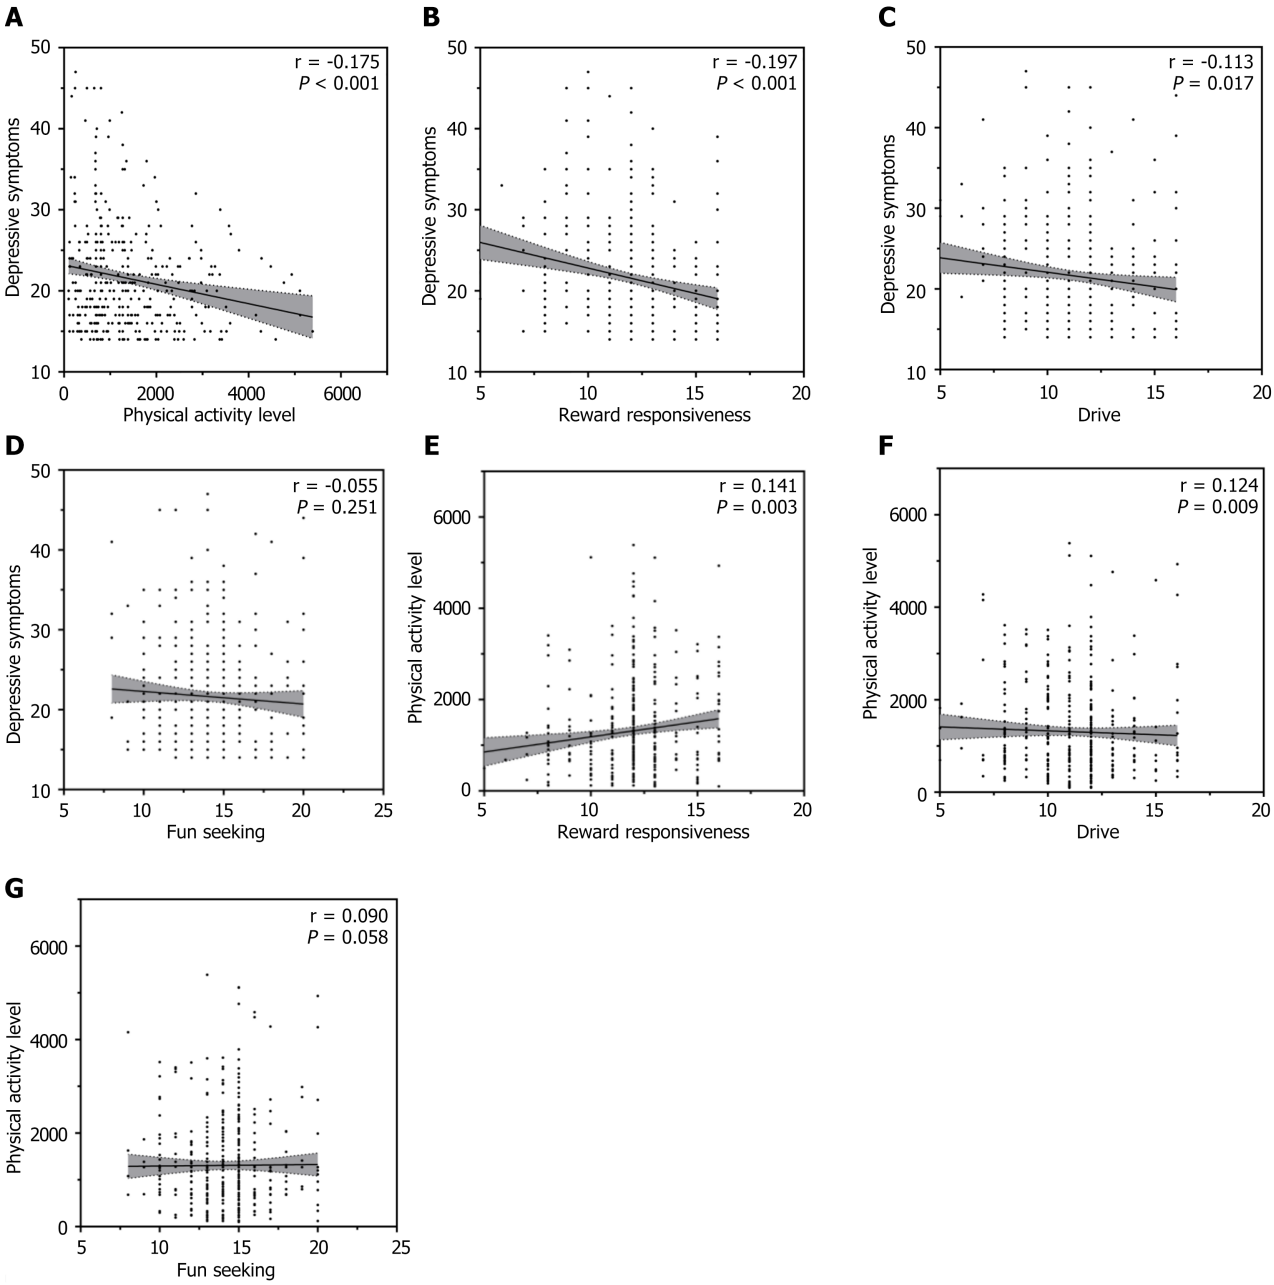
Independent variables	B	95%CI		Beta	Coefficient significance test		SE	Collinearity diagnostics	
		Lower limit	Upper limit		*t*-value	*P* value		Tolerance	VIF
Reward responsiveness	-0.176	-0.268	-0.084	-0.176	-3.766	< 0.001[a]	0.047	0.980	1.020
Physical activity	-0.116	-0.242	-0.058	-0.116	-3.217	0.001	0.047	0.980	1.020

[a]*P* < 0.001.

Model summary: F = 14.259[a]; R = 0.247; R^2 = 0.061; Adjusted R^2 = 0.057. VIF: Variance inflation factor; 95%CI: 95% confidence interval.

Harman's single factor test was used to examine the effects of common method bias. Structural equation modeling was conducted to examine the role of behavioral activation system in mediating the relationship between physical activity and depressive symptoms. The non-parametric percentage bootstrap method was adopted for parameter estimation in the path analysis. Number of samples was set at 5000, with a bias-corrected 95% confidence interval (95%CI) for the product of the mediated paths, without 0 defining the mediating effect as statistically significant. Data calculations were performed using SPSS Statistics version 23.0, and Amos version 23.0.

RESULTS



Specificity of physical activity and behavioral activation system in college students with different depressive symptom scores

There were no significant differences in FS behavior, physical activity, RR, and drive ($P < 0.05$) among college students with different depressive symptom scores. Post-hoc multiple comparisons indicated significant differences in physical activity and RR ($P < 0.05$) between college students with severe depressive symptoms and those with moderate depressive symptoms. In addition, there were also differences in physical activity, RR, and drive ($P < 0.01$) between those with severe depressive symptoms and those with mild depressive symptoms. Other indicators had no statistically significant differences. See Table 1 for further details.

Relationship between physical activity, depressive symptoms and behavioral activation system

Depressive symptoms were significantly negatively correlated with physical activity (r = -0.175, $P < 0.001$), RR (r = -0.197, $P < 0.001$), and drive (r = -0.113, $P = 0.017$). Furthermore, it was also negatively correlated with FS (r = -0.055, $P = 0.251$); however, it was not significant. Physical activity was significantly positively correlated with RR (r = 0.141, $P = 0.003$) and drive (r = 0.124, $P = 0.009$), and not significantly positively correlated with FS (r = 0.090, $P = 0.058$). Further details are shown in Figure 2.

To examine the extent of which physical activity and behavioral activation system explained depressive symptoms and explore the feasibility of the structural relationship model, depressive symptoms were considered as dependent variables, and physical activity, RR, drive, and FS as independent variables. Furthermore, a linear regression analysis was performed *via* stepwise regression. The goodness-of-fit of the prediction model was demonstrated (R = 0.247, R^2 = 0.061, adjusted R^2 = 0.057, and changed variable F = 10.349), which excluded drive and FS. As shown in Table 2, RR and physical activity were negative influencing factors, with 6.1% explanatory power for depressive symptom scores. The tolerance of each independent variable was > 0.1, and the variance inflation factor was < 5; thus, the effect of multicollinearity was excluded.

