AIMS AND SCOPE

The primary aim of *World Journal of Psychiatry* (*WJP*, *World J Psychiatry*) is to provide scholars and readers from various fields of psychiatry with a platform to publish high-quality basic and clinical research articles and communicate their research findings online.

WJP mainly publishes articles reporting research results and findings obtained in the field of psychiatry and covering a wide range of topics including adolescent psychiatry, biological psychiatry, child psychiatry, community psychiatry, ethnopsychology, psychoanalysis, psychosomatic medicine, *etc*.

INDEXING/ABSTRACTING

The *WJP* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Current Contents/Clinical Medicine, Journal Citation Reports/Science Edition, PubMed, PubMed Central, Reference Citation Analysis, China National Knowledge Infrastructure, China Science and Technology Journal Database, and Superstar Journals Database. The 2023 Edition of Journal Citation Reports® cites the 2022 impact factor (IF) for *WJP* as 3.1; IF without journal self cites: 2.9; 5-year IF: 4.2; Journal Citation Indicator: 0.52; Ranking: 91 among 155 journals in psychiatry; and Quartile category: Q3.

Abstract

Standard management protocols are lacking and specific antidotes are unavailable for acute carbamazepine (CBZ) poisoning. The objective of this review is to provide currently available information on acute CBZ poisoning, including its management, by describing and summarizing various therapeutic methods for its treatment according to previously published studies. Several treatment methods for CBZ poisoning will be briefly introduced, their advantages and disadvantages will be analyzed and compared, and suggestions for the clinical treatment of CBZ poisoning will be provided. A literature search was performed in various English and Chinese databases. In addition, the reference lists of identified articles were screened for additional relevant studies, including non-indexed reports. Non-peer-reviewed sources were also included. In the present review, 154 articles met the inclusion criteria including case reports, case series, descriptive cohorts, pharmacokinetic studies, and *in vitro* studies. Data on 67 patients, including 4 fatalities, were reviewed. Based on the summary of cases reported in the included articles, the cure rate of CBZ poisoning after symptomatic treatment was 82% and the efficiency of hemoperfusion was 58.2%. Based on the literature review, CBZ is moderately dialyzable and the recommendation for CBZ poisoning is supportive management and gastric lavage. In severe cases, extracorporeal treatment is recommended, with hemodialysis as the first choice.

Key Words: Carbamazepine poisoning; Management; Activated charcoal therapy; Extracorporeal treatment; Intravenous lipid emulsion

Core Tip: There is no effective Antidote and standard treatment management for carbamazepine (CBZ) poisoning. This paper describes and summarizes the detailed clinical evidence of the treatment and management of CBZ poisoning, including gastric lavage and activated carbon therapy, hemoplavage, hemodialysis, continuous renal replacement treatment and plasmapheresis. Finally, this paper also provides the lipid resuscitation therapy to provide help for clinical treatment. In general, this paper summarized the results of CBZ poisoning related research, and provided the best plan for CBZ poisoning treatment.

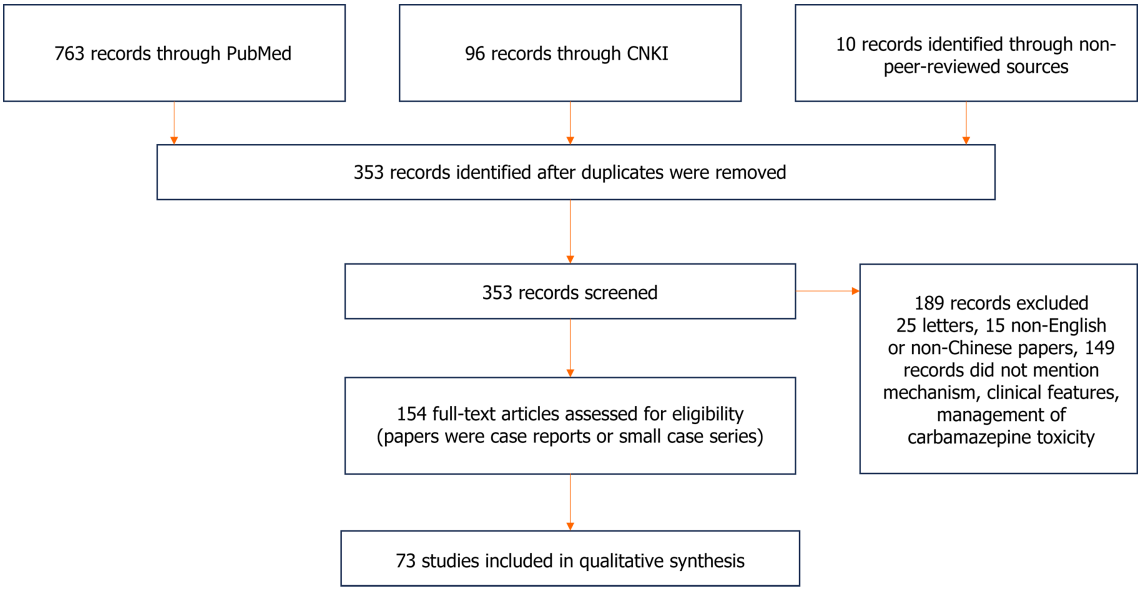
INTRODUCTION

Carbamazepine (CBZ) was discovered by Walter Schindler in 1953 and first utilized to treat partial tonic-clonic seizures in the United States in 1974[1]. Currently, CBZ is widely used for the treatment of epilepsy and peripheral neuralgia. Broad indications for the use and widespread availability of CBZ increase the risk of overdose, and CBZ intoxication accounts for a large proportion of life-threatening cases of anticonvulsant toxicity[2-4]. A systematic review of CBZ was published in 2014 by the Extracorporeal Treatments in Poisoning (EXTRIP) workgroup that provides recommendations for the use of extracorporeal treatments (ECTRs) in cases of CBZ poisoning[5]. Currently, standard management protocols are lacking and specific antidotes for acute CBZ poisoning are unavailable; thus, we reviewed and summarized the various therapeutic methods for the treatment of CBZ poisoning described in previous studies. Our goal was to provide currently available information on acute CBZ poisoning, including its management. We believe this paper will help clinicians effectively manage patients suffering from CBZ intoxication.

METHODOLOGY



A literature search was performed in the following databases: PubMed, Embase, Chinese National Knowledge Infrastructure (CNKI), and Wanfang. The search strategy, in English and Chinese, used the terms "acute" and "carbamazepine" in combination with the keywords "poisoning", "intoxication", "toxication", "toxicity", "overdose", and "overdosage". These search terms identified 861 records. In addition, the reference lists of the identified articles were screened for additional relevant studies, and these additional searches added three records. Non-peer-reviewed sources were also searched, including books and Internet resources, which yielded 10 records. A total of 874 records were found, which were screened based on title, author, journal name, and publication date for repeatability and relevance. We excluded papers that were duplicates, non-English or non-Chinese papers, letters to editors, and those not referring specifically to the mechanisms of action, clinical features, and management of CBZ toxicity in humans. Finally, 154 articles were considered eligible for review. The majority of papers were case reports or small case series. The literature selection process is described in Figure 1.

PHARMACOLOGY

CBZ is an iminostilbene derivative that is structurally similar to tricyclic antidepressants and is mainly used as a potent first-line agent to treat epilepsy, including simple partial, complex partial, and general tonic-clonic seizures[6,7]. The therapeutic effects of CBZ have also been proven for the treatment of neuropathic pain, especially prosopalgia, central diabetes insipidus, attention-deficit/hyperactivity disorder, and bipolar disorder. CBZ is thought to exert its anticonvulsant effects by blocking presynaptic voltage-gated sodium channels in the central nervous system (CNS), which further prevents the release of glutamate and similar neurotransmitters, ultimately inhibiting high-frequency epileptic foci.

CBZ has a molecular weight of 236 Da and high protein binding affinity (70%-80%) for both albumin and alpha-1-acid glycoprotein. This percentage does not markedly decline, even in cases of overdose[8]. CBZ is highly lipophilic, a property that allows it to be rapidly distributed after ingestion with a moderately large volume of distribution ranging between 0.8 L/kg and 1.4 L/kg. Thus, at therapeutic doses, the immediate-release tablets and controlled-release formulation of CBZ have peak serum concentrations at approximately 6-8 h and 12-24 h post-ingestion, respectively[9-11]. However, following overdose, peak concentrations may be delayed up to 106 h[12] due to the anticholinergic properties of CBZ, which are responsible for decreased gastrointestinal (GI) motility and delayed and prolonged absorption[10,13].

CBZ metabolism predominantly and extensively occurs in the liver by epoxidation and hydroxylation reactions through the cytochrome P450 system. Only 1%–3% of the drug is not metabolized and excreted through the kidney. CBZ-

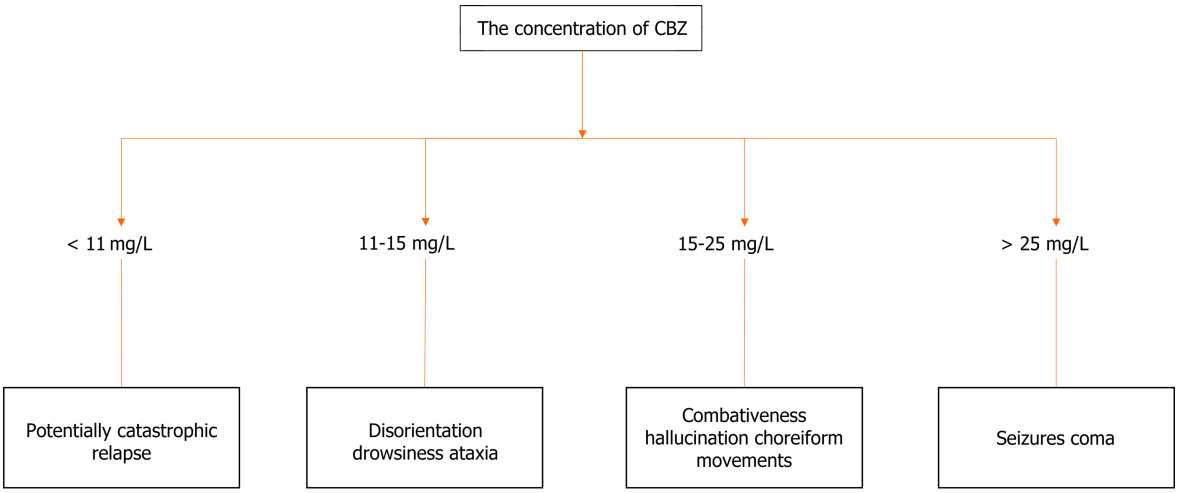
Figure 1 Flow diagram of the literature search.

10,11-epoxide is the primary active metabolite and equally produces antiepileptic and toxic effects based on its capacity to form covalent protein conjugates[14,15]. CBZ-10,11-epoxide blood concentrations vary substantially between individuals, ranging from 15% to 55% of CBZ levels in adults and from 5% to 81% of CBZ levels in children[11]. CBZ metabolism is complicated because both normal metabolism and autoinduction of metabolism occur with chronic use.



There is wide interindividual variability in the pharmacokinetics of CBZ, as well as general adaptation[16]. CBZ is eliminated according to zero-order kinetics (*i.e.* a constant amount of drug is eliminated per unit time) in the case of elevated plasma drug levels, as seen in overdose; however, a delay in CBZ elimination occurs when no intervention is available[16]. The reported biological half-life of the initial dose of CBZ is 25-65 h, but is shortened to 12-17 h in chronically treated epileptic patients due to self-induction[17]. Nevertheless, the half-life is apparently much longer after excessive dosing and the use of controlled-release preparations[1,12], likely reflecting delayed or continuous absorption, impaired elimination, or a combination of both.

OVERVIEW OF CBZ POISONING

Toxicity from CBZ overdose was first described by Guntelberg in 1967[18]. CBZ intoxication increasingly accounts for a large proportion of life-threatening cases among anticonvulsant poisonings[2,3]. A total of 3734 toxic exposures to CBZ were reported in 2014 by the American Association of Poison Control Centers. Of these, 1880 were isolated ingestions. There were no deaths, but 62 cases were life-threatening or severely disabling due to the significant toxicity[19].

Although the toxic concentration of CBZ in patients is not completely consistent with clinical manifestations of toxicity, doctors often initially treat patients based on the patient's clinical status. However, serum CBZ concentration is a practical method used to confirm clinical exposure, and severe intoxication occurs at serum levels > 20 mg/L [therapeutic index range: 4-12 mg/L (17-51 μmol/L)][20]. Serum CBZ levels > 40 mg/L are generally predictive of severe toxicity[21], which potentially occurs at a lower concentration[22], especially in children[23-25], and tends to be associated with an increased risk of seizure, coma, respiratory depression, and cardiotoxicity[26,27]. In addition, the pharmacologically active metabolite of CBZ, CBZ-10,11-epoxide, contributes to the risk of toxicity[28,29]. Based on the circulating level of CBZ in blood, the effects of CBZ on the CNS can be classified into four stages: (1) Seizures and coma at levels > 25 mg/L; (2) Combativeness, hallucinations, and choreiform movements at levels of 15-25 mg/L; (3) Disorientation, drowsiness, and ataxia at levels of 11-15 mg/L; and (4) Potentially catastrophic relapse at levels < 11 mg/L[30]. The duration and severity of these stages are variable and depend upon the magnitude of the overdose[31]. The detailed clinical symptoms corresponding to the toxic dose are described in Figure 2.

Toxicity usually occurs within 1-3 h after ingestion, but may be prolonged due to the delayed and erratic absorption of CBZ[32,33]. A wide diversity of clinical manifestations such as neurologic, respiratory, and cardiac findings can be seen in CBZ poisoning[22,34]. CBZ intoxication primarily manifests as CNS symptoms including nystagmus, movement disorders, disturbance of consciousness, altered mental status ranging from drowsiness to coma, and convulsions[35-39]. Seizures are not uncommon, occurring in 11%-18% of overdose cases[40,41]. Respiratory depression, a common manifestation of severe overdose, may delineate the severity of toxicity in the respiratory system and may be complicated by concomitant aspiration. Myocardial depression, sinus tachycardia, hemodynamic instability hypotension, and cardiac conduction disturbances are characteristics of CBZ cardiotoxicity. Some rare electrocardiogram (ECG) abnormalities may also occur such as atrioventricular block, QRS interval prolongation, QTc (corrected QT time in ECG) prolongation (> 420

Figure 2 Toxic dose and clinical manifestations of carbamazepine according to blood concentration. CBZ: Carbamazepine.

ms), bundle branch block, Brugada-type patterns, and premature ventricular contractions[42,43]. Death, though very uncommon (approximately 2% of cases), generally results from cardiovascular toxicity[44,45]. An overall mortality rate of 13% was documented and reported in a cohort study of 427 patients with CBZ intoxication, with an average CBZ intake in lethal cases of 23.6 g[22]. Refractory cardiovascular toxicity has also been reported[46,47].

MANAGEMENT OF ACUTE POISONING

In clinical practice, doctors initially treat patients based on their clinical symptoms, and supportive care plays a key role at this stage. For example, seizures are treated with benzodiazepines[48], hypotension is treated with vasopressors, and endotracheal intubation is used for patients with respiratory insufficiency. GI decontamination techniques such as gastric lavage (GL) and single-dose activated charcoal (AC) (SDAC) can be applied if patients are administered care within 1-2 h after ingestion without contraindications[49]. However, CBZ metabolism and distribution are complicated, and specific life-saving antidotes for CBZ poisoning are unavailable. Several modalities have been proposed to enhance CBZ clearance in patients with severe or life-threatening ingestion, including multiple-dose AC (MDAC), ECTRs, and lipid resuscitation therapy (LRT)[50].

Supportive care

Application of appropriate supportive care is adequate to deal with the vast majority of CBZ intoxication cases. Supportive care may involve airway protection with endotracheal intubation, treatment of seizures with benzodiazepines, and correction of hypotension with fluid challenges and vasopressors, if needed. The use of hypertonic sodium bicarbonate is indicated if ECG findings (QRS duration exceeding 100 msec) show that the sodium channel is blocked.

Serum CBZ concentrations in an acute overdose should be monitored serially (typically every 4-6 h) until a definitive downward trend is observed and the patient is improving clinically[51,52]. Continuous monitoring of serum CBZ concentrations in patients is necessary, especially in those with severe poisoning. These patients are likely to deteriorate after the initial improvement of clinical symptoms or develop a delayed toxic reaction due to a rebound effect (*i.e.* sudden rise in serum drug concentration following intermittent treatment due to drug redistribution from tissue to serum[53]) or sustained increase in serum concentration.

Patients with significant CNS depression may lose protective airway reflexes and should be intubated, particularly due to their lower seizure threshold. Short-acting neuromuscular blocking agents (*e.g.*, succinylcholine) are preferable so subsequent seizure activity is not masked. Induction agents with gamma-amino butyric acid agonist activity (*e.g.*, midazolam) may be preferable, depending on the patient's hemodynamic status.

Hypotension is initially treated with isotonic crystalloid. Caution should be exercised in patients at risk of volume overload, such as those with underlying heart disease or CBZ-induced myocardial dysfunction. Direct-acting vasopressors are used if intravenous fluids fail to correct the hypotension.

Sodium channel blockade may cause QRS interval prolongation, which, in other poisonings, has been shown to predispose patients to ventricular arrhythmias[54,55]. QRS prolongation due to CBZ toxicity is treated with sodium bicarbonate. Currently, there are no clearly established treatment thresholds based on QRS duration or dosing guidelines or evidence regarding the preferred method of administering sodium bicarbonate with respect to boluses, infusions, or treatment duration[56]. The proposed methods of administration are for patients with QRS intervals longer than 110 ms, particularly those with hypotension, and include boluses of a 1 mEq per 1 mL (8.4%) solution at a quantity of 1-2 mEq/kg to obtain a serum pH of 7.45-7.55 and an infusion of 150 mEq mixed with 1 L of 5% dextrose in water at a rate to maintain

that pH[54]. Continuous cardiac monitoring of patients with a 12-lead ECG is simultaneously needed. Volume overload, hypokalemia, hypernatremia, and metabolic alkalosis may result from prolonged bicarbonate infusions, and clinical and laboratory parameters must be closely followed to avoid these complications.

GL

GL has been routinely used to manage cases of poisoning for more than 200 years. However, GL carries significant risks, which, given its questionable clinical benefit, usually outweigh arguments in favor of its use; thus, it is not recommended for routine GI decontamination[57]. GL works by eliminating poison remaining in the GI tract and should be considered based on the time elapsed from oral ingestion to admission to the emergency department. In cases of suspected CBZ intoxication, prior to the determination of the current plasma concentration of CBZ, it is imperative to remove undigested tablets through GL to further reduce GI absorption. This one simple measure may be particularly helpful for CBZ intoxication given its anticholinergic effects on the GI tract that would delay gastric emptying[58]. However, there is less conclusive evidence showing that GL has clear effects on CBZ poisoning[59,60]. As noted in a position statement related to GL use, GL should not be considered unless a potentially life-threatening amount of a poison is ingested by the patient, and this approach should be initiated within 60 min of ingestion[61]. Nevertheless, the clinical benefit has not been confirmed in controlled studies. Moreover, GL is not appropriate for all patients, and not all patients can benefit from GL. GL is contraindicated in patients who have impaired consciousness, recent surgery, no protection of the airway, risk of GI bleeding and perforation, and potentially increased risk and severity of aspiration[57]. The major complications of GL include perforation of the esophagus and stomach, pulmonary aspiration, and aspiration pneumonia[62].

MDAC

AC therapy is still the most frequently employed method of GI decontamination for acute drug overdoses in developed countries. With a highly developed internal pore structure, the tremendous surface area of AC permits the adsorption of drugs and toxins in the GI tract within minutes of contact, which reduces their systemic absorption and subsequent toxicity and enhances their elimination[63]. AC therapy involves SDAC and MDAC, which indicates scheduled administration of more than two small doses of AC.

MDAC should only be considered if a patient has ingested a life-threatening amount of CBZ. MDAC therapy is effective in poisoning due to three distinct mechanisms: (1) Reducing ongoing absorption of extended or delayed-release formulations remaining in the gut[49]; (2) Interfering with enterohepatic and enterogastric circulation of drugs[64-66]; and (3) Promoting the diffusion of drugs from circulation into the gut lumen and trapping them there to be discharged later in the excrement (this process is sometimes called "GI dialysis")[67].

The "routine" use of MDAC has not been shown to reduce morbidity and mortality in poisoned patients in controlled clinical trials. However, evidence from animal and volunteer studies, as well as poisoning cases, indicates that MDAC therapy significantly enhances total body clearance and shortens the half-life of CBZ[33,68-71]. Mittag *et al*[19] recently reported a case of CBZ overdose in which the patient was treated with AC (1 g/kg body weight); his CBZ concentration dropped from the initial value of 41.5 mg/L to approximately 12 mg/L after 24 h. A randomized crossover study in 5 fasted volunteers performed by Neuvonen and Elonen[65] showed that the elimination of CBZ could be significantly enhanced by MDAC. In a study by Boldy *et al*[70] involving 15 patients with CBZ poisoning, researchers gave patients MDAC therapy and found that the mean half-life decreased to 8.6 ± 2.4 h and the mean total body clearance increased to 113 ± 44 mL/min. By comparison, the mean elimination half-life in another two groups of patients managed with supportive treatments only was approximately 19 h[8,72]; similar conclusions have been reached in other studies[73,74].

MDAC enhances the clearance of CBZ in the body and has been approved by the latest joint statement issued by the American Academy of Clinical Toxicology and the European Association of Poisons Centres and Clinical Toxicologists [64]. The statement recommends that MDAC be considered only if a patient has ingested a life-threatening amount of CBZ. In addition, several conditions are considered contradictions including an unprotected airway, the presence of intestinal obstruction, and a GI tract not anatomically intact. Attention should be paid to prevent complications such as constipation, ileus, and aspiration pneumonia in an unprotected airway, although these occurrences are rare[75].

The efficacy of AC is inversely related to the time elapsed after the ingestion of toxic substances[42,76]; thus, administration of charcoal as soon as possible yields the best results. However, the considerably delayed absorption of drugs is often noted in cases of acute poisoning due to inhibition of gastric emptying and gut motility and the limited solubility of drugs, among other reasons[21,22]. Therefore, AC administration is apparently indicated if delayed or prolonged absorption is anticipated, even after a delay of 24-48 h[75].

There is no established optimal dosage regimen for AC; however, available data indicate a dose-response relationship: An AC: Drug ratio of 10:1 or higher is considered optimal for AC adsorption[77-79]. However, the efficacy of AC is influenced by many variables, making it difficult to administer the optimum dose[63]. Consequently, in practice, a fixed dose of 1 g/kg is generally recommended with the maximum amount not exceeding 50-70 g. A flexible dose of 0.25-1.0 g/kg is used for MDAC, and the dosing interval varies based on laboratory (*e.g.*, increasing blood concentrations) or clinical evidence for continuing drug absorption and ranges from 1 h to 4 h. Vomiting is an important factor to consider when substantial doses of AC are administered repeatedly. Continuous nasogastric infusion of AC or frequent administration of AC with smaller doses, at least following a large initial dose (50-100 g), may contribute to reduced vomiting[80,81]. In some cases, the combined use of antiemetics, such as metoclopramide or ondansetron, may have desirable effects.

ECTR

ECTR, also known as blood purification treatment, is a medical technology that removes poison from the blood by moving the blood from the patient into a purification device. ECTRs are classified based on their mechanism:

Hemodialysis (HD) and peritoneal dialysis act by diffusion; hemoperfusion (HP) acts by adsorption; hemofiltration acts by convection; and therapeutic plasma exchange acts by centrifugation[82,83]. Each technique has a potentially different role in eliminating poison from the body. Whatever modality is used, optimizing ECTR characteristics to achieve maximum removal of poison is crucial; for example, higher flow rates of blood and dialysate, filters with larger surface area, and longer duration of ECTR maximize poison removal[84].

According to the EXTRIP workgroup on the use of ECTR in CBZ poisoning, ECTRs are recommended for patients with significant or potentially significant clinical poisoning because they are preferable interventions for rapidly and substantially removing CBZ[5]. Even when considering its weaknesses, such as high risks, high costs, and relative uncertainty, ECTR is generally considered by the workgroup to be worth implementing in patients with severe CBZ poisoning (as manifested by signs such as multiple refractory seizures, hemodynamic instability requiring vasopressors, or life-threatening dysrhythmias). ECTR can prevent the worsening of CBZ poisoning symptoms such as severe hypotension, as well as comatose complications associated with chronic shortness of breath such as ventilator-associated pneumonia and pulmonary emboli[5]. In addition, ECTR is expected by most participants in the workgroup to be a potentially cost-saving technique by minimizing the mechanical ventilation period and residence time in the intensive care unit (ICU), ultimately reducing ICU-related costs[5]. Whether and when to initiate ECTR should be primarily based on clinical symptoms and signs, rather than serum CBZ concentrations, although more severe toxicity apparently occurs when CBZ concentrations are > 40 mg/L[21,85]. The optimal duration of extracorporeal removal should be adjusted to the patient's clinical condition and CBZ levels. Furthermore, the continuous and regular monitoring of CBZ serum concentrations after ECTR is essential, as concentrations may rebound[86]. If concentrations rebound to threatening levels or if there is a recurrence of toxic symptoms, another session of ECTR may be required. ECTR is recommended for patients with significant or potentially significant clinical poisoning. Intermittent HD is the preferred modality for ECTR in CBZ poisoning. Intermittent HP and continuous renal replacement modalities are alternatives if intermittent HD is not available.

HP: HP refers to anticoagulated blood that circulates through a cartridge containing adsorbent particles (AC particles or resin beads) onto which the poison can be adsorbed to achieve the goal of blood purification[87,88]. This modality is suitable for removing poisons with medium or large molecular weight, high lipid solubility, and high protein binding. CBZ is a highly lipid-soluble drug that can be rapidly distributed in tissues, and its plasma protein binding is as high as 70%-80%. Therefore, HP is historically identified as the preferred modality for extracorporeal removal in cases of severe CBZ poisoning[89-92], although the EXTRIP workgroup published a contrary opinion. Despite limitations such as early saturation of the cartridges, the successful removal of CBZ through either resin or charcoal HP has been reported with varying clearance efficiencies ranging from 25% to 55%[93-97]. In a recent study conducted by Yang *et al*[98], the authors concluded that the early initiation of HP during treatment of CBZ poisoning would significantly lower the serum concentration and minimize the CBZ detection time, leading to symptom relief and shortening of the overall treatment period. However, this procedure is often difficult to perform and carries risks such as thrombocytopenia, leukopenia, coagulopathy, and hypocalcemia, which are thought to be associated with cell adsorption and continuous replenishment of the AC[99,100]. Therefore, the frequent monitoring of platelet counts or application of new biocompatible polymer membranes is indispensable for decreasing these complications[101].

HD: HD takes advantage of the principle of diffusion, allowing poison to pass through a semipermeable membrane from a higher- to lower-level side to remove the poison in the blood. This modality is suitable for poisons with high water solubility, low molecular weight (< 500 D), medium molecular weight, and low protein binding. Although intermittent HP is historically preferred for the removal of CBZ, HD should be considered based on its theoretical superiority in clearing protein-bound poisons such as CBZ, and the EXTRIP workgroup recommends intermittent HD over HP. Indeed, several factors prove that HD is superior to HP. First, its clearance efficiency is superior. Although a previous study showed that HP has higher clearance than HD, the comparison was based on older, less efficient cuprophane dialyzers [5]. Recent data have shown that high-efficiency HD is almost as effective as charcoal HP and results in rapid clinical improvement[13,102-104] when equipped with a highly permeable high-flux membrane with increased dialysate flow, which produces comparable efficacy by allowing the removal of larger molecules and highly protein-bound poisons[105-109]. In addition, there is a risk of hemolysis. Blood flow circulating in cartridges during HP remains limited to 300-350 mL/min; however, the use of brand new catheters during HD enables blood flow up to 400 mL/min[110]. Furthermore, there are high amounts of free CBZ molecules and its metabolites in blood at increased concentrations, which are good candidates for removal by HD[111,112]. Second, the manipulability of HD is superior; HD is more available than HP, and HD is the preferred technique for dialysis for patients with acute kidney injury and end-stage kidney disease worldwide. Early initiation of ECTR is critical, considering that clinical improvements are likely associated with how quickly poisons can be cleared from the body. In addition, physicians and nurses are more familiar and experienced with HD; thus, this technique is more likely to be implemented with fewer delays and uncertainties. Third, outcomes of HD are superior; complications are less likely to occur with HD than with HP[113]. Finally, HD has a favorable cost compared with HP. A recent investigation of availability, time to initiation, and cost of ECTR in acute settings worldwide confirmed the lower cost of HD compared with other ECTRs (median cost ratio of HP:HD = 1.7)[114]. The high spending associated with HP is largely due to multiple replacements of expensive charcoal cartridges because of its easy saturation, which would decrease poison clearance[12,91]. Moreover, monitoring and treating complications of HP contribute to its high expenses.

Continuous renal replacement treatment: Continuous renal replacement treatment (CRRT), also known as continuous blood purification, is a treatment involving the continuous, slow removal of water and solutes. CRRT includes continuous venovenous HD, continuous venovenous hemodiafiltration (CVVHDF), and continuous venovenous hemofiltration[115]. These continuous therapies are usually performed in the ICU to facilitate management of hemodynamically unstable patients who cannot withstand high-efficiency intermittent treatments. Therefore, lower dialysate rates during CRRT (up

to 10 L/h) than the dialysate flow rates used in intermittent HD (500–800 mL/min) are routinely offered, leading to markedly lower clearance[5]. However, CRRTs play a better role in mitigating rebound effects than intermittent techniques, regardless of the drug clearance rate. Numerous studies are available documenting the use of CRRTs in patients with CBZ intoxication; however, techniques and outcomes vary substantially. Thus, the benefits of these techniques to eliminate CBZ from the body are unable to be determined[89,116-119]. Consequently, continuous techniques are regarded as low-priority modalities by the EXTRIP workgroup and are only advocated when intermittent treatments are unavailable (because of technical or personnel reasons in critical care settings). Nevertheless, some authors approve of the joint use of intermittent procedures and CRRTs in patients with poisoning to avoid "rebound phenomenon".

Recently, the addition of albumin to the dialysate appeared to improve CBZ clearance compared with conventional CRRT in some studies[120-124]. In a study conducted by Choi *et al*[122], the applied CVVHDF showed a 24% increase in CBZ clearance when using dialysate with the addition of 20% albumin. Another *in vitro* study using modeled continuous HD performed in 2009 also confirmed that CBZ clearance was significantly enhanced with 2.5% or 5% albumin-supplemented dialysate compared with control (albumin-free) dialysate[123]. This technique could be explained by basic principles of thermodynamic protein-binding affinity and solute movement along a concentration gradient. The albumin added to the dialysate works as a "sink" to bind CBZ that moves across the dialyzer membrane along the concentration gradient formed between the blood side and dialysate side[124]. However, extremely high costs have limited their widespread use. In addition, whether these procedures have superiority to either HP or HD remains unclear and further investigation is needed.

LRT

LRT is a relatively new method to improve the clinical manifestations of toxicity from overdose of certain drugs through administration of intravenous lipid emulsions (ILEs). ILE was conventionally used for parenteral nutrition and first applied in 1998 by Weinberg and colleagues[125] as a treatment option in toxicology. The first human case of ILE clinical use was reported by Rosenblatt *et al*[126] in 2006 to treat local anesthetic (bupivacaine) systemic toxicity. Since then, ILEs have been widely used in clinical toxicology as a life-saving treatment for local anesthetic-induced cardiotoxicity[127]. With further research, the field has expanded progressively with successful clinical translation and expansion of use to treat other types of non-local anesthetic lipophilic drug overdoses[128-132].

The ILE mechanisms of action are not entirely clear but can be partially explained by dynamic scavenging/partitioning and direct cardiovascular effects[133,134]. In 1998, Weinberg and colleagues originally proposed a mechanistic hypothesis, namely, that ILE provides a novel compartment into which lipophilic drugs circulating in the blood are able to partition, preventing them from affecting other organs. This theory was widely accepted and referred to as "the lipid sink". However, with improved understanding of this treatment, a "lipid shuttle" or a capture/release mechanism has been suggested in which ILEs play a role in accelerating the redistribution of drugs and moving drugs around, as opposed to acting like a "lipid sink" that catches and segregates drugs[135]. In addition, ILEs exert direct effects on myocardial tissue that improve cardiac output; however, the relevant potential mechanisms are not fully understood[136, 137]. Based on these mechanisms of action, ILEs have been used to manage toxicity from non-local anesthetic lipophilic drugs.

CBZ is a highly lipophilic molecule and can induce cardiotoxicity in cases of significant overdose. ILEs have been administered to treat CBZ intoxication in several cases with varying results[116,138-141]. ILE treatment was used in two case reports for CBZ-induced cardiotoxicity and showed beneficial effects[138,139]. In a retrospective study investigating the clinical effects of lipid emulsion for the treatment of childhood CBZ poisoning, researchers enrolled 48 patients and divided them into Group A (lipid emulsion + HP) and Group B (HP); a statistically significant difference was not observed in the blood concentration of CBZ between groups ($P > 0.05$). After 24, 48, and 72 h of treatment, the CBZ blood concentration in Group A was significantly lower than that in Group B ($P < 0.05$), and the researchers concluded that the lipid emulsion could be used for the treatment of CBZ poisoning in children to reduce the blood CBZ concentration as quickly as possible[142]. Although the sole effect of ILE in CBZ clearance has not been proven, ILE is still considered to be a potentially beneficial alternative to ECTR methods in CBZ intoxication. Whether and when to initiate LRT is discretionary and depends on the clinical judgment of the treating physician. Blood clotting and fat deposition commonly occur in extracorporeal circuits when combined with LRT[140,141], and thus should be monitored during therapy.

DISCUSSION

We conducted a retrospective review of selected literature. The case reports contained detailed data describing patient status and treatments, and an aggregate description was made (Table 1). After discussion and analyses of CBZ poisoning cases, we established recommendations for the treatment of CBZ poisoning (Table 2); 67 patients were included and no randomized controlled trials were identified. The median CBZ peak concentration was 39.0 mg/L and the median age was 42.3 years. Notably, all patients had varying degrees of consciousness impairment, which were due to individual differences. In addition, some patients experienced respiratory depression, dysrhythmias, hypotension, seizures, or a combination of these symptoms. Among the patients, 32 showed varying degrees of respiratory depression. Overall, 4 cases were described as deaths caused by CBZ poisoning rather than the effect of the treatment[43,44,105]. GL is a simple and convenient treatment, but only 6 patients received GL because the treatment is prohibited in patients with impaired consciousness, recent surgery, no airway protection, risk of GI bleeding and perforation, or potential for increased risk

Table 1 Clinical outcomes of the 67 patients described in the case reports

Patient demographics	Values
Median age (yr)	25 (1.5-85)
Male sex	49.3
Poisoning exposure	
Mean peak carbamazepine concentration in mg/L	39.0 (17.7-93.8)
Clinical symptoms and signs	
Respiratory depression	47.8
Decreased consciousness	100
Seizure	20.9
Hypotension	14.9
Dysrhythmias	19.4
Treatment measure[1]	
Supportive care	9.0
Gastric lavage	29.9
Multiple-dose activated charcoal	58.2
Hemoperfusion	22.4
Hemodialysis	22.4
Continuous renal replacement treatment	12.0
Plasma exchange and plasmapheresis	4.5
Lipid resuscitation therapy	4.5
Outcome	
Recovery	82.0
Sequelae	12.0
Fatalities	6.0

[1]Some patients received more than one treatment.
Data are presented as *n* (range) or %. The source of cases is listed in Supplement Material.

and severity of aspiration[16,19,21,23,26,28]. In these situations, considering the patient's economic conditions and affordability, MDAC was chosen instead of GL. For decades, MDAC has been used as a universal antidote for the majority of poisons because of its ability to prevent absorption of the most toxic agents from the GI tract and enhance the elimination of some agents already absorbed[143,144]. The optimum dose of MDAC is difficult to precisely determine for an individual patient. Optimum dosage depends on many variables such as the volume and pH of gastric and intestinal fluid, and the presence of other agents or food absorbed by AC[145-148]. Notably, repeated administration is still effective against substances that stay longer in the stomach, which is another advantage of MDAC. The recommended dose for adults is typically 50 g; however, the amount administered to children is determined based on body weight (0.5-1 g/kg). Reported complications and adverse effects of MDAC include diarrhea, constipation, vomiting, pulmonary aspiration, and intestinal obstruction. Consequently, MDAC should be used with caution in the following situations: unprotected airway; presence of intestinal obstruction; or GI tract not anatomically intact. Therefore, intestinal motility in patients receiving MDAC should be continuously monitored as necessary to maintain electrolyte and water balance.

HP was the most common treatment for the patients in our review, accounting for 58.2% of cases. HP was considered the most timely and effective treatment for patients with excessive CBZ toxicity and life-threatening symptoms because it can remove mid-to-large-sized toxin molecules bound to proteins. However, the earlier enthusiasm for HP has decreased and HD is currently the treatment of choice for poisoned patients. HP presents some challenges compared with HD. For example, HP is associated with more complications than HD (namely, hypocalcemia, leucopenia, thrombocytopenia[147,148]), and the rate of complications is greater during HP than HD. Furthermore, HP is more expensive and results in the early saturation of columns. Notably, the same percentage of patients received HD and CRRT therapy (22.4%). HD and CRRT are commonly used to provide renal support to critically ill patients with acute kidney injury, particularly those who are hemodynamically unstable. Although initially developed as an arteriovenous therapy, most CRRT is now performed using pump-driven venovenous extracorporeal circuits. However, initiation of CRRT requires vascular access, which is generally established through placement of a large-bore double lumen catheter in an internal jugular, femoral, or

Table 2 Executive summary of recommendations for the treatment of carbamazepine poisoning

General statement
The primary treatment for CBZ poisoning is GL
A mainstay of treatment is multiple-dose activated charcoal
ECTR is suggested in cases of severe CBZ poisoning
Intermittent hemodialysis is the preferred ECTR for CBZ poisoning
Lipid resuscitation therapy is an effective adjunctive treatment to ECTR
Supportive care
Severe central nervous system depression requires endotracheal intubation
To avoid masking subsequent seizures, short-acting neuromuscular blockers are recommended
Isotonic crystalloid to correct hypotension should be considered first; when isotonic crystals do not work, direct-acting vasopressors can be applied
QRS prolongation is treated with sodium bicarbonate
Management precautions
GL is contraindicated when patients have impaired consciousness, recent surgery, no protection of airway, risk of gastrointestinal bleeding and perforation, and the potential for increased risk and severity of aspiration
Multiple-dose activated charcoal should be used with caution in cases of an unprotected airway, presence of intestinal obstruction, or gastrointestinal tract not anatomically intact

CBZ: Carbamazepine; ECTR: Extracorporeal treatment; GL: Gastric lavage.

subclavian vein. Furthermore, hypotension during CRRT is common, occurring in some series in more than one-third of patients, but is most often unrelated to the CRRT procedure. Increased hemodynamic instability due to ultrafiltration may be the most likely treatment-related factor contributing to hypotension[149]. Therefore, we conclude that in the absence of accurate, scientific data indicating effectiveness and risk, a sound recommendation for the use of CRRT cannot be made. Again, the treating physician must weigh the theoretic benefit against the potential for complications in each clinical scenario. HD is indicated for the therapeutic management of acute poisoning or drug overdose and is the most commonly favored extracorporeal technique in poisoning situations due to its availability, cost, and safety profile. With the development of science and technology, the advent of high-efficiency, high-flux dialyzers has rendered other techniques, such as HP, almost obsolete. Furthermore, HD enables the correction of acid-base and electrolyte abnormalities.

Among patients, plasma exchange and plasmapheresis as well as lipid emulsion were the least frequent (both 4.5%). Plasma exchange and plasmapheresis refer to the extracorporeal technique preformed in an apheresis device where the patient's plasma is separated from whole blood and removed, and the cellular blood components are returned to the patient together with a replacement fluid[150]. Therapeutic procedures commonly include therapeutic plasma exchange and red blood cell exchange with or without depletion, in addition to more specialized procedures, such as low-density lipoprotein (LDL) apheresis and extracorporeal photopheresis, which was widely used in China to treat patients with coronavirus disease 2019[151]. However, because performing extracorporeal photopheresis is complex and requires precision, the method is rarely used in drug intoxication cases. The mechanism of action in LDL apheresis creates an expanded, intravascular lipid phase in which equilibria are established that drive the offending drug from target tissues into the newly formed "lipid sink". Based on this theory, LDL has been considered a candidate for generic reversal of toxicity caused by overdose of any lipophilic drug. However, the use of LDL apheresis requires caution, especially in patients with a history of hypersensitivity to lipid emulsion or ingredients (*e.g.*, eggs, soy), severe sepsis, severe liver disease, acute pancreatitis, and acute myocardial infarction. Therefore, we suggest that LDL apheresis be considered under circumstances of refractory hemodynamic instability.

CONCLUSION

Herein, we presented recommendations for therapies in CBZ poisoning. Risk assessment of selected case reports showed that in most poisoned patients, general supportive measures usually suffice, including airway management and protection, ventilatory support, fluid resuscitation, correction of electrolyte and acid-base disorders, and management of poison-related hypo/hyperthermia. Primary GI decontamination with AC and routine GL are widely used. Aggressive ECTR is required for rapid and substantial removal of CBZ and its metabolites when clinical symptoms and signs are serious or deteriorated. Choice of ECTR modality should be based on clearance efficiency, availability, cost, and complications. Among the various ECTRs available, HD provides the best expected removal for CBZ poisoning with the lowest incidence of complications and should therefore be the preferred modality in most cases.

Abstract

The latest global cancer burden data released by the International Agency for Research on Cancer of the World Health Organization in 2020 shows that there were 19.29 million new cancer cases worldwide, with 4.57 million in China, ranking first. The number of cancer survivors is increasing, with a 5-year survival rate exceeding 85%, but there are emotional disorders. Cognitive behavioral therapy (CBT) can improve negative emotions and has significant effects on patients. However, there is a limited number of physicians and high costs, so internet interventions have become a solution. The feasibility of web-based interventions for breast cancer patients has been proven. Research on internet-delivered CBT is also increasing. The purpose of this study was to review the concept of web-based CBT and its application status in cancer survivors, in order to provide relevant intervention for scholars and provide reference and supplement for patients to provide psychological therapy.

Key Words: Cancer survivors; Network; Cognitive behavioral therapy; Negative emotions

Core Tip: The number of cancer survivors is increasing, but emotional disorders persist. Cognitive behavioral therapy (CBT) has shown significant effects in improving negative emotions. Due to limited physicians and high costs, internet interventions have become a solution. Web-based interventions for breast cancer patients have proven feasible, and research on internet-delivered CBT is growing. It is helpful to reviewing web-based CBT and its application in cancer survivors and provide intervention insights for scholars and psychological therapy references for patients.

INTRODUCTION

According to the latest global cancer burden data released by the International Agency for Research on Cancer[1] of the World Health Organization, there were 19.29 million new cancer cases worldwide in 2020, and 4.57 million in China, which ranks first in the world. Thanks to improvements in diagnosis and treatment, the number of cancer survivors is increasing, with 5-year survival rates > 85%. Cancer survivors have varying degrees of mood disorders, including negative emotions, cancer-related fatigue, and sleep disturbances. It has been reported that mood disorders in cancer survivors are 2-4 times more prevalent than in the general population, leading to a lower quality of life, poorer daily functioning, and poor prognosis[2,3]. Meta-analyses show that cognitive behavioral therapy (CBT) improves negative mood, with effect sizes of 0.97 and 0.95 for patients with mood disorders, and 0.39 and 0.44 for cancer patients and survivors. However, due to the limited number of trained therapists, high cost, and limited time and space for cancer patients and survivors, providing CBT to patients in need remains a challenge[4]. Interventions delivered *via* the internet have become an increasingly popular way to overcome these challenges, and a review of e-health intervention systems for breast cancer patients and survivors demonstrated the universal feasibility and acceptability of interventions delivered *via* the internet[5]. There are also increasing studies on the intervention of patients with internet-delivered CBT (ICBT)[6-8].

OVERVIEW OF CBT

The origins of CBT can be traced back to Skinner and Joseph[9], who pioneered the CBT movement in the 1950s. CBT refers to changing adverse emotional reactions by correcting irrational cognitive concepts and/or behaviors, so as to resolve a series of physiological and psychological problems in patients[10]. In other words, changing behaviors will lead to emotional and cognitive changes. ICBT provides health education information to patients through the internet[11]. In ICBT, patients can obtain the same health information as CBT (such as psychological education on cognitive behavioral patterns, cognitive reorganization, behavioral skills, and relapse prevention)[12-14]. The material content of ICBT usually includes text, image, video and audio, *etc*., and generally the intervention duration varies from 5 to 15 wk[15]. CBT is a problem-centered and action-oriented approach that aims to eliminate negative emotions and behaviors by changing thoughts and behaviors to change negative cognition[9]. It focuses more on the current situation than on past experiences, mental problems, and connections between wrong ways of thinking and ways of acting, which helps patients to better identify their own negative thinking, use cognitive technology to combat negative thinking, correct wrong cognition to improve anxiety, depression and other negative emotions, and relieve pain, sleep disorders, and other physical and mental symptoms. This study conducted a literature search using the keywords "internet-delivered cognitive-behavioral therapy" or "web-based cognitive-behavioral therapy" and "tumor" or "cancer" on PubMed, China National Knowledge Infrastructure, and Wanfang Database to retrieve relevant Chinese and English articles. After screening, a total of 49 articles were obtained for reviewing the concept of ICBT and its application in cancer survivors.

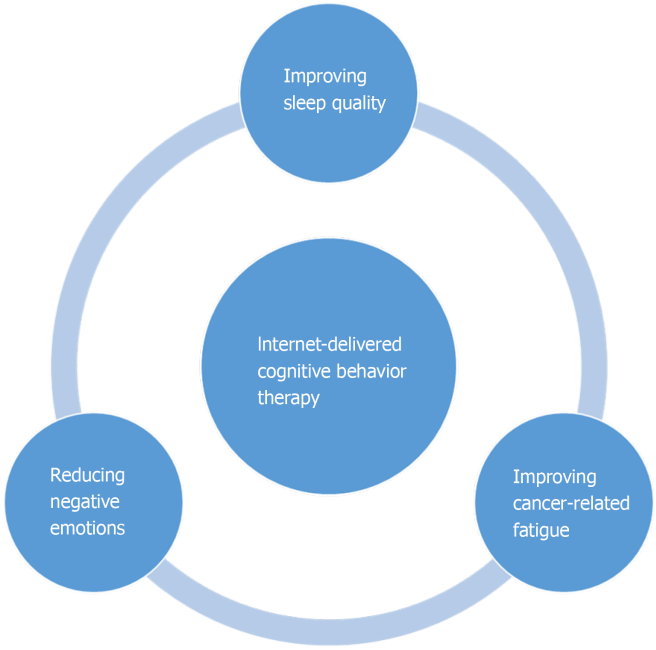
APPLICATION AND EFFECT OF CBT IN CANCER SURVIVORS

Reducing negative emotions

Compared with healthy people, cancer patients are more likely to experience negative emotions such as anxiety and depression[16]. A large Canadian study on mental disorders in 10153 cancer patients[17] showed that 19% had clinical anxiety symptoms, 22.6% had subclinical anxiety symptoms, 12.9% reported clinical depression symptoms, and 16.5% reported subclinical depression symptoms. Therefore, it is important to find treatment that can improve the psychological problems of cancer patients to improve their prognosis. Palay *et al*[17] found that breast and prostate are common cancer types with high survival rate, and such cancer survivors have some psychological distress, so they developed ICBT to improve the anxiety and depression symptoms of cancer patients in their daily life. The study began with screening of cancer patients at cancer hospitals and controlled follow-up of patients after initial treatment for symptoms of anxiety and depression in their daily lives. A total of 206 cancer patients were recruited for the study. These participants were randomly assigned to either the intervention group or the waiting control group for 10 wk each, with follow-up at week 5 (T2/mid-intervention), week 10 (T3/post-treatment), and week 34 (T4/6 mo post-treatment). The ICBT intervention program for improving anxiety and depression symptoms in cancer patients was developed by clinical psychologists who modified the original face-to-face CBT manual[19,20]. It lasted for 1 wk and consisted of eight modules, each consisting of written materials and audio exercises, writing tasks, examples of cancer patients, and expert videos. Participants completed a weekly training diary and mailed it to a therapist, who gave corresponding asynchronous written feedback[21]. The basic points of this treatment plan are as follows: (1) Nine therapists: Eight CBT-trained masters in psychology and

one experienced psychologist; (2) Supervision: Based on written feedback from therapists to participants, a manual reminder guide was developed, undertaken by therapist assistants, to urge participants to complete online questionnaires at stages T2, T3 and T4. If participants do not complete the questionnaire within 1 wk, they will receive three reminder emails, and if they do not respond, a research assistant will call to ask the reason; (3) Treatment compliance: To improve compliance of participants, researchers will give gifts or bonuses to participants at the middle and end of treatment as incentives; and (4) Internet platform: This is a website compatible with smart phones, and patients carry out daily exercises through their personal accounts. The waiting control group was given a cancer hospital health manual and followed up with a questionnaire at four time points. The study used the State-trait Anxiety Scale, the Patient Health Depression Questionnaire and the World Health Organization Quality of Life Index questionnaire[22-24] (Figure 1).

This study found that 5 wk after intervention, anxiety and depression in the ICBT group were significantly lower than those in the waiting control group[25], indicating that anxiety and depression were improved immediately after intervention. Model fitting analysis showed that depression scores were in line with a log-linear curve, indicating that the improvement in the ICBT group occurred at the beginning of the study and continued to improve over a period of time. At the 6-mo follow-up assessment, the improvement in anxiety and depression was 2.35 times greater in the ICBT group than in the waiting control group, and was effective in maintaining its effect on patients' negative mood. A meta-analysis showed that mindfulness-based behavioral therapy can be used as a basic treatment for emotional rehabilitation of cancer [26], while interventions provided by the internet may alleviate the suffering of cancer survivors who are unable to access face-to-face psychotherapy[27] (Figure 1).



Improving sleep quality

Sleep deprivation can have significant effects on daily functioning, mood, and self-management in cancer survivors. Sheikhzadeh *et al*[28] developed ICBT for breast cancer patients with insomnia by combining mindfulness meditation and CBT for insomnia. The study used two parallel randomized controlled trials in which 50 patients with cancer insomnia were recruited from 10 hospitals and randomly assigned 1:1 to a mindfulness intervention group or an education-only control group. The mindfulness intervention included a 6-wk online self-directed learning module that covered mindfulness meditation, sleep challenges, and behavioral strategies for improving sleep. The intervention strategy focused on using mindfulness as a sleep self-management technique to increase total sleep time and sleep efficiency. The development of the intervention module was published online. Each module each week contains instructional content on sleep and mindful meditation, using interactive text, video and audio meditation. Each module lasts about 20 min and can be completed at a time of the participant's choosing. There is also a message board for interaction with other participants and researchers[29]. During the day, patients communicate with researchers *via* text or email to obtain support. Reminders to complete daily sleep diaries and weekly modules were sent to participants at intervals by text message or email. During the study, participants completed an online or paper sleep diary each morning, which was modified to include symptoms of sleep disturbances and reports of daily meditation practices. At the end of the second week of the program, weekly feedback reports on adherence to the participants' personally recommended sleep schedules were provided *via* email. The control group was given only health education and no mindfulness or meditation (Figure 1).

The study found that ICBT significantly improved insomnia symptoms. After 6 wk of intervention, 71.2% of patients in the intervention group had sustained significant improvement in insomnia and fatigue symptoms. This study innovatively addressed sleep problems in cancer survivors, using a self-managed study design and methodology that was both available and cost-effective for a large number of cancer survivors, and larger randomized controlled trials can be conducted in the future to guide and refine intervention regimens (Figure 1).

Improving cancer-related fatigue

Fatigue is a symptom commonly experienced by cancer survivors at all stages of disease development. Survivors identified fatigue as an important problem that was not adequately addressed by healthcare providers[30]. Fatigue has a greater negative impact on functioning and health-related quality of life than other symptoms such as pain or depression [31-33]. Mak *et al*[34] selected 100 cancer patients with severe fatigue symptoms from 160 patients diagnosed with cancer according to inclusion and exclusion criteria for an 8-wk randomized controlled trial. The project was developed based on MacDonald and O'Hara's 10 elements of mental health[35], with resources for mental health promotion from the World Health Organization and government reports from the United Kingdom and Australia[36,37]. ICBT courses include didactic reading (such as transmitting Buddhist views on the nature of human suffering), experiential learning (such as guided meditation), and everyday life applications (such as developing an awareness of how attachment to letting go of a person can lead to inner peace). In order to improve the user experience, the project improved on the basis of the preliminary design. Weekly health tracking, built-in multimedia in each class, and dynamic content display made the content more interactive. The page and content color coordination, theme consistent graphics, and easy navigation made the web page more aesthetically attractive. The project incorporated the core concepts of traditional Buddhism, including discernment, compassion, impermanence, interdependence and nonattachment. By incorporating our mindfulness training into a traditional Buddhist foundation, the training program was designed to help participants build their own foundation of practice. Such an intention will lay the foundation for continuous and regular practice and may potentially influence the outcome of practice[38,39]. Participants were also given videos of stretching exercises, body scans, and audio of sitting meditation to guide them through the exercises. During the intervention, participants were given worksheets that included a mood diary, cognitive reconstruction, and a healthy lifestyle program to record their responses. All content was developed by members of the research team, who were clinical psychologists and mindfulness practitioners. The control group received routine nursing (Figure 1).

Figure 1 Application and effect of internet-delivered cognitive behavioral therapy in cancer survivors.

The study used the Cancer Related Fatigue Scale and the European Organization for Cancer Research and Treatment Quality of Life Scale to assess patients' quality of life and fatigue symptoms. The results showed that ICBT could significantly reduce cancer-induced fatigue and improve the quality of life of patients. The web page was designed reasonably, and course of treatment was moderate, with good patient feedback and high treatment compliance. Compared with face-to-face interventions, internet-based interventions are more accessible and affordable, and have the potential to satisfy the need to promote and prevent mental health in community settings and are worth scaling up in the future (Figure 1).

Limitation of ICBT

High dropout rate and poor compliance. Since ICBT courses are carried out in a standardized content and structured format, and therapists are not able to provide timely feedback and adjust the program according to the patient's response, this affects patient compliance[40]. Many complex problems in practice. Implementation of ICBT in five different European countries faced issues such as how to integrate it into the mental health care system, how to recruit patients, how to ensure the quality of the work of therapists, and how to provide long-term sustainable ICBT treatment[41]. Many influencing factors are unclear. At present, there are few studies on factors affecting treatment outcomes. One study explored the influ-encing factors from the content of emails from patients and therapists, and found that affirmation, encouragement, and self-exposure by therapists had a positive impact on treatment outcomes[42].

CONCLUSION

CBT is commonly used as first-line treatment for cancer survivors[43], and the American Medical Association recommends[10] that CBT be administered personally by trained therapists to promote self-management in cancer patients. Face-to-face CBT has been proven to be effective and worthy of promotion, but due to time, space and economic constraints, not all patients can easily access this treatment. With the increasing popularity of the internet, the combination of the internet and continuous care, and the full use of the advantages of the internet, can achieve the goal of promoting health education and prevention. ICBT has the advantages of low cost, easy access, and not being limited by time and space. ICBT can promote cancer patients' self-management, improve negative emotions, improve sleep quality, and relieve cancer-induced fatigue[44-46].

The research of the application of ICBT in cancer patients were summarized in Table 1. In the future, researchers can explore the influence of the duration of ICBT intervention on the intervention effect, so as to select the appropriate intervention time. It is imperative to cultivate high-quality therapists with a background in psychological medicine. In addition, ICBT is a psychological intervention that requires high-quality, multicenter, and large-sample randomized controlled trials. Qualitative interviews and descriptive data collection can be carried out to understand patients' subjective feelings, and improve intervention methods and guide intervention research.

Table 1 Research of the internet-delivered cognitive behavioral therapy application in cancer patients

Ref.	Patients (*n*)	Intervention	Indicators	Conclusion
Nissen *et al* [18]	Cancer survivors (1282)	Therapist-assisted iMBCT	Outcomes of anxiety and depression	iMBCT is a helpful intervention for cancer survivors suffering from symptoms of anxiety
Zachariae *et al*[47]	Breast cancer survivors (255)	ICBT-i or waitlist control	Sleep-related outcomes	ICBT-i appears to be effective in breast cancer survivors, with additional benefit in terms of reduced fatigue
Nissen *et al* [48]	Breast- and prostate cancer survivors (82)	iMBCT	Improvement in anxiety and depression scores from baseline to post-treatment and from baseline to six-months follow-up	iMBCT can be provided for cancer survivors regardless of their age, educational level, and time since diagnosis (up to five years) and therapeutic alliance is not crucial for treatment response
Dirkse *et al* [49]	Cancer survivors with symptoms of anxiety or depression (86)	ICBT program guided by a technician	Anxiety, depression, fear of cancer recurrence, quality of life	ICBT was associated with improved levels of anxiety, depression, fear of cancer recurrence, and quality of life
Murphy *et al*[50]	Breast cancer patients with generalized anxiety disorder (14)	ICBT	Health status, adherence, acceptability	ICBT has significant potential to be a suitable modality supervised by clinican
Murphy *et al*[51]	Cancer survivors (114)	ICBT or TAU	Anxiety and depression symptoms, fear of cancer recurrence, quality of life	Clinician-supervised iCBT has significant benefits for cancer survivors with clinical depression and anxiety disorders
Carbajal-López *et al*[52]	Gastrointestinal stromal tumors (99)	ICBT or internet-delivered cognitive program	General fatigue, reduced motivation, distress and global health status	Both intervention programs showed reductions in the dimensions of fatigue and improvements in distress and dimensions of quality of life

iMBCT: Internet-delivered mindfulness-based cognitive therapy; TAU: Treat-as-usual; ICBT: Internet-delivered cognitive behavioral therapy.

Abstract

BACKGROUND

The background of this study was analgesia in natural delivery. The combined spinal-epidural anesthesia has obvious analgesic effect on the parturients in natural labor, and combined spinal-epidural anesthesia has been widely used in anesthesia for various diseases.

AIM

To study the effects of combined spinal-epidural anesthesia on anxiety, labor analgesia, and motor blocks in parturients during natural delivery.

METHODS

A total of 120 women who gave birth at Changning District Maternal and Child Health Hospital between December 2021 to December 2022 were included; a random number table approach was employed to divide the women into a control group and a joint group, with each group consisting of 60 women. The control group was given epidural anesthesia, while the joint group was given combined spinal-epidural anesthesia. The visual analog scale (VAS) was used to evaluate the degree of maternal pain. Comparisons were made between the two groups' conditions of childbirth and the duration of labor. Apgar scores were used to evaluate the status of the newborns at birth; Self-rating Anxiety Scale (SAS) and General Self-Efficacy Scale (GSES) scores, umbilical artery blood gas analysis indices and stress indices were compared between the two groups; and the frequencies of motor block and postpartum complications were analyzed.

RESULTS

In comparison to the control group, in the joint group, the VAS scores for the first, second, and third stages of labor were lower ($P < 0.05$). The rates of conversion to cesarean section and postpartum blood loss in the joint group were lower than those in the control group ($P < 0.05$). No significant differences were observed in the Apgar score, the duration of the first stage of labor, or the total duration of

labor between the two groups ($P > 0.05$). The second and third stages of labor in the joint group were shorter than those in the control group ($P < 0.05$). When compared to the control group, the postpartum SAS score of the joint group was lower, while the GSES score was greater ($P < 0.05$). Between the control group and the joint group, the differences observed in pH, arterial carbon dioxide partial pressure, arterial oxygen partial pressure, or arterial hydrogen ion concentration were not significant ($P > 0.05$). Nitric oxide, cortisol, and adrenaline levels were lower in the joint group than in the control group ($P < 0.05$). There were no substantial differences in Bromage grade or rate of complications between the two groups ($P > 0.05$).

CONCLUSION

For parturients during natural delivery, combined spinal-epidural anesthesia can reduce anxiety, provide labor analgesia, shorten labor time, and reduce postoperative stress levels but did not result in a motor block.

Key Words: Combined spinal-epidural anesthesia; Natural delivery; Anxiety level; Labor analgesia; Motor block

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: The pain of parturients in natural delivery is serious. Spinal anesthesia and epidural analgesia are widely used, but the analgesia effect is not good, and the nerve block effect of lumbar epidural anesthesia is better. The objective of this study was to compare the effects of combined epidural and lumbar anesthesia on labor analgesia and movement block.

INTRODUCTION

Labor is a complicated physiological and psychological process, and labor pain is a subjective feeling of the human body that lacks objective indicators. Currently, combined spinal-epidural anesthesia is widely used to relieve the pain of parturients during natural childbirth, which has less impact on contraction pain than other analgesic methods[1]. However, various research studies have shown that epidural anesthesia alone has a poor analgesic effect in parturients. Based on this fact, intraspinal anesthesia can be used to effectively enhance the analgesic effect[2]. Combined spinal-epidural anesthesia has a more rapid analgesic effect and better nerve block efficacy than epidural anesthesia[3]. Childbirth is a natural biological process as well as a complex period involving volatile emotions. Related research suggests that the intensity of labor pain is associated with individual pain thresholds as well as many other influencing factors[4]. Poor mood around the time of delivery can directly reduce a woman's pain threshold, making her more sensitive to pain. In addition, severe pain during childbirth increases the fear, tension, and anxiety of parturients, forming a vicious cycle, which keeps them in a state of high stress and has adverse effects on delivery[5,6]. Therefore, reducing negative emotions in patients during childbirth is crucial for smooth deliveries. Based on the above, this study explored the effects of combined spinal-epidural anesthesia on anxiety levels, labor analgesia and motor blocks in women during natural delivery, with the view of selecting a better method of labor anesthesia and promoting smooth deliveries.

MATERIALS AND METHODS

Clinical data

A total of 120 women who gave birth in Changning District Maternal and Child Health Hospital from December 2021 to December 2022 without signs of cesarean section were studied. By employing a random number table, they were separated into control and joint groups, each of which included 60 women. Table 1 demonstrates that no significant differences were present in the general data between the two groups ($P > 0.05$).

The inclusion criteria were as follows: (1) Women aged 23-34 years old; (2) Women with American Society of Anesthesiologists physical status grade I; (3) Primiparas; and (4) Women with a gestational age of 36-40 wk. The exclusion criteria were as follows: (1) Patients with a medical history of hematological diseases; (2) Patients with long-term use of anticoagulants or drugs that affect coagulation function; (3) Patients with contraindications for combined spinal-epidural anesthesia; and (4) Patients with pregnancy-induced hypertension and other obstetric complications.

Methods

The joint group was given combined spinal-epidural anesthesia. When the uterine orifice was opened to 1 cm, puncture was performed in the lumbar L2-3 space. After successful subarachnoid puncture, cerebrospinal fluid flow was

Table 1 Comparison of general data between the two groups

Classification	Joint group (*n* = 60)	Control group (*n* = 60)	*T* value	*P* value
Age (yr)	26.79 ± 3.18	27.03 ± 3.21	0.411	0.682
Gestational age (wk)	39.35 ± 0.24	39.28 ± 0.21	1.700	0.092
Number of pregnancies	1.84 ± 0.17	1.89 ± 0.21	1.433	0.154
Parity	1.59 ± 0.12	1.61 ± 0.15	0.806	0.422
Estimated newborn body mass (kg)	3.58 ± 0.53	3.65 ± 0.49	0.751	0.454

continuous. A subarachnoid injection of 1 μg sufentanil (Yichang Humanwell Pharmaceutical Co., LTD., batch number: SFDA approval number H20054171) and 0.2 mg ropivacaine (Jiangsu Hengri Pharmaceutical Co., LTD., batch number: SFDA approval number H20060137) was given. Epidural catheterization was performed. After successful catheterization, 3 mL of 1.5% lidocaine (Shanghai Pujin Linzhou Pharmaceutical Co., LTD., batch number: SFDA approval number H41022244) was given as the experimental dose. After confirming correct placement in the epidural space, the epidural catheter was fixed with adhesive tape. Sufentanil (0.5 μg/mL) and +0.1% ropivacaine was combined with an epidural infusion pump. The first dose of the infusion pump was set at 10 mL, the patient-controlled analgesia dose was set at 9 mL, and the patient-controlled lockout time was 20 min. The infusion pump was turned on 1 h after anesthesia. Epidural anesthesia was given to the control group with the same specific method as that in the joint group.

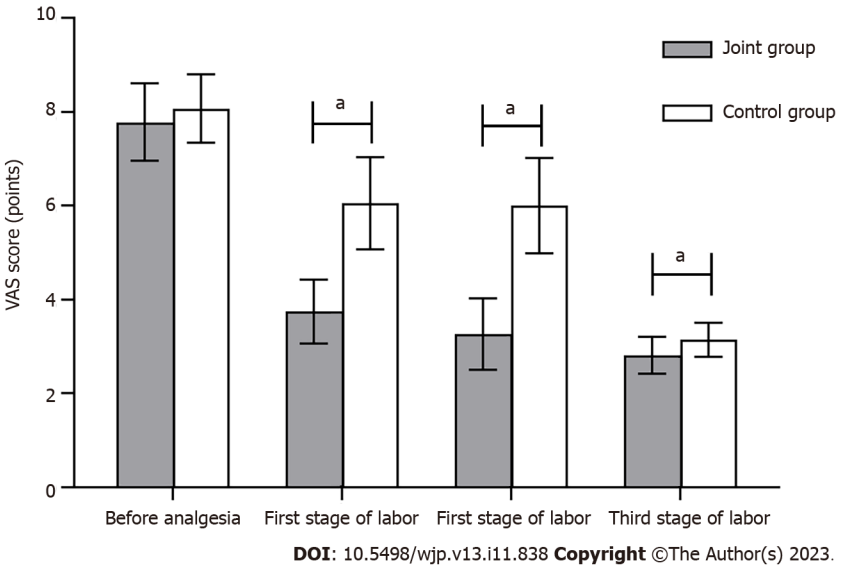
The observation targets were as follows: (1) Labor pain: The degree of labor pain in each stage of labor was evaluated by employing the visual analog scale (VAS)[7]. The scores ranged from 0-10, and the severity of the pain increased with the score; (2) Childbirth-related conditions: The two groups' rates of conversion to cesarean section, forceps-assisted delivery, and postpartum blood loss and newborn Apgar scores were compared. The Apgar score was utilized to evaluate the status of newborns[8]. The Apgar scores ranged from 0-10, with a score of 10 representing healthy newborns and a score < 7 indicating asphyxia; (3) Labor duration: Between the two groups, the first, second, and third stages of labor as well as the overall duration of labor were compared; (4) Emotion: The Self-Rating Anxiety Scale (SAS) was employed to evaluate the anxiety levels of patients[9]. The scores ranged from 20-80, and a score of > 50 indicated anxiety. The General Self-Efficacy Scale (GSES) was utilized to evaluate the patients' self-efficacy[10], with scores ranging between 10 and 40 points. Higher scores suggested a stronger sense of self-efficacy; (5) Blood gas analysis indices of the umbilical artery: After delivery, 1 mL of umbilical artery blood was extracted with a heparin anticoagulant syringe. Then, the pH, partial pressure of oxygen (PO_2), partial pressure of carbon dioxide (PCO_2) and arterial hydrogen ion concentration (BE) of the maternal umbilical artery were detected by an ABL77 automatic blood gas analyzer (Radiometer, Denmark); (6) Stress index: Before and 3 d after delivery, 3 mL of maternal venous blood was drawn and subjected to centrifugation, serum cortisol (Cor) and adrenaline (ADR) levels were measured by ELISA, and serum nitric oxide (NO) levels were measured by the NO enzyme method; (7) Degree of motor block: The modified Bromage score was employed to evaluate the degree of motor block[11]. Level 0 indicated that there was no motor block, and the lower limbs could be raised; level 1 indicated the inability to lift the thigh; level 2 indicated difficulty in bending the knee; and level 3 indicated difficulty in bending the ankle; and (8) Complications: In both groups, the frequency of postoperative issues such as hypotension, nausea, and vomiting was measured.

Statistical analysis

SPSS 22.0 software was utilized to process the data. Counting data are reported as percentages, and differences between groups were compared by Fisher's exact test or the χ^2 test. Measurement data are reported as mean ± SD after the normality test, and the differences between groups were compared *via t* tests. Ranked data were analyzed by *Z* tests. $P < 0.05$ indicated a statistically significant difference.

RESULTS

Comparison of labor pain between the two groups: Before anesthesia, no significant difference was observed in the VAS scores of the two groups ($P > 0.05$). In comparison to the control group, in the joint group, the VAS scores for the first, second, and third stages of labor were lower ($P < 0.05$) (Figure 1).



Comparing the childbirth-related conditions between the groups: The rates of conversion to cesarean section and postpartum blood loss were lower in the joint group than in the control group ($P < 0.05$); no significant differences were observed in the two groups' Apgar scores ($P > 0.05$) (Table 2, Figure 2).

Comparison of labor duration between the two groups: The initial stage of labor and the overall duration of labor did not substantially differ between the two groups ($P > 0.05$); the joint group experienced slightly shorter second and third stages of labor in comparison to the control group ($P < 0.05$), as shown in Figure 3.

Comparison of anxiety and depression between the two groups: Prenatal SAS and GSES scores did not differ significantly between the groups ($P > 0.05$). The SAS scores of both groups were lower in the postpartum period than the prenatal period, and the SAS scores of the joint group were lower than those of the control group ($P < 0.05$). The GSES scores were higher in both groups in the postnatal period compared to the corresponding scores in the prenatal period,

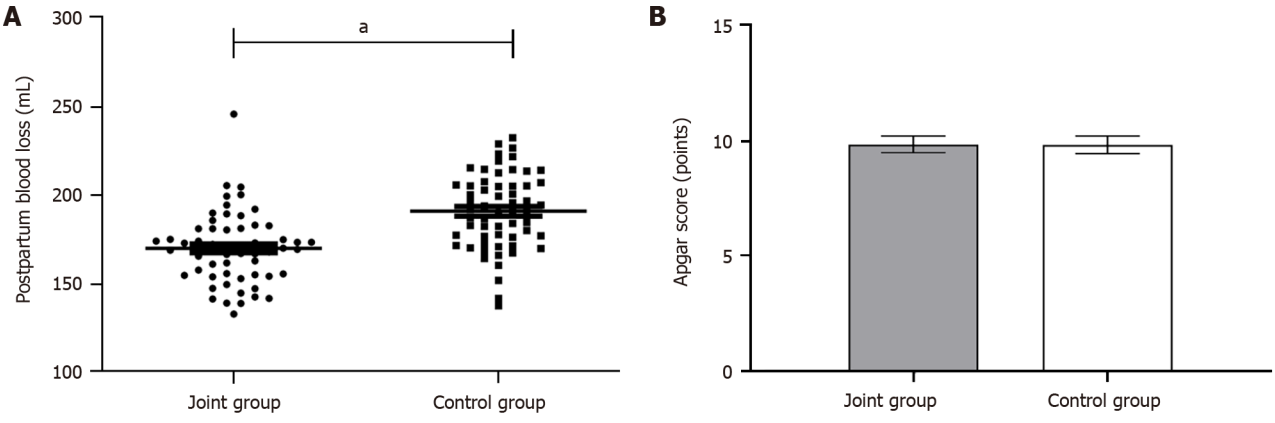


Table 2 Comparison of childbirth-related conditions between the two groups

Group	*n*	Rate of conversion to cesarean section	Rate of forceps-assisted delivery
Joint group	60	0.00 (0)	3.33 (2)
Control group	60	8.33 (5)	6.67 (4)
P value		< 0.05	> 0.05

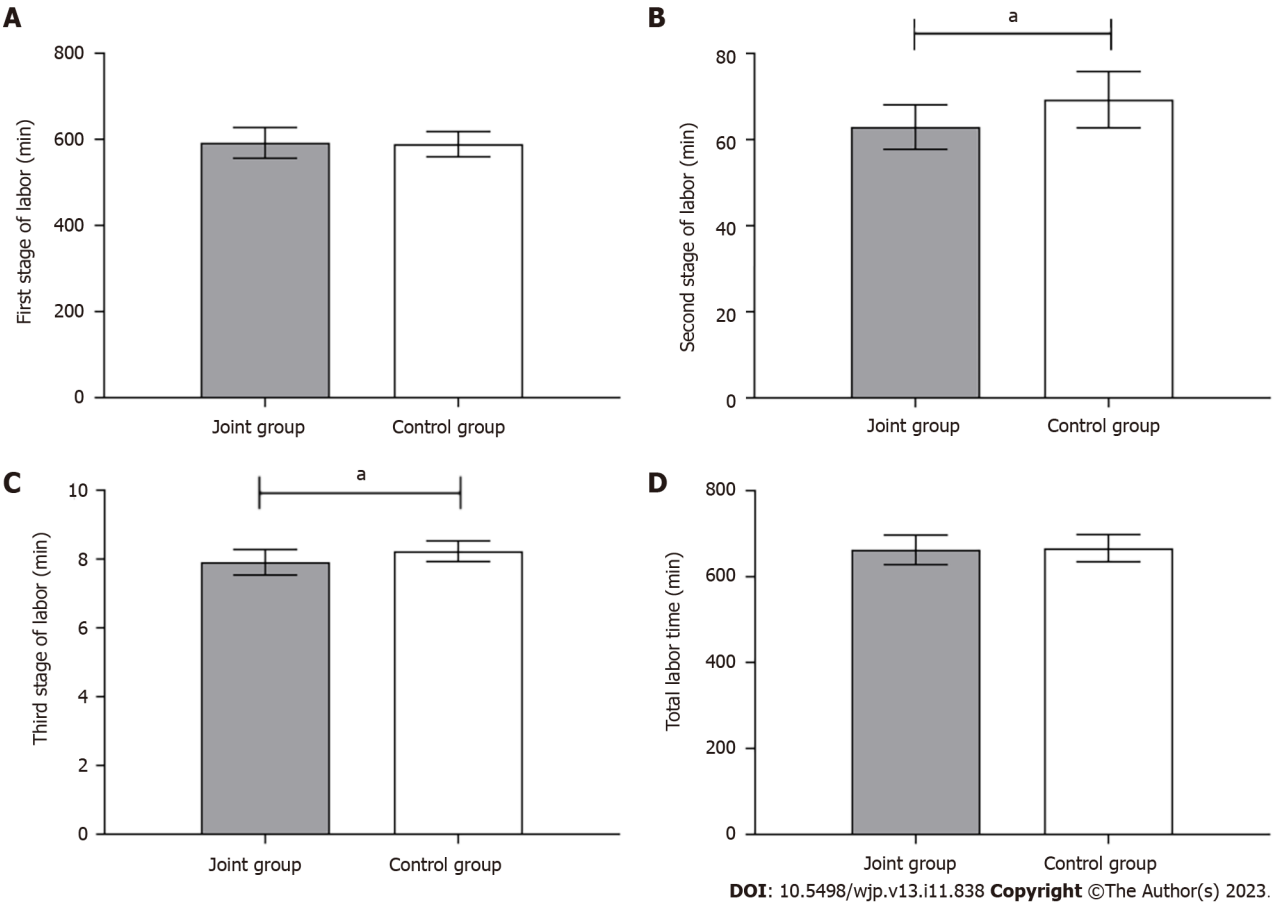
with the joint group having higher scores than the control group ($P < 0.05$) (Figure 4).

Comparison of blood gas analysis indices of the umbilical artery between the two groups: The changes observed in pH, PCO_2, PO_2, and BE between the control and joint groups were not significantly different ($P > 0.05$), as shown in Figure 5.

Comparison of stress indices between the two groups: No significant differences were observed in the prenatal Cor, ADR, and NO levels between the groups ($P > 0.05$). Following delivery, the levels of Cor, ADR, and NO increased in both groups compared to those before delivery. Additionally, the scores in the control group were elevated compared to those in the joint group ($P < 0.05$) (Figure 6).



Comparison of motor block effects between the two groups: The Bromage grade did not substantially differ between the two groups ($P > 0.05$) (Table 3). Comparison of complication rates between the two groups. The complication rates between the two groups did not differ significantly ($P > 0.05$) (Table 4).

DISCUSSION

Labor pain refers to the pain caused by strong uterine contractions, pelvic floor muscle expansion, and contraction of uterine tissue. Relevant studies have pointed out that intense and sustained pain during natural labor can directly lead to the occurrence of postpartum depression[12]. Hence, it is important to explore a better method of pain relief during labor. Specifically, optimal pain relief during labor can make pain relief easy to control, which is conducive to the smooth progress of labor. Continuous epidural block has been widely used internationally, with exact analgesic effects, lasting effects, little influence on circulation, and no side effects or complications of general anesthesia, such as changes in consciousness, hypoxia, hypercapnia, or aspiration[13]. Previous studies have shown that combined spinal-epidural anesthesia can reduce the pain of women during natural childbirth[14]. Intravertebral analgesia is currently considered by most scholars to be the most effective labor analgesia method. This method can effectively reduce pain during uterine contraction, reduce the stress response during labor, and contribute to the stability of the internal environment of the parturient and the smooth recovery of the body in the postpartum period[15]. The current study revealed that the VAS scores during the first, second, and third stages of labor were lower in the joint group than in the control group, suggesting that combined spinal-epidural anesthesia could alleviate labor pain for women during natural labor, which was consistent with the above research results. However, it should be noted that although combined anesthesia reduces the degree of labor pain, the analgesic drugs used will still have varying degrees of impact on the mother and child, and analgesic drug use during labor can easily hide excessive contractions and can also lead to contraction inhibition. Hence, it is necessary to choose the appropriate delivery method according to the patient's condition. Moreover, the outcomes of the present research demonstrated lower rates of conversion to cesarean section and postpartum blood loss in the joint group than in the control group, suggesting that combined anesthesia can promote the smooth progress of natural delivery. Because pain during labor can be alleviated, a series of physiological changes caused by labor pain can be relieved, and maternal fear and tension can be alleviated, which is conducive to the smooth progress of labor and indirectly reduces the rate of cesarean section[16].

Childbirth is a complex physiological and psychological process that is affected by mental, psychological, and environmental factors. Fear-tension-pain syndrome is common in parturient women. Due to a lack of understanding of the delivery process, an abnormal pregnancy history, existing mental and psychological disorders, and endocrine changes during childbirth, parturient women, especially primiparous parturient women, experience negative emotions such as fear, tension, anxiety, and depression, which are different from those in nonpregnancy[17]. According to literature reports, approximately 5% of the normal population has anxiety, and the incidence of prenatal anxiety can reach 8%-16.5%[18]. Childbirth self-efficacy refers to the belief or confidence that one can apply some techniques to manage and reduce pain during labor. According to some studies, the threshold of childbirth pain for women with poor mental health is reduced, and the psychological advantages generated by the participation of parturients in analgesia can eliminate the tension and anxiety caused by childbirth, increase their self-confidence, reduce the rates of dystocia and childbirth complications, and create favorable conditions for ensuring the safety of the mother and child during childbirth[19]. In the present study, it was found that the SAS score was decreased and the GSES score was increased in the postpartum period in the joint group, implying that the combined spinal-epidural anesthesia improved the sense of self-efficacy and reduced the degree of anxiety. Therefore, medical workers need consider parturients are a whole, determine their mental state in a timely manner, choose safe, rapid, effective, and appropriate analgesic methods, and implement individualized treatment for parturients to achieve ideal labor analgesia. For parturients with low anxiety and depression levels, psychotherapy can be used to comfort them by addressing doubts, relieving tension and loneliness and enhancing maternal confidence in giving birth. In addition, the durations of the second and third stages of labor in the joint group were slightly decreased compared to those in the control group, indicating that combined spinal-epidural anesthesia could reduce the duration of labor in women with natural delivery, which may be related to the reduction of labor pain and anxiety by combined anesthesia.

Umbilical cord blood gas is affected not only by the process of labor but also by placental function, umbilical cord factors, and maternal blood gas status. According to relevant reports, abnormal blood gas indices of cord blood are related to maternal emotions in addition to labor pain[20]. During childbirth, appropriate tension and anxiety can improve a mother's ability to adapt to the environment, which can be accompanied by activation of the sympathetic nervous system. Increased catecholamines acting on α receptors constrict peripheral blood vessels, increase the heart rate, redistribute cardiac output, and ensure the supply of vital organs such as the heart and brain, making up for the shortage of the maternal supply and improving the fetus's tolerance to hypoxia; however, excessive anxiety can affect umbilical cord blood hemodynamics, leading to fetal hypoxia[21,22]. Since the above research results showed that combined anesthesia can help to reduce patients' anxiety, the author believes that this anesthesia method can improve umbilical artery blood gas indices. In the present research, no significant differences were seen in pH, PO_2, PCO_2, and BE between the joint group and the control group, indicating that combined spinal-epidural anesthesia and single epidural anesthesia had little impact on the umbilical artery blood gas indices in parturients who gave birth naturally, which is inconsistent with the relevant research results[23]. This might be due to the study's small sample size; thus, the sample size should be increased for further analysis.

Experiencing high levels of tension, anxiety, and intense pain during labor can trigger a cascade of neuroendocrine reactions within the body. This can lead to elevated levels of catecholamines and adrenal corticosteroids in the bloodstream, resulting in increased oxygen consumption, heightened cardiac burden, uterine vasoconstriction, decreased blood flow, fetal distress, and potential uterine inertia. Pain can cause hyperventilation in parturients, which has adverse effects on their cardiovascular, endocrine, and psychological conditions and can increase the incidence of uterine inertia and uncoordinated uterine contraction. The current study demonstrated that Cor, ADR, and NO levels were comparatively lower in the joint group than in the control group, implying that the combination of lumbar and epidural

anesthesia could reduce the postoperative stress level of the body, which was largely associated with the reduction in postoperative pain and improvement in negative emotions of the women in the combined anesthesia group. Related research demonstrates that the degree of motor block can be reduced by giving combined spinal-epidural anesthesia to women during natural childbirth[24]. Nevertheless, no significant differences were found in the Bromage grade or complication rate between the two groups, indicating that combined anesthesia and epidural block alone had little effect on motor block. The reason for this remains unknown, so further analysis should be conducted.

CONCLUSION

Combined spinal-epidural anesthesia for women during natural labor can reduce anxiety, ease pain, shorten the labor time, and reduce the postoperative stress level of the body, but did not result in a motor block. This study shows that, in addition to improving the method of anesthesia, prenatal education should also be carried out. By fully providing knowledge on labor and labor pain, prenatal education can help parturients understand how to judge labor pain, which is conducive to improving continuous muscle tension and enhancing the analgesic effect for painless labor.

ARTICLE HIGHLIGHTS

Research background

The background of this study is that the rate of natural childbirth is increasing, the rate of cesarean section is decreasing, and anesthesia and analgesia in natural childbirth are getting more and more clinical attention. The significance of this study is to explore new methods of anesthesia and analgesia in natural childbirth.

Research motivation

The main topic of this study is anesthesia and analgesia for natural parturients, and it is necessary to explore more effective anesthesia and analgesia methods for natural parturients. The significance of this study is to confirm the effectiveness of combined spinal-epidural anesthesia in the analgesia of women in natural childbirth, and encourage clinical teams to continue to explore more effective analgesia methods for women in natural childbirth.

Research objectives

The purpose of this study was to compare the analgesic effect of different analgesic methods on women in natural childbirth, and to observe the analgesic advantage of combined spinal-epidural anesthesia on women in natural childbirth. It was found that the combined spinal-epidural anesthesia can effectively improve the labor pain, shorten the labor process, relieve the bad mood and reduce the postoperative stress of the parturients. To provide a new reference for the analgesia of parturients in clinical natural labor in the future.

Research methods

In this study, the pregnant women were divided into two groups by randomized control method, and the general data, pain degree, newborn condition, self-efficacy, umbilical artery blood gas analysis index, stress index and movement blocker complications of the two groups were statistically analyzed by independent sample *t* test, paired sample *t* test and χ^2 test.

Research results

Combined spinal-epidural anesthesia has a more significant effect on the improvement of labor pain in women with natural delivery, with significant improvements in labor pain, cesarean section rate, blood loss, adverse emotions, stress reaction and other aspects, providing a new analgesic method for women with natural delivery. Further large-scale studies are needed to verify the effectiveness of this method.

Research conclusions

The bad mood of natural childbirth women can affect the pain threshold of women, making them more sensitive to pain, and pain strengthens the bad mood of women, affecting childbirth. Therefore, we should pay attention to the influence of analgesic methods on maternal bad mood. Combined spinal-epidural anesthesia has good analgesic effect on parturients in natural labor.

Research perspectives

Natural childbirth women should not only consider the outcome of childbirth, but also pay attention to the personal state of the mother during childbirth. Future research aims to further explore the effects of analgesia on maternal adverse mood and stress response.

Abstract

BACKGROUND

Perioperative hypothermia (PH) negatively affects the physical and mental health of patients to varying degrees. Currently, there is no effective multidisciplinary team (MDT) intervention for gynecological patients with PH.

AIM

To apply the best evidence on the prevention and management of PH in gynecological patients, improve the quality of perioperative evidence-based care based on treatment by an MDT for gynecological patients and analyze the effect of MDT- and evidence-based practice (EBP) projects on the psychological status and cognitive function of gynecological patients with PH.

METHODS

Under the guidance of knowledge translation and combined with the opinions of involved stakeholders and clinical experts, the best evidence for PH prevention and management in gynecological patients was selected and adjusted to suit the practice setting. Based on the evidence, the practice plan was developed, and the MDT intervention was carried out in the preoperative ward, the preoperative preparation room, the intraoperative operating room, the postanesthesia care unit, and the 24-hour postoperative gynecological ward through the EBP program. The incidence of hypothermia, the nurses' awareness, the implementation rate of examination indicators, and the thermal comfort level, psychological status and cognitive function of patients were compared before and after the implementation of the program.

RESULTS

The incidence of PH in gynecological patients decreased from 43.33% to 13.33% after the implementation of the scheme. The implementation rate of examination

indicators 6-10, 12, 14, 16-18, 21, and 22 reached 100%, and that of other indicators was above 90%, except for examination indicators 5 and 13, which was 66.67%; the indices were significantly improved compared with the baseline (before evidence application) ($P < 0.05$). The score of nurses' awareness of PH prevention and management in gynecological patients increased from 60.96 ± 9.70 to 88.08 ± 8.96, and the difference was statistically significant ($P < 0.001$). The total score of the perioperative thermal comfort level of patients undergoing gynecological surgery was 27.97 ± 2.04, which was significantly increased compared with the score of 21.27 ± 1.57 observed by researchers at baseline ($P < 0.001$). The perioperative Hamilton Depression Scale and Hamilton Anxiety Scale scores of patients undergoing gynecological surgery decreased from 15.03 ± 3.16 and 13.93 ± 2.64 to 4.30 ± 1.15 and 3.53 ± 0.78, respectively, with statistically significant differences ($P < 0.001$). The perioperative Montreal Cognitive Assessment Scale score of the gynecological surgery patients increased from 23.17 ± 1.68 to 26.93 ± 1.11, also with statistical significance ($P < 0.001$).

CONCLUSION

MDT-based EBP for PH prevention and management in gynecological patients during the perioperative period can standardize nursing operations, improve nurses' awareness and behavioral compliance with gynecological hypothermia management, and reduce the occurrence of PH in gynecological patients while playing a positive role in reducing patients' negative emotions and enhancing their cognitive function.

Key Words: Hypothermia; Gynecology; Evidence-based care; Knowledge translation; Multidisciplinary team

Core Tip: At present, there is a lack of effective measures for perioperative hypothermia (PH) management in gynecological patients in China. This study verified the effectiveness of evidence-based practice project based on multi-disciplinary team in PH management of gynecological patients from the aspects of incidence of hypothermia, nurses' awareness, implementation rate of examination indicators, and the thermal comfort level, psychological status and cognitive function of patients.

INTRODUCTION

Perioperative hypothermia (PH) refers to the phenomenon in which the body's core temperature is lower than 36 °C for various reasons in surgical patients[1] and has a high incidence. PH can delay the action time of anesthetic drugs, trigger unexpected events such as respiratory depression, vomiting and chills, and increase postoperative cardiovascular system complications, postoperative infection risk, coagulation dysfunction and other adverse consequences[2], prolonging the hospitalization time of surgical patients, increasing their hospitalization medical expenses and economic burden, and reducing social satisfaction[3]. Due to preoperative transfer, intraoperative anesthesia, the use of large amounts of flushing fluid, and the placement of patients in special positions, the incidence of PH in gynecological patients in China ranges from 31.3% to 65%[4,5], which is high, and the incidence in postanesthesia care units (PACUs) reaches 22.0%[6], necessitating improvement. The prevention and management of PH in gynecological patients is the responsibility of the multidisciplinary team (MDT)[7]. At present, the foreign practice guidelines and evidence summary on PH prevention and management are relatively comprehensive and mature. In contrast, although there are relevant studies and evidence on PH in China, none of them have been carried out according to the characteristics of gynecological patients, nor have they been effectively applied to clinical practice in China, resulting in a substantial difference between practice and evidence. In addition, there is no MDT intervention to improve the status quo of PH in patients. All these factors can explain the high incidence of PH in gynecological patients in China.

Knowledge translation (KT) refers to studying how to apply research evidence or clinical practice guidelines based on research evidence to clinical practice. The Knowledge-to-Action (KTA) framework, the most commonly used in KT theoretical frameworks, divides the KT process into knowledge creation and knowledge application, promoting the synthesis, dissemination and application of knowledge. The KT framework is a dynamic process through which knowledge producers (*i.e.*, researchers) and knowledge applicators (*i.e.*, practitioners) are integrated in a cooperative and interactive manner, reflecting a complete cycle from knowledge creation to application and providing a clear conceptual framework for the translation of knowledge into practice[8]. The application of an MDT under the guidance of KT may be of great help to the management of PH in gynecological patients. The MDT model of diagnosis, treatment and care has been shown to be one of the important models in medicine worldwide, which emphasizes patient-centered, curative effect-oriented, and evidence-based medicine to provide patients with all-round, personalized, refined, effective and

reasonable medical services[9]. MDT management has been shown to effectively improve the quality of life of patients with gynecological malignancies[10], promote their rapid recovery[11], and enhance the comprehensive ability of gynecological nurses[12]. To effectively prevent and manage the occurrence of PH in gynecological patients, the MDT-based evidence-based practice (EBP) project applies the best evidence scheme for the prevention and management of PH in gynecology, providing new ideas for solving the problem of PH in gynecological patients.

MATERIALS AND METHODS

Presentation of clinical problems

Based on a literature review and clinical practice, the clinical question "How can the incidence of PH be reduced in gynecological patients?", was identified and transformed into evidence-based problems according to the Population, Intervention, Control, and Outcome approach: (1) Population: Adult patients (≥ 18 years old) who underwent gynecological surgery (laparoscopy/hysteroscopy/Laparotomy) for 2 h or more; (2) Intervention: Prevention and management strategies of unplanned PH; (3) Control: Clinical routine nursing measures; and (4) Outcome: The implementation rate of examination indicators, nurses' awareness scores, incidence of hypothermia in gynecological patients, standardized procedures for PH prevention and management in gynecological patients, and psychological status and cognitive function of gynecological patients.

Construction of an evidence-based group

The team consisted of 9 members, including 2 operating room head nurses, 1 head nurse in the anesthesiology department, 1 head nurse in the gynecology department, 3 floor nurses, and 2 postgraduate students. Among them, the operating room head nurses were responsible for the overall research design and guidance; the postgraduates were responsible for evidence extraction, baseline review, data collection and analysis; and the remaining team members were responsible for nurse training, organization and coordination, and quality supervision.

Evidence acquisition

In this study, relevant clinical practice guidelines, expert consensus, evidence summaries and systematic reviews were retrieved from databases such as PubMed/Medline, JBI's Evidence-based Practice Database, the Cochrane Library, National Institute of Health and Care Excellence, Registered Nurses Association of Ontario, OVID, Science Direct, Association of the Scientific Medical Societies in Germany (AWMF), Association of Operating Room Nurses, China National Knowledge Infrastructure, Wanfang Data Knowledge Service Platform, and Chinese BioMedical Literature Database from 2000 to April 2021. Of the 592 documents retrieved, 7 articles were included after reading the abstracts and full texts and evaluating the literature quality, including 2 guidelines[13,14], 2 expert consensuses[2,15], and 3 systematic reviews[16-18]. For the guidelines included, the quality was quantitatively evaluated using the Appraisal of Guidelines for Research and Evaluation instrument II[19], and the results are shown in Table 1. The Assessment of Multiple Systematic Reviews score[20] was used for quality assessment of the systematic reviews included, with the results presented in Table 2. For expert consensus, the quality was assessed by referring to JBI's critical appraisal tools[21]; the evaluation results of all the other items of the two articles were "Yes" except Item 6, "Are there any inconsistencies between all the proposed opinions and previous documents?" The research design of the included articles was complete, and the overall quality was high, which met the inclusion criteria. A total of 26 pieces of relevant evidence were obtained through the included studies, as shown in Table 3.

Selection of evidence suitable for clinical settings

The KTA model emphasizes the appropriate selection of evidence to suit specific clinical scenarios[8] and the adjustment of evidence with the input of stakeholders. In this study, 16 nurses and doctors from different departments (operating room, department of gynecology, and department of anesthesiology) with different academic qualifications and working years were selected as stakeholders by purposive sampling to select evidence suitable for clinical settings. Then, the stakeholders selected and adjusted evidence from the aspects of applicability, suitability, effectiveness and clinical significance. According to the opinions of the involved stakeholders, the applicability of heating humidification for oxygen inhalation was not considered feasible, so the evidence "to provide heated and humidified oxygen therapy for patients" was deleted (see Table 4 for the final included evidence).

Identification of gaps between evidence and clinical practice

To introduce evidence into clinical practice, this study evaluated the readiness of EBP. According to the evidence introduced into clinical practice, a total of 23 examination indicators were used as the evaluation criteria to investigate the current status of evidence application for PH prevention and management in gynecological patients in the pilot wards. The research subjects and examination methods are shown in Table 4. The review was jointly completed by the researcher and another member of the research team. Before the review, the examination contents and evaluation methods were further confirmed with the research team to ensure consistency. Except for indicators 1, 10, 12, 18, and 19, the implementation rate of other indicators was less than 50%, with the implementation rate of indicators 4 and 22 even being 0, suggesting the need to improve the completion of evidence implementation by medical staff. Therefore, this study investigated the awareness of relevant medical staff in the pilot wards on the prevention and management of PH in gynecological patients. A self-designed questionnaire was developed based on the evidence content to assess nurses' knowledge

level (20 items for hypothermia identification, assessment, prevention, treatment and health education domains, with 2.5 points for each item) and practice level (10 items for the aspects of attitude and awareness of the prevention and management of PH in gynecological patients, with 5 points for each item), with a total score of 100 points. A total of 49 nurses in the pilot wards were enrolled, and the inclusion criteria were as follows: (1) Working in the department for more than 2 years; and (2) Voluntary participation in this study. The awareness of nurses regarding PH prevention and management in gynecological patients was 60.96 ± 9.70 points, which was at the medium level.

Development of MDT-based EBP project

Based on the evidence content, the investigation results of the implementation of the examination indicators in the pilot wards and the awareness of the associated medical staff, as well as the "Promoting Action on Research Implementation in Health Services Integrated Framework (i-PARIHS)"[22], semistructured interviews were conducted among nurses from different wards with different seniority levels to identify barriers and facilitators for the implementation of the protocol. After the formulation of action strategies, the evidence-based team developed an EBP project for PH prevention and management in gynecological patients, compiled a manual of relevant surgical education and knowledge, developed a thermal comfort rating scale, and unified the comprehensive thermal insulation methods and procedures for gynecological surgery patients. After the formation of the scheme, the evidence-based team discussed the comprehensiveness and clinical feasibility of the scheme item by item with the hospital management team members and nine experts with extensive perioperative nursing experience in gynecology, and the program was unanimously recognized.

EBP program application and effect evaluation

Practice site: The EBP program of this study was conducted in the operating room and gynecology and anesthesiology departments of a grade III-A hospital in Sichuan Province, with a total of 49 nurses participating (see 1.5 for the inclusion criteria).

Implementation of the EBP project: The EBP project was implemented from August to October 2021. The KTA model notes that to promote changes in practice, effective action strategies should be developed according to the barriers to evidence application. This study drew on the i-PARIHS framework to analyze the barriers and facilitators in the application of evidence for the prevention and management of PH in gynecological patients in pilot wards, with the

Table 3 Contents of the best evidence

Stage	Evidence
Preoperative ward	To educate patients on thermal insulation and matters needing attention before surgery
	To measure and record the patient's axillary temperature before surgery
	To actively warm patients whose body temperature is below 36°C to 36°C and keep the patient warm during transfer
Preoperative preparation room	To assess the risk factors for hypothermia in patients
	To use a temperature monitoring equipment to measure and record the patient's body temperature before anesthesia induction
	To preheat 10-30 min before anesthesia induction
	To use carbon fiber heating wire to actively and continuously warm patients with body temperature below 36°C to above 36°C
	To maintain the operating room temperature no less than 24°C, and to lower the temperature only when active heating is established
Intraoperative operating room	To adopt an effective comprehensive thermal insulation strategy after anesthesia and maintain the axillary temperature at least 36.5°C
	To expose the surgical area and cover the rest for thermal insulation
	The infusion pipeline is continuously heated to 37°C if the intravenous infusion volume is more than 500ml.
	To heat the washing solution with a thermostatic chamber to 38-40°C
	To perform continuous intraoperative monitoring and recording every 15 min
	To evaluate intraoperative risk factors and hypothermia symptoms and signs
Postanesthesia care unit	To measure the body temperature and record it every 15 min. Passive insulation is adopted if there is no hypothermia. Monitoring site: armpit
	To adjust the PACU ambient temperature to 24°C
	To evaluate the patient's thermal comfort level
	To actively warm patients whose body temperature is below 36°C to above 36°C
	To heat the intravenous fluids
	To provide heated and humidified oxygen therapy for patients
	To transfer the patient out of PACU only when her body temperature is ≥ 36°C
24-hour postoperative gyneco-logical ward	To measure, monitor and record the body temperature every 4 h
	To cover to keep warm
	To educate family members thermal insulation methods: blankets, socks, clothes, raising the ambient temperature, hot water, *etc*.
	To continuously and actively warm patients below 36°C until they feel warm and comfortable, and to monitor and record every 30 min
	To evaluate the patient's thermal comfort level
	To pay close attention to patients' psychological changes, perceive their potential negative emotions such as anxiety and depression, and give timely relief and comfort
	To patiently answer any problems that may cause psychological distress to patients, and help them establish a positive attitude

PACU: Postanesthesia care unit.

results presented in Table 5. According to the barriers and the actual situation in the wards, the following action strategies were developed for the smooth implementation of the EBP project.

Effect evaluation: The research participants consisted of 16, 13, and 20 nurses from the gynecological operating room, anesthesiology department, and gynecology department, respectively, as well as 60 patients undergoing gynecological surgery (inclusion criteria: Age ≥ 18 years; operation time ≥ 2 h; good cognitive and responsive skills; voluntary participation in this study). The effect of the EBP project was evaluated by a controlled before-and-after trial among nurses and a nonconcurrent control trial among patients.

Table 4 Relationship between evidence, practice protocol related documentation and examination indicators

Stage	Evidence suitable for clinical scenarios	Practice protocol related documentation	Examination indicators	Examination objectives and methods
Preoperative ward	To educate patients on thermal insulation and matters needing attention before surgery	Manuals and videos of perioperative health education (patient edition)	The operating room has propaganda materials on hypothermia prevention and management	Department: Document consultation
			Checking the preoperative follow-up sheet of gynecological surgery patients	Medical staff: Document consultation and observation
	To measure and record the patient's axillary temperature before surgery	Surgical patient handover/transfer proforma	Checking the surgical patient handover/transfer proforma	Medical staff: Document consultation and observation
	To actively warm patients whose body temperature is below 36°C to 36°C and keep the patient warm during transfer	Hypothermia emergency procedures	The operating room has a hypothermia emergency process to ensure continuous heat preservation during patient transfer	Medical staff: Document consultation and observation
Preoperative operating room	To assess the risk factors for hypothermia in patients	Hypothermia risk factor evaluation sheet	The operating room has an evaluation sheet to evaluate the risk factors of hypothermia in patients	Operating Room: document consultation
	To use a temperature monitoring equipment to measure and record the patient's body temperature before anesthesia induction	Procedure for the use of temperature monitoring equipment	Before anesthesia induction, a temperature monitoring equipment is used for patients with operation duration of 2h or longer	Medical staff: Observation and document consultation
	To actively warm patients whose body temperature is below 36°C to above 36°C	Active heat preservation methods for hypothermia patients	Effective warming strategies are taken for hypothermia patients	Medical staff: Observation and document consultation
	To preheat 10-30 min before anesthesia induction	Pre-heat preservation methods	10-30 min of pre-heat preservation is performed on gynecological patients before anesthesia induction	Medical staff: Observation
	To maintain the operating room temperature no less than 24°C, and to lower the temperature only when active heating is established	-	The operating room ambient temperature is adjusted to 24°C and above before surgery	Medical staff: Observation
Intraoperative operating room	To adopt an effective comprehensive thermal insulation strategy after anesthesia and maintain the axillary temperature at least 36.5°C	Intraoperative comprehensive thermal insulation strategies (active and passive thermal insulation, blood transfusion and infusion warming, continuous dynamic monitoring of body temperature, *etc.*)	According to the probability of hypothermia in gynecological patients during operation, a corresponding comprehensive heat preservation strategy is selected to maintain the axillary temperature of the patient at least 36.5°C	Medical staff: Observation, document consultation
	To expose the surgical area and cover the rest for thermal insulation	-	The surgical area is exposed and the rest is covered for thermal insulation	Medical staff: Observation
	To warm the intravenous fluid or blood transfusion with a warming device to 37°C if the amount was ≥ 500 mL	Procedure for the use of infusion pipeline heating instrument	The infusion pipeline was warmed for those with a intravenous fluid or blood transfusion volume ≥ 500 mL	Medical staff: Observation
	To heat the intraoperative washing solution with a thermostatic chamber to 38-40°C	-	The washing solution is used at 38-40°C	Medical staff: Observation
	To continuously monitor and record the patient's body temperature once every 30 min intraoperatively, and to record it once every 15 min during recovery from anesthesia	-	The body temperature is continuously monitored and recorded on time intraoperatively	Medical staff: Observation, document consultation
	To evaluate hypothermia symptoms and signs during the operation	Evaluation methods of symptoms and signs of hypothermia in patients during operation	The patient is observed for symptoms and signs of hypothermia during the operation	Medical staff: Observation
PACU	To measure the body temperature and record it every 15 min. Passive	Active insulation methods and temperature handover record for	The patient's temperature is measured and the hypothermia patients are	Medical staff: Observation,

	thermal insulation is adopted for those without hypothermia, and active thermal insulation is taken to above 36°C for those below 36°C	hypothermia patients	warmed effectively, and the temperature handover record is established	document consultation
	To adjust the PACU ambient temperature to 24°C	-	The PACU temperature is adjusted to 24°C and above	Medical staff: Observation
	To send the patient back to the ward when the body temperature is not lower than 36°C	-	The patient is transferred out from the PACU only when the body temperature is ≥ 36°C	Medical staff: Observation, document consultation
24-hour postoperative gynecological ward	To monitor and record the patient's axillary temperature every 4 h	-	The patient's axillary temperature is measured and recorded every 4 h	Medical staff: Observation, document consultation
	To cover to keep warm	-	The patient is covered to keep warm	Medical staff: observation
	To teach the patient's family how to keep warm effectively	Health education handbook	The patient's family members' are informed of effective thermal insulation methods	Medical staff: Observation and questioning
	To continuously and actively warm patients below 36°C until they feel warm and comfortable, and to monitor and record every 30 min	Active heat preservation methods for hypothermia patients	The hypothermia patients are continuously and actively warmed, with their body temperatures monitored and recorded every 30 min	Medical staff: Observation, document consultation
	To evaluate the patient's thermal comfort level	Thermal comfort rating scale	The patient's thermal comfort level is assessed	Medical staff: Document consultation

PACU: Postanesthesia care unit.

Table 5 Barriers and action strategies for prevention and management of hypothermia in patients

Serial number	Obstacle	Action strategy
1	Nurses lack relevant knowledge and awareness of perioperative hypothermia management of gynecological patients	To hold special training to explain relevant knowledge to nurses with PPT combined with nursing knowledge handbook, and to explain various procedures and nursing norms through on-site demonstration and watching operation videos. To ensure that nurses in the operating room, anesthesiology department and gynecology department receive knowledge training on hypothermia prevention at least once every six months, and to assess them for knowledge and practice at least once a year after training
2	The contents of health education on the day before surgery vary greatly and lacks gynecological expertise	To formulate a preoperative education manual of gynecology specialty, and to push the preoperative education video for gynecological patients by WeChat official account
3	The lithotomy position is mostly commonly used posture in gynecological surgery, resulting in inadequate ankle and foot warmth. In addition, there is a lack of special thermal insulation equipment for the lithotomy position	To purchase lithotomy position-dedicated strip-shaped inflatable heating blankets, wrap the patient's legs with cotton pads, and use sterile leg covers to meet the warm-keeping requirements of patients undergoing surgery in the lithotomy position
4	There are communication barriers among multi-department nurses on the prevention and management of perioperative hypothermia in gynecological patients	To establish a perioperative hypothermia prevention and management group led by the head nurses who also play a key role in the practice reform, with operating room gynecological specialists, anesthesiology nurses, gynecological nurses as the team members and the head nurses of the three departments as the group leaders. To establish a WeChat exchange group to remind, supervise and control the quality in the preoperative ward, preoperative preparation room, intraoperative operating room and postoperative PACU. To listen to the feedback and suggestions of nurses and patients during field observation, and adjust and optimize the nursing process. The head nurse should report the practice changes to the evidence-based practice group every month, so as to discuss, analyze and solve the problems that arise
5	There is a lack of corresponding evaluation tools	To introduce the intraoperative hypothermia risk prediction model calculation software constructed by Professor Huang Yuguang to evaluate the hypothermia risk of patients, and to explain the checked contents. To self-develop a thermal comfort scale, and conduct unified training for medical staff

PACU: Postanesthesia care unit; PPT: Power point.

Outcome measures: (1) The implementation rate of examination indicators was as follows: The evidence suitable for clinical situations was converted into measurable and easy-to-assess quality examination indicators. If the examination indicators were correctly executed, they were marked with "√". Unimplemented or incorrectly implemented indicators were marked with "×". The percentage of correct implementations was calculated as the percentage of the number of correct implementations out of the total number of implementations; (2) The incidence of PH was evaluated as follows: The incidence of PH in 30 gynecological patients from April to June 2021 and another 30 gynecological patients from October 2021 to December 2021 was statistically analyzed; (3) The awareness level of nurses (gynecological operating room, anesthesiology department, and gynecology department) regarding PH prevention and management in gynecological patients was evaluated as follows: A self-designed questionnaire based on evidence content was used for assessment (see 1.5 for details); (4) The thermal comfort level of gynecological patients was investigated as follows: The operating room, PACU and gynecological ward patients were scored by the Visual Analog Scale. The scale has 10 items, with 10 points each and a full score of 30; (5) Psychological status was evaluated as follows: Patients' depression and anxiety were evaluated by the Hamilton Depression Scale (HAMD) and Hamilton Anxiety Scale (HAMA), respectively, whereby the HAMD score range was 0-68 and the HAMA score range was 0-56, both of which were directly proportional to depression and anxiety; and (6) Cognitive function was analyzed as follows: Patients' cognitive function was evaluated with the Montreal Cognitive Assessment Scale (MoCA; score range: 0-30). A score of 26 was considered normal, and a score less than 26 was indicative of cognitive function decline; in addition, the score was increased by 1 point if the patient's years of schooling was less than 12 years.

Data collection methods: Baseline review data were collected from April 2021 to June 2021, and data collection and analysis after program application were carried out from October 2021 to December 2021. A researcher followed up and observed the implementation of examination indicators and the occurrence of hypothermia on a daily and patient-by-patient basis and recorded it truthfully. (1) Document consultation: For indicators 1-7, 10, 14, 16, 18-19, and 22-23, the rules and regulations of the department, the relevant processes and the training records were checked; (2) Observation and questioning: For indicators 2-4 and 6-22, the "Checklist for Prevention and Management of Unplanned Hypothermia in Gynecological Surgery Patients" was formulated, and the nurses' implementation of the best evidence was evaluated through data analysis after clinical implementation; and (3) Questionnaire survey method: Based on the implementation of the examination indicators, a questionnaire on nurses' knowledge and practice was designed and prepared and distributed by the head nurse to the nurses to complete.

Statistical methods: SPSS 20.0 statistical software and Excel software were used for data entry and analysis. The quantitative data that conformed to a normal distribution are described by means ± standard deviations, and between-group comparisons were made by the *t* test; count data are described as frequencies and percentages, and chi-square tests were performed to identify differences between groups. All analyses relied upon a $P < 0.05$ statistical significance criterion.

RESULTS

General information

A total of 49 nurses (16, 13, and 20 nurses in the gynecological operating room, anesthesiology department, and gynecology department, respectively), including 44 females and 5 males aged 22-50 (32.1 ± 5.9) years, were investigated before and after the application of this scheme. Most of the nurses had bachelor's degrees (87.76%) and professional titles (67.35%). Thirty patients each were included before and after evidence application, and no significant intergroup differences were identified in terms of age, sex, length of hospital stay, education level, occupation, payment method of medical expenses, or operation duration ($P > 0.05$).

Incidence of hypothermia

The incidence of hypothermia among gynecological perioperative patients decreased from 43.33% to 13.33% after the application of the scheme, with statistical significance ($\chi^2 = 12.381$, $P < 0.001$).

Implementation rate of examination indicators

After the application of evidence, the implementation rate of examination indicators 6-10, 12, 14, 16-18, and 21-22 reached 100%; in addition to indicators 5 and 13 with an implementation rate of 66.67%, the implementation rate of other indicators was 90% or above. Except for indicators 10, 12, and 18, whose implementation rate had been 100% before evidence application, all the other indicators were significantly improved after evidence application ($P < 0.05$) (Table 6).

Nurses' awareness of PH prevention and management in gynecological patients

After the application of the EBP project, the nurses' awareness of PH prevention and management in gynecological patients increased from 60.96 ± 9.70 to 88.08 ± 8.96, with a statistically significant difference ($t = -29.866$, $P < 0.001$).

Perioperative thermal comfort level of patients undergoing gynecological surgery

The total score of the perioperative thermal comfort level of gynecological surgery patients was 27.97 ± 2.04 after the application of the EBP project, which was statistically significant compared with the score of 21.27 ± 1.57 established by

Table 6 Comparison of nurses' implementation of examination indicators before and after application of the evidence-based program

Examination indicators	Before evidence application (n = 30)			After evidence application (n = 30)			X^2	P value
	Implemented	Unimplemented	Implementation rate (%)	Implemented	Unimplemented	Implementation rate (%)		
Indicator 1	16	14	53.33	28	2	93.33	12.273	< 0.001

researchers before the intervention (t = 13.693, P < 0.001).

Perioperative psychological status of patients undergoing gynecological surgery

The total score of the perioperative HAMD of gynecological surgery patients was 4.30 ± 1.15 after the application of the EBP project, which was statistically significant compared with the score of 15.03 ± 3.16 established by researchers before the intervention (t = 17.500, P < 0.001); the total HAMA score decreased from 13.93 ± 2.64 before the intervention to 3.53 ± 0.78 after the intervention, with statistical significance (t = 20.713, P < 0.001).

Perioperative cognitive function of patients undergoing gynecological surgery

The total MoCA score among gynecological surgery patients was 26.93 ± 1.11 after the application of the EBP project, which was statistically significant compared with the score of 23.17 ± 1.68 established by researchers before the

intervention (t = 10.226, P < 0.001).

DISCUSSION

The EBP project based on an MDT was scientific and feasible

A top-down literature search according to the "6S" retrieval model was conducted in this study, as well as rigorous study screening and quality evaluation. The quality evaluation results of the included documents were all high, which ensured the reliability of the evidence sources. To make the summarized evidence of MDT nursing of gynecological patients at different stages of the perioperative period feasible, appropriate, effective and clinically significant, this study followed the FAME principle and invited relevant stakeholders (clinical practitioners) from gynecology, anesthesiology and the operating room to participate in the evidence selection process, which enhanced the clinical practitioners' recognition of the evidence[23]. In addition, relevant experts were invited for consultation, and the clinical experience of clinical decision-makers, managers and practitioners was combined with the clinical evidence application sites, such as the operating room, gynecology and anesthesiology, so that the examination indicators were practical in clinical work. Moreover, based on continuous quality improvement advocated by the KT model and drawing on the i-PARIHS framework (which takes into account all issues that need to be considered, evaluated and planned in the process of evidence application and has been effectively applied in clinical practice as a theoretical framework to guide quality improvement and for the identification of prestudy barrier factors and facilitating factors[22]), this study analyzed the barriers and facilitators in the application of evidence related to the prevention and management of PH in gynecological patients in pilot wards. After determining the major barriers, action strategies were drawn up, and evidence-based intervention programs were formed. The whole process is standardized and scientific, which makes the EBP project scientific and feasible.

The MDT-based EBP project improved the implementation rate of examination indicators and enhanced nurses' awareness of hypothermia prevention and management

Based on the KT model, this EBP project transformed the evidence into clinical practice, formulated an intervention plan for PH prevention and management suitable for local gynecological surgery patients, and filled the relevant vacancies in the pilot operating room. Through the analysis of barriers, tailored action strategies were formed, contributing to the increase in the scores of ward nurses, operating room nurses and anesthesia nurses on PH prevention and management in gynecological patients from 60.96 ± 9.70 to 88.08 ± 8.96 and the increase in the examination indicator implementation rate from 0-100% to 66.67-100%, which was significantly improved compared with the values before evidence application (P < 0.05). This suggests that the EBP project enhanced the awareness of hypothermia prevention and management among nursing staff, especially gynecological nurses, and that most of the evidence was well applied in clinical practice. This may be related to the construction of practice plans, the implementation of action strategies and quality supervision, which clarified the job responsibilities and standardized the behavior of nurses, thus promoting changes in clinical practice, consistent with the results of a number of studies[24,25].

The EBP project based on an MDT reduced the incidence of PH in gynecological patients

The necessity and importance of the prevention and management of PH in surgical patients, an important part of operating room care, have been emphasized in the guidelines[13,14] when selecting the best evidence in this study. After the implementation of this EBP project, the incidence of PH in gynecological patients in the pilot wards decreased from 43.33% to 13.33%, and the score of perioperative thermal comfort level increased from 21.27 ± 1.57 to 27.97 ± 2.04, with statistical significance. It is suggested that the EBP project can effectively reduce the incidence of PH in gynecological patients and improve their thermal comfort level, similar to the findings of Xiao *et al*[26]. This may be related to the fact that this EBP project takes evidence-based evidence as the theoretical basis, implements patient-centered and multidisciplinary cooperation, and focuses on temperature management of gynecological patients throughout the perioperative period, including gynecology, operating room and PACU. The specific measures include giving health education about body temperature to patients and their families before and after surgery in gynecological wards; conducting preoperative hypothermia risk assessment and preinsulation in the operating room; using a lithotomy position-dedicated inflatable heating blanket during the operation according to the characteristics of commonly used lithotomy positions for gynecological patients, which can effectively cover the whole body of the patient with a better heating effect compared with the whole-body inflatable heating blanket in the supine position[27]; implementing comprehensive warm-keeping measures such as intravenous infusion and transfusion heating, lavage fluid heating and continuous body temperature monitoring; emphasizing continuous body temperature monitoring and passive thermal insulation when patients are in the PACU; performing temperature monitoring and active thermal insulation measures of abnormal hypothermia in the gynecological ward 24 h after surgery; and paying attention to the patient's thermal comfort level during the whole perioperative period. However, due to the short application time of evidence in this study and the small number of patients included, the effectiveness of this protocol needs validation through continuous application.

The EBP project based on an MDT improved the psychological status and cognitive function of gynecological patients during the perioperative period

In this study, the psychological status of gynecological patients during the perioperative period was evaluated by the HAMD and HAMA, and cognitive function was assessed by the MoCA. Before the implementation of the MDT-based

EBP project, gynecological perioperative patients suffered from varying degrees of negative emotions and cognitive impairment. Negative emotions such as anxiety and depression were significantly alleviated after the implementation of the MDT-based EBP project, and cognitive function was also significantly improved, mainly manifested in the significant reduction in HAMD and HAMA scores and the significant increase in MoCA scores. The above results suggest that the EBP project based on MDTs can effectively improve the psychological status and cognitive function of gynecological patients during the perioperative period. This may be attributed to the identification of potential psychological distress in perioperative gynecological patients and psychological interventions in the MDT-based EBP project. In addition to hypothermia prevention and thermal comfort intervention in the wards 24 h after surgery, the relevant members of the evidence-based team were also required to pay close attention to the psychological changes of patients and provide timely relief and comfort to minimize their negative emotions. At the same time, it is also necessary to give careful attention and patient answers to problems that may cause psychological distress to patients, which helps patients establish a positive psychological attitude and improve their compliance with relevant EBP steps. In the study of Meng *et al*[28], the application of an EBP project based on MDT to postpartum anxiety and depression also significantly reduced adverse mood and improved patients' nursing satisfaction, which supports our findings. Another study pointed out that the EBP project based on MDT can assist patients undergoing gynecological laparoscopic surgery with propofol and fentanyl to improve their mental health, similar to our research results[29]. Dai *et al*[30] also reported that evidence-based nursing interventions based on MDTs are beneficial for improving the cognitive function of patients in intensive care units, which is mainly reflected in significantly increased Mini-Mental State Examination scores and a reduced incidence of delirium after intervention, which is consistent with our research results. In this study, the improvement in cognitive function in gynecological perioperative patients by the MDT-based EBP project may be related to its effective reduction in the incidence of hypothermia.

MDTs facilitate the effective management of PH in gynecological patients

Munday *et al*[7] reported that intervention strategies based on the MDT model can maximize the effect of PH prevention and management. Drawing on the i-PARIHS framework, this study found that communication was blocked in the prevention and management of PH in gynecological patients among nurses from different departments. At present, there is a fault segmentation in the temperature management of patients in the operating room, gynecological ward and PACU, and patient transport and handover are neglected. To solve this obstacle, the EBP project established a multidisciplinary collaboration team led by nurses, clarified the division of team roles, detailed the professional responsibilities of the preoperative ward, preoperative preparation room, intraoperative operating room, postoperative PACU, and postoperative 24-hour gynecological ward in the prevention and management of hypothermia throughout the perioperative period of gynecological patients, and set up a WeChat communication group to ensure smooth and timely response of information among disciplines, thus promoting communication and cooperation among multiple disciplines, which was consistent with the research results of Shi *et al*[31]. In addition, the body temperature supervision mechanism and the overall quality control process led by the head nurses of the operating room, gynecology and anesthesiology departments were improved. Furthermore, the head nurses reported the practice changes to the evidence-based team monthly to allow for time identification of barriers and facilitators. Moreover, the evidence-based team conducted a quality inspection every quarter to solve problems such as nurses' inadequate assessment of hypothermia risk factors, insufficient supply of 38-40 °C irrigation solution during operations, and inadequate adjustment of ambient temperature to ensure reasonable, feasible and perfect implementation of all aspects and further promote the effective management of PH in gynecological patients. MDTs can integrate medical resources and lead patients to better rehabilitation outcomes [32].

The MDT-based EBP project needs further continuous improvement

The KTA model emphasizes the continuous use and consolidation of knowledge[8], that is, continuous quality improvement of the project after implementation and evaluation. The commonly used quality improvement models are PDCA circulation and quality control circles, which have been widely applied in medical and nursing fields and have achieved remarkable results in advocating medical and nursing quality improvement. In this study, the implementation rate of intraoperative temperature monitoring equipment use and intraoperative temperature monitoring every 15 min in gynecological surgery patients was 66.67% after the application of the EBP project, indicating the poor implementation of intraoperative body temperature monitoring and the need for further improvement. This is related to the use of wireless temperature monitoring equipment in the pilot operating room. This device can realize continuous monitoring of core temperature every minute, but there are some problems, such as a high cost of use, discontinuous temperature monitoring due to a weak Bluetooth signal during operations, and equipment failure, which makes some patients refuse to use temperature monitoring equipment, resulting in loss of temperature monitoring values. Patients who refuse to use wireless temperature monitoring equipment have to be monitored manually by visiting nurses every 15 min, which increases the nurses' workload and leads to the low implementation rate of nurses' norms. On the other hand, in this EBP project, although body temperature management of patients in the PACU was strengthened, there was a lack of thermal insulation equipment for patients with hypothermia. Studies have shown that using the modified inflatable thermal insulation quilt for patients with mild hypothermia has the same warming effect as the inflatable heating blanket, which can not only reduce costs but also be suitable for rewarming PACU patients with hypothermia. Therefore, the common quality improvement model can be combined in the future to further optimize PH prevention and management in gynecological patients.

CONCLUSION

This study focused on the high incidence of PH in gynecology. Guided by KT drawing on the best evidence and i-PARIHS framework and combined with the wishes of stakeholders and expert opinions, an EBP project based on an MDT was formulated and implemented, which effectively promoted the application of evidence, strengthened multidisciplinary cooperation, standardized the prevention and management of PH in gynecology, improved nurses' awareness, and effectively enhanced nursing quality. For gynecological patients during the perioperative period, this project lowered the incidence of PH and improved their thermal comfort level, psychological status and cognitive function. However, the implementation effect of some examination indicators was still not satisfactory, and relevant procedures and systems need further optimization. In the future, how to standardize the monitoring of patients' continuous body temperature during surgery needs further discussion.

ARTICLE HIGHLIGHTS

Research background

Perioperative hypothermia (PH) has varying degrees of negative effects on the physical and mental health of patients, and there is no effective multidisciplinary team (MDT) intervention for PH in gynecological patients.

Research motivation

Despite the comprehensiveness and maturity of the practice guidelines and evidence summaries on PH prevention and management in foreign countries, there is a lack of effective clinical practice for PH in gynecological patients in China, so it is necessary to conduct this analysis to fill in this gap.

Research objectives

To apply the best evidence on the prevention and management of PH in gynecological patients, to improve the quality of perioperative evidence-based care based on MDT treatment of gynecological patients, and to analyze the effect of MDT-based evidence-based practice (EBP) project on the psychological status and cognitive function of gynecological patients with PH.

Research methods

Under the guidance of knowledge translation and combined with the opinions of stakeholders involved and clinical experts, the best evidence for PH prevention and management in gynecological patients was selected and adjusted to suit the practice setting. Based on the evidence, the practice plan was developed, and the MDT intervention was carried out in the preoperative ward, the preoperative preparation room, the intraoperative operating room, the postanesthesia care unit, and the 24-hour postoperative gynecological ward through the EBP program. The incidence of hypothermia, the nurses' awareness, the implementation rate of examination indicators, and the thermal comfort level, psychological status and cognitive function of patients were compared before and after the program application.

Research results

The incidence of PH in gynecological patients decreased from 43.33% to 13.33% after the application of the scheme. The implementation rate of examination indicators 6-10, 12, 14, 16-18, 21, and 22 reached 100%, and that of other indicators was above 90% except for examination indicators 5 and 13, which was 66.67%; the indexes were significantly improved compared with the baseline (before evidence application), with statistically significance ($P < 0.05$). The score of nurses' awareness of PH prevention and management in gynecological patients increased from (60.96 ± 9.70) to (88.08 ± 8.96), and the difference was statistically significant ($P < 0.001$). The total score of perioperative thermal comfort level of patients undergoing gynecological surgery was (27.97 ± 2.04), which was statistically increased compared with the score of (21.27 ± 1.57) investigated by researchers at baseline ($P < 0.001$). The perioperative Hamilton Anxiety Scale and Hamilton Depression Scale scores of patients undergoing gynecological surgery decreased from (15.03 ± 3.16) and (13.93 ± 2.64) to (4.30 ± 1.15) and (3.53 ± 0.78), respectively, with statistically significant differences ($P < 0.001$). The perioperative Montreal Cognitive Assessment Scale score of the gynecological surgery patients increased from (23.17 ± 1.68) to (26.93 ± 1.11), also with statistical significance.

Research conclusions

MDT-based EBP of PH prevention and management in gynecological patients during the perioperative period can standardize nursing operations, improve nurses' awareness and behavioral compliance with gynecological hypothermia management, and reduce the occurrence of PH in gynecological patients, while playing a positive role in reducing patients' negative emotions and enhancing their cognitive function.

Research perspectives

MDT-based EBP has certain effectiveness in perioperative PH prevention and management of gynecological patients and can improve patients' psychological state and cognitive function. However, it is still necessary to solve the problem that the accuracy rate of intraoperative temperature monitoring is less than 80%.

Abstract

BACKGROUND

There are many drawbacks to the traditional midwifery service management model, which can no longer meet the needs of the new era. The Internet + continuous midwifery service management model extends maternal management from prenatal to postpartum, in-hospital to out-of-hospital, and offline to online, thereby improving maternal and infant outcomes. Applying the Internet + continuous midwifery service management model to manage women with high-risk pregnancies (HRP) can improve their psycho-emotional opinion and, in turn, minimize the risk of adverse maternal and/or fetal outcomes.

AIM

To explore the effectiveness of a midwife-led Internet + continuous midwifery service model for women with HRP.

METHODS

We retrospectively analyzed the clinical data of 439 women with HRP who underwent prenatal examination and delivered at Shanghai Sixth People's Hospital (affiliated to the Shanghai Jiao Tong University School of Medicine) from April to December 2022. Among them, 239 pregnant women underwent routine obstetric management, and 200 pregnant women underwent Internet + continuous midwifery service mode management. We used the State-Trait Anxiety Inventory, Edinburgh Postnatal Depression Scale, and analysis of delivery outcomes to compare psychological mood and the incidence of adverse delivery outcomes between the two groups.

RESULTS

The data showed that in early pregnancy, the anxiety and depression levels of the two groups were similar; the levels gradually decreased as pregnancy progressed, and the decrease in the continuous group was more significant [31.00 (29.00, 34.00) *vs* 34.00 (32.00, 37.00), 8.00 (6.00, 9.00) *vs* 12.00 (10.00, 13.00), $P < 0.05$]. The maternal self-efficacy level and strategy for weight gain management were better in the continuous group than in the traditional group, and the effective rate of midwifery service intervention in the continuous group was significantly higher than in the control group [267.50 (242.25, 284.75) *vs* 256.00 (233.00, 278.00), 74.00 (69.00, 78.00) *vs* 71.00 (63.00, 78.00), $P < 0.05$]. The incidence of adverse delivery outcomes in pregnant women and newborns and fear of maternal childbirth were lower in the continuous group than in the traditional group, and nursing satisfaction was higher [10.50% *vs* 18.83%, 8.50% *vs* 15.90%, 24.00% *vs* 42.68%, 89.50% *vs* 76.15%, $P < 0.05$].

CONCLUSION

The Internet + continuous midwifery service model promotes innovation through integration and is of great significance for improving and promoting maternal and child health in HRP.

Key Words: Internet + continuous midwifery service; High-risk-pregnancy management; Psychological mood; Pregnancy outcome; Traditional midwifery service model; Midwife

Core Tip: The Internet + continuous midwifery service model promotes innovation through integration, breaks the limitations of time and space in the traditional midwifery service supply mode, and enables pregnant women to enjoy high-quality nursing services at home. However, it is necessary to determine the feasibility and effectiveness of the midwife-led Internet + continuous midwifery service model, especially in women with high-risk pregnancies (HRP). By retrospectively analyzing the clinical data of 439 women with HRP, we clarified the positive effect of the midwife-led Internet + continuous midwifery service model on the psychological mood and pregnancy outcomes of women with HRP.

INTRODUCTION

High-risk pregnancies (HRP) are those with a high probability of dystocia, endangering the safety of the parturient and child. Data show that women with HRP in foreign countries account for 6% to 33% of all pregnant women[1], while the incidence of HRP in China is as high as 30%, which means that nearly one-third of pregnant women face adverse pregnancy outcomes such as dystocia, intrauterine death, postpartum hemorrhage, and puerperal infection. The National Institute for Health and Care Excellence (NICE) guidelines[2] indicate that effective communication, timely care, and treatment in early pregnancy, as well as professional care during and after delivery, can minimize the risk of adverse maternal and/or fetal outcomes.

In recent years, after a long period of practical exploration and theoretical research, domestic experts have achieved fruitful results in Internet + continuous midwifery service models. This service model overcomes the limitations of time and space of midwifery services, combines the advantages of the Internet, and gives full play to the subjective initiative of midwifery personnel. It can fully grasp the dynamic changes in parturients and newborns before, during, and after delivery and realize the long-term, continuous, and real-time management of pregnant and lying-in women by combining online and offline methods[3,4]. A systematic review pointed out that this nursing model enables pregnant women and midwives to establish partnerships during the prenatal, childbirth, and postpartum stages. Compared to other nursing models, it can reduce the necessity for maternal and infant treatment interventions[5]. Due to the gradual implementation of the Internet + continuous midwifery service model in maternal healthcare, a number of women with HRP were helped by the Internet + continuous midwifery service model between 2021 and 2022. However, it is necessary to determine the feasibility and effectiveness of the midwife-led Internet + continuous midwifery service model, especially the psychological emotions and pregnancy outcomes of women with HRP. This study retrospectively analyzed the role of the Internet + continuous midwifery service model for women with HRP.

MATERIALS AND METHODS

Patient characteristics

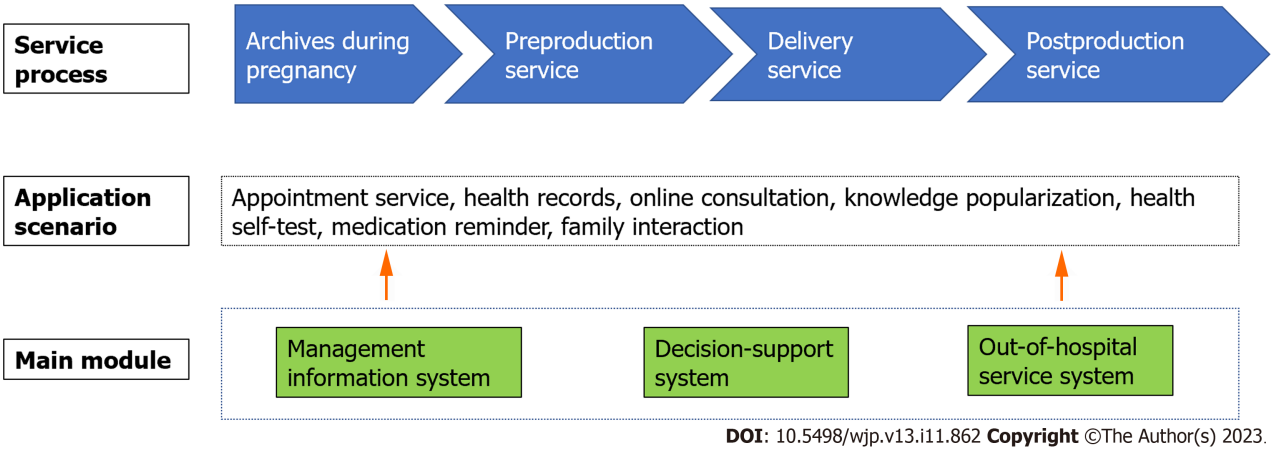
First, this was a retrospective study. Clinical data of 439 women with HRP, who underwent prenatal examination and delivered at Shanghai Sixth People's Hospital affiliated to the Shanghai Jiao Tong University School of Medicine from April 2022 to December 2022, were analyzed. According to the different midwifery service modes, participants were divided into a traditional group (TG, n = 239) and a continuous group (CG, n = 200). Inclusion criteria: (1) Age ≥ 18 years; (2) women with HRP with pregnancy risk assessment grade of "orange," "red," or "purple" in the "Maternal Pregnancy Risk Assessment and Management Standards" issued by the National Health and Family Planning Commission of the People's Republic of China; (3) women with HRP who can skillfully use an Internet smartphone; and (4) women with HRP who signed informed consent forms. Women with HRP with mental illness, who could not communicate, or lacked research data were excluded.

TG

The TG adopted a routine obstetric management mode; that is, the prenatal and postpartum stages were mainly managed by doctors, and midwives participated in the entire process of maternal production. During the prenatal checkup phase, obstetricians perform routine examinations and provide health education to pregnant women. In the waiting room, midwives provide prenatal care to pregnant women experiencing pain. In the delivery room, midwives assist parturients with delivery, perform lateral incisions, correctly assess fetal conditions, and provide basic care. An obstetric nurse is responsible for nursing management in the postpartum stage, such as health education, diet guidance, and puerperal care. On the day of discharge, the obstetric nurse provides health education to the parturient and instructs her to attend the obstetric clinic for review and health guidance 42 d after delivery.

CG

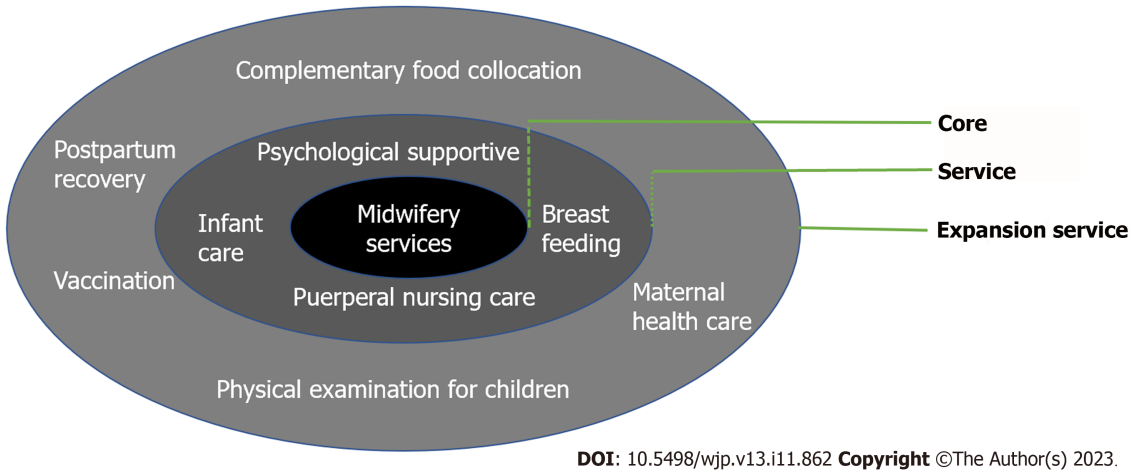
The CG implemented an Internet + continuous midwifery service model based on a traditional group, which was completed in three steps.



Step 1: Conduct expert meetings and establish a continuous midwifery service management team. Experts in related fields set up an expert group to put forward opinions and suggestions on the process and connotations of the Internet + continuous midwifery service mode. We have revised and improved these details. The continuous midwifery service management team comprised eight midwifery specialist nurses, three maternal and infant specialist nurses, and two neonatal specialist nurses. The head nurse of the department served as the group leader and was responsible for providing suggestions and opinions on the processes and connotations of continuous midwifery services. As the deputy leader, the head nurse was responsible for leading the team members to construct the initial implementation plan and organizing the members to carry out relevant training and assessment. In addition to participating in the above work, the remaining team members needed to implement Internet + continuous midwifery services for pregnant women.

Step 2: Establish an HRP Maternal Internet Communication Platform. During the recruitment of pregnant women participants, midwives invited them to join an Internet communication WeChat group and introduced WeChat group functions such as viewing popular science articles, downloading educational videos at different stages, and making group videos or voice calls. At the same time, team members were responsible for the implementation of WeChat group online interactions, irregularly and dynamically carrying out relevant health knowledge education for pregnant women and their families, and encouraging pregnant women to share their experiences and exchange experiences to indirectly alleviate maternal fear, anxiety, and other adverse psychological emotions. In addition, the midwives used videoconferencing software to regularly conduct pregnancy care courses and answer questions online. At the same time, the questionnaire star is used to collect relevant data.

Step 3: Carrying out Internet and continuous midwifery services. The midwife-led Internet + continuous midwifery service is divided into three periods: Prenatal stage [(1) first trimester < 14 wk; (2) 14-28 wk in the second trimester; and (3) > 28 wk in the third trimester), delivery stage (labor to 2 h after delivery), postpartum stage (4-6 wk after delivery)]. The specific process is shown in Figures 1 and 2.



Prenatal stages: Midwives used pregnancy anxiety, fear of childbirth, delivery efficiency, and weight management scales to evaluate the relevant situations of pregnant women. Based on the results of the nutritional analysis and the situation of the pregnant women, a personalized pregnancy management plan was initially formulated. The WeChat group regularly introduced knowledge related to pregnancy care, childbirth, and child-rearing every week through video teaching, text, pictures, and small videos. At this stage, midwives regularly used online video conference calls to communicate with pregnant women one-on-one to understand their needs and conditions. In the third trimester of pregnancy, midwives provided maternal health education related to the delivery stage, including delivery methods, processes, and techniques, and played introductory online videos of maternity wards and delivery rooms to familiarize them with the environment and relieve anxiety.

Delivery stage: During the period from labor to two hours after delivery of the placenta, the team leader selected team members to be responsible for midwifery according to the individual situation of the parturient and provided corresponding nursing services. This included the assessment of maternal and infant conditions, regular monitoring of maternal and fetal conditions, all basic care during labor and delivery, preliminary examination of newborns after delivery, breastfeeding, treatment of the placenta, perineal incision or wound suture, and registration of neonatal birth.

Figure 2 Extension of out-of-hospital midwifery services.

Postpartum stage: Midwives provided postpartum health education for parturients and their families, including wound treatment, postpartum exercise nursing, neonatal feeding knowledge, and nursing. Midwives regularly communicated with parturients on WeChat every week to provide advice on puerperal care, breastfeeding, and maternal and child nutrition.

Effect evaluation

Main outcome measures: (1) Psychological Mood. The State-Trait Anxiety Inventory (STAI)[6] was used to evaluate anxiety. It included a total of 20 items, with a score of 1-4 and a total score of 20-80 points. The higher the score, the more serious the anxiety. The Edinburgh Postnatal Depression Scale (EPDS)[7,8] was used for the psychological assessment of depression, with a total of 10 items, a score of 0-3, and a total score of 0-30. Higher scores indicate more severe depression; and (2) Adverse delivery outcomes. The delivery outcomes of pregnant women and newborns were recorded, including postpartum hemorrhage, postpartum infection, premature rupture of membranes, neonatal asphyxia, fetal distress, fetal weight abnormalities, and premature delivery.

Secondary outcome: (1) Self-efficacy. A simplified Chinese version of the Childbirth Self-Efficacy Scale (CBSEI-C32)[9] was used for the measurements. The total score ranges from 32 to 320 points. Higher scores indicate higher delivery self-efficacy; (2) Childbirth Attitudes Questionnaire (CAQ)[10] was used to assess the fear of childbirth for women in late pregnancy. The total score was 16-64 points, with < 28 points indicating no fear of childbirth, 28-39 points indicating mild fear, 40-51 points indicating moderate fear, and 52-64 points indicating high fear; (3) Weight management. Pregnancy Weight Management Strategy Scale (PWMSS)[11] consists of 18 items, a 1-5 grade score, and a total score of 18-90 points. The higher the score, the more weight gain management strategies were used during pregnancy; and (4) Maternal nursing satisfaction was assessed using a self-administered nursing satisfaction questionnaire.

Statistical analysis

All data were analyzed using SPSS 24.0. Enumeration data were expressed as frequencies and constituent ratios, and

Table 1 Clinical information of women with high-risk pregnancies

Variables	TG (*n* = 239)	CG (*n* = 200)	χ^2/*Z* value	*P* value
Age (yr), IQR	29.00 (27.00, 32.00)	30.00 (26.25, 33.00)	-1.591	0.112
Types of pregnant women, *n* (%)			2.196	0.138
Primipara	49 (20.50)	53 (26.50)		
Pluripara	190 (79.50)	147 (73.50)		
Educational level, *n* (%)			0.415	0.813
Junior high school and below	40 (16.70)	37 (18.50)		
High school or technical secondary school	124 (51.80)	98 (49.00)		
Junior college and above	75 (31.30)	65 (32.50)		
HRP factor, *n* (%)				
Pregnancy complication	87 (36.40)	68 (34.00)	0.275	0.600
Abnormal body mass index	54 (22.50)	33 (16.50)	2.545	0.111
Scarred uterus	41 (17.10)	37 (18.50)	0.135	0.713
Adverse pregnancy	40 (16.70)	31 (15.50)	0.123	0.726
Arrhythmia	39 (16.30)	25 (12.50)	1.275	0.259

Pregnancy complications refer to pregnancy with anemia, diabetes, hypertension, *etc*.; Abnormal body mass index (BMI) refers to a BMI > 25 kg/m^2 or < 18.5 kg/m^2; The same women with high-risk pregnancies can experience two or more risk factors. HRP: High-risk pregnancies; IQR: Interquartile range; TG: Traditional group; CG: Continuous group.

measurement data with a non-normal distribution were expressed as interquartile ranges. Enumeration data were analyzed by χ^2 test, and measurement data were analyzed by a nonparametric Mann-Whitney *U* test. Repeated-measures analysis of variance was used to analyze the results of multiple measurements. The rank-sum test was used for the grade data. $P < 0.05$ was considered as statistically significant.

RESULTS

Clinical characteristics

There was no statistical difference in the general clinical data between the two groups ($P > 0.05$) (Table 1).

Psychological and emotional changes in women with HRP

In the first trimester, the anxiety and depression levels of the two groups were similar and decreased gradually as pregnancy progressed; the CG decreased more significantly ($P < 0.05$) (Table 2).

Self-efficacy changes of women with HRP

There was no statistically significant difference between the two groups in the CBSEI-C32 scores in the first trimester ($P > 0.05$). The CBSEI-C32 scores increased as pregnancy progressed ($P < 0.05$), and the extent of the increase in the CG was greater than that in the TG ($P < 0.05$) (Table 3).

The fear of childbirth in women with HRP in the third trimester of pregnancy

Overall, the effectiveness rate of midwifery interventions in the CG was significantly higher than that in the TG, and the degree of maternal fear of childbirth was lower; the difference was statistically significant ($Z = -4.190$, $P < 0.05$) (Figure 3).

Weight management during pregnancy for women with HRP

In early pregnancy, there was no significant difference in PWMSS scores between the two groups ($P > 0.05$). The PWMSS score increased with an increase of pregnancy ($P < 0.05$). The PWMSS scores of the CG were better than those of the TG ($P < 0.05$) (Table 4).

Adverse birth outcome

In the TG, the incidence of adverse birth outcomes was 18.83% (45/239), and the incidence of adverse neonatal outcomes was 15.90% (38/239). In the CG, the incidence of adverse birth outcomes was 10.50% (21/200), and the incidence of adverse neonatal outcomes was 8.50% (17/200). The CG level was lower than the TG level (all $P < 0.05$) (Table 5).

Nursing satisfaction

In the CG, nursing satisfaction was 89.50%, which was significantly higher than 76.15% in the TG ($P < 0.05$) (Table 6).

DISCUSSION

The World Health Organization has reported that 50% of maternal deaths and more than 60% of neonatal deaths are caused by poor quality of care. Midwives who have received international standard education can provide women with planned pregnancy guidance and 87% of parturients and child basic care needs, while also avoiding more than 80% of maternal deaths, stillbirths, and neonatal deaths[12]. Among these, the quality of nursing before and after delivery and during puerperium is the focus of promoting maternal health. Prenatal monitoring and postpartum rehabilitation nursing are difficult to perform. It is difficult to fully understand the situation of parturients and newborns by simply relying on community home visits. To meet the nursing needs of women with HRP and compensate for the shortcomings of traditional maternal care services, the Internet + continuous midwifery service model, led by hospital midwives and combined with the advantages of the Internet, provides care to women with HRP and improves adverse pregnancy outcomes.