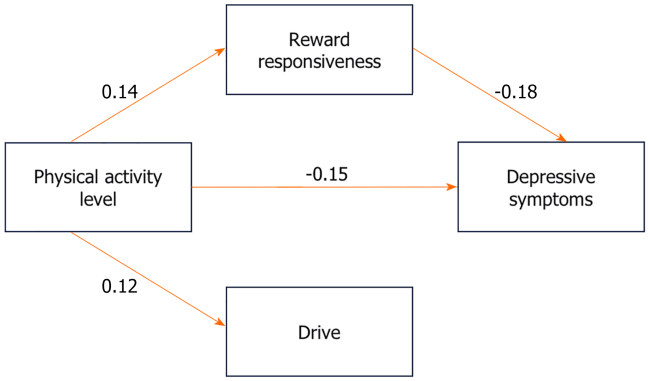
Figure 2 Correlations among the variables. A: Depressive symptoms were significantly negatively correlated with physical activity; B: Depressive symptoms were significantly negatively correlated with reward responsiveness; C: Depressive symptoms were significantly negatively correlated with drive; D: Depressive symptoms were negatively, but not significantly, associated with fun-seeking; E: Physical activity was significantly positively correlated with reward responsiveness; F: Physical activity was significantly positively correlated with drive; G: Physical activity were positively, but not significantly, associated with fun-seeking.



Construction and validation of a structural relationship model of indicators of physical activity, behavioral activation system, and depressive symptoms

To assess for common method bias, a validation factor analysis was conducted on the International Physical Activity Questionnaire, the Behavioral Activation System Scale, and the BDI *via* Harman's single factor test, nine factors with characteristic roots greater than 1 were obtained. The amount of variance explained by the first factor was 17.980%, which was less than the critical value of 40%. Therefore, the effect of common method bias was excluded. Based on the inter-relationships among physical activity, behavioral activation system, and depressive symptoms in college students, a model was established with physical activity, depressive symptoms, and behavioral activation system as the independent, dependent, and mediating variables, respectively. Mediated paths with insignificant coefficients were individually removed and recalculated until all mediated path coefficients passed the bootstrap significance test. Discrepancies divided by degrees of freedom (CMIN/df) = 0.286, root mean square residual (RMR) = 0.006, root mean square error of approximation (RMSEA) < 0.001, goodness-of-fit index (GFI) = 1.000, normed fit index (NFI) = 0.999, and comparative fit index (CFI) = 1.000 reached the reference standards of CMIN/df < 3, RMR < 0.05, RMSEA < 0.08, GFI, NFI, and CFI > 0.9[17], which indicated that the structural equation model fit well and was reasonable and reliable. The

Table 3 List of the intermediary effect coefficients

Types of effects	B	SE	Bias-corrected 95%CI		
			Lower limit	Upper limit	*P* value

Figure 3 Schematic diagram of the structural relationship model between physical activity, behavioral activation system, and depressive symptom indicators in college students with depressive symptoms. There are direct pathways and reward responsiveness-mediated indirect pathways between physical activity and depressive symptoms.

path analysis is shown in Figure 3, and the results of the mediating effect test are presented in Table 3. The path coefficients of physical activity on FS were not significant. Furthermore, those of FS and driving on depressive symptom scores were not significant, and were excluded. There were significant path coefficient for physical activity on drive (B = 0.124, 95%CI: 0.034 to 0.211, P = 0.007), mediating effect mediated by RR (B = -0.025, 95%CI: -0.051 to -0.008, P = 0.001), direct effect of physical activity on depressive symptoms (B = -0.150, 95%CI: -0.233 to -0.073, P < 0.001), and total effect of physical activity on depressive symptoms (B = -0.175. 95%CI: -0.260 to -0.099, P < 0.001).

DISCUSSION

These results showed that the higher the level of physical activity among college students with depressive symptoms, the higher the behavioral activation system and lower their depressive symptom scores. Furthermore, the direct effect of physical activity on depressive symptoms was significant. The results supported those of previous studies on the relationship between behavioral activation system and depressive symptoms. Furthermore, our findings were generally consistent with previous results. Takagaki *et al*[18] found a negative association between the behavioral activation system and depressive symptoms among 18-19 years old college students with depressive symptoms in a Japanese University. Absence of pleasure was a core symptom of depression[19] which was related to the dysfunction of the brain's DA reward system[20]. Deficits in the reward system served as a susceptibility factor and predictor of depression, with state independence and heritability[21,22]. A cross-sectional study found that college students with higher levels of physical activity had lower detection rates of depressive symptoms and insufficient physical activity was a risk factor for depressive symptoms among college students. Experimental studies confirmed that increased physical activity was effective in improving depressive symptoms and stimulated the secretion of neurotransmitters, which increased the behavioral activation system and also alleviated depressive symptoms.

This study showed that only RR mediated the relationship between physical activity and depressive symptoms. Physical activity promoted the secretion of neurotransmitters, such as DA in the brain, enhanced the neuroplasticity of the DA system, and improved the reward function. This enhanced the RR and contributed to the maintenance and regulation of good emotions in individuals, promoted the generation of positive emotions, and suppressed negative emotions[23]. High reward responses acted as a protective factor against depression[24]. Furthermore RR purely reflected extroversion and convergent motivation[25], which maintained and regulated individual behavior. Hence, impulsive behaviors that met short-term interests were subordinated to needs more closely related to the individual's long-term

interests[26]. High RR prompted a positive response to rewards. It enhanced an individual's ability to obtain pleasurable experiences to avoid the exacerbation of their depressive symptoms[27,28]. Only the RR pathway mediated the relationship between physical activity and depressive symptoms. A possible reason was that RR, as the initial evaluation of reward, measured early "reward interest," "goal-drive", and "persistence." Furthermore, its effect on depressive symptoms may precede the other two dimensions. Reasons why drive and FS did not mediate the relationship between physical activity and depressive symptoms were drive referred to the degree of willingness to exert effort to obtain a reward and measured late "reward responsiveness" and "impulsivity;" FS was a continuous evaluation of the reward. Hence, drive and FS were more significant for major depression, and better predictors of treatment effect[29,30]. Our participants had different conditions, and relatively few individuals reported severe depression symptoms.

This study has some limitations. First, the data were from subjective reports, which may have some bias. Furthermore objective indicators are recommended for future measurements. This study was conducted as a cross-sectional study. Hence, longitudinal studies are required to further confirm the pathways of action.

CONCLUSION

The higher the level of physical activity, the higher the behavioral activation system and lower the depressive symptom score in college students with depression. Furthermore, there was only one pathway of action in the behavioral activation system, RR, which had a significant mediating effect between physical activity and depressive symptoms. Therefore, colleges and universities should encourage college students with depression to increase their physical activity and improve their behavioral activation system. Particular attention should be paid to RR, which may reduce the prevalence of depressive symptoms.

ARTICLE HIGHLIGHTS

Research background

Depression is a common mental disorder among college students. Key symptoms include persistent depressed mood, sad emotional experiences, lack of pleasure, listlessness, and impaired cognitive function, accompanied by self-harm and suicidal tendencies.

Research motivation

Reduce the prevalence of depressive symptoms in college students.

Research objectives

Elucidating pathways and effects of behavioral activation systems between physical activity and depressive symptoms in college students with depressive symptoms.

Research methods

One-way analysis of variance and Pearson correlation, linear regression, and structural equation modeling were used to explore the correlation and pathway of interactions between variables.

Research results

The mediating effect of reward responses between physical activity and depressive symptoms was significant [B = -0.025, 95% confidence interval (95%CI): -0.051 to -0.008, $P = 0.001$]. The direct and total effects of physical activity on depressive symptoms were significant ((B = -0.150, 95%CI: -0.233 to -0.073, $P < 0.001$; B = -0.175, 95%CI: -0.260 to -0.099, $P < 0.001$, respectively).

Research conclusions

Colleges and universities should encourage college students with depression to increase physical activity and improve behavioral activation systems. Particular attention should be paid to the ability to reward responses, which may reduce the prevalence of depressive symptoms.

Research perspectives

It is recommended to use objective measurement tools in future measurements; longitudinal studies are needed to further define the course of action.

Abstract

BACKGROUND

Acute cerebral infarction (ACI) is characterized by a high incidence of morbidity, disability, recurrence, death and heavy economic burden, and has become a disease of concern in global researchers. As ACI has serious effects on patients' physical status, life and economy, often causing anxiety, depression and other psychological problems, these problems can lead to the aggravation of physical symptoms; thus, it is very important to understand the factors affecting the mental health of these patients.

AIM

To understand the elements that affect the mental health of patients who have suffered an ACI.

METHODS

A questionnaire survey was conducted among patients with ACI admitted to three tertiary hospitals (Quanzhou First Hospital, Fuqing City Hospital Affiliated to Fujian Medical University, and the 900 Hospital of the Joint Service Support Force of the People's Liberation Army of China) in Fujian Province from January 2022 to December 2022 using the convenience sampling method. ACI inpatients

who met the inclusion criteria were selected. Informed consent was obtained from the patients before the investigation, and a face-to-face questionnaire survey was conducted using a unified scale. The questionnaire included a general situation questionnaire, Zung's self-rating depression scale and Zung's self-rating anxiety scale. All questionnaires were checked by two researchers and then the data were input and sorted using Excel software. The general situation of patients with ACI was analyzed by descriptive statistics, the influence of variables on mental health by the independent sample *t* test and variance analysis, and the influencing factors on psychological distress were analyzed by multiple stepwise regression.