Regarding the prevalence of anxiety and depression in women with HRP, Dagklis *et al*[13,14] studied the incidence of depression in two HRP inpatient maternal samples (24.3% and 28%, respectively). Goetz *et al*[15] reported significant results. We found a similar trend in this study when compared to recently published inpatient samples. Women with HRP had significantly higher levels of anxiety and depression during early pregnancy. After the intervention of the Internet + continuous midwifery services, the levels of anxiety and depression gradually decreased as pregnancy progressed. As far as we know, the anxiety and depression of women with HRP are caused by many factors. On the one hand, the fear, worry, and pressure of coronavirus disease 2019 may endanger their own and fetal life and health; on the other hand, women with HRP are constrained by time and transportation problems and are unable to perform pregnancy tests on time, thus creating anxiety[16]. From the perspective of the space in which pregnant women receive midwifery services, traditional midwifery services are limited to the management process of pregnant women in hospital, unable to effectively supervise and guide pregnant women outside hospital and predict in advance the risk signals that may trigger HRP or produce adverse pregnancy outcomes. In the Internet + continuous midwifery service dominated by midwives, relying on the WeChat communication group, midwives can provide long-term, continuous, and real-time health counseling for pregnant women, management of normal pregnancy, delivery and puerperium, neonatal care, follow-up postpartum rehabilitation, women's health care, children's physical examinations, and vaccinations[17,18]. In long-term communication, midwives and pregnant women form a stable nurse-patient relationship, reduce the psychological

burden on pregnant women, and alleviate anxiety and depression[19]. Self-efficacy refers to the belief that an individual can perform certain behavioral operations. It plays an important role in controlling or adjusting individual behavior and is related to psychological emotions[20]. Studies have found that the main cause of maternal anxiety is uncertainty in the delivery process and that good self-efficacy can reduce anxiety[21]. The above shows that Internet + continuous midwifery services can effectively improve the psychological mood of women with HRP and improve their self-efficacy.

The self-management ability of pregnant women plays an indispensable role in weight control during pregnancy, especially in compliance and daily life behaviors of pregnant women. Internet + continuous midwifery service completes the monitoring of health indicators independently by adopting online and offline methods, enhancing the sense of self-control of perinatal health care, promoting the formation of good self-management consciousness in pregnant women, and promoting the transformation of health behavior[22]. Ge *et al*[11] found that the self-efficacy of pregnant women can affect their weight management behaviors. Pregnant women can have a high degree of self-evaluation after realizing that they can manage their pregnancy weight well, which promotes weight management behaviors.

Due to the separate nature of previous midwifery services, contact between midwives and pregnant women was limited by time and space, resulting in problems such as a lack of knowledge and fear of childbirth. In CG, mobile Internet technology can effectively meet the diverse needs of pregnant women during pregnancy[23]. Midwives encouraged their families to participate in the learning of knowledge during pregnancy, delivery, and postpartum, and understand the psychological and physiological changes of pregnant women. They can provide pregnant women with more emotional support and positive encouragement during labor, which is conducive to reducing the fear of childbirth and achieving good pregnancy outcomes. This is consistent with the results of a previous study[5]. In addition, midwives work closely with the grassroots medical staff to cooperate and support each other in providing extended midwifery services. When necessary, midwives can use Internet technology to achieve information sharing and two-way referrals.

CONCLUSION

The combination of Internet- and midwife-led continuous midwifery services can effectively expand the use of high-quality nursing service resources, realize the integrated management of women with HRP before and after delivery, and support special groups of women with HRP. Midwives provide effective, economical, and convenient personalized nursing measures for pregnant women during pregnancy, childbirth, and puerperium, which not only reduces the anxiety and depression of women with HRP, but also improves the quality of life of women with HRP and newborns.

ARTICLE HIGHLIGHTS

Research background

There are many drawbacks to the traditional midwifery service management model that can no longer meet the needs of the new era. Dominated by midwives and combined with the advantages of the Internet, continuous midwifery services are provided to women with high-risk pregnancies (HRP) to alleviate adverse psychological emotions and improve pregnancy outcomes.

Research motivation

It is necessary to determine the feasibility and effectiveness of the midwife-led Internet + continuous midwifery service model, especially the psychological emotions and pregnancy outcomes of women with HRP.

Research objectives

To analyze the effect of a midwife-led Internet + continuous midwifery service model on the psychological mood and pregnancy outcomes of women with HRP.

Research methods

The clinical data of 439 women with HRP were retrospectively analyzed. They were divided into different midwifery service modes (traditional and continuous groups). Psychological and emotional conditions, self-efficacy, incidence of adverse delivery outcomes, and nursing satisfaction were compared between the two groups.

Research results

The State-Trait Anxiety Inventory and Edinburgh Postnatal Depression Scale scores of the two groups gradually decreased, with the continuous group decreasing faster than the traditional group. The incidence of adverse delivery and neonatal outcomes in the continuous group was 10.50% (21/200) and 8.50% (17/200), respectively, significantly lower than in the traditional group (18.83%, 45/239; 15.90%, 38/239, respectively).

Research conclusions

The Internet + continuous midwifery service model gives full play to the subjective initiatives of pregnant women and midwives. It is of great significance to realize long-term, continuous, and real-time maternal management and ensure maternal and child safety through "prenatal-intrapartum-postpartum," in-hospital and out-of-hospital, online, and offline

care.

Research perspectives

Midwives carry out corresponding Internet services according to different stages of pregnancy (early, middle, and late pregnancy), including the release of popular science articles on the public account, WeChat group communication, questionnaire star collection of relevant information, and network video conferences answering questions to guide women with HRP to carry out prenatal examinations and self-monitoring. Midwives can not only provide professional advice during pregnancy and childbirth but also provide extended quality nursing services to improve maternal satisfaction.

Abstract

BACKGROUND

Blood pressure variability (BPV) has been shown to be related to mild cognitive impairment and Alzheimer's disease in a number of studies. However, the relationship between BPV and subtle cognitive decline (SCD) has received minimal attention in this field of research to date and has rarely been reported.

AIM

To examine whether SCD is independently associated with changes in BPV in older adults.

METHODS

Participants were selected based on having participated in cognitive function evaluation and ambulatory blood pressure measurement at the Shanghai Sixth People's Hospital Affiliated with Shanghai Jiao Tong University School of Medicine between June 2020 and August 2022. The participants included 182 individuals with SCD as the experimental group and 237 with normal cognitive function as the control group. The basic data, laboratory examinations, scale tests, and ambulatory blood pressure test results of the two groups were analyzed retrospectively, and the relationship between SCD and BPV was subsequently evaluated.

RESULTS

Significant differences were observed between the two groups of participants ($P < 0.05$) in terms of age, education level, prevalence rate of diabetes, fasting blood glucose level, 24-h systolic blood pressure standard deviation and coefficient of

variation, 24-h diastolic blood pressure standard deviation and coefficient of variation. The scale monitoring results showed significant differences in the scores for memory, attention, and visual space between the experimental and control groups. Logistic regression analysis indicated that age, education level, blood sugar level, and BPV were factors influencing cognitive decline. Linear regression analysis showed that there was an independent correlation between blood pressure variation and SCD, even after adjusting for related factors. Each of the above differences was still significant.

CONCLUSION
This study suggests that increased BPV is associated with SCD.

Key Words: Blood pressure; Variability; Elderly; Subtle cognitive decline relationship

Core Tip: Cognitive dysfunction is a disease that seriously endangers human health, and its current treatment measures are far from perfect. Early identification, which can facilitate the implementation of early treatment, is the primary focus of this research. Our aim was to explore the correlation between blood pressure variability (BPV) and subtle cognitive decline and to understand whether BPV can be used for early detection of cognitive impairment.

INTRODUCTION

Alzheimer's disease (AD) is a highly harmful disease. Epidemiological surveys have shown that there are more than 30 million AD patients globally, and it is expected that in 30 years, this number will have expanded to 130 million. Cognitive impairment resulting from AD is serious and irreversible, carries a high disability rate, and is difficult to cure, placing a huge burden on both families and society as a whole[1,2]. Although much work has already been performed in this area, there remains no truly effective therapy for AD. Early identification, screening, detection, and intervention are important for preventing the progression of the disease[3-6]. The National Institute on Aging and the Alzheimer's Association have classified AD into three distinct stages[7]: The AD preclinical stage [subjective cognitive decline and subtle cognitive decline (SCD), AD-derived mild cognitive impairment (MCI), and the dementia stage]. SCD refers to the initial phase of cognitive decline. Memory loss is the primary symptom of AD during this period, although a routine examination cannot indicate MCI caused by dementia. According to prior research, early identification and prompt intervention can help prevent 30% of the risk factors associated with AD[4,8,9]. Therefore, SCD has become a popular topic in early-stage AD research. Unlike gene testing, cerebrospinal fluid, and positron emission tomography (PET), blood pressure variability (BPV) testing is inexpensive, non-invasive, and easy for patients to accept. Determining the correlation between BPV and cognitive impairment can provide valuable insight for clinicians regarding the process of diagnosis and treatment.

BPV, also known as blood pressure volatility, indicates the degree to which an individual's blood pressure fluctuates during a certain period of time and does not depend on blood pressure levels[10-12]. BPV is an indicator of spontaneous fluctuations in blood pressure, which are closely related to arterial remodeling, left ventricular hypertrophy, stroke, and hypertensive renal damage. In the physiological process that emerges during the progression from hypertension to cardio-cerebrovascular events, BPV plays an adverse role at every stage[13-16]. Blood pressure changes that occur within 24 h (short-term BPV) are more valuable for predicting the risk of cardiovascular death than clinical blood pressure. Previously published articles have found that the predictive effect of clinical blood pressure is limited, and short-term BPV can serve as a more accurate indicator than clinical blood pressure; therefore, the use of ambulatory blood pressure monitoring (ABPM) should be widely promoted over the use of clinical blood pressure[17-19]. Previous studies have shown that that BPV is associated with MCI and AD[20-22], but studies on BPV and SCD to date have proven rare. SCD is an early stage of AD, and those with SCD face a significantly higher risk of developing MCI and AD people with SCD than those with normal cognitive function[23-25]. Our aim was to evaluate the correlation between BPV and SCD and to analyze whether BPV could be used as a screening index for early cognitive decline.

MATERIALS AND METHODS

Participants

From June 2020 to August 2022, 1095 people who participated in a routine physical examination at the Department of

Geriatrics of Shanghai Sixth People's Hospital completed the neuropsychological scale test and 24-h ABPM. According to the test results, 237 individuals had normal cognitive function and were classified as the control group (NC), and 182 had SCD and were classified as the experimental group (SCD). The basic data, laboratory examinations, scale tests, and ABPM test results of the SCD and NC groups were retrospectively analyzed, and the relationship between BPV and SCD was subsequently assessed.

Inclusion criteria: (1) Participants aged 60 or older; (2) those who have a primary school level education or higher; and (3) those who possess a normal level of hearing and eyesight.

Exclusion criteria: (1) Patients with MCI and AD; (2) those with a history of cerebrovascular disease, such as brain trauma, cerebral infarction, cerebral hemorrhage, Parkinson's disease, brain tumor, epileptic psychosis, or dysplasia; (3) those with a Hamilton Depression Rating Scale 17-item score of more than 12; (4) those with other diseases affecting cognitive function, such as B12 deficiency, alcoholism, folic acid, drug abuse, syphilis, and AIDS; (5) those with visual impairment, hearing impairment, and limb dysfunction resulting in an inability to complete the neuropsychological scale; and (6) those with serious diseases in major organs, such as the liver, kidneys, heart, and lungs.

Clinical-demographic data

Participants' sex, age, height, weight, educational attainment, and history of chronic diseases were recorded. On the same day, routine blood tests, blood lipids, liver and kidney function, and blood glucose were checked, and a head magnetic resonance imaging examination was conducted.

Cognitive function

In a specialized neuropsychological room, the scale was assessed by trained professionals. Scale detection participants did not participate in the judgment of cognitive diagnosis. Each participant was screened using strict scale tests to assess memory, space, attention, language, execution, and social cognition; the scales utilized included a mini-mental state examination (MMSE), the Chinese version of the Montreal Cognitive Assessment (MoCA; MoCA-CV), Hamilton Depression Scale, Auditory Verbal Learning Test (AVLT), Animal Verbal Fluency Test (AFT), Boston Naming Test (BNT), Symbol Digit Modalities Test (SDMT), Rey-Osterrieth Complex Figure Test (CFT), Trail Making Test Part A (TMT-A) and part B (TMT-B), Prospective Memory Test (PrM), Functional Activities Questionnaire (FAQ), and so on.

ABPM and BPV indices

Twenty-four-hour ABPM: The testing period was from 7:00 on day one to 7:00 the following day, from 7:00 to 21:59 during the day, and was recorded every 30 minutes. At nighttime, the testing period was from 22:00 to 6:59 on the second day, with tests taken every 60 min. To be included in the group, the valid readings had to be greater than 90%. BPV indices included 24-h systolic blood pressure standard deviation (SBP SD) and coefficient of variation (SBP CV) as well as 24-h diastolic blood pressure standard deviation (DBP SD) and coefficient of variation (DBP CV). The coefficient of variation was calculated using the formula CV = 100 × SD/mean.

Biochemical indicators

On the day of the scale test, after fasting for 8 h, venous blood samples were taken and immediately tested for blood glucose (fasting and two hours postprandial blood glucose), blood lipids, serum creatinine, serum uric acid, and so on.

Diagnostic criteria of SCD

A total of six neuropsychological scores were examined using the method by Jak and Bondi: the AFT and a 30-item BNT were administered to evaluate language; the TMT-A and TMT-B were administered to evaluate attention/executive function; and two scales were applied to evaluate memory function - the Rey AVLT, a 30-min delayed free recall test, and AVLT recognition. The criteria were used to determine whether participants had SCD: (1) Cognitive decline on two of the six neuropsychological measures in different cognitive fields, defined as > 1 SD below the age-corrected normative mean; and (2) a FAQ score of 6-8[23].

Statistical analysis

The statistical analysis was conducted using SPSS 24.0. We used the mean ± SD to represent the measurement data, and a *t*-test was applied to compare the NC and SCD groups. A χ^2 test was utilized to compare the counting data between the two groups. A binary logistic regression was used to analyze the related factors of cognitive impairment, and a multiple linear regression was performed to determine cognitive domain scores were correlated with BPV. The level of significance was set at $P \leq 0.05$.

RESULTS

Demographic characteristics of the subjects

Table 1 presents the general characteristics of the participating researchers. Significant differences were observed in age, education level, incidence of diabetes, fasting blood glucose levels, SBP SD, SBP CV, DBP SD, and DBP CV between the NC ang SCD groups. No significant differences in other indices were observed.

TG (mmol/L)	1.32 ± 0.75	1.42 ± 0.81	0.055
HDL-C (mmol/L)	1.15 ± 0.51	1.17 ± 0.49	0.213
LDL-C (mmol/L)	2.39 ± 0.83	2.21 ± 0.79	0.314
SBP SD	10.52 ± 2.94	14.15 ± 4.37	0.000
DBP SD	7.32 ± 2.74	9.45 ± 3.07	0.040
SBP CV	12.35 ± 3.74	16.97 ± 4.91	0.000
DBP CV	9.85 ± 2.73	12.63 ± 3.81	0.006

NC: The control group; SCD: Subtle cognitive decline; BMI: Body mass index; CAD: Coronary artery disease; FBG: Fasting blood glucose; PBG: Postprandial blood glucose; Scr: Serum creatinine; TC: Total cholesterol; TG: Triglycerides; HDL-C: High-density lipoprotein cholesterol; LDL-C: Low-density lipoprotein cholesterol; SBP SD: 24-h systolic blood pressure standard deviation; SBP CV: 24-h systolic blood pressure coefficient of variation; DBP SD: 24-h diastolic blood pressure standard deviation; DBP CV: 24-h diastolic blood pressure variation coefficient.

Cognitive scale score

As shown in Table 2, a significant difference was observed between the two groups on the MMSE and the MoCA. A comparison of the scores for each cognitive domain revealed significant differences in attention, memory, and visual space between the two groups.

Analysis of influencing factors of cognitive impairment

Using cognitive decline as a dependent variable and other influencing factors as independent variables, multivariate logistic regression analysis revealed that cognitive decline was significantly correlated with age, education level, diabetes, SBP SD, DBP SD, SBP CV, and DBP CV (Table 3).

Effect of blood pressure variation on cognitive performance

Multiple linear regression analysis demonstrated that memory, attention, and visual-spatial dysfunction in the SCD group were significantly correlated with SBP SD and CV, while DBP SD and CV were significantly correlated with memory impairment. Even adjusting for age, sex, drinking, smoking, education level, body mass index, blood glucose, and blood lipid levels, these differences remained significant (Table 4).

DISCUSSION

This study aimed to identify a simple method for detecting cognitive decline in its early stages. In this retrospective study, BPV was observed to be independently associated with SCD and increased BPV in individuals aged 60 or above and may be seen as a risk factor for SCD.

Current reports on the correlation between BPV and cognitive impairment are inconsistent. Most researchers believe that cognitive impairment is associated with increased BPV. However, different views have been expressed on this topic,

Table 2 Scores of personnel cognition scale in two groups

Index	NC (*n* = 207)	SCD (*n* = 175)	*F* (*P* value)
MMSE	28.97 ± 2.13	26.15 ± 1.62	49.327 (< 0.001)

SBP SD: 24-h systolic blood pressure standard deviation; SBP CV: 24-h systolic blood pressure coefficient of variation; DBP SD: 24-h diastolic blood pressure standard deviation; DBP CV: 24-h diastolic blood pressure coefficient of variation.

such as that higher BPV has nothing to do with dementia[26-28]; that patients with increased BPV have higher cognitive scores; and that only the increase in systolic blood pressure variation is related to cognitive decline, while the increase in diastolic blood pressure variation is not. In addition, there are significant differences in the cognitive assessment tools, BPV calculation method, duration of blood pressure monitoring, study population, and sample size among different studies[29-31]. Thus, standardized methods should be considered to compare and determine the significance of various studies. The results of the 24-h ABPM were used to calculate BPV, which is a more objective form of measurement than clinic blood pressure; the equipment is simple, primary medical institutions can use it, and research participants can easily accept this method.

At present, effective treatment for dementia remains far from perfect, and many people with cognitive impairment seek treatment in community medical institutions. Identifying changeable risk factors is important for preventing dementia in primary healthcare institutions. ABPM to evaluate blood pressure levels and BPV is a simple method for assessing the risk of dementia and evaluating the effectiveness of treatment.

There are several viewpoints on the mechanism underlying cognitive impairment caused by BPV[32-36]: (1) Hemodynamic instability has harmful effects on neurovascular units and results in endothelial injury and vascular smooth muscle dysfunction, leading to accelerated neuronal damage and neuronal loss; (2) arterial remodeling is beneficial to β-amyloid deposition and reactive glial hyperplasia; (3) the fluctuation of arterial blood pressure leads to inconsistent perfusion attacks of tissue hypoxia-ischemia, promoting the activation of microglia and the production of brain amyloid proteins, resulting in neuronal injury and cell death; and (4) oxidative stress and inflammation. There may be direct connections between vascular and metabolic factors and the deposition of β-amyloid proteins in the brain,

Table 4 Correlation between blood pressure variability and cognitive function by multivariate linear regression analysis

promoting oxidative stress and inflammation as well as neurodegeneration.

The results of this study show that BPV can be used as a tool to screen for early-stage cognitive decline; therefore, it is possible to delay or prevent further cognitive decline by improving BPV. The sample size of future studies should be increased and long-term follow-up assessments should be conducted to identify the correlation between BPV and cognitive impairment, especially in primary medical institutions as BPV can be considered a valuable tool for screening for cognitive decline.

This study had several limitations, including that it was a small cohort study and that participants were not randomly selected, which could potentially have biased the results. Other indicators that could have an impact on the results were not used in this study to measure BPV. Cerebrospinal fluid and PET tests were not performed, and variations in blood pressure and intracranial lesions could not be identified. Follow-up work should be carried out to extend the results of the study and determine whether effective control of BPV can reduce or reverse the decline in cognitive function. Effective control of BPV was not considered in this study.

CONCLUSION

According to this study, an increase in BPV is one of the risk factors for early cognitive decline. BPV was found to be

independently associated with SCD. BPV should be controlled effectively in clinical practice, especially in the treatment of hypertensive patients. The goal is not only to reach a standard blood pressure level but also to steadily reduce blood pressure and control BPV to better protect cognitive function and try to prevent or delay the occurrence of AD.

ARTICLE HIGHLIGHTS

Research background

Cognitive impairment is a highly harmful disease for which there is no perfect treatment. Early detection and treatment are the main focus of related research. Variation in blood pressure has been correlated with cognitive impairment in previous studies; however, few studies have examined subtle cognitive decline.

Research motivation

Our purpose was to analyze the influencing factors for subtle cognitive decline (SCD) and find a simple and effective index through which to assess cognitive decline that can be used to guide clinical work.

Research objectives

The study aimed to determine whether blood pressure variability (BPV) leads to cognitive impairment. The results showed that an increase in BPV is independently related to SCD and that BPV may be used as a tool for evaluating cognitive impairment and the effectiveness of treatment.

Research methods

We used a standard neuropsychological scale to evaluate cognitive function and retrospectively analyzed the correlation between BPV and SCD.

Research results

The results show that increased BPV may be a factor leading to cognitive decline. The results of such studies are rare; however, the sample size is not sufficiently large, and no further research has been carried out to determine whether it can be used as an index to analyze the effectiveness of treatment.

Research conclusions

This study demonstrates that BPV is a clinical indicator of early cognitive decline. In this study, 24-h ambulatory blood pressure monitoring test was used as an index from which to calculate BPV, one that is simple, effective, and can be readily used in primary healthcare institutions.

Research perspectives

Long-term follow-ups should be considered in the future to further the collective comprehension of the correlation between BPV and cognitive decline and the progress of cognitive impairment as well as to estimate the benefits of improving BPV in the treatment of cognitive impairment.

FOOTNOTES

Co-corresponding authors: Hui-Feng Guo and Yi Wu.

Author contributions: HF Guo and Y Wu analyzed the data and wrote the paper; Li J was responsible for execution and data collection; Pan FF was responsible for the study conception and design; the final version of the manuscript has been approved by all authors. Guo HF and Wu Y contributed equally to this work as co-corresponding authors. The reasons for designating them as co-corresponding authors are as follows: Firstly, this manuscript is a collaborative work. The designation of co-corresponding authorship accurately reflects the distribution of responsibilities and burdens associated with the time and effort required to complete the study and the resultant paper. Secondly, Guo HF and Wu Y contributed equally to this work. The choice of these researchers as co-corresponding authors acknowledges and respects this equal contribution, while recognizing the spirit of teamwork and collaboration of this study. Guo HF is responsible for the overall planning and the organization of clinical data, Wu Y is responsible for the data summary and statistical analysis. In summary, we believe that designating Guo HF and Wu Y as co-corresponding authors of is fitting for our manuscript as it accurately reflects our team's collaborative spirit, equal contributions, and diversity.

Abstract

BACKGROUND

According to the trend of global population aging, the proportion of elderly patients with chronic kidney disease (CKD) is expected to increase. However, there are more than 20 million people in China with decompensated kidney function, of which 19.25% are elderly people. Therefore, special attention should be paid to the education years, sleep quality, anxiety status, comorbidities with diabetes, cardiovascular disease (CVD), and anemia as independent risk factors for depression in elderly CKD patients. This study explores the clinical management of elderly CKD patients that should address these risk factors to prevent depression and improve their prognosis.

AIM

To investigate depression risk factors in older patients receiving peritoneal dialysis, aiding future prevention of depression in these patients.

METHODS

This retrospective study included a primary study population of 170 patients with CKD who received peritoneal dialysis from January 2020 to December 2022. We assessed the patients' mental status using the Beck Depression Inventory Score-II (BDI-II), Self-Rating Anxiety Scale (SAS), Anxiety Inventory Score, and the Pittsburgh Sleep Quality Index (PSQI). Logistic regression was employed to identify depression independent risk factors among these patients.

RESULTS

The non-depressed group had a significantly longer education period than the depressed group ($P < 0.05$). The depressed group exhibited significantly higher mental status scores than the non-depressed group ($P < 0.001$). Patients with diabetes mellitus (DM) or CVD had a higher probability of developing depression. Patients with depression had significantly lower hemoglobin and albumin levels than patients without depression ($P < 0.05$). Spearman correlation

analysis of BDI-II scale scores, measuring depression, indicated positive correlations with BDI-II and SAS scores as risk factors for depression in patients with CKD. In contrast, years of education, hemoglobin levels, and peritoneal Kt/V were negatively correlated, serving as protective factors against depression. An analysis of variance for influences with significant differences in the univariate analysis revealed that years of schooling, BDI-II, SAS, PSQI, DM, CVD, and hemoglobin levels independently influenced depression in older patients with CKD.

CONCLUSION

Education, BDI-II, SAS, PSQI, DM, and CVD are independent risk factors for depression in older patients with CKD; therefore, post-treatment psychological monitoring of high-risk patients is crucial to prevent depression.

Key Words: Depression; Chronic kidney disease; Peritoneal dialysis; Older adults; Risk factors for depression; Beck Depression Inventory Score-II

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: We identified independent risk factors for depression in older patients with chronic kidney disease receiving peritoneal dialysis, including fewer years of education, higher Beck Depression Inventory Score-II and Self-Rating Anxiety Scale scores, poorer sleep quality, the presence of diabetes mellitus and cardiovascular disease, and lower hemoglobin and albumin levels. Conversely, more years of education, higher hemoglobin levels, and better peritoneal Kt/V ratio were associated with a lower risk of depression. These findings emphasize the importance of considering psychological well-being and addressing potential risk factors in the management of older patients on peritoneal dialysis, particularly in patients at high-risk of depression.

INTRODUCTION

Chronic kidney disease (CKD), a severe condition, is associated with a group of syndromes and results from progressive kidney structure and function degradation over three months[1]. Patients with CKD exhibit clinical manifestations such as varying urinary protein levels, swelling, hypertension (HTN), and impaired kidney function[2]. Age significantly contributes to CKD, as kidneys decrease in size and lose with age[3]. In China, at least 20 million people have decompensated kidney function[4], with 19.25% being older adults. With global aging, the proportion of older patients with CKD is also likely to increase, necessitating special treatment and prognosis considerations.

Due to kidney shortages, CKD is often managed with renal replacement therapy, mainly hemodialysis and peritoneal dialysis[5]. Peritoneal dialysis utilizes the peritoneum as a semi-permeable membrane to remove dialysis fluid and metabolic waste[6]. Compared with hemodialysis, peritoneal dialysis is less expensive and has a lower ischemic effect on the kidneys, preserving residual function, and is more accessible[7]. However, CKD not only represents a financial burden to the patients but also leads to a rising rate of CKD-associated disabilities, causing patient suffering[8].

With advances in medical technology, the survival rates of patients with CKD is increasing, resulting in a growing population of patients with CKD[9]. Identifying means to improve their quality of life and prognosis has become a critical research focus. The prevalence of depression among patients with CKD is four times higher than that in the general population[10]. Among patients with CKD receiving ambulatory peritoneal dialysis, most often complain of poor sleep quality, moodiness, and lethargy, with a 58.1% prevalence of depression[11]. Despite variations in depression scales, ethnic groups, and geographic regions, various national and international studies have associated CKD-related depression to higher hospitalization rates, cardiovascular events, and suicide and mortality rates[12-14].

Based on the previous findings, this retrospective study explored the independent risk factors for depression in older patients with CKD receiving peritoneal dialysis to provide a scientific basis for reducing depression and improving the prognosis of older patients.

MATERIALS AND METHODS

Study participants and design

We selected 170 patients with CKD who received peritoneal dialysis treatment at the Cangzhou Central Hospital in the Hebei Province from January 2020 to December 2022. The study was approved by the ethics committee of the Cangzhou Central Hospital and all participants signed informed consent. The patient inclusion criteria were: (1) Age > 65 years; (2)

Met the diagnostic criteria for patients with CKD receiving peritoneal dialysis; (3) Ambulatory with unrestricted activity; and (4) No comorbid psychiatric conditions prior to observation and conscious and able to communicate autonomously. Patients were excluded if they had: (1) An emergency cardiovascular event with impaired consciousness; (2) other serious illnesses, such as cancer, myocardial infarction, and cerebrovascular accident (CVA); and (3) depression and anxiety before receiving peritoneal dialysis.

This retrospective study analyzed patients previously treated with peritoneal dialysis, collected their basic information and clinical data, and assessed their mental status using the Beck Depression Inventory Score-II (BDI-II), Self-Rating Anxiety Scale (SAS), Anxiety Inventory Score, and the Pittsburgh Sleep Quality Index (PSQI).

Clinical characteristics

Demographic information and prevalence data were collected from all participants. These data included age, sex, education level, body mass index (BMI), presence of HTN, presence of diabetes mellitus (DM), and history of cardiovascular disease (CVD). CVDs included coronary heart disease, congestive heart failure, myocardial infarction, and a history of CVA.

Laboratory methods

Peritoneal dialysis was continued after the patients were given a night meal. Venous blood was collected from all participants for routine blood tests. Blood tests were conducted using a fully automated chemistry analyzer (indicators included serum sodium, albumin, calcium, phosphate, cholesterol, and hemoglobin). Midmorning urine samples were collected to determine renal function. The total Kt/V and creatinine clearance of the patients' body after peritoneal dialysis were evaluated to determine the effectiveness of dialysis treatment.

Depressive state measurement

The BDI-II, SAS Anxiety Inventory Score, and PSQI scores were used to measure the depression status of the patients.

BDI-II: This scale assesses the degree of depression. It consists of 21 groups of items, with each group having four statements. Each question is scored from 0 to 3. Depression was classified as follows: patients with scores < 13 were considered non-depressed, 14–19 were considered mildly depressed, 20–28 were considered moderately depressed, and 29–63 were considered severely depressed[15].

SAS: This scale assesses the degree of anxiety. The standard SAS score has a cutoff of 50, with 50–59 indicating mild anxiety, 60–69 indicating moderate anxiety, and 70 or more indicating severe anxiety[16].

PSQI: This index is used to assess sleep quality over the last month. The total PSQI score ranges from 0 to 21. A negative correlation was observed between these scores and sleep quality (higher scores indicating poorer sleep quality). A score > 16 indicated poor sleep quality[17].

Statistical analysis

The data were processed using SPSS 26.0, with measurements expressed as the mean ± SD. Analysis of variance (ANOVA) or Student's *t*-test was performed to evaluate statistical significance. The *t*-test for independent samples was performed to compare the data between the two groups, and the chi-square test was performed to compare the count data in terms of composition ratio (%). Correlations were analyzed using the Spearman method, and influencing factors were analyzed using multiple linear regression models, with $P < 0.05$ considered as a statistically significant difference. Spearman's rank correlation was used to analyze the relationship between depression and each parameter, and logistic regression was performed to analyze the factors influencing depression.

RESULTS

Patient baseline characteristics

We collected demographic data and medical histories for analysis (Table 1). Among 170 patients, 59 were assessed as having depression based on the scale and clinical symptoms. Age, BMI, HTN, triglyceride, P, Ca, Na levels, and renal function did not significantly differ between the depressed and non-depressed groups ($P > 0.05$). However, a significant difference was observed in the length of education between the two groups ($P < 0.05$). The depressed group had significantly higher mental state scores compared to the control group ($P < 0.001$). Patients with DM and CVD were more prone to develop depression, and those in the depressed group had significantly lower hemoglobin and albumin levels than patients in the non-depressed group ($P < 0.05$).

Correlation between depression and relevant indicators in peritoneal dialysis patients

The results of the Spearman correlation analysis of BDI-II scale scores measuring depression with each factor revealed that BDI-II and SAS scores were positively correlated as risk factors for depression in patients with CKD. In contrast, years of education, hemoglobin levels, and peritoneal Kt/V were negatively correlated as protective factors against depression (Table 2).

Dichotomous logistic regression analysis of patient depression

ANOVA results revealed that years of schooling, BDI-II, SAS, PSQI, DM, CVD, and hemoglobin levels independently influenced depression in older patients with CKD (see Table 3 for indicator assignments) (Table 4).

Table 1 The baseline characteristics of the study patients

Factors	No-depression (*n* = 59)	Depression (*n* = 111)	*P* value
Age (yr, mean ± SD)	67.23 ± 0.23	68.11 ± 0.36	0.590
Sex (male/female)	78/33	41/18	0.975

DISCUSSION

Because the older adult population comprises an increasing proportion of patients with CKD, improving their quality of life and prognostic outcomes has become a priority for their clinical management. Depression often results in reduced sleep quality and worry in older patients, which can lead to self-harm and, in severe cases, to suicidal behavior. Studies have evidenced that patients with CKD are more prone to depression than patients without CKD, possibly due to prolonged dialysis treatment and physical and psychological stress[18]. In this retrospective study, we analyzed cross-sectional data and the results revealed that indicators such as years of education and sleep quality are independent risk factors for depression in older patients with CKD.

Association between years of schooling and depression

Educational attainment has consistently been considered as a protective factor against depression. Our study reinforces this connection, revealing a significant negative correlation between that years of education and depression scores. Higher education often equates to lower depression rates associated to greater financial stability and access to health knowledge, fostering better acceptance of the patient's condition[19]. Moreover, the alleviating effect of education on depression increases with age[20]. Therefore, the protective effect of education on depression is more likely to be noted in the older adult population.

Table 2 Correlation between depression and relevant indicators in peritoneal dialysis patients

Factors	r_s	*P* value
Year of education	-0.415	< 0.001[3]
BDI-II	0.925	0.015[2]
SAS	0.982	< 0.001[3]
Hemoglobin	-0.332	0.002[2]
Peritoneal Kt/V	-0.456	0.023[1]

Studies have suggested that the education might strengthen the resilience of patients with CKD, reducing their susceptibility to depression. Our findings highlight that patients with lower educational levels are more prone to depression. In China, the majority of the older adults has a low education level, with a 13.90% of those aged ≥ 60 years having a high school education or higher as of 2021. This proportion may be even lower among older patients with CKD who have depression[21].

Association of sleep quality and anxiety with depression

Sleep quality and anxiety levels often conform with depression. Studies have reported that people experiencing poor sleep quality and higher anxiety levels are more likely to develop depression. This result is consistent with that of our study[22]. Sleep quality is crucial for health; however, older adults have significantly shorter sleep duration and generally poorer sleep quality than people from other age groups. From a neurobiological perspective, people with insomnia tend to exhibit increased activity in their arousal systems, leading to alterations in corticothalamic neural activity and neurotransmitter release. This includes the production of high levels of adrenocorticotropic hormones and cortisol, factors that increase susceptibility to mental health conditions such as depression and anxiety[23]. Sleep quality influences cognitive function as well as anxiety and depression in older adults. For example, Wang *et al*[24] found a significant association between sleep disturbance and depression scale and geriatric anxiety scale scores in Asian older adults. Therefore, monitoring sleep quality is crucial for the effective management of older patients with CKD.

Association of DM and CVD with depression

A large proportion of patients with Parkinson's disease develop diabetic nephropathy. A meta-analysis revealed a bidirectional association between diabetic nephropathy and depression. Similarly, a Japanese survey reported that the progression of diabetic nephropathy might increase the risk and severity of depression[25]. In cases of diabetic nephropathy, patients require long-term medication or insulin injections to control their blood glucose. Prolonged exposure to this disease can exacerbate depression. This depressive state may make patients less able to self-regulate and less aware of health protection, thereby exacerbating their overall medical condition, which can lead to progressive kidney failure.

Proteinuria is a risk factor of CVD. Advanced kidney disease can be exacerbated by CVD, leading to higher levels of depression[26]. Thus, a history of CVD is also a risk factor for depression in older patients with CKD[27]. The incidence of CVD tends to increase significantly with age; therefore, older patients with CKD are more likely to experience cardiovascular events that can exacerbate depression than the general population.

The relationship between anemia and depression

Anemia is a common complication in patients undergoing peritoneal dialysis and is caused by reduced erythropoietin production, toxin accumulation-induced erythropoietic depressants, shortened erythrocyte survival, and iron deficiency. Anemia is significantly associated with quality of life, CVD, hospital admissions, cognitive impairment, and death. In addition, patients with anemia often exhibit poor concentration and may also experience syncope and myocardial infarction, which can seriously affect their normal life and work[28]. Increased dyspnea and fatigue due to anemia may lead to a substantial decrease in physical and social activity, which in turn may increase depression. Hemoglobin and albumin levels serve as markers for anemia, and these two indicators were among the risk factors for depression in older patients with CKD, with a significantly higher incidence of depression in patients with anemia than in patients who did not present this condition.

Strengths and limitations

A strength of this study is its retrospective design, which enabled the analysis of independent risk factors associated with depression in older patients with CKD, providing a wider understanding of the patients' condition. Through correlation and logistic regression analyses, involving various factors associated with the incidence of depression in patients with CKD, the study compiled robust evidence, lending to more reliable results.

A limitation of this study is the absence of a comparative analysis involving other age groups. Therefore, the applicability of the study's findings is limited to the older adult population. However, at this stage, CKD patients are predominantly old. Although we believe that our findings can be generalized to other age groups, further studies are warranted to validate these hypothesis.

CONCLUSION

This study evidenced that years of education, sleep quality, anxiety status, comorbid DM, CVD, and anemia were independent risk factors for depression in older patients with CKD. Moreover, clinical management of older patients with CKD should address these risk factors to prevent depression and improve their prognosis.

ARTICLE HIGHLIGHTS

Research background

Previous studies demonstrated that over 20 million people in China experience decompensated kidney function, with 19.25% of them being older adults. Given the trend in global aging population, the proportion of older patients with chronic kidney disease (CKD) is expected to increase. Therefore, special attention should be focus on the treatment and prognosis of older patients with CKDs.

Research motivation

This study aimed to investigate the independent risk factors for depression in older patients with CKD undergoing peritoneal dialysis.

Research objectives

The study aimed to provide a clinical basis for the prevention of depression in older patients with CKDs.

Research methods

This retrospective study included a primary study population of 170 patients with CKD who received peritoneal dialysis from January 2020 to December 2022. We assessed the patients' mental status using the Beck Depression Inventory Score-II, Self-Rating Anxiety Scale, Anxiety Inventory Score, and the Pittsburgh Sleep Quality Index. Logistic regression was employed to identify depression independent risk factors among these patients.

Research results

The results of this study suggest that years of education, sleep quality, anxiety status, comorbid diabetes, cardiovascular diseases, and anemia are independent risk factors for depression in older patients with CKDs.

Research conclusions

This study found that years of education, sleep quality, anxiety status, comorbid diabetes mellitus, cardiovascular disease, and anemia were independent risk factors for depression in older patients with CKDs, and future clinical management of patients should address these risk factors to prevent depression and improve prognosis.

Research perspectives

This study investigated the independent risk factors for depression in older patients with CKD to provide a scientific basis for improving their prognosis, as well as to reduce the risk of depression in old age.

Abstract

BACKGROUND

Alcohol addiction, or alcohol dependence, refers to a psychological state of strong craving for alcohol caused by drinking when both the drinking times and alcohol consumption reach a certain level. Alcohol addiction can cause irreversible damage, leading to mental illness or mental disorders, negative changes in their original personality, and a tendency to safety incidents such as committing suicide or violent attacks on others. Significant attention needs to be given to the mental health of alcohol addicts, which could reflect their abnormal personality traits. However, only a few papers on this issue have been reported in China.

AIM

To investigate the correlation between mental health and personality in patients with alcohol addiction.

METHODS

In this single-center observational study, we selected 80 patients with alcohol addiction as the research subjects, according to the criteria of the K10 scale to evaluate the mental health of patients with alcohol addiction, and divided these patients into four groups based on the evaluation results: Good, average, relatively poor and bad. And then analyzed the correlation between mental health conditions and personality characteristics from these four groups of patients.

RESULTS

The average score of the K10 scale (Kessler 10 Simple Psychological Status

Assessment Scale) in 80 patients with alcohol addiction was 25.45 points, the median score was 25 points, the highest score was 50 points, and the lowest score was 11 points. *Pearson*'s analysis showed that the K10 score was positively correlated with the scores of these two subscales, such as the P-subscale and the N-subscale ($P < 0.05$). In contrast, the K10 score had no significant correlation with the scores from the E-subscale and the L-subscale ($P > 0.05$).

CONCLUSION

The mental health conditions of patients with alcohol addiction are positively correlated with their personality characteristics.

Key Words: Alcohol addiction; Mental health; Personality characteristics; Public health; Patients; Correlational analysis

Core Tip: Alcohol addiction, as a special behavioral pattern, can cause serious mental and physical burdens, and therefore must be highly valued. This article aims to explore the correlation between the formation of alcohol addiction as a behavioral pattern and personality. By randomly grouping alcohol addicted patients and evaluating their mental health using the K10 scale, the results showed that the mental health status of alcohol addicted patients was positively correlated with their personality traits.

INTRODUCTION

Alcohol addiction, or alcohol dependence, refers to a psychological state of strong craving for alcohol caused by drinking when both the drinking times and alcohol consumption reach a certain level. Alcohol addicts may get to the point of failing to control their drinking behavior, and a series of physical tolerance or withdrawal symptoms will appear[1]. These reactions will manifest as the patient's compulsive craving for alcohol. After the cessation of drinking behavior, some physical withdrawal symptoms may occur, such as palpitations, trembling, and dyspnea, or psychological withdrawal symptoms, such as anxiety, depression, and delusions of victimization. The above symptoms could disappear with the resumption of the drinking behavior[2]. Alcohol addiction is a disease that is difficult to cure, with a high prevalence rate and a high rate of relapse. According to data from the World Health Organization in 2018[3], approximately 237 million men and 46 million women worldwide suffered from alcohol dependence syndrome. The data shows that, in 2018, the annual drinking volume per capita in Chinese was 7.14 L, the annual drinking volume per capita in Northern American countries was 9.71 L, the annual drinking volume per capita in Western Europe countries was 11.13 L, and the yearly drinking volume per capita in Australia was 10.47 L. The proportion of heavy drinkers among China adults was 22.6%. The proportion of heavy drinkers among North American adults was 25.7%; among Western European adults was 30.5%; and among Australian adults was 34.4%[3].

According to the World Health Organization, health is defined as the absence of disease or being free of infirmity and the balanced and normal state of physical, psychological, and social[4]. Mental health is one of the most important public health issues in the world all the time. Psychological health, like physical health, can also affect the life quality of individuals; this fact should be prompting people to pay more attention to mental illness as to physical diseases[5]. Alcohol addiction can cause irreversible damage to the physical status, psychological conditions, and social adaptations of patients who suffer from it. It results in mental illness or mental disorders, causing negative changes in their original personality characteristics[6] and leading to vicious public safety incidents such as committing suicide or launching violent attacks on others. It is important to pay attention to the mental health of people with alcohol addiction.

Personality is the organic unity of the dynamic internal organization and the corresponding behavior patterns formed by individuals in various interactions. It is a complex structural system, mainly including two aspects; the tendency of personality and the rational characteristics of personality, the former is the driving force of personality, and the latter refers to the differences that exist among individuals[7]. In addition to physical damage like alcoholic liver disease, long-term heavy drinking can disturb their social adaptation and potentiate negative personality changes[8]. Alcohol addiction is strongly associated with personality disorders[9,10]. Personality disorders are considered important factors in the pathogenesis, persistence, and outcome of alcohol dependence in patients with these pernicious features[11].

The mental health condition of individuals is closely related to their personality characteristics. The mental health of alcohol addicts may reflect their unique but abnormal personality traits. However, at present, few related research has been reported in China. Based on this, this study aimed to investigate the correlation between mental health status and personality characteristics in people suffering from alcohol addiction.

MATERIALS AND METHODS

Research subject

In this single-centered observational study, we selected 80 patients with alcohol addiction treated in our hospital from January 2022 to January 2023 as the research subjects. And the inclusion criteria were the following: (1) Patients clinically diagnosed with alcohol addiction[12]; (2) The patient being aware and consciously participating in the investigation; and (3) The patient able to fill out the questionnaire independently or with the help of an investigator. Exclusion Criteria: (1) Patients with other serious illnesses that may affect their psychological condition (such as disability, cancer, *etc.*); (2) Patients with severe mental disorders that could impact affect the accuracy of the study; and (3) Those who are unwilling to cooperate with the investigation standards. All proceedings were carried out per the *Declaration of Helsinki*.

General demographic information questionnaire

The content of the questionnaire mainly included; (1) The basic personal information on alcohol addicts; their gender, age, marital status, education level, *etc.*; (2) The participants' financial situation, including the self-assessment of the financial level, whether they are autonomous, and whether they were indebted; (3) Daily life behaviors of patients, whether smoking, suffering from a sleep disorder, maintaining a good frequency of daily exercise, *etc.*; (4) The number of years set to the establishment of the alcohol addiction; and (5) Other related psychological conditions, including whether they had close friends to talk to, whether they encountered major setbacks or unfortunate situations, *etc.*

Mental health rating scale (K10)

The K10 scale[13], developed by Kessler and Mrocze of the University of Michigan, assesses patients' mental health and can screen for self-management scoring scales on the population's psychological status risk factors[14]. The scale is convenient to operate, owns the non-specific character in assessment, and has been widely used in the survey of mental health group in the United States, Canada, and other countries. The K10 scale contains ten items about anxiety, depression, and stress levels experienced in the last four weeks before the assessment. These are: (1) How often do you feel tired for no reason? (2) How often do you feel nervous? (3) How often do you feel nervous, and nothing else can calm you down? (4) How often do you feel hopeless about life? (5) How often do you feel uneasy and irritable? (6) How often do you feel restless and irritable so that it is difficult for you to calm down? (7) How often do you feel depressed? (8) How often do you feel strenuous when doing anything? (9) How often do you feel sad and nothing can interest you? and (10) How often do you you're your existence as meaningless? To each question corresponds five response criteria and scored in this manner; 5 points for "all time," 4 for "most of the time," 3 for "sometimes," 2 for "occasionally present," and 1 for "almost nonexistent." The total score is calculated according to the respondent's responses, with a score ranging from 10 to 50 points, where a maximum of 50 points could indicate that the patient has serious psychological distress, and a minimum score of 10, indicates that the patient has no psychological distress. This study was designed according to previous assessment criteria, and the overall score was classified into four levels: 10-19 points at the first level, which represented good mental health; level 2, 20-25 points, representing average mental health; level 3 score of 26-29, which represented relatively poor mental health; a score of 30-50 on a fourth scale represented bad mental health. The evaluation items of the K10 scale mainly focused on the two routine measurements such as anxiety and depression, which ascertain the degree of anxiety, depression, and life stress of the respondent during the previous four weeks and contribute to analyzing the population's mental health.

Eysenck personality questionnaire

Compiled by Eysenck in 1952, revised by Professor Gong Yaoxian in 1983, and formed a Chinese edition. The adult version of the questionnaire consists of four subscales, psychotropic (P), extrovert (E), neuroticism (N), and lie (L), with 88 questions[15]. Among them, psychopathic tendencies are reflected by the P dimension, introversion and extroversion are reflected by the introvert-E dimension, emotional stability is reflected by the N dimension, and the L tendency is used as an effectiveness scale. The P, E, N, and L scales include 23, 21, 24, and 20 items in the adult questionnaire, each of which only answers "yes" and "no," with 1 point per question. Among them, the introvert-E: A high score indicates that the person is extroverted, emotionally impulsive, adventurous, and good at interacting with people. A low score can indicate introversion, emotional stability, taciturn, indifference to people, quietness, introspection, and conformity. N: A high score would suggest depression, anxiety, preoccupation, emotional instability, and sometimes irrationality. Mental quality (P): High scores may indicate delayed reaction, being withdrawn and lazy, having no contact with anyone, being emotionally cold, poorly adaptable, eccentric and bizarre, and being incongruous with the environment. L: A high score indicates it is disguised and untrue. Disguise itself has a stable personality function related to various elements of other people. In this study, Cronbach's α of the P, E, N, and L subscales were 0.71, 0.78, 0.87, and 0.71, respectively.

Statistical analysis

SPSS22.0 statistical software was used to analyze and process data. Continuous variables were confirmed by the normality test and homogeneity test for variance, and it determined that they have the homogeneity of variance based on approximately normal distribution, expressed as mean ± SD, *t*-test, and ANOVA (analysis of variance). Categorical variables expressed as percentages, chi-square test, Fisher exact test or Mann-Whitney test, the correlation using *Pearson* correlation analysis, and taking the result of $P < 0.05$ to indicate that the difference was statistically significant.

Biostatistics statement: The statistical methods of this study were reviewed by the clinical research office from the corresponding author's institution prior to the submission.

RESULTS

General demographic information of patients with alcohol addiction

Eighty patients with alcohol addiction were included in this study, 67 male patients, 13 female patients, aged 20-65 years, and the duration of the addiction was 5-30 years. For other information (Table 1).

Analysis of mental health status of patients with alcohol addiction

The average K10 score of the 80 patients with alcohol addiction was 25.45, with a median score of 25, with the highest score being 50 and the lowest being 11. A score of K10 between 10 and 19 indicated that the patient's mental health was good (Grade 1, low risk of mental illness) in 17 people, accounting for 21.25%; A score of K10 on a score of 20-24 indicated that the patient's mental health status is average (Grade 2, low risk of mental illness), and there are 20 people in this group, accounting for 20.00%; A K10 score of 25-29 indicated that the patient's mental health is poor (Grade 3, higher risk of mental illness) in 32 people, accounting for 40.00%; A K10 score of 30-50 indicated that the patient's mental health is poor (Grade 4, high risk of mental illness) in 11 people, accounting for 13.75% (Table 2).

Analysis of personality characteristics of patients with alcohol addiction

The scores of the two subscales, including P-subscale and N-subscale in the 10-19 group, 20-24 group, 25-29 group, and 30-50 group of the K10 score, were statistically significant ($P < 0.05$). In contrast, the overall comparison of scores in E-subscale and L-subscale was not statistically significant ($P > 0.05$). Among them, the scores of the P-subscale were compared in the following groups, the 10-19 groups, and the 20-24 groups were smaller than the 25-29 groups and 30-50 groups, and the differences were statistically significant ($P < 0.05$). About the comparison in N-subscale scores, 10-19 groups < 20-24 groups < 25-29 groups, and 30-50 groups, and the differences were statistically significant ($P < 0.05$) (Table 3).

Correlation analysis of mental health conditions and personality characteristics

Pearson's analysis showed that the K10 score was positively correlated with the scores of the P-subscale, N-subscale, and other two subscales ($P < 0.05$). In contrast, the K10 score had no significant correlation with the scores of E-subscale and L-subscale ($P > 0.05$) (Table 4 and Figure 1).

DISCUSSION

Alcohol dependence, namely alcohol addiction, is a chronic and recurrent encephalopathy characterized by compulsive, intense cravings for alcohol, loss of control over alcohol use, and negative emotions and physical discomfort that will emerge when alcohol is unavailable. Harmful use of alcohol is one of the largest risk factors for death, disease, and disability[15-18]. The *Global Report on Alcohol Use and Health WHO in 2018* states that[3] in 2016, the global prevalence of alcohol use disorders (AUD) among people aged 15 and above reached 5.1%, and the prevalence of alcohol dependence in this age group reached 2.6%. The harmful use of alcohol caused approximately 3 million deaths worldwide in the same year, accounting for 5.6% of all deaths. According to the 2019 survey of Chinese groups of mental illnesses, the 12-month prevalence of AUD in China was 1.8%, and the lifetime prevalence was 4.4%, of which the 12-month prevalence of alcohol dependence was 0.7% and the lifetime prevalence was 1.3%[19]. Alcohol abuse can cause damage to multiple systems, including the nervous system, cardiovascular system, digestive system, respiratory system, *etc.* Long-term drinking can also cause the breakdown of family relationships, disturb normal work, and cause accidents after drinking that seriously endanger personal and social safety. Exploring the mechanisms of addiction in alcohol dependence, actively seeking new treatment options, and encouraging patients with alcohol dependent to receive professional treatment for alcohol withdrawal would be essential methods to reduce the harm due to alcohol abuse[20].

Addictive substances such as alcohol can activate the brain's reward system, and the reward hypothesis is a widely accepted neurobiological hypothesis of addiction[21]. The central nervous system can produce a rewarding effect on natural rewards, such as food, sex, *etc.*, thereby maintaining the continuity of the species. Almost all addictive substances can stimulate the brain's reward circuit, making it faster and more intense than natural rewards, resulting in intense pleasure in the individual. Positron emission tomography studies have shown that drunken doses of alcohol can promote the release of dopamine and opioid peptides from the brain to the ventral striatum, and rapid and high amounts of dopamine in the midbrain limbic system are associated with the subjective feeling of "hi," which is the rewarding effect [22]. Individuals associate alcohol use with positive rewards, which is positive reinforcement. The neurotransmitters and neuromodulators involved in alcohol reward include not only dopamine but also the opioid peptides, γ-aminobutyric acid, glutamic acid, serotonin, acetylcholine, and endocannabinoids acting on the ventral tegmental area or nucleus accumbens[23,24].

Patients with alcohol addiction are given to addictive substances, which greatly affect their mental health and personality characteristics. Jung[25] used the California Personality Questionnaire to implement the longitudinal measurement on adolescents who initially did not have drinking problems. Comparing boys who later developed drinking problems with the control group without similar issues, it was found that male alcohol addicts exhibited more rebellion and extroversion than others before they started drinking. While among female subjects, heavy drinkers showed more pessimism, introversion, and dependence as adolescents than light drinkers[25]. Cloninger *et al*[26] followed 431 subjects longitudinally for 16 years using a Three-dimensional Personality Questionnaire, which played an important role in clarifying the relationship between personality characteristics and alcohol abuse[26]. Cloninger *et al*[26] evaluated the

participants' personality characteristics at 11 by behavioral assessment; Participants were then assessed for alcohol addiction at 27. The results showed that high sensation seeking and low harm avoidance were risk traits for alcohol addiction and that participants with these two traits in childhood were 20 times more likely to experience alcohol addiction in adulthood than those without these two traits. The thesis of De la Rosa-Cáceres *et al*[27] in 2022 noted that medium-to-high-risk personality characteristics in participants correlated with the diagnostic criteria for alcohol addiction[27]. Labouvie and McGee[28] conducted longitudinal studies of subjects aged 12 to 21 years, reaffirming that personality predicts alcohol and substance abuse and that adolescents with early substance abuse scored with a low degree on fulfillment, cognitive structure, and avoidance of harm but scored with a high degree on relationships, independence, depression, impulsivity, and play[28]. Gmel *et al*[29] analyzed the questionnaire results in 5125 young men and pointed out that high impulsivity and sensory seeking are also risk factors for alcohol addiction.

The results of this study showed that the K10 score of patients with alcohol addiction was positively correlated with the scores of two subscales such as P-subscale and N-subscale (r = 0.477, 0.518, 0.454, P < 0.05), patients with higher K10 scores had higher scores in P-subscale and N-subscale. The personality characteristics of those with high scores on the P-subscale presented social withdrawal trait, with strange behaviors like apathy and poor control. Herein, they responded strongly to various stimuli. People with high scores on N-subscale often have overt nervousness, fear, terror, irritability, restlessness, anxiety, depression, and panic; when these people encounter abnormal psychosocial problems, they are more difficult to extricate themselves than ordinary people and will be worried, depressed, and hesitant.

Alcohol-dependent patients with higher scores on P-subscale on the eysenck personality questionnaire (EPQ) score tend to have personality characteristics such as isolation, isolation, bizarre behavior, apathy, poor control, and therefore strong responses to various stimuli[30-32]. The reason may be that individuals who are withdrawn and introverted when

Figure 1 The correlation between the K10 score and the subscale score. A: P-subscale score; B: E-subscale score; C: N-scale score; D: L-scale score. P: Psychotropic; E: Extrovert; N: Neuroticism; L: Lie.

they encounter unsatisfactory and unpleasant life events in daily life are neither good at alleviating their bad emotions by confiding inward troubles and depression to others, nor can they self-regulate through healthy and effective coping, so it is easier to apply the simple, direct but self-anesthesia method of drinking because of "Quench a thirst with poison" to avoid the bad reality, which is the so-called "Drinking can relieve thousands of worries." It might achieve certain results in the short term. Although individuals can also realize that long-term drinking could harm their bodies due to poor self-control. When they reencounter unsolvable life problems, they will involuntarily apply the so-called "effective" method as before, that is, "drinking." Consequently, they enter a vicious circle, increasing the possibility of "alcohol dependence." In addition, if the individual's sensitivity is high and it is easy to have a strong rational response to various stimuli, especially in the trivial matters of life, then it will be easier for them to all day long bothered by life dissatisfaction, which increases the possibility of "drinking" as a bad coping style. Moreover, patients with alcohol dependence due to long-term drinking habits will undergo certain changes. They will no longer care about their family, life, and work, having no emotional expression on their families and friends, just immersed in the "anesthesia" of alcohol all day. The general social interaction cannot interest them. Naturally, they will be like outliers and indifferent to anything. The patient will also have "foraging" behavior; that is, the patient will take all possible ways to find alcohol and meet the purpose of their drinking in the process of the patient's "foraging" in juncture to the conventional way. It may also include unconventional methods such as "Proposing a toast," "Cheating others to drink," "Gifting alcohol as private bribery," "Stealing alcohol," *etc.* these strange behaviors usually do not appear in normal individuals and represent the embodiment of "Weird behaviors."

Patients with alcohol dependence with higher N scores in the EPQ questionnaire had more obvious personality characteristics such as nervousness, fear, fear, irritability, restlessness, anxiety, depression, panic, anxiety, anxiety, depression, depression, and indecision[32-34]. The reasons could be that when individuals with tense, fearful, and indecisive personalities deal with life events, they are prone to cause difficulties in dealing with them correctly and in time due to their personality defects. When faced with choices in life, they will also miss the best time of choice and decision because of their indecision, so they might often fall into self-regret and afterward complain. Although individuals have also tried to apply healthy coping methods for solving problems, because of their nervous, fearful, and hesitant personality. These healthy coping styles are difficult to succeed in, so individuals will easily apply bad coping methods such as "drinking" to solve their adverse reactions. For individuals, "drinking" can not only solve the current dilemma in the short term, but

more importantly, it does not require too many personality characteristics and self-effort and successfully "avoids" the "negative influence" and "self-denial" brought about by their bad personality characteristics in the process of solving problems. Therefore, when individuals encounter similar life difficulties and other adverse conditions in the future, they will naturally use "drinking" to deal with it, which lays a certain foundation and conditions for forming later "alcohol dependence." In addition, if the individual's attitude to life is more negative, the individual is prone to be dissatisfied and disappointed with life and the future and will adopt more avoidance coping methods to deal with bad emotions and produce a sense of self "abandoned" by the world. At this time, the individual cannot solve his inner depression and resentment, and it is easy to use “drinking” to escape reality and self-anesthetize, and over time, the possibility of "alcohol dependence" will increase.

CONCLUSION

However, there were some limitations worth highlighting in this study. Firstly, the size of the sample studied was relatively smaller. And secondly, because this research was a single-center-based study, thus, the selection of these patients was limited to the scope of the patients in this hospital, which may have brought some biases in the interpretation of the results. Therefore, it appears necessary to design a larger, multi-center and multiethnic sample to further analyze and probe into the results of this study with an in-depth and sophisticated method.

ARTICLE HIGHLIGHTS

Research background

Correlation analysis of the correlation between alcohol addiction behavior and personality traits, exploring the causes of this behavior pattern, and thus serving the clinical treatment of alcohol addiction.

Research motivation

Alcohol addiction behavior is related to the personality characteristics of patients, and psychotropic (P) and neuroticism (N) dimensions of personality can positively induce alcohol addiction behavior.

Research objectives

There is a positive correlation between the scores of mental health assessment and the scores of P and N dimensions in personality assessment.

Research methods

Using the K10 Mental Health Assessment Scale, analyze the mental health status of alcohol addiction patients and its correlation with personality.

Research results

Based on existing research on the mental health of alcohol addiction, explore the correlation between the occurrence of alcohol addiction behavior and self-personality.

Research conclusions

Based on the existing talent gap of clinical research nurses, the training scheme of nurses should be scientifically customized to promote the development of clinical trials.

Research perspectives

Alcohol addiction, as a serious pattern of physical and mental harm, can lead to irreversible harm in severe cases. However, research reports on the causes of alcohol addiction behavior are not yet clear.

Abstract

BACKGROUND

The degree of psychological stress and the difficulty and efficacy of laparoscopic surgery differ in patients with pelvic abscesses after different durations of anti-infection treatment.

AIM

To compare and analyse the effects of different durations of anti-infective therapy on patients' preoperative psychological stress level and the clinical efficacy of laparoscopic surgery in patients with pelvic abscesses to offer a reference for the selection of therapy plans.

METHODS

A total of 100 patients with pelvic abscesses who were admitted to the Department of Gynecology of Suzhou Ninth Hospital affiliated to Soochow University (Suzhou Ninth People's Hospital) from January 2018 to December 2022 were retrospectively enrolled. According to the different durations of anti-infective therapy, they were divided into Group S (50 patients, received anti-infective therapy for 24-48 h) and Group L (50 patients, received anti-infective therapy for 48-96 h). Baseline data, state-trait anxiety score at admission and before surgery, self-rating anxiety scale (SAS) + self-rating depression scale (SDS) score, surgery time, adhesion grading score, intraoperative blood loss, presence or absence of intraoperative intestinal injury, ureteral injury or bladder injury, postoperative body temperature, length of hospital stay, and presence or absence of recurrence within 3 mo after surgery, chronic pelvic pain, incision infection, dysmenorrhea, menstrual disorder or intestinal obstruction were compared between the S group and the L group.

RESULTS

There was no significant difference in the background data between the S group

and the L group ($P < 0.05$). There was no significant difference in the state-trait anxiety score or SAS + SDS score between the S group and the L group on admission ($P < 0.05$). The state-trait anxiety score and SAS + SDS score of the S group were lower than those of Group L after receiving different durations of anti-infective therapy ($P < 0.05$). There was no significant difference in the incidence of intestinal, ureteral or bladder injury between the S group and the L group ($P < 0.05$). The surgery time of Group S was shorter than that of Group L, and the adhesion score and intraoperative blood loss volume were lower than those of Group L ($P < 0.05$). There was no significant difference in the incidence of incision infection, dysmenorrhea, menstrual disorder or intestinal obstruction between the S group and the L group ($P < 0.05$). The postoperative body temperature of Group S was lower than that of Group L ($P < 0.05$), and the hospital stay was shorter than that of Group L ($P < 0.05$). The incidences of recurrence and chronic pelvic pain within 3 mo after surgery were lower than that of Group L ($P < 0.05$).

CONCLUSION

Twenty-four to forty-eight hours of anti-infective therapy is better than 48-96 h of anti-infective therapy for patients with pelvic abscesses because the degree of psychological stress is lower, which is more conducive to achieving better outcomes after laparoscopic surgery.

Core Tip: A pelvic abscess is a typical manifestation of pelvic inflammatory disease that can endanger the patient's life in severe cases. Here, we analysed the data of 100 patients with pelvic abscesses and divided them into Group S (anti-infective treatment for 24-48 h) and Group L (anti-infective treatment for 48-96 h) according to different durations of anti-infection. Through statistical analysis of the data of the two groups of patients, the authors researched the effects of different durations of preoperative anti-infective therapy on the psychological stress of patients and the postoperative effects of laparoscopic surgery in China to select the optimal duration of anti-infective therapy.

INTRODUCTION

One of the most common serious infections in nonpregnant women of childbearing age is pelvic inflammatory disease (PID)[1]. PID is caused by mixed microbial infections of the upper reproductive tract, predominantly affects sexually active young women, and may be asymptomatic or present with tubuloovarian abscesses, which may be life threatening [2]. One of the most prevalent types of pelvic abscesses in women of childbearing age is tubo-ovarian abscesses. The best therapy for pelvic abscesses should be safe, effective, economical, minimally invasive, and have minimal effect on female fertility. Salpingo-ovarian abscesses have traditionally been treated with broad-spectrum antibiotics[3]. Long-term conservative therapy with drugs and long-term repeated use of antibiotics often lead to chronic pelvic abscesses or secondary adhesion, which decreases the patient's fertility, causes chronic pelvic pain, and seriously affects quality of life. Surgical intervention is required for patients who fail to receive conservative therapy. Except for a few patients with low-lying abscesses and a palpable posterior fornical incision and drainage tube, surgery has replaced conservative drug therapy and has become the first choice for the treatment of pelvic abscesses. Laparoscopic surgery has less biological impact on the body but a stronger protective effect on the immunity of the body, thereby reducing the incidence of infectious complications[4,5]. Preoperative anti-infective therapy can limit lesion development, prevent the spread of inflammation, and improve the efficacy of surgery. However, clinical observation shows that different durations of anti-infective therapy have different effects on surgery and postoperative outcomes. In our study, the data of 100 patients with pelvic abscesses who were admitted to our hospital in recent years were collected, and the differences in the outcomes of anti-infective therapy administered preoperatively, intraoperatively or postoperatively for different durations in patients with pelvic abscesses were analysed to find a more appropriate duration of anti-infective therapy.

MATERIALS AND METHODS

Patient characteristics

Data from a total of 100 patients with pelvic abscesses who were admitted to our hospital from January 2018 to December 2022 were retrospectively collected. According to different durations of anti-infective therapy, they were divided into

Group S and Group L. Group S was treated with anti-infective therapy for 24-48 h, and Group L was treated with anti-infective therapy for 48-96 h. There were 50 patients in Group S and 50 patients in Group L.

Inclusion and exclusion criteria

Inclusion criteria: (1) Patients with pelvic abscesses that were diagnosed by symptoms, physical examination, ultrasound, routine blood examination and vaginal fornix puncture; (2) Patients undergoing elective laparoscopic surgery who were treated with sulperazon plus ornidazole for anti-infection treatment before surgery; (3) Patients who received anti-infective therapy and were evaluated with the state-trait anxiety[6], self-rating anxiety scale (SAS) and self-rating depression scale (SDS) scales[7]; and (4) Patients with complete data.

The exclusion criteria were as follows: (1) Patients with blood diseases or infectious diseases, who were pregnant or lactating, or with mental disorders or severe organ failure; (2) Patients with ruptured pelvic abscesses or who received other antibiotics before antibiotic therapy; and (3) Patients who refused to participate or had family members who were not supportive.

Patients and their relatives understood the content of our study and signed informed consent forms.

Methods

After the patients were diagnosed with pelvic effusion by examination, the Group S and the Group L were treated with sulperazon combined with ornidazole for anti-infective therapy; that is, according to the results of germ culture and drug sensitivity tests of puncture fluid, the patients were given 3.0 g sulperazon (H20020597; Pfizer Pharmaceuticals Co., LTD) and 0.25 g ornidazole (Hunan Jiudian Pharmaceutical Co., LTD). Both drugs were administered by intravenous drip twice every 24 h. Group S received 24-48 h of anti-infective therapy, while Group L received 48-96 h of anti-infective therapy. State-trait anxiety and SAS + SDS scores were obtained from both groups before and after admission.

After anti-infective therapy, laparoscopic surgery was performed in both groups. After general anaesthesia, the patient was intubated and mechanically ventilated to assist respiration, and the patient was placed in the head-down and bladder lithotomy position. After routine skin disinfection and skin draping, a 1 cm curved incision was made below the umbilical margin of the patient, and CO_2 pneumothorax was established with a pressure range of 10-12 mmHg. The laparoscope was placed in the abdomen, and surgery holes of 1 cm and 0.5 cm in size were cut at the left and right McHolley points of the lower abdomen, respectively. The exposed abscesses were incised, and pus and fragments were aspirated with an aspirator and sent to the laboratory. The surgical scope should be determined according to the patient's fertility requirements and the extent of the lesion and adjusted according to the patient's situation and needs. Patients with fertility requirements should undergo salpingostomy. After the surgery, normal saline and metronidazole solution were used to wash the pelvic cavity repeatedly, the patient's position was adjusted to head up and foot down, and the pelvic cavity was washed again. If the abscesses involved the fallopian tube, they were removed by bipolar coagulation, and haemostasis was performed. After abscess removal, the pelvis was flushed with 250 mL of 0.5% metronidazole solution, and a pelvic drainage tube was placed. According to the results of the germ culture and drug sensitivity test of abscess secretion, the corresponding antibiotics were given after the surgery. The body temperature was maintained at the normal level for 24 h. Then, oral antibiotics were administered for 1 to 2 wk.

Observation indicators

(1) The psychological stress of the patients in Group S and Group L was investigated by the scale at admission and before surgery. The state-trait anxiety score includes two parts: State anxiety (S-AI) and trait anxiety (T-AI). Each item is scored from 1 to 4 points, with positive emotions scored in reverse order. The total score of the S-AI and T-AI is 20 to 80 points. The higher the score, the higher the anxiety level. The SAS and SDS compiled by Zung[8,9] (the SAS/SDS self-rating scale includes 20 items, and each item is scored from 1 to 4; the higher the score, the greater the degree of psychological stress) were used to evaluate the patients; (2) Surgery time, adhesion score (the modified classification standard of adhesion of the American Society for Reproductive Medicine in 1996[10] was used to evaluate the extent, degree and nature of the adhesion during surgery), intraoperative blood loss, the presence or absence of intraoperative intestinal, ureteral and bladder injuries; and (3) Postoperative body temperature, length of hospital stay, and the presence or absence of recurrence within 3 mo after the surgery, chronic pelvic pain, incision infection, dysmenorrhea, menstrual disorder, or intestinal obstruction.

Statistical procedure

SPSS 26.0 was used for statistical analysis. Measurement data are expressed as the mean ± SD, and a *t* test was used. Count data are expressed as a percentage (%), the χ^2 test was used, and $P < 0.05$ was regarded as statistically significant.

RESULTS

The difference in baseline data

There was no significant difference in age, sex, body temperature, mass diameter or reproductive history between Group S and Group L ($P > 0.05$). As shown in Table 1.

The difference in psychological stress

There was no significant difference in the state-trait anxiety score or SAS + SDS score between the Group S and the Group

Table 1 Comparison of baseline data between the S group and the L group

Baseline data	Group S (*n* = 50)	Group L (*n* = 50)	t/χ^2	*P* value
Age (mean ± SD)	32.2 ± 4.1	33.9 ± 5.3	1.794	0.076
Duration disease (mo, mean ± SD)	14.7 ± 3.2	15.4 ± 2.9	1.146	0.255
Body temperature (°C, mean ± SD)	37.5 ± 1.5	37.7 ± 1.3	0.713	0.478
Diameter of mass (cm, mean ± SD)	5.9 ± 1.9	6.3 ± 1.6	1.139	0.258
Reproductive history [*n* (%)]	46 (82)	43 (86)	0.919	0.338

L at admission ($P > 0.05$). The state-trait anxiety score and SAS + SDS score of Group S were significantly lower than those of Group L after 24-48 h and 48-96 h of anti-infective therapy ($P < 0.05$) (Figure 1).

Differences in intraoperative clinical indicators

There was no significant difference in the incidence of intestinal, ureteral and bladder injuries between the Group S and the Group L ($P > 0.05$). The surgery time of Group S was shorter than that of Group L, and the adhesion score and intraoperative blood loss were lower than those of Group L ($P < 0.05$). As shown in Table 2 and Figure 2.

The difference in postoperative efficacy

There was no significant difference in the incidence of postoperative incision infection, dysmenorrhea, menstrual disorder, or intestinal obstruction between the Group S and the Group L after different durations of anti-infective therapy ($P > 0.05$). Postoperative body temperature was lower in Group S after 24-48 h of anti-infective therapy than in Group L after 48-96 h of anti-infective therapy ($P < 0.05$), and the hospital stay was shorter than that of Group L ($P < 0.05$) (Figure 3). The incidences of recurrence and chronic pelvic pain within 3 mo after surgery in Group S were lower ($P < 0.05$) than that in Group L (Table 3).

DISCUSSION

In the past, pelvic abscesses were often treated with conservative drug therapy[11], that is, long-term repeated use of antibiotics, because antibiotic therapy alone was not only ineffective in achieving a complete cure but could also cause the disease to develop into chronic PID or chronic pelvic abscesses, leading to secondary pelvic adhesion[12]. Therefore, surgery gradually replaced conservative therapy to become the main therapy method. In laparoscopic surgery, the advantages are the small incision, sufficient surgical field, no unnecessary interference, no exposure of abdominal organs to the air, less interference with the pelvic environment, less intraoperative blood loss, and fewer complications[13]. However, a pelvic abscess is an inflammatory reaction caused by a pathogenic bacterial infection. If surgical therapy is carried out directly after diagnosis, it is easy for inflammation to spread and affect the surgical outcome. Preoperative anti-infective therapy can control the spread of systemic inflammation, relieve pelvic abscesses, and facilitate a smooth course of surgery. However, there is no consensus on the optimal duration of preoperative anti-infective therapy.

In our study, the incidences of intraoperative injury and postoperative complications in Group S were lower than that in Group L, but the difference was not statistically significant, which may be related to the small sample size and individual differences between patients. However, the state-trait anxiety score and SAS + SDS score of Group S were statistically lower than those of Group L ($P < 0.05$), indicating that patients who received 24-48 h of anti-infective therapy had less preoperative psychological stress than those who received 48-96 h of anti-infective therapy. This may be because a long duration of preoperative anti-infective therapy diminishes patients' expectations for surgery or because patients have a misunderstanding of their illness. Stevens *et al*[14] showed that the higher the patients' preoperative expectations for surgery, the higher their depression and anxiety scores. Therefore, we speculated that with a prolonged anti-infection treatment time, patients' expectations of the operation effect increased, and they were more likely to have anxiety, depression and other psychological conditions. The study by Kılıç *et al*[15] showed that the longer the treatment time, the heavier the patients' psychological burden. According to this, we believe that a longer period of anti-infection treatment may make patients with pelvic abscesses think that preoperative preparation is not sufficient, their physical weakness cannot withstand the surgical trauma, or their disease will be suddenly worsened, thus causing them to experience worry, anxiety, depression and other adverse emotions. Therefore, we suggest that surgeons pay attention to patients who have undergone anti-infection treatment for an extended period before surgery or have anxiety and depression to be able to provide certain preoperative psychological education if necessary. However, after reviewing a large number of studies, we did not find any correlation between preoperative anti-infective treatment time and preoperative psychological state in patients with pelvic abscesses. Therefore, the specific relationship between preoperative anti-infective treatment time, psychological stress effect and surgical effect in patients with pelvic abscesses needs to be further investigated.

After 24-48 h of anti-infective therapy, the surgery time, adhesion score, intraoperative blood loss volume, postoperative body temperature was significantly lower and the hospital stay was significantly shorter in Group S than those in Group L ($P < 0.05$), indicating that compared with 24-48 h of anti-infective therapy, long-term anti-infective

Table 2 Comparison of intraoperative clinical indicators

Clinical indicators	Group S (n = 50)	Group L (n = 50)	t/χ^2	P value
Surgery time (min)	55.45 ± 16.48	78.78 ± 17.87	2.714	< 0.01
Adhesion score	3.17 ± 0.84	4.04 ± 0.49	6.326	< 0.001
Intraoperative blood loss (mL)	45.54 ± 11.94	72.15 ± 9.21	12.48	< 0.001
Intraoperative intestinal injury	1 (2.00)	3 (6.00)	1.042	0.307
Intraoperative ureteral injury	2 (4.00)	6 (8.00)	2.174	0.140
Intraoperative bladder injury	0 (0.00)	2 (4.00)	2.041	0.153

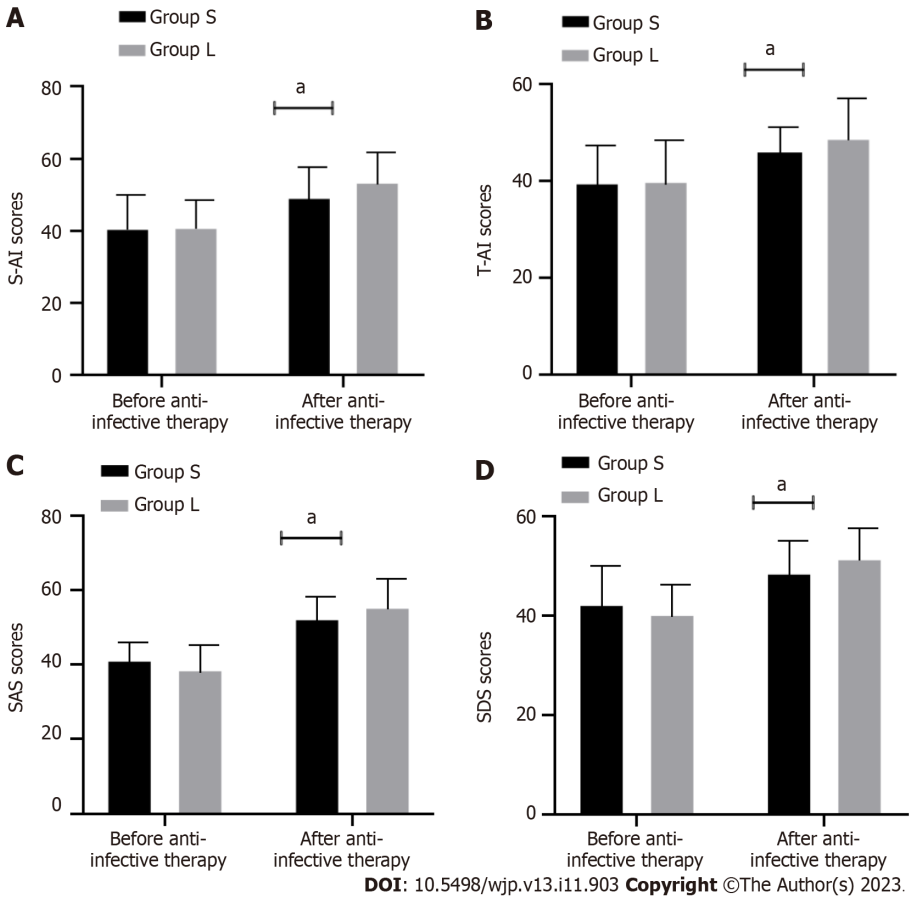

Table 3 Comparison of efficacy

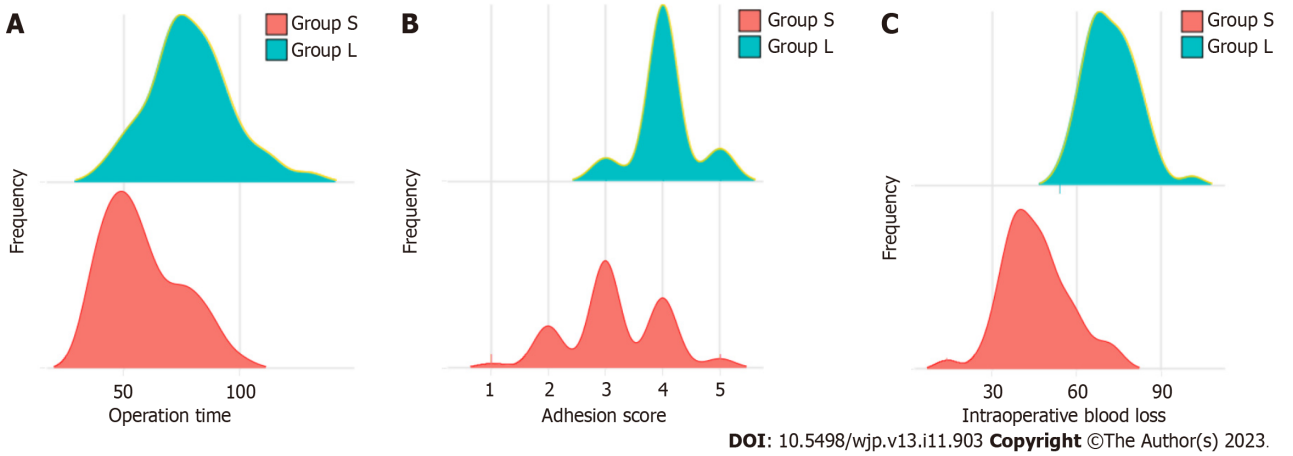
Indicators	Group S (n = 50)	Group L (n = 50)	t/χ^2	P value
Postoperative body temperature	38.02 ± 0.98	38.94 ± 1.37	3.862	< 0.001
Length of stay (d)	7.68 ± 1.41	9.94 ± 2.01	6.509	< 0.001
Tumour recurrence within 3 mo after surgery	1 (2.00)	8 (6.00)	5.983	0.014
Chronic pelvic pain	2 (12.00)	12 (20.00)	8.306	0.004
Incision infection	0 (0.00)	3 (6.00)	3.093	0.079
Dysmenorrhea	5 (10.00)	11 (22.00)	2.679	0.102
Menstrual disorders	2 (4.00)	4 (8.00)	0.709	0.4
Intestinal obstruction	0 (0.00)	1 (2.00)	1.01	0.315

therapy is more likely to produce abdominopelvic adhesion[16]. Adhesions occur in 60% to 90% of gynaecological patients after abdominal pelvic surgery[17], and fibrous connections connecting tissue surfaces at abnormal locations can lead to chronic pelvic pain, infertility, intestinal obstruction, and the need for a complex reoperation[18-20]. In addition, it was found that in patients with long-term anti-infective therapy who underwent laparoscopic surgery, the abdominopelvic adhesion was more serious, the adhesion range was large, and the adhesion was dense, making it difficult to separate and a hindrance to surgery. The reason may be that 24-48 h after anti-infective therapy, the pelvic lesions are mainly composed of inflammatory exudate, and the membranoid adhesion is loose and easy to separate, which is more conducive to the surgery and thus to the postoperative effect. After 48-96 h of anti-infective therapy, inflammatory exudate on the surface of various organs of the patient's body can organize to form fibrin-like adhesion bands. Inflammatory exudates and tissue adhesions with increased density are hindrances to surgery and increase the incidence of postoperative complications. In addition, according to the above findings, we speculate that a smooth course of laparoscopic surgery and its increased efficacy after 24-48 h of anti-infective treatment may be related to the lower degree of psychological stress of patients before surgery. Ki *et al*[21] showed that compared with patients without anxiety before surgery, patients with anxiety before surgery had worse postoperative recovery quality. The researchers noted that anxiety before surgery can affect the quality of physical and mental recovery after surgery. In addition, Park *et al*[22] confirmed that anxiety and depression had a negative impact on the clinical outcome of rotator cuff repair. For the results of this study, we believe that a short period of anti-infection treatment before surgery can reduce the degree of psychological stress of patients before surgery and relieve anxiety and depression to promote a smooth operation and improve its curative effect. However, our views are limited to the research centre and the study population, thus it is necessary to expand the research scope to enhance the reliability of the results of this study.



The data showed that in addition to pelvic pain and incision infection, there were complications such as injury to the surrounding organs in the Group S and the Group L after the surgery, and the incidence of dysmenorrhea was higher, which was mainly related to the difficulty of separation of a thick-walled abscess or the difficulty of removing inflammatory exudates on the surface of organs[23,24]. In addition, surgery may also be one of the reasons for a high incidence of complications. Laparoscopic operators should be aware of potential complications and how to prevent them, strictly adhere to the surgical indications during therapy and learn how to identify complications early to deal with them safely and effectively. In cases of difficult surgery, experienced surgeons are better suited to operate[25,26].

However, our study still has some limitations: (1) The patient data were collected from a single centre, making extrapolation difficult; (2) it is a retrospective study, and the results of our study can only offer recommendations, thus future prospective studies are needed to verify the research findings; and (3) The sample size was small, and there was considerable bias, so a large sample study is still needed to verify the conclusion.

Figure 2 Operation time, adhesion score, and intraoperative blood loss of the two groups. A: Operation time; B: Adhesion score; C: Intraoperative blood loss. The surgery time of Group S was shorter than that of Group L, and the adhesion score and intraoperative blood loss were lower than those of Group L (*P* < 0.05).

CONCLUSION

Compared with 48-92 h, 24-48 h of anti-infective therapy followed by laparoscopic surgery for pelvic abscesses is associated with less psychological stress in patients, is more conducive to surgery, and increases surgical efficacy.

Figure 3 Postoperative body temperature and length of stay of the two groups. A: Postoperative body temperature; B: Length of stay. Postoperative body temperature was lower in Group S after 24-48 h of anti-infective therapy than in Group L after 48-96 h of anti-infective therapy ($P < 0.05$), and the hospital stay was shorter in Group S than in Group L ($P < 0.05$).

ARTICLE HIGHLIGHTS

Research background

Pelvic abscess is a serious pelvic inflammatory disease (PID). It can be caused by a variety of factors, including surgery (*e.g.*, low anterior resection), pelvic visceral perforation, diverticulitis, appendicitis, ischaemic colitis, inflammatory bowel disease, or PID.

Research motivation

Different durations of anti-infective therapy have different effects on patients' psychological state, the difficulty of laparoscopic surgery and surgical efficacy.

Research objectives

The aim of this study was to determine the optimal duration of preoperative anti-infective therapy in patients with pelvic abscesses.

Research methods

This study retrospectively analysed the differences in preoperative psychological stress, intraoperative operation difficulty and postoperative recovery of patients with pelvic abscesses after different durations of anti-infection treatment.

Research results

Among the 100 patients with pelvic abscesses, the patients who received 24-48 h of anti-infection treatment had less preoperative psychological stress, less intraoperative operation difficulty and better postoperative recovery than those who received 48-96 h of anti-infection treatment.

Research conclusions

Through observation, we put forward the theory that 24-48 h of anti-infection treatment is better than 48-96 h of anti-infection treatment for patients with pelvic abscesses undergoing laparoscopic surgery.

Research perspectives

The different effects of anti-infection treatment on patients' preoperative psychological stress and the difficulty and efficacy of laparoscopic surgery in patients with pelvic abscesses were observed.

Abstract

BACKGROUND

The psychological state of patients with post stroke limb movement disorders undergoes a series of changes that affect rehabilitation training and recovery of limb motor function.

AIM

To determine the correlation between motor rehabilitation and the psychological state of patients with limb movement disorders after stroke.

METHODS

Eighty patients with upper and lower limb dysfunction post stroke were retrospectively enrolled in our study. Based on Hospital Anxiety and Depression Scale (HADS) scores measured before rehabilitation, patients with HADS scores ≥ 8 were divided into the psychological group; otherwise, the patients were included in the normal group. Motor function and daily living abilities were compared between the normal and psychological groups. Correlations between the motor function and psychological status of patients, and between daily living ability and psychological status of patients were analyzed.

RESULTS

After 1, 2, and 3 wk of rehabilitation, both the Fugl-Meyer assessment and Barthel index scores improved compared to their respective baseline scores ($P < 0.05$). A greater degree of improvement was observed in the normal group compared to the psychological group ($P < 0.05$). There was a negative correlation between negative emotions and limb rehabilitation ($-0.592 \leq r \leq -0.233$, $P < 0.05$), and between negative emotions and daily living ability ($-0.395 \leq r \leq -0.199$, $P < 0.05$).

CONCLUSION

There is a strong correlation between motor rehabilitation and the psychological state of patients with post stroke limb movement disorders. The higher the negative emotions, the worse the rehabilitation effect.

Key Words: Stroke; Limb movement disorders; Motor rehabilitation; Psychological state; Correlation

Core Tip: Stroke, also known as a cerebrovascular accident, is characterized by an acute and rapid onset and is the most common cerebrovascular disease. Stroke can cause limb dysfunction, resulting in functional limitations. Some people may experience a series of changes in their psychological state after illness, which affects rehabilitation training and recovery of limb function. The results of this study showed a strong correlation between the recovery of limb function with rehabilitation and psychological state of stroke patients. Therefore, it is necessary to pay close attention to psychological changes during rehabilitation, and implement timely adjustments and interventions for future rehabilitation.

INTRODUCTION

Stroke can be subdivided into cerebral hemorrhage and cerebral infarction[1]. It is a clinical emergency that causes ischemic damage to the brain tissue due to the blockage or sudden rupture of small- and medium-sized blood vessels in the brain. According to the most recently published statistics, stroke ranks first as the leading cause of mortality in China, and is the main cause of accidental deaths, except for car accidents and falls from high altitudes[2]. Patients with stroke may experience swallowing and limb dysfunction, and in severe cases, they may lose their ability to take care of themselves, increasing the burden on their families and taking a serious negative toll on their mental health and resilience [3]. Therefore, it is necessary to pay close attention to psychological changes during rehabilitation, and implement timely adjustments and interventions for future rehabilitation and restoring the patient's quality of life.

The current medical disease model incorporates biological, psychological, and social factors. Medical workers should shift their treatment methods from traditional treatments to biological, psychological, and social models[4]. As the patient is anxious and worried when seeking medical treatment, the complex psychological effects can have pathogenic consequences[5]. Therefore, we should pay attention to the patients' psychological states, carefully observe their psychological reactions, and implement targeted psychological interventions based on their characteristics[6]. Related studies have shown that psychological interventions can reduce anxiety, depression, and fear in patients by reducing the heart rate, blood pressure, and catecholamine levels in blood and urine, and alleviate tension during exercise[7]. It can inhibit the activity of nociceptive neurons in the central area of the cerebral cortex, reduce their excitability, increase the pain threshold, and alleviate pain[8].

According to previous reports, there is a correlation between recovery and psychological state of the patient[9]. The better the patient's psychological state, the better will be their limb function recovery, and their quality of life will also improve accordingly[10]. This article mainly studied the correlation between the recovery of limb function owing to rehabilitation and psychological resilience in elderly stroke patients to provide a reference for psychological nursing and quality of life intervention in elderly stroke patients.

MATERIALS AND METHODS

Patient characteristics

Eighty patients with limb dysfunction after stroke who were admitted to the First Affiliated Hospital of Henan University of Science and Technology from May 2022 and May 2023 were retrospectively selected. The inclusion criteria were as follows: (1) A confirmed diagnosis of stroke on head computed tomography or magnetic resonance imaging according to

the diagnostic criteria proposed by the American Heart Association/American Stroke Association for stroke[11]; (2) The course of treatment is more than 21 d, and the condition is stable without recurrence; (3) The patient has a clear sense of autonomy and good cognitive ability; and (4) Patients with limb dysfunction after stroke. The exclusion criteria included: (1) Other serious cardiovascular and cerebrovascular diseases; (2) Patients with malignant tumors; (3) Patients with mental illness; (4) Patients with unstable vital signs; (5) Patients with previous stroke but residual upper and lower limb dysfunction and other sequelae; and (6) Patients with a history of surgery, fractures, arthritis, or pain that affects the recovery of upper and lower limb function. Based on the Hospital Anxiety and Depression Scale (HADS) scores before the start of rehabilitation, the patients were divided into the psychological group (those with HADS scores ≥ 8) and the normal group (those with HADS scores < 8).

Evaluation indices

The HADS index was used to evaluate the psychological state of patients[12]. This is a 14-item scale with seven items rated as anxiety and seven items rated as depression. If the HADS score is ≥ 8, it indicates symptoms of anxiety and depression. If the HADS score is < 8, the patient's psychological state is considered normal.

The Fugl-Meyer assessment (FMA) was used to evaluate the patient's upper and lower limb motor function[13]. There were 50 items with a total maximum score of 100 points. The upper limb score consists of 33 items and 66 points. The lower upper limb score consists of 17 items and with a total of 34 points.

The Barthel index (BI) for activities of daily living[14] was used to assess the patients' daily living abilities. The BI includes 10 items, with a total of 100 points. Except for walking on flat ground and bed-to-chair transfer, the full score was 15 points, whereas the full score for grooming and bathing was 5 points. The remaining items had a total score of 10 points.

Statistical analysis

SPSS 20.0 was used to statistically analyze the data. The measurement data were represented by (mean ± SD), and the *t*-test was used for intergroup comparisons. The counting data is represented in the form of percentage, and χ^2 is used for the intergroup comparisons. Pearson's correlation analysis was used to analyze the relationship between the rehabilitation of limb function and the psychological status of patients as well as the relationship between daily living ability and psychological status. Statistical significance was set at $P < 0.05$.

RESULTS

The comparison of general data

As shown in Table 1, there were no differences between gender (male, 60% *vs* 62.5%), age (65.33 ± 4.59 *vs* 65.90 ± 4.91), body mass index (25.43 ± 2.08 *vs* 25.86 ± 1.74), and course of disease (27.93 ± 7.11 *vs* 27.83 ± 7.88) between the normal and psychological groups ($P > 0.05$). The results showed that most stroke patients with motor disorders were classified as elderly and the duration of the disease was between 1 and 2 mo.

The comparison of motor function between normal and psychological groups

As shown in Figures 1A and B, there was no difference in the FMA scores of the upper and lower limbs between the normal and psychological groups ($P > 0.05$). After 1, 2, and 3 wk of rehabilitation, the FMA scores of the upper and lower limbs improved in both groups ($P < 0.05$). In addition, the FMA scores of the upper and lower limbs in the normal group had more substantial improvement than those in the psychological group ($P < 0.05$).

The comparison of daily living ability between the normal and psychological group

Figure 1C shows that before rehabilitation, there was no difference in the BI scores between the normal and psychological groups ($P > 0.05$). After 1, 2, and 3 wk of rehabilitation, the BI score improved in both groups ($P < 0.05$), and the BI score in the normal group was higher than that in the psychological group ($P < 0.05$).

The correlation between negative emotions and limb rehabilitation

As shown in Table 2, there was a negative correlation between anxiety and upper, lower limb FMA scores at 1-, 2- and 3-wk post rehabilitation ($P < 0.05$). There was a negative correlation between depression and upper, lower limb FMA scores at 1-, 2- and 3-wk post rehabilitation ($P < 0.05$). These results suggested a negative correlation between negative emotions and limb rehabilitation.

The correlation between negative emotions and daily living ability

There was a negative correlation between anxiety and BI scores at 2- and 3-wk post rehabilitation ($P < 0.05$), and there was a negative correlation between depression and BI scores at 1-, 2- and 3-wk post rehabilitation ($P < 0.05$) (Table 3). These results suggest a negative correlation between negative emotions and activities of daily living.

Table 1 The comparison of general data between normal and psychological groups

Index	Normal group (n = 40)	Psychological group (n = 40)	t/χ^2	P value
Gender (male, %)	24 (60%)	25 (62.5%)	-0.053	0.818
Age (yr)	65.33 ± 4.59	65.90 ± 4.91	-0.541	0.590
BMI (kg/m^2)	25.43 ± 2.08	25.86 ± 1.74	-0.997	0.322
Course of disease (d)	27.93 ± 7.11	27.83 ± 7.88	0.060	0.953

BMI: Body mass index.

DISCUSSION

The incidence of cerebrovascular diseases and stroke, which is the most common type of cerebrovascular disease[15], has increased annually, and they generally occur in the younger and middle-aged group[16]. Once affected by stroke, patients with mild disease may experience delayed movement, whereas those with severe disease phenotypes may experience limb dysfunction and even death. Some people may experience a series of changes in their psychological state after illness, which affects rehabilitation training and recovery of limb function[17]. Elderly people have decreased bodily functions, more comorbidities, and a strong psychological dependence on their families[18]. After a period of illness, they not only have to endure the torment of illness but also the inconveniences of life. These patients bear significant psychological pressure as a result.

Many patients find it difficult to complete role conversion in a short time; the rehabilitation training initiative is poor, the effect is not obvious, depression and pessimism appear, psychological resilience becomes affected, and it is easily complicated with acute stress disorder; that is, some separation symptoms, such as mental, movement, and personality dysfunction appear in the early stages of the illness[19]. Those with avoidance and high vigilance towards illness events deliberately avoid the facts about one's own illness, suspect the gaze of others, are unable to control one's emotions and temper, and are prone to irritability, anger, and poor sleep quality[20].

This study used the HADS to evaluate the psychological status of patients with limb movement disorders after stroke and to determine whether they had anxiety and depression before rehabilitation initiation. In previous studies that followed-up stroke patients, it was hypothesized that fear of pain affects post-stroke functional recovery; however, there was no correlation between the two[21]. It is recommended that patients pay attention to their fears and receive reasonable psychological interventions. Related studies suggest that anxiety and depression affect the recovery of limb function in stroke patients[22]. Our study showed that the motor function and daily living ability of stroke patients in the psychological group were lower than those in the normal group after 1-, 2-, and 3-wk of rehabilitation, indicating that anxiety and depression negatively impact the recovery of motor function and daily living ability. Further, our research showed a significant negative correlation between negative emotions such as anxiety and depression, motor function, and self-life ability. This was because patients in the psychological group had a poor psychological state and lacked the ability to withstand stress[23]. They are unable to establish a good buffer time after the illness, which is not conducive to the creation of positive emotions and is even less conducive to the recovery of upper and lower limb function after stroke[24].

Therefore, we should attach importance to the psychological state of patients before rehabilitation, and it is recommended that future studies address the following points to achieve better outcomes: Firstly, rehabilitation plans should be developed to improve patients' quality of life, take effective psychological intervention measures, and observe and evaluate the actual effects. This may be done by equipping dedicated psychologists with the correct resources to strengthen research on the psychological status of stroke patients before rehabilitation. Secondly, optimal treatment methods should be adopted to reduce and eliminate the adverse effects of psychological factors on limb motor function before rehabilitation. Furthermore, attention should be paid to the psychological rehabilitation of patients after discharge and to strengthen follow-up procedures. Finally, the active cooperation between psychologists and rehabilitation physicians must be strengthened to minimize negative psychological impacts.

Our study has several limitations. There are many factors that affect the recovery of limb motor function, and psychological factors are only one of them. This study only considered the effects of anxiety and depression on limb motor function recovery before rehabilitation. Further research is needed to investigate the effects of other factors on recovery of limb motor function. The evaluation of various indices in this study are mostly in the form of a subjective numeric rating scale. At the same time, due to differences in language expression and understanding among ethnic minorities, there may have been errors in the measurement of each indicator. In the future, more objective indicators such as imaging findings should be used to quantify the results more accurately. This study only examined the impact of psychological factors before rehabilitation on limb motor function rehabilitation, without considering the impact of psychological factors, and it did not consider effective psychological intervention measures for adverse psychological outcomes. This must be investigated in the future. Finally, sample size of this study was small, and future multi-center studies with larger sample sizes are needed to confirm this finding.

CONCLUSION

In summary, there is a certain correlation between the psychological state of patients with limb disorders after stroke and their level of limb rehabilitation; the greater the negative emotions, the worse the rehabilitation effect. In clinical practice, healthcare workers can assist in the rehabilitation of patients' limb functions by improving their psychological state, indirectly improving their quality of life.

ARTICLE HIGHLIGHTS

Research background

The rehabilitation of limb function in patients with limb movement disorders after stroke is influenced by their psychological state.

Research motivation
Exploring whether healthcare workers can accelerate the recovery of limb function in stroke patients by improving their psychological state and indirectly improving their quality of life.

Research objectives
The aim of this study was to investigate the correlation between the level of motor rehabilitation and the psychological state of patients with limb movement disorders post stroke.

Research methods
Eighty patients with limb dysfunction after stroke were retrospectively selected. The Fugl-Meyer assessment motor function and Barthel index daily living ability scales were used to investigate limb movement disorders and daily living ability, and a correlation between the two indices and psychological state was observed.

Research results
There was a negative correlation between negative emotions and limb rehabilitation and between negative emotions and daily living ability.

Research conclusions
The better the psychological state of patients with limb movement disorders after stroke, the more significant the rehabilitation effect on limb function recovery.

Research perspectives
When performing limb function rehabilitation in patients with limb movement disorders after stroke, it is necessary to pay attention to the patient's psychological state. A good psychological state can accelerate recovery.

Abstract

BACKGROUND

An acute myocardial infarction (AMI) is often treated with direct coronary intervention and requires home-based rehabilitation. Caregivers of patients with AMI need adequate social support to maintain high-quality care; however, their social support function is low, and relevant indicators for intervention must be identified.

AIM

To analyze the correlation between social support for primary caregivers, their anxiety, and depression, when caring for patients with AMI after interventional therapy.

METHODS

Using convenience sampling, we selected 300 primary caregivers of patients with AMI who had undergone interventional therapy. The Social Support Rating Scale (SSRS), Self-Rating Anxiety Scale (SAS), and Self-Rating Depression Scale (SDS) were used to assess the primary caregivers. A Pearson's correlation analysis was used to analyze the correlations between the SSRS, SAS, and SDS, and a multiple logistic regression analysis was used to analyze the factors influencing the low social support function of primary caregivers. The receiver operating characteristic curve and area under the curve (AUC) were used to evaluate the predictive ability of the SAS and SDS for low social support function in primary caregivers.

RESULTS

Considering the norm among Chinese people, AMI caregivers' objective support, subjective support, support utilization, and SSRS scores were lower, while their SAS and SDS scores were higher. The SSRS scores of female caregivers were higher than those of the male caregivers (t = 2.123, P = 0.035). The Pearson correlation analysis showed that objective support, subjective support, support utilization, and SSRS total scores were significantly correlated with both SAS (r = -0.414, -0.460, -0.416, -0.535) and SDS scores (r = -0.463, -0.379, -0.349, -0.472). Among the 300 AMI caregivers, 56 cases (18.67%) had a low level of support function (SSRS ≤ 22 points). Logistic regression model analysis showed that SAS and SDS were independent risk factors for low social support function of AMI caregivers, regardless of adjustment for other variables (P < 0.05). SAS and SDS predicted that the AUC of AMI caregivers with low support function was 0.84, sensitivity was 67.9 and 71.4, and specificity was 84.0 and 70.9, respectively.

CONCLUSION

The social support function of the primary caregiver of patients with AMI after interventional therapy was lower and negatively correlated with anxiety and depression in the primary caregiver.

Key Words: Acute myocardial infarction; Primary caregivers; Social support function; Anxiety; Depression; Relationship

Core Tip: High levels of social support help caregivers implement care. Intervention in the social support function of the primary caregiver is beneficial for the postoperative recovery of patients with acute myocardial infarction (AMI) after interventional therapy. To find a new intervention direction, we proposed a relationship between the social support function of primary caregivers of patients with AMI, and anxiety and depression; this is a breakthrough in improving the social support function of primary caregivers.

INTRODUCTION

Acute myocardial infarction (AMI) is myocardial necrosis caused by acute or persistent ischemia and hypoxia in the coronary arteries. It is typically characterized by persistent chest pain[1]. Usually, after rest and use of nitrates, patients do not receive complete relief but experience arrhythmia, shock, or heart failure, resulting in loss of daily living ability and serious mental and behavioral disorders. According to relevant surveys and research data, the incidence of AMI in China has increased sharply in recent years, with the average annual number of new cases exceeding 500000[2]. Acute ST-elevation myocardial infarction (STEMI) within 12 h is usually treated with direct coronary intervention[3]. Postoperatively, most patients require home-based rehabilitation and caregiver care. During rehabilitation, the physical and mental state of the caregiver affects the prognosis and degree of recovery of the patient. The patient's condition also affects the physical and psychological states, as well as the quality of the caregiver's life, thus affecting their ability and quality of care[4]. Caregivers experience physical and emotional stress during the long-term care process. As a relative of the patient, the caregiver experiences heavy emotional stress and shoulders financial pressure. Studies have found that if caregivers receive sufficient social support, they can maintain their physical and mental health better and adapt to their caregiving role[5]. Ensuring a high social support function for caregivers has a positive clinical significance for patients' rehabilitation. However, there is a lack of effective intervention strategies to improve caregivers' social support, and more clinical evidence is needed to support the factors related to social support. Research has found that caregivers of patients with AMI often have different negative emotional levels of anxiety and depression[6,7]. Therefore, we propose that the social support function of caregivers of patients with AMI may be related to anxiety and depression. Based on this, we selected 300 primary caregivers of patients undergoing interventional treatment for AMI.

Considering the above, this study aims to investigate the levels of social support, anxiety, and depression among caregivers of AMI patients, and analyze the correlation between the social support function of main caregivers and their anxiety and depression after interventional therapy, to provide a reference for improving the quality of home care.

MATERIALS AND METHODS

Source of research object

Using convenience sampling, we selected 300 primary caregivers of patients with AMI who received concurrent interventional treatment at the Affiliated Hospital of Jiangnan University, between January 2021 and December 2022.

Patients needed to comply with the following conditions: (1) Show AMI symptoms and evidence of myocardial ischemia[8]; (2) Be diagnosed with acute STEMI within 12 h and treated with coronary intervention; and (3) Be 18 years or older. The caregiver was required to meet the following conditions: (1) Be at least 18 years of age; (2) Be the patient's immediate family member and has been caring for the patient for the longest time (*i.e.*, is the patient's primary caregiver); (3) Have normal reading and writing ability and be able to complete the questionnaire independently; and (4) Be aware of this research and voluntarily agree to be investigated. The caregiver could not have the following conditions: (1) Mental abnormalities or intellectual disabilities; (2) Language expression and communication barriers; (3) A history of alcohol or drug dependence; or (4) Be a paid caregiver.

Survey tool

General information questionnaire. Based on a literature review and expert consultation, a general information questionnaire was prepared, which included age, gender, number of hospitalizations, payment method of medical expenses, proportion of out-of-pocket medical expenses to family income, course of the disease, heart function, and daily living ability. Caregivers' general information included age, gender, education level, marital status, relationship with patients, monthly family income, caretaking experience, number of other caregivers, *etc.*, as well as the age of patients, time from onset to admission, and Killip grade.

The Social Support Rating Scale (SSRS)[9] was created by domestic scholar Xiao Shui-Yuan in 1986, to assess the status of people's social support, including subjective support, objective support, and support utilization. The scale comprises three dimensions and ten items, with the total score being the sum of the scores for each item. Higher scores indicate higher levels of social support. The total score is 66 points, of which ≤ 22 points are rated as low level, 23–44 points as medium, and 45–66 points as high. The retest reliability is 0.92, and the reliability and validity of all items are high (Cronbach's α coefficient was 0.89–0.94). The SSRS Chinese norm refers to the work of Zhang *et al*[10], in which a norm established based on the population of the whole country as a sampling population. This is the reference value.

The Self-Rating Anxiety Scale (SAS)[11], developed by Zung in 1971, was used to assess the subjective feelings of patients with anxiety. The scale contains 20 items and the score criteria are as follows: 1 point for no or very little time; 2 points for a small amount of time; 3 points for more time; and 4 points for most of the time. The scores were added together to obtain a rough score, and multiplied by 1.25 to obtain a standard score. The higher the score, the greater the anxiety. The Cronbach's α coefficient of the scale was 0.931.

The Self-Rating Depression Scale (SDS)[12] developed by Zung in 1965 was used to assess the subjective feelings of patients with depression, with a total of 20 items. The scoring criteria for each item were as follows: Occasionally, 1 point; sometimes, 2 points; often, 3 points; and always, 4 points. The total score is rough, and the gross score multiplied by 1.25 equals the standard score. Higher scores indicate more severe depression. The Cronbach's α coefficient of the scale was 0.927. Both SAS and SDS Chinese norms refer to the literature of Kang[13], which provides a norm based on the population of the whole country as a sampling population, and has reference value.

Investigation method

Community doctors or nurses with uniform training conducted household surveys with primary caregivers or invited them to community health service institutions to complete the surveys. The researcher informed the primary caregivers of the purpose, significance, and participation method of the survey and encouraged them to provide their informed consent, which was explained to them in simple and understandable language. Subsequently, the primary caregivers completed the questionnaire. The researchers assisted those with low cultural or language abilities in completing the questionnaires. Questionnaires were completed with confidential information and collected immediately. A total of 329 questionnaires were sent out; 306 questionnaires were returned, and 300 effective questionnaires were obtained; an effective rate of 98.04%.

Quality control

To reduce the risk of privacy disclosure, the respondents were surveyed anonymously. We arranged the questionnaire survey in an independent room, allowed the investigator and primary caregiver to be present during the investigation, and entered the data through double cross-entry and cross-examination.

Statistical analysis

SPSS (version 23.0) was used for the data analysis and processing. Case numbers described counting data; mean ± standard deviation describes measurement data tested by a line test or an F-test; a Pearson's correlation was used to analyze correlation, a multiple linear regression explored risk factors, and receiver operator characteristic curve (ROC) and area under the curve (AUC) predicted ability evaluation; Test level: $\alpha = 0.05$.

Table 1 Comparison of Social Support Rating scale scores of primary caregivers with Chinese norms

SSRS items	SSRS score (*n* = 300)	Chinese norm (*n* = 3342)	*t* value	*P* value
Objective support	7.05 ± 1.6	9.1 ± 3.0	11.690	< 0.001
Subjective support	16.9 ± 5.0	23.5 ± 4.3	25.110	< 0.001
Support utilization	4.7 ± 1.3	7.8 ± 2.0	26.350	< 0.001
Total scores of AMI caregivers	28.56 ± 5.31	40.5 ± 2.8	64.230	< 0.001

SSRS: Social Support Rating scale; AMI: Acute Myocardial Infarction.

Table 2 Comparison of Self Rating Anxiety Scale scores and SDS scores of primary caregivers with Chinese norms

Items	Scores (*n* = 300)	Chinese norm (*n* = 1338)	*t* value	*P* value
SAS	41.26 ± 6.58	29.78 ± 10.07	18.860	< 0.001
SDS	44.16 ± 7.54	33.46 ± 8.55	20.000	< 0.001

SAS: Self Rating Anxiety Scale; SDS: Self Rating Depression Scale.

RESULTS

Primary caregivers had low SSRS

Compared with the Chinese norm, the objective support, subjective support, support utilization, and total scores of AMI caregivers were lower ($P < 0.05$) (Table 1).

The SAS and SDS scores of primary caregivers were higher

Compared with the Chinese norm, the scores of SAS and SDS among caregivers of patients with AMI were higher ($P < 0.05$) (Table 2).

SSRS scores of primary caregivers with different characteristics

There were no differences in the SSRS scores among different age groups, gender, education level, marital status, relationship with patients, monthly family income, caregiving experience, number of other caregivers, age of patients, time from onset to admission, or Killip rating of patients ($P > 0.05$); however, the SSRS scores of female caregivers were higher than those of male caregivers ($P < 0.05$) (Table 3).

Correlation between the SSRS score and SAS score or SDS score

Through the Pearson correlation analysis, objective support, subjective support, support utilization, and total SSRS scores were found to be negatively correlated with SAS (r = -0.414, -0.460, -0.416, -0.535, respectively) and SDS scores (r = -0.463, -0.379, -0.349, -0.472, respectively) ($P < 0.05$) (Table 4).

Multiple regression analysis affecting primary caregiver support function

Among the 300 AMI caregivers, 56 cases (18.67%) had a low level of support function (SSRS ≤ 22 points). We used the support function (1 = low level, 0 = medium-high level) as the dependent variable and the characteristic indicators as self-variables (assigned values are shown in Table 5) of the logistic regression model analysis. SAS and SDS were independent determinants of low support function among AMI caregivers, regardless of adjustment for other variables ($P < 0.05$) (Table 6).

The ability of SAS and SDS scores to predict low social support function in AMI caregivers

The AUC of the SAS and SDS for predicting AMI caregivers with low social support function was 0.84, sensitivity was 67.9 and 71.4, and specificity was 84.0 and 70.9, respectively (Table 7 and Figure 1).

DISCUSSION

At present, the mental health outlook of family caregivers of patients with AMI in China is not optimistic, which directly affects their caring ability. The poor caring ability of caregivers not only affects the condition and prognosis of patients with AMI but also affects their physical and mental health. Therefore, it is necessary to explore the relationship between the social support function of primary caregivers, their anxiety, and their depression.

Table 3 Social Support Rating Scale scores of primary caregivers with different characteristics

Characteristics	Cases	SSRS scores	*t/F* value	*P* value

The occurrence of AMI affects not only patients, but also their families and caregivers[14]. Compared with the norms in China, caregivers' objective support, subjective support, support utilization, and total SSRS scores were lower, while the SAS and SDS scores were higher. This indicates that the social support function of primary caregivers was generally low, and that negative emotions of anxiety and depression were more common, which should be considered. These results confirm those of previous studies[15,16]. The social support function of primary caregivers was generally low, which may be due to an imperfect medical security system and deficiencies in follow-up and community nursing, resulting in less social support for primary caregivers. Additionally, problems such as drug side effects and social discrimination can indirectly lead to primary caregivers' self-isolation and reluctance to seek outside help, thereby greatly reducing the availability of social support. Good social support stems from the need for spiritual comfort and support from family, friends, and community. This situation serves as a warning to medical staff to pay attention to social support, assist primary caregivers in establishing social support systems, and enhance their social support functions.

Anxiety is defined as an inner restlessness and fear with no obvious objective causes, whereas depression is defined as persistent low mood in terms of clinical characteristics of the state of mind. The long-term care of patients with AMI undergoing interventional surgery negatively affects the mental health of their primary caregivers. Because AMI is often associated with varying degrees of dysfunction after surgery, the primary caregiver must provide frequent in-bed turning and back-patting to prevent bedsores and transfer patients between beds and wheelchairs. The primary caregiver takes care of the patient in various aspects, such as daily activities, daily living, and diet, and expends a lot of physical strength, time, and energy, which is extremely costly for the body and mind of the primary caregiver and must be maintained for a long time. Primary caregivers also face personality changes in patients with AMI, which will produce psychological reactions such as helplessness, depression, anger, loneliness, and boredom during the care process, affecting normal emotional functions. Patients who have not fully recovered after surgery may relapse[17]; moreover, their primary caregivers must consider both the patient's condition and the financial burden it brings. Such repeated worries aggravate anxiety and depression.

Social support refers to the help people receive from society or others through their social networks; it includes objective support, subjective support, and support utilization. According to the results of our Pearson's correlation analysis, objective support, subjective support, support utilization, and total SSRS scores were significantly negatively correlated with SAS and SDS scores, suggesting that with the increase in anxiety and depression among primary caregivers of patients with AMI, their social support function is lower, which is consistent with some existing research results[18,19]. Further, our multiple linear regression analysis found that the SAS score [odds ratio (OR) = 1.194] and SDS score (OR = 1.072) were independent influencing factors of low social support function in primary caregivers; these two indicators could accurately predict the risk of low social support, and the sensitivity and specificity of the prediction reached more than 65%. The results showed that, after excluding other interfering factors, the lower the anxiety and depression experienced by the primary caregiver, the stronger the social support function. A possible explanation for this effect is that the lower the social support function of the primary caregiver, the greater the caring burden[20], and the more likely it is to produce anxiety and depression. Research also shows that good social support can not only promote the physical health of caregivers, but also effectively relieve their depression and anxiety[13]. According to research by the Chinese Academy of Social Sciences, social support can not only improve the psychological satisfaction of the body, but also alleviate its negative emotions[21]. Therefore, the community should not only pay attention to the primary caregivers of AMI patients undergoing interventional surgery, but should also strengthen the care and help of caregivers by providing adequate psychological support and encouragement. Family visits, caregiver experience exchange platforms, rehabilitation guidance, and other measures can reduce the burden on caregivers, improve the mental health of caregivers and patients, and achieve a win–win outcome.

The limitations of this study is that it is a single-center study, and the results can only reflect part of the population; therefore, whether it can be generalized to the general population is unknown. Further, the inclusion of characteristic indicators of primary caregivers is limited, meaning that potential impact indicators may have been overlooked. Therefore, future studies should include multi-center data and add characteristic indicators to enhance the reliability of the results of this study.

CONCLUSION

The social support function of the primary caregiver of patients with AMI after interventional therapy was low and negatively correlated with anxiety and depression of the primary caregiver. For primary caregivers with anxiety and depression, timely attention and providing a deep examination of underlying issues should be provided to reduce adverse emotional distress, so that the caregiver can maintain a happy mood and implement care.

ARTICLE HIGHLIGHTS

Research background

After interventional therapy, most patients need care at home, from their caregivers. The social support function of primary caregivers is an important factor affecting the quality of care and prognosis of patients. Primary caregivers often experience varying degrees of anxiety and depression.

Research motivation

It is necessary to understand the correlation indicators of primary caregivers' social support functions to better guide clinical interventions. Considering that primary caregivers tend to have different levels of anxiety and depression, we speculate that their social support function may be related to anxiety and depression.

Research objectives

To explore the relationship between anxiety, depression, and the social support function of primary caregivers of patients with acute myocardial infarction (AMI) undergoing interventional surgery.

Research methods

Investigate the primary caregivers of AMI patients undergoing interventional surgery using the Social Support Rating Scale (SSRS), Self-Rating Anxiety Scale (SAS), and Self-Rating Depression Scale (SDS). The correlation between the SSRS and SAS or SDS was evaluated using a Pearson's correlation analysis, multiple linear regression, receiver operator characteristic curve (ROC), and area under the curve (AUC).

Research results

The SSRS was negatively correlated with the SAS and SDS scores. SAS and SDS were independent factors for low SSRS and could predict the risk of low SSRS.

Research conclusions

The social support function of primary caregivers of AMI patients undergoing interventional surgery is associated with anxiety and depression.

Research perspectives

Based on the Pearson's correlation analysis, multiple linear regression, ROC, and AUC, we comprehensively analyzed the correlation between the SSRS, SAS, and SDS scores of primary caregivers of patients with AMI who underwent interventional surgery, confirming that the social support function of primary caregivers is closely related to anxiety and depression, which is instructive for clinical intervention.

Abstract

BACKGROUND

Observational studies have suggested that depression is associated with sarcopenia. However, the causal relationship between depression and sarcopenia remains unclear.

AIM

To investigate the causal relationship between depression and sarcopenia.

METHODS

We performed a Mendelian randomization (MR) analysis to identify the bidirectional relationship between depression and sarcopenia-related traits. Summary-level data and independent variants used as instrumental variables came from large genome-wide association studies of depression (414055 cases and 892299 controls), of appendicular lean mass (ALM, 450243 participants), and of hand grip strength (exposure: 360000 participants; outcome: 334925 participants).

RESULTS

We identified a negative association of depression with lower ALM [odds ratio (OR): 0.932, 95% confidence interval (95%CI): 0.889-0.979, $P = 0.005$]. In the reverse MR analysis, we also observed an inverse association of hand grip strength with depression (OR: 0.200, 95%CI: 0.108-0.370, $P < 0.001$). Similar results were obtained in sensitivity analyses.

CONCLUSION

Depression was causally related to decreased muscle mass, and declined muscle strength might lead to a higher risk of depression.

Key Words: Appendicular lean mass; Depression; Hand grip strength; Mendelian randomization; Older adults; Sarcopenia

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: In this Mendelian randomization study, we established a bidirectional relationship between depression and reduced muscle mass, specifically lower appendicular lean mass and hand grip strength. Our findings highlight a potential bidirectional relationship between depression and sarcopenia with implications for both mental and physical health.

INTRODUCTION

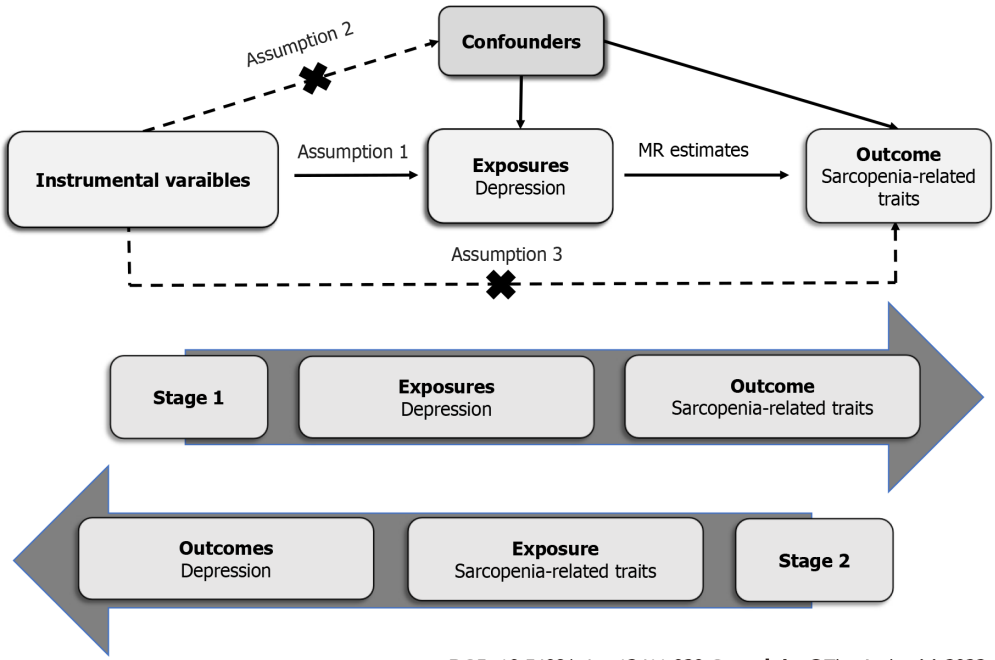
Sarcopenia is a complex geriatric disorder marked by a gradual and progressive reduction of skeletal muscle mass, decrease in skeletal muscle strength, and deterioration in physical performance[1]. In addition to elevating the risks of disability, sarcopenia also relates closely to a wide range of adverse consequences, such as falls, hospitalization due to fall-related injuries, and even mortality[2,3]. As the population ages, the prevalence of sarcopenia increases, making it an important public health issue and a global health burden. In addition, depression is common among the elderly, with an average 12-mo occurrence rate of approximately 6%. This is related to negative health consequences, including increased mortality and reduced quality of life[4,5]. Thus, depression and sarcopenia are important concerns for the elderly population, and it is crucial to establish a clear understanding of their relationship.

Numerous observational studies have suggested that depression and sarcopenia are common comorbidities, but there is no direct evidence of causality[6-8]. In a clinical trial investigating sarcopenia as a therapeutic target, the management of sarcopenia was found to be associated with a notable reduction in depressive symptoms[9]. Some studies have suggested that skeletal muscle may influence psychiatric illnesses through neurotrophic factors[10]. However, those studies were unable to provide convincing evidence to elucidate a null association for the effect of depression on sarcopenia.

Mendelian randomization (MR) represents a compelling genetic epidemiological approach that utilizes genetic variants associated with exposures, which can effectively avoid the potential methodological limitations of observational studies, including reverse causation bias. We conducted this bidirectional MR study to examine the causal relationship between depression and sarcopenia.

MATERIALS AND METHODS

Study design



The diagram of this MR study is displayed in the Figure 1. The genetic variations selected as instrumental variables (IVs) were based on three predominant assumptions: (1) Selected IVs are strongly associated with exposures; (2) There is no observed association between the IVs and potential confounding factors; and (3) The IVs affect outcomes only through exposures without any other pathways[11].

IVs

The IVs for the MR analyses were derived from several different genome-wide association studies (GWASs). Single nucleotide polymorphisms (SNPs) were chosen as IVs when the SNPs for exposures reached genome-wide significance ($P < 5.0 \times 10^{-8}$). All IVs were clumped for independence (linkage disequilibrium $r^2 < 0.1$; region size, 3000 kb) according to the European data from the 1000 Genomes Project. If the SNPs for exposures were not available in the outcome datasets, proxy SNPs (linkage disequilibrium $r^2 > 0.8$) were adopted online (ldlink.nci.nih.gov/). Palindromic SNPs were excluded in the analyses when harmonizing the directions of SNP effects on exposures and outcomes. We also calculated the F-statistics to assess the instrument strength. IVs with F-statistics < 10 were considered to have a weak instrument bias.

Data sources

Genetic IVs associated with depression were obtained from a GWAS meta-analysis that included 414055 cases and 892299 controls from the UK Biobank, 23andMe_307k, and PGC_139k[12]. In the UK Biobank cohort, the depression phenotype, referred to as "broad depression," was determined based on self-reported responses to a web-based questionnaire. In the cohort from 23andMe_307k, the depression phenotype was determined based on self-reported information regarding clinical diagnosis or treatment for depression. In PGC_139k, the depression phenotype was clinically diagnosed. In total, this GWAS identified 102 independent SNPs located at 101 Loci that were associated with depression at a level of

Figure 1 Principles of the Mendelian randomization study for depression and sarcopenia-related traits. MR: Mendelian randomization.

genome-wide significance, which led to an 8.9% variance in depression.

Appendicular lean mass (ALM) and hand grip strength were selected as a measure of muscle mass and strength. Unlike whole body lean mass, ALM is primarily affected by skeletal muscle and is recommended by the European Working Group on Sarcopenia in Older People due to its high predictive power for sarcopenia-related health outcomes [1]. The summary statistic for ALM was obtained from a GWAS of the UK Biobank (n = 450243)[13]. That GWAS had measured ALM by bioelectrical impedance analysis (BIA) for fat-free mass at the arms and legs. The summary statistic for hand grip strength was obtained from the UK Biobank (nealelab.is/uk-biobank) and included approximately 360000 participants from Europe. Right-hand grip strength (n = 359729) and left-hand grip strength (n = 359704) were meticulously assessed using a calibrated Jamar J00105 hydraulic hand dynamometer adjusted to accommodate hand size variations. We derived 139 independent genetic IVs associated with hand grip from a GWAS from the UK Biobank, which included 334925 individuals[14]. These variants accounted for 1.7% of the variability in grip strength. In this study, relative grip strength was applied, as it may show a better correlation with physical capability than absolute hand grip strength.

Each study incorporated in the GWAS used in the present study was approved by local research ethics committees or Institutional Review Boards, and all participants had given their informed consent.

Statistical analysis

In the main analyses, the random-effects inverse-variance weighted (IVW) approach was applied to evaluate a bidirectional relationship between depression and sarcopenia-related traits[15]. In addition, several sensitivity analyses were also conducted to identify potential pleiotropy. Cochran's Q test was used to assess the heterogeneity among various IVs. The weighted median method was used to include only valid IVs, allowing less than 50% of the genetic variants to be invalid IVs[16]. The MR-Egger method was conducted to detect and correct for any pleiotropic bias[17]. Furthermore, we used the MR Pleiotropy Residual Sum and Outlier (MR-PRESSO) method to conduct a global test of heterogeneity and to identify horizontal pleiotropy. Any identified SNPs with pleiotropic effects were excluded, and a repeated IVW analysis was subsequently performed to ensure the robustness of the results[18].

All tests were two-sided, and the Bonferroni-corrected significance threshold was set to $P \leq 0.01$ (correcting for 5 outcomes) to account for multiple comparisons. The P values ranging from 0.05 to 0.01 were considered to be suggestive of a potential association between exposures and outcomes. All analyses were conducted using TwoSampleMR and MR-PRESSO packages in R software (Version 4.1.3).

RESULTS

The main characteristics of all SNPs adopted in the MR analyses are shown in Table 1. The F-statistics for all IVs were higher than the threshold of 10, indicating the absence of weak instrument bias in the present study. The summary information of SNPs for the three traits is displayed in Supplementary Tables 1 and 2. The results of Cochran's Q tests and MR-Egger regression are shown in Table 2.

Table 1 Studies and datasets adopted in the Mendelian randomization analyses

Trait	Data source	Sample size, cases/controls	Ancestry
Depression	UK Biobank[1]	127552/233763	European
	23andMe_307K[2]	75607/231747	
	PGC_139K[3]	43204/95680	
	Replication	474574/1032579	
Appendicular lean mass	UK Biobank[1]	450243	European
Hand grip strength, exposures	UK Biobank[1]	Approximately 360000	European
Hand grip strength, outcomes	UK Biobank[1]	334925	European

[1]UK biobank: (1) The broad definition of depression was used in the UK Biobank. Measured in a variety of ways, as follows: Have you ever seen a general practitioner for nerves, anxiety, tension or depression? and have you ever seen a psychiatrist for nerves, anxiety, tension or depression? and (2) Does not include the participants who were identified with bipolar disorder, schizophrenia, or personality disorder using self-declared data as well as prescriptions for antipsychotic medications.
[2]23andMe_307k: (1) The data were derived from the genome-wide association study results from the 23andMe Interactive Discovery projects; and (2) Depression was defined based on responses to web-based surveys, with individuals that self- reported as having received a clinical diagnosis or treatment for depression classified as cases.
[3]PGC_139k: (1) The PGC_139k cohort was obtained from the meta-analysis of major depressive disorder utilizing European-ancestry PGC cohorts with the 23andMe_307k and the previous UK Biobank cohorts removed; and (2) Depression was defined based on structured diagnostic interviews, or electronic medical records, with individuals that self-reported as having received a clinical diagnosis or treatment for depression.

Table 2 Results of potential pleiotropy and heterogeneity assessments in the bidirectional analyses

Parameter	Cochran's Q	*P* for Cochran's Q	Intercept	*P* for intercept
Outcome				
Appendicular lean mass	911.568	< 0.001	-0.002	0.602
Left hand grip strength	409.92	0.004	0.002	0.486
Right hand grip strength	379.511	< 0.001	0.002	0.243
Exposure				
Appendicular lean mass	1401.776	< 0.001	0.001	0.953
Hand grip strength	306.463	< 0.001	0.003	0.887

In the random-effect IVW estimates, genetically determined depression was causally associated with lower ALM [odds ratio (OR): 0.932, 95% confidence interval (95%CI): 0.889–0.979, $P = 0.005$; Figure 2]. This association was robust in the weighted median. The MR-PRESSO analysis identified 18 potential SNP outliers. After removing the outliers, the result was similar. There was significant association of depression with left hand grip and right hand grip (OR: 0.962, 95%CI: 0.936–0.989, $P = 0.007$; OR: 0.961, 95%CI: 0.935–0.987, $P = 0.004$). However, these results were not confirmed in the sensitivity analyses. Several potential SNP outliers were identified in the MR-PRESSO tests. After removing the outliers, the results remained significant.

A significant association was observed between decreased ALM and depression (OR: 0.969, 95%CI: 0.947–0.992, $P = 0.047$; Figure 3). In the sensitivity analyses, weighted median and MR-Egger tests revealed similar effects but with broader confidence intervals. Nine SNPs were detected in the MR-PRESSO test. After removing outliers, the result indicated a suggestive association (OR: 0.978, 95%CI: 0.957–0.999, $P = 0.044$). In addition, genetically determined hand grip strength was causally associated with depression by the IVW method (OR: 0.200, 95%CI: 0.108–0.370, $P < 0.001$). The weighted median method yielded similar results despite the MR-Egger test revealing a null association. In the MR-PRESSO test, three outliers were identified and removed, and the result remained significant.

DISCUSSION

We performed this MR study to explore the bidirectional causal association between depression and sarcopenia. In the forward MR analyses, depression was associated with decreased ALM. Results from IVW suggested that decreased ALM was associated with depression and that depression was associated with lower hand grip strength. However, these results could not be repeated in sensitivity analyses. In the reverse MR analyses, lower hand grip strength was associated with a higher risk of depression. Overall, we reported a significant bidirectional association between depression and

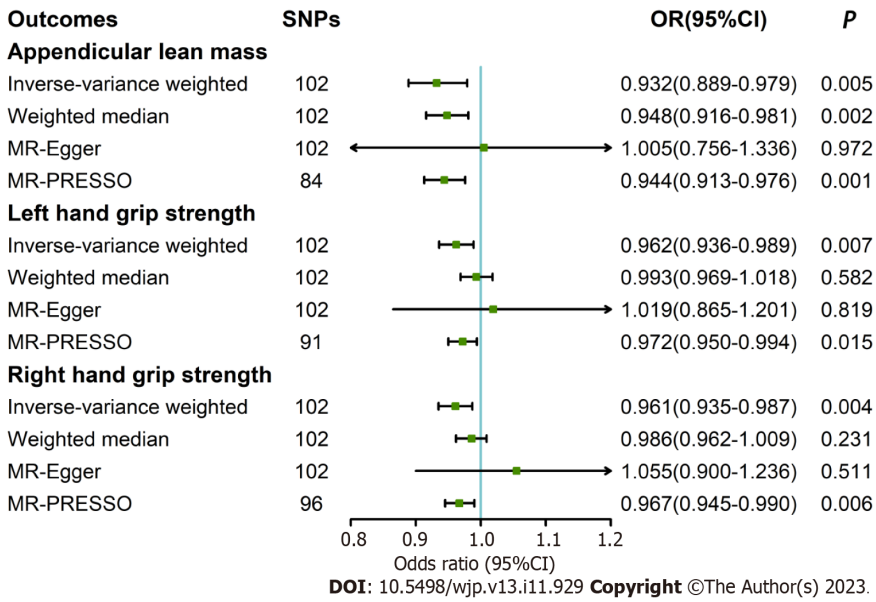

Figure 2 Effect of depression on sarcopenia-related traits. 95%CI: 95%confidence interval; OR: Odds ratio; PRESSO: Pleiotropy Residual Sum and Outlier; SNPs: Single nucleotide polymorphisms.

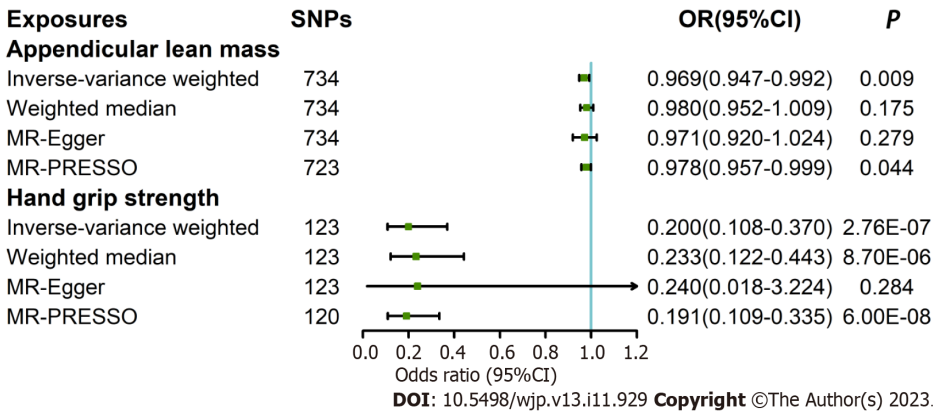

Figure 3 Effect of sarcopenia-related traits on depression. 95%CI: 95%confidence interval; OR: Odds ratio; PRESSO: Pleiotropy Residual Sum and Outlier; SNPs: Single nucleotide polymorphisms.

sarcopenia.

Previous observational studies, mainly cross-sectional in design, suggested that there was a positive association between depression and sarcopenia[8,19-22]. Two meta-analyses included also drew the conclusion that the prevalence of depression in patients with sarcopenia is higher than in the general population[6,7]. Despite considering many common covariates, these studies were still unable to provide evidence of causality between the two conditions. A recent longitudinal study comprising 115601 older adults reported that higher hand grip strength was associated with a lower risk of depression among older adults[23]. Similar results were also drawn from a 7-year prospective cohort study conducted in China[24]. Although this topic has received widespread attention, few studies have investigated the effect of depression on sarcopenia. Overall, our MR study provided evidence that depression and sarcopenia are possibly connected in a bidirectional manner, whereas previous studies primarily focused on investigating the effect of depression on sarcopenia in a unidirectional manner.

The exact mechanism between depression and sarcopenia remains inconclusive. However, there are several potential connections between the two conditions. First, in the original GWAS of hand grip strength, expression quantitative trait loci analyses revealed multiple genes associated with neurodevelopmental disorders or brain function[14]. The results of a meta-analysis demonstrated a significant enrichment of gene expression of brain-related transcripts[14]. In another study, researchers used twin data from China to explore the genetic overlap between depression and grip strength[25]. They observed potential genetic correlations, SNPs, genes, and pathways common to both conditions, which indicates a shared genetic basis[25]. Second, some studies have suggested that brain-derived neurotrophic factor secreted by skeletal muscle may play a role in depression and anxiety[10]. Brain-derived neurotrophic factor drives hippocampal neurogenesis, and the hippocampus is a key region of the brain implicated in psychiatric illness[26]. Third, chronic inflammation could potentially serve as a shared risk factor for both depression and sarcopenia[27]. Inflammatory biomarkers,

such as C-reactive protein and interleukin 6, are negatively associated with ALM[28]. Meanwhile, increased C-reactive protein and interleukin 6 are also associated with future depression[29]. This could be attributed to increased inflammatory cytokines in patients with sarcopenia, which could negatively impact the central nervous systems of older adults leading to a depressed mood and reduced mobility[27]. Finally, patients with depression are typically lacking in physical activity, which is a well-known factor leading to sarcopenia[30]. These findings collectively supported the conclusion of our current MR analysis, indicating a bidirectional relationship between depression and sarcopenia.

One of the key strengths of this analysis was the utilization of well-powered GWAS data for depression and sarcopenia-related traits. The implementation of a bidirectional MR design allowed for a comprehensive evaluation of the mutually causal relationship. Nevertheless, there are several limitations that need to be addressed. First, sample overlap between the exposure and outcome populations might potentially influence the study results. There was also a study, however, supporting the applicability of a single large dataset from large biobanks in two-sample MR studies[31]. Second, ALM was not directly measured by the BIA equipment but was estimated based on whole-body electrical conductivity. The estimates of BIA can be influenced by factors such as age, ethnicity, hydration status, and other related discrepancies. All of these factors may subsequently influence the MR results. Third, in the original GWAS the authors reported that they used the broad definition of depression in the cohort of the UK Biobank. This reporting mechanism differed from the self-declared clinical depression phenotype of the 23andMe_307k cohort and the clinically obtained phenotype of the PGC_139k cohort. This difference may have an impact on the results of the MR analysis. Fourth, the population in our study was restricted to Europe, which limits the generalizability of our findings to non-European populations. Finally, potential directional pleiotropy may contribute to bias in the estimation of causal inference even though MR-Egger regression and MR-PRESSO methods were applied.

CONCLUSION

We provided evidence of a bidirectional association between depression and sarcopenia. Depression was causally related to decreased muscle mass. Meanwhile, declined muscle strength might lead to a higher risk of depression. Our study highlighted the importance of assessing sarcopenia and depression among older adults to understand and address the interplay between physical and mental health.

ARTICLE HIGHLIGHTS

Research background

Sarcopenia is a complex geriatric disorder marked by a gradual and progressive reduction of skeletal muscle mass, decrease in skeletal muscle strength, and deterioration in physical performance. Depression is also common among the elderly. Observational studies have suggested that depression is associated with sarcopenia.

Research motivation

The causal relationship between depression and sarcopenia remains unclear.

Research objectives

To investigate the causal relationship between depression and sarcopenia.

Research methods

We performed a Mendelian randomization (MR) analysis to identify the bidirectional relationship between depression and sarcopenia-related traits. Summary-level data and independent variants were used as instrumental variables that came from large genome-wide association studies of depression (414055 cases and892299 controls), of appendicular lean mass (ALM, 450243 participants), and of hand grip strength (exposures: 360000 participants; outcomes: 334925 participants).

Research results

We identified a negative association of depression with lower ALM. In the reverse MR analysis, we also observed an inverse association of hand grip strength with depression. Similar results were obtained in the sensitivity analyses.

Research conclusions

Depression was causally related to decreased muscle mass. Declined muscle strength might lead to a higher risk of depression.

Research perspectives

Our findings highlighted a potential bidirectional relationship between depression and sarcopenia with implications for both mental and physical health.

ACKNOWLEDGEMENTS

The authors thank the participants in the UK Biobank for their contribution to the study.

Abstract

BACKGROUND

Schizophrenia is a psychiatric disorder characterized by chronic or recurrent symptoms. Lurasidone was licensed in China in 2019 for the treatment of adult schizophrenia in adults with a maximum dose of 80 mg/d. However, post-market surveillance (PMS) with an adequate sample size is required for further validation of the drug's safety profile and effectiveness.

AIM

To conduct PMS in real-world clinical settings and evaluate the safety and effectiveness of lurasidone in the Chinese population.

METHODS

A prospective, multicenter, open-label, 12-wk surveillance was conducted in mainland China. All patients with schizophrenia from 10 sites who had begun medication with lurasidone between September 2019 and August 2022 were eligible for enrollment. Safety assessments included adverse events (AEs), adverse drug reactions (ADRs), extrapyramidal symptoms (EPS), akathisia, use of EPS drugs, weight gain, and laboratory values as metabolic parameters and the QTc interval. The effectiveness was assessed using the brief psychiatric rating scale (BPRS) from baseline to the end of treatment.

RESULTS

A total of 965 patients were enrolled in the full analysis set and 894 in the safety set in this interim analysis. The average daily dose was 61.7 ± 19.08 mg (mean ± SD) during the treatment. AEs and ADRs were experienced by 101 patients (11.3%) and 78 patients (8.7%), respectively, which were mostly mild. EPS occurred in 25 individuals with a 2.8% incidence, including akathisia in 20 individuals (2.2%). Moreover, 59 patients received drugs for treating EPS during the treatment, with an incidence of 6.6% which dropped to 5.4% at the end of the treatment. The average weight change was 0.20 ± 2.36 kg (P = 0.01687) with 0.8% of patients showing a weight gain of ≥ 7% at week 12 compared with that at the baseline. The mean values of metabolic parameters and the QTc interval at baseline and week 12 were within normal ranges. The mean changes in total BPRS scores were -8.9 ± 9.76 (n = 959), -13.5 ± 12.29 (n = 959), and -16.8 ± 13.97 (n = 959) after 2/4, 6/8, and 12 wk, respectively (P < 0.001 for each visit compared with the baseline) using the last-observation-carried-forward method.

CONCLUSION

The interim analysis of the PMS of adult patients with schizophrenia demonstrate the safety and effectiveness of lurasidone in the Chinese population. No new safety or efficacy concerns were identified.

Core Tip: We conducted the first post-marketing surveillance of the actual use of lurasidone in the treatment of patients with schizophrenia in real-world clinical practice since the drug was licensed in mainland China in 2019, and evaluated the safety profile and effectiveness of lurasidone in Chinese population. Here, we report an interim analysis based on 965 patients who received the medication between 2019 and 2022. This study hold significance as it contributes additional safety and effectiveness data on lurasidone beyond what was gathered in pre-marketing trials. Furthermore, it provides valuable reference information for clinical decision-making of schizophrenia treatment.

INTRODUCTION

Schizophrenia is a psychiatric disorder marked by chronic or recurrent symptoms, often resulting in an impairment of social and occupational functioning. The characteristics of schizophrenia typically include incoherent or illogical

thoughts, delusions, hallucinations, unusual behaviors, and cognitive impairment[1]. Its global prevalence is approximately 1%, with an incidence of about 1.5 per 10000[2]. It is a highly disabling and costly condition, ranking among the top 10 burdensome diseases[3].

The goal of schizophrenia treatment is to reduce acute symptoms and prevent recurrence while maximizing the patient's quality of life[4]. Lurasidone is a second-generation antipsychotic drug with a high affinity for dopamine D_2, serotonin 5-$HT_{2A,}$ and 5-HT_7 receptors and a low affinity for H_1 and 5-HT_{2C} receptors. It is considered to be associated with relatively less side effects[5-7].

Lurasidone was licensed in mainland China in 2019 for the treatment of schizophrenia in adults, with a maximum dose of 80 mg/d. A series of clinical studies have been conducted to verify its efficacy and safety[8,9] and numerous clinical experiences have been accumulated for Chinese patients with schizophrenia since the launch. However, a post-market surveillance (PMS) for the drug with an adequate sample size is also required by the Chinese government. This study thus aimed to conduct a surveillance of the actual use of lurasidone among Chinese patients with schizophrenia in real-world clinical practice and evaluate the safety profile and effectiveness of the drug in the Chinese population. Here, we report an interim analysis based on 965 patients who received lurasidone between 2019 and 2022.

MATERIALS AND METHODS

Study design and population

This study represents an interim analysis of a 12-wk, prospective, observational, multi-center, open-label PMS conducted in China. Patients with schizophrenia from 10 sites across China who had begun treatment with Latuda® between September 2019 and August 2022 were enrolled. The patients were required to provide informed consent before participating. An electronic data capture system was used for the collection of diagnostic and treatment information such as details on drug use, adverse events (AEs), and other related parameters including but not limited to laboratory examinations. All patients who met the inclusion requirement were included in the full analysis set (FAS), whereas the safety set (SS) consisted of patients who had received at least one treatment and had data on safety indicators recorded after the treatment. The study protocol was approved by the ethics committees of Shanghai Mental Health Center (the leading site) and other sites.

Dose and concomitant therapy

The administered dose of lurasidone was decided by the treating physicians, typically initiating at 40 mg/d with no requirement for titration. Depending on the treatment response and tolerability, the dose could be increased to a maximum daily dose of 80 mg/d, according to the approved prescribing information in China (a dose of 160 mg/d is approved overseas). Because this study was non-interventional, concomitant therapy deemed essential by the physician was permitted and reported on the electronic Case Report Form, including but not limited to antipsychotic drugs, mood stabilizers, antidepressants, anxiolytics, and antiepileptics.

Safety evaluation

Safety analyses were based on the SS and evaluated by the frequency and severity of AEs that occurred during the trial. AEs were coded according to the International Council for Harmonisation International Dictionary of Medical Terms (MEDDRA 24.0, Medical Dictionary for Regulatory Activities). Assessments were made at visit 1 (week 0), visit 2 (weeks 2-4), visit 3 (weeks 6-8), and visit 4 (week 12) and were reported by the treating physicians. The assessment included the incidence of total AEs, extrapyramidal symptoms (EPS), akathisia, use of EPS drugs, and mean changes in weight from baseline. Adverse drug reactions (ADRs) were defined as AEs for which the participating physicians could not rule out lurasidone as the cause.

Effectiveness evaluation

The assessment of effectiveness was based on FAS and assessed by the change in the overall brief psychiatric rating scale (BPRS) score relative to the baseline at weeks 2-4/ weeks 6-8, and week 12. The BPRS is a scale that was created to assess clinical changes in patients with schizophrenia, with 18 items designed to represent discrete symptom areas. Items are rated on a 7-point Likert scale, from 1 = "not present" to 7 = "extremely severe", with the total scores ranging from 18 to 126 (calculated by summation of the item scores). The BPRS evaluates five areas: Anxiety-depression, anergia, thought disturbance, activation, and hostility-suspiciousness. Scores for the 5-factor model were also calculated[10].