RESULTS

The average age of the 220 patients with ACI was 68.64 ± 10.74 years, including 142 males and 78 females. Most of the patients were between 60 and 74 years old, the majority had high school or technical secondary school education, most lived with their spouse, and most lived in cities. The majority of patients had a personal income of 3001 to 5000 RMB yuan per month. The new rural cooperative medical insurance system had the largest number of participants. Most stroke patients were cared for by their spouses and of these patients, 52.3% had previously smoked. Univariate analysis showed that gender, age, residence, course of disease, number of previous chronic diseases and smoking history were the main factors affecting the anxiety scores of patients with ACI. Age, living conditions, monthly income, course of disease and knowledge of disease were the primary variables influencing the depression score in patients with ACI. The findings of multivariate analysis revealed that the course of disease and gender were the most important factors influencing patients' anxiety scores, and the course of disease was also the most important factor influencing patients' depression scores.

CONCLUSION

Long disease course and female patients with ACI were more likely to have psychological problems such as a high incidence of emotional disorders. These groups require more attention and counseling.

Key Words: Acute cerebral infarction; Mental health; Self-rating depression scale; Self-rating anxiety scale; Influencing factor; Correlation analysis

Core Tip: In recent years, research on acute cerebral infarction has not only focused on the effects of the infarction on the body, but also the psychological effects. In this study, we found that long disease course may be the main factor leading to psychological problems in patients, and female patients with a high incidence of emotional disorders are more likely to have psychological problems. Such groups require more attention and psychological counseling.

INTRODUCTION

Acute cerebral infarction (ACI) has become a disease of concern in global researchers due to its high incidence of morbidity, disability, recurrence, death and heavy economic burden[1,2]. Most patients have different degrees of limb function, cognitive function and other disorders following sudden ACI. Patients find it difficult to accept physical changes which have a greater impact on their psychological status. These cannot be resolved in a short period of time, and there are some emotional changes such as suspicion and anxiety. Long-term negative emotions are psychological burdens, which affect physical and mental health[3-5]. Early detection of psychological problems, exploring the source of these psychological problems, providing targeted solutions, reducing patients' psychological disorders while improving the recovery in limb function or cognition, and promoting rehabilitation are essential. Therefore, it is necessary to carry out a cross-sectional survey to understand the influencing factors on mental health status in patients with ACI, examine the key factors affecting mental health, improve the mental health status of patients with ACI, and pave the way for early clinical intervention.

MATERIALS AND METHODS

Study population and data collection

From January 2022 to December 2022, a questionnaire survey was conducted in patients with ACI admitted to three tertiary hospitals in Fujian Province (Quanzhou First Hospital, Fuqing City Hospital Affiliated to Fujian Medical University, and the 900 Hospital of the Joint Service Support Force of the People's Liberation Army of China).

Inclusion criteria were: (1) Diagnosis consistent with that in the Chinese acute stroke clinical research consensus; (2) High research compliance; (3) Basic listening and speaking ability; and (4) Patients with a temporary stable condition and clear consciousness.

Exclusion criteria were: (1) Patients with language communication, cognitive, hearing or mental disorders; (2) Those with severe respiratory failure, malignant tumor, liver, renal, and cardiac dysfunction; and (3) Incomplete clinical data or participation in other research.

All patients with ACI who met the inclusion requirements were included in the study. Before the investigation, consent was obtained from the subjects and the informed consent was signed. A unified scale was used to conduct a face-to-face questionnaire survey. Those with good reading and writing ability completed the questionnaire. If the patients had difficulty in completing the questionnaire, the researcher used a unified guidance language to describe the questions. When the patient understood the questions, the survey was completed according to the patient's opinions. The researcher collected and checked the questionnaires, and corrected any errors.

General information questionnaire

This questionnaire included demographic characteristics (gender, age, education level, marital status, medical insurance type, inpatient caregivers, smoking history, *etc*.) and disease-related data (course of disease, type of stroke, number of strokes, past chronic disease status, *etc*).

Assessment of anxiety and depression

To evaluate potential anxiety and depression, the Chinese versions of Zung's self-rating depression scale (SDS) and Zung's self-rating anxiety scale (SAS) were utilized. The commonly used SAS and SDS measures are quick and practical tools for assessing respondents' signs of anxiety and depression, and they have strong reliability and validity in the Chinese population. Each scale has 20 items that are rated on a scale of 1 to 4 to evaluate the assertions (rarely, occasionally, frequently, or always). The standard scale was created by multiplying the 20-80 point range of the overall score by 1.25. The higher the score, the more severe the anxiety or depression. According to the findings of the Chinese norm, the cut-off value of the SDS standard score was 53 points; mild depression was defined as 53-62 points, moderate depression as 63-72 points, and severe depression as more than 73 points. The SAS standard deviation cutoff was 50 points, with mild anxiety being between 50 and 59 points, moderate anxiety being between 60 and 69 points, and severe anxiety being more than 69 points.

Statistical analysis

All questionnaires were checked by two researchers, and then Excel software was used for data entry and collation. The SPSS26.0 program was utilized for data analysis. Descriptive statistical analysis was used for the general situation of patients with ACI. The independent sample *t* test and variance analysis were used to analyze the influence of each variable on mental health. Multiple stepwise regression analysis was used to analyze the influencing factors of psychological distress. $P < 0.05$ was considered statistically significant.

RESULTS

Demographic characteristics of patients with ACI

Demographic characteristics of the 220 patients with ACI (Table 1).

Disease-related information on patients with ACI

The disease course, frequency of onset, history of hypertension, history of diabetes, history of coronary heart disease, and history of chronic diseases patients with ACI was counted (Table 2).

Mental health status of patients with ACI

Among the 220 patients with ACI in this survey, 122 had depression, including 73 cases of mild depression, 39 cases of moderate depression, and 10 cases of severe depression. One hundred and sixty-three cases had anxiety, including 65 cases of mild anxiety, 61 cases of moderate anxiety, and 37 cases of severe anxiety (Table 3).

Effects of demographic sociological characteristics on mental health

The SAS score and SDS score of ACI patients were used as dependent variables, and gender, age, occupation, education level, marital status, living conditions, place of residence, personal monthly income, type of medical insurance, inpatient nursing staff, and smoking history were used as independent variables for univariate analysis. The results showed that gender, age, living conditions and smoking history were the main factors affecting the SAS score of ACI patients. Age, living conditions and personal monthly income were the main factors affecting the SDS score of ACI patients (Table 4).

Effects of ACI on mental health

The SAS score and SDS score of stroke patients were used as dependent variables, and the duration of disease, number of strokes, history of hypertension, history of diabetes, history of coronary heart disease, number of previous chronic diseases, and knowledge were used as independent variables for univariate analysis. The results showed that the course of disease, chronic history and the number of previous chronic diseases were the main factors affecting the SAS score of ACI patients. The course of disease and the status of knowledge of the disease were the main factors affecting the SDS score of patients with ACI (Table 5).

Multivariate analysis of anxiety in patients with ACI

The data obtained from this survey were analyzed by stepwise regression analysis, the SAS score in patients with ACI was used as the dependent variable, and the variables that showed statistically significant SAS scores in the patient data (gender, age, location, disease course, number of chronic diseases, and smoking history) as independent variables. The

findings demonstrated that gender and progression of the illness were factors in the regression model (Table 6).

Multivariate analysis of depression in patients with ACI

The data obtained from this survey were analyzed by stepwise regression analysis, the SDS score in patients with ACI was used as the dependent variable, and the variables that showed statistically significant SAS scores in the patient data (age, place of residence, disease course, personal monthly income, and disease awareness) as independent variables. The findings demonstrated that the disease course was a factor in the regression equation (Table 7).

ACI: Acute cerebral infarction; SDS: Self-rating depression scale; SAS: Self-rating anxiety scale.

DISCUSSION

ACI is a sudden cerebrovascular disease. It is an acute attack when the patient's brain is blocked by blood vessels such as coronary arteries[6,7]. Due to the close connection between the cerebrovascular and central nervous system, patients with ACI often have a poor prognosis. Even after treatment, neurological dysfunction may persist. Some patients are prone to unpleasant feelings such as depression and anxiety during the onset of the disease, and then sleep disorders, neurasthenia and other symptoms, such psychological changes may be related to the occurrence of nerve defects[8-10]. In recent years, the study of ACI has not only focused on the effects on the body, but psychological effects have received more and more attention[11-13]. Patients with anxiety and depression often have a poor prognosis, longer recovery time and are

more likely to relapse[13,14]. Therefore, this study analyzed the influencing factors on mental health in patients with ACI, with the hope of identifying the key factors affecting mental health.

The SAS score and SDS score in the 220 patients with ACI included in this study were statistically significant. The total SAS score was 57.49 ± 12.56, which was significantly higher than the standard cut-off value. The total SDS score was 54.21 ± 11.73, which was significantly higher than the standard cut-off value, indicating that psychological problems are common in patients with ACI in China. The results of univariate analysis showed that gender, age, residence, course of disease, number of chronic diseases and smoking history were the primary elements influencing the anxiety score in patients with ACI. Age, living conditions, monthly income, course of disease and knowledge of ACI were primary elements influencing the depression score in patients with ACI. The analysis results showed that female patients had more severe anxiety than male patients. The levels of anxiety and depression increased with age. Similar to previous research results, a possible reason for this is that women and the elderly belong to a high-risk group with emotional disorders[15-17], and psychological problems are more likely to occur after ACI. The SAS and SDS scores of patients living with their children were higher, which matched the outcomes of earlier studies[18,19]. This may be because patients living with their children often need to take care of their families, and the lack of ability regarding family care after infarction leads to serious anxiety. The longer the disease course, the higher the SAS and SDS scores in patients, which matched the outcomes of earlier studies[20,21], and might be the result of an aggravation of psychological problems caused by long-term distress; the anxiety score in patients without a history of chronic disease was highest, which may be due to the increase in psychological pressure caused by the patient's abilities in their previous healthy state and their sudden need for care. The depression score in patients with ACI and higher monthly income was greatest, which may be due to the impact on work and income after illness, resulting in psychological problems. Patients who do not understand the disease have higher depression scores, which may be due to the fact that patients do not understand their disease status and do not know why they are more likely to worry about hospitalization, resulting in psychological problems. Furthermore, multivariate analysis showed that the course of disease and gender were the key factors affecting the anxiety score in patients, and the course of disease was also the key factor affecting the depression score in patients. According to these findings, psychological issues are more likely to occur in patients who have had their disorder for a longer period of time and in women.

The limitation of this study is that the sample size is too small to fully analyze more factors affecting the mental health status of ACI patients. In future studies, we will continue to collect data of ACI patients, and further evaluate the key factors affecting the mental health of ACI patients in a more comprehensive way, as well as the mediating and regulating effects of other influencing factors.

CONCLUSION

In summary, patients with ACI generally have psychological issues including despair and anxiety. A long disease course may be the main factor leading to psychological problems in patients, and female patients are more likely to have psychological problems such as a high incidence of emotional disorders. Such groups require more attention and psychological counseling.

ARTICLE HIGHLIGHTS

Research background

Acute cerebral infarction (ACI) is a sudden cerebrovascular disease. ACI occurs when the patient's brain is blocked by coronary arteries and other blood vessels, resulting in ischemia and hypoxia. Even after receiving treatment, there may be persistent neurological dysfunction. Patients with anxiety and depression tend to have a poor prognosis, take longer to recover and are more likely to relapse.

Research motivation

This study analyzed the factors affecting the mental health of patients with ACI, with the hope of identifying the key factors affecting mental health.

Research objectives

The object of this study is to improve the mental health status of patients with ACI, and pave the way for early clinical intervention.

Research methods

A questionnaire survey was conducted among patients with ACI admitted to three tertiary hospitals in Fujian Province from January 2022 to December 2022 using the convenience sampling method. Patients with ACI who were inpatients and met the inclusion criteria were selected. A face-to-face questionnaire survey was conducted using a unified scale. To evaluate potential signs of anxiety and depression, the Zung's self-rating depression scale and Zung's self-rating anxiety scale were used. All questionnaires were checked by two researchers and then the data were input and sorted using Excel software. The general situation of ACI patients was analyzed by descriptive statistics, the influence of variables on mental

health by the independent sample *t* test and variance analysis, and the influencing factors on psychological distress were analyzed by multiple stepwise regression.

Research results

Univariate analysis showed that gender, age, residence, course of disease, number of previous chronic diseases and smoking history were the main factors affecting anxiety scores in ACI patients. Age, living conditions, monthly income, course of disease and knowledge of ACI were the main factors affecting the depression score in ACI patients. According to the results of the multivariate analysis, the course of disease and gender were the key factors affecting the anxiety score, and the course of disease was also the key factor affecting the depression score.

Research conclusions

Patients with ACI generally have psychological issues including depression and anxiety. A long disease course may be the main factor leading to psychological problems in patients, and female patients are more likely to have psychological problems such as a high incidence of emotional disorders. Such groups require more attention and psychological counseling.

Research perspectives

More patient records should be collected to more comprehensively evaluate the key factors affecting the mental health of patients with ACI.

Abstract

BACKGROUND

The debate regarding diagnostic classification systems in psychiatry (categorial *vs* dimensional systems) has essential implications for the diagnosis, prevention and treatment of stress reactions. We previously found a unique pattern of stress reaction in a study executed during the coronavirus disease 2019 pandemic using large representative samples in two countries, and termed it the Complex Stress Reaction Syndrome (CSRS).

AIM

To investigate CSRS, Type A (psychiatric symptoms, spanning anxiety, depression, stress symptoms, and post-traumatic stress disorder (PTSD)), with or without long-coronavirus disease (COVID) residuals (CSRS, Type B, neuropsychiatric symptoms spanning cognitive deficits and fatigue, excluding systemic symptoms). Our two-tailed hypothesis was that CSRS is a condition related to an unrecognized type of stress reaction in daily life in the general population (Type A) or that it is related to the severe acute respiratory syndrome coronavirus 2 infection and its long-COVID residuals (Type B).

METHODS

977 individuals in four continents (North America, Europe, Australia and the Middle East) completed the online study questionnaire in six languages using the Qualtrics platform. The study was managed by six teams in six countries that promoted the study on social media. The questionnaire assessed anxiety, depression, stress symptoms and PTSD (CSRS, Type A), cognitive deficits and fatigue (CSRS, Type B). The data were analyzed using Proportion Analyses, Multivariate Analysis of Co-Variance (MANCOVA), linear regression analyses and validated clinical cutoff points.

RESULTS

The results of the Proportion Analyses showed that the prevalence of 4 symptoms spanning anxiety, depression, stress symptoms, and PTSD was significantly higher than the most prevalent combinations of fewer symptoms across 4 continents, age groups, and gender. This supports the transdiagnostic argument embedded in the CSRS (Type A). The same pattern of results was found in infected/recovered individuals. The prevalence of the 4 psychiatric symptoms combination was significantly greater than that of 5 and 6 symptoms, when adding cognitive deficits and fatigue, respectively. MANCOVA showed a significant three-way interaction (age × gender × continent). Further analyses showed that the sources of this three-way interaction were threefold relating to two sub-populations at-risk: (1) Individuals that self-identified as non-binary gender scored significantly higher on all 4 psychiatric symptoms of the CSRS, Type A at young age groups (< 50 years old) in North America compared to (self-identified) women and men located in the 4 continents studied, and to other ages across the adult life span; and (2) This pattern of results (CSRS, Type A) was found also in women at young ages (< 40 years old) in North America who scored higher compared to men and women in other continents and other ages. Linear regression analyses confirmed the MANCOVA results.

CONCLUSION

These results show a combined mental health risk factor related to stress reactivity, suggesting that the CSRS is sensitive to populations at risk and may be applied to future identification of other vulnerable sub-populations. It also supports the transdiagnostic approach for more accurate prevention and treatment. Time will tell if such transdiagnostic syndromes will be part of the discussions on the next revisions of the traditional classification systems or whether the crisis in psychiatry further evolves.

INTRODUCTION

The debate on diagnostic classification systems and the resulting crisis in psychiatry is evolving[1]. Many professionals doubt the validity of the categorical model, Diagnostic and Statistical Manual of mental disorders (DSM) and International Classification of Diseases (ICD), as clinical practice, supported by scientific evidence, shows that mixed symptomology is often presented by many patients without meeting the full criteria of any traditional diagnostic category[2]. Updated search in *Reference Citation Analysis* (https://www.referencecitationanalysis.com/), Google Scholar and PubMed, shows that the transdiagnostic approach is evolving and that cutting edge studies are published in very high-ranked journals[3-7].

There are at least four transdiagnostic new classification systems: Hierarchical Taxonomy to Psychopathology[8], Research Domain Criteria[9], Bipolar-Schizophrenia Network on intermediate phenotypes[10], and Neuroscience-Based Nomenclature[11]. These dimensional transdiagnostic approaches showed biological evidence of specific underlying mechanisms for several mental disorders[12-15]. However, others claim that the findings on underlying biological mechanisms relate to a too wide range of disorders, ruling out the option of differential diagnosis and more accurate derived prevention and treatment[15,16]. The option of including dimensional categories in the traditional classifications has yet to be discussed.

The debate in psychiatry has crucial implications for the diagnosis of stress reactions. Optimal stress reactions are prerequisites of adaptive coping from evolutionary perspectives[17-19]. However, stress reactions are patient-specific, environment-specific, and timing-specific. Therefore, they include a wide range of behaviors and emotional conditions, which cross traditional classification categories and are addressed only partially by these systems[12-14,20,21]. Of special interest is the condition of exposure to multiple stressors, investigated mostly in disaster situations such as flooding, pandemics, hurricanes, earthquakes, and wars[22-25]. In the etiological explanations of the traditional nosology, the interactions of individual differences in coping capacities with the number and extent of environmental stressors have not been evidence-based to date.