Statistical analysis

The data were in the form of descriptive statistics as the study was non-interventional and were analyzed using R software version 4.1.0 (The R Foundation for Statistical Computing, Vienna, Austria). Categorical variables are presented as frequencies and proportions and shown as *n* (%). Continuous variables are presented as mean ± SD and compared using paired *t*-tests, with $P < 0.05$ indicating statistical significance. Effectiveness endpoint data were analyzed using the last-observation-carried forward (LOCF) approach for the missing values.

Biostatistics statement

The statistical methods of this study were reviewed by a member of the Biostatistical Service from the Shanghai Medical Insight Technology Co., Ltd.

RESULTS

Patient characteristics and baseline demographics

A total of 965 participants were enrolled in the FAS. The SS comprised 894 participants after excluding 71 patients owing to a lack of AE documentation (Figure 1).

The baseline demographics showed that 39.2% of the patients were male and 60.8% were female. The average age was 35.4 ± 14.27 years and 7.5% of the patients were aged < 18 years. The average height was 166.1 ± 7.97 cm and average body weight was 66.0 ± 13.86 kg. Overall, 55.3% of the patients had obtained antipsychotic medication within 1 mo prior to the baseline (Table 1).

Dosing and concomitant medication

In the FSA comprising 965 patients, the mean exposure level of lurasidone was 5547.5 ± 3477.04 mg with 88.4 ± 40.98 exposure days and an average daily dose of 61.7 ± 19.08 mg during treatment. A total of 57.3% of the 949 participants in the FAS received concomitant medication during the surveillance, comprising drug (n = 520, 54.8%) and non-drug (n = 156, 16.4%) therapies. The number and proportion of patients in each treatment category are detailed in Table 2.

Safety of lurasidone

Overall, 101 (11.3%) and 78 (8.7%) of the 894 patients in the SS cohort developed AEs and ADRs, respectively. Most of these were mild AEs (n = 87, 9.7%) and ADRs (n = 65, 7.3%). Fourteen (1.6%) and 12 (1.3%) patients developed AEs and ADRs, respectively, prompting discontinuation, whereas the presence of SAEs was only reported in one patient (Table 3). According to the System Organ Class (SOC) classification, the most common SOC AEs were investigations and nervous system disorders, and the most frequent AEs were akathisia (n = 22, 2.5%), blood prolactin increased (n = 21, 2.3%), and nausea (n = 9, 1.0%) (Supplementary Table 1).

EPS: EPS ADRs occurred in 25 patients (2.8%); of these, 2.2% experienced akathisia, 0.8% acute dystonia, and 0.2% parkinsonism, as demonstrated by the subgroup analysis. No reports of tardive dyskinesia or other EPS ADRs occurred during treatment (Table 4).

Use of EPS drugs: In the SS, 59 of 894 participants used EPS drugs to reduce the incidence and severity of extrapyramidal side effects during the treatment period. The incidence was 6.6%, which dropped to 5.4% at the end of the treatment. The most frequent EPS drug used was Benzhexol, which was used by 46 patients (5.1%).

Weight gain: The mean body weights of the patients at baseline and week 12 were 66.21 ± 14.01 kg and 66.21 ± 13.70 kg, respectively, resulting in a mean weight change of 0.20 ± 2.36 kg. This weight change demonstrated statistical significance in the intra-group comparison (P = 0.0168). Furthermore, 7 (0.8%) patients were found to have gained ≥ 7% of their weight at visit 4 (Table 5).

Laboratory values: The mean values of glutamic-pyruvic transaminase (GPT), glutamic oxaloacetic transaminase, serum creatinine, fasting blood glucose, total cholesterol, triglycerides, high-density lipoprotein cholesterol, low-density lipoprotein cholesterol, and QTc interval were within normal ranges at baseline and had not significantly changed when measured at the week 12 visit, except for GPT (P = 0.0189) (Table 6).

Effectiveness of lurasidone

The changes observed in the total BPRS score indicated a significant improvement in the severity of schizophrenia throughout the course of the treatment. The total BPRS score stood at 43.6 ± 15.28 (n = 959) at baseline. Over the course of treatment, it progressively decreased to 34.7 ± 12.22 (n = 959), 30.1 ± 10.68 (n = 959), and 26.8 ± 9.58 (n = 959), respectively, at 2/4, 6/8, and 12 wk, with overall mean changes of -8.9 ± 9.76, -13.5 ± 12.29, and -16.8 ± 13.97, respectively (P < 0.001 for each visit compared with the baseline) based on the LOCF method. The changes in the 5-factor model scores exhibited a similar trend as the total BPRS score, with highly significant reductions in the score observed on each visit (P < 0.001) (Table 7).

DISCUSSION

Lurasidone is a novel benzisothiazole antipsychotic drug that was authorized by the FDA in 2010 for the treatment of adult patients with schizophrenia[5] and has been licensed in many other countries, including China in 2019. Numerous pre-marketing trials have been conducted, which have demonstrated the efficacy and safety of lurasidone[8,11-13]. However, pre-marketing research has limitations. These include a small sample size, difficulties in detecting AEs with low incidence but high severity during the trial phase, and relatively strict participant inclusion and exclusion criteria, preventing the participation of certain patients with specific diseases in the trials. Thus, safety issues may not be fully identified and the use of concomitant medication tends to be controlled, which is inconsistent with real-world clinical practice. The use of PMS is thus important to further evaluate the safety and effectiveness of drugs. This study represents the initial PMS of lurasidone conducted in a Chinese population. The interim analysis confirmed that lurasidone was effective, generally safe, and well-tolerated as a treatment option for schizophrenia in adult Chinese patients.

Table 1 Baseline demographics and clinical characteristics (*n* = 965)

Background factor	Category	*n* (%)
Sex	Male	378 (39.2%)
	Female	587 (60.8%)

Other categories	142	15

[1]*n* = 949, number of patients in the full analysis set with concomitant therapy data documentation.
EPS: Extrapyramidal symptoms; ECT: Electroconvulsive shock therapy; rTMS: Repetitive transcranial magnetic stimulation.

Common adverse reactions of lurasidone include akathisia, EPS, somnolence, and nausea[14,15]. The most frequent treatment-emergent AEs (TEAEs) among Asian participants during a 6-wk study were found to be headache, constipation, akathisia, and nausea, with the latter two being more common in the 80 mg/d group compared with that in the 40 mg/d group[16]. During 26 wk of open-label extension treatment with lurasidone, the most frequently observed TEAEs were EPS, insomnia, akathisia, nasopharyngitis, schizophrenia, anxiety, nausea, and headache[17]. In the current PMS, the most frequently reported AEs included akathisia, elevated blood prolactin levels, and nausea, with the majority of the cases characterized as mild in severity. The pattern of AEs/ADRs identified in this interim analysis closely resembled the AE/ADR profile with the use of lurasidone 40 mg/d in previous trials for the treatment of schizophrenia [13]. The most frequently employed measures in response to EPS ADRs involve reduction of the antipsychotic drug, transitioning to antipsychotic drugs with a lower propensity to induce EPS, or utilization of specific medications designed for EPS treatment. In this study, the proportion of EPS drugs used during the treatment was 6.6%, which was higher than the incidence of EPS ADR (2.8%). The primary reasons for this could be attributed to two factors: (1) EPS treatment

Table 3 Summary of adverse events and adverse drug reactions (*n* = 894)

Category	*n*	%
Any AE	101	11.3%
Any ADR	78	8.7%

induced by antipsychotic drugs other than lurasidone in participants who were administered concomitant antipsychotics (47%); and (2) the utilization of prophylactic medications aimed at preventing patients from developing EPS during the course of treatment. The latter strategy is mainly aimed at patients who are susceptible to EPS (patients in the early stages of treatment and young males), to reduce their discomfort and improve compliance.

Lurasidone exhibits a strong affinity for dopamine D_2, 5-HT_7, and serotonin 5-HT_{2A} receptors. This favorable D_2/5HT_{2A} balance not only ensures the drug's antipsychotic effectiveness but also helps mitigate the EPS resulting from D_2 blockade [18]. Thus, as with other atypical agents, lurasidone has antipsychotic effects with limited EPS risk[14,19,20]. The incidence of EPS-related events (excluding akathisia and restlessness) was found to be 14.7% for lurasidone and 5.1% for placebo in short-term clinical trials[15]. In two long-term trials, the proportions of participants reporting EPS AEs in the lurasidone group during 12 mo of treatment were 12.9% and 11.9%, respectively[21,22].

Akathisia is one of the most frequent ADRs observed in multiple trials conducted in different regions. In a pooled analysis of European data from three randomized controlled trials (RCTs), the incidence of akathisia was 11.3%, representing 8.1% in the 40–80 mg/d group and 15.8% in the 120–160 mg group[23]. In the Asian population, the proportion of

patients that experienced akathisia was found to be 7.3% and 10.4% in the 40 and 80 mg/d groups, respectively, in another RCT that included mostly patients from East Asia[16]. In Chinese patients, the incidence of akathisia was reported to be 7.2% and 13.6% in patients treated separately with lurasidone and risperidone, respectively, by a pre-marketing RCT[8]. In the current PMS, the incidence of EPS ADRs was 2.8%; of these, 2.2% was contributed by akathisia, which is lower than the rates reported in previous studies. It is speculated that this inconsistency may result from three factors. First, the dosage of the drug. The development of akathisia was found to be dose-dependent in a previous trial [13]. In the current surveillance study, the average daily dose of lurasidone was 61.7 ± 19.08 mg, which is relatively low and, importantly, unlike pre-marketing clinical studies where fixed doses are commonly used, the treatment dosage in this PMS could be adjusted by the physicians based on the patient's tolerance, which may also help in reducing the occurrence of ADRs. Second, the concomitant medication. Drugs for treating EPS were allowed in the present study owing to its observational design of real-world clinical practice, and these medications may have led to reduced EPS and akathisia side effects. Last, sample size and monitoring requirements. Compared with pre-marketing RCTs, PMS studies typically entail larger sample sizes and involve less stringent monitoring protocols, which may occasionally result in a relatively lower proportion of AEs/ADRs reported by the participating physicians. However, a direct comparison of the data between these studies is generally not appropriate owing to differences in eligibility criteria and study methods.

Weight gain has been demonstrated to be a risk factor for treatment non-adherence in patients with schizophrenia[24,25] as it results in a worse quality of life, social exclusion, and increased stigma[26]. Moreover, a higher risk of developing metabolic syndrome (MetS) is linked to increased body weight[27,28]. A network meta-analysis of 100 RCTs comprising 25952 patients with schizophrenia found evidence of weight gain associated with the use of nine antipsychotics[29]. The reason why antipsychotic drugs induce weight gain remains unclear but might partly be ascribed to 5-HT_{2C}- and H_1-receptor affinity, which leads to hyperphagia and increased food intake[30,31]. However, lurasidone has only weak

affinity for 5-HT_{2C} receptors and poor or no affinity for histamine H_1[32]. Thus, the risk of weight gain might be relatively low from a mechanistic perspective, as confirmed by multiple clinical trials[33,34]. For short-term outcomes, 15 antipsychotic medications were evaluated for their effectiveness and tolerability by a meta-analysis of 212 trials and it was found that lurasidone, compared with placebo, is one of the only three drugs that did not lead to increased weight gain[33]. In terms of long-term outcomes, a pooled analysis of six studies showed that the mean weight change at month 12 was significantly greater in patients treated with risperidone and quetiapine extended-release (quetiapine XR) than those with lurasidone (+ 2.6 kg, + 1.2 kg *vs* − 0.4 kg)[34]. Previous trials did not find a dose-response relationship between the drugs and weight gain [11-13,16], and Wu *et al*[35] observed that the dose-response curve plateaued at 60 mg/d in a dose-response meta-analysis of 97 studies. In the current PMS, although the body weights of the patients at week 0 and week 12 were remarkably close (66.21 ± 14.010 kg *vs* 66.21 ± 13.696 kg), the number of participants with weight data recorded at these two visits varied (888 *vs* 801). Therefore, we used paired *t*-tests to analyze the mean change in weight, which was found to be 0.20 ± 2.356 kg at week 12 compared with the baseline paired population, showing a significant difference (P = 0.0168). However, this change remained minimal, and only 0.8% of patients showed a weight gain of ≥ 7% from baseline to week 12. Overall, in line with prior studies, there was a low chance of clinically significant weight gain in patients treated with lurasidone according to the results of the current PMS.

MetS is a collection of clinical and laboratory findings that are associated with an increased risk of cardiovascular disease[36]. The causes of MetS in patients with schizophrenia are not entirely elucidated, with antipsychotic drug side effects being a considered contributing factor[37]. Second-generation antipsychotics appear to be more likely to cause metabolic disturbances than first-generation antipsychotics, probably because of their affinity for the $5HT_{2C}$- and H_1-receptors as well as the M3 receptors that regulate the release of insulin, and thus maintain glucose homeostasis[37,38]. Previous studies have found that lurasidone is associated with a relatively low incidence of MetS[39,40]. The odds of developing MetS during the study period were significantly lower in patients receiving lurasidone than those treated with olanzapine and quetiapine XR in short-term treatment, and risperidone in long-term treatment, as demonstrated by a pooled analysis[41]. Despite the lack of a control group, the metabolic parameters of the study participants recorded at each visit in the current PMS were predominantly within the normal range, and a high proportion of those who were normal at baseline continued to remain normal during further follow-up visits (data not shown). This supports previous findings that lurasidone treatment has limited risk for adverse metabolic effects.

Hyperprolactinemia may be developed in patients with schizophrenia with or without antipsychotic medication[42]. Elevated prolactin levels induced by antipsychotic drugs are mainly associated with D_2 receptor affinity[43]. Several short-term studies have found no evidence of clinically significant changes in prolactin levels in patients treated with lurasidone[11-13]. A multicenter RCT conducted in mainland China showed that compared with the risperidone-treated group, the incidence of increased prolactin was remarkably lower in the lurasidone-treated group (3.1% *vs* 14.1%)[8]. In the current PMS, the incidence of increased prolactin was 2.3%, verifying that lurasidone has limited effects on prolactin levels, consistent with prior studies.

Lurasidone is a full antagonist of the dopamine D_2 receptor, with a receptor occupancy ratio of the latter after taking lurasidone 40 mg/d of 60%–80%, which is a prerequisite for its antipsychotic effectiveness[6]. Its targeting of the 5-HT_7 receptors can potentially enhance cognition by improving emotional regulation and sensory processing[6]. For acute phase treatment, a post hoc analysis of five studies in patients with acute schizophrenia found that lurasidone can reduce agitation early and sustainably, as measured by the PANSS-EC score[44]. Another meta-analysis of eight short-term RCTs confirmed that lurasidone was superior to placebo irrespective of positive or negative symptoms[45]. For maintenance treatment, an extension trial of 6 mo following a 6-wk acute-phase treatment of lurasidone showed further reduction and stabilization of the total PANSS score after receiving a flexible dose of lurasidone[46]. In terms of mood disorder, a pooled analysis of four studies verified significant improvement in depressive symptoms by lurasidone with greater decreases in MADRS score[47]. Overall, previous studies have supported the effectiveness of lurasidone in the treatment of schizophrenia and the interim analysis of the current PMS confirmed this conclusion, as supported by the continuous decrease in the total BPRS and the 5-factor model scores across all four visits during the surveillance period.

This study has some limitations. It was a single-armed, observational study with no control group, and the use of concomitant therapy, such as antipsychotic and EPS drugs, was allowed, which may represent confounders to the analysis and interpretation of the results. The sample sizes at each visit varied significantly and several participants did not provide their complete information, especially at visits 2 and 3. This may have an impact on the average of the measured data values and may not reflect the actual changes in the patients' condition. Although we used paired *t*-tests to partially address this issue, bias remains inevitable. The study period of this interim analysis was only 12 wk, and thus some AEs/ADRs that require a relatively long time to manifest may have not been observed and recorded during this period. It is worth mentioning that the study will be followed by a 12-month extension period, which we believe will provide further data support for clinical applications.

CONCLUSION

This preliminary data analysis from the PMS of lurasidone in adult patients with schizophrenia demonstrated its safety and effectiveness in a Chinese population, without emergence of any novel safety or efficacy issues. The study is ongoing and will facilitate continue to provide additional data and insights into the characteristics of lurasidone and its practical application in clinical settings.

ARTICLE HIGHLIGHTS

Research background

Schizophrenia is a psychiatric disorder characterized by chronic or recurrent symptoms. Lurasidone was licensed in China in 2019 for the treatment of adult schizophrenia in adults.

Research motivation

To further validate the safety profile and effectiveness of lurasidone.

Research objectives

To evaluate the safety and effectiveness of lurasidone in the Chinese population.

Research methods

We conducted a prospective, multicenter, open-label, 12-wk surveillance in mainland China, and reported the interim analysis based on 965 patients who received the medication between 2019 and 2022.

Research results

Mean changes in total brief psychiatric rating scale scores were -8.9 ± 9.76 (n = 959), -13.5±12.29 (n = 959), and -16.8 ± 13.97 (n = 959) after 2/4, 6/8, and 12 wk, respectively (P < 0.001 for each visit compared with the baseline) using the last-observation-carried-forward method. adverse events and adverse drug reactions were experienced by 101 (11.3%) and 78 patients (8.7%), respectively, which were mostly mild.

Research conclusions

The interim analysis of the post-market surveillance demonstrate the safety and effectiveness of lurasidone in the Chinese population.

Research perspectives

This study contributes additional safety and effectiveness data on lurasidone, surpassing those obtained in pre-marketing trials. It offers essential guidance for clinical decision-making in the treatment of schizophrenia.

ACKNOWLEDGEMENTS

We would like to acknowledge all the physicians and patients who participated in this surveillance study.

Abstract

BACKGROUND

Traditional treatments for major depressive disorder (MDD), including medication and therapy, often fail and have undesirable side effects. Electroconvulsive therapy (ECT) uses electrical currents to induce brief seizures in the brain, resulting in rapid and potent antidepressant effects. However, owing to misconceptions and controversies, ECT is not as widely used as it could and often faces stigmatization.

AIM

To evaluate the efficacy and safety of ECT compared to those of medication and/or therapy in patients with severe MDD.

METHODS

This prospective cohort study included 220 individuals with severe MDD who were divided into the ECT and non-ECT groups. The patients in the ECT group underwent bilateral ECT three times a wk until they either achieved remission or reached a maximum of 12 sessions. The non-ECT group received medication and/or therapy according to clinical guidelines for MDD. The primary outcome was the variation in the hamilton depression rating scale (HDRS) score from treatment/ECT initiation to week 12. In addition, patients' quality of life, cognitive abilities, and biomarkers were measured throughout the study.

RESULTS

Although both groups showed significant improvements in their HDRS scores over time, the improvement was more pronounced in the ECT group than in the non-ECT group. Additionally, the ECT group exhibited a more substantial improvement in the quality of life and cognitive function than those of the non-ECT group. Compared with the non-ECT group, the ECT group exhibited evidently lower variations in the brain-derived neurotrophic factor (BDNF) and

cytokine interleukin-6 (IL-6) levels. The side effects were generally mild and comparable between the two groups. ECT is safer and more potent than medication and/or therapy in mitigating depressive symptoms, enhancing well-being, and bolstering cognitive capabilities in individuals with severe MDD. ECT may also affect the levels of BDNF and IL-6, which are indicators of neuroplasticity and inflammation, respectively.

CONCLUSION

ECT has emerged as a potentially advantageous therapeutic approach for patients with MDD who are unresponsive to alternative treatments.

Key Words: Alternative therapies; Biomarkers; Cognitive function; Electroconvulsive therapy; Major depressive disorder; Medication therapy

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Electroconvulsive therapy (ECT) is more efficient and safer in treating severe major depressive disorder (MDD) compared to medication and/or therapy. Here, ECT led to more pronounced improvements in depressive symptoms, quality of life, and cognitive function than non-ECT treatments. Additionally, ECT affected biomarkers related to neuroplasticity (brain-derived neurotrophic factor) and inflammation (interleukin-6). These findings highlight the potential of ECT as a therapeutic approach for individuals with severe MDD who do not respond to conventional treatments. By providing evidence of its beneficial outcomes, this study aimed to address the stigmatization surrounding ECT and facilitate its broader adoption in clinical practice.

INTRODUCTION

Major depressive disorder (MDD) is a prevalent mental health condition with a profound impact on many individuals worldwide. The World Health Organization reported that MDD contributes significantly to the global health burden[1]. This condition is characterized by a persistent sense of sadness, diminished interest in daily activities, and a reduction in function that lasts for at least 2 wk. MDD can negatively affect physical, psychological, social, and occupational aspects of life, leading to increased morbidity, mortality, and suicide risk[2].

Conventional treatments for MDD include pharmacotherapy and psychotherapy, which aim to restore mood balance, reduce distress, and enhance coping strategies[3]. Pharmacotherapy involves the use of antidepressants, such as serotonin, dopamine, and norepinephrine, which act by targeting neurotransmitter systems[4]. Psychotherapy comprises a variety of psychological interventions that address the cognitive, behavioral, interpersonal, and emotional factors that contribute to depression[5]. Widely practiced and documented psychotherapy techniques include cognitive-behavioral therapy (CBT), interpersonal therapy (IPT), and supportive therapy[6]. However, conventional therapies are often insufficient and associated with adverse effects. Approximately 50% of patients achieve remission after a typical course of antidepressants, and approximately 30% remain resistant to multiple types of treatment[7]. Furthermore, antidepressants can cause adverse reactions, including nausea, weight gain, sexual issues, insomnia, and agitation[8]. Psychotherapy can also be ineffective or inaccessible to some patients because of a lack of availability, affordability, or motivation. Moreover, conventional therapies may take several wks or months before significant improvements are evident[9].

Electroconvulsive therapy (ECT) is a medical procedure performed under general anesthesia, using electrical currents to induce brief seizures in the brain. ECT has been used since 1938, primarily for treating schizophrenia, and was pioneered by Cerletti and Bini[10]. ECT has been widely used to treat many psychiatric disorders, particularly severe or treatment-resistant MDD[11]. It is a highly potent and safe remedy for acute or suicidal MDD, with remission rates ranging from 60% to 90%. ECT has been shown to improve the overall well-being and mental processing abilities of patients with severe MDD[11] and can produce rapid and robust antidepressant effects, with improvements observed within 1-2 wk[12].

However, ECT remains underutilized and stigmatized owing to misconceptions and controversies. Many patients and even some healthcare professionals have negative attitudes and beliefs concerning ECT, finding it cruel, dangerous, or outdated or believing that its effects can be substituted by long-term psychotherapy or hospitalization[13]. Some of these misconceptions are based on the historical use of ECT, which involves the delivery of large amounts of electrical charge, inadequate anesthesia, and frequent sessions, resulting in severe side effects, such as memory loss, brain damage, or death. However, modern ECT is a safe, effective, and regulated treatment that involves minimizing the amount of electrical charge delivered, administering adequate anesthesia, and designing patient-centered personalized sessions, resulting in minimal side effects, including transient headaches, nausea, and confusion[14]. Modern ECT does not cause

brain damage or permanent memory loss and would not affect the personality or intelligence of patients[15].

The primary objective of the present study was to compare the efficacy and safety of ECT with those of pharmacotherapy and/or psychotherapy in patients with severe MDD. We hypothesized that ECT would be superior to pharmacotherapy and/or psychotherapy in terms of improving the hamilton depression rating scale (HDRS) scores, a validated clinician-rated outcome measure for MDD. We also hypothesized that ECT would be superior to pharmacotherapy and/or psychotherapy in improving the quality of life and cognitive function in patients with severe MDD. Brain-derived neurotrophic factor (BDNF), cytokine interleukin-6 (IL-6), and cortisol levels were also measured as biomarkers of neuroplasticity and inflammation.

MATERIALS AND METHODS

Study design and participants

This prospective cohort analysis was conducted at The First Hospital of Hebei Medical University in China between January 2021 and June 2022. The research methodology was approved by the ethics boards of all involved institutions and strictly adhered to the Declaration of Helsinki and Standards for Reporting Observational Research. All participants provided written informed consent before participating in the study.

The study recruited individuals aged ≥ 18 years who had been diagnosed with MDD according to the Diagnostic and Statistical Manual of Mental Disorders guidelines, had an HDRS score > 24 points, were willing to participate in the study, and attended subsequent visits. The exclusion criteria included a history of allergic reaction to ECT or anesthesia, prior neurological issues, brain trauma, seizure-related disorders, substance misuse or dependency in the past 6 mo, receiving any medication that may influence the seizure threshold or cognitive abilities in the preceding month (such as anticonvulsants, benzodiazepines, or antipsychotics), pregnancy or breastfeeding, diagnosis of any other mental or physical ailment that might affect the study results, or inability to provide blood samples for biomarker evaluation.

Eligible participants were allocated to the ECT and non-ECT groups depending on their treatment approach. In the ECT group, individuals underwent ECT as routine treatment for MDD. In the non-ECT group, individuals underwent drug therapy and/or psychotherapy (without ECT) as a routine MDD treatment. The treatment group was chosen at the discretion of the attending psychiatric team based on their clinical assessment and inclination. Participants were paired across groups based on age, sex, and HDRS scores at baseline.

Interventions

Participants in the ECT group underwent bilateral ECT using an apparatus specifically designed to deliver brief pulses (Thymatron System IV; Somatics LLC, Lake Bluff, IL, United States) according to a standardized protocol[16]. The protocol commenced with an initial assessment, including physical checkups, electrocardiography (ECG), blood testing, and cognitive evaluation. ECT was performed under general anesthesia using propofol and succinylcholine. Stimulus power was estimated using titration technique and fine-tuned according to the seizure duration and quality. ECT was administered thrice a wk until remission was achieved or a maximum of 12 sessions were completed. Vital signs, oxygen levels, ECG findings, and side effects were recorded during and after each ECT session.

The non-ECT group was treated with medication and/or psychotherapy according to the clinical guidelines for the treatment of MDD[17]. Medications included antidepressants (selective serotonin reuptake inhibitors, serotonin and norepinephrine reuptake inhibitors, tricyclic antidepressants, or monoamine oxidase inhibitors), mood balancers (lithium or valproate), and supplementary agents (thyroid hormones or antipsychotics). Psychotherapy included CBT, IPT, or supportive therapy. Medication type, dosage, length of course, and the use or absence of psychotherapy were determined by the attending psychiatrists based on patient feedback and tolerance.

Both groups were advised not to use other treatments or medications that could influence their mood or cognitive function during the study period. They were also encouraged to maintain their regular lifestyle and environment and report any physical changes or side effects to the research team.

Outcomes

The main metric of interest was the change in the HDRS score between the initial assessment and 12-wk mark. The HDRS consists of 17 clinician-evaluated items that measure the intensity of depressive signs[18]. Scores on the HDRS range from 0 to 52 points, with higher scores indicating more pronounced depression. A score of ≤ 7 points on the HDRS was considered to signify remission, a reduction of ≥ 50% from the initial score was considered a response, and a reduction of < 50% was classified as non-response.

Additional outcomes of interest included changes in quality of life, cognitive capabilities, and specific biomarkers between the baseline and 12-wk assessments. The World Health Organization Quality of Life-BREF (WHOQOL-BREF) questionnaire[19], a 26-item tool, was used to measure participants' quality of life and covered the domains of physical well-being, mental health, interpersonal relations, and the surrounding environment. The WHOQOL-BREF scores range from 0 to 100 points, with higher scores indicating higher quality of life. The Montreal Cognitive Assessment (MoCA) [20], a concise evaluation instrument, was used to gauge cognitive function, covering the areas of attention span, memory retention, linguistic skills, executive decision-making, and spatial cognition. The MoCA scores range from 0 to 30 points, with higher scores indicating greater cognitive ability. Blood samples collected at the ECT initiation and 12-wk mark were analyzed to measure BDNF, IL-6, and cortisol levels. BDNF is crucial for neuronal survival, differentiation, and adaptability. IL-6, a cytokine that promotes inflammation, is involved in immune reactions and mood and cognitive regulation. Cortisol, a hormone associated with stress, influences the hypothalamic (pituitary) axis and neuroendocrine

mechanisms. Any adverse reactions were documented during each visit and categorized as mild, moderate, or intense based on their severity and association with the study interventions.

Sample size

The required sample size was determined based on the primary outcome, HDRS, with an anticipated clinically meaningful difference of 5 points between the groups, a standard deviation of 10 points, a significance level of 0.05, and a statistical power of 0.8. Based on these criteria, we calculated that at least 100 individuals were required in each group to discern meaningful differences. Anticipating a 10% dropout rate, a prudent sample of 110 individuals was recruited from each group, totaling 220 participants.

Statistical analysis

All statistical analyses were performed using SPSS version 26.0 (IBM Corp., Armonk, NY, United States). Data normality was rigorously verified using histograms and Kolmogorov-Smirnov tests. Comparative analyses of the groups' baseline attributes were conducted using independent t-tests or Mann-Whitney U tests for continuous data and chi-square or Fisher's exact tests for categorical data. Changes in HDRS scores and secondary outcomes from baseline to 12 wk were assessed between the groups using analysis of covariance. Differences in means and 95% confidence intervals (CIs) were calculated using descriptive statistics. Adverse events between the groups were analyzed using chi-square or Fisher's exact tests. Statistical significance was set at $P < 0.05$.

RESULTS

Participant flow and characteristics

A total of 220 participants were recruited, of whom 110 were allocated to the ECT group and 110 to the non-ECT group. The participants' progress throughout the study is shown in Figure 1. Eight participants withdrew from each group due to personal choices or were lost to follow-up, culminating in 204 participants (102 in each cohort) included in the final analysis.

Table 1 presents the baseline attributes of the participants. No significant baseline differences were observed between the groups in terms of age, sex, MDD duration, MDD type, HDRS score, WHOQOL-BREF score, MoCA score, BDNF level, IL-6 level, or cortisol level (all $P > 0.05$).

Primary outcome

Table 2 displays the changes in HDRS scores from the initial assessment to the 12-wk mark. Both groups showed notable improvements in HDRS scores over time ($P < 0.001$ for both cohorts). The enhancement was significantly greater in the ECT than in the non-ECT group ($P < 0.001$). The average change in HDRS score between the cohorts was -5.4 (95%CI: -7.8 to -3.0), suggesting a substantial improvement in the ECT group.

Recovery by 12 wk was significantly higher in the ECT than in the non-ECT group (68% *vs* 42%, $P < 0.001$). Similarly, the rate of positive response by the 12th wk was also significantly higher in the ECT cohort than in the non-ECT cohort (86% *vs* 64%, $P < 0.001$). Conversely, the rate of no response by 12 wk was significantly lower in the ECT than in the non-ECT group (14% *vs* 36%, $P < 0.001$).

Secondary outcomes

Table 2 presents the variations in the quality of life, cognitive ability, and biomarker levels from the initial assessment to the 12-wk mark. Both participant groups exhibited notable enhancements in the WHOQOL-BREF and MoCA scores over time ($P < 0.001$ for both metrics and groups). However, the ECT group displayed significantly greater enhancement than the non-ECT group for both metrics ($P < 0.05$). The average difference between the groups was 6.2 points (95%CI: 3.4 to 9.0) for the WHOQOL-BREF and 1.6 points (95%CI: 0.8 to 2.4) for the MoCA.

Both groups showed a significant decrease in BDNF levels and a significant increase in IL-6 levels over time ($P < 0.001$ for both metrics and groups). However, these changes were significantly smaller in the ECT than in the non-ECT group for both metrics ($P < 0.05$). The average differences between the groups were -5.8 units (95%CI: -9.2 to -2.4) for BDNF and -1.2 units (95%CI: -2.1 to -0.3) for IL-6. None of the groups exhibited any notable changes in cortisol levels over the study duration ($P > 0.05$) or at the 12-wk mark ($P > 0.05$).

Adverse events

Table 3 shows that there were no significant differences in the occurrence of adverse effects between the two groups ($P = 0.62$). Commonly reported adverse effects included headache, nausea, dizziness, and memory issues, all of which were generally mild and short-lived. Moreover, throughout the study duration, no severe adverse effects were documented.

DISCUSSION

This study demonstrated that ECT is safer and more effective than pharmacotherapy and/or psychotherapy in alleviating depressive symptoms, improving well-being, and boosting cognitive ability in individuals with severe MDD. ECT also

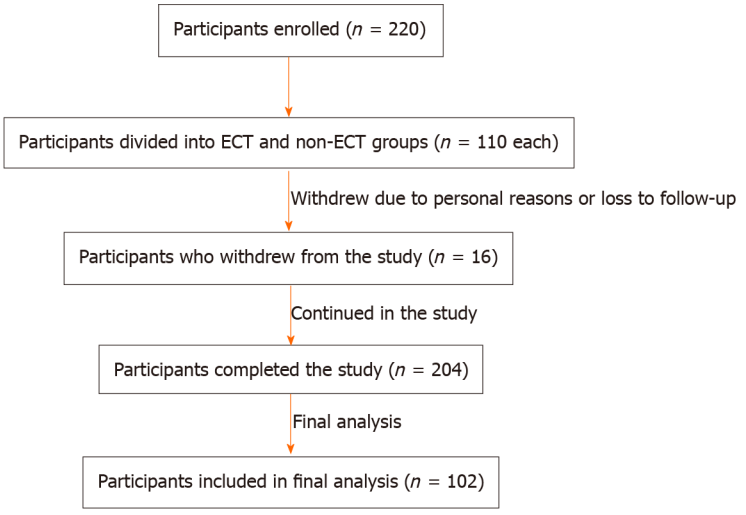
IL-6 level (pg/mL)	+2.2 ± 0.9 (+65)	+3.4 ± 1.2 (+97)	< 0.001
Cortisol level (ng/mL)	-0.2 ± 3.8 (-2)	-0.1 ± 4.1 (-1)	0.92

Values are depicted as average ± deviation with percentage alteration in brackets. ECT: Electroconvulsive treatment; HDRS: Hamilton depression evaluation scale; WHOQOL-BREF: World Health Organization Quality of Life-BREF Assessment; MoCA: Montreal cognitive evaluation; BDNF: Brain-derived neurotrophic factor; IL-6: Interleukin-6.

appears to regulate the levels of BDNF and IL-6, which are biomarkers for neuroplasticity and inflammation, respectively.

These findings concur with those of previous studies highlighting the advantages of ECT over other treatments for patients with severe MDD. A meta-analysis of 16 randomized controlled trials (RCTs) involving 1391 patients with MDD found that ECT was more effective than pharmacotherapy or placebo in inducing remission and response[21]. Another meta-analysis of nine RCTs involving 619 patients with treatment-resistant depression found that ECT outperformed pharmacotherapy and placebo ECT in reducing the signs of depression[22]. Furthermore, a systematic review of 24 studies involving 1708 patients with MDD found that ECT produced greater improvements in patient well-being and cognitive abilities than other treatments[23].



Although the precise mechanism underlying the action of ECT is unclear, it is likely related to its effects on the brain structure and function. ECT may induce neurogenesis, synaptogenesis, angiogenesis, and neurotrophic factor expression in multiple brain regions, particularly in the hippocampus, amygdala, and prefrontal cortex[24], which are involved in mood regulation, memory formation, and executive functions. ECT may also modulate neurotransmitter systems, including serotonin and dopamine, which are implicated in depression and cognition[25] and may normalize the hypothalamo-pituitary-adrenocortical axis activity and reduce the inflammatory response, both of which are associated with stress and depression[26,27].

The merits of the present study include its prospective cohort design, large sample size, use of a standardized protocol for ECT administration, use of validated and objective outcome measures, and long follow-up duration. The potential limitations of this study include its confinement to a single nation, absence of randomization and blinding of participants, potential variability in the prescribed pharmacotherapy and psychotherapy given to participants in the non-ECT group, and lack of assessment of other outcomes, such as cost-effectiveness or patient satisfaction.

Table 3 Adverse events reported by the participants, *n* (%)

CONCLUSION

In conclusion, this study demonstrated that ECT is safer and more effective than pharmacotherapy and/or psychotherapy in enhancing signs of depression, overall well-being, and cognitive abilities in individuals with severe MDD, and in modulating the levels of BDNF and IL-6, which are biomarkers of neuroplasticity and inflammation, respectively. ECT may be a valuable treatment option for patients with MDD refractory to other treatments.

ARTICLE HIGHLIGHTS

Research background

Major depressive disorder (MDD) is a prevalent mental health condition characterized by persistent feelings of sadness and loss of interest. Traditional treatments for MDD, such as medications and therapy, often have limited effectiveness and can lead to undesirable side effects. Electroconvulsive therapy (ECT) is an alternative treatment that uses electrical currents to induce controlled brain seizures, resulting in rapid and potent antidepressant effects. However, ECT is associated with misconceptions, controversies, and stigmatization, which hinder its wider acceptance and utilization.

Research motivation

The main theme of this study is to evaluate the efficacy and safety of ECT compared to medication and/or therapy in patients with severe MDD. The key problems that need to be addressed are the limited effectiveness and undesirable side effects of traditional treatments for MDD, which often lead to treatment failure. Despite its rapid and potent antidepressant effects, ECT faces misconceptions, controversies, and stigmatization, resulting in its underutilization.

Research objectives

The main objective of this study was to evaluate the efficacy and safety of ECT compared to medication and/or therapy in individuals with severe MDD. The specific goals accomplished were as follows: (1) Variation in the hamilton depression rating scale (HDRS) scores between the ECT and non-ECT groups over a 12-wk period; (2) improvements in the quality of life and cognitive function between the ECT and non-ECT groups were compared; (3) variations in the levels of brain-derived neurotrophic factor (BDNF) and interleukin-6 (IL-6), potential biomarkers of neuroplasticity and inflammation, respectively, between the ECT and non-ECT groups; and (4) evaluation of the safety and tolerability of ECT compared to medication and/or therapy. The achievement of these objectives has significant implications for future research. First, it provided evidence supporting the superior efficacy and safety of the ECT as a treatment option for individuals with severe MDD who do not respond to traditional therapy. This challenges the prevailing misconceptions and stigmatization surrounding ECT and encourages further investigation and acceptance of this modality. Second, the identification of biomarkers influenced by ECT opens avenues for future studies to explore the underlying mechanisms of its antidepressant effects and potentially identify predictors of treatment response. Overall, this study contributes to optimizing therapeutic approaches for severe MDD and guides future research toward better understanding and improved treatment outcomes for affected individuals.

Research methods

A prospective cohort design was used to achieve the research objectives. The study included 220 individuals with severe MDD who were divided into the ECT and non-ECT groups. In the ECT group, bilateral ECT was administered three times a wk until remission was achieved or a maximum of 12 sessions were reached. The non-ECT group received medication and/or therapy according to clinical guidelines for MDD. The HDRS score was used as the primary outcome measure, with variations in scores assessed from the beginning to 12 wk. In addition to the HDRS score, this study measured the patients' quality of life, cognitive abilities, and biomarkers throughout the study. The biomarkers of interest were BDNF and IL-6, which are indicators of neuroplasticity and inflammation, respectively. The collected data were analyzed using appropriate statistical methods, such as t-tests or analysis of variance, to compare the outcomes between the ECT and non-ECT groups. The study also assessed the safety and tolerability of ECT compared to medication and/or therapy by monitoring and documenting any side effects experienced by the participants. The novelty of this study lies in its comprehensive evaluation of the efficacy, safety, and biomarker influences of ECT compared to conventional treatments for severe MDD. By incorporating multiple outcome measures and biomarker assessments, this study provides a holistic understanding of the effects of ECT on depressive symptoms, well-being, cognitive function, neuroplasticity, and inflammation. This prospective cohort design allows the observation of treatment outcomes over time and contributes to a growing body of evidence supporting the potential advantages of ECT as a therapeutic approach for treatment-resistant MDD.

Research results

The results of this study indicated that ECT was more effective and safer than medication and/or therapy for severe MDDs. Both the ECT and non-ECT groups showed significant improvements in the HDRS scores over the 12-wk period. However, the ECT group demonstrated a more pronounced improvement in depressive symptoms than that of the non-ECT group. Moreover, the ECT group exhibited greater improvements in quality of life and cognitive function. The study also revealed that the ECT group had lower variations in the levels of BDNF and IL-6 compared with the non-ECT group. This suggests that ECT influences neuroplasticity and inflammation, potentially contributing to its therapeutic effects. These findings highlight the superior efficacy and safety of ECT as a treatment option for severe MDD, particularly in cases where traditional therapies fail. This study emphasizes the potential advantages of ECT in mitigating depressive symptoms, improving well-being, and enhancing cognitive capabilities. Furthermore, the exploration of biomarkers provides insights into the mechanisms underlying the effects of ECT and opens avenues for future research on personalized treatment approaches. Despite these positive outcomes, further investigations are required to address certain unresolved questions. Future studies should focus on the long-term effects, potential mechanisms of action, and comparisons between ECT and emerging treatment modalities. Further research is necessary to optimize therapeutic approaches, address stigmatization, and improve outcomes in patients with treatment-resistant MDD.

Research conclusions

The conclusions of this study indicate that ECT is a potentially advantageous therapeutic approach for individuals with severe MDD who do not respond to traditional treatments. This study found that ECT is safer and more potent than medication and/or therapy in mitigating depressive symptoms, enhancing well-being, and bolstering cognitive capabilities. This study also demonstrated that ECT may influence the levels of BDNF and the cytokine IL-6, indicators of neuroplasticity and inflammation, respectively. This study provides new evidence for the efficacy and safety of ECT as a treatment option for severe MDD and challenges the misconceptions and stigma surrounding this alternative therapy. These findings have implications for the development of new therapeutic approaches for MDD and underscore the need for further research in this area.

Research perspectives

Future studies in this field should focus on several aspects. First, further investigations are needed to examine the long-term effects of ECT on depressive symptoms, quality of life, and cognitive function in individuals with MDD. Longitudinal studies can provide valuable insights into the durability of the effects of ECT and its potential as maintenance therapy. Additionally, future research should explore the underlying mechanisms of ECT, particularly its influence on neuroplasticity and inflammatory markers such as BDNF and IL-6. Understanding these mechanisms could guide the development of targeted interventions and improve treatment outcomes. Moreover, studies should be conducted to directly compare ECT with other emerging treatments, such as transcranial magnetic stimulation or ketamine infusion therapy, to determine the most effective and personalized treatment options for different subgroups of patients with MDD. These research perspectives can contribute to advancing the field and optimizing therapeutic approaches for patients with severe MDD.

Abstract

BACKGROUND

Adolescents with autism spectrum disorder (ASD) may encounter many difficulties with their menstrual cycles. Potential challenges that adolescents with ASD may face include understanding physical changes, coping with symptoms, emotional sensitivity, communication, personal care, and hygiene.

AIM

To evaluate the effect of menstrual hygiene skills training given to adolescents with ASD on their menstrual hygiene skills.

METHODS

The study was conducted with 15 adolescents diagnosed with ASD by the single group pre-test and post-test model in three special education centers in Türkiye. Data were collected with the Adolescent and Parent Information Form and the Adolescent-Specific Menstrual Hygiene Skill Registration Form.

RESULTS

While the mean age of adolescents was 16.06 ± 0.88 years, the mean age of individuals responsible for adolescent care was 43.66 ± 5.56 years. While 60.0% of the adolescents noticed the onset of bleeding before training, this rate was 93.3% after training. The Adolescent-Specific Menstrual Hygiene Skill Registration Form showed a statistically significant increase in the application steps after the training. The difference between the menstrual hygiene skill scores of adolescents

diagnosed with ASD before and after training was significant.

CONCLUSION

The menstrual hygiene skills training given to adolescents with ASD was beneficial in increasing their menstrual hygiene skills. These individuals must take responsibility during menstruation and independently manage their continuous care activities.

INTRODUCTION

Adolescence is a transitional stage of development between childhood and adulthood. It is characterized by rapid physical, cognitive, emotional, and social changes. Most healthy adolescents adapt to this physical and psychosocial developmental process[1]. According to the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition definition, autism spectrum disorder (ASD) is a pervasive developmental disorder characterized by disorders in social interaction and communication and limited and repetitive behaviors, and causes limitations in the individual's daily life functions with its early symptoms[2]. The challenges faced by adolescents with ASD are multifaceted and can vary from person to person. Some difficulties faced by adolescents diagnosed with ASD are social difficulties, communication challenges, restricted and repetitive behaviors, sensory sensitivities, transitioning to adulthood, and mental health concerns. The transition to puberty can be particularly challenging for individuals with ASD. However, many of the challenges and experiences faced by individuals with ASD can be changed. Supportive interventions, individualized strategies, and a multidisciplinary approach can significantly help address these challenges and promote the well-being and development of adolescents with ASD[1,3,4].

Adolescents with ASD may encounter many difficulties with their menstrual cycles. Potential challenges that adolescents with ASD may face include understanding physical changes, coping with symptoms, emotional sensitivity, communication, personal care, and hygiene. They may have difficulty dealing with newly emerging situations such as foul odor, blood flow situation/feeling, and using sanitary pads, especially during menstruation[5]. If these changes are not adequately explained to adolescents with ASD, periodic crises and coping problems may occur. Even a simple skill like changing menstrual pads can become a complex motor skill for them[6]. It is essential to approach these challenges with sensitivity, individualized support, and an understanding of the specific needs and abilities of each adolescent with ASD. Collaborating with healthcare providers, educators, and caregivers can help create tailored strategies to address these challenges effectively[3,5,7,8].

A limited number of studies were found in the literature on menstruation periods in individuals with autism. One of these studies was conducted with two mentally disabled individuals[7]. There has been no study with a well-explained methodology and sufficient sample size that evaluates the effectiveness of training on menstrual hygiene skills with only a single focus group, such as adolescents with ASD. This study was planned to evaluate the effect of menstruation hygiene skill training given to adolescents with ASD on the ability to change and wear menstrual pads.

Research hypotheses

H_1: The menstrual hygiene skill level of the adolescent with ASD who is given menstrual hygiene skill training increases.

H_2: Menstrual hygiene skills training increases the independence of adolescents.

MATERIALS AND METHODS

Research design

This study was conducted in three special education centers in the provinces of Istanbul and Muğla between April 2022 and February 2023, using the "Single Group Pre-Test and Post-Test Model," which is one of the semi-experimental study methods. Creswell[9] sees the preference for single-group experimental design as necessary for the nature of the research in studies where a new training module is developed and applied.

Setting, participants, and recruitment

In calculating the sample size, studies compatible with the purpose and design of the research were examined. There is no research in the literature on the menstrual hygiene skill requirements of adolescents with ASD. Therefore, the research of Gölbaşi *et al*[10] on the effectiveness of peer education on menstrual hygiene with healthy adolescents was the basis for calculating the sample. According to this research, Menstrual Health Behaviors change was used in calculating the sample. When an increase of 5.69 points in the mean Menstrual Health Behaviors score was considered significant, the minimum sample size to be reached was 15. Since only the positive change in menstrual hygiene behavior was taken as the basis in our study, the sample size for this study was calculated as 15 adolescents with ASD using the G-Power software program with a margin of error of 0.05 and 80% power.

For this research, permission to conduct the study was requested from all special education units affiliated with the National Education in Istanbul and Muğla. However, only two private education institutions in Istanbul and one private education institution in Muğla granted permission for the research. The study was conducted in three centers affiliated with national education that had granted permission.

A total of 26 females with ASD were present across the participating institutions. Six females were excluded from the study: three females diagnosed with severe autism according to the Gilliam Autism Rating Scale-2 (GARS-2) score; and three females who were older than 18 years of age. Considering the data loss in the specified date range, 20 participants were invited to the research. Sample selection was not made. Three adolescents/parents did not volunteer to participate in the study, and two participants did not perform the post-test. As a result, 15 adolescents diagnosed with ASD were included in the study.

Inclusion criteria for the study were that the adolescent was diagnosed with ASD, the adult responsible for the adolescent's care was older than 18 years, and the adolescent was between the ages of 9-18 years (determined by considering the beginning of the menstrual cycle and the age of enrollment in special education centers), the adolescent's menstrual cycle started, the adolescent's hand washing skills, the adolescent's ability to fulfill instructions that require a single action, the adolescent's ability to watch visual stimuli such as projection shows, video viewing, *etc*, the adolescent's ability to perform the movements shown, the GARS-2 score as "mild" and "moderate," and the adolescent and the adult responsible for her care did not have hearing and visual impairment.

Data collection

Menstruation hygiene skills training: The training was a menstrual hygiene skill training in which visual methods and resuscitation methods were used to teach menstrual hygiene skills to adolescents with ASD. The training was given to the adolescents for half an hour 3 d a week. In each training group, two adolescents with ASD with similar characteristics and a teacher participated. Based on GARS-2 scores, adolescents with moderate autism were placed in one training group, while those with mild autism were placed in another training group. All training was completed in the same group, with the same teacher and researcher. The same researcher and a special education teacher gave the training in each training interview to standardize education. The training frequency, duration, and the number of participants were prepared with the recommendation of a pedagogue/psychologist so that adolescents could best understand and reinforce the skill. In addition, the researchers attended a seminar titled "Autism and Sexuality." For the visual method, a presentation consisting of only pictures prepared by the researchers was used. A pedagogue and special education teacher checked the suitability of the pictures in the presentation. A doll the size of an adolescent was used in the demonstration. With the help of this doll, the menstrual pad change skill was explained practically, and the adolescents were asked to repeat this skill (Table 1).

In addition to the training given to adolescents with ASD, video-assisted "Menstrual Hygiene Training: For Adults" was shown to the adults responsible for their care. Thus, individual differences in menstrual hygiene habits were minimized.

Procedure

Data were collected with the Adolescent and Parent Information Form and Adolescent-Specific Menstrual Hygiene Skill Registration Form, which the researchers created in line with the literature. First, training groups consisting of two participants with common characteristics were determined according to the adolescent's score and learning ability from the GARS-2. While determining the training groups, a consultation was received from the expert pedagogue and special education teacher. The pre-test and post-test of the study were performed by the individual responsible for the care of the adolescent. The aim of the research and how to use the data collection tools were explained to the individuals responsible for the care of the adolescents included in the study. A training video on menstrual hygiene was watched and then sent to the individual for viewing. In the first interview, the Adolescent and Parent Information Form and the Adolescent-Specific Menstrual Hygiene Skill Registration Form were administered to the participants included in the study through the individual responsible. In the post-test, only the Menstrual Hygiene Skills Registration Form was used. The individuals responsible for the care of the adolescents completed the post-test at home during the adolescent's first

Table 1 Application steps of changing sanitary pads

No	Steps
1	She noticed that she had started bleeding
2	She informed me about it
3	She either took off her clothes on her own or I helped her
4	She either removed her underwear on her own or I assisted her
5	She washed her hands
6	She retrieved a fresh pair of underwear
7	She opened the bag and took out a sanitary pad
8	She placed the sanitary pad onto her underwear without touching it directly, either by herself or with my assistance
9	She put on her underwear, either independently or with my help
10	She put on her pants, either by herself or with my assistance
11	She washed her hands and dried them using a towel
12	She realized that she needed to change her pad when the menstrual pad was dirty
13	She successfully removed the soiled pad
14	She either independently wrapped the dirty pad in her bag or I assisted her in doing so
15	She disposed of the dirty pad in the trash
16	She used toilet paper to wipe her perineum from front to back and discarded the used toilet paper in the trash
17	She took the clean, sanitary pad out of its bag and positioned it in her underwear
18	She put on her underwear and pants, either on her own or with my assistance
19	She washed her hands

menstrual cycle after training.

Data collection tools

Adolescent and parent information form: This form, which the researchers prepared, consisted of 11 questions to evaluate the sociodemographic characteristics of adolescents and parents, such as age, education status, income status, and menstrual pattern of adolescents (how many days they have menstrual bleeding and duration). The researchers filled this form with the face-to-face interview technique with the individuals responsible for the care of the adolescents.

GARS-2: The scale was used to determine inclusion criteria and training groups. The Turkish adaptation and validity and reliability studies of the scale were performed by Diken *et al*[11]. GARS-2 is a rating scale that aims to evaluate individuals aged 3–23 years who exhibit behaviors that characterize the autistic disorder. The GARS-2 is a Likert-type scale scored with an opinion-based four-point rating. GARS-2 consists of three subscales: stereotypical behaviors; communication; and social interaction. The scale consists of 42 items in total, with 14 items in each subscale. The highest score that can be obtained from the scale is 153, while the lowest score is 55. A high score indicates a high level of autistic disorder, while a low score indicates a low level of autistic disorder[11].

Adolescent-specific menstrual hygiene skill registration form: This form was created by researchers in parallel with Menstrual Hygiene Skills Training. This form was developed since no scale or form evaluates menstrual hygiene skills in the literature. Expert opinions from 10 individuals (academics in women's health and gynecologic nursing and pediatric nursing, psychologist, pedagogue, and special education teacher) were taken in developing and creating the form. The applicability and comprehensibility of the form were evaluated in a pilot study with five adolescent caregivers before the research data was collected. Incomprehensible items were renewed again. The adolescent was expected to complete 19 skill items in the form. Next to each skill item were "applied" and "not applied" options. In the form, "applied" was scored as 1 point and "did not apply" as 0 points. This scoring compared the pre-test and post-test. A minimum of 0 and a maximum of 19 points were taken.

Statistical analysis

Data were analyzed using the SPSS Statistics program (version 22; IBM Corp., Armonk, NY, United States). Descriptive statistics, mean, and standard deviation were used for continuous variables. Categorical variables were calculated as numbers and percentages. The normality of the distribution of the data was evaluated with the Shapiro-Wilks test, and it was found that the data were not normally distributed. Data were calculated as numbers and percentages before and after training and analyzed using the Wilcoxon signed-rank test. A statistical significance value of $P < 0.05$ was adopted.

Table 2 Descriptive characteristics of the adolescents

Descriptive characteristics	mean ± SD	Min-max
Age in yr	16.06 ± 0.88	15-17
Parent's age in yr	43.66 ± 5.56	36-52
Age of menarche	13.73 ± 1.09	11-15
Menstruation frequency in d	38.60 ± 39.25	21-180
Period of menstruation in d	5.13 ± 0.99	4-7
	n	%
Is the menstrual cycle regular?		
Yes	13	86.7
No	2	13.3
Adult caregiver		
Mother	14	93.3
Other	1	6.7
Adult education level		
Literate	1	6.7
Primary education	6	40.0
High school	8	53.3

SD: Standard deviation.

RESULTS

While the mean age of adolescents was 16.06 ± 0.88 years, the mean age of adults responsible for adolescent care was 43.66 ± 5.56 years. The mean age of menarche in adolescents was 13.73 ± 1.09 years, the frequency of menstruation was every 38.60 ± 39.25 d, the mean duration of menstruation was 5.13 ± 0.99 d, and the menstrual cycle of 86.7% of the adolescents was regular. The mothers of 93.3% of the adolescents were responsible for their care, and 53.3% of the adults were high school graduates (Table 2).

Table 3 shows the distribution of adolescents' menstrual hygiene skills before and after the training. While 60.0% of the adolescents noticed the onset of bleeding before the training, this rate was 93.3% after the training. Informing the adult about the application steps (80.0%), removing clothes/getting help (60.0%), removing underwear/getting help (66.7%), washing hands (73.3%), receiving clean underwear (66.7%), and removing the sanitary pad out of its bag (60.0%) reached 100% after the training. While the rate of placing the sanitary pad in underwear without touching anything or doing it with help was 60.0% before the training, it was 93.3% after the training. The steps of putting on underwear/getting help (60.0%), putting on pants/getting help (73.3%), and washing hands and drying with a towel (73.3%) reached 100% after the training. Before the training, 66.7% of the adolescents understood that the pad should be changed when it gets soil, while 73.3% understood it after the training. Being able to remove the soiled pad (60.0%), wrap the soiled pad in a bag or do it with help (66.7%), throw it in the trash (66.7%), wipe the perineum from front to back with toilet paper, throw the toilet paper in the trash (60.0%), removing the sanitary pad from its bag and placing it in the underwear (60.0%), putting on the underwear and trousers or doing it with help (86.7%), and washing hands (93.3%) reached 100%. The differences in the following steps of the menstrual hygiene training given to adolescents with ASD were statistically significant before and after the training: took off her clothes/did it with help (P = 0.014); took off her underwear/did it with help (P = 0.025); washed her hands (P = 0.046); took clean underwear (P = 0.025); took the menstrual pad and took it out of its bag (P = 0.014); put on the underwear/did it with help (P = 0.014); put on the pants/do it with help (P = 0.046); washed her hands and dried them with a towel (P = 0.046); took out the dirty pad (P = 0.014); wrapped the soiled pad in her bag/did it with help (P = 0.025); threw the pad in the trash (P = 0.025); wiped her perineum with toilet paper from front to back and threw the toilet paper in the trash (P = 0.014); and removed the sanitary pad out of its bag and placed it in her underwear (P = 0.014) (Table 3).

The difference between the menstrual hygiene skill scores of adolescents diagnosed with ASD before and after training was statistically significant (P < 0.005) (Table 4).

DISCUSSION

In this study, menstruation hygiene skill training was given to adolescents with ASD, video-based menstruation hygiene training was given to the individuals responsible for their care, and the hygiene skills of adolescents with ASD were revealed for the first time. The menstruation process in ASD-diagnosed adolescents was the same as in their healthy peers. These young people may have difficulty coping with emerging situations such as foul odor, blood flow situations/feelings, and using menstrual pads during menstruation. If ASD-diagnosed adolescents are not educated about these changes, periodic crises and coping problems can be seen in adolescents. When we look at the literature, the importance of training young people and their parents about the menstruation process is emphasized. However, young people with ASD remain in the background of this training process.

In many societies, the general viewpoint towards adolescents with ASD may cause the problems, especially during the menstrual period, to be ignored. Menstruation management of adolescents with ASD is complex and requires great patience. Menstruation hygiene skills are one of the biggest problems of adolescents with ASD and their caregivers. Communicating with adolescents with ASD is very important in terms of menstruation management. These young people face many complications during the menstruation process. In order to manage this process in the best way, adolescents and their caregivers should be taught to explain menstruation, physical changes, and especially hygiene

skills. One of the hygiene skills is noticing the start of menstrual bleeding. The current study applied menstrual hygiene skill training to adolescents with ASD. Most adolescents (93.3%) noticed the onset of menstrual bleeding after the training. In addition, all of the adolescents informed their caregivers that menstrual bleeding occurred after the training. In addition to the limited number of studies on this subject in the literature, the current study was consistent with the cross-sectional study of Rodgers *et al*[12] and the mixed-method study of adolescents with mental retardation[12,13].

Adolescents with ASD must be able to perform their daily routine and self-care skills to exist in society and continue their lives like healthy adolescents. For adolescents with ASD to continue their daily routines effectively in their communities, they must first have the ability to provide self-care and general hygiene and be able to dress independently. In particular, they should be able to change menstrual pads independently, which is an important aspect of self-care and menstruation management. Adolescents with ASD should be trained to develop skills and behaviors to acquire self-care skills. In the current study, it was observed that after the menstrual hygiene skill training, all of the adolescents took off their clothes and underwear by themselves or got help and were able to remove the menstrual pad from the bag before changing the menstrual pad. In addition, all the adolescents took out the soiled pad, wrapped it in their bags, and disposed of it properly after the training. In addition, after the training, it was determined that all adolescents with ASD completed the perineum cleaning properly by wiping their perineum with toilet paper from front to back. Another striking study result was that all participants washed their hands before and after changing the soiled pads after the training. In addition, while 60.0% of the adolescents could take the clean menstrual pad out of its bag and place it in their underwear before the training, it was observed that this rate was 100% after the training. According to the study results, adolescents' menstrual hygiene skill analysis scores before and after training increased significantly. In another practical study on dolls in Türkiye, pad-changing training was given to mentally retarded adolescents. It was observed that the training increased the pad-changing skills of adolescents[8]. In addition, the study results aligned with the limited study emphasizing the importance of menstruation training given to adolescents with special needs[14-17]. Further research must reveal the positive results of menstrual hygiene skills training given to adolescents with ASD.

CONCLUSION

In this study, menstruation hygiene skill training was given to adolescents diagnosed with ASD, and the effect of this training on the menstrual hygiene behavior of adolescents was evaluated. As a result of the study, it was observed that the self-care skills, such as hand washing and perineal cleaning especially in changing hygienic pads, of adolescents diagnosed with ASD increased after the training. With the successful results of this study, the importance of dividing the menstruation hygiene skill training into more than one step in adolescents with ASD and conducting this training in small groups became evident. Future research should focus on identifying developmentally sensitive pathways to reveal the voices of adolescents with ASD on their menstruation and puberty experiences. In addition, this study was one of the rare studies that increased the menstrual hygiene skills of adolescents with ASD by training groups of two participants with visual methods and demonstration methods.

Limitations

The present study had some limitations, and future researchers may consider addressing these as they explore this topic. First, this study focused only on ASD adolescents enrolled in special education centers. On the other hand, some adolescents diagnosed with ASD may be unable to access special education centers and face different difficulties. In addition, since the research data were collected from the people responsible for the care of adolescents with ASD, the information obtained may lead to positive or negative biases. The other limitation affecting the generalization of these results was the relatively small sample size. Nonetheless, the data obtained will serve as a valuable foundation for guiding future randomized controlled studies with a larger number of patients.

ARTICLE HIGHLIGHTS

Research background

Adolescents with autism spectrum disorder (ASD) may encounter many difficulties with their menstrual cycles. Potential challenges that adolescents with ASD may face include understanding physical changes, coping with symptoms, emotional sensitivity, communication, personal care, and hygiene. They may have difficulty dealing with newly emerging situations such as foul odor, blood flow situation/feeling, and using sanitary pads, especially during menstruation.

Research motivation

One of the important problems faced by adolescents with ASD during the menstrual period is to practice menstrual hygiene skills. This study was carried out in order to teach this skill to adolescents with ASD and to support their independence.

Research objectives

This study was planned to evaluate the effect of menstruation hygiene skill training given to adolescents with ASD on the

ability to change and wear menstrual pads.

Research methods

This study was conducted in three special education centers in the provinces of Istanbul and Muğla between April 2022 and February 2023, using the "Single Group Pre-Test and Post-Test Model," which is one of the semi-experimental study methods. Before the training, the Adolescent and Parent Information Form and the Adolescent-Specific Menstrual Hygiene Skill Registration Form were administered to the participants included in the study through the individual responsible. In the post-test, only the Menstrual Hygiene Skills Registration Form was used. The individuals responsible for the care of the adolescents completed the post-test at home during the adolescent's first menstrual cycle after training.

Research results

The mean age of adolescents was 16.06 ± 0.88 years. The mean age of menarche in adolescents was 13.73 ± 1.09 years, the frequency of menstruation was every 38.60 ± 39.25 d, the mean duration of menstruation was 5.13 ± 0.99 d, and the menstrual cycle of 86.7% of the adolescents was regular. The mothers of 93.3% of the adolescents were responsible for their care, and 53.3% of the adults were high school graduates. The difference between the menstrual hygiene skill scores of adolescents diagnosed with ASD before and after training was statistically significant ($P < 0.005$).

Research conclusions

It was observed that the self-care skills, such as hand washing and perineal cleaning especially in changing hygienic pads, of adolescents diagnosed with ASD increased after the training.

Research perspectives

With the successful results of this study, the importance of dividing the menstruation hygiene skill training into more than one step in adolescents with ASD and conducting this training in small groups became evident. In addition, this study was one of the rare studies that increased the menstrual hygiene skills of adolescents with ASD by training groups of two participants with visual methods and demonstration methods.

Abstract

BACKGROUND

Cerebrotendinous xanthomatosis (CTX) is a rare autosomal recessive lipid-storage disorder caused by mutations in *CYP27A1*. Psychiatric manifestations in CTX are rare and nonspecific, and they often lead to considerable diagnostic and treatment delay.

CASE SUMMARY

A 33-year-old female patient admitted to the psychiatric ward for presentation of delusions, hallucinations, and behavioral disturbance is reported. The patient presented with cholestasis, cataract, Achilles tendon xanthoma, and cerebellar signs in adulthood and with intellectual disability and learning difficulties in childhood. After the characteristic CTX findings on imaging were obtained, a pathological examination of the Achilles tendon xanthoma was refined. Replacement therapy was then initiated after the diagnosis was clarified by genetic analysis. During hospitalization in the psychiatric ward, the nonspecific psychiatric manifestations of the patient posed difficulty in diagnosis. After the patient's history of CTX was identified, the patient was diagnosed with organic schizophrenia-like disorder, and psychotic symptoms were controlled by replacement therapy combined with antipsychotic medication.

CONCLUSION
Psychiatrists should be aware of CTX, its psychiatric manifestations, and clinical features and avoid misdiagnosis of CTX for timely intervention.

Key Words: Cerebrotendinous xanthomatosis; Psychotic symptom; *CYP27A1* gene mutation; Novel likely pathogenic variant; Case report

Core Tip: Cerebrotendinous xanthomatosis (CTX) is a rare autosomal recessive lipid-storage disorder, characterized by diverse systemic and neuropsychiatric manifestations. Psychiatric manifestations in CTX are typically nonspecific, and past cases have reported a scarcity of psychotic symptoms, particularly delusions and hallucinations. In this report, we present a case of CTX exhibiting a hallucinatory-paranoid syndrome and describe the diagnostic and therapeutic processes associated with CTX. The long-term treatment effect in CTX may depend on age at start of treatment and psychiatrists should be cognizant of CTX to facilitate timely intervention.

INTRODUCTION

Cerebrotendinous xanthomatosis (CTX) is a rare autosomal recessive inherited metabolic lipid-storage disorder related to bile acid biosynthesis pathways. It is caused by biallelic pathogenic variants in *CYP27A1* (2q35), which codes sterol 27-hydroxylase, a mitochondrial enzyme of the cytochrome P450 oxidase system. Reduction in the activity of this enzyme leads to an increased formation and storage of abnormal lipid content in several tissues, especially tendons, lenses, and the peripheral and central nervous systems. Typically, the affected individuals develop tendon xanthomas, cataracts, dementia, pyramidal paresis, cerebellar ataxia, and peripheral neuropathy. As epidemiologic data are limited and CTX may be substantially underdiagnosed, the prevalence of the disease is underestimated. No consensus exists on the prevalence of CTX, with an estimated rate of < 3:100000–5:100000 worldwide[1]. A recent worldwide genetic epidemiological study estimated the incidence of CTX to be 1:36042-1:468624 and highest among South Asians and East Asians, followed by North Americans, Europeans, and Africans[2]. The psychiatric manifestations of CTX are variable, with the most common manifestations being intellectual disability, behavioral disorders, and mood disorders. Few patients have delusions, hallucinations, paranoid ideas, or catatonia, similar to the features of schizophrenia. Thus, making a timely diagnosis is difficult for clinicians. Early diagnosis and treatment initiation in patients with CTX is of great importance because significant reversal of the disease progression could be achieved. Consequently, an enhanced understanding of this rare disease is necessary.

CASE PRESENTATION

Chief complaints

A 33-year-old woman was admitted to the psychiatric acute ward with the following symptoms: delusions of persecution, auditory hallucination, impulsive behavior, and emotional instability.

History of present illness

For 6 mo, the patient showed hostility towards her colleagues, firmly believing that they wanted to harm her. She could hear abusive voices of colleagues when she was alone. The false belief and voice interfered with the social relations and behavior of the patient, leading to outrunning behavior. In addition, the patient exhibited impulsive acts and temperamental behavior, such as tearing people's clothes, smashing things, standing outside naked when she became excited, and running around at midnight. She also experienced severe depression for several days, with crying and expressing a desire to commit suicide by euthanasia.

History of past illness

According to her mother, the patient has been weak and obtuse since childhood and was unable to pass primary school exams. She required supervision and care from her family in her personal life. Despite being able to work, she could not perform her job well and did not get along with her colleagues, leading to her dismissal from several companies. At age

18, she underwent cataract surgery, and at age 26, she underwent cholecystectomy for cholestasis.

A review of the patient's medical records revealed that she presented with swelling in her left Achilles tendon, pain, and skewed walking to the right side 5 years ago. Three years ago, she was admitted to the neurology department, where biochemical tests revealed an elevated total biliary acid level of 11.2 μmol/L (normal value ≤ 10.0) and decreased levels of chenodeoxycholic acid and ursodeoxycholic acid. Subsequently, a biopsy of the left Achilles tendon was performed, revealing numerous lipid crystals and a few foamy macrophages (Figure 1A). The patient underwent genetic analysis, which identified two mutations in the *CYP27A1* gene associated with CTX: c.1263 + 3G>C and c.379C>T. On the basis of these findings, the patient was ultimately diagnosed with CTX and prescribed chenodeoxycholic acid (750 mg/d) and rosuvastatin (10 mg/d).

Personal and family history

There was no family history of psychiatric diseases.

Physical examination

During hospitalization in the psychiatric ward, the patient's brief psychiatric rating sale (BPRS) score was 40, her Wechsler intelligence scale score was 65, and the total biliary acid returned to normal levels. Nervous system examination showed normal muscle tone in the extremities, grade 5 muscle strength, instability in the heel-knee-tibia test of the right lower extremity, and a positive Romberg sign. In the mental status examination, the patient exhibited the following: verbal auditory hallucination; delusions of persecution; negative perceptions; irritability; childish emotions; poor general knowledge, understanding, judgment, and calculation; impulsivity; and lack of insight.

Laboratory examinations

After nearly 3 years of adequate chenodeoxycholic acid treatment, the total biliary acid level returned to normal.

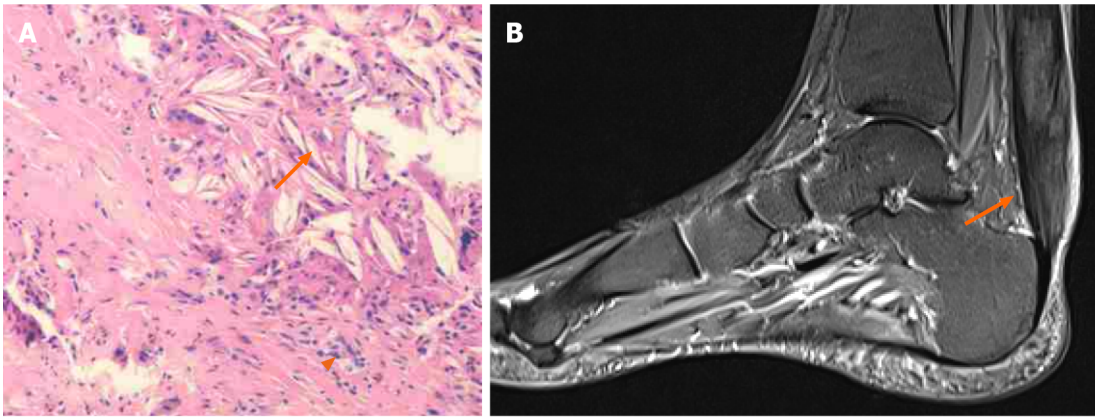
Imaging examinations

Brain magnetic resonance imaging (MRI) revealed symmetrical patchy abnormal signals in the dentate nuclei and deep medulla of the bilateral cerebellar hemispheres. These signals exhibited a slight decrease in signal intensity on T1-weighted images (T1WI) (Figure 2A) and a slight increase in signal intensity on fluid attenuated inversion recovery (FLAIR) (Figure 2B). Left-ankle-joint MRI showed that the inhomogeneous area had a considerable local thickening of the left Achilles tendon. The area displayed clear boundaries measuring approximately 6.6 cm × 1.2 cm and exhibited a slightly elevated signal intensity on T1WI and a similar slightly elevated signal intensity on the proton density weighted image, accompanied by linear hypointensity within (Figure 1B). Brain magnetic resonance spectroscopy (MRS) showed decreases in N-acetylaspartate (NAA) intensities and increases in lactate and lipid signals (Figure 2C and D).

FINAL DIAGNOSIS

In accordance with International Classification of Diseases-10 criteria, the patient received the following diagnoses: Organic schizophrenia-like disorder and CTX.