Specifically, we previously found a unique transdiagnostic pattern of stress reaction in a binational study using large representative samples in two countries, Italy and Israel, executed during the coronavirus disease 2019 (COVID-19) pandemic[26]. The results showed a transdiagnostic combination of four stress-related symptoms [anxiety, depression, stress symptoms, and post-traumatic stress disorder (PTSD)] that was significantly more prevalent than combinations of fewer symptoms. We termed this combination of four symptoms the Complex Stress Reaction Syndrome (CSRS). We found this pattern of results in the two countries despite cultural and language differences between the two countries and between the methodologies used, suggesting convergent validity of the CSRS.

The pattern of multiple associated symptoms has been widely reported by others regarding the COVID-19 pandemic's impacts on mental health[27-29]. According to WHO reports, 22% of the population develops mental health problems in a dimensional pattern, reactive to emergencies[30]. Accordingly, we related the CSRS to the COVID-19 situation and included CSRS, Type A (psychiatric symptoms) and Type B (psychiatric and neuropsychiatric symptoms in COVID-infected and recovered individuals, excluding systemic symptoms of long-COVID)[26,31]. However, the possibility that CSRS is relevant in the post-COVID era, to capture the mixed clinical picture resulting from concomitant daily stressors in the general population, has only recently been proposed[16].

In a recent paper, we outlined the detailed description of the conceptual development of the CSRS, including its origins in clinical practice and its uniqueness as one transdiagnostic category[16], rather than a total transdiagnostic denial of the traditional psychiatric classifications as suggested by others. The framework underpinning the current study presents an elaboration of the first validation of the CSRS in our published binational study[26], by the inclusion of participants located in four continents in this current study, beyond the validation of the CSRS in only two countries.

In the current multi-lingual international study, conducted across four continents, we aimed to investigate our two-tailed hypothesis that the CSRS is a condition related to the unrecognized type of stress reaction in daily life in the general population (Type A) or related to the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) viral infection and its long-COVID neuropsychiatric residuals (Type B).

MATERIALS AND METHODS

Institutional review board

Institutional review board approvals for this international study were provided by The Johns Hopkins University, Baltimore, Maryland, United States, and by Bar Ilan University, Ramat-Gan, Israel. The study survey used the Qualtrics platform (Qualtrics, Provo, Utah, United States) for data collection.

Sample

From a sample of 2024 individuals who approached the study questionnaire and partially completed it, 977 completed the entire study questionnaire, and this sample was used for the statistical analyses.

Inclusion criteria: Age > 18 years old.

Recruitment regions: Middle East, North America, Australia, Europe.

Activating recruitment teams: A team of research assistants executed the study on media platforms in each of the six active countries located in four continents. These teams were located in Israel, Jordan, Italy, Sweden, United States and Australia. Each team was led by at least one psychiatrist or psychologist.

Languages: The survey (*i.e.* the clinical research tools) was translated from English to 5 languages (Arabic, Hebrew, Italian, Swedish and German) using back translations to English for validation. All posts on the social media platforms were published in all 6 languages of the study to enhance recruitment.

Qualtrics: We uploaded the study survey in 6 languages on the Qualtrics platform. The data were saved on this platform and analyzed periodically for the recruitment rate. The final statistical analyses were executed using the data saved on this platform.

Study period: February 1, 2022-March 1, 2023.

Clinical research tools: We used the following clinical screening tools to identify mental health status (CSRS, Type A): Generalized anxiety disorder-7 (anxiety measure[32]; Cronbach's alpha = 0.931), patient health questionnaire-8[33] (depression measure; Cronbach's alpha = 0.903), perceived stress scale[34] (stress measure; Cronbach's alpha = 0.901), international trauma questionnaire[35] (a PTSD measure; Cronbach's alpha = 0.921). We also used neuropsychiatric measures for infected or recovered individuals (CSRS, Type B): (1) The Perceived Deficits Questionnaire-5, (a cognitive impairment measure[36]; Cronbach's alpha = 0.88); and (2) Fatigue[37], (Cronbach's alpha = 0.654). Participants were asked whether they were SARS-CoV-2 infected/recovered or not. These data were analyzed using validated clinical cutoff points to identify symptomatic conditions above the normative scores on each tool. Anonymity of participants was maintained throughout the study.

Participation time: Surveys took approximately 15 min to complete as measured in a pilot study before the onset of this research.

Recruitment

Instagram: We opened an account with promoting videos and photos related to the study and periodically added more related materials. The materials were translated and posted in all six languages of the study. The account displayed a link to the survey's international Qualtrics platform. Each post was user friendly.

Facebook: We used Facebook online groups to post a link to the survey. In the case of private Facebook groups, the research assistants in each active participating country contacted the group managers for permission.

Reddit: We promoted the study using this social media platform which is friendly and popular in the United States and Australia.

Online meetings: The international study teams in the six active countries conducted periodical, online meetings with the leading author and professional leads across each recruitment site to track the recruitment process and rate. To manage recruitment goals in each region, the leading author shared figures of the participants' rate per region, extracted from the data already gathered at those points.

Statistical analyses

The statistical approach included three steps: (1) We analyzed the frequency of all combinations of symptoms, to determine the most frequent combinations of two, three, four (CSRS, Type A), five and six (CSRS, Type B) symptoms. We then compared between the most prevalent combinations of each number of symptoms using Proportion Analyses; (2) Multivariate Analysis of Co-Variance (MANCOVA) to identify subpopulations at risk; and (3) We confirmed the identification of the subpopulations at risk by linear regression analyses.

RESULTS

This sample included 655 women, 296 men, and 26 individuals who self-identified as non-binary gender. Of those, 253 aged 18-29, 294 aged 30-39, 204 aged 40-49, 151 aged 50-59, and 75 aged above 60 years old.

All symptoms were significantly correlated (Table 1). Proportion Analyses showed that in the general population, the prevalence of the four-symptom combination (CSRS, Type A) Anxiety, Depression, Stress and PTSD (30.98%, 95%CI: 28-33.8) was greater than that of the most prevalent combination of three symptoms (Anxiety, Stress, and PTSD; 12.78%, 95%CI: 10.7-14.9, $P < 0.001$) and the most prevalent combination of two symptoms (Anxiety and Stress; 6.24%, 95%CI: 4.8-7.8, $P < 0.001$), as well as more prevalent than the one most prevalent symptom (Stress; 18.81%, 95%CI: 16.6-21.6, $P < 0.001$) (Table 2).

In the infected population we found the same pattern of results. As shown for the general population, in infected individuals the prevalence of the combination of four symptoms, Anxiety, Depression, Stress and PTSD (27%, 95%CI: 24.1-31.8) was greater than that of the most prevalent combination of three symptoms (Anxiety, Stress, and PTSD; 12.2%, 95%CI: 9.7-15.3, $P < 0.001$), greater than that of the most prevalent combination of two symptoms (Anxiety and Stress; 5.9%, 95%CI: 4.2-8.3, $P < 0.001$), and that of the one most prevalent symptom (Stress; 21%, 95%CI: 18-25, $P < 0.01$).

However, when we added long-COVID neuropsychiatric symptoms (Cognitive deficits and Fatigue, CSRS, Type B) to the four psychiatric symptoms (CSRS, Type A), the prevalence of four psychiatric symptoms (CSRS, Type A) was still significantly greater than the most prevalent combinations of five symptoms (when adding Cognitive deficits, 8%, 95%CI: 6.3-11.1) or six symptoms (when adding Cognitive Deficits and Fatigue, 4%, 95%CI: 2.8-6.3) at $P = 0.003$, $P < 0.001$, respectively), showing that the prevalence of CSRS, Type A is significantly greater than all combinations of symptoms studied. Thus, these results endorse our two-tailed hypothesis, confirming that one tail of the two (CSRS, Type A) is significant. These findings suggest that the CSRS, Type A is applicable for the general population without direct association with the neuropsychiatric part of long-Covid (CSRS, Type B), and that it is not necessarily related to the viral infection and its suspected residuals. Bonferroni correction for multiple comparisons was conducted and the results were significant at $P < 0.01$.

As shown in Table 2, more people reported the combination of all 4 psychiatric symptoms (CSRS, Type A) than the combinations of fewer symptoms.

In further analyses to detect subpopulations at risk, a MANCOVA was conducted with four continents, five age groups and three types of gender as independent variables, while keeping the 4 psychiatric components of the CSRS, Type A as dependent variables, controlling for COVID-infected/recovered *vs* non infected/recovered individuals as a covariate. A three-way interaction was found: Continent × age × gender [$F(14,925) = 1.747$, $P < 0.05$ with observed power of 0.903] (Figures 1 and 2). The covariate did not significantly add to the explained variance. Follow up analyses showed that the sources of the three-way interaction were threefold, consistently over the 4 dependent variables (Anxiety, Depression, Stress and PTSD, CSRS, Type A): (1) In North America, participants aged < 50 years old, self-identifying as non-binary, reported significantly higher scores than both women and men ($P < 0.05$); (2) Women at young ages (< 40 years old) in North America scored higher compared to men and women in other continents and other ages; and (3) In North America, women at young ages (< 40 years old) and participants self-identifying as non-binary gender, aged < 50, scored above the clinical cutoff points, although women's scores were significantly lower ($P < 0.05$) than the scores of the non-binary gender at these young ages.

The sources of the three-way interaction, which in turn correspond to identified populations at risk, were confirmed by linear regression analyses, which do not require an assumption of variables' normal distributions.

Specifically, Anxiety score was negatively associated with being a man [b = -1.42 (-2.22, -0.62)] and positively associated with non-binary gender [b = 3.81 (1.53, 6.10)], negatively associated with age groups 50-60 [b = -1.36 (-2.56, -0.15)] and > 60 [b = -3.06 (-4.59, -1.53)] and living in Australia [b = -2.96 (-3.85, -2.07)] or the Middle-East [b=-2.06 (-3.84, -1.36)] compared to North America.

Depression score was negatively associated with being a man [b = -1.57 (-2.42, -0.72)] and positively associated with non-binary gender [b = 5.08 (2.65, 7.51)] while negatively associated with age group > 60 [b = -2.89 (4.52, 1.26)] and living in Australia [b = -2.01 (-2.96, -1.06)] or the Middle-East [b = -2.97 (-4.28, -1.64)] compared to North America.

Stress symptoms score was negatively associated with being a man [b = -2.02 (-3.15, -0.88)] and positively associated with non-binary gender [b = 4.65 (1.40, 7.90)], negatively associated with age groups 50-60 [b = -2.12 (-3.84, -0.40)] and > 60 [b = -5.33 (-7.51, -3.16)] and living in Australia [b = -3.24 (-4.51, -3.98)] or the Middle East [b = -4.49 (-6.25, -2.72)] compared to North America.

PTSD score was negatively associated with being a man [b = -2.89 (-4.09, -1.70)] and positively associated with non-binary gender [b = 6.34 (2.92, 9.75)], negatively associated with older age group > 60 [b = -4.86 (-7.15, -2.57)] and living in Australia [b = -3.53 (-4.86, -2.20)], Europe [b = -3.43 (-6.02, -0.85)] or the Middle East [b = -4.44 (-6.29, -2.59)] compared to North America.

DISCUSSION

The results of this study show that the prevalence of 4 symptoms, combining anxiety, depression, stress symptoms and PTSD, was significantly higher than the most prevalent combinations of fewer symptoms across 4 continents, age groups (> 18 years old), and gender. This supports the transdiagnostic hypothesis embedded in the CSRS (Type A) and shows its clinical value as a future potential diagnosis spanning 4 conventional diagnostic categories.

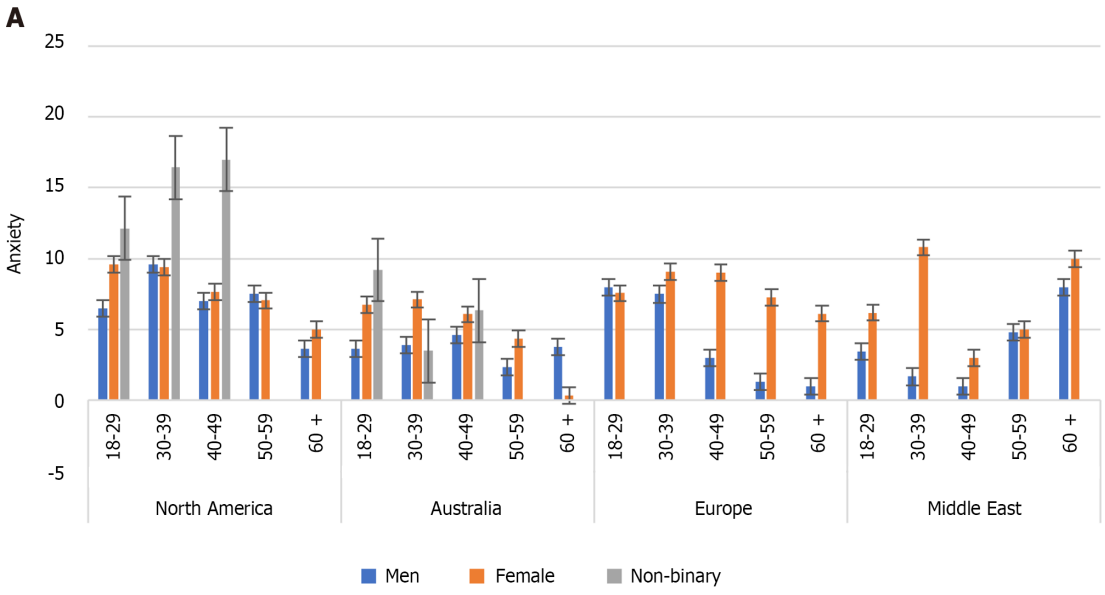
Table 1 Correlation coefficients between all six dependent variables

Correlation table	PHQ	PSS	ITQ	GAD	Cognitive	Fatigue
PHQ	1	0.79[a]	0.74[a]	0.80[a]	0.4[a]	0.24[a]
PSS	0.79[a]	1	0.74[a]	0.79[a]	0.3[a]	0.25[a]
ITQ	0.74[a]	0.74	1	0.71[a]	0.34[a]	0.31[a]
GAD	0.80[a]	0.79[a]	0.71	1	0.311	0.25[a]
Cognitive	0.4[a]	0.3[a]	0.34[a]	0.311[a]	1	0.30[a]
Fatigue	0.24[a]	0.25[a]	0.31[a]	0.25[a]	0.30[a]	1

[a]$P < 0.001$.

As shown in Table 1, all components of the CSRS type A and type B are significantly correlated. PHQ: Patient Health Questionnaire; PSS: Perceived Stress Scale; ITQ: International Trauma Questionnaire; GAD: Generalized Anxiety Disorder.

Table 2 All combinations of symptoms reported



General population	Percentage
Combination	
None	10
Stress	20

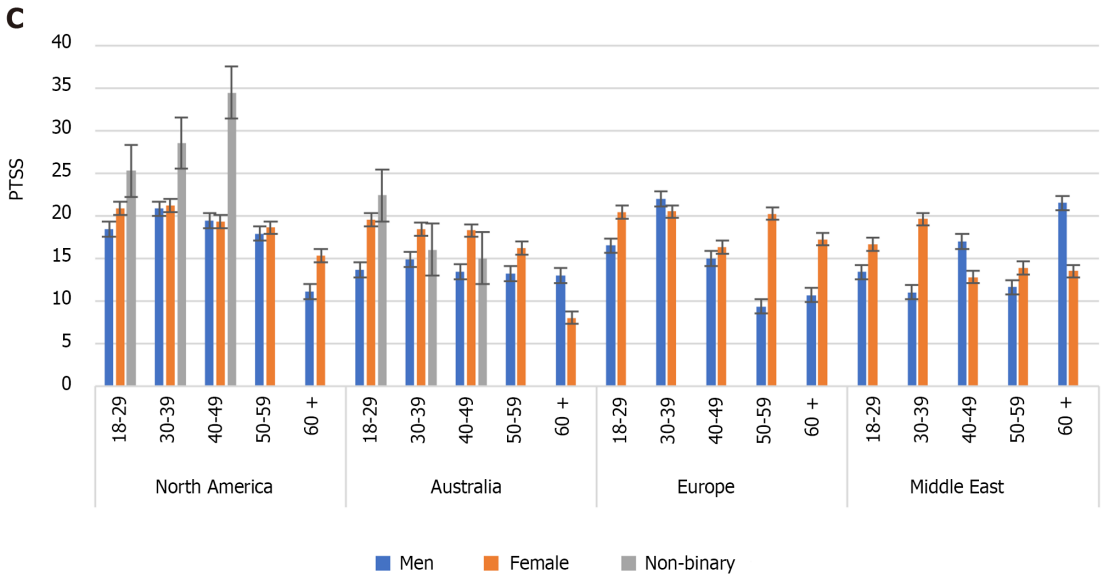
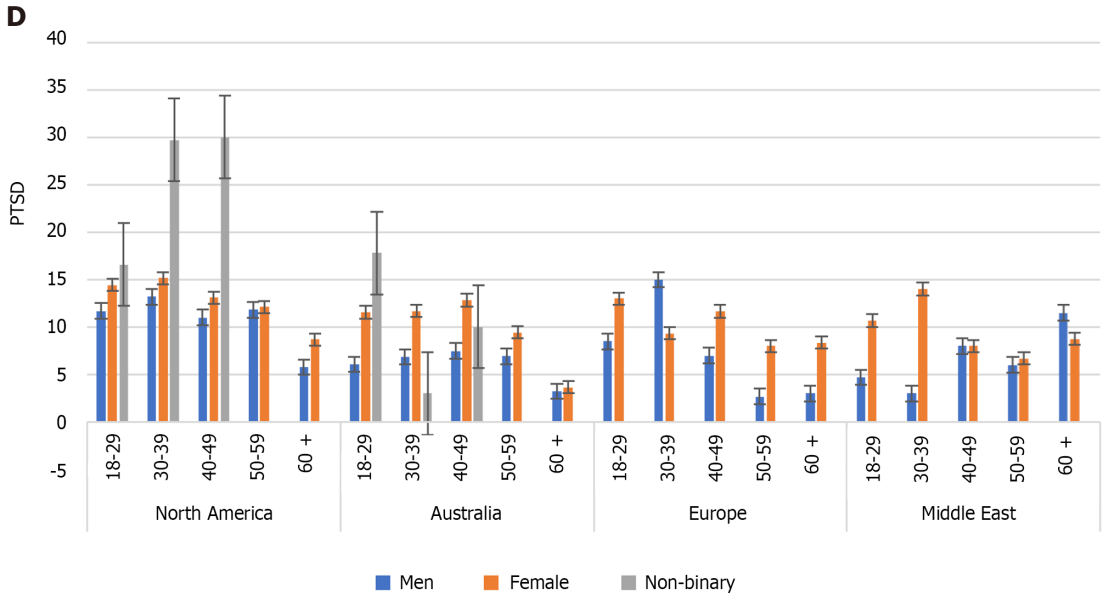
PTSD: Post-traumatic stress disorder.