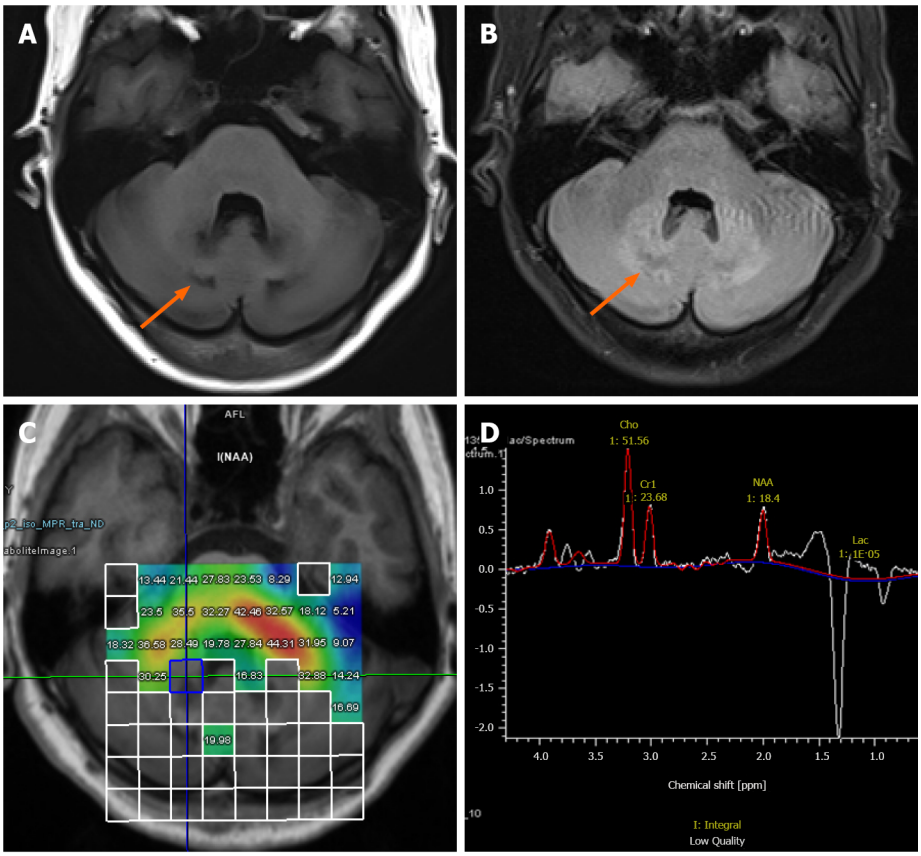
TREATMENT



Concurrent with chenodeoxycholic acid treatment for the primary condition, we administered olanzapine to manage the patient's psychotic symptoms, and sodium valproate to stabilize mood while augmenting the antipsychotic medication.

OUTCOME AND FOLLOW-UP

After treatment, the psychotic symptoms were remarkably relieved, her emotions were relatively stable, and impulsive or noisy behavior did not manifest itself. The reassessed BPRS score was 21. During the 3-mo outpatient follow-up, the patient took medication on time and occasionally experienced emotional fluctuations but was able to listen to persuasion and did not exhibit any more impulsive behavior or running.



DISCUSSION

The clinical presentation of CTX is characterized by diverse systemic and neuropsychiatric manifestations and combinations of symptoms that vary from patient to patient. Of these, psychiatric disturbances are considered a strong diagnostic indicator of CTX, but the symptoms are so variable, as in this case, that making a timely diagnosis is difficult for clinicians. CTX is estimated to have a 15–20-year diagnostic delay[3,4].

Figure 2 Brain imaging findings. A: Brain magnetic resonance imaging reveals patchy symmetrical abnormal signals in the dentate nuclei and deep medulla of bilateral cerebellar hemispheres and a slight decrease in signal intensity on T1 weighted image; B: Slight increase in signal intensity on fluid attenuated inversion recovery; C: Magnetic resonance spectroscopy shows right cerebellar dentate nuclei; D: Decreases in N-acetylaspartate intensities and increases in lactate signals and lipid signals.

The lack of specificity of the early clinical symptoms of CTX is the main reason why the disease is difficult to diagnose in a timely manner, and clinicians must often consider the clinical features of multiple systems, biochemical tests, and radiological examination. Among them, the dentate nucleic signal change in MRI is considered a strong diagnostic indicator[3]. The distinctive neuroradiological findings of CTX show symmetrical abnormalities in the bilateral cerebellar dentate nuclei region with a low signal intensity on T1WI and a high signal intensity on T2 weighted image and FLAIR. The brain MRS shows decreases in NAA intensities and increases in lactate signals[5]. The gold standard for diagnosing CTX is the analysis of the *CYP27A1* gene. In the present case, two mutations were confirmed in the *CYP27A1* gene by

genetic sequencing, with c.379C > G being previously reported as pathogenic and considered one of the most frequent mutations in the Chinese population[6]. However, the relationship between the unreported mutation at the c.1263 + 3G > C locus and the CTX disease phenotype must be further explored.

The psychiatric manifestations of CTX among the Chinese population are infrequently discussed, but foreign literature suggests that intellectual disability, attention deficit hyperactivity disorder, and autism spectrum disorder are often present in childhood or adolescence, with mood and impulsive behavioral symptoms becoming more prominent in adulthood[7]. In the present case, the patient exhibited psychiatric manifestations consistent with those in previous studies. A notable detail that the patient also exhibited hallucinatory-paranoid syndrome, which was scant in past cases and is the first description in Asian population[8]. Psychotic manifestations in CTX are rare, especially in younger patients, and they are often misattributed to psychiatric disease. Most of the psychiatric manifestations of CTX appear after xanthomas and neurological symptoms[7], allowing psychiatrists to identify this organic disorder more easily. Chenodeoxycholic acid is currently the first-line treatment for CTX, and its combination with antipsychotic medication may be beneficial for most patients if psychotic symptoms are present[8]. In the present case, the bile acid level returned to normal after nearly 3 years of adequate chenodeoxycholic acid treatment. The psychiatric symptoms remarkably improved after the combination of the antipsychotic olanzapine and the mood stabilizer sodium valproate during hospitalization. Moreover, the condition was stable at the 3-mo follow-up, indicating that such drugs have good efficacy on psychiatric symptoms associated with CTX.

The long-term treatment effect in CTX may depend on the age at start of treatment. At a point in time demarcation, two different therapeutic effects were observed. A study showed that patients with CTX who started chenodeoxycholic acid treatment before the age of 24 have a better prognosis[9], whereas a follow-up revealed minimal progression in MRI imaging compared with baseline[10].

CONCLUSION

In psychiatric clinical practice, patients with intellectual disability come to the clinic because of concomitant psychiatric behavioral symptoms, and psychiatric specialists need to pay attention to the differential diagnosis, especially when patients are found to have Achilles tendon xanthomas, juvenile cataracts, childhood-onset chronic diarrhea, and cholestasis. Thus, further improvement of biochemical tests, such as serum cholestanol, radiological examination of the Achilles tendons and brain, and genetic analysis, is needed to avoid a missed or misdiagnosis of CTX for timely intervention.

ACKNOWLEDGEMENTS

We would like to thank the patient for her understanding and willingness to participate in this study.

AIMS AND SCOPE

The primary aim of *World Journal of Psychiatry* (*WJP*, *World J Psychiatry*) is to provide scholars and readers from various fields of psychiatry with a platform to publish high-quality basic and clinical research articles and communicate their research findings online.

WJP mainly publishes articles reporting research results and findings obtained in the field of psychiatry and covering a wide range of topics including adolescent psychiatry, biological psychiatry, child psychiatry, community psychiatry, ethnopsychology, psychoanalysis, psychosomatic medicine, *etc*.

INDEXING/ABSTRACTING

The *WJP* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Current Contents/Clinical Medicine, Journal Citation Reports/Science Edition, PubMed, PubMed Central, Reference Citation Analysis, China Science and Technology Journal Database, and Superstar Journals Database. The 2023 Edition of Journal Citation Reports® cites the 2022 impact factor (IF) for *WJP* as 3.1; IF without journal self cites: 2.9; 5-year IF: 4.2; Journal Citation Indicator: 0.52; Ranking: 91 among 155 journals in psychiatry; and Quartile category: Q3.

Abstract

Delirium is an acute reversible neuropsychiatric syndrome caused by multiple factors. It is associated with many adverse clinical outcomes including cognitive impairment, functional decline, prolonged hospitalization, and increased nursing service. The prevalence of delirium was high in department of cardiology, geriatric, and intensive care unit of hospital. With the increase in the aged population, further increases in delirium seem likely. However, it remains poorly recognized in the clinical practice. This article comprehensively discusses the latest research perspectives on the epidemiological data, risk factors, preventive interventions, overlapping symptoms, and clinical measures of delirium, including specific measures to manage delirium in clinical real-world situations. This article helps readers improve their knowledge and understanding of delirium and helps clinicians quickly identify and implement timely therapeutic measures to address various delirium subtypes that occur in the clinical settings to ensure patients are treated as aggressively as possible.

Key Words: Delirium; Risk factors; Preventive interventions; Research progress; Review; Clinical practice

DOI: https://dx.doi.org/10.5498/wjp.v13.i12.973

INTRODUCTION

Delirium is a group of syndromes characterized by acute changes in attention, consciousness, and cognitive function that cannot usually be attributed to pre-existing neurocognitive disorders. According to ICD-11, delirium is an acute or subacute onset of attention deficit (*i.e.*, diminished ability to direct, focus and maintain attention) and impaired consciousness (*i.e.*, diminished orientation to the environment), with symptoms often fluctuating throughout the day with other cognitive deficits (*e.g.*, memory, language, visuospatial function, or perceptual deficits) that can interfere with the sleep-wake cycle; the etiology is often nonpsychiatric behavioral disorders, substance or drug intoxication or withdrawal.

Regarding delirium incidence, epidemiological data vary across countries or regions, medical scenarios, and assessment methods[1]. In Table 1, the highest delirium incidence was found in post-surgical patients, intensive care unit (ICU) patients, and patients with dementia, with extremely high incidence in the elderly population with dementia (up to 56%), postcardiac surgery patients (range: 11%-46%), and patients in the ICU ward (range: 19%-82%).

Delirium leads to increased treatment needs, longer hospital stays, and increased burden of care for patients, with extremely high medical costs. However, 30%–40% of delirium cases can be prevented[1-3]. Therefore, a comprehensive and systematic understanding of the entire delirium process is important for preventing and responding to its occurrence. This study reviews the whole delirium process and its latest research progress in risk factors, preventive interventions, identification of superimposed symptoms, and clinical measures to provide a comprehensive and systematic account of delirium and to present the latest medical information.

LITERATURE REVIEW METHODOLOGY

A search of PubMed and EMBASE databases was performed in July 2022. The search strategy focused on terms for "delirium AND risk factors AND epidemiology," "delirium AND preventive interventions," "delirium AND overlapping symptoms," "delirium AND clinical measures," and "delirium AND prevention and therapy" in 10 years. Although 8290 papers were initially evaluated, only those that fulfilled the following criteria were included in the study: (1) The article was published in English; (2) The trials included original data, as full articles in peer-reviewed journals were included; (3) The studies were representative of the general population or of specific patient populations; and (4) When two or more articles reported data from the same study sample, only the most relevant article was considered. Ultimately, 128 articles were retrieved, which were manually examined for relevance, and 89 articles were identified for further assessment.

RISK FACTORS

Delirium is usually not triggered by a single factor. Patients are often exposed to multiple risk factors, broadly classified into inherent (or predisposing) and controllable risk factors (or precipitating)[4]. Identifying various factors, such as brain tissue hypoxia, inflammation, and drowsiness triggered by sedation, and controlling them can help prevent or improve delirium[5]. Patients with more inherent risk factors can trigger delirium with the action of a few controllable factors[6,7].

Predisposing factors

Advanced age: Delirium is very common among hospitalized older adults; however, its etiology remains unclear[6]. With increase in age, organs deteriorate, and brain and cerebrovascular functions decline even in a non-diseased individual[8]. Neurons use glucose provided by the cerebral microvascular system to produce ATP *via* glycolysis as an energy uptake pathway[9]. The accumulation of neuronal and cerebral microvascular damage throughout life disrupts the energy uptake pathway, leading to inadequate energy uptake and decreased energy metabolism in the brain or specific areas of the brain. This can result in dysfunction in various ways and lead to delirium development in older individuals[10].

Cognitive decline or impairment: Dementia and neurodevelopmental delay are risk factors for delirium. Patients with Alzheimer's disease have a relatively high risk of delirium. Delirium occurred at a significantly higher rate in patients with faster cognitive decline than in those with slower cognitive decline[11]. The same higher prevalence of delirium exists for neurodevelopmental delays in childhood[12]. This evidence confirms that a low cognitive level is a risk factor for delirium.

History of delirium: The duration of delusions varies greatly among individuals, with most cases lasting a few days and some lasting several months. Persistent delirium is not uncommon, with 20% of patients still having some symptoms 6 mo after delirium onset[13]. In such cases, the likelihood of delirium recurrence is extremely high. Patients who have experienced delirium once are more likely to experience delirium again. Moreover, delirium maybe a predictor of

NR: Not reported; NA: Not available; ICU: Intensive care unit; DSM: Diagnostic and Statistical Manual of Mental Disorders; DRS: Delirium Rating Scale; CAM: Confusion Assessment Method.

cognitive decline and dementia[14]. History of delirium is common in patients with Alzheimer's disease dementia and dementia with Lewy bodies[15].

History of emotional disturbance: Severe depressive symptoms in preoperative patients were significantly associated with higher delirium incidence[16]. A cohort study showed that depression and post-traumatic stress disorder severity were positively associated with delirium duration during a 3-mo follow-up[17].

History of alcohol abuse: During alcohol withdrawal, norepinephrinergic hyperexcitability causes symptoms such as increased blood pressure, tremors, and anxiety, which can be controlled with adrenergic agonist drugs[18]. Such drugs are also used to prevent delirium in elderly patients undergoing cardiac surgery or other procedures, including clonidine or dexmedetomidine treatment[19]. Opioids increase norepinephrine release, thereby increasing the risk of delirium development[20,21]. The use of benzodiazepines in the clinical management of alcohol withdrawal syndrome has been associated with disrupted sleep patterns and delirium[22].

Malnutrition: Nutritional deficiency is a risk factor for delirium development[23]. Preoperative malnutrition is correlated with postoperative delirium. Moreover, elevated nutrition levels may reduce the risk of postoperative delirium[24].

Visual and auditory impairment: Visual and hearing impairment increases risk of delirium; in general medical patients, the risk of delirium is 2.1-3.5 times higher in patients with visual impairment than in those without. In contrast, in surgical patients, the risk of delirium is 1.1 and 1.3 times higher in patients with visual and hearing impairment, respectively[1].

Other factors: Other factors include frailty, cardiovascular disease, cerebral atrophy, white matter disease, low education level, male sex, and comorbidities[10].

Precipitating factors

Brain function impairment: Delirium is affected by various factors of brain function, including cerebrovascular injury [25], altered metabolic levels in the brain[26], neurotransmitter imbalance[27], and damage to brain network connections

[28,29]. Excessive microglial activation, impaired endothelial barrier function, and blood-brain barrier dysfunction may be associated with delirium and severe cognitive impairment[30].

Acute somatic diseases: Acute somatic illnesses such as sepsis, hypoglycemia, and liver failure can increase the risk of delirium[31]. Septicaemia-related encephalopathy is a common neurological complication of sepsis that is poorly understood and is associated with increased morbidity and mortality. The clinical manifestations of the disease ranges from mild confusion and delusion to severe cognitive impairment and deep coma[30]. Recent popular theories such as the brain-gut axis, brain-kidney axis, and brain-spleen axis suggest that physical health can affect brain function to a certain extent[32,33].

Infection: Patients who develop delirium after infection show a significant increase in the presence of synaptic damage markers[34]. Patients with neocoronary pneumonia may also develop cerebral hypoxia and delirium[35].

Drug use: Drug use and withdrawal, including changes in medication use, are associated with delirium. Benzodiazepines, dihydropyridines, L-type calcium channel blockers commonly used to treat hypertension, antihistamines, and opioids may pose a high risk of delirium[36].

Sleep rhythm disorders: Sleep rhythm disturbance and sleep deprivation are important factors in delirium development in ICU patients[37]. Sleep disorders and delirium share many symptoms, and their similarity has led to the belief that they are highly correlated[38].

Electrolyte imbalance: Electrolyte imbalance is a risk factor for delirium. Studies have reported that in 53 patients with delirium with serum electrolyte imbalance, correction led to a significantly shorter delirium duration in 18 patients than in 35 patients without electrolyte correction[39].

Environment: The probability of delirium increases by being in a 24-h light environment in the ICU ward or by changes in the senses, including vision and hearing, due to environmental changes[40].

Pain and surgical anesthesia: Both pain and anesthetic drug use for pain relief may trigger delirium; however, the interaction between the two and the extent of their contribution to delirium remains unclear[36]. A multicenter randomized clinical trial, among patients over 65 years old with fragile hip fractures, reported no significant difference in the incidence of delirium between general anesthesia and regional anesthesia within 7 d after surgery[41].

Other factors: Other factors include poor feeding, drug combinations, lack of communication, and physical restraint (physical activity restriction).

PREVENTIVE INTERVENTIONS

Prevention, targeting controllable factors, can effectively control delirium, including reducing its incidence by avoiding functional brain damage or preoperative precautions. Yale University School of Medicine conducted a randomized controlled trial for delirium prevention that demonstrated the feasibility of a multimodal non-pharmacologic protocol to reduce the delirium incidence from 15% to 9%[4]. In this study, the delirium prevention protocol focused on managing the following six risk factors: disorientation, inactivity, sleep deprivation, visual impairment, hearing impairment, and dehydration. This prevention program also applies to healthcare settings such as nursing homes[42]. The long-term care plan adaptation for elderly patients with high delirium risk factors in the geriatric ward care can effectively prevent delirium[43].

Non-pharmacological approaches to effective delirium prevention include occupational therapy. Tobar provides a detailed review of the role of occupational therapy in delirium prevention in critically ill patients and provides a vision for future research in this area[44]. Environmental improvements, including minimizing noise and light at night and promoting sleep consolidation, can also help prevent delirium onset[45]. Reducing physical activity limitations is also important to allow patients to move early; physical activity restriction triples the odds of delirium[46].

Pharmacological approaches to delirium prevention include the use of melatonin to preventing delirium. Melatonin improves sleep quality and increases sedation levels, preventing and reducing delirium incidence. However, melatonin does not reduce delirium duration in patients who already have delirium[47]. In response to sleep problems, it is also necessary to determine in the clinic whether the problem is organic or functional; organic diseases, such as heart and respiratory disease, can also include sleep problems. In functional sleep problems, adjusting the sleep rhythm can help prevent delirium occurrence. In addition, patients with sleep problems caused by fear of surgery and changes in the sleep environment are considered functional. The use of melatonin in such cases improves sleep rhythm and prevents delirium [48]. The use of other sleep-improving drugs, such as ramelteon, for delirium prevention has also been studied[49].

Antipsychotic use for delirium prevention remains highly controversial. A randomized placebo-controlled study showed that haloperidol had a preventive effect in elderly hip surgery patients at risk of delirium[50]. Numerous studies have been conducted on haloperidol for delirium prevention[51,52]. A risperidone trial for delirium prevention in postoperative cardiac patients found that postoperative delirium incidence was significantly lower in the 1 mg risperidone group than in the placebo group (11.1% *vs* 31.7%, $P = 0.009$)[53]. A review of studies concluded that antipsychotic medication use was not related to delirium duration, severity, or place of care and that there was high heterogeneity among studies[54]. Second-generation antipsychotics are more effective than placebo in preventing delirium onset; however, delirium severity was not reduced in patients receiving prophylactic antipsychotics[55].

IDENTIFICATION OF OVERLAPPING SYMPTOMS

Clinical manifestations

The clinical manifestations of delirium are complex and vary, and they are described by the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition, as altered attention, significantly different from the basal level and accompanied by changes in consciousness, cognitive decline, and sleep rhythm disturbances[56]. Delirium has a rapid onset and appearance of symptoms, duration of several hours or days, and a fluctuating nature. For ease of memory, the diagnostic criteria for delirium have been described more simply as A (attention and awareness), disturbances in attention and awareness; B (short period, hours or days), developing over a short period, usually hours or days; C (cognitive deficit), cognitive decline; D (disturbances in A and C), other cognitive deficits that interfere with A and C judgment, such as a complete coma state, are excluded; and E (exposure to medical conditions or drugs), exposure factors, such as surgery and medications.

The diagnostic process consisted of two basic steps. First, a bedside patient assessment was performed to determine the level of attention and arousal and the presence of other cognitive deficits, psychotic features, or mental status abnormalities. Second, the patient's baseline attention and consciousness status were determined by accompanying relatives or caregivers to obtain evidence of acute change.

Assessment methods

After the initial diagnosis, the patient must be further evaluated to obtain more details, including features such as delusions, hallucinations, and mood changes. These details are very important and affect the patient's subsequent treatment or management plan.

Neuropsychological scales: More than 50 assessment tool scales have been developed, with varying conditions of use, mainly including use when delirium first appears or is suspected, when monitoring delirium in hospitalized patients on a regular daily basis, during brief screening, during detailed symptom documentation and neuropsychological assessment, and when assessing delirium severity[57]. Table 2 shows the commonly used neuropsychological scale of delirium assessment.

Ancillary investigations: Delirium assessment should also consider its precipitating factors; therefore, detailed ancillary examinations such as blood, computed tomography (CT), magnetic resonance imaging (MRI), and electroencephalography (EEG) should be performed. In routine blood parameters, the mean red blood cell volume and aspartate aminotransferase can be delirium predictors in trauma patients[58]. Routine blood tests should corroborate the patient's medical history and clinical features. In addition, some cases of delirium are caused by primary central nervous system disease. Specific brain tests, such as CT or MRI, EEG, lumbar puncture, and antibody testing for autoimmune encephalitis, are selectively performed in such cases. However, it is not reasonable to perform CT in all patients with delirium. A study that included 1653 patients showed that only 11% of patients had positive CT findings, with cerebral hemorrhage being the most common cause of delirium[59]. MRI showed that reduced cerebral blood flow, oxygenation, and abnormal glucose uptake might be associated with delirium, including a high white matter signal in the brain[60].

Differential diagnosis and superimposed symptoms

Although there are similarities in clinical manifestations between the delirium and dementia subtype, including fluctuating cognitive decline exhibited by dementia with Lewy body (DLB), visual hallucinations or delusions exhibited by DLB and Parkinson's disease dementia, and attention deficit in severe Alzheimer's disease (AD), all are similar to delirium presentation. However, there are also significant differences: in terms of the mode of onset, delirium is acute and dementia is slowly progressive; concerning duration, delirium usually lasts for a few hours or days, while dementia lasts for a long time; and there is decreased arousal in delirium and that in dementia remains relatively intact.

Previous studies have shown that symptoms such as dementia and depression sometimes appear in parallel with delirium, leading to poor prognosis and high in-hospital mortality and readmission rates. Identifying delirium superimposed dementia (DSD) is important for timely treatment. Patients with dementia who suddenly present with symptoms such as irritability, unexplained falls, resistance or reluctance to communicate with caregivers, drowsiness, and hallucinations need to be closely monitored for DSD and promptly treated symptomatically[61]. Delirium and depression are very common neuropsychiatric syndromes in the elderly, and accurate condition determination is necessary for providing the best treatment plan. However, the considerable clinical overlap of symptoms makes proper identification difficult, leading to adverse medical outcomes, such as clarifying whether the patient's mood disorder is a manifestation of delirium or depression or the comorbidity or primary stage before implementing therapeutic measures [62].

CLINICAL MEASURES AFTER DELIRIUM ONSET

The best management strategy is a multifaceted intervention focused on treating precipitating illnesses, reviewing medication regimens, managing distress, mitigating comorbidities, and maintaining environmental comfort. Clinical measures are divided into non-pharmacologic, non-antipsychotic, and antipsychotic measures.

Table 2 Common delirium assessment scales

Name	Time (min)	Application	Sensitivity (%)	Specificity (%)	Rigorous training	Suitable for examining DSD
Confusion Assessment Method (CAM)[92,93]	3-10	No ICU	46-94	63-100	Yes	Yes
The 4A's test (4AT)[94]	< 2	No ICU	86-100	65-82	No	Yes
The 12-item Stanford Proxy Test for Delirium (S-PTD)[95]	5	No ICU	80	90	No	No
Richmond Agitation Screening Scale (RASS)[96,97]	1	Delirium has just started	65-75	82-90	No	Yes
The Recognizing Acute Delirium As part of your Routine (RADAR)[98]	< 1	Delirium has just started	73	67	No	Yes
Confusion Assessment Method for ICU (CAM-ICU)[99]	< 5	ICU	28-100	53-99	Yes	Yes
Intensive Care Delirium Screening Checklist (ICDSC)[100]	7-10	ICU	73-97	69-97	Yes	No
Delirium Triage Screen (DTS)[101]	< 1	Screening	82	96.1	No	No
Ultra Brief 2 Item Screener (UB-2)[102, 103]	< 1	Screening	93	64	No	No
Simple Question for Easy Evaluation of Consciousness (SQEEC)[104]	< 1	Screening	93	81	No	No
Delirium Rating Scale revised-98 (DRS-R98)[105]	20	Detailed neuropsychological assessment	57-93	82-98	Yes	Yes
Memorial Delirium Assessment Scale (MDAS)[106]	7-10	Detailed neuropsychological assessment	64-82	75-100	Yes	No
CAM Severity (CAM-S)[107]	5	Detailed neuropsychological assessment	NR	NR	No	No

NR: Not reported; ICU: Intensive care unit; DSD: Delirium superimposed dementia.

Non-pharmacologic measures

Non-pharmacological measures are recognized to be effective in dealing with delirium. The intervention protocols vary among studies and mainly include orientation, cognitive stimulation, early activity, non-pharmacological sleep improvement, sensory impairment correction, identification and intervention of potential controllable risk factors or postoperative complications, pain management, gastrointestinal function improvement, supplemental nutrition, and enhancing oxygen delivery.

The Hospital Elder Life Program (HELP) is a systematic non-pharmacological intervention program[63]. According to the British Institute for Health Care Excellence guidelines for preventing, diagnosing, and managing delirium, HELP added entries for coping with hypoxia, infection, pain, and constipation[64].

After delirium onset, non-pharmacological approaches are an indispensable way. Summarily, the main points are ABCDEF: A (assessing, preventing, and managing pain); B (both spontaneous awakening and spontaneous breathing trials), promoting spontaneous awakening and breathing; C (choice of analgesia and sedation), selection of a reasonable analgesic regimen; D (delirium assessment, management, and prevention), delirium pre-assessment, management, and prevention; E (early mobility), early activity; and F (family engagement), family involvement[65].

The primary treatment of delirium is still focused on identifying and managing potential triggers. In practice, the choice of clinical measures will vary according to patient-specific situations. It is crucial to summarize treatment strategies that minimize delirium severity and duration.

Non-antipsychotic measures

Antiepileptic drugs: Valproic acid is effective in both case reports and retrospective cohort studies for delirium treatment [66,67]. Valproic acid can be administered orally or intravenously and is effective in patients with delirium associated with alcohol withdrawal, a history of traumatic brain injury, or mood disorders. Valproic acid should be avoided in pregnant women and patients with significant hepatic or pancreatic dysfunction, active bleeding, or low platelet counts. Before starting valproic acid treatment, patients should have their blood counts and liver enzyme levels checked and monitored.

Alpha-2 agonists: Dexmedetomidine, an alpha-2 agonist, effectively reduces agitation associated with delirium, decreases CNS sympathetic activity, and indirectly reduces the risk of drug combinations by reducing the use of other delirium medications. A national study showed that dexmedetomidine effectively controlled delirium in postoperative patients

other than those undergoing cardiac surgery[68].

Melatonin: The effects of melatonin on delirium have been described previously. Case and retrospective studies have shown that ramelteon helps treat delirium, especially active delirium[69,70]. Melatonin is well-tolerated and safe in the population. The role of melatonin and its receptor agonists in delirium treatment deserves to be studied in-depth. It can enhance sleep consolidation and maintain a good sleep-wake cycle in delirious patients.

Vitamin B1: Nutritional deficiencies, especially vitamin B deficiencies, are associated with delirium[71]. Vitamin B1 deficiency can lead to a range of changes in mental status, including Wernicke's encephalopathy (a triad of nystagmus, oculomotor paralysis, and altered mental status), Korsakoff's syndrome (irreversible memory impairment, usually the result of untreated Wernicke's encephalopathy), and delirium.

Antipsychotic measures

Although no medications have been approved by the United States Food and Drug Administration (FDA) specifically for treating delirium, antipsychotic medications are often used as first-line medications to respond to and manage patients when non-pharmacologic measures are insufficient to control or improve symptoms. However, antipsychotic use for delirium treatment remains controversial. Several studies have shown that the benefits of using antipsychotic medications outweigh the risks for patients, particularly in improving agitation and psychotic symptoms[72,73]. For the control of delirium incidence, duration, severity, length of hospital stay, and mortality, antipsychotic use does not achieve satisfactory results[54].

Obvious psychotic symptoms, such as hallucinations and delusions, can be controlled using antipsychotic drugs. Antipsychotic medications' sedative effect can effectively resolve agitation in patients with delirium. For the core delirium symptoms, including decreased attention and cognition, there is no evidence that antipsychotic medications are effective. More importantly, patients should be carefully monitored for adverse reactions and side effects after antipsychotic medication use.

The choice of medication should be based on the actual clinical situation of the patient to choose the option that maximizes the benefit[74]. For patients with severe circadian rhythm and perceptual disturbances, sedative antipsychotics, such as quetiapine, can be selected for nighttime use; for patients with overexcited delirium, haloperidol can be selected and administered intravenously or intramuscularly for those who cannot tolerate oral administration; for delirium in patients with PD or DLB, quetiapine is preferable because first-generation antipsychotics can aggravate motor symptoms in patients with PD; if these two groups of patients need parenteral medication, olanzapine or ziprasidone can be selected to be administered intramuscularly at minimal doses; olanzapine and risperidone can be selected for patients who cannot swallow; and olanzapine can be used to exert its antiemetic effect when delirium occurs in cancer patients.

Drug dosage was initially administered at the lowest dose and frequency, as assessed by symptom severity[74]. In addition, three major critical values need to be monitored: QTc prolongation (increased risk of sudden death from ventricular tachycardia), extrapyramidal symptoms, and all-cause death in patients with dementia. QTc prolongation is usually associated with antipsychotic use. An investigational study conducted by Pfizer for FDA comparing the QTc interval before and after the use of the maximum daily dose found QTc prolongation ranging from 4.7 ms (haloperidol) to 20.3 ms (ziprasidone)[75]. Patients with delirium should have an electrocardiogram before receiving antipsychotic medication and ensure no significant QTc prolongation interval during treatment. Patients with delirium receiving antipsychotics must also be monitored for extrapyramidal symptoms, such as inability to sit still, rigidity, and dystonia, which can exacerbate emotional disturbances and cause them to change their treatment plans.

DISCUSSION

The complexity and variability delirium symptoms make determining treatment plans more difficult. Patients with delirium are usually admitted to the hospital from the emergency room. The key to treatment is to quickly identify the cause and promptly remove susceptibility factors and triggers, while supporting with symptomatic treatment, maintaining electrolyte balance, and supplementing nutrition. It is also important to prevent complications such as falls, aspiration (aspiration pneumonia), decubitus ulcers, and deep vein thrombosis. A thorough physical examination, detailed history taking, and necessary ancillary laboratory tests are important for detecting the primary cause. Common factors that cause delirium, including infection, cerebrovascular factors, pharmacological factors, surgical anesthesia, and major physical diseases of the heart, lungs, liver, and kidneys, were excluded. Symptomatic treatment of delirium caused by such factors effectively improves symptoms.

In addition, numerous somatic diseases can cause mild edema in the brain cells, leading to transient consciousness impairment. From this perspective, non-pharmacological measures, although not directly therapeutic, can facilitate and accelerate recovery. These include psychotherapy (suggestion), environmental measures (placement of familiar objects in the room), soft lighting (light therapy), and restraint (use during the attack period to avoid accidents). Subsequently, after correcting the primary physical illness, the brain function was restored and delirium symptoms disappeared.

A primary method to prevent delirium is to simply shorten hospitalization, as much as possible[76,77]. Unfamiliar environment, and lack of separation between day and night and disorientation are frequent during admission are also major causes for delirium. Notably, early discharge is beneficial to patient recovery when their health condition is accurately assessed[78].

The following aspects should be noted for the more controversial use of psychiatric drugs. First, psychiatric medications (first or second generation) usually inhibit a person's cognitive-behavioral activity. The principle is to use them as little as possible and for as short a time as possible. Second, psychiatric drugs were selected in the following cases: (1) The patient was agitated; (2) There were many hallucinatory delusions; (3) Behavioral disturbances; (4) Sleeplessness at night; and (5) Non-cooperation and poor compliance with general supportive therapy. Third, ECG should be checked regularly during treatment with psychiatric drugs, and QT interval changes should be closely monitored. When the following two factors are encountered: (1) Prolonged QT interval suggested by ECG on admission; and (2) electrolyte disturbance, psychiatric drugs should be used with caution. The safety of valium drugs is higher than that of psychiatric medications. When the two factors mentioned above improve after clinical treatment, psychiatric drugs or tranquilizer administration should be considered. When using valium, attention should be paid to whether the patient has obstructive respiratory diseases, myasthenia gravis, and other valium contraindications. Protective restraint is more appropriate when both psychotropic drugs and tranquilizers are at greater risk of use. Fourth, clinical readiness to assess the benefit of patients with psychotropic medications: (1) From the patient's perspective, the improvement of psychiatric-behavioral symptoms; and (2) from the caregiver's perspective, there is usually a significant psychosomatic burden of care for patients with delirium, and the severity of the caregiving burden directly affects the quality of patient care.

Patients usually recover within 7-10 d, with a few recovering in 2-4 wk, rarely developing into chronic delirium. Delirium has also been reported to have long-term effects on cognition[24]. The cognitive impairment that occurs after delirium onset in ICU patients is similar to that caused by moderate traumatic brain injury. Moreover, delirium can lead to more severe dementia in AD patients in addition to original dementia, and the risk of dementia development after delirium onset in older adults is eight times higher than that in normal older adults.

CONCLUSION

Summary and outlook

This study comprehensively discussed the latest national and international research perspectives on delirium in terms of risk factors, preventive interventions, overlapping symptoms, and clinical and specific measures to clinically deal with delirium in real-world situations.

Key points

This paper reviews the whole delirium process and its latest research progress in risk factors, preventive interventions, identification of superimposed symptoms, and clinical measures to provide a comprehensive and systematic account of delirium and present the latest medical information. This article helps readers improve understanding of delirium and helps clinicians quickly identify and take timely therapeutic measures to address the various delirium subtypes that occur in the clinic setting. This is to ensure that patients can be treated as aggressively as possible.

Abstract

BACKGROUND

Patients with thalamic infarction experience abnormal blockages of multinucleated vessels, affecting the body and thereby the thalamus. Most patients with thalamic infarction have an adverse prognosis, which seriously affects their safety. Therefore, it is essential to analyze the independent risk factors that influence the prognosis of patients with thalamic infarction and develop corresponding preventive measures.

AIM

To explore the effect of non-high-density lipoprotein cholesterol (non-HDL-C) and Homocysteine (Hcy) levels in cognitive impairment in thalamic infarction.

METHODS

From March 2019 to March 2022, 80 patients with thalamic infarction were divided into a group with cognitive impairment [Montreal Cognitive Assessment (MoCA) score < 26; 35 patients] and a group with normal cognitive function (MoCA score of 26-30; 45 patients) according to the MoCA score. In addition, 50 healthy people in the same period were selected as the control group. A correlation between the non-HDL-C and Hcy levels and the MoCA score and receiver operating characteristic curve was observed, and the serum non-HDL-C and Hcy levels were analyzed for the diagnosis of cognitive impairment in patients with thalamic infarction. According to the Modified Rankin Scale (MRS) score, 80 patients with thalamic infarction were divided into a good prognosis group (MRS score ≤ 2) and a poor prognosis group (MRS score >2).

RESULTS

The non-HDL-C and Hcy levels were significantly higher in the group with cognitive impairment than in the group with normal cognitive function ($P < 0.05$).

There was no significant difference in the non-HDL-C level between the control group and the group with normal cognitive function ($P > 0.05$). The MoCA scores of the group with cognitive impairment were significantly lower than those of the group with normal cognitive function and the control group ($P < 0.05$). There was a significant difference between the control group and the group with normal cognitive function ($P < 0.05$). The non-HDL-C and Hcy levels were correlated with the MoCA score ($P < 0.05$), cognitive impairment [areas under the curve (AUC) = 0.709, 95% confidence interval (95%CI): 0.599-0.816], the non-HDL-C level, and could predict cognitive impairment in patients with thalamic infarction (AUC = 0.738, 95%CI: 0.618-0.859). Hcy combined with non-HDL-C levels can predict cognitive impairment in patients with thalamic infarction (AUC = 0.769, 95%CI: 0.721-0.895).

RESULTS

There were 50 patients in the good prognosis group and 30 patients in the poor prognosis group. Compared with the good prognosis group, in the poor prognosis group, the National Institutes of Health Stroke Scale (NIHSS) score, non-HDL-C level, Hcy level, large-area cerebral infarction, atrial fibrillation, and activated partial prothrombin time were statistically significant ($P < 0.05$). The non-HDL-C level, the Hcy level, the NIHSS score, extensive cerebral serum, and atrial fibrillation may all be independent risk factors for poor prognosis in patients with thalamic infarction ($P < 0.05$).

CONCLUSION

Non-HDL-C and Hcy levels are positively correlated with cognitive impairment in patients with thalamic infarction. Non-HDL-C and Hcy levels can be used in the diagnosis of cognitive impairment in patients with thalamic infarction, and the combined detection effect is better. The main factors affecting the prognosis of patients with thalamic infarction are the non-HDL-C level, the Hcy level, the NIHSS score, large-area cerebral infarction, and atrial fibrillation. Clinically, corresponding preventive measures can be formulated based on the above factors to prevent poor prognosis and reduce mortality.

Core Tip: This study explored the diagnostic and prognostic implications of non-high-density lipoprotein cholesterol (non-HDL-C) and Homocysteine (Hcy) levels for cognitive impairment in patients with thalamic infarction. Both non-HDL-C and Hcy levels were found to be useful for the diagnosis of cognitive dysfunction in patients with thalamic infarction, with their combined detection being more effective. In addition, clinical precautions can be formulated based on their levels to prevent poor prognosis and reduce mortality.

INTRODUCTION

The organization and structure of the thalamus is extremely complex, such as the medial nuclear group and the former nuclear group. In patients with thalamic infarction, an abnormal blocking phenomenon occurs in the blood vessels of multiple nuclei, affecting the body and thereby the thalamus. The majority of patients are mainly characterized by dementia, aphasia and stubborn sexual behavior and insomnia, aggravating the degree of the thalamic infarction, which can lead to cognitive impairment[1]. One study reported that abnormal homocysteine (Hcy) levels led to changes in hippocampal signaling and neuroplasticity in mice[2]. Therefore, abnormal Hcy levels are believed to be related to cognitive impairment in patients with thalamic infarction. Non-high-density lipoprotein cholesterol (non-HDL-C), which mainly contains low density lipoprotein (LDL), intermediate density lipoprotein and chylomicron, is calculated by subtracting HDL from total cholesterol (TC). Other studies have also reported that there is a relationship between non-HDL-C levels and cognitive impairment[3]. For example, in the study of Weaver *et al*[4], non-HDL-C levels were positively correlated with cognitive impairment in patients with lacunar cerebral infarction. As the non-HDL-C level increased in patients with lacunar cerebral infarction, the degree of cognitive impairment increased. However, whether the same occurs in patients with thalamic infarction needs to be further explored. Hcy and non-HDL-C levels are related to cognitive impairment due to disease to a certain extent. Whether Hcy and non-HDL-C levels can be used in the diagnosis of cognitive dysfunction in patients with thalamic infarction is worth exploring. Most patients with thalamic infarction have a poor prognosis, and their safety is seriously affected. The analysis of independent risk factors, especially

Hcy levels, for the prognosis of patients with thalamic infarction and the formulation of relevant prevention measures have important meaning for improving the prognosis of these patients, and whether non-HDL-C level changes can predict the prognosis of patients with thalamic infarction is worth studying. Therefore, this study mainly evaluated the use of Hcy and non-HDL-C levels in the diagnosis of cognitive impairment in patients with thalamic infarction, as well as the influencing factors of poor prognosis to provide a reference for the clinical development of preventive measures to improve the prognosis of these patients. At the same time, the efficient diagnosis of cognitive impairment in patients with thalamic infarction provides a reference for improving the prognosis of these patients, which is of great significance.

MATERIALS AND METHODS

General information

From March 2019 to March 2022, 80 patients diagnosed with thalamic infarction were selected and divided into a group with cognitive dysfunction [Montreal Cognitive Assessment (MoCA) score < 26, 35 patients] and a group with normal cognitive function (MoCA score of 26-30, 45 patients) according to the MoCA score. In addition, 50 healthy people in the same period were included as the control group. There was no significant difference in sex or age among the three groups ($P > 0.05$, see Table 1). After 2 years of follow-up, the prognosis of the 80 patients was evaluated. The selected patients with thalamic infarction were divided into a good prognosis group (Modified Rankin Scale (MRS) score ≤ 2 points) and a poor prognosis group (MRS score > 2 points) according to the MRS score. The inclusion criteria were as follows: patients who were diagnosed by computed tomography or magnetic resonance imaging; patients who met the Cerebrovascular Disease Conference criteria for the diagnosis of thalamic infarction[5]; patients who were admitted within 72 h of onset; and patients who had not taken diuretic drugs or antibiotics within 1 mo after admission. The exclusion criteria were as follows: Patients with dysfunction of the heart, lungs or other organs; patients with malignant tumors or other diseases; patients with immune system diseases; and patients with severe disorders of consciousness. Details are shown in Table 1.

Research methods

Non-HDL-C and Hcy level detection: After fasting for 12 h, venous blood was drawn from the elbow at 6 am the next day, and the serum levels of TC and HDL-cholesterol were detected by an automatic biochemical analyzer. Non-HDL-C levels were calculated as follows: TC-HDL-C.

First, blank wells, standard wells and sample wells were set, corresponding to the addition of standard solution or the solution to be tested, and incubated. Then, biotinylated antibody and enzyme conjugate working solution was added. Next, the liquid in the wells was cleared, and the substrate solution was added.

MoCA score[6]: An MoCA score of less than 26 indicates cognitive impairment, and an MoCA score of 26-30 indicates normal cognition. The evaluation content mainly includes the following aspects: Visuospatial executive ability, naming, attention, language ability, abstraction, delayed recall and orientation. According to the MoCA score, patients with thalamic infarction were divided into a group with normal cognitive function and a group with cognitive dysfunction.

MRS score[7]: An MRS score ≤ 2 indicated a good prognosis, and an MRS score of 3-6 indicated a poor prognosis; a higher score indicated a worse prognosis. An MRS score of 0 indicated that no symptoms were present, and scores of 1 to 5 points indicated different degrees of disability; the higher the score was, the more severe the disability was. A score of 6 indicates patient death. For clinical symptoms, a score of 1 point indicated mild but not significant disability. Scores of two and three points indicated moderate disability, but with the ability to walk alone. A score of 4 points indicated a moderately severe disability, with the inability to walk independently, and a score of 5 points indicated a severe disability and the complete inability to take care of oneself. According to the MRS score, patients with thalamic infarction were divided into a good prognosis group and a poor prognosis group.

National Institutes of Health Stroke Scale score[8]: The Stroke Scale developed by the National Institutes of Health[9] includes level of consciousness, level of consciousness questioning, level of consciousness commands, and optimal gaze. The total score ranges from 0 to 42, with higher scores indicating more severe neurological damage.

Outcome measures: The diagnosis of cognitive impairment was determined and the prognosis of patients with thalamic infarction was predicted using non-HDL-C and Hcy levels. MoCA score, onset time, National Institutes of Health Stroke Scale (NIHSS) score, and activated partial prothrombin time (APTT) were also used as outcome measures.

Statistical methods

SPSS 26.0 and GraphPad Prism software were used to analyze the data. Data on the non-HDL-c level, Hcy level, MoCA score, onset time, NIHSS score, APTT, *etc.* were collected. The chi square test, LSD test (homogeneity of variance test $P < 0.05$) and Tamheeni test (homogeneity of variance test $P < 0.05$) were performed in the three groups (group with cognitive impairment, control group and group with normal cognitive function), and χ^2/t tests were performed in the two groups (good prognosis group and poor prognosis group) (all were in line with a normal distribution). The *t* test was used for quantitative data and the χ^2 test was used for qualitative data. The correlation between non-HDL-C and Hcy levels and the MoCA score was analyzed by Pearson correlation analysis. The diagnostic value of non-HDL-C and Hcy levels in patients with thalamic infarction was analyzed by receiver operating characteristic (ROC) curve analysis. The independent risk factors for poor prognosis in patients with thalamic infarction were analyzed by logistic regression analysis. Logistic regression analysis was used to analyze independent risk factors for a poor prognosis in patients with

thalamic infarction.

RESULTS

Non-HDL-C and Hcy levels in the diagnosis of cognitive impairment in patients with thalamic infarction

Differences in non-HDL-C and Hcy levels in each group: The non-HDL-C and Hcy levels in the group with cognitive impairment were significantly higher than those in the group with normal cognitive function and the control group ($P < 0.05$), and there was no significant difference between the control group and the group with normal cognitive function ($P > 0.05$). Details are shown in Table 2.

Table 2 Differences in non-HDL-C and Hcy levels in each group (X ± S)

Group	The number of cases	Non-HDL-C (tendency/L)	Hcy (mol/L)
The control group	50	3.11 ± 0.52	11.66 ± 0.71
Cognitively normal group	45	3.24 ± 0.54	23.22 ± 3.68
Cognitive impairment group	35	3.98 ± 0.87[1,2]	30.34 ± 4.72[1,2]
F/P value	-	6.393/0.000	25.417/0.000

[1]$P < 0.05$ compared with the control group.
[2]$P < 0.05$ compared with the group with normal cognitive function.
Non-HDL-C: Non-high-density lipoprotein cholesterol; Hcy: Homocysteine.

Observation of differences in MoCA scores: The MoCA score of the group with cognitive impairment was significantly lower than those of the group with normal cognitive function and the control group ($P < 0.05$), and there was no significant difference between the control group and the group with normal cognitive function (P>0.05). Details are shown in Table 3.

Correlation analysis of non-HDL-C and Hcy levels with MoCA scores: Non-HDL-C and Hcy levels were positively correlated with the MoCA score ($P < 0.05$). See Table 4 for details.

ROC curve analysis of the use of serum non-HDL-C and Hcy levels in the diagnosis of cognitive impairment in patients with thalamic infarction: The areas under the curve (AUC) of Hcy levels in predicting cognitive impairment in patients with thalamic infarction was 0.709 [95% confidence interval (95%CI): 0.599-0.816]. The AUC of non-HDL-C levels in predicting cognitive impairment in patients with thalamic infarction was 0.738 (95%CI: 0.618-0.859). The AUC of Hcy combined with non-HDL-C levels in predicting cognitive impairment in patients with thalamic infarction was 0.769 (95%CI: 0.721-0.895). See Table 5 and Figure 1 for details.

The prognostic value of non-HDL-C and Hcy levels in patients with thalamic infarction

Differences in the clinical characteristics of patients with thalamic infarction in the good and poor prognosis groups: There were 50 patients in the good prognosis group and 30 patients in the poor prognosis group. There were significant differences in NIHSS scores, non-HDL-C levels, Hcy levels, and rates of massive cerebral infarction, atrial fibrillation, and APTT between the poor prognosis group and the good prognosis group ($P < 0.05$). Details are shown in Table 6.

Multivariate logistic regression analysis of the influencing factors of a poor prognosis in patients with thalamic infarction: Non-HDL-C levels, Hcy levels, NIHSS scores and atrial fibrillation may be independent risk factors for poor prognosis in patients with thalamic infarction ($P < 0.05$). Details are shown in Table 7.

DISCUSSION

This study first analyzed the use of non-HDL-C and Hcy levels in the diagnosis of cognitive impairment in patients with thalamic infarction; 80 patients with thalamic infarction were selected as the research object, and the MoCA score was used to evaluate the degree of cognitive impairment in the patients. Patients with thalamic infarction were divided into a group with cognitive impairment and a group with normal cognitive function, and medical healthy people were included as controls. The non-HDL-C and Hcy levels in the group with cognitive impairment were significantly higher than those in the group with normal cognitive function and the control group. At the same time, the MoCA scores of the group with cognitive impairment were higher than the scores of each subgroup. In addition, the scores of the group with normal cognitive function and the control group were higher. The higher the MoCA score was, the more normal a patient's cognitive function. The above results showed that there was a certain relationship between the non-HDL-C and Hcy levels and cognitive function in patients. The higher the non-HDL-C and Hcy levels were, the lower the cognitive function of patients. Pearson correlation analysis also showed that the non-HDL-C and Hcy levels were correlated with the MoCA score. The higher the non-HDL-C and Hcy levels were, the lower the MoCA score, indicating more severe cognitive impairment in patients. The results of this study have also been confirmed in a number of studies, such as the study by Fu *et al*[10]. The study found that the Hcy level was associated with cognitive dysfunction in patients with cerebral infarction. The relationship between non-HDL-C and Hcy levels and cognitive dysfunction was further analyzed. The increase in Hcy levels resulted in an abnormal decrease in the vasodilation response, and the activity of CO synthetase was affected; this increased the degree of endothelial injury, further leading to abnormal endothelial function, and promoting the shedding of a large number of endothelial cells. In turn, the formation of arteriosclerosis was affected, ultimately leading to cognitive dysfunction[11]. In addition, an abnormal increase in non-HDL-C levels in the body leads to cognitive dysfunction, which may be mainly related to atherosclerosis. The increased levels of non-HDL-C and LDL-C in the body may lead to the development of atherosclerosis, which may lead to arterial stenosis, increased plaque formation and changes in hemodynamics. An abnormal blood supply in the thalamus may lead to some structural dysfunction, such as in the hippocampus and adjacent tissues, eventually leading to cognitive dysfunction[12].

The ROC curve was further used to analyze the diagnostic efficacy of non-HDL-C and Hcy levels for cognitive impairment in patients with thalamic infarction. The results showed that the combination of non-HDL-C and Hcy levels had higher diagnostic efficacy, which suggested that the combined measurement of non-HDL-C and Hcy levels could be considered to improve the diagnostic efficacy in the diagnosis of cognitive dysfunction in patients with thalamic

cerebral infarction, atrial fibrillation and APTT between the good prognosis group and the poor prognosis group. Logistic regression analysis showed that there were statistically significant differences in the NIHSS score, non-HDL-C level, Hcy level, and rates of atrial fibrillation and APTT between the groups. The non-HDL-C level, Hcy level, NIHSS score, massive cerebral infarction, and atrial fibrillation may be independent risk factors for poor prognosis in patients with thalamic infarction. Hcy levels can lead to an inflammatory response and abnormal endothelial cell function and promote thrombosis, which is one of the influencing factors for poor prognosis in patients with thalamic infarction[13]. Non-HDL-C levels can lead to the development of atherosclerosis in the body and increase the risk of cognitive dysfunction. The NIHSS score is a protective factor in patients with thalamic infarction. The NIHSS score can predict the recovery of patients' neurological function and be used to further judge patient prognosis[14]. Atrial fibrillation is a common arrhythmia and is also a risk factor in patients with thalamic infarction. Due to the generation of atrial fibrillation, cardiac structural abnormalities, hemodynamics, and the micro embolus synthetic quantity are increased, cerebral perfusion and cerebral hypoperfusion are reduced, differences in the ventricular rate occur and the heart rate, cerebral blood flow, and neuronal energy is affected. The nerve fiber and amyloid beta protein levels are reduced, which leads to disorders of speech speed and thinking expression and ultimately affects the prognosis of patients with thalamic infarction[15]. Clinically, for patients with thalamic infarction, relevant preventive measures can be formulated according to the above influencing factors, such as anticoagulant drug therapy to reduce the incidence of atrial fibrillation[16]. The NIHSS was used to evaluate neurological function in patients. Appropriate supplementation with folic acid or other antipsychotic drugs can reduce the Hcy level to a certain extent[17], and the prophylactic use of statins can reduce the non-HDL-C level [18].

CONCLUSION

In conclusion, non-HDL-C and Hcy levels are positively correlated with cognitive impairment in patients with thalamic infarction. Non-HDL-C and Hcy levels can be used for the diagnosis of cognitive impairment in patients with thalamic infarction, and the combined detection effect is better. The prognostic factors of patients with thalamic infarction mainly include the non-HDL-C level, Hcy level, NIHSS score, and rates of large area cerebral infarction and atrial fibrillation. Clinically, corresponding preventive measures can be formulated according to the above factors to prevent poor prognosis and reduce mortality. However, there are some shortcomings in this study. The sample source is biased, the sample size is small, and thalamic infarction is not a common disease because non-HDL-C and Hcy levels may also be affected by other factors. Only the combination of non-HDL-C and Hcy levels in the diagnosis of cognitive dysfunction in patients indicates great deficiencies. This only indicates that non-HDL-C and Hcy levels can be detected simultaneously in the auxiliary diagnosis of cognitive dysfunction in patients with thalamic infarction to improve the diagnostic efficiency.

ARTICLE HIGHLIGHTS

Research background

In patients with thalamic infarction, the blood vessels of multiple nuclei are abnormally blocked, affecting the body and thus the thalamus. Abnormal Homocysteine (Hcy) levels are believed to be related to cognitive impairment in patients with thalamic infarction. Meanwhile, there is a positive correlation between non-high-density lipoprotein cholesterol (non-HDL-C) levels and cognitive impairment in lacunar cerebral infarction.

Research motivation

The analysis of the impact of independent risk factors, especially Hcy levels, on the prognosis of patients with thalamic infarction and the formulation of relevant prevention measures carries great clinical implications for improving patient outcomes. In addition, the value of changes in non-HDL-C levels in predicting the prognosis of patients with thalamic infarction deserves investigation.

Research objectives

To provide a reference for the clinical development of preventive measures to improve the prognosis of patients with thalamic infarction and to efficiently diagnose cognitive impairment in such patients.

Research methods

Eighty patients with thalamic infarction were included and divided into a group with cognitive impairment [Montreal Cognitive Assessment (MoCA) score: < 26] and a group without (MoCA score: 26-30), depending on their MoCA scores. In addition, 50 concurrent healthy controls were selected as a control group. Correlations of the non-HDL-C and Hcy levels with the MoCA score and receiver operating characteristic curve were observed. Serum non-HDL-C and Hcy levels were further analyzed. Furthermore, patients were grouped as a good prognosis group [Modified Rankin Scale (MRS) score: ≤ 2] and a poor prognosis group (MRS score: > 2) according to the MRS score, and the clinical characteristics were comparatively analyzed.

Research results

There was a certain relationship between non-HDL-C and Hcy levels and cognitive function in patients, with higher non-HDL-C and Hcy levels indicating worse cognitive function of patients. Pearson correlation analysis also identified an association between non-HDL-C and Hcy levels and MoCA scores. Specifically, the higher the levels of non-HDL-C and Hcy, the lower the MoCA score, indicating more severe cognitive impairment in patients.

Research conclusions

Non-HDL-C and Hcy levels are positively correlated with cognitive impairment in patients with thalamic infarction, indicating their potential to diagnose cognitive impairment in such patients. In addition, their combined detection contributes to higher diagnostic efficacy.

Research perspectives

Simultaneous detection of non-HDL-C and Hcy levels can assist in the diagnosis of cognitive dysfunction in patients with thalamic infarction, which is of great clinical significance for improving the prognosis of these patients.

Abstract

BACKGROUND

There are systematic differences in clinical features between women and men with schizophrenia (SCZ). The regulation of sex hormones may play a potential role in abnormal neurodevelopment in SCZ. Brain-derived neurotrophic factor (BDNF) and sex hormones have complex interacting actions that contribute to the etiology of SCZ.

AIM

To investigate the influence of BDNF and sex hormones on cognition and clinical symptomatology in chronic antipsychotic-treated male SCZ patients.

METHODS

The serum levels of follicle-stimulating hormone, luteinizing hormone (LH), estradiol (E2), progesterone, testosterone (T), prolactin (PRL) and BDNF were compared between chronic antipsychotic-treated male (CATM) patients with SCZ (n = 120) and healthy controls (n = 120). The Positive and Negative Syndrome Scale was used to quantify SCZ symptoms, while neuropsychological tests were used to assess cognition. Neuropsychological tests, such as the Digit Cancellation Test (DCT), Semantic Verbal Fluency (SVF), Spatial Span Test (SS), Paced Auditory Serial Addition Test (PASAT), Trail Making Task (TMT-A), and Block Design Test (BDT), were used to assess executive functions (BDT), attention (DCT, TMT-A), memory (SS, PASAT), and verbal proficiency (SVF).

RESULTS

Although E2 levels were significantly lower in the patient group compared to the

healthy controls, T, PRL, and LH levels were all significantly higher. Additionally, the analysis revealed that across the entire sample, there were positive correlations between E2 Levels and BDNF levels as well as BDNF levels and the digital cancellation time. In CATM patients with SCZ, a significant correlation between the negative symptoms score and PRL levels was observed.

CONCLUSION
Sex hormones and BDNF levels may also be linked to cognitive function in patients with chronic SCZ.

Key Words: Brain-derived neurotrophic factor; Clinical symptoms; Cognitive function; Schizophrenia; Sex hormones

Core Tip: Brain-derived neurotrophic factor (BDNF) and sex hormones are known to be involved to the psychopathology of schizophrenia (SCZ). However, the influence of BDNF and sex hormones on cognition and symptoms in chronic antipsychotic-treated male (CATM) SCZ patients have yet to be investigated. Testosterone, prolactin (PRL) and luteinizing hormone were significantly higher in the patient group than in the healthy controls while estradiol (E2) levels were significantly lower. Analysis also identified positive correlations between E2 levels and BDNF levels, and BDNF levels and the digital cancellation time, in the whole sample. we found significant correlations between PRL levels and negative symptoms score in CATM patients with SCZ.

INTRODUCTION

It has been proved that there are differences in schizophrenia (SCZ) clinical side effects between females and males[1]. In SCZ, gender differences may play a significant role in the factors that mediate schizophrenic expression[2]. The current study hypothesizes that sex hormones alter the manifestation of symptoms, either directly or indirectly, and account for many of the observed gender differences[3]. The organizational and activational effects of sex hormones on SCZ have received a lot of critical attention[4]. During a crucial period in the fetus's life, organizational effects have a permanent impact on the developing brain. Evidence recommends that adjustments to sex hormones might be related to the neurodevelopmental etiology of SCZ[5]. The actuating impacts are the immediate impact of circulating chemicals. When hormone levels rise, the impact will appear, and when hormone levels fall, the impact will become weaker. Both luteinizing hormone (LH) and testosterone (T) play a role in puberty by promoting the expansion of white matter in the frontal and temporal connections[6]. It is important to note that the regions of the brain that are most affected by adolescent gonadal hormones are also the regions of the brain that are most relevant to the pathophysiology of SCZ[7]. Recent research indicates that T and masculinity predict hippocampus or cerebellum volumes that are typically larger in men[8], whereas estradiol (E2) levels were associated with bilateral insula resting-state functional connectivity in girls[9]. Adolescent hormonal changes may activate genes that regulate normal neurodevelopment, leading to an increase in connectivity and a decrease in gray matter[10].

T has genomic and non-genomic impacts on the cerebrum through androgen receptors, and is involved in hippocampal CA1 neuron morphology[11]. It has been established that estrogen plays a role in cognitive processes such as memory, learning, and mood regulation[12]. Studies in rats have shown that progesterone (P), a neurosteroid, has numerous impacts on cognition, for example, upgrading learning and memory, advancing nerve development and myelination[13].

Sex hormones and brain-derived neurotrophic factor (BDNF) have been linked to cognitive function in an increasing number of studies. For example, a new investigation on ovariectomized rodents showed that E2 essentially expanded spatial learning and memory by increasing 17 β-E2 and BDNF levels in the hippocampus[14]. The BDNF pathway plays a role in the protective effects of estrogen. Additionally, P interferes with estrogen's protective effect under certain conditions[15]. In grown-up male rodents, treatment with T and BDNF intuitively affected androgen receptor articulation [16] as well as dendritic length[17]. According to our previous research, patients with chronic SCZ who suffer from attention and spatial memory impairments have elevated serum T levels[18]. However, there are currently insufficient systematic studies on the interplay between BDNF and follicle-stimulating hormone (FSH), LH, E2, P, T, and prolactin (PRL) in chronic antipsychotic-treated male (CATM) patients.

We hypothesize that neurotrophic factors mediate cognitive decline in male patients with chronic SCZ *via* hormones. This article focuses on the following issues: (1) Whether patients with chronic SCZ have altered levels of BDNF and sex hormones (including FSH, LH, E2, P, T, and PRL); (2) Whether there is a connection between BDNF and sex hormone levels; and (3) Whether the communication between BDNF and sex hormones is involved in the clinical symptoms and

cognition of SCZ patients.

MATERIALS AND METHODS

Participants

This was a case-control study, and the sample size calculation method was as follows: = 0.05, β = 0.20, Meant = 0.25, and Meanc = 0.21; the sample size calculation was input into the Biostatistics website (www.cnstat.org/samplesize/12/), and the difference between the two sets of means was compared, n = 200 (cases). If the maximum number of lost cases was considered to be 20%, then the total number of cases in both groups should be: 200 + 200 0.2 ≈ 240 (cases), nt = 120 (cases), nc = 120 (cases) and power = 0.8036.

A total of 120 CATM patients with SCZ from the Affiliated WuTaiShan Hospital of the Medical College of Yangzhou University (Yangzhou, China) were recruited between February 2018 and July 2019. According to the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition, these patients fulfilled the criteria for SCZ. In addition, 120 healthy males were included as control subjects. The controls were matched by age and education with the SCZ group. All the controls were in good physical health and had no mental illness. Table 1 depicts the demographic characteristics of the patient group and the healthy control group. Participants in this study must have taken antipsychotic medication for at least a year. Psychopathology was assessed using the Positive and Negative Syndrome Scale (PANSS). Subjects were excluded if they had a history of substance abuse or dependence, neurological diseases, or serious psychiatric comorbidities.

The WuTaiShan Hospital Ethics Committee approved the study (approval No. 2018-011), and written informed consent was provided by each participant.

Hormone assay

Serum samples were centrifuged (3000 rpm for 10 min) and then stored at -80°C. Sex hormone levels (FSH, LH, E2, P, T, PRL) were estimated using an Entrance immunoassay analyzer and the manufacturer's reagents (Beckman Coulter Inc., Brea, CA, United States). After that, an enzyme-linked immunosorbent assay (Emax Immunoassay System kit) was used to measure the concentration of BDNF (Promega, Madison, WI, United States) according to the instructions of the manufacturer.

Neurocognitive assessments

A neuropsychological battery of cognitive tests, such as the Digit Cancellation Test (DCT), Semantic Verbal Fluency (SVF), Spatial Span Test (SS), Paced Auditory Serial Addition Test (PASAT), Trail Making Task (TMT-A), and Block Design Test (BDT), were used to assess cognitive performance.

The followings were evaluated by the neurocognitive battery: Executive functions: Executive functions were evaluated using the BDT. Maintaining focus and attention: Attention was evaluated using the DCT and TMT-A. Memory: The SS and PASAT were used to measure memory. Verbal proficiency: Verbal fluency was assessed by the SVF test.

Statistical analysis

SPSS 17.0 was used for the statistical analysis (SPSS Inc., Chicago, IL, United States). We first compared the qualities and mental execution between the controls and patients, and then compared the BDNF and sex hormone levels of patients and controls using the independent samples t-test. The next step was to investigate the connections between BDNF levels and cognitive function in the entire sample (n = 240) and between sex hormone levels and BDNF levels. Pearson's product moment correlation was used to investigate the connections between the patient group's PANSS scores and sex hormone levels. After taking into account any potential confounders, the relationship between sex hormone levels and PANSS scores, BDNF levels, and cognitive function was modeled using multiple linear regression. The Bonferroni correction was used to adjust for multiple comparisons. The significance level was set at $P < 0.05$.

RESULTS

Demographic data, sex hormones, BDNF, and cognitive performances in patients and healthy controls

The characteristics and clinical data of 120 CATM patients with SCZ and 120 controls are presented in Table 1. There were significant differences in body mass index (BMI) between patients and controls ($P < 0.001$). The patient group had significantly higher levels of LH ($P < 0.05$), T ($P < 0.05$), and PRL ($P < 0.001$) than the controls (both $P < 0.001$), and significantly lower levels of BDNF and E2 than the controls (both $P < 0.001$). The patients performed worse in all mental subscales (all $P < 0.001$). These data are shown in Table 2.

Interrelationships of sex hormones and BDNF in all subjects

In all subjects (n = 240), LH, E2, T, and PRL ($P < 0.05$) were all fundamentally connected to BDNF levels before adjustment of confounding factors (age, schooling, smoking, BMI). Only the relationships between BDNF levels and LH, E2, and PRL remained significant ($P < 0.05$) after confounding factors were removed. The relationship between E2 and BDNF remained statistically significant after Bonferroni correction ($P < 0.01$). These data are shown in Table 3.

Table 1 Demographic characteristics, clinical data, brain-derived neurotrophic factor, and sex hormones in chronic antipsychotic-treated male patients with schizophrenia and healthy controls (mean ± SD)

Variable	CATM patients (*n* = 120)	Healthy controls (*n* = 120)	F or χ^2 (*P* value)
Age (yr)	51.0 ± 10.3	52.2 ± 6.4	27.4 (0.28)

Smokers (%)	60.8	65.9	0.6 (0.4)
BMI (kg/m^2)	25.7 ± 3.4	24.0 ± 2.2	33.5 (< 0.001)
BDNF (ng/mL)	2.5 ± 1.6	9.7 ± 3.2	35.5 (0.00)
FSH (ng/mL)	8.6 ± 6.7	9.0 ± 6.6	0.1 (0.67)
LH (ng/mL)	6.7 ± 3.3	4.9 ± 2.6	1.6 (0.00)
E2 (ng/mL)	40.5 ± 17.1	56.2 ± 24.3	4.5 (0.00)
P (ng/mL)	0.8 ± 0.3	0.8 ± 0.4	0.2 (0.84)
T (ng/mL)	4.8 ± 1.8	4.0 ± 1.2	2.4 (0.01)
PRL (ng/mL)	25.4 ± 22.4	10.6 ± 5.5	24.1 (0.00)
Age of onset (yr)	22.9 ± 5.8		
Duration of illness (yr)	28.0 ± 9.3		
PANSS score			
Positive symptoms	11.3 ± 4.9		
Negative symptoms	20.1 ± 10.0		
General psychopathology	31.2 ± 9.0		
Total score	62.6 ± 20.2		

BDNF: Brain-derived neurotrophic factor; CATM: Chronic antipsychotic-treated male; BMI: Body mass index; FSH: Follicle-stimulating hormone; LH: Luteinizing hormone; E2: Estradiol; P: Progesterone; T: Testosterone; PRL: Prolactin; PANSS: Positive and Negative Syndrome Scale.

Table 2 Comparison of cognitive scores between chronic antipsychotic-treated male schizophrenia patients and healthy controls

Cognitive index	CATM patients	Controls	F (*P* value)	MD (95%CI)
DCT	304.1 ± 215.0	130.8 ± 43.3	50.8 (< 0.001)	173.2 (124.0 to 222.4)
SVF	16.0 ± 7.8	27.6 ± 7.9	0.0 (< 0.001)	-11.6 (-8.7 to -14.5)
SS	11.6 ± 4.2	16.4 ± 4.2	0.1 (< 0.001)	-4.7 (-3.4 to -6.1)
TMT-A	101.3 ± 57.9	50.0 ± 21.7	26.5 (< 0.001)	51.3 (35.6 to 67.0)
BDT	17.1 ± 9.0	31.8 ± 8.8	0.2 (< 0.001)	-14.7 (-11.6 to -17.8)
PASAT correct	19.8 ± 10.5	34.0 ± 10.2	0.0 (< 0.001)	-14.1 (-9.5 to -18.7)
PASAT try	23.9 ± 11.0	36.9 ± 10.7	0.4 (<0.001)	13.0 (-8.2 to 17.8)

95%CI: 95% confidence interval; DCT: Digit Cancellation Test; SVF: Semantic Verbal Fluency; SS: Spatial Span Test; PASAT: Paced Auditory Serial Addition Test; TMT-A: Trail Making Task; BDT: Block Design Test.

Relationships between BDNF and cognitive functions in all subjects

In all subjects, the DCT, class familiarity, SS, TMT-A, block design, and PASAT were all fundamentally connected to BDNF levels prior to adjustment of confounding factors (all $P < 0.001$). Only the relationships between BDNF levels and the DCT, category fluency, TMT-A, and block design remained significant ($P < 0.05$) after confounding factors were taken into account. The relationship between DCT and BDNF levels remained significant after Bonferroni correction ($P < 0.0023$). These data are shown in Table 4.

Relationships between PRL levels and psychotic symptoms in CATM patients

0.05) and the score for general psychopathology was found (r = 0.181, P < 0.05). The relationship between PRL levels and general psychopathology or negative factors remained significant (P < 0.05) after adjusting for confounding factors. As shown in Table 5, only the relationship between PRL levels and the negative factors remained significant after the Bonferroni correction (P < 0.017).

DISCUSSION

The CATM group's elevated levels of LH, PRL, and T, in addition to their decreased levels of E2, were examined in depth for the first time in this study in comparison to the controls. One of the major findings in this study was that E2 Levels and BDNF levels, as well as BDNF levels and the DCT, were correlated in all subjects. Even after Bonferroni correction and adjusting for confounding factors, these correlations remained significant.

Previous studies have shown that in men, LH and T seem to have a role in advancing the development of white matter [6,10]. As gender differences play a significant role in SCZ, hormones may play a role in the pathophysiology of SCZ. In the initial period of SCZ in men, higher T levels in puberty and youth, show that T might be related to the initiation of psychosis in patients[19]. Recently, an ever-increasing number of studies have focused on dehydroepiandrosterone (DHEA)/T in addition to standard antipsychotic treatment in relation to the side effects of SCZ[20]. These studies demonstrated that patients with SCZ experiencing negative, depressive, and anxiety symptoms could benefit from DHEA augmentation as a treatment. However, we found that CATM patients with SCZ had T levels higher than those in the

controls, but that there was no correlation between this increase and psychopathology. It was demonstrated that decreasing levels of LH reduced short-term episodic memory loss in an SCZ model treated with phencyclidine[21]. We found that the LH levels in the CATM patients with SCZ were higher than those in controls, even though there was no relationship between this increment and mental capability.

It has been hypothesized for a considerable amount of time that the blocking effect of antipsychotic medications on dopamine D2 receptors is the cause of the elevated PRL levels associated with psychotic symptoms. PRL levels were found to be elevated in CATM patients with SCZ in the current study. However, unlike a previous study that investigated patients with chronic SCZ, we found no link between elevated PRL and impaired cognitive function[22]. Hyperprolactinemia was most significantly associated with executive function, working memory, and processing speed in a previous study of prolactinoma patients[23]. In addition, it was discovered that a decrease in the volume of gray matter in the frontal cortex and hippocampus was correlated with PRL concentration. In the future, the connection between PRL levels and cortical thickness and hippocampal base volume in patients with ongoing SCZ should be examined to determine the connection between hyperprolactinemia and diminished mental capability.

Research focusing on the connection between PRL levels and the side effects of SCZ has been primarily conducted in male patients; however, no consistent conclusion has been reached. Positive symptoms, delusions, and speech incoherence are all negatively correlated with PRL levels, according to some researchers[24]. On the other hand, one study found a correlation between positive symptoms in schizophrenic patients and elevated PRL levels[25]. Another review showed that PRL levels were significantly connected with negative side effects[26]. One study found no link between psychopathology and PRL levels[27]. In previous studies[25,28], we found that higher PRL levels and negative side effects were connected.

The "estrogen hypothesis" has been used for more than three decades to explain how estrogen protects the brain. E2 and selective estrogen receptor modulators are helpful adjunctive treatments for patients with SCZ[29]. Our study found that CATM patients with SCZ had lower levels of the protective hormone E2 than normal male controls. This finding is consistent with the preceding hypotheses. It was found that BDNF gene expression can be controlled by estrogen[30]. Indeed, even after two measurement revisions, this study found a huge direct connection between E2 and BDNF, which is consistent with previous investigations.