The results show that the CSRS is sensitive to demographic variability and especially to the differences between cultures, locations and gender types. The overall analyses confirm the transdiagnostic hypothesis by showing that over 4 continents and gender types more symptoms were significantly more prevalent than fewer symptoms.



One identified source for the significant three-way interaction found in this study (age × gender × continent), and confirmed by regression analyses showed, that the group that self-identified as non-binary gender scored significantly higher on all four psychiatric symptoms of the CSRS at young ages (< 40 years old) in North America compared to (self-identified) women and (self-identified) men located in the 4 continents studied, and to other ages across the adult life span. These results show a combined mental health risk factor, suggesting that the CSRS, Type A is sensitive to populations at risk and may be applied to future identification of other vulnerable sub-populations.

In the scientific literature, identifying as non-binary at a young age has been recognized as a risk factor for increased mental health problems compared to other age groups and to other gender identities including other types on the gender identity spectrum such as the transgender identity[38,39]. The reduced affective wellbeing of those who identify as non-binary gender have been documented in research and theoretical conceptualizations[38,40,41]. To describe the unique type of distress that non-binary gender individuals might experience the term "gender minorities stress" was suggested

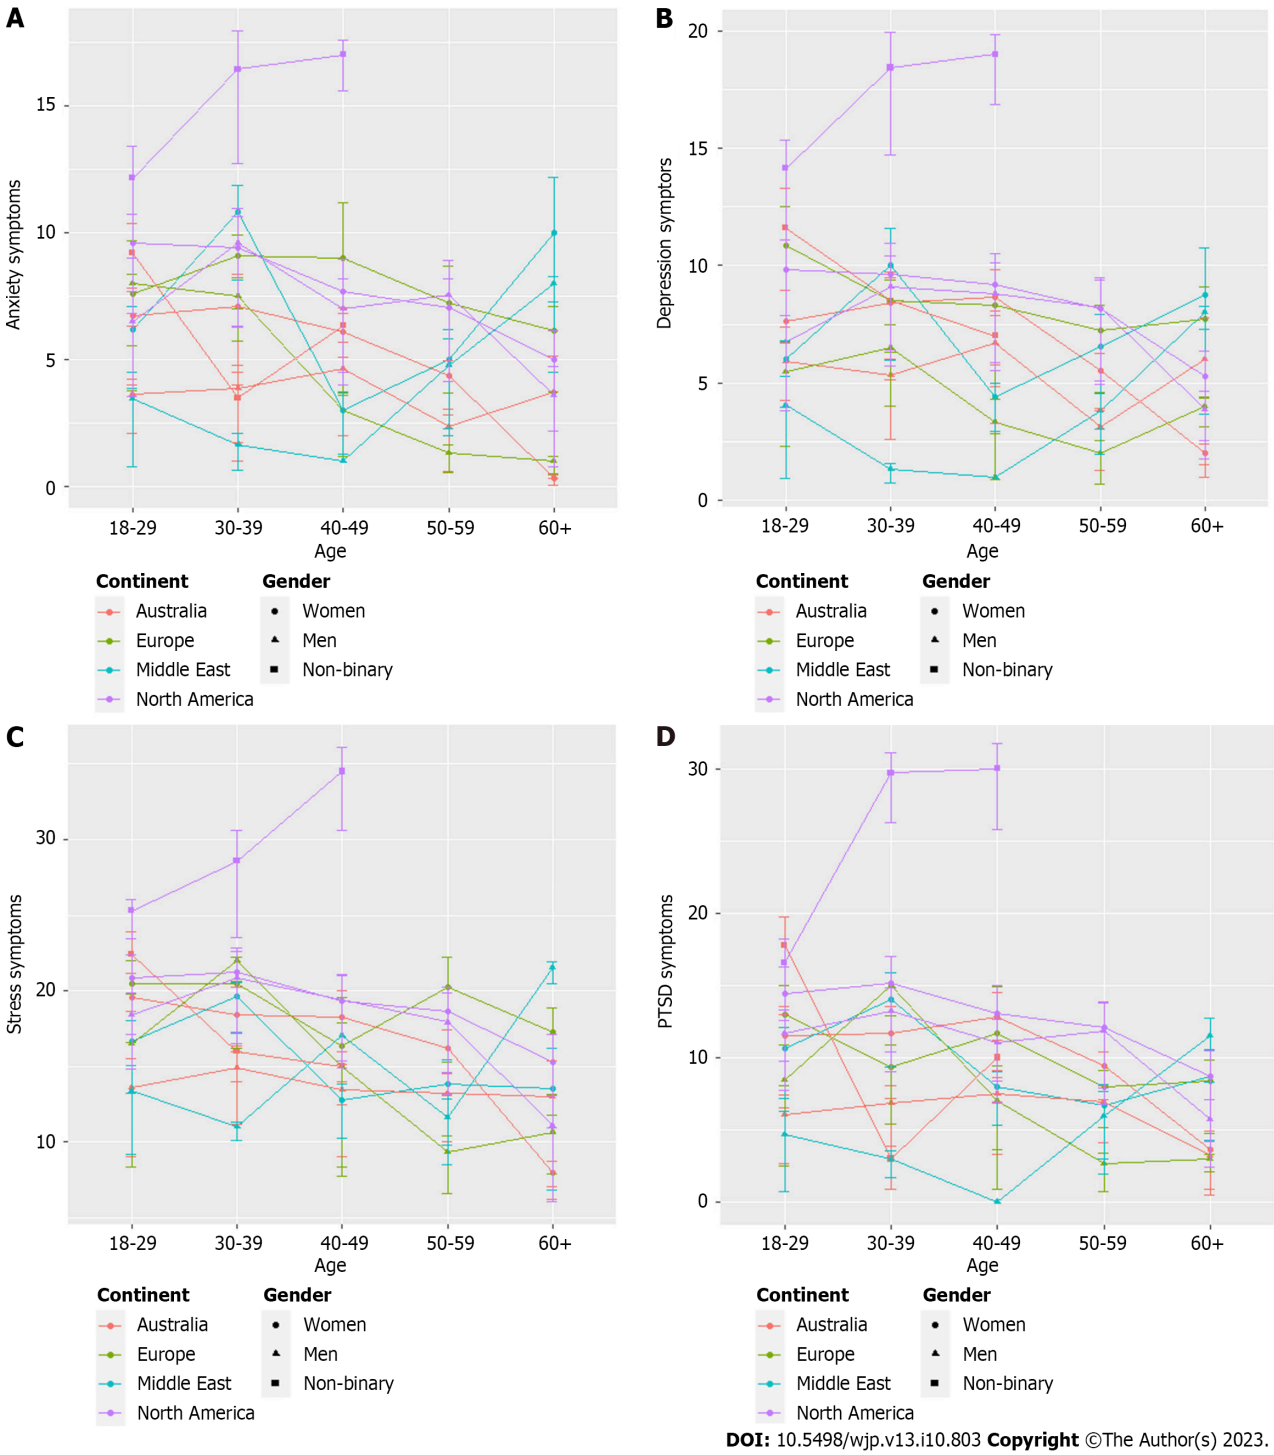
Figure 1 The measures assessing the four psychiatric features of the Complex Stress Reaction Syndrome (CSRS, Type A, mean ± SD). A: The Generalized Anxiety Disorder (anxiety measure); B: The Patient Health Questionnaire-8 (depression measure); C: The Perceived Stress Scale (perceived stress measure); D: The International Trauma Questionnaire (post-traumatic stress disorder measure).