The higher incidence of SCZ in men and the earlier age of onset may be partially explained by T[31]. Our current findings were consistent with those of another study[32] in which SCZ cases had significantly higher T levels and significantly lower BDNF levels compared to controls. A previous study with a small sample size found a significant

correlation between low T levels and penile-related symptoms in men taking antipsychotics and a trend in hyperprolactinemia was associated with low T[33]. Antipsychotics frequently result in hyperprolactinemia, which can affect the measurement of other gonadal hormone levels[34]. It should be noted that antipsychotics such as clozapine and aripiprazole are less likely to cause hyperprolactinemia.

Even though these conclusions are not consistent, more and more researchers are focusing on the connection between SCZ with impaired cognitive function and abnormal serum BDNF levels[35,36]. However, a recent study found that first-episode and drug-naive SCZ patients had significantly higher BDNF serum levels and better Repeatable Battery for the Assessment of Neuropsychological Status scores[37]. In a previous study, we found that the improvement in clinical symptoms was linked to higher BDNF levels in schizophrenic patients[38]. Similarly, we observed that the level of BDNF in SCZ patients was lower than that in controls and that there was a positive relationship between BDNF levels and mental capability. We also found critical and positive relationships between E2 and BDNF levels, and between BDNF levels and the DCT. Even after Bonferroni correction and adjusting for confounding factors, these correlations remained significant. Rashidy-Pour *et al*[14] in 2019 demonstrated that E2 significantly increased spatial learning and memory by increasing 17-E2 and BDNF levels in the hippocampus of ovariectomized rats. The BDNF pathway is responsible for estrogen's neuroprotective effects[16]. However, we found no correlation between BDNF levels and clinical symptoms. This necessitates further investigation into the reasons for this finding.

The limitations of this study require consideration. The lack of confirmation regarding the consistency of the markers in the central nervous system and peripheral blood is the primary limitation of this study. As the biomarkers were only measured once in this case-control study, the study was constrained by the lack of longitudinal comparisons. Thirdly, the study did not determine how antipsychotic medication affected BDNF and gonadal hormone levels.

CONCLUSION

In conclusion, CATM patients with SCZ showed lower levels of BDNF and E2 and elevated levels of LH, T, and PRL compared to controls. In all cognitive subscales, we found that CATM patients with SCZ performed significantly worse. In CATM patients with SCZ, we also found a marked relationship between PRL levels and the negative side effects score. Sex hormones and BDNF levels may also be linked to cognitive function. With the exception of PRL and negative symptoms, this case-control study only found positive correlations across the entire sample. As a result, our findings ought to be regarded as preliminary.

ARTICLE HIGHLIGHTS

Research background

Due to gender differences in the clinical manifestations of schizophrenia (SCZ), this study assumes that sex hormones directly or indirectly alter the clinical manifestations of SCZ.

Research motivation

An increasing number of studies have shown that sex hormones act through brain derived neurotrophic factors (BDNF), which can also affect the expression of sex hormone receptors.

Research objectives

The purpose of this study is to explore the significant impact of the interaction between BDNF and sex hormones on the clinical manifestations and cognitive function of chronic antipsychotic-treated male (CATM) SCZ patients.

Research methods

We used a cross-sectional case-control study method to collect blood from both normal control and CATM SCZ patients for testing BDNF and sex hormone levels, as well as cognitive function in both groups.

Research results

We found a significant decrease in estradiol (E2) levels in the patient group, and a significant correlation between prolactin levels and negative symptom scores. In the entire sample, there is a positive correlation between E2 level, BDNF level, and the Digit Cancellation Test (reflecting attention function).

Research conclusions

Compared with the normal control group, there were changes in the levels of BDNF and sex hormones in the patient group. The levels of sex hormones in the patient group are related to negative symptoms.

Research perspectives

The interaction between BDNF and sex hormones may be involved in negative symptom expression and cognitive impairment in chronic male SCZ patients.

FOOTNOTES

Co-corresponding authors: Qiu-Fang Jia and Xiao-Bin Zhang.

Author contributions: Li J and Zhang XB designed the study and manuscript preparation; Li J and Xiao WH recruited subjects, collected clinical data, laboratory samples, and cognitive assessment and did preliminary data analysis; Ye F and Tang XW assisted in the symptoms of schizophrenia assessment and data analysis; Jia QF did literature search, final analysis of the data, and prepared the final manuscript; All authors contributed to manuscript preparation and approved its final version. Qiu-Fang Jia and Xiao-Bin Zhang contributed equally to this work as co-corresponding authors. The reasons for designating Qiu-Fang Jia and Xiao-Bin Zhang as co-corresponding authors are threefold. First, the research was performed as a collaborative effort, and the designation of co-corresponding authorship accurately reflects the distribution of responsibilities and burdens associated with the time and effort required to complete the study and the resultant paper. This also ensures effective communication and management of post-submission matters, ultimately enhancing the paper's quality and reliability. Second, the overall research team encompassed authors with a variety of expertise and skills from different fields, and the designation of co-corresponding authors best reflects this diversity. This also promotes the most comprehensive and in-depth examination of the research topic, ultimately enriching readers' understanding by offering various expert perspectives. Third, Qiu-Fang Jia and Xiao-Bin Zhang contributed efforts of equal substance throughout the research process. The choice of these researchers as co-corresponding authors acknowledges and respects this equal contribution, while recognizing the spirit of teamwork and collaboration of this study. In summary, we believe that designating Qiu-Fang Jia and Xiao-Bin Zhang as co-corresponding authors of is fitting for our manuscript as it accurately reflects our team's collaborative spirit, equal contributions, and diversity.

Abstract

BACKGROUND

Our previous study reported that the single-nucleotide polymorphism (SNP) rs155979 GC in the promoter region of long-chain non-coding RNA (lncRNA) NONHSAT102891 affects depression susceptibility in a Chinese population.

AIM

To explored associations of two SNPs and haplotypes in the lncRNA NONHSAT102891 promoter region with depression susceptibility in Chinese population.

METHODS

This this case-control association study was approved by the Ethics Committee of Chengdu Medical College (approval number: 201815). Patient diagnosis was based on DSM-IV criteria. We selected a total of 480 patients with depression and 329 healthy controls with no history of psychopathology, and performed genotyping of two SNPs by extracting peripheral venous blood samples from the subjects. The function of the two lncRNA NONHSAT102891 promoter G/C and A/T haplotypes was detected by dual-luciferase reporter assays of human embryonic kidney 293T transfected cells.

RESULTS

Stratified analysis of clinical and genotypic characteristics of our cohort showed that the degree of mild depressive episodes associated with the rs6230 TC/CC genotype increased by 1.59 times [TC/CC *vs* TT: odds ratio (OR) = 1.59, 95%

confidence interval (CI): 1.08-2.35, P = 0.019]. The haploid analysis revealed linkage disequilibrium between rs3792747 and rs6230, and the double SNP CG haplotype was more common in the control group compared to case group, indicating that this haplotype significantly reduced the risk of depression (C/G *vs* T/A: OR = 0.42, 95%CI: 0.21-0.83, P = 0.01). There was no significant difference in the dual-luciferase reporter activity of the G/C and A/T haplotypes compared with the control group (P > 0.05), indicating that the double SNP haplotype has no transcriptional activity.

CONCLUSION

The rs3792747 and rs6230 CG haplotypes of the lncRNA NONHSA T102891 promoter may be related to a reduced risk of depression in the Han Chinese population.

Core Tip: Depression has risen to the top of the global burden of non-fatal diseases. Recently, emerging evidence supports long-chain non-coding RNA (lncRNA) may be involved in the occurrence and development of depression, and may serve as potential diagnostic and prognostic markers. Our previous study showed lncRNA NONHSAT102891 rs155979 GC affects depression susceptibility; this study genotyped 480 depression patients and 329 healthy controls for the two single-nucleotide polymorphisms and made dual-luciferase reporter assays to explore and elucidate the function of the two lncRNA NONHSAT102891 promoter G/C and A/T haplotypes. We found the rs6230 and rs3792747 CG haplotypes may reduce the risk of depression, which expanded our knowledge about this disease.

INTRODUCTION

Depression is a highly heterogeneous and multifactorial mental illness with symptoms spanning domains of emotion and behavior, including changes in mood, anhedonia, sleep, and psychomotor activity[1]. With an estimated 5% of adults worldwide suffering from depression each year, depression has risen to the top of the global burden of non-fatal diseases [2]. In the post-coronavirus disease 2019 era, the global burden of mental disorders has become heavier, and has brought greater challenges to the diagnosis and treatment of depression. In China, health service utilization for depressive disorders is very low, with only 9.2% of depressed patients receiving adequate treatment[3]. Depression can also occur in patients with other underlying diseases, including Alzheimer's disease, stroke, multiple sclerosis and cardiovascular disease[4-6].

Long-chain non-coding RNAs (lncRNAs) are the most abundant class of ncRNAs in the human genome. Characteristically, lncRNAs are more than 200 bp in length and do not encode a protein, but may interact with DNA, RNA or protein molecules at multiple levels (epigenetic, transcriptional and post-transcriptional) to control the expression of related genes and participate in many biological processes, especially differentiation and development[7,8]. Approximately 40% of the lncRNAs in the mammalian genome are expressed in the brain[9]. LncRNAs are involved in regulation of neuronal function and play an important role in neuropsychiatric diseases. Through alternative splicing or binding to NRG1, v-erb-a erythroblastic leukemia viral oncogene homolog 4 gene expression inhibits downstream neurons, reduces the release of the neurotransmitter gamma-aminobutyric acid, and has negative effects on brain functions, such as cognition and working memory, in addition to an association with an increased risk of depression and schizophrenia[10-12]. LncRNAGm^{2}694 destroys endoplasmic reticulum homeostasis, significantly reduces expression of the A-amino-3-hydroxy-5-methyl-4-isoxazole propionate receptor on the postsynaptic membrane of neurons, reduces the excitatory synaptic transmission function of neurons, increases stress susceptibility in mice, and mediates the pathogenesis of depression[13]. In addition, some single-nucleotide polymorphisms (SNPs) in lncRNAs are associated with the risk of depression. A human-specific Alu insertion polymorphism (rs70959274) in the 5' flanking region of the lncRNA LINC01360 is in strong linkage disequilibrium with the major depression SNP rs12129573[14]. Identifying functional variants of non-coding SNPs is essential for understanding the molecular mechanism and biological basis of depression [15]. Changes in lncRNAs can be detected in cerebrospinal fluid as well as the circulatory system and brain, therefore, providing important prospects for use as biomarkers for disease identification or risk prediction. These biomarkers can also be employed to provide new insights into the genetic structure and biological etiology of neuropsychiatric diseases.

The term "haplotype" refers to several closely linked SNPs that determine the same trait on the same chromosome or in a certain region, either as two loci or the entire chromosome. CONVERGE consortium conducted sparse whole-genome sequencing on Chinese female patients with recurrent major depression and found two depression-related mutations, both located on chromosome 10, one near SIRT1, and the other in an intron of the *LHPP* gene[16]. LncRNA NONHSA T102891, which is located on chromosome 5 (CHR5): 95768987-95770845, has a transcript length of 1860 bp. A recent genome-wide association study (GWAS) revealed five genomic domains on CHR5 that were significantly associated with depression. The underlying background of these regions also includes LINC00461, MEF2C, and LOC101927421[17]. In human tissues, lncRNA NONHSAT 102891 is expressed in the thyroid, brain, adrenal glands and placenta[18]. Downregulated expression of lncRNA NONHSAT102891 in peripheral blood mononuclear cells of major depressive disorder (MDD) patients has been explored previously[19]. Furthermore, changes in the expression of NONHSA T102891 may be a potential non-invasive biomarker for the diagnosis of MDD[20].

In our previous study, we investigated the diagnostic and differential diagnostic value of lncRNA NONHSAT10289 (rs155979, rs3762983, rs3762984 and rs102891) SNPs in severe depression[21]. Because the polymorphism of a single locus in a gene often cannot reveal its true association with disease, haplotype analysis of multiple loci has become an effective means to find complex disease genes. Therefore, in this study, we compared the expression of the other two SNP (rs6230 and rs3792747) in the lncRNA NONHSAT102891 promoter region in patients with depression to further assess the association of lncRNANONHSAT102891 promoter SNPs and/or haplotypes with risk of depression in a Chinese population and to determine the functional correlation of risk haplotypes.

MATERIALS AND METHODS

Study subjects

From March 2018 to December 2019, a total of 480 patients with depression and 329 healthy individuals from three hospitals in China (Sichuan Provincial People's Hospital, Jining Psychiatric Hospital and Yunnan Provincial Mental Health Center) were recruited to the case and control groups, respectively. All participants were Han Chinese adults. The study protocol was approved by the Ethics Committee of Chengdu Medical College (No. 201815). All participants provided written informed consent. Patient diagnosis was based on the DSM-IV criteria, and the symptom severity was scored using the 24-item Hamilton Depression Rating Scale (HAMD-24). Patients with neurological diseases or other mental disorders, acute or chronic infections, thyroid dysfunction, being pregnant, or breastfeeding at the time of the study were excluded. Control subjects were volunteers with no history of self-reported mental illnesses and who participated in physical examination in the research hospitals. The following clinical data were collected from medical records: Age, sex, age of onset, HAMD-24 score, pulse rate, degree of depression, family history, suicide attempt/behavior and first episode.

The average age of the healthy control group (105 males and 224 females) was 44.0 ± 16.9 years. The case and control groups were matched according to sex, age and place of residence. Details of the participants can be found in our previous report[21].

SNP selection

The UCSC Genome Browser was used to explore SNPs of the lncRNA NONHSAT102891 promoter region (3-kb region upstream of the transcription initiation site)[22]. The SNPs rs6230 and rs3792747 were selected as loci with minor allele frequencies > 10% in the Asian population to study their correlation with depression susceptibility and clinical characteristics in a Han Chinese population.

Genotyping

Genomic DNA was extracted from peripheral venous blood samples using the whole blood genomic DNA extraction kit [Shenggong Bioengineering (Shanghai) Co., Ltd.]. The concentration of the DNA was determined as a measure of the quality by using a NanoDrop 2000/2000C [Thermo Fisher (China) Co., Ltd.]. The lncRNA NONHSAT102891 promoter region containing the rs6230 and rs3792747 polymorphisms was amplified by two-step polymerase chain reaction (PCR) to prepare an Illumina compatible library using the following primer sequences: rs3792747-F: *5'-TCAATGCAGCAGCATCATCAGATCCAAG-3'*, rs3792747-R: *5'-CGGGCAAAGTTATGAAGCTTGGACT-3'*, rs6230-F: *5'-GATCCCAGCAAACAGTTCCT-3'*; rs6230-R: *5'-CCAGCCAGAATGGAAATGAG-3'*.

The first-step PCR (25 μL reaction volume) amplification was performed under the following reaction conditions: 98 ℃, 3 min; 98 ℃, 30 s; 50 ℃, 30 s; 72 ℃ 30 s; 98 ℃, 30 s; 66 ℃ 30 s; 25 cycles for 30 s at 72 ℃, and 72 ℃ for 5 min. Using the first-step PCR product as the template, the Illumina sequencing library was obtained by the second round of PCR (30 μL reaction volume) amplification performed under the following reaction conditions: 98 ℃, 5 min; 94 ℃, 30 s; 55 ℃, 20 s; 5 cycles of 72 ℃, 30 s. The sizes of the two PCR products were confirmed by 1% agarose gel electrophoresis and then recovered using AMPure XP magnetic beads. Equal amounts of the two PCR products were then mixed and sequenced using HiSeqXTen platform (Illumina, San Diego, CA, United States).

Construction of luciferase reporter gene plasmids

The DNA fragments containing the haplotypes of the lncRNA NONHSAT102891 promoter region were amplified and different SNP sites (rs6230 and rs3792747) were selected as described above using the following primers sequences: upstream: *5'-GCTAGCAGCCAAGGAAAGGAAAGCTC-3'* (for-ward), downstream: *5'-TAAGCAGCAGGATTAG-*

GACTCGAG-3' (reve-rse). The target fragments were inserted into the PmirGLO-Vector (Promega) to construct the recombinant plasmids designated pmirGLO-AT and pmirGLO-GC, respectively, and sent to Chengdu Qingke Company for plasmid DNA synthesis. The recombinant plasmids were transfected into HEK-293T cells and the difference in the amount of luciferase protein expressed by the A-T and G-C haplotypes consisting of rs6230 and rs3792747 was detected.

Cell lines and cell culture

HEK-293T cell lines, provided by the National collection of authenticated cell cultures, were used for recombinant vector transfection and assessed by routine PCR and microscopic analysis to ensure that no cells were contaminated with mycoplasma during the research process. HEK-293T cells were cultured at 37 ℃ under 5% CO_2 in Dulbecco's Modified Eagle's Medium (Gibco) containing 10% fetal bovine serum (Gibco), 1% GlutaMAX (Invitrogen, Carlsbad, CA, United States) and 1% sodium pyruvate (Invitrogen) were added.

Transfection and luciferase reporter gene assays

HEK-293T cells were seeded into 24-well plates (2×10^5 cells per well) and cultured for 24-36 h to 90% confluence before transfection in serum-free medium with equal amounts of plasmid-free enzyme-free water (as blank control group), pmirGLO-AT, pmirGLO-GC, and the empty PmirGLO-Vector (no promoter) using the LipofectamineTM 2000 kit (Invitrogen). pRL-TK Luciferase Control Reporter Vectors (Promega, Madison, WI, United States) were co-transfected into HEK-293T cells for 24-48 h as a normal control. Luciferase activity in equal numbers of cells from each group was then measured using the dual-luciferase reporter gene assay system (Promega, Madison, WI, United States) according to the manufacturer's instructions. After adding the LAR II reagent (Promega) and cell lysis solution, the optical signal was detected by BioTek PowerWave XS2 full-wavelength scanning spectrophotometer. the measurement reading was recorded as The fluorescence value F (Firefly luminescence) was measured and after adding the Stop and Glo ®Reagent, the fluorescence value R (Renilla luminescence) was measured. Relative luciferase activity was calculated as the ratio of fluorescence value F to fluorescence value R. All samples were analyzed in triplicate and experiments were repeated in three independent occasions.

Statistical analysis

Continuous variable data were expressed as mean ± SEM and the categorical variable data were expressed as numbers (percentages). Moreover, for comparison between groups, *t*-tests were used for continuous variables, and χ^2 tests were used for categorical variables. The genotype frequencies of rs6230 and rs3792747 were obtained by direct counting. The χ^2 test was used to analyze the distribution and Hardy-Weinberg equilibrium of rs6230 and rs3792747 genotypes in the two groups. The correlation between gene polymorphisms and disease was evaluated using odds ratio (OR) and 95% confidence interval (CI), with the OR values adjusted based on age and sex data. Codominant, dominant and recessive genetic models were used for comparative analysis.

In the haplotype correlation analysis, the luciferase activity corresponding to each configuration was expressed as the mean ± SD, and the differences among the experimental data were analyzed by one-way analysis of variance. $P < 0.05$ was considered to indicate statistical significance. All data were analyzed using SPSS 25.0 (SPSS Inc., Chicago, IL, United States).

RESULTS

LncRNA NONHSAT102891 promoter genotypes and risk of depression

We first investigated the association of the rs6230 and rs3792747 variants of the lncRNA NONHSAT102891 promoter with the risk of depression. For this purpose, we summarized the frequency distribution of genotypes and alleles of lncRNA NONHSAT102891 SNP rs6230 and rs3792747 in depressed patients and controls. In the control group, the genotype frequencies of the two polymorphisms were both in Hardy–Weinberg equilibrium (rs6230 $P = 0.101$; rs3792747 $P = 0.104$). There were significant differences in genotype and allele frequencies between the case and control groups (Table 1).

After further stratification by degree of depressive episode, suicide attempt, first episode patient and family history, we observed a correlation between depressive episode stratification and depressive risk in the rs6230 polymorphism group. The frequency of the TC/CC genotype was 69.3% in patients with moderate depression, which was higher than that in patients with severe depression (60.3%) (TC/CC *vs* TT, 95%CI: 1.59 (1.08-2.35), $P = 0.019$). These findings indicated that the rs6230 TC/CC genotype is associated with an increased risk of moderate depression; however, there was no significant correlation between rs3792747 polymorphism and the four variables used for stratification ($P > 0.05$) (Table 2).

LncRNA NONHSAT102891 promoter haplotypes and the risk of depression

We also evaluated the association of the two SNP haplotypes (rs3792747 and rs6230) of the lncRNANONHSAT102891 promoter with the risk of depression. LD analysis showed that these two common polymorphisms had higher D' values and lower R2 values ($D' = 0.71$, $r^2 = 0.07$) in the control, indicating the existence of gene recombination between the two SNP and that both were suitable for haplotype reconstruction.

Haplotype reconstruction analysis based on the genotyping data of depressed patients and controls revealed that the CG haplotype was more common in the control group than in the depressed patients These findings indicated that the CG haplotype is significantly associated with reduced risk of depression [CG *vs* TA: 95%CI: 1.59 (0.21-0.83], $P = 0.01$. There was no significant correlation between other haploid types and risk of depression (Table 3).

Effects of different haplotypes of lncRNA NONHSAT102891 promoters on transcriptional activity

Next, we tested the hypothesis that the G/C and A/T haplotypes change the transcriptional activity of the lncRNA NONHSAT102891 by comparing the luciferase reporter activity of HEK-293T cells transfected with the pmirGLO-AT and pmirGLO-GC constructs. There was no significant difference in the dual-luciferase reporter activity of the G/C and A/T haplotypes compared with the control group ($P > 0.05$) (Table 4), indicating that the G/C and A/T haplotypes do not alter the transcriptional activity of the lncRNA NONHSAT102891.

DISCUSSION

After excluding organic brain lesions, clinicians mainly identify depression on the basis of the key symptoms of the disease. However, the most important basis for diagnosis is still based on the patient's clinical manifestations, which are affected by the patient's subjective experience and the clinical experience of the doctor. Finding objective and effective molecular indicators for the diagnosis of depression is the current focus of clinicians. Depression-related biomarkers in the peripheral blood or brain are attracting increasing attention for the development and exploration of clinical objective diagnostic indicators. LncRNAs are known to play an important role in the normal functions of cells and the pathological consequences of disorders, which lays a molecular foundation for understanding the similarities and differences in the pathophysiological mechanisms behind depression. Using targeted reverse transcription PCR analysis of lncRNA expression levels in peripheral blood and brain tissue of depression patients or a mouse model of depression, Seki *et al* [23] found that the expression levels of Y5, MER11C, PCAT1, and PCAT29, were upregulated in patients with major depressive disorder compared to healthy controls, while the expression level of RMRP was downregulated. Low expression of RMRP in peripheral blood leukocytes of depressed patients and mice correlated strongly with the severity of the symptoms. Thus, these findings implicate RMRP in peripheral blood leukocytes as a potential biomarker of depression. Zhou *et al*[24] performed RNA-sequencing in the rostral anterior cingulate cortex of 26 depressed suicidal individuals and 24 controls who died naturally or by accident with no history of psychopathology, and identified 23 differentially expressed lncRNAs, including SNORD3C and ZNF833P, and their differentially expressed overlapping and

antisense protein-coding genes, several of which were associated with interferon signaling. Bioinformatics approaches have also been adopted to identify differential expression of depression-related genes. Liu *et al*[25] analyzed the genes for seven mental traits identified in large-scale GWAS and found that LINC00461 has a pleiotropic effect and is associated with five mental traits, including depression, schizophrenia, and Alzheimer's disease. Als *et al*[26], identified 243 risk loci in more than 1.3 million individuals through GWAS and found that depression is highly polygenic, which could help deepen depression research and precise treatment. This information provides a better understanding of the genetic associations of depression and could aid in the development of more effective treatments.

In this study, we explored the possible association of other SNPs and haplotypes in the lncRNANONHSAT102891 promoter region with susceptibility to depression in a Chinese population. Our results suggest that the TC/CC genotype of rs6230 in the lncRNA NONHSAT102891 promoter region may be associated with the risk of moderate depression. In the haplotype analysis of rs3792747 and rs6230, the frequency of the CG haplotype was more common in the patients with severe depression than in the control group, indicating that the haplotype was associated with a reduced risk of depression. However, no significant correlation was found between the two haplotypes and lncRNA NONHSAT102891 promoter transcriptional activity in dual-luciferase reporter assays.

In recent years, lncRNAs have provided significant advances in our understanding of the pathogenesis of severe depression as well as its diagnosis and treatment. Li *et al*[22] suggested that nine lncRNA, including NONHSAT102891, TCONS_00019174, and ENST00000566208, may be biomarkers of MDD. LncRNAs can participate in the epigenetic, transcriptional, and post-transcriptional regulation of the pathogenesis of depression. LncRNA XR351665 has been reported to promote the development of chronic pain-induced depression by upregulating DNMT1 *via* sponge miR-152-3p[27]. Long-intergenic non-coding RNA (Linc) 01360 expression is affected by rs70959274Alu polymorphism, and the Alu insertion induces DNA methylation, which significantly reduces the transcriptional activity of linc01360 compared with the control group, thus reducing the genetic risk of human MDD[14]. Differentially expressed lncRNAs also affect the pathogenesis of depression by participating in the regulation of a variety of signaling pathways. Microdeletion of FAAH-OUT lncRNA expressed in the brain and dorsal root ganglia led to downregulation of FAAH expression and a sharp increase in BDNF levels, thereby reducing the risk of depression and anxiety[28]. Decreased levels of lncRNAMIR155HG were shown to induce increased microRNA (miR)-155 expression in the hippocampus and inhibit BDNF expression, leading to depression-like behavior in a chronic unpredictable mild stress model of depression in mice. MiR-155HG/miR-155/BDND axis damage is a key cause of depression[29]. Low levels of linc00473 and upregulated expression of FEDORA in prefrontal cortex (PFC) neurons were detected in female depressed patients; the expression of linc00473 affected the pre-and postsynaptic features of mPFC pyramidal neurons and participated in regulation of the cAMP response element binding protein (CREB), and low levels of linc00473 in PFC neurons promoted stress recovery in female mice[30-32]. Selective expression of FEDORA in mouse mPFC neurons or oligodendrocytes confirmed its role as a sex-specific regulator of anxiety and depression-like behavior, since this phenomenon occurred only in female mice. Abedpoor *et al*[33] found that exercise and leucine consumption can alleviate depression-related behaviors by increasing the expression of four lncRNAs (MEG3, HOTAIR, GAS5 and TUG1 related to KDR/VEGF-α/PTEN/BDNF) in the lncRNA network of the brain-gut axis in depression-like mice. KEGG enrichment analysis revealed the involvement of important signaling pathways such as hippo, MAPK, Wnt, PI3K/Akt, cGMP-PKG, RAS, and IL-17 in the regulation of hippocampal function or pathological processes associated with depression[34-38]. For example, overexpression of lncRNA TCONS_00019174 can activate the Wnt classical pathway in mice, inactivating GSK3β phosphorylation, while also upregulating β-catenin protein expression, thereby exerting antidepressant effects in mice[39]. Silencing lncRNA GAS5 can activate the PI3K/AKT pathway to protect hippocampal neurons from depression-like injury by regulating the miR-26a/EGR1 axis[40]. LncRNA84277 ameliorated chronic pain-associated depressive-like behavior by upregulating SIRT1 expression *via* the competitive sponge miR-128-3p[41]. Thus, there is accumulating evidence that these biomarkers play a key role in the pathogenesis of depression and provide new targets for the treatment of depression.

The limitations of current research should be noted. First, the case group comprised 71% females and only 29% males. The incidence of depression is sex-biased, and the higher heritability of women than men may lead to a higher incidence of depression in women[42]. Therefore, the role of epigenetic factors in the occurrence and development of depression represents an important focus of future research. Evaluating the effect of lncRNA on depression and targeted control of the phenotype of depression in a research population will promote the discovery of new and more effective treatments. Second, due to the limited sample size, the results of this study may be biased, and further studies with a larger sample size are required to determine the reference expression range of biomarkers. Third, existing evidence suggests that patients with late-onset depression have more severe and frequent patchy lesions in the deep frontal white matter and basal ganglia detected by magnetic resonance imaging as compared with the control groups or patients with early-onset depression[43]. Due to barriers such as the lack of scientific basis for diagnostic systems and structures, uncertainty in brain function, indeterminate time-course of recovery in patients with functional mental disorders, and lack of diagnostic tools, no causal relationships have been identified for functional mental disorders such as depression[44]. In the future, we aim to explore a multidimensional framework that incorporates epigenetic and neurological impact data, thereby enhancing the practical ability of clinicians to diagnose[45].

CONCLUSION

Our results indicate that the rs3792747 and rs6230 CG haplotypes of the lncRNA NONHSA T102891 promoter are related to a reduced risk of depression in the Han Chinese population.

ARTICLE HIGHLIGHTS

Research background

Depression is a common life-threatening and disabling mental illness, and long-chain non-coding RNA (lncRNA) abnormal expression may affect the pathophysiological processes of depression. Our previous study reported that the single-nucleotide polymorphism (SNP) rs155979 GC in the promoter region of lncRNA NONHSAT102891 affects depression susceptibility in a Chinese population.

Research motivation

The complex interplay of species between major depressive disorder and lncRNA remains unclear.

Research objectives

To explored associations between two SNPs and haplotypes within lncRNA NONHSAT102891 promoter region and depression susceptibility in Chinese population.

Research methods

We conducted a case-control study in a cohort of 480 patients with depression and 329 healthy controls, and performed genotyping by gene sequencing. The function of the two lncRNA NONHSAT102891 promoter G/C and A/T haplotypes was detected by dual-luciferase reporter assays of human embryonic kidney 293T transfected cells.

Research results

The degree of mild depressive episodes associated with the rs6230 TC/CC genotype increased by 1.59 times. The haploid analysis revealed linkage disequilibrium between rs3792747 and rs6230, and the double SNP CG haplotype was more common in the control group compared to case group, indicating that this haplotype significantly reduced the risk of depression (C/G *vs* T/A: odds ratio = 0.42, 95% confidence interval: 0.21-0.83, P = 0.01). There was no significant difference in the dual-luciferase reporter activity of the G/C and A/T haplotypes compared with the control group (P > 0.05).

Research conclusions

The rs3792747 and rs6230 CG haplotypes of the lncRNA NONHSA T102891 promoter may be associated with a reduced risk of depression in the Chinese population. However, further studies with a larger sample size are required to determine the reference expression range of biomarkers.

Research perspectives

This study provides insights into the early prediction and diagnosis of depression and important clues for development of tools that will facilitate more accurate diagnosis and treatment of depression in the clinic.

ACKNOWLEDGEMENTS

We sincerely thank the patients, their families, and the healthy volunteers for their participation, as well as the medical staff involved in collecting the specimens.

Abstract

BACKGROUND

Osteonecrosis of the femoral head (ONFH) is a prevalent orthopedic issue, leading to the collapse and fragmentation of the femoral head in its advanced stages, which can severely impair patients' quality of life. Total hip arthroplasty (THA) is a clinical intervention frequently used to alleviate ONFH symptoms and reinstate hip functionality. The conventional surgical technique is invasive and comes with an extended recuperation period, posing significant challenges for patients. With the progression of medical technology, the use of the mini-incision technique in minimally invasive THA (MITHA) has become more prevalent. However, comparative studies examining the effectiveness of these two surgical procedures in treating ONFH remain scarce. Furthermore, understanding patients' psychological well-being is crucial given its profound influence on postoperative recuperation.

AIM

To evaluate the impact of mini-incision MITHA on ONFH treatment and to identify the risk factors associated with postoperative anxiety and depression.

METHODS

A retrospective study was conducted on 125 patients treated for ONFH at Xi'an Hong Hui Hospital between February 2020 and January 2022, with the term "consecutive" indicating that these patients were treated in an unbroken sequence without any selection. Among these, 60 patients (control group) underwent traditional THA, while 65 patients (observation group) were treated with mini-incision MITHA. Variations in the visual analog scale (VAS) score and the Harris hip score were monitored. Additionally, shifts in pre- and posttreatment Hamilton anxiety (HAMA) and Hamilton depression (HAMD) scale scores were recorded. Patients with both postoperative HAMA and HAMD scores of ≥ 8 were

identified as those experiencing negative emotions. Logistic regression was utilized to analyze the determinants influencing these negative emotional outcomes. Comparative analyses of surgical and postoperative metrics between the two groups were also conducted.

RESULTS

Posttreatment results indicated a significantly higher VAS score in the control group than in the observation group, while the Harris score was considerably lower ($P < 0.0001$). The observation group benefited from a notably shorter operation duration, reduced blood loss, diminished incision size, and a decreased postoperative drainage time ($P < 0.0001$), accompanied by a reduced hospital stay and lower treatment costs ($P < 0.0001$). The control group had elevated posttreatment HAMA and HAMD scores in comparison to the observation group ($P < 0.0001$). Multivariate logistic regression revealed that being female [odds ratio (OR): 4.394, 95%CI: 1.689-11.433, $P = 0.002$], having a higher postoperative VAS score (OR: 5.533, 95%CI: 2.210-13.848, $P < 0.0001$), and having higher treatment costs (OR: 7.306, 95%CI: 2.801-19.057, $P < 0.0001$) were significant independent determinants influencing postoperative mood disturbances.

CONCLUSION

Compared to conventional THA, mini-incision MITHA offers advantages such as reduced operation time, minimal bleeding, and a shorter incision in ONFH patients. Moreover, factors such as sex, postoperative pain (reflected in the VAS score), and treatment costs significantly impact postoperative anxiety and depression.

Key Words: Necrosis of the femoral head; Total hip arthroplasty; Minimally invasive total hip arthroplasty; Postoperative recovery; Anxiety; Depression

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Minimally invasive total hip arthroplasty has shown significant advantages in the treatment of osteonecrosis of the femoral head, including a short operation time and less bleeding. However, the psychological stress of postoperative patients, especially female patients, those with high postoperative pain scores, and those with high treatment costs, cannot be ignored as these patients are more susceptible to adverse emotions. Therefore, although improvements in technology and surgical methods are essential, psychological counseling, which can help improve the treatment effect and the quality of life of patients, is equally important.

INTRODUCTION

Necrosis of the femoral head (ONFH) is a disease that causes partial or total ischemia of the femoral head due to blood circulation interruption or injury, which leads to the death of osteocytes, bone marrow hematopoietic cells and adipocytes and may eventually trigger a series of structural changes, such as femoral head collapse[1]. Such a disease is considered to be a disease with a high disability rate in orthopedics[2]. Early diagnosis of ONFH is challenging due to the atypicality of its clinical presentation[3]. As the condition worsens, the femoral head collapses on images, and complete loss of the original femoral head shape occurs in severe cases, which can further develop into degenerative hip osteoarthritis[4]. Therefore, choosing effective treatment methods to improve the patient's condition is critical.

Clinically, total hip arthroplasty (THA) is a common treatment that can achieve joint function reconstruction in patients with ONFH, thus significantly improving patient quality of life[5]. However, conventional THA has some drawbacks, such as a large incision, heavy trauma, and a high incidence of surgical complications[6,7]. Hence, it is necessary to reduce the risk of surgical trauma and complications while ensuring the safety and effectiveness of surgery. In recent years, there has been an increase in the application of minimally invasive THA (MITHA) with the development of minimally invasive technology[8]. This procedure has the advantages of less trauma and quick recovery, which can more effectively help patients relieve pain and restore joint function[9,10]. However, whether MITHA is advantageous over conventional THA with a more significant effect on improving patients' conditions remains to be further studied.

Currently, the treatment of ONFH relies mainly on surgery, which results in a long recovery time, especially for elderly patients. During the recovery period, patients may experience a great reduction or even loss of self-care ability, as well as varying degrees of motor system damage. These factors have placed great pressure on the physiology and psychology of patients, predisposing them to psychological stress and negative emotions (NEs).

Accordingly, the purpose of this study was to explore the effect of MITHA in the treatment of ONFH and to analyze the risk factors that may affect postoperative anxiety and depression. This study can provide more rigorous evidence for clinical treatment and intervention, with important practical significance for improving patient quality of life and mental health.

MATERIALS AND METHODS

Patient data

A retrospective analysis was performed on 125 ONFH patients who were treated at Xi'an Hong Hui Hospital from February 2020 to January 2022. Among them, 60 patients who received conventional THA and 65 patients who received MITHA were assigned to the control group and observation group, respectively.

Eligibility and exclusion criteria

The inclusion criteria were as follows: (1) Patients whose physical condition was at an acceptable level and with an American Association of Anesthesiologists score ranging from 1 to 3 points[11]; (2) Those meeting the indications for THA; (3) Diagnosis of CNFH by imaging examination; (4) Awareness of and voluntary participation in the study by patients and their families; (5) Unilateral lesions that met surgical indications; and (6) Complete clinical data.

The exclusion criteria were as follows: (1) Severe cardio-cerebrovascular diseases and other chronic wasting diseases; (2) Multiple hip replacement procedures; (3) Concurrent surgery of other parts; (4) Incomplete information or loss to follow-up; or (5) Active infection in the affected hip or surgical area.

Treatment methods

Patients in the control group underwent conventional THA. The procedure was performed under general anesthesia with the patient placed in a lateral decubitus position. After successful anesthesia, the surgeon successively cut the skin of the patient to expose the femoral head and the acetabulum edge, viewing the acetabulum damage and repairing it. Then, an appropriate prosthesis was selected for implantation according to the patient's specific condition. After confirmation of the correct placement of the implant, the surgeon cleaned the incision and placed a drainage tube to complete the procedure.

Patients in the observation group underwent MITHA using a mini-incision technique, with the anesthesia method and surgical position the same as the control group. During the operation, the surgeon made a small incision of 6 to 10 cm along the gluteus maximus muscle fibers on the posterior side of the greater trochanter of the femur. The gluteus maximus muscle was then cut open, and the external rotators at the attachment of the trochanter were cut off and pulled posteriorly so that the joint capsule could be exposed for incision to expose the femoral head and acetabulum. Then, within 10 to 15 cm of the femur, the surgeon used a chainsaw to cut the neck of the femur and remove the severed femoral head. Next, the stump of the ligamentum teres of the acetabulum and the glenoid lip were removed, and the exposed ligamentum teres fossa was ground flat. At the same time, reaming was performed on the acetabulum with an anteversion angle of 20° and an abduction angle of 45°. Then, a prosthesis with a suitable size was selected for a trial mold, and the prosthesis was implanted after confirming its stability and tightness. At the end of the surgery, the surgeon drilled 3 to 4 holes in the suture of the external rotators, washed the operation field and placed a drainage tube to end the operation. Both groups received routine anti-infection therapy after surgery.

Clinical data collection

The following information was collected: (1) Clinical data, namely, age, sex, body mass index (BMI), pathogeny, affected side, smoking history, alcoholism history, education level, annual income and marital status; (2) Surgical indicators, namely, operation time, intraoperative blood loss, incision length, and postoperative drainage time; (3) Postoperative indicators, namely, length of stay and treatment cost; (4) Scoring indices, namely, visual analog scale (VAS) scores[11] and Harris hip score (HHS) before and after operation; and (5) Pre- and posttreatment Hamilton anxiety and depression scale scores, namely, the Hamilton anxiety scale (HAMA) and Hamilton depression scale (HAMD) scores[12].

Outcome measures

Primary outcome measures: Changes in VAS and HHS scores before and after treatment were observed. Alterations in pre- and posttreatment HAMA and HAMD scores were compared between the two groups. According to postoperative scores, patients with both HAMA and HAMD scores ≥ 8 were considered to have NEs, and the risk factors affecting the occurrence of NEs were analyzed by logistic regression.

Secondary outcome measures: Clinical data, surgical indicators and postoperative indicators were compared.

Statistical analysis

SPSS 26.0 and GraphPad Prism 9 were used for data analysis, and the threshold of statistical significance was $P < 0.05$. Count data are expressed as frequencies (percentages), and comparisons between groups were made by means of the χ^2 test. Measurement data are expressed as the mean ± SD. Two independent samples t tests were used for comparisons between groups, independent samples t tests were used for comparisons between groups, and paired t tests were used for comparisons within groups. Logistic regression was used to analyze the risk factors affecting patients' NEs.

RESULTS

Comparison of clinical data

In the comparisons of the patients' clinical data, it was found that the observation and control groups were not significantly different in age, sex, BMI, pathogeny, affected side, smoking history, alcoholism history, education level, annual income, or marital status ($P > 0.05$, Table 1).

Changes in pain and functional scores

Changes in VAS and HHS scores before and after treatment were compared between groups. The two groups did not differ significantly in terms of their pretreatment VAS or HHS scores ($P > 0.05$). A reduction in the VAS score and an increase in the HHS score were observed in both groups after treatment ($P < 0.0001$). Further intergroup comparison revealed a higher VAS score and a lower HHS score in the control group than in the observation group ($P < 0.0001$, Figure 1).

Comparison of surgical indices

The intergroup comparison of surgical indices showed that the operation time was significantly shorter in the observation group than in the control group, with less intraoperative blood loss, shorter incision length, and less postoperative drainage time ($P < 0.0001$, Figure 2).

Comparison of postoperative indices

Comparing the postoperative indices, it was found that the length of stay and treatment cost of patients were significantly lower in the observation group than in the control group ($P < 0.0001$, Figure 3).

Evaluation of patients' NEs

Patients' anxiety and depression were evaluated before and after treatment. There were no significant difference in the pretreatment HAMA or HAMD scores between the two groups ($P > 0.05$). However, significantly reduced HAMA and HAMD scores were observed in both groups after treatment ($P < 0.0001$). Further comparison showed that the posttreatment HAMA and HAMD scores were significantly higher in the control group than in the observation group ($P < 0.0001$, Figure 4).

Analysis of risk factors affecting patients' NEs

We conducted a statistical evaluation of the postoperative HAMA and HAMD scores. Using a screening threshold of a postoperative score ≥ 8, we identified 71 patients exhibiting postoperative anxiety and 77 manifesting postoperative depression. Based on these findings, patients were categorized into two distinct groups: the NE group ($n = 71$) and the emotional stability group ($n = 54$). In the univariate analysis, several factors emerged as potential risk determinants affecting patients' NEs. These included age ≥ 60 years, female sex, an education level below middle school, an annual income less than 50000 CNY, opting for the conventional surgical plan, elevated postoperative VAS scores, prolonged operation times, and increased treatment costs ($P < 0.05$, Table 2). To refine our understanding, we assigned numerical values to the identified variables, as shown in Table 3. Our subsequent multivariate logistic regression analysis highlighted three prominent factors. Specifically, being female, having a higher postoperative VAS score, and incurring elevated treatment costs were significant independent risk factors influencing postoperative NEs in patients ($P < 0.01$, Table 4).

DISCUSSION

ONFH is a common condition in orthopedics with symptoms such as femoral head collapse and fragmentation in the later stage, which can cause great pain to patients and even loss of mobility[13]. The interruption of the blood supply to the femoral head leads to the production of free radicals, as well as hypoxia and reperfusion injury, which can accelerate osteocyte death and eventually lead to the necrosis of bone marrow stromal stem cells or the formation of adipocytes, leading to local osteoporosis[14]. Hip replacement has been clinically shown to be an effective method to relieve hip pain and restore hip function in ONFH patients[15]. However, this procedure is highly invasive and is associated with a long postoperative recovery period and long-term bed rest, which increases the difficulty of rehabilitation training and the risk of developing lower extremity deep venous thrombosis, affecting postoperative rehabilitation.

The development of minimally invasive surgery technology has enabled the gradual application and popularization of mini-incision MITHA in clinical practice[16]. In addition, the rapid development of medical technology and equipment has made it possible to improve and optimize the incision method of THA[17]. In long-term clinical practice, mini-incision THA has become a standard surgical approach with many advantages. However, little has been reported about the difference between conventional and minimally invasive THA procedures for the treatment of ONFH. Repantis *et al* [18] found no significant difference in intraoperative blood loss between the two THA methods but identified markedly lower postoperative pain scores in the minimally invasive group. The present study also comparatively analyzed the two surgical modalities and found a significantly shorter operation time in patients undergoing MITHA *vs* those receiving conventional THA, with less intraoperative bleeding, a shorter incision length, less surface peeling and clear joint exposure, which greatly shortened the operation time and reduced the body's traumatic stress response.

BMI: Body mass index.

For patients with either osteoporotic fracture or ONFH, THA will cause psychological stress and cause greater psychological pressure[19]. Anxiety and depression are the most common psychological complications, both of which have a certain impact on patients' cognitive and psychological states[19,20]. In addition, anxiety and depression can significantly reduce patients' motivation and adherence to treatment during hospitalization, leading to a significant decline in treatment effectiveness. Evidence has shown that psychological factors have an impact on the outcome of THA[21]. In contrast, a good state of mind helps patients recover as quickly as possible. Therefore, identifying factors that influence anxiety and depression helps clinical medical staff to take relevant nursing measures and carry out targeted treatment in time. In our study, anxiety and depression were found before surgery in both groups and were relieved in some patients after treatment. To determine the risk factors for postoperative NEs in ONFH patients, we performed a regression

analysis. The results showed that sex, postoperative VAS score, and treatment cost were risk factors for postoperative NEs in ONFH patients. The reason may be that women, who are affected by psychological and physiological characteristics, are more sensitive and emotional and therefore more susceptible to NEs after illness. In addition, the activity limitation of postsurgical patients leads to aggravated depression and anxiety. In the research of Liu and Wang[22], the incidence of anxiety and depression increased significantly among female patients after gastric cancer surgery and was related to poor prognosis, which was the main risk factor. Pain itself is a kind of physical discomfort that can negatively affect the individual's mood and behavior. Pain can also lead to decreased sleep quality, further aggravating the patient's emotional distress. Persistent pain can cause the patient to worry about the prospect of future recovery, exacerbating anxiety and depression. Park *et al*[23] suggested that severe postoperative pain was a risk factor for postoperative anxiety and depression in patients with lung cancer. Although ONFH does not require long-term treatment, conventional

replacement surgery is not affordable for all families, increasing the financial burden on patients' families. In addition, from the perspective of the patients, the psychological pressure felt is enormous due to fear of becoming a burden to their families. They may also worry that they will not be able to pay for medical expenses in the long term and that follow-up treatment will be difficult to guarantee, resulting in negative feelings such as guilt and anxiety[24,25]. Therefore, to improve patients' psychological states, it is necessary to strengthen communication with patients and encourage them to express their inner thoughts. For patients with NEs, targeted psychological counseling can be implemented to help relieve stress. In addition, those patients with effectively controlled conditions after treatment and a good state of mind can be invited to share their treatment experiences and exchange opinions on overcoming difficulties. Such measures are helpful to improve patients' confidence in treatment and prevent the occurrence of NEs.

In this study, we determined the therapeutic effect of MITHA on ONFH patients and the risk factors for postoperative NEs through analyses. However, this study still has some limitations. First, the insufficient sample size may lead to errors in the results of the regression analysis. Second, patients' long-term follow-up cannot be determined due to the retrospective nature of this study, resulting in uncertainty regarding the long-term outcomes of patients treated by the two surgical methods. Finally, as a single-center study, the applicability and generalizability of the results of this study need

to be validated and supported by external data. Therefore, the hope is that more in-depth research can be carried out in the future and that more samples will be collected to support the conclusions of this study.

CONCLUSION

In this paper, the application and clinical effectiveness of THA in ONFH patients, particularly the influence of MITHA on patients' treatment outcomes, were studied. The results show that MITHA contributes to a shorter operation time, less blood loss and a shorter incision length. At the same time, anxiety and depression before surgery were prevalent in all patients, and these NEs may be related to the patient's sex, postoperative pain score, and treatment cost.

ARTICLE HIGHLIGHTS

Research background

Osteonecrosis of the femoral head (ONFH) is a complex and multifactorial disease, which can seriously affect the quality of life of patients at the advanced stage. Although conventional total hip arthroplasty (THA) is effective in relieving symptoms, the procedure is invasive, resulting in a long recovery period for patients. Minimally invasive THA (MITHA) has begun to be used clinically with the development of minimally invasive techniques.

Research motivation

There is a lack of studies comparing MITHA with conventional THA, especially its effects on postoperative pain, recovery, and psychological distress in patients with ONFH.

Research objectives
This study aims to compare the effects of MITHA *vs* conventional THA in patients with ONFH and to further explore risk factors for postoperative negative emotions (NEs).

Research methods
The two surgical methods were comparatively analyzed, and the emotional state of the patients before and after surgery was investigated and analyzed using the regression model.

Research results
Patients undergoing MITHA had shorter operation time, less intraoperative bleeding and smaller incision length. Both groups of patients developed anxiety and depression before surgery, but some of them experienced emotional relief after treatment. Sex, postoperative pain score, and treatment cost were identified as risk factors affecting postoperative NEs of ONFH patients.

Research conclusions
MITHA is obvious advantageous over conventional THA in the treatment of ONFH, with short operation time and less bleeding. Sex, postoperative pain score, and treatment cost are risk factors that affect patients' postoperative mood. Targeted psychological counseling can effectively relieve the pressure of patients.

Research perspectives
A larger sample size and a long-term patient follow-up are needed to further determine the long-term effects of MITHA, as well as the depth and durability of the psychological impact on patients. Meanwhile, we need to better understand and deal with patients' postoperative psychological problems to improve the overall effectiveness of treatment.

Abstract

BACKGROUND

Cerebral apoplexy patients are prone to cognitive impairment, and it is very important to choose appropriate treatment methods to improve their cognitive impairment after stroke.

AIM

To evaluate the effects of enhanced external counterpulsation (EECP) in conjunction with atorvastatin on cognitive function, neurotransmitter levels, and the repair of brain tissue damage in patients with cognitive impairment due to stroke.

METHODS

In this retrospective study, data from 60 patients with poststroke cognitive impairment due to stroke who were treated in our hospital from February 2021 to July 2022 were analyzed and divided into a treatment group (n = 30) and a control group (n = 30) according to the different nursing methods applied. Patients in the treatment group received EECP in addition to atorvastatin, while those in the control group received atorvastatin alone. Mini-Mental State Examination (MMSE), Montreal Cognitive Assessment (MoCA) and activities of daily living (ADL) scale scores were compared between the two groups. Additionally, the two groups were compared in terms of serum acetylcholine (ACh), acetylcholinesterase (AChE), nitric oxide (NO), endothelin-1 (ET-1), β2-microglobulin (β2-MG), glial fibrillary acidic protein (GFAP), and visinin-like protein 1 (VILIP-1) in the serum. Blood flow measurements from the anterior cerebral artery (ACA), middle cerebral artery (MCA) and posterior cerebral artery (PCA) were compared between the two groups before and after treatment, and the pulsatility index (PI) and resistance index (RI) of each artery were determined.

RESULTS

MMSE, MoCA, and ADL scores all improved in both groups following treatment, with the study group showing more improvement than the control group ($P < 0.05$). After treatment, there were statistically significant increases in both ACh and NO levels, whereas decreases occurred in AChE, ET-1, β2-MG, VILIP-1, and GFAP, levels and the PI and RI of the left-ACA, right-ACA, left-MCA, right-MCA, left-PCA, and right-PCA. The study group showed greater gains in all metrics than the control group ($P < 0.05$).

CONCLUSION

EECP combined with atorvastatin is effective in the treatment of cognitive impairment after stroke and can effectively improve the cognitive function, neurotransmitter levels, and brain tissue damage status of patients.

Key Words: Enhanced extracorporeal counterpulsation; Atorvastatin; Cognitive impairment after stroke; Neurotransmitters; Brain tissue damage status

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Enhanced extracorporeal counterpulsation and atorvastatin are widely used in the treatment of stroke patients with cognitive impairment, but the effect of enhanced counterpulsation combined with atorvastatin on cognitive function of stroke patients with cognitive impairment has not been discussed. The objective of this study was to compare the efficacy of enhanced external counterpulsation combined with atorvastatin *vs* atorvastatin alone in the treatment of post-stroke cognitive impairment. Combined therapy is better than atorvastatin therapy alone.

INTRODUCTION

A patient's quality of life is drastically altered after suffering a stroke, which is an acute cerebrovascular event that can result in brain ischemia, hypoxic damage, and neurological abnormalities as well as sequelae such as language dysfunction, limb malfunction, and cognitive impairment. Cognitive impairment after stroke is caused by degenerative diseases resulting from neural tissue ischemia. Therefore, patients with cognitive impairment following a stroke may achieve some improvement in their clinical symptoms with clinical therapy for nutritional neuropathy, improvement of microcirculation, and hemorheology, along with physical exercise[1,2]. Safe, effective, and noninvasive, enhanced external counterpulsation (EECP) is a mechanical circulatory aid method commonly employed in the treatment of coronary heart disease and angina pectoris. Multiple recent studies have demonstrated the efficacy of EECP in treating ischemic cerebrovascular disease, sleep disturbances, and psychological and psychiatric diseases[3,4]. The mechanism of EECP is to increase both the arterial and venous return of both lower limbs, increase coronary blood flow, and improve the perfusion of the heart, brain, kidneys, and other organs[5]. Statins, which are hydroxymethylglutaryl coenzyme A reductase inhibitors, can significantly boost patients' cognitive performance and postpone disease progression[6] through their anti-inflammatory, antithrombotic, endothelium-protective, and antioxidant properties. The purpose of this research was to examine the effects of EECP in conjunction with atorvastatin on cognitive performance, neurotransmitter levels, and recovery from brain tissue damage in patients with poststroke cognitive impairment. The findings are detailed below.

MATERIALS AND METHODS

General information

Data from 60 patients with poststroke cognitive impairment due to stroke who were treated in our hospital from February 2021 to July 2022 were analyzed, and the patients were divided into a treatment group ($n = 30$) and a control group ($n = 30$) according to the different nursing methods applied. There were 21 men and 9 women in the study group, with ages ranging from 49 to 74 (mean = 61.40, SD = 5.59) years; the average duration since stroke onset was 6.30 ± 1.62 mo, and the average duration since cognitive impairment onset was 5.57 ± 1.14 mo. In the control group, the age ranged from 49 to 73 years, with a mean of 60.30 ± 5.84 years. There were 19 men and 11 women in the control group; the mean duration since stroke onset was 6.50 ± 1.28 mo, and the mean duration since the onset of cognitive impairment was 3.75 ± 0.78 mo. Overall, there was little to no difference in these data between the two groups ($P > 0.05$). All protocols in this study were approved by the ethics committee of the Shengjing Hospital of China Medical University and abided by the ethical guidelines of the Declaration of Helsinki. The ethics committee waived the requirement for informed consent.

Diagnostic criteria

All patients were diagnosed with stroke by imaging examination, and color ultrasound examination showed that there was a mural thrombus in the bilateral carotid arteries. The patients were diagnosed with mild cognitive impairment as described in the study of Ismail *et al*[7]: (1) All imaging examinations showed findings in accordance with the diagnostic criteria for stroke; (2) Progressive impairment of cognitive function; (3) Mild memory impairment; (4) Ability to continue daily life; and (5) Cognitive impairment less severe than the threshold for a diagnosis in the Diagnostic and Statistical Manual of Mental Disorders[8]. Reduced capacity to orient oneself, recognize objects, and express oneself in language served as the primary clinical indications.

Inclusion criteria

(1) Imaging findings, physical examination findings, and a thorough review of the patient's medical history all corroborated the diagnosis, which matched all of the criteria laid forth in the Diagnostic Essentials of Various Cerebrovascular Diseases[9]; (2) Absence of any life-threatening organ malfunction; and (3) Voluntary participation in the research.

Exclusion criteria

(1) Neurological disease, such as Alzheimer's disease, Parkinson's disease, or epilepsy; (2) History of brain trauma; (3) Previous stroke or stroke-like event; (4) Existing mental disability before the stroke; and (5) Severe anxiety, depression, or other mental illness.

Methods

Atorvastatin was used in conjunction with EECP to treat patients in the research group (Pfizer Pharmaceutical Co., Ltd., National Drug Approval No.: H20051408). Patients in the control group were given only atorvastatin. Oxygen saturation was tracked using an EECP instrument (a PECP/TM) to measure EECP. The machine was first warmed for approximately 10-15 min. After the patient was positioned in an appropriate posture for treatment, sandpaper was used to smooth the skin around the electrode connection site, and alcohol was used to disinfect the immediate area. The white, red, and black electrodes were fixed under the left clavicle or near the manubrium, the apex of the heart, the upper right abdomen, or the lower right rib. Then, a finger pulse oximeter was placed on a finger of the right hand of the patient, ensuring that the electrode was in a position free from or minimally affected by vibration, the red and white electrodes were not too close, and the electrode position did not affect the inflatable cuff. The standard inflation pressure ranged from 0.025 to 0.045 MPa, with adjustments made during the operation based on the patient's response to the pressure. At the end of treatment, the finger pulse oximeter was removed, the inflatable cuff was unfastened, the electrode leads and electrodes were removed, and the patient was helped in tidying up his or her clothes and leaving the counterpulsation bed. The patient was required to remain under observation for 10 min without any discomfort before leaving. The treatment was performed once a day, 1 h/session, 6 d a week for 6 consecutive weeks, for a total of 36 sessions. Atorvastatin (20 mg) was given once daily for 24 wk.

Observational indexes

Clinical data of patients in the two groups were collected, and the Mini-Mental State Examination (MMSE)[10], Montreal Cognitive Assessment (MoCA)[11] and activities of daily living (ADL)[12] scores were compared between the two groups. Serum acetylcholine (ACh), acetylcholinesterase (AChE), nitric oxide (NO), endothelin-1 (ET-1), β2-microglobulin (β2-MG), visinin-like protein-1 (VILIP-1) and glial fibrillary acidic protein (GFAP) levels were compared between the two groups. The blood flow conditions of the bilateral anterior cerebral artery (ACA), middle cerebral artery (MCA) and posterior cerebral artery (PCA) were compared between the two groups before and after treatment. The pulsatility index (PI) and resistance index (RI) of each artery were calculated according to the blood flow velocity of the left and right arteries during the peak systolic period (Vs), end-diastolic blood velocity (Vd) and average blood flow velocity (Vm), with PI = (Vs-VD)/Vm, and RI = (Vs-VD)/Vs.

The MMSE includes five different elements, with a total of 30 items and a total score of 30 points. The better the patient's mental condition, the higher the score. The total possible score on the MoCA is 30 points, and a MoCA score < 26 points indicates that the patient has cognitive impairment. The total possible score on the ADL scale is 100 points, and the higher the score, the better the patient's daily living ability. The abbreviations for the cerebral arteries are left ACA (LACA), right ACA (RACA), left MCA (LMCA), right MCA (RMCA), left PCA (LPCA), and right PCA (RPCA).

Statistical methods

SPSS 20.0 was employed for processing and analyzing the data. The values for the measurements are presented as "mean ± SD". The *t* test for independent samples was used to evaluate differences between the groups. Within-group comparisons of pre- and posttreatment values were performed using the paired *t* test. The χ^2 test was used to make comparisons, with count data being reported as frequencies and category ratios. $P < 0.05$ was considered to indicate a statistically significant difference.

Table 1 Comparison of Mini-Mental State Examination, Montreal Cognitive Assessment and activities of daily living scores between the two groups (mean ± SD, points)

Group	MMSE score		MoCA score		ADL score

[a]P < 0.05, compared to the same group before treatment.
Ach: Acetylcholine; AChE: Acetylcholinesterase.

RESULTS

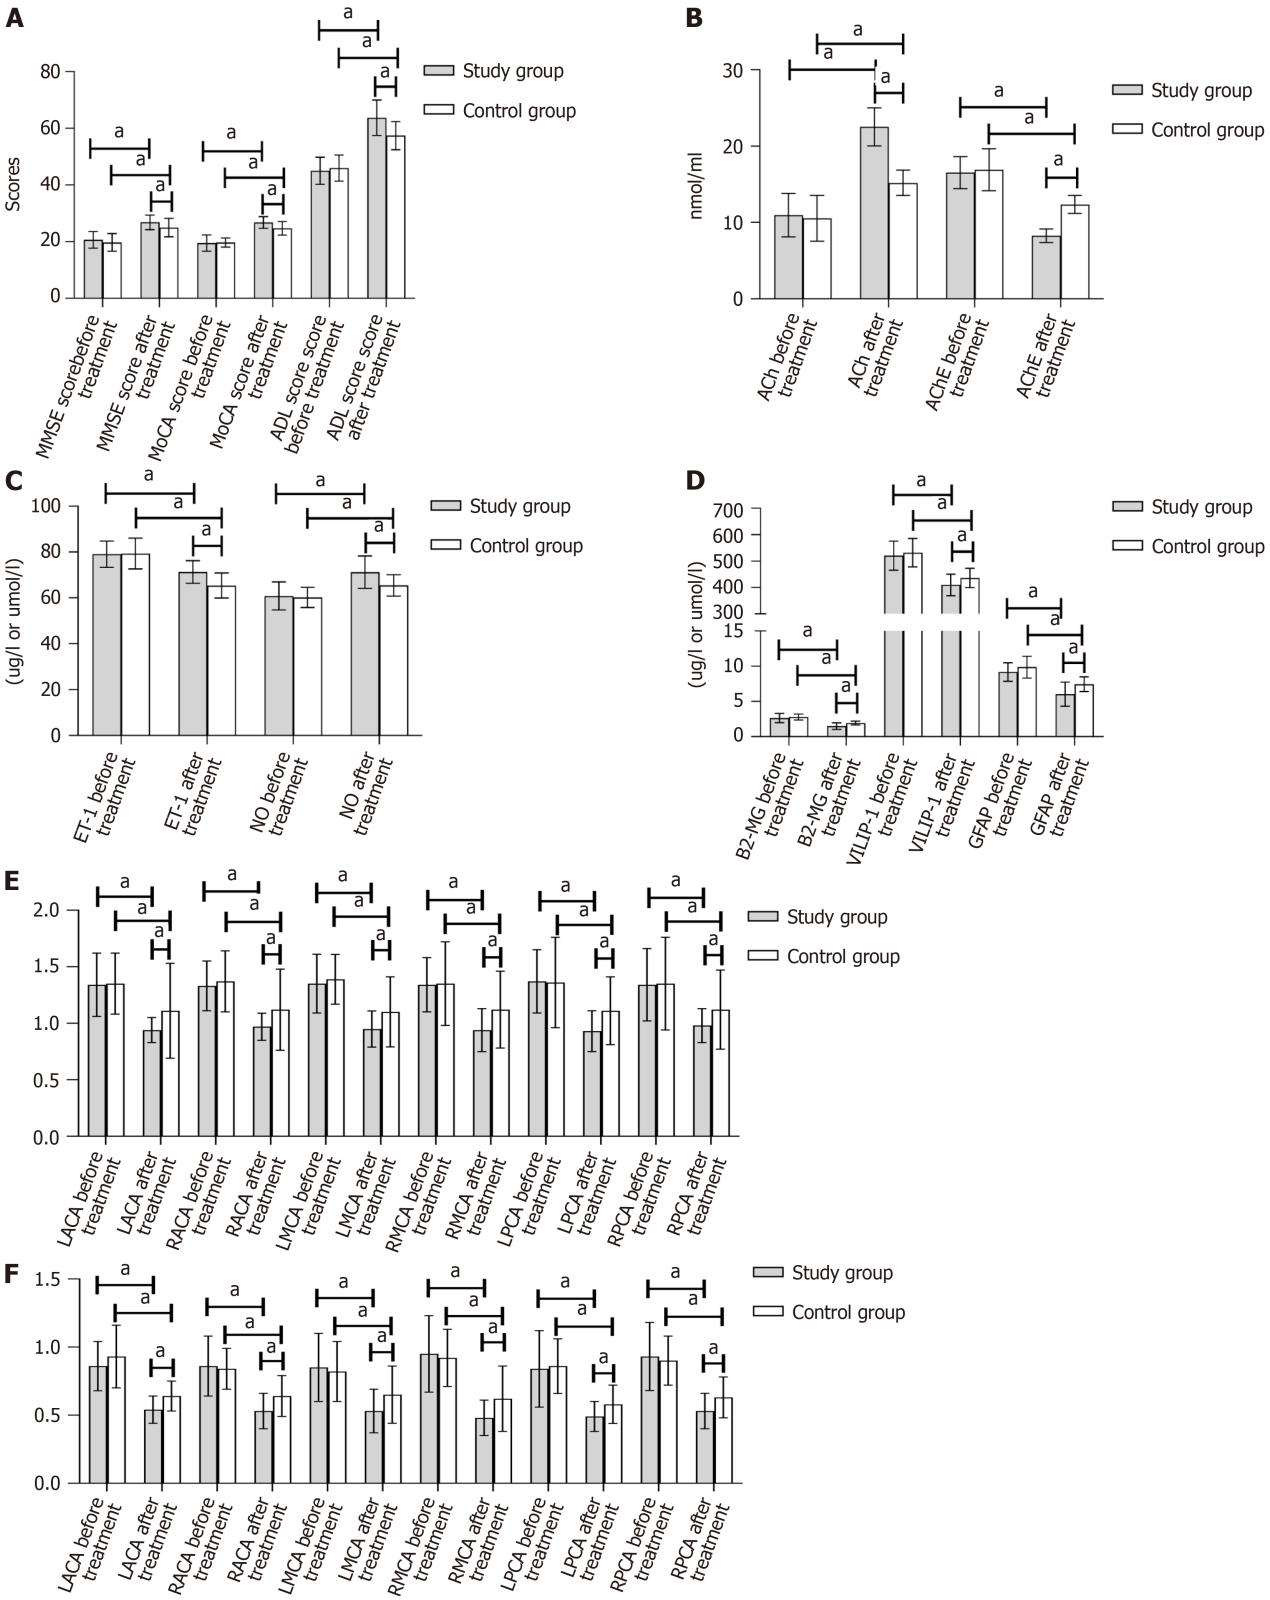
Comparison of MMSE, MoCA, and ADL scores between the two groups

There were no statistically significant differences between the groups in the pretreatment MMSE, MoCA, or ADL scores (P > 0.05). The treatment group showed statistically significant (P < 0.05) improvements in the MMSE, MoCA, and ADL scores after treatment compared to the control group, as shown in Table 1 and Figure 1A.

Comparison of neurotransmitter levels between the two groups

There were no statistically significant differences in the pretreatment ACh or AChE level between the two groups. In both groups, the ACh level increased after therapy, while the AChE level decreased (P < 0.05). There were statistically significant (P < 0.05) improvements in all indices in the experimental group that were not present in the control group, as shown in Table 2 and Figure 1B.

Comparison of vascular endothelial function markers between the two groups



There was no significant change in the ET-1 or NO level between the two groups before treatment (P > 0.05). After therapy, the ET-1 level in both groups decreased, and the NO level increased. The study group showed significantly (P < 0.05) greater improvement than the control group in all areas, as shown in Table 3 and Figure 1C.

Evaluation of serum levels of β2-MG, VILIP-1, and GFAP between the two groups

There were no significant variations in the β2-MG, VILIP-1, or GFAP levels between the two groups prior to therapy (P > 0.05). After treatment, the β2-MG, VILIP-1, and GFAP levels decreased in both groups, with significantly lower levels in the study group (P < 0.05), as shown in Table 4 and Figure 1D.

Comparison of PI values of the cerebral vasculature between the two groups

The PI values of the LACA, RACA, LMCA, RMCA, LPCA, and RPCA were not significantly different between the two groups before treatment (P > 0.05). As expected, therapy resulted in a reduction of pretreatment PI values in all examined vessels (LACA, RACA, LMCA, RMCA, LPCA, and RPCA) in both groups, with the study group showing significantly (P < 0.05) lower PI levels than the control group, as presented in Table 5 and Figure 1E.

Analyzing the difference in RI values of the cerebral vessels between the two groups

The RI values of the LACA, RACA, LMCA, RMCA, LPCA, and RPCA were similar in the two groups before treatment (P > 0.05). Treatment resulted in a substantial (P < 0.05) reduction in the RI values of the LACA, RACA, LMCA, RMCA, LPCA, and RPCA in both groups, as shown in Table 6 and Figure 1F.

DISCUSSION

The degree of cognitive impairment in stroke patients is strongly correlated with their prognosis, and elderly individuals are especially prone to cognitive impairment as a sequela of cerebral infarction. Therefore, it is crucial to find efficient ways to reduce stroke patients' cognitive impairment. According to relevant studies, atorvastatin serves antioxidant and antithrombotic functions and protects vascular endothelial function. It can play a direct role in protecting nerves, reducing the abundance of macrophages in atherosclerotic plaques, enhancing the integrity of fibrous plaque caps, inhibiting vascular inflammation, protecting the vascular endothelium, and inhibiting cognitive impairment after a stroke caused by vascular factors. EECP is a safe and cost-effective treatment that is mainly suitable for the treatment of coronary heart disease and angina pectoris. Numerous investigations conducted recently have demonstrated that EECP significantly affects ischemic cerebrovascular disorders and heart failure[13,14]. According to a prior study, EECP can reduce the clinical symptoms of coronary artery disease by enhancing vascular endothelial function[15]. EECP is an important means of cardiovascular auxiliary circulation that can simultaneously increase the arterial and venous return of both lower limbs and improve coronary blood flow. Patients' diastolic blood pressure and cardiac output as well as blood perfusion to the heart, brain, kidneys, and other organs can all be improved by wrapping balloon sleeves around the thighs, calves, and buttocks and then inflating and deflating the balloons using an air supply system. EECP has been shown to enhance arterial blood flow, increase blood perfusion in brain tissue, improve brain cell metabolism, and facilitate neurological function recovery[16]. Numerous clinical trials have demonstrated that EECP is able to successfully increase blood flow to ischemic areas, restore nerve cell activity, and facilitate the opening of collateral circulation in the ischemic penumbra[17,18].

This research compared the effects of EECP combined with atorvastatin to those of atorvastatin alone between two groups. The results indicated that after therapy, the MMSE, MoCA, and ADL scores in the study group improved more than those in the control group (P < 0.05). These findings demonstrate that the combined application of EECP and atorvastatin might be more effective than atorvastatin alone in enhancing patients' cognitive function and daily living abilities and that such enhancements could serve as direct indicators of the efficacy of therapy. The endothelium lining

the blood vessels is vulnerable to oxidative damage, which can be caused by atherosclerosis. Atorvastatin is a commonly used lipid-lowering drug that stabilizes atherosclerotic plaques. EECP can play a role in increasing cerebral blood flow and perfusion and improving neural function, such that the combined application of these two treatments is more effective. Previous studies have also shown that EECP combined with conventional drugs can be used to treat poststroke cognitive impairment more effectively than the same drugs alone[19]. Learning and memory are two physiological processes that benefit greatly from the functioning of the central cholinergic system. AChE catalyzes the decomposition reaction that produces ACh, which binds to ACh receptors. Degeneration of cholinergic neurons is common in patients with cognitive impairment after stroke[20]. ACh can participate in neuronal activity and regulate synaptic plasticity. In this investigation, the improvement in ACh and AChE levels following therapy was larger in the study group than in the control group (P < 0.05). The treatment of cognitive impairment following a stroke, which may be connected to the management of AChE and ACh levels, is said to benefit significantly from the combination of EECP and atorvastatin. The vascular endothelium serves both barrier and endocrine functions. Dysfunction of vascular endothelial cells can lead to damage to the blood-brain barrier, causing toxic substances to accumulate around nerve cells; triggering inflammatory reactions; damaging brain white matter, neuronal axons and synapses; and leading to cognitive impairment. Vascular endothelial damage, atherosclerosis, brain tissue damage, increased ET-1 expression, and decreased NO expression result in spasms of small cerebral vessels and damage to the nerve fiber network. It has been reported that the serum ET-1 and NO levels in patients with dementia are closely related to endothelial dysfunction of small cerebral vessels and can be used as a marker of endothelial dysfunction[21]. Patients with cognitive impairment following stroke showed significant improvement in ET-1 and NO levels in the treatment group compared to the control group, suggesting that combination therapy can increase the degree of vascular endothelial function more effectively than pharmacotherapy alone. Atorvastatin's lipid-lowering action, ability to mitigate atherosclerosis and protective effect on vascular endothelial function are all well documented. EECP has been shown to ameliorate cognitive impairment by normalizing systolic and diastolic vascular function, controlling vascular tension, and boosting endothelial function in blood vessels. Thus, when

applied in combination, they could play synergistic roles, resulting in an enhanced therapeutic effect.