[42]. We note that more conservative social views in continents other than North America may have inhibited people from identifying as non-binary and prevented an even larger magnitude of the non-binary gender stress reactivity in our findings. The emotional burden of this minority and its dramatic impact on this study's results attests to the extreme distress experienced by this sub-population.



An additional source for the three-way interaction is related to another sub-population at risk which scored above the clinical cutoffs of all the four types of symptomatology included in the CSRS, Type A, young age groups identifying as a woman in North America. Being a woman at young age has been reported as a risk factor long before the COVID-19 outbreak[43,44], during the COVID-19 pandemic[45] and in the post-COVID era[46] in very large, epidemiological studies. Thus, our results show the sensitivity of the CSRS, Type A in measuring a specific stress reactivity spanning several conventional categories in both minoritized and majority subpopulations.

In this study, the psychiatric pattern of symptoms (CSRS, Type A) was similar in infected/recovered SARS-CoV-2 patients and in the non-infected population, suggesting that the CSRS, Type A is sensitive to a clinical picture in daily life, beyond its relevance to catastrophes, including the COVID-19 pandemic[16]. The neuropsychiatric part of the CSRS relating to neuropsychiatric components of the long-COVID syndrome (CSRS, Type B), did not add to the explained variance and the same pattern of results was found in infected/recovered individuals. These results show that the psychiatric part of the CSRS (Type A), when controlling for infected-non infected conditions, is the type of CSRS which is sensitive to at-risk sub-populations. In accordance with a current debate, this study also suggests that the long-COVID syndrome is a too broad diagnostic category in neuropsychiatry, resulting in recent contradictory results[47,48]. Thus, the CSRS shows relevance for daily life stressors, beyond the pandemic situation and not as a mandatory result of the viral infection.

Thus, the CSRS, Type A represents a unique transdiagnostic clinical picture combining symptomatology of affective disorders with stress reactivity[16,26,31]. The prevalence of affective disorders spans a wide range of symptomatology, with dramatic cross-cultural differences[49]. Reports on prevalence of stress reactions are also present across a wide range mental disorders[50]. Furthermore, earlier studies reported that at-risk populations do not necessarily meet the full criteria of affective disorders and stress reactivity categories[40,44]. As it arises from the current findings, and according to our previous arguments[26], the CSRS, Type A identifies, and is sensitive to individual differences in stress reactivity and reduced positive affectivity, within a transdiagnostic spectrum.

The correlative design of this study is the most appropriate for the current stage of CSRS development as only after assuring the face validity of the hypothesized syndrome by empirical data, including its highly associated symptoms, a follow up design on etiological questions related to more causal assumptions may be investigated. In fact, to show that any transdiagnostic hypothesis is related to associations between symptoms spanning several traditional categories, a correlative design should be employed.

As the aim of this research is primarily transdiagnostic, its correlative design affords testing the relationship and extent of association between a given number of variables (symptoms) spanning traditional classifications without meeting them in full. This type of design also allows testing whether a correlative combination of more symptoms is more prevalent than a combination of fewer symptoms from a given number of hypothesized variables, in a given hypothesized combination.

DOI: 10.5498/wjp.v13.i10.803 **Copyright** ©The Author(s) 2023.

Figure 2 Three-way interactions between continents, age groups and gender identifying the sub-populations at risk by the four psychiatric features of the Complex Stress Reaction Syndrome (CSRS, Type A). A: Three-way-interaction for the Generalized Anxiety Disorder (anxiety measure); B: Three-way-interaction for the Patient Health Questionnaire-8 (depression measure); C: Three-way-interaction for the Perceived Stress Scale (perceived stress measure); D: Three-way-interaction for the International Trauma Questionnaire (post-traumatic stress disorder measure).

The correlative design used in this study aimed also to show the sensitivity of CSRS to populations at risk who score beyond the clinical cutoff of the measures used. As such, the study also aimed to investigate the generalizability of the CSRS across continents, gender types and age-groups. This required comparisons between continents, gender types and age-groups. Thus, a correlative design and its aligned conclusion on associations between symptoms as related to demographic factors, may be derived even when employing statistical comparisons between independent (demographic, in this case) variables, and their assumed related "causal" impact on the dependent (CSRS, Type A) variables. The advantage of this approach and conclusions regarding association between independent (demographic) and dependent (CSRS, Type A) variables is threefold from both scientific and clinical perspectives: (1) It shows the generalizability of the CSRS; (2) It shows the CSRS, Type A as clinically essential for the identification of populations at risk, suggesting that the CSRS, Type A is sensitive to a unique transdiagnostic mental health condition; and (3) It includes a suspected indication

to treat. Furthermore, the results of the analysis of variance were confirmed by significant associations between the same demographic variables and the most prevalent combination of symptoms (CSRS, Type A) in linear regression analyses. Thus, the same populations at risk, as well as the sensitivity of the CSRS to these populations, are apparent in the results of this study.

The limitations of this study lie in the sampling methods utilized, which used convenience sampling[51]. This type of convenience online sampling became very popular and legitimate during the pandemic, although very large samples have been criticized before and after the pandemic[52,53]. Additional limitations include the use of self-report measures (symptoms) and not diagnostic interviews (signs), and the possible bias towards samples who are computer literate. However, in our binational research[26], we combined the methodology of representative sampling (Israel) with convenience sampling (Italy) and found similar results, although employing two different sampling methodologies, supporting the validity of the online convenience sampling. Yet to come, international studies with representative sampling, are warranted for further support of the CSRS, Type A validity and its clinical value.

This current international study emphasizes the importance of transdiagnostic approaches for clinical identification of individual differences and sub-populations at risk that do not meet the full criteria of any traditional category. This will afford the development of more accurate prevention and treatment for those with emotional needs who remain without a clear diagnosis and proper clinical care.

CONCLUSION

This study shows a global new picture of the indication to treat derived from (1) The different populations included from around the globe; and (2) Allowing a transdiagnostic perspective. Although the categorical model of diseases remains largely used worldwide[26], the future will tell if transdiagnostic categories will be part of the next revisions of the DSM and ICD conventional systems to facilitate a resolution of the crisis in the field of psychiatry[1]. Indeed, a transdiagnostic approach recognizes the inherent complexity and heterogeneity of mental disorders by focusing on shared underlying dimensions rather than rigid diagnostic categories. This allows for a more nuanced understanding of psychopathology and better captures the overlapping symptomatology often observed across different disorders. Hence, future international transdiagnostic clinical research is warranted. To support psychiatrists in their clinical practice, future research may utilize transdiagnostic approaches to classify patients who show a mixed clinical picture when applied in face-to-face clinical meetings (signs) compared to remote self-scoring (symptoms) by the same patients.

ARTICLE HIGHLIGHTS

Research background

The debate regarding diagnostic classification systems in psychiatry (categorial *vs* dimensional systems) has essential implications for the diagnosis, prevention and treatment of stress reactions.

Research motivation

We previously found a unique pattern of stress reaction in a study executed during the coronavirus disease 2019 pandemic using large representative samples in two countries, and termed it the Complex Stress Reaction Syndrome (CSRS). In the current international study, in four continents, using six languages we aimed to investigate the generalization of the CSRS and its sensitivity to populations at risk.

Research objectives

We aimed to investigate CSRS, Type A [psychiatric symptoms, spanning anxiety, depression, stress symptoms, and post-traumatic stress disorder (PTSD)], with or without long-COVID residuals (CSRS, Type B, neuropsychiatric symptoms spanning cognitive deficits and fatigue, excluding systemic symptoms). Our two-tailed hypothesis was that CSRS is a condition related to an unrecognized type of stress reaction in daily life in the general population (Type A) or that it is related to the severe acute respiratory syndrome coronavirus 2 infection and its long-COVID residuals (Type B).

Research methods

Media-supported study using the Qualtrics platform.

Research results

The results of the Proportion Analyses showed that the prevalence of 4 symptoms spanning anxiety, depression, stress symptoms, and PTSD was significantly higher than the most prevalent combinations of fewer symptoms across 4 continents, age groups, and gender (CSRS, Type A). Further analyses identified two populations at risk: (1) Individuals that self-identified as non-binary gender; and (2) Women at young ages (< 40 years old) in North America.

Research conclusions

These results show a combined mental health risk factor related to stress reactivity, suggesting that the CSRS is sensitive to populations at risk and may be applied to future identification of other vulnerable sub-populations. It also supports the

transdiagnostic approach for more accurate prevention and treatment. Time will tell if such transdiagnostic syndromes will be part of the discussions on the next revisions of the traditional classification systems or whether the crisis in psychiatry further evolves.

Research perspectives

A follow-up international study to investigate whether the condition of multiplicity of stressors is the etiological source for developing the CSRS, Type A clinical status, is warranted.