All nucleated cells contain β2-MG, which might increase the risk of an inflammatory response and subsequent brain injury. With a negative effect on cognition, β2-MG has been linked to a host of serious health problems[22]. According to relevant studies, serum β2-MG levels are high in patients with cognitive impairment after stroke[23]. It has been shown that the expression level of VILIP-1, a small-molecule cytosolic protein typically dispersed in nerve cells, is positively linked with the presence of brain damage[24]. Serum levels of GFAP, an intermediate filament protein found in glial cells, are significantly elevated in those who have had a stroke and are experiencing cognitive impairment[25]. The fact that the levels of β2-MG, VILIP-1, and GFAP improved more in the study group than in the control group suggests that the combination therapy may promote the healing of damaged brain tissue in patients, which merits additional investigation into the specific mechanism of action. Patients with poststroke cognitive impairment who received combination therapy showed greater improvements in the PI and RI values of the LACA, RACA, LMCA, RMCA, LPCA, and RPCA than those who received atorvastatin therapy alone. This is because of the synergistic impact of atorvastatin's lipid-lowering and antithrombotic effects and the capacity of EECP to increase cerebral blood flow perfusion.

CONCLUSION

In conclusion, EECP combined with atorvastatin can effectively improve cognitive function, daily living ability, vascular endothelial function, neural function, and cerebral blood flow in patients with poststroke cognitive dysfunction, indicating the clinical value of this combination. A limitation of this study is that it was a retrospective study, and the number of cases that could be included in the observation was small, which may have led to bias in the results. In the future, a prospective multicenter study with a larger sample should be conducted to further verify the results of this study.

ARTICLE HIGHLIGHTS

Research background

The research background is the discussion on the treatment of patients with cognitive dysfunction after stroke. The current research status is that atorvastatin is widely used to treat cognitive impairment after stroke, and the research significance is to provide a new treatment plan for cognitive impairment after stroke and improve clinical efficacy.

Research motivation

With the treatment of stroke patients with cognitive dysfunction as the research topic, more effective treatment plans need to be explored to improve the prognosis of stroke patients with cognitive dysfunction. The significance of this study is to affirm the better treatment of cerebral stroke patients with cognitive dysfunction, and promote the innovation of clinical treatment of cerebral stroke cognitive endometrial methods.

Research objectives

The objective of this study was to compare the therapeutic effect of different treatment methods and to observe the advantages of enhanced external counterpulsation (EECP) combined with atorvastatin over atorvastatin alone. In this study, enhanced *in vitro* rebuttal combined with atorvastatin was effective in the treatment of cognitive dysfunction in stroke patients, including cognitive function, ability of daily living, vascular endothelial function, nerve function and cerebral blood flow, confirming that the combined treatment has good clinical effects and providing a new reference for the treatment of cognitive dysfunction in stroke patients in the future.

Research methods

The clinical data of the patients were analyzed retrospectively and grouped according to different treatment methods. Then, independent sample *t* test, paired sample *t* test and χ^2 test were used to statistically analyze the general data of the two groups, including mental state, cognitive function, daily living ability score, neurotransmitter level, vascular endothelial function index level, cognitive-related index and cerebral blood flow index before and after treatment. The feature of retrospective study is to explore the cause through the results, and it is easier to obtain the case data.

Research results

EECP combined with atorvastatin can significantly improve cognitive function, mental state, ability of daily living, vascular endothelial function, nerve function and cerebral blood flow in the treatment of stroke patients with cognitive dysfunction, which provides a new treatment method for the treatment of stroke patients with cognitive dysfunction and requires further prospective exploration. To further verify the effectiveness of this treatment method.

Research conclusions

Vascular endothelial dysfunction can lead to impairment of the blood-brain barrier, leading to cognitive dysfunction. Therefore, attention should be paid to the effect of treatment on vascular endothelial function. Based on the better treatment effect of EECP combined with atorvastatin, the more effective treatment scheme should be selected in clinic.

Research perspectives

Biological indicators can effectively reflect the severity of the patient's disease, and the effect of treatment regimen on the level of novel biomarkers in patients with post-stroke cognitive dysfunction needs to be further explored.

Abstract

BACKGROUND

Western medicine is beneficial for the recovery of neurological function in patients with depression, but some patients experience side effects such as headaches, dizziness, nausea, gastrointestinal symptoms, insomnia, and cardiac dysfunction. In recent years, integrative medicine has achieved positive results in the treatment of various diseases.

AIM

To study Chuanjin Qinggan decoction combined with selective serotonin reuptake inhibitors (SSRIs) in patients with herpes zoster complicated by depression.

METHODS

Patients with herpes zoster complicated by depression who were treated at the Yantai Hospital of Traditional Chinese Medicine from January 2021 to December 2022 were retrospectively selected as research participants. Among them, 43 patients with herpes zoster complicated by depression who received SSRI treatment between January and December 2021 were assigned to the Western medicine group, while those who received combined treatment of traditional Chinese and Western medicine between January and December 2022 were assigned to the combined group. Both groups were treated for eight weeks. The degree of pain, effect of herpes zoster treatment, degree of improvement in depressive symptoms, serum neurotransmitter levels, sleep quality, and occurrence of adverse reactions were compared between the two groups.

RESULTS

We found that after eight weeks of drug treatment, the two treatment schemes achieved differing efficacy. In further comparison, we found that, compared with

patients treated with SSRIs alone, patients treated with Chuanjin Qinggan decoction combined with SSRIs showed more significant improvement in depression and a greater increase in dopamine and 5-hydroxytryptamine levels after treatment ($P < 0.05$). Patients treated with Chuanjin Qinggan decoction combined with SSRIs also experienced lower pain, better treatment efficacy for herpes zoster, better sleep quality, and a lower incidence of adverse reactions compared to those treated with SSRIs alone ($P < 0.05$). All minor adverse reactions occurring during treatment were resolved after symptomatic treatment.

CONCLUSION

The treatment scheme of Chuanjin Qinggan decoction combined with SSRIs can improve the psychological state of patients with herpes zoster complicated by depression and alleviate adverse reactions.

Key Words: Chuanjin Qinggan decoction; Selective 5-hydroxytryptamine reuptake inhibitor; Herpes zoster; Depression; Sleep quality; Adverse reaction

Core Tip: Chuanjin Qinggan decoction is an important decoction composed mainly of Ligusticum chuanxiong Hort, Curcuma, and Sedum rosea. There is a synergistic effect between the active ingredients in Chuanjin Qinggan decoction which helps to reduce neurological damage and improve the depressive state of patients by providing raw materials and energy for protein and nucleic acid synthesis in brain tissue. This study confirmed that the treatment scheme of Chuanjin Qinggan decoction combined with selective serotonin reuptake inhibitors can effectively improve the depressive state of patients with herpes zoster complicated by depression.

INTRODUCTION

Herpes zoster is an acute herpetic skin disease characterized by clusters of blisters on the skin and burning pain[1]. It is characterized by the sudden occurrence of these blisters arranged in a ribbon along one side of the peripheral nerve distribution area, accompanied by tingling and lymphadenopathy[2]. Herpes zoster usually occurs in spring or autumn, and older adults constitute the majority of the affected population[3]. Most patients with herpes zoster do not experience recurrence after illness, although recurrence sometimes occurs[4]. Herpes zoster can cause burning, knife-cutting, or electric shock-like pain, with erythema and blisters on the skin's surface. It affects a patient's appearance and can cause physical and mental harm. If patients with herpes zoster do not receive effective treatment for an extended period, they may experience different degrees of depressive symptoms as the pain progresses.

Recent studies suggest that secondary depression in patients with herpes zoster is related to postherpetic neuralgia (PHN)[5,6]. PHN is an intractable neuropathic pain syndrome secondary to herpes zoster that causes the irreversible destruction of nerve fibers. When PHN destroys the neural pathways regulating emotion, it leads to the dysfunction of monoamine neurotransmitters. If the lesion site involves the thalamus, basal ganglia, amygdala, frontal lobe, hippocampus, or interconnected fibers, it can damage serotonergic neurons and reduce the level of 5-hydroxytryptamine (5-HT), eventually leading to depression[7]. The World Health Organization estimates that by 2030, depression may rank first in the global burden of disease[8]. Herpes zoster combined with depression brings a great psychological burden to patients and may reduce their medication compliance and rehabilitation process.

Selective 5-hydroxytryptamine reuptake inhibitors (SSRIs) are safe and can effectively regulate the concentration of monoamine transmitters in the body and reduce depression-like symptoms. They are the first-line antidepressants recommended by various guidelines. A previous study showed that SSRIs are beneficial for the recovery of neurological function in patients with depression[9]. However, some patients experience side effects such as headaches, dizziness, nausea, gastrointestinal symptoms, insomnia, and cardiac dysfunction. SSRIs have also been shown to affect the cardiac and cerebral vessels of patients[10]. Compared to patients with depression alone, patients with herpes zoster combined with depression are more likely to have aggravated depressive symptoms due to physiological pain. Therefore, there is an urgent need to develop a treatment plan that can relieve physiological pain and improve the psychological state of patients with herpes zoster and depression.

According to traditional Chinese medicine, depressive symptoms are mainly related to the dysfunction of the five internal organs and poor emotions. The depressive symptoms of patients with herpes zoster include depression, chest and flank fullness, and irritability caused by physiological and psychological pressure. Chuanjin Qinggan decoction promotes Qi, relieves depression, maintains the liver, clears heat, and detoxifies. However, the specific efficacy of Chuanjin Qinggan decoction combined with SSRIs in treating herpes zoster complicated by depression remains unclear.

In recent years, integrative medicine has achieved positive results in the treatment of various diseases. Since 2022, our hospital has actively attempted integrated traditional Chinese and Western medicine therapy for patients with herpes zoster complicated by depression, achieving good results. This study aims to explore the effect of Chuanjin Qinggan decoction combined with SSRIs in patients with herpes zoster complicated by depression.

MATERIALS AND METHODS

Patients

Patients with herpes zoster complicated by depression who were treated at the Yantai Hospital of Traditional Chinese Medicine between January 2021 and December 2022 were retrospectively selected as research participants. Inclusion criteria were as follows: (1) Meeting the relevant diagnostic criteria for herpes zoster[11]; (2) Hamilton Depression Scale (HAMD) score > 8[12]; (3) age ranging from 30 to 75 years; (4) complete clinical data required for this study; and (5) no history of depression before from the onset of herpes zoster. The exclusion criteria were as follows: (1) Patients with organic mental disorders; (2) patients with significant organ dysfunction; (3) patients with congenital cognitive dysfunction; (4) patients with less than one course of treatment; and (5) patients with allergies to the drugs used in this study.

Grouping and treatment

Eighty-six patients were finally included in the study, and all patients were treated with the same method: acyclovir tablets (specification: 0.1 g/tablet), 0.4 g each time, five times a day; acyclovir cream applied externally, once every two hours, 4-6 times a day. The treatment lasted for two weeks. According to the treatment plan for depression, the patients were divided into Western medicine and combination groups.

Western medicine group: Patients with herpes zoster complicated by depression who received SSRIs between January and December 2021 were included in the Western medicine group. SSRIs include fluoxetine, sertraline, paroxetine, citalopram, escitalopram, and fluvoxamine. The following SSRIs and dosages were used by the patients in this study: The starting dose of sertraline tablets (specification: 50 mg/tablet) was 50 mg/d, administered after breakfast. Clinicians can adjust the drug dose within 7-14 d according to the actual condition of the patient, and the adjustment range is 50-150 mg/d. The starting dose of the enteric-coated paroxetine tablets (20 mg/tablet) was 20 mg/d, taken after breakfast. Clinicians can adjust the drug dose within 7-14 d according to the actual condition of the patient, and the adjustment range is 20-60 mg/d. The starting dose of escitalopram tablets (20 mg/tablet) was 10 mg/d, taken after breakfast. Clinicians can adjust the drug dose within 7-14 d according to the actual condition of the patient, and the adjustment range is 10-20 mg/d. The total treatment duration was eight weeks.

The combination group included patients with herpes zoster complicated by depression who received combined treatment of traditional Chinese and Western medicines between January and December 2022. The Western medicine treatment method was the same as that used in the Western medicine group. The traditional Chinese medicine treatment was Chuanjin Qinggan decoction: Ligusticum chuanxiong Hort (10 g), Curcuma (10 g), Rhodiola (15 g), Bupleurum (12 g), Gardenia (10 g), Paeonia alba (12 g), Rehmannia glutinosa (20 g), Peony bark (10 g), Poria cocos (20 g), Alisma orientalis (10 g), Acanthopanax senticosus (15 g), Schisandra (15 g), Albizzia julibrissin bark (15 g), Glycyrrhiza uralensis (6 g), and Forsythia suspensa (10 g). They were added or removed according to the patient's condition and decocted in 500 mL of water. This was administered once in the morning and evening for 14 d as a course of treatment for four consecutive courses (eight weeks).

Outcome measures

Patient depression before and after treatment was the primary outcome measure. The HAMD scale was used to evaluate the depression status of patients one week before treatment, four weeks after treatment, and eight weeks after treatment. The HAMD scale used in this study has 17 items, of which a score ≤ 7 points indicates normal; the higher the score, the more severe the participant's depression.

The secondary outcome measures were as follows. (1) Patients' pain before and after treatment: The visual analog scale (VAS)[13] was used to evaluate the degree of pain in patients one week before and at the end of treatment. The VAS scores range from 0 to 10, with 0 indicating no pain and 10 indicating severe pain; (2) The effectiveness of herpes zoster treatment: remarkable effect: more than 70% of the rash disappeared, and the pain symptoms were alleviated; effective: 30%-70% of the rash disappeared, and the pain symptoms were alleviated; ineffective: less than 30% of the rash disappeared, and the pain did not change or worsened; (3) Neurotransmitter levels: The serum levels of dopamine (DA) and 5-HT were monitored before and after treatment; (4) Sleep quality: The Pittsburgh Sleep Quality Index (PSQI)[14] was used to evaluate sleep quality. The PSQI scale was compiled by psychiatrists and scholars at the University of Pittsburgh with seven factors derived from clinical practice; each factor had a score range of 0 to 3 points. The final PSQI score was the sum of the seven factor scores. The scale's total score was 21 points; the higher the total score, the worse the sleep quality; and (5) Patients' adverse reactions during treatment were recorded, including headache, blurred vision, nausea, vomiting, and cognitive dysfunction.

Statistical analysis

SPSS 26.0 and GraphPad 9.0 were used for statistical analysis. The statistical data were expressed by frequency and percentage, and the χ^2 test was used for comparison between groups (the rank sum test was used for the count data with hierarchical characteristics). The measurement data that conform to and do not conform to the normal distribution are

expressed by the mean (standard deviation) and median (P25, p75), respectively. The data that conformed used a *t*-test and repeated-measures analysis of variance for comparison between groups, and the data that did not conform used the Mann-Whitney *U* test. Statistical significance was set at $P < 0.05$.

RESULTS

Clinical characteristics of study participants

To ensure the comparability of different drug treatment results, the baseline data of the two groups of patients were compared. After comparison, the statistical analysis showed no significant differences in the baseline data of the two groups of patients receiving different drugs, such as sex, age, duration of herpes zoster, residence, and years of education ($P > 0.05$) (Table 1).

Comparison of the degree of pain

As shown in Table 2, after eight weeks of treatment, the overall VAS scores of the two groups decreased compared to those before treatment, and the VAS scores of patients treated with Chuanjin Qinggan decoction combined with SSRIs decreased more significantly ($P < 0.05$).

Comparison of the therapeutic effectiveness against herpes zoster

In the comparison of the therapeutic effects of the two treatment groups against herpes zoster, it was found that the effect observed in patients treated with Chuanjin Qinggan decoction combined with SSRIs was higher than that in patients treated with SSRIs alone, the ineffective rate was lower than that in patients treated with SSRIs alone, and there was a significant difference in the overall efficacy between the two groups ($P < 0.05$) (Table 3).

The changing trend of patients' depression

As shown in Figure 1, after eight weeks of treatment, the overall HAMD score of patients in both groups decreased compared to that before treatment, and the decrease in HAMD score of patients treated with Chuanjin Qinggan decoction combined with SSRIs was more significant ($P < 0.05$).

Effects of different treatment schemes on neurotransmitter levels in patients

Both treatment regimens improved the serum DA and 5-HT levels of patients, and patients treated with Chuanjin Qinggan decoction combined with SSRIs showed a greater increase in DA and 5-HT levels (both $P < 0.05$) (Figure 2).

Effect of different treatment schemes on sleep quality of patients

Both treatment regimens reduced the PSQI score of patients, and the decrease in the PSQI score of patients treated with Chuanjin Qinggan decoction combined with SSRIs was more significant ($P < 0.05$) (Figure 3).

Occurrence of adverse reactions

Neither treatment method had adverse effects on cognitive function. A few patients experienced minor adverse reactions such as headaches, blurred vision, nausea, and vomiting, which were alleviated after symptomatic intervention. The overall incidence of adverse reactions in patients treated with Chuanjin Qinggan decoction combined with SSRIs was lower than that in patients treated with SSRIs alone ($P < 0.05$) (Table 4).

DISCUSSION

In addition to the core symptoms of depression such as low mood, reduced willpower, and reduced interest, patients with depression also have a severe inferiority complex accompanied by varying degrees of memory loss, sluggish thinking, irritability, and refusal to eat[15]. If the psychological state of a patient with depression cannot be improved for an extended period, the development of severe depression may lead to self-mutilation or even suicide. In recent years, with the development of social psychology, people have begun to pursue comprehensive physical and mental health. Given the negative effects of depression on patients' physiology and psychology, the treatment of depressive symptoms in patients with herpes zoster combined with depression is necessary to improve their well-being. Simultaneously, the treatment of depressive symptoms in patients with herpes zoster and depression can also reduce the burden on their families and society. Therefore, society and most medical workers attach great importance to the treatment of depressive symptoms in patients with herpes zoster combined with depression.

To understand the therapeutic effects of different treatment schemes in patients with herpes zoster complicated by depression, the clinical data of 86 patients were retrospectively analyzed. The results showed that although both treatment regimens could achieve efficacy, patients treated with Chuanjin Qinggan decoction combined with SSRIs showed more significant improvement in depression and a greater increase in DA and 5-HT levels after treatment compared to those treated with SSRIs alone. SSRIs exert antidepressant effects by inhibiting the resorption of 5-HT by the presynaptic membrane, and their efficacy in treating depression has been confirmed. The depressive symptoms of patients treated with SSRIs in this study also improved, similar to the results of previous studies. Findling *et al*[16]

reported that SSRIs can achieve good efficacy in the treatment of depression in adolescents and adults. Fagiolini *et al*[17] also reported that SSRIs could improve depressive symptoms in patients with severe depression. DA is the most abundant catecholamine neurotransmitter in the brain (accounting for approximately 80% of the total). It controls various functions, such as motor activity, cognition, emotion, food intake, and endocrine regulation. Diseases such as Parkinson's disease, schizophrenia, and addictive behavior are all related to dopaminergic system dysfunction[18,19]. Abnormal function of the serotonin system is closely related to loss of appetite, sleep disorders, decreased activity, sexual dysfunction, endocrine dysfunction, depression, and anxiety[20]. Chuanjin Qinggan decoction is mainly composed of Ligusticum chuanxiong Hort, Curcuma, Sedum rosea, and other drugs, among which Ligusticum chuanxiong Hort has

Figure 3 Effect of different treatment schemes on the sleep quality of patients. ^{d}P < 0.0001. PSQI: Pittsburgh Sleep Quality Index.

antioxidant, anticoagulant, anti-tumor, anti-inflammatory, analgesic, microcirculation improvement, anti-aging, antidepressant, anti-radiation, and other effects[21]. Curcuma can regulate neurotransmitters, regulate neuroendocrine function, protect neurons, and inhibit neuroinflammation[22]. Salidroside, an effective component of Sedum rosea, has anti-fatigue, antidepressant, immune-enhancing, and anti-tumor properties[23]. There is a synergistic effect between the active ingredients in Chuanjin Qinggan decoction which helps to improve the depressive state of patients by reducing neurological damage and providing raw materials and energy for protein and nucleic acid synthesis in the brain tissue.

In addition, this study also found that patients treated with Chuanjin Qinggan decoction combined with SSRIs experienced less pain, better treatment efficacy for herpes zoster, better sleep quality, and a lower incidence of adverse reactions compared to those treated with SSRIs alone. These results suggest that the treatment scheme of Chuanjin Qinggan decoction combined with SSRIs can not only significantly improve the depressive state of patients but also improve the treatment of herpes zoster. Chronic pain is an adverse subjective and emotional experience with attributes in multiple dimensions, including sensory recognition, emotional motivation, and cognitive evaluation. Chronic pain increases the psychological burden on patients and causes negative emotions such as disgust, anxiety, and depression. The physical and mental suffering of patients with herpes zoster and depression is severe. Psychological state has a reverse regulatory effect on physiological state, and a good psychological state can improve the effect of treatment for physiological diseases. Shahimi *et al*[24] pointed out in their study that a good psychological state can reduce the risk of falls in older adults and the risk of cardiovascular and cerebrovascular diseases. In this study, the two groups of patients received eight weeks of drug treatment, and the symptoms of herpes zoster and depression significantly improved. However, this study has certain limitations. Specifically, the sample size of this study is small and it comes from a single research center, which may result in selection bias. Further studies with larger samples or joint studies with other centers are needed to confirm the reliability of the results.

CONCLUSION

This study retrospectively analyzed the clinical data of patients with herpes zoster complicated by depression and found that different treatment schemes had different therapeutic outcomes. Patients treated with Chuanjin Qinggan decoction combined with SSRIs experienced less pain, better treatment efficacy for herpes zoster, more significant improvement in depression, a greater increase in DA and 5-HT levels, better sleep quality, and a lower incidence of adverse reactions compared to those treated with SSRIs alone. The overall curative effect of the Chuanjin Qinggan decoction combined with SSRIs was better than treatment with SSRIs alone.

ARTICLE HIGHLIGHTS

Research background

The physical and mental suffering of patients with herpes zoster combined with depression is significant. Although traditional Western medicine can alleviate the depressive symptoms in patients to a certain extent, it also causes many adverse reactions. There remains a need to identify drugs with high clinical safety that can effectively improve the depressive symptoms in patients with herpes zoster combined with depression.

Research motivation

To search for safe drugs that can effectively improve the depressive symptoms of patients with herpes zoster combined with depression, and to provide references for the formulation and modification of the treatment plan for herpes zoster combined with depression.

Research objectives

We analyzed the value of Chuanjin Qinggan decoction combined with a serotonin- selective reuptake inhibitor in the treatment of patients with herpes zoster complicated by depression.

Research methods

We retrospectively analyzed depression status, treatment effect, degree of pain, neurotransmitter levels, sleep quality, and adverse reactions in patients with herpes zoster complicated by depression who received different treatment schemes.

Research results

Compared with patients treated with selective serotonin reuptake inhibitor (SSRIs) alone, patients treated with Chuanjin Qinggan decoction combined with SSRIs showed a greater improvement in depression after treatment, and the incidence of adverse reactions was lower.

Research conclusions

The treatment scheme of the Chuanjin Qinggan decoction combined with SSRIs can improve the depressive state of patients with herpes zoster complicated by depression, and improve the effect of treatment for herpes zoster without increasing the risk of adverse reactions.

Research perspectives

In the future, the specific mechanism of Chuanjin Qinggan decoction in the treatment of herpes zoster complicated by depression should be clarified through cell or animal experiments, to provide references for further improving the therapeutic effect.

Abstract

BACKGROUND

The emergency department plays a crucial role in providing acute care to patients. Nursing interventions in this setting are essential for improving the continuity of care, enhancing patients' self-care abilities, and reducing psychological symptoms.

AIM

To evaluate the effect of nursing interventions in the emergency department on these indicators in an emergency department.

METHODS

A retrospective analysis was conducted on 120 patients admitted to the emergency department between January 2022 and May 2023. The patients were divided into two groups: The control group (conventional nursing intervention) and the observation group (conventional nursing intervention + emergency department nursing intervention). The two groups were compared regarding continuity of care, self-care ability, psychological symptoms, and satisfaction with care.

RESULTS

The emergency department nursing interventions significantly improved the continuity of care, enhanced patients' self-care abilities, and reduced psychological symptoms such as anxiety and depression.

CONCLUSION

Nursing interventions in the emergency department positively impact continuity of care, self-care, and psychological symptoms. However, it is important to acknowledge the limitations of this study, including the small number of studies, variable methodological quality, and the heterogeneity of the study population. Future research should address these limitations and further explore the effects of

different types of nursing interventions in the emergency department. Additionally, efforts should be made to enhance the application and evaluation of these interventions in clinical practice.

Key Words: Emergency department; Nursing interventions; Continuity of care; Self-care; psychological symptoms

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Future research should address these limitations and further explore the effects of different types of nursing interventions in the emergency department. Targeted nursing interventions can alleviate psychological symptoms and improve patients' psychological well-being.

INTRODUCTION

The emergency department is crucial for providing treatment for acute illnesses and trauma. Nursing interventions in this setting are essential for improving the continuity of care, enhancing self-care abilities, and alleviating psychological symptoms[1-5]. Emerging evidence from clinical practice indicates that these interventions positively impact the patients' overall health status[6-9]. Therefore, conducting a comprehensive study of these effects can enhance the quality of care and improve patient outcomes.

Continuity of care in the emergency department involves providing uninterrupted care throughout the patient's stay, including monitoring their condition, implementing care measures, and assessing outcomes. It has been shown that good continuity of care can effectively reduce complications and improve patient outcomes[10-15]. Self-care refers to a patient's ability to independently perform activities of daily living (ADL) and self-care while in the emergency department. Nursing interventions can improve patients' self-care abilities, reduce their reliance on healthcare professionals, and enhance their quality of life[16-23]. Psychological symptoms such as anxiety, depression, and fear are common among emergency department patients. These symptoms can negatively affect patient recovery and prolong the hospital stay [24]. Targeted nursing interventions can help alleviate psychological symptoms and improve patients' psychological well-being.

MATERIALS AND METHODS

General information

We retrospectively analyzed the data of 120 patients admitted to our hospital's emergency department between January 2022 and May 2023. The inclusion criteria were as follows: (1) Age range: Patients in the emergency department were adults aged 18 years and older; (2) primary diagnosis: patients with acute illness, trauma, or other acute medical problems requiring emergency department nursing intervention; (3) self-care: patients had some ability to care for themselves and could understand and follow instructions for nursing intervention; and (4) consent to participate: patients or their legal representatives agreed to participate in the study and signed an informed consent form. Exclusion criteria were as follows: (1) Age restriction: patients under the age of 18 years were excluded from the study; (2) critical status: severe illness or trauma requiring urgent intensive care or surgical treatment; (3) state of consciousness: patients with impaired consciousness or an unstable mental status who were unable to cooperate with the nursing intervention assessment; (4) unable to provide informed consent: patients unable to understand, express, or sign an informed consent form; and (5) previously received similar interventions: patients who had previously received an emergency department nursing intervention or a similar research intervention. The study design considered the feasibility, ethical requirements, and practicalities to ensure scientific validity and reliability.

The control group consisted of 60 patients who received conventional nursing intervention, whereas the observation group received both conventional nursing intervention and emergency department nursing intervention. The control group consisted of 30 males and 30 females, with an age range of 43-75 years (58. 41 ± 3. 17), and the length of hospital stay ranged from 7-20 d (10. 54 ± 2. 57). The observation group consisted of 29 males and 31 females, aged 44-77 years (58. 47 ± 3. 22).

The duration of hospitalization ranged from 8 to 22 d [(mean: 10. 68 ± 2. 61) d]. There were no statistically significant differences between the two groups in terms of sex, age, or duration of hospitalization (P > 0. 05).

Methodology

In the control group, routine care was provided, including maintaining a constant room temperature, regularly opening windows and doors, providing a balanced diet based on the patient's preferences, guiding the patient to change positions, and providing psychological care.

In the observation group, emergency department nursing interventions were carried out in addition to conventional nursing care: (1) Optimizing the nursing process: Improving the efficiency and quality of patient care by optimizing the nursing process and operational specifications in the emergency department. This includes the rapid assessment of patients, prioritization of treatment for critically ill patients, and prompt examinations and treatments; (2) personalized care plans: developing personalized care plans based on each patient's specific situation and diagnosis. Considering the patients' conditions, needs, and preferences, nursing interventions were tailored to their individual situations; (3) nursing education: providing relevant health education and nursing guidance to patients and their family members. This includes educating patients about the disease, treatment plans, and medication to help them better understand and cope with acute medical problems; (4) psychological support: recognizing that patients in the emergency department often experience psychological symptoms such as anxiety, fear, and stress. Nursing staff can reduce patients' psychological burdens and provide positive psychological support through active listening, reassurance, and emotional support; (5) pain management: effectively addressing and managing pain in patients with pain in the emergency department. The nursing staff assessed pain, managed medication, and provided physiotherapy to alleviate pain; (6) critical care: providing close monitoring of patients in critical conditions, including continuous monitoring of vital signs, ongoing assessment of the patient's condition, and timely intervention to ensure patient safety and stability; (7) rehabilitation and referral arrangements: Offering relevant rehabilitation advice and referral to other departments. Nursing staff can provide relevant rehabilitation advice, referral arrangements, and follow-up for patients who require rehabilitation care or need to be referred to other departments; and (8) establishing a nursing team to summarize key considerations in nursing care and improve emergency care foresight by reviewing and summarizing nursing care.

Indicators of observation

(1) The observation indicators for continuity of care include re-attendance rate into the emergency department after a visit: This indicator assesses the frequency at which patients return to the emergency department within a certain period after their initial visit; hospitalization rate: This indicator assesses whether patients require hospitalization or not. Outpatient follow-up rate: This indicator measures the proportion of patients requiring further treatment or follow-up in the outpatient clinic; and (2) Self-care ability observation indicators include assessment of ADL (0-100 points, the higher the score, the stronger the ability): This assessment evaluates the patient's ability to perform daily activities, such as eating, washing, dressing, toileting, and walking; and self-assessment scales: Patients self-report their level of self-care ability through self-assessment scales, such as the Barthel Index and Lawton Self-care Ability Scale. The observation indicators for psychological symptoms include the Symptom Self-Rating Scale (SCL-90): This scale assesses the severity of the patient's psychological symptoms.

RESULTS

The observed indicators of continuity of care were compared between the two groups of patients. Based on the data presented in Table 1, patients in the observation group demonstrated significantly lower rates of re-attendance at the emergency department after their initial visit than patients in the control group ($P < 0.05$). The ADL scores of both groups were compared before and after the intervention. Furthermore, after the intervention, the ADL scores of the patients in both groups were significantly higher than those before the intervention ($P < 0.05$), and the ADL scores of the patients in the observation group were significantly higher than those in the control group ($P < 0.05$) (Table 2). The self-care abilities of the two groups were compared before and after the intervention. The Barthel index scores of the patients in the observation group were significantly higher than those in the control group ($P < 0.05$) (Table 3). After the intervention, there was a significant decrease in the SCL-90 scores for both groups compared to those before the intervention ($P < 0.05$) (Figure 1). Additionally, the SCL-90 scores of the patients in the observation group were significantly lower than those in the control group ($P < 0.05$). The SCL-90 scores of patients in the observation group were significantly lower than those in the control group ($P < 0.05$) (Table 4).

DISCUSSION

With global economic development, the overall quality of life has improved, leading to an increase in accidents and acute diseases. Consequently, the number of patients admitted to hospitals increased annually. Patients in the emergency department commonly present severe functional disorders of the limbs, including motor, sensory, and autonomic dysfunction. These impairments significantly reduce the patient's self-care ability and can result in complications such as autonomic reflex disorders, deep vein thrombosis, and pressure sores. These complications not only cause physical and psychological harm to the patients but also impose a significant economic burden on their families.

In the emergency department, the primary treatment principle is to save the lives of patients. Additionally, efforts would be made to prevent or minimize the loss of function, reduce the occurrence of complications, and achieve the best possible recovery in the shortest time to enhance the quality of life. Although most patients are generally stable after

Table 1 The observed indicators of continuity of care between the two groups of patients are compared

Group	Re-visit rate	Hospitalization rate	Recurrence rate
Observation group (n = 60)	10 (16.67)	15 (25.00)	20 (33.33)
Control group (n = 60)	40 (66.67)	50 (83.33)	54 (90.00)
χ^2	7.281	6.310	5.431
P value	< 0.001	< 0.001	< 0.001

Table 2 Comparison of activities of daily living scores between the two groups before and after the intervention

Group	Pre-intervention	Post-intervention
Observation group (n = 60)	44.37 ± 7.32	96.74 ± 9.91[a]
Control group (n = 60)	43.28 ± 6.24	85.66 ± 8.78[a]
T value	0.124	8.732
P value	0.938	< 0.001

[a]P < 0.05 *vs* pre-intervention group.

Table 3 Comparison of self-care ability between the two groups before and after intervention (mean ± SD, points)

Group	Pre-intervention	Post-intervention	Barthel index rating scale score difference
Observation group (n = 60)	52.34 ± 6.85	78.63 ± 5.44[a]	26.28 ± 6.62
Control group (n = 60)	52.00 ± 6.32	69.72 ± 5.81[a]	17.72 ± 4.55
T value	0.209	6.330	6.032
P value	0.835	< 0.001	< 0.001

[a]P < 0.05 *vs* pre-intervention group.

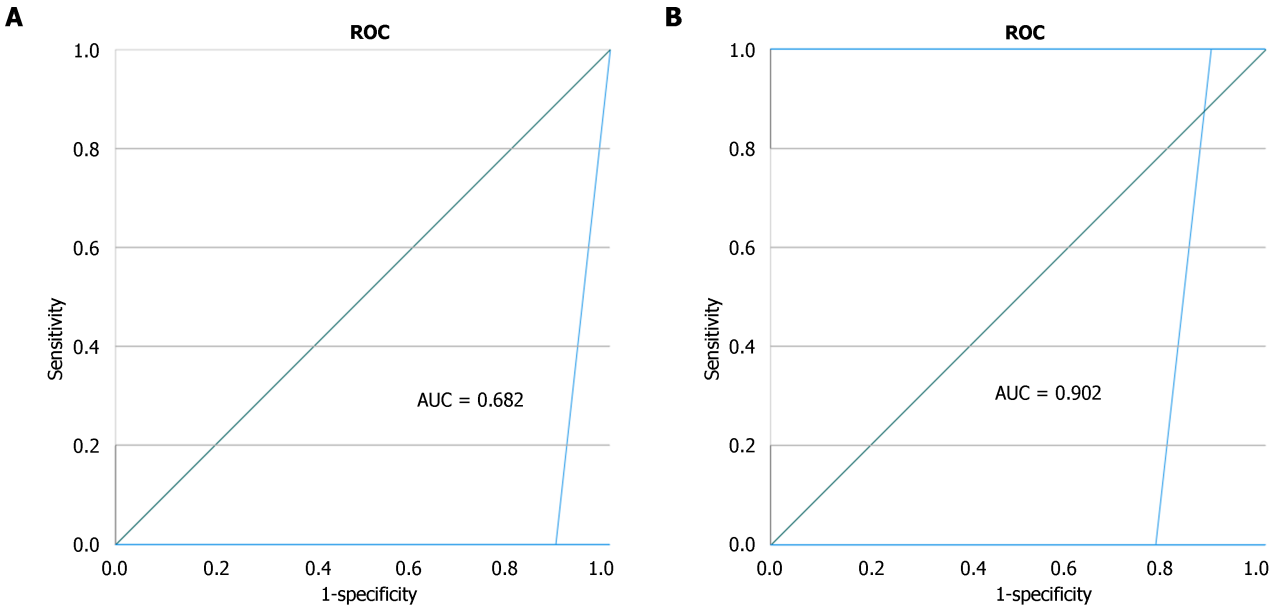

Table 4 Comparison of Symptom Self-Rating Scale scores before and after the intervention in the two groups (mean ± SD, points)

Group	Pre-intervention	Post-intervention	Poor SCL-90 score
Observation group (n = 60)	234.69 ± 25.35	162.44 ± 15.48[a]	72.25 ± 20.00
Control group (n = 60)	235.50 ± 26.29	187.41 ± 16.53[a]	48.09 ± 17.45
T value	-0.126	6.236	5.149
P value	0.900	< 0.001	< 0.001

treatment, they still require long-term care. Studies have confirmed that emergency department nursing, in addition to routine nursing, can improve patients' motor functions, reduce the incidence of complications, and improve their quality of life.

The impact of emergency department nursing interventions on continuity of care, self-care, and psychological symptoms is an area of considerable research interest[25]. The literature review presented here highlights the fact that numerous studies have explored the impact of various emergency department nursing interventions on these aspects. In the cardiovascular field, interventions, such as home environment interventions and telephone support, have been found to enhance patient self-care and quality of life. These interventions empower patients to manage their condition better and provide them with support, thereby improving their understanding and ability to cope with their illness. Additionally, studies have focused on emergency department nursing interventions for critically ill patients and those with heart failure, indicating the potential of these interventions in improving patients' self-care and psychological symptoms. In addition, for patients with heart failure and severe infections, the implementation of early fluid resuscitation in the emergency department has shown potential benefits in improving self-care and reducing psycho-

Figure 1 Impact of emergency department nursing intervention on continuity of care, self-care and psychological symptoms. A: Before intervention; B: After intervention. ROC: Receiver operating characteristic; AUC: Area under the curve.

logical symptoms. These interventions can improve the physiological status of patients and facilitate their recovery and rehabilitation. Taken together, emergency department nursing interventions have a positive impact on the continuity of care, self-care, and psychological symptoms.

CONCLUSION

Emergency department care can help patients improve their caregiving capacity, reduce psychological symptoms, and improve their quality of life through individualized nursing interventions, self-management support, and early interventions. However, further research is needed to explore the impact of different types of emergency department nursing interventions on diverse populations and conditions to provide more accurate guidance and best practices. This study has limitations in terms of sample size, diversity of interventions, and time constraints. Additionally, the complexity of the emergency department settings may introduce other uncontrolled interventional factors.

ARTICLE HIGHLIGHTS

Research background

The emergency department plays a crucial role in providing acute care to patients, and nursing interventions in this setting are essential for improving continuity of care, enhancing patients' self-care abilities, and reducing psychological symptoms.

Research motivation

To evaluate the impact of nursing interventions in the emergency department on these indicators in an emergency department.

Research objectives

This study examined various indicators of continuity of care, self-care, and psychological symptoms.

Research methods

A retrospective analysis was conducted on 120 patients admitted to the emergency department between January 2022 and May 2023. The patients were divided into two groups: The control group (conventional nursing intervention) and the observation group, which received both conventional nursing and emergency department nursing interventions. Patients in both groups were compared in terms of continuity of care, self-care ability, psychological symptoms, and satisfaction with care.

Research results

The emergency department nursing interventions significantly positively impacted various aspects. Specifically, these interventions improved the continuity of care, enhanced patients' self-care abilities, and reduced psychological symptoms such as anxiety and depression.

Research conclusions

Additionally, the complexity of the emergency department settings introduces the possibility that other uncontrolled intervention factors may have an impact.

Research perspectives

Emergency department nursing interventions have the potential to improve patients' self-care and psychological symptoms, suggesting their effectiveness. Furthermore, the implementation of early fluid resuscitation in the emergency department has shown potential benefits for patients with heart failure and severe infections, leading to improved self-care and reduced psychological symptoms. These interventions can improve the patient's physiological status and facilitate recovery and rehabilitation.

Abstract

BACKGROUND

The severe physical and psychological impact of pain on the physical and mental health of women during labor leads to increased risks and complications during childbirth, presenting a major public health concern. Some studies have shown that cognitive behavioral therapy (CBT) has a positive effect on maternal psychology during delivery, reducing stress and shortening labor time. Thus, CBT training for mothers and delivery room staff may be beneficial in minimizing complications and adverse effects during natural birth.

AIM

To investigate the clinical effects of CBT training and psychological care during delivery, and their therapeutic effects on women in labor.

METHODS

This study used a retrospective analysis and included 140 mothers admitted to the maternity ward between January 2021 and January 2023. The study subjects were randomized into two groups: control (n = 70) and observation (n = 70). Routine care, CBT training, and psychological care were provided to mothers in both groups. Psychological status scores, delivery time, and satisfaction with care pre- and post-delivery were compared, and the incidence of complications after receiving care was analyzed between the two groups.

RESULTS

Although the psychological state of both groups improved significantly in the late stages of labor, the psychological state scores of the mothers in the observation group were significantly lower than those of the mothers in the control group (P < 0.05). The duration of labor and incidence of complications in the observation group were significantly lower than those in the control group (P < 0.05). The mothers in the observation group were significantly more satisfied with nursing care during the course of labor than those in the control group (P < 0.05).

CONCLUSION
CBT training and psychological care for mothers in the midwifery process can effectively improve anxiety and depression, shorten labor duration, reduce postnatal complications, and improve nursing satisfaction and nurse-patient relationships. Its clinical application is effective and has popularization value, providing a new way to protect maternal mental health.

Key Words: Cognitive behavior therapy; Cognitive behavior therapy training; Psychological care; Childbirth; Mental health

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: The application of cognitive behavior therapy training and psychological care in the delivery process can effectively improve the psychological condition of mothers, shorten labor duration, reduce the incidence of complications, and improve nurse-patient relationships and nursing satisfaction. Compared to either approach alone, the effect of the combined intervention was more significant.

INTRODUCTION

During labor, the resulting pain causes strong psychological stimulation in women, often leading to accidents due to excessive mental stress[1,2]. Psychological factors have a strong influence on childbirth and are considered to be the fourth stage after the dilation, expulsion, and placental stages[3]. Mild anxiety is a normal psychological stress that can be accompanied by moderate activation of the sympathetic nervous system, improving the body's ability to adapt to the environment; however, the following question arises: How can excessive anxiety or stress lead to physiological alterations during labor[4,5]? First, excessive anxiety leads to a decrease in norepinephrine production, resulting in weak uterine contractions, which can, in turn, lead to obstructed labor and is a possible factor in increasing the risk of postpartum hemorrhaging[6]. Second, stress and anxiety may exacerbate contraction pain by causing a relative decrease in the mother's pain threshold. Severe pain and poor maternal mood also promote catechol secretion in the body, causing uncoordinated uterine contractions, thus impeding the ongoing labor process and increasing the chances of obstructed childbirth as well as decreasing uterine blood flow, which can also cause fetal hypoxia[7,8].

Previous surveys have shown that more than 90% of pregnant women experience labor pain, physiological changes during pregnancy, and anxiety prior to delivery. Mothers who are fearful of a natural birth are more likely to develop other psychological conditions after birth, such as postnatal depression, than those who are not[9]. Incidences of obsessive-compulsive disorder and generalized anxiety disorder are also much higher in postpartum women than in those who have not given birth[10]. Especially in China, since the implementation of the two-child policy, the incidence of postpartum depression has increased significantly. Statistics show that the annual incidence of postpartum depression in China is 5.36%-11.09%[11]. However, numerous studies have demonstrated that timely and effective psychological interventions during labor can significantly reduce maternal fear and tension and increase the rate of successful delivery. Natural childbirth, led by midwives, reduces the risks of pregnancy[12]. Midwives are primarily responsible for providing health education to mothers and their families during labor and delivery, increasing mothers' confidence in a smooth delivery through constant encouragement and reassurance, and by reducing fear, pain, and anxiety[13]. A previous study found that cognitive behavioral therapy (CBT) training before childbirth can help reduce anxiety and tension, decrease the duration of childbirth, and improve mothers' quality of life[14]. Psychological care, however, is aimed at changing the mother's psychological condition during childbirth and is targeted to help improve her mood and reduce fear of a natural birth, thus reducing the incidence of adverse birth events. However, to the best of our knowledge, only a few studies have combined CBT training and psychological care to provide childbirth assistance.

This study used a retrospective approach to investigate the clinical effects of CBT training and psychological care for mothers during assisted delivery and provide new insights into reducing labor complications as well as safeguarding mothers' physical and mental health.

MATERIALS AND METHODS

Study design, setting, and participants

This retrospective study included 140 women who had previously received CBT training and psychological care from midwives as study subjects in the hospital. Subjects who received combined care were included in the observation group

(n = 70), and those who received either psychological care or CBT training alone were included in the control group (n = 70). The psychological status scores, delivery time, and satisfaction with nursing care were compared pre- and post-delivery and the rate of complications after receiving nursing care were analyzed in both groups. The study subjects met the following criteria: (1) Single full-term vaginal births; (2) complete, true, and valid clinical data; (3) signed informed consent form subjects and their families after being informed of the study purpose and content; (4) no history of psychiatric or psychological disorders, or language or cognitive impairment; and (5) no serious comorbidities. The attending physicians met the guidelines for vaginal delivery.

The control group was selected from among the subjects who received either CBT training or psychological care only during the midwifery process, whereas the observation group received both. Except for the noted cognitive and/or psychological interventions, the same care model was applied to both groups.

Regarding routine nursing care, the nursing staff conducted consistent routine nursing care for all mothers, including the following: (1) Providing health education to the mothers and their families (*i.e.*, informing them of the relevant precautions and popular knowledge related to childbirth); (2) assisting the mother in the correct position during labor, instructing her to breathe and exert herself reasonably, and answering her questions about the childbirth process; and (3) enhancing the monitoring of maternal vital signs during labor, instructing family members and mothers to implement postnatal care, and instructing mothers to pay attention to rest, scientific diet, and good hygiene.

Regarding CBT training, when a mother is admitted to the hospital for delivery, the nursing staff learn about her cognitive and comprehension abilities. This, in turn, allows for the adoption of various informational approaches, such as lectures, videos, props and models, and health education manuals to help her grasp the delivery-related knowledge, making her comprehensively aware of the advantages and disadvantages of vaginal delivery and cesarean section, and helping enhance her confidence in delivery. The following is an overview of the instructions: (1) During the first stage of labor, close attention is paid to the mother's labor contractions, instructing her to conduct breathing training and leading her to a free position where she chooses to stand, squat, sit, or lay down while waiting for delivery to provide favorable conditions for the fetus's head to descend, rotate, and be delivered; (2) During the second stage of labor, when the vagina is fully dilated, the recorded video is played back to correctly guide exertion, while changes in the vital signs are closely observed. If abnormalities are found, the doctor is promptly informed and helps in strictly implementing an aseptic operation to avoid infection during labor and the contraction period, to guide the food and water, and to maintain good stamina to lead the head of the fetus to the crown; and (3) During the third stage of labor, when the placenta is delivered, the presence of soft birth canal laceration is checked and, if present, timely suture treatment is provided. At the end of childbirth, the mother is closely monitored, especially for any instances of vaginal bleeding, and guidance for perineal cleansing, supplemented by abdominal massage, is provided to promote contractions and reduce bleeding. If a vaginal delivery is not possible, the mode of delivery should be changed according to the actual situation to avoid irreversible and serious consequences.

Regarding psychological care, prior to delivery, women often experience negative psychological emotions, such as anxiety and depression, due to labor pain and fear for fetal safety. Nursing staff must comprehensively assess changes in their psychological emotions, determine the influencing factors, and provide targeted guidance and encouragement, allowing mothers to maintain a normal or positive state of mind prior to delivery. During labor, an entire process of encouragement and guidance for women is implemented to alleviate such adverse emotions and emotional stress. Post-delivery, the mother is informed promptly of the successful completion of the delivery process to eliminate her worries. Simultaneously, the mother and baby are placed in the same room as soon as possible, and breastfeeding is started as early as possible to help with breast milk secretion and support the mother's adaptation to motherhood.

Measurement of variables

The psychological state score, delivery time, and satisfaction with nursing care before and after delivery in both patient groups were compared, and rates of complications after receiving nursing care were analyzed. The psychological state score is comprised of the self-rating anxiety scale (SAS) and self-rating depression scale (SDS); the lower the score, the better the psychological state of the patient. The duration of childbirth in both groups included the average duration of the first, second, and third stages. Incidence of postpartum complications in the two groups included weak contractions, postpartum hemorrhage, and postpartum depression. Satisfaction with nursing care was assessed using a self-developed scale with four dimensions: basic nursing care, nursing methods, nursing intervention, and nursing care attitude. The scores showed a positive correlation with satisfaction with nursing care; the higher the scores, the higher the satisfaction with nursing care.

Statistical analysis

Data in this study were statistically analyzed using SPSS 26.0. Continuous data conformed to the normal distribution described by means and percentages, median range (interquartile range) was used to describe continuous variables with skewed distributions, and categorical variables were summarized as numbers and percentages (%). Differences between two groups of quantitative data were analyzed using t-tests, and multiple groups of data were analyzed using chi-square tests. Analyses were set to a significance level of $\alpha = 0.05$, and differences were specified as statistically significant at $P < 0.05$.

RESULTS

Baseline data and pathological characteristics

A total of 140 subjects were included in the study. The baseline data of the study subjects were collected for comparison, which showed no statistically significant difference between age, weight, domicile, number of births, or gestational weeks between the two study groups ($P > 0.05$), and the data of the two groups were comparable. The mean age of the study subjects in the observation group was 27.23 ± 1.46 years, the mean weight was 72.91 ± 5.44 kg, the gestational period was 39.41 ± 1.22 wk, and the number of births was 1.23±0.30. In the control group, the mean age of the study subjects was 27.25 ± 1.25 years, the mean weight was 72.91 ± 5.44 kg, the gestational period was 39.25 ± 1.30 wk, and the number of births was 1.18 ± 0.21. The characteristics of the study subjects are presented in Table 1.

Mental status scores before and after delivery in both groups

The psychological state scores of the mothers before and after delivery were assessed in both groups, and the results showed no statistically significant differences from those of the mothers before delivery. After childbirth, the SAS and SDS scores of the observation group were significantly higher than those of the control group ($P < 0.05$). The mental status results are presented in Table 2.

Comparative analysis of delivery time in the two groups

Labor duration was recorded in both groups, showing differences from the first stage of childbirth onwards, with a significant decrease in childbirth time in the observation group compared with the control group ($P < 0.05$). The findings show that the combined intervention was effective in shortening childbirth time (Table 3).

Incidence of complications in both groups

Statistics on the incidence of complications during delivery in both groups showed that in the observation group, two (2.86%) women had postpartum depression, three (4.29%) had postpartum hemorrhage, three (4.29%) had weak contractions, and the total incidence of complications was eight (11.43%). In the control group, 10 (14.29%) mothers developed postpartum depression, seven (10.0%) had postpartum hemorrhage, and 11 (15.71%) developed contraction weakness; the overall complication rate was 28 (40.0%). There was a statistically significant difference in the incidences of complications between the two groups ($P < 0.05$). The complications results are presented in Table 4.

Comparative analysis of nursing satisfaction

Both groups of mothers were asked to rate their satisfaction with nursing care during childbirth. Subjects rated their satisfaction in four dimensions: basic nursing care, nursing methods, nursing intervention, and nursing care attitude. The results show that nursing care satisfaction in the observation group was higher than that in the control, and the difference was statistically significant ($P < 0.05$). The results are presented in Table 5.

DISCUSSION

This study compared the clinical effects of combined CBT training and psychological care for mothers during the process of assisted delivery with those of a single psychological intervention. The results demonstrated that, although the psychological state of mothers in both groups improved significantly in the later stages of labor, the psychological state scores in the observation group were significantly lower than those in the control group. The duration of labor and incidence of complications in the observation group were significantly lower than those in the control, and the satisfaction of mothers with care during the process of labor in the observation group was significantly higher than that in the control. In addition, labor duration and complication rates in the observation group were significantly lower than those in the control group, and the satisfaction rate in the observation group was significantly higher than that in the control group.

Childbirth is an important physiological process that mothers must undergo[15]. During childbirth, many mothers experience greater stress and emotional fluctuations accompanied by anxiety and fear. This leads to sympathetic nerve excitation, resulting in an increased small rate, respiratory frequency, and insufficient gas exchange in the lungs. These changes can cause uterine hypoxia and slow expansion of the uterine opening, causing difficulty in childbirth, prolonging labor duration, and increasing the rate of obstructed labor, as well as the risk of postpartum complications. Previous studies have demonstrated that both CBT training and psychological care can significantly reduce maternal anxiety and fear during labor and improve postnatal quality of life[16,17]. That is, the use of CBT training is effective in reducing maternal anxiety during the postpartum period. It has also been shows to reduce the complications of postpartum stress and depression, with follow-up showing improvements in family well-being and parent-child relationships during the postpartum period[18,19]. The results of this study show that compared to either CBT training or psychological care alone, a combination of the two is more effective in improving the psychological state of mothers after delivery and in reducing the incidence of postpartum depression.

Labor duration has been associated with childbirth complications in previous studies, and maternal anxiety during labor significantly affects its duration[20,21]. The present study showed that CBT training and psychological care during assisted labor were effective in reducing labor duration. The study also found a relative reduction in the incidence of post-delivery complications in the observation group. Moreover, increased satisfaction with care was effective in improving the relationship between mothers and caregivers, leading to mothers' increased trust in midwives during

labor[22].

The strength of this study is in its combined use of CBT training and psychological care, evaluated in terms of psychological status scores, labor duration, postpartum complications, and satisfaction with care. However, due to the retrospective nature of the study, the extent of support for the exact efficacy and safety of the intervention was not as high as that of a prospective study. Nonetheless, we obtained complete clinical data and avoided errors caused by incomplete data.

CONCLUSION

In conclusion, CBT training and psychological care for mothers in the midwifery process can effectively improve maternal anxiety and depression, shorten labor duration, reduce postnatal complications, and improve nursing satisfaction and nurse-patient relationships. Its clinical application is effective and has popularization value, offering a new way to protect maternal mental health.

ARTICLE HIGHLIGHTS

Research background

The severe physical and psychological impact of pain on the physical and mental health of women during childbirth, leads to increased risks and complications, presenting a major public health issue.

Research motivation

During childbirth, labor pain causes strong psychological stimulation in women, which often leads to accidents due to excessive mental stress.

Research objectives

To provide new insights into reducing accidents during childbirth and safeguarding mothers' physical and mental health.

Research methods

This study used a retrospective analysis and included 140 mothers admitted to the maternity ward between January 2021 and January 2023. The two groups were randomized: Routine care, cognitive behavior therapy (CBT) training, and psychological care were, respectively, provided to mothers in the control (n = 70) and the observation (n = 70) groups.

Research results

The results showed that although the psychological state of mothers in both groups improved significantly in the late stage of labor, that of the mothers in the observation group was significantly lower than that of mothers in the control group. The labor duration and incidence of complications in the observation group were significantly lower than those in the control group, and the satisfaction of mothers with care during the process of labor in the observation group was significantly higher than that in the control group. In addition, labor duration and complication rates in the observation group were significantly lower than those in the control group, and the satisfaction rate in the observation group was significantly higher than that in the control group.

Research conclusions

CBT training and psychological care for mothers in the midwifery process can effectively improve maternal anxiety and depression, shorten labor duration, reduce postnatal complications, and improve nursing satisfaction and nurse-patient relationships. Its clinical application is effective and has popularization value, providing a new way to protect the mental health of mothers.

Research perspectives

CBT training and psychological care were administered during the delivery process, and the clinical effects were assessed by evaluating the psychological state scores of the mothers after delivery, observing labor duration, incidence of post-delivery complications, and satisfaction with nursing care.

Abstract

BACKGROUND

The literature has discussed the relationship between environmental factors and depressive disorders; however, the results are inconsistent in different studies and regions, as are the interaction effects between environmental factors. We hypothesized that meteorological factors and ambient air pollution individually affect and interact to affect depressive disorder morbidity.

AIM

To investigate the effects of meteorological factors and air pollution on depressive disorders, including their lagged effects and interactions.

METHODS

The samples were obtained from a class 3 hospital in Harbin, China. Daily hospital admission data for depressive disorders from January 1, 2015 to December 31, 2022 were obtained. Meteorological and air pollution data were also collected during the same period. Generalized additive models with quasi-Poisson regression were used for time-series modeling to measure the non-linear and delayed effects of environmental factors. We further incorporated each pair of environ-

mental factors into a bivariate response surface model to examine the interaction effects on hospital admissions for depressive disorders.

RESULTS

Data for 2922 d were included in the study, with no missing values. The total number of depressive admissions was 83905. Medium to high correlations existed between environmental factors. Air temperature (AT) and wind speed (WS) significantly affected the number of admissions for depression. An extremely low temperature (-29.0 ℃) at lag 0 caused a 53% [relative risk (RR)= 1.53, 95% confidence interval (CI): 1.23-1.89] increase in daily hospital admissions relative to the median temperature. Extremely low WSs (0.4 m/s) at lag 7 increased the number of admissions by 58% (RR = 1.58, 95%CI: 1.07-2.31). In contrast, atmospheric pressure and relative humidity had smaller effects. Among the six air pollutants considered in the time-series model, nitrogen dioxide (NO_2) was the only pollutant that showed significant effects over non-cumulative, cumulative, immediate, and lagged conditions. The cumulative effect of NO_2 at lag 7 was 0.47% (RR = 1.0047, 95%CI: 1.0024-1.0071). Interaction effects were found between AT and the five air pollutants, atmospheric temperature and the four air pollutants, WS and sulfur dioxide.

CONCLUSION

Meteorological factors and the air pollutant NO_2 affect daily hospital admissions for depressive disorders, and interactions exist between meteorological factors and ambient air pollution.

Core Tip: This retrospective study assessed the influence of environmental factors on depressive disorders. Daily hospital admissions for depressive disorders at a hospital in Harbin, China from 2015 to 2022 were obtained. Four meteorological factors and six air pollutants were considered predictors in the time-series models. Air temperature, atmospheric pressure, wind speed, relative humidity, and nitrogen dioxide have effects on daily hospital admissions for depressive disorders, and interactions exist between meteorological factors and ambient air pollution.

INTRODUCTION

Depressive disorder (also known as depression) is a common mental disorder that involves depressed mood and loss of pleasure or interest in activities for long periods of time[1]. Approximately 280 million people (3.8%) worldwide experience depression[2]. Depressive disorder is a complex phenomenon that represents the interplay between social, psychological, and biological mechanisms[1]. The crucial biochemical mechanism underlying depression lies in the disruption of synaptic chemical transmission, which leads to a functional deficiency in the brain's monoaminergic transmitters including norepinephrine, serotonin (5-hydroxytryptamine), and/or dopamine[3]. These mechanisms have become targets of antidepressant action; for example, selective serotonin reuptake inhibitors such as fluoxetine are typical antidepressant medications[1] used for regulating serotonergic transmission.

In the last couple of years, accumulated evidence suggests that depressive disorder is also affected by environmental factors[4], including meteorological factors[5-8], ambient air pollution[9-13], light exposure[14-16], and access to green space[17,18]. An increase in temperature has been found to exacerbate psychiatric disease hospitalizations[19] in Greece, deteriorate mental well-being, and increase depressive language and suicide rates[20] in North America. Exposure to fine particles ($PM_{2.5}$), inhalable particles (PM_{10}), nitrogen dioxide (NO_2), sulfur dioxide (SO_2), and carbon monoxide (CO) was positively associated with depression, and the risk of depression increased with exposure to high levels of these pollutants[21]. Sunlight intensity may also be associated with depressive symptoms[22]. People reporting inadequate natural light in their dwellings were more likely to report depression[15]. This strongly suggests that environmental factors play a role in altering serotonin levels, leading to depression. Corresponding therapies, such as bright-light therapy, have been developed and used, and have evolved into effective treatments that act on serotonin and other monoaminergic pathways[16].

While the literature has discussed the relationship between environmental factors and depressive disorders, the interactions between different environmental factors have rarely been considered. Moreover, the results of different studies have been inconsistent. This study aimed to investigate the effects of environmental factors on depressive disorders. We obtained environmental data containing four meteorological factors and six air pollutants and modeled the

interactions between these environmental factors simultaneously to gather more precise evidence and obtain a regional supplement for this research field.

MATERIALS AND METHODS

Study design

To measure the precise effects of and the interaction between meteorological factors and air pollution on depressive disorders, we obtained as our sample daily hospital admission data for depressive disorders at a class 3 hospital in Harbin, China from January 1, 2015 to December 31, 2022. Data on the meteorological factors and air pollution for each day of admission were also collected to construct a predictive model.

Data collection

Data from 2922 d were obtained from the information management system developed and used by the hospital. Patient information included the visit time and diagnosis. Individual identifiers were excluded. Patients with permanent residence in Harbin were selected, and those with other mental disorders were excluded. Daily depressive disorder admission data equaled the sum of depressive outpatient and hospitalization data. The diagnosis of depressive disorder (coded as F32-F33 ICD-10 diagnoses) refers to GB/T 14396-2016", classification and Code of Diseases"[23].

Meteorological data for the same period from 2015 to 2022 for Harbin, China, were collected from the China meteorological data service centre[24], including daily mean air temperature (AT), daily mean atmospheric pressure (AP), wind speed (WS), and relative humidity (RH).

Ambient air pollution data included six international standard air pollutants that have been extensively investigated previously[12]: $PM_{2.5}$, PM_{10}, SO_2, CO, NO_2, and ozone (O_3, usually measured at maximum 8-h average concentrations). The pollutant data were collected from the China Air Quality Online Monitoring and Analysis platform[25]. For all ambient air pollutants, we averaged all valid monitoring measurements each day to obtain their daily mean concentrations, in line with previous studies[12,26].

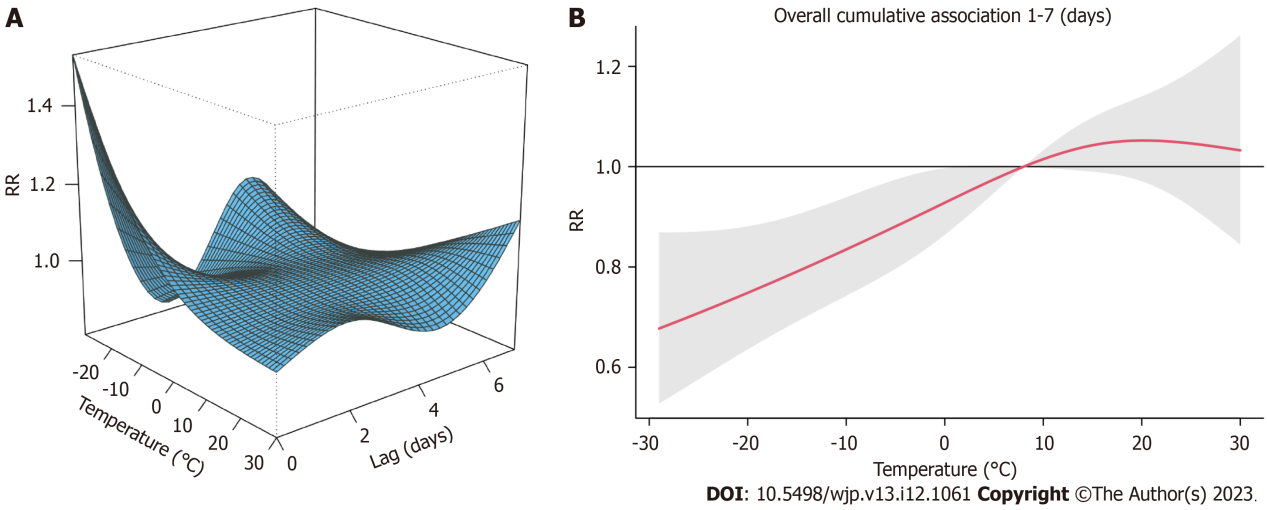
To conduct a time-series analysis, information on time-related variables was collected for modeling, such as the day of admission and public holidays. A sequence of calendar times was generated to indicate the time trends.

Statistical analysis

All data were inspected and preprocessed using Microsoft excel and IBM SPSS 25.0. No missing values or outliers were identified. Descriptive analysis, correlation calculations, time-series modeling, and plotting were conducted using R version 4.2.3. The mean value; SD; and minimum, maximum, median, and quartile (P_{25} and P_{75}) were used to describe the data. The correlation coefficients between variables were calculated using Spearman's correlation analysis with the R package psych. We conducted a time-series analysis using the R packages dlnm[27], mgcv[28], rsm[29], and splines, modeling the effects of and interactions between various environmental factors. The R package ggplot2[30] was used to visualize the results. All statistical tests were two-tailed probability tests, $\alpha = 0.05$. Statistical results with $P < 0.05$, such as associations and differences, were considered statistically significant.

We used generalized additive models with quasi-Poisson regression to estimate the meteorological effects of each factor. The covariates in the models included a natural cubic spline of calendar time with 14 degrees of freedom, which modeled time trends in hospital admissions for depressive disorders, and two indicator variables for the day of the week and public holidays, accounting for potential variations in hospital admissions over weekdays, weekends, and holidays. Natural cubic splines of the daily AT, AP, WS, and RH with three degrees of freedom were included as predictors. To assess the potential lagged effects of meteorological factors, we included lags of up to seven days in the model for non-cumulative effects, similar to the methodology of a previously published study[31]. The choice of calendar time *df* was determined by calculating the minimum sum of the absolute values of the partial autocorrelation function based on the residuals of the underlying model, consistent with the residual independence principle[31]. Choices of meteorological factors *df*s have been recommended by papers on time-series analyses[32] and have been adopted by most studies. The time-series analysis model for a single meteorological factor is as follows:

$$Y_t \sim quasiPoisson\,(\mu_t)$$



$$log\,E\,([Y_t]) = \alpha + ns_t\,(calendar\ time, df = 14) + DOW_t + holiday_t + \beta_{it} \times ns_{it}\,(meteological\ factor, df = 3)$$

Where E (Y_t) denotes the expected number of depressive disorder admissions on day t; α is the intercept; ns represents the natural cubic spline function; and β_{it} is the exposure coefficients of meteorological factors and their lagged effects. We included the immediate and lagged effects of each air pollutant in the model and used meteorological factors as covariates. The time-series analysis model for a single air pollutant is as follows:

$$Y_t \sim quasiPoisson\,(\mu_t)$$

$$\log E\,([Y_t]) = \alpha + ns_t\,(calendar\ time, df = 14) + DOW_t + holiday_t + \beta_{it} \times ns_{it}\,(meteological\ factor, df = 3) + \beta_{jt} \times (air\ pollutant)_{jt}$$

Where (air pollutant) represents lags of 0 to 7 for cumulative and non-cumulative exposures. Finally, we incorporated each meteorological factor and air pollutant into a bivariate response surface model to inspect the interaction effects of each pair of meteorological factors and air pollutants on hospital admissions for depressive disorders. The model for interaction effects is as follows:

DOI: 10.5498/wjp.v13.i12.1061 **Copyright** ©The Author(s) 2023.

Figure 1 Effects of air temperature on hospital admissions for depressive disorder. A: 3D plot of relative risk (RR) along air temperature and lags, with reference to the median temperature of 7.8 ℃; B: Overall RR of lags 1-7 by air temperature, with reference at 7.8 ℃. RR: Relative risk.

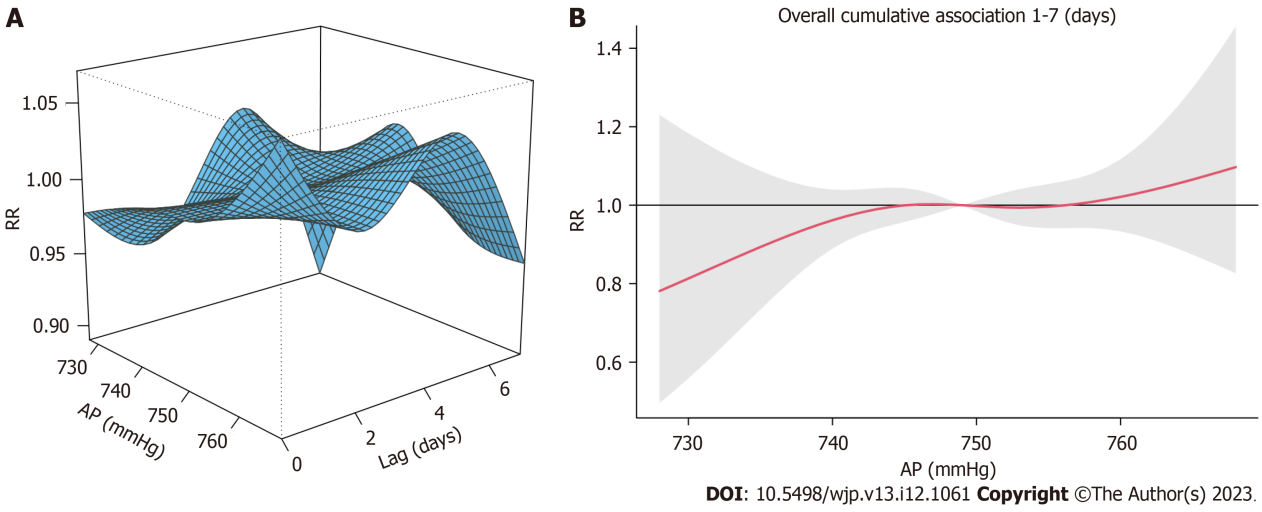
$$Y_t \sim quasiPoisson\,(\mu_t)$$

$$\log E\,([Y_t]) = \alpha + ns_t\,(calendar\ time, df = 14) + DOW_t + holiday_t + t_e\,(meteological\ factor_t, air\ pollutant_{t-i})$$

Where t_e is the interaction effect of meteorological factors and air pollutants (on the day with the strongest lag effect) on daily hospital admissions for depressive disorders. Results are expressed as relative percentage change (%) and estimated 95% confidence intervals (CIs) at hospital admissions for depressive disorders of certain meteorological factor levels or per unit increment of air pollutants.

RESULTS

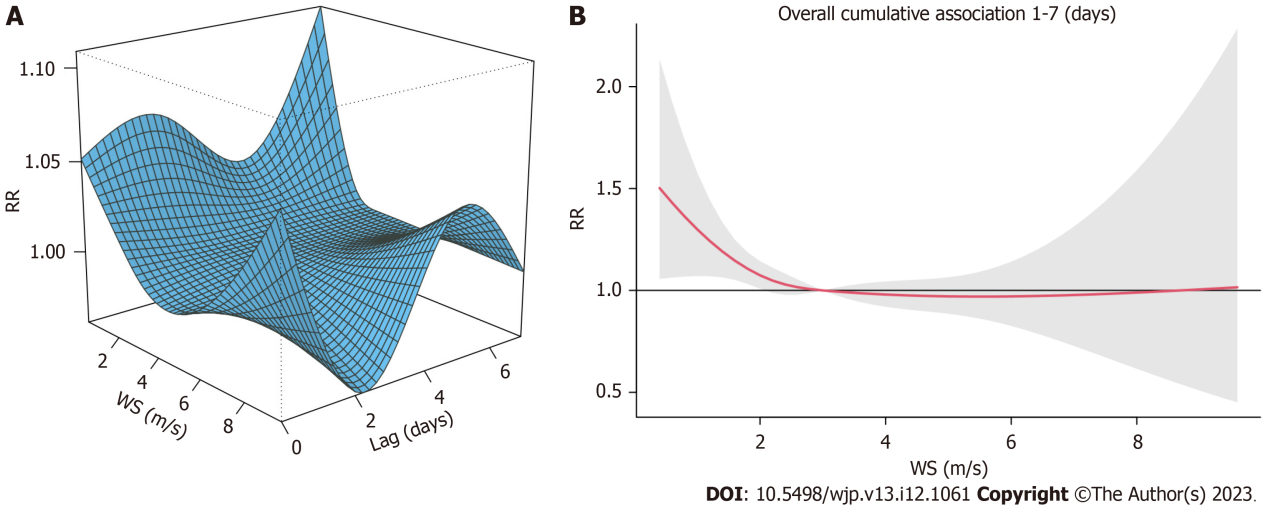
Descriptive statistics and correlation



The general features of all the variables are summarized in Table 1. The total number of hospital admissions for depressive disorders from January 1, 2015 to December 31, 2022 included in the study was 83905, with a daily average admissions of 28.7. During the studied period, the daily average AT in Harbin was 5.4 ℃, and the daily average AP was 749.3 mmHg. The average WS was 2.9 m/s. The mean RH was 66.2%. The climate in Harbin is cold but mild, which means that it is not excessively windy or dry most times of the year, and the AP remains slightly lower than the standard. The daily average concentrations of $PM_{2.5}$, PM_{10}, SO_2, CO, NO_2, and O_3_8h (the maximum 8-h average concentration of ozone) were 47.2 μg/m^3, 71.3 μg/m^3, 22.0 μg/m^3, 0.9 mg/m^3, 36.7 μg/m^3, and 75.8 μg/m^3, respectively. There is relatively high variability in air pollution, although the concentration levels are usually low according to the quartiles.

The correlation coefficients between the meteorological factors and air pollutants are shown in Table 2. All Spearman's correlation coefficients were statistically significant, except for the correlation between RH and CO. There was a moderate correlation among AT, AP, and air pollutants. Relatively high correlations among the air pollutants (except for O_3) were found.

Time-series analysis modeling



In the single meteorological factor model for AT, AP, WS, and RH, we reported relative risks (RRs) with 95%CIs of the depressive disorder admissions for each level of the meteorological factor. The overall relationships between each meteorological factor and hospital admissions for depressive disorders are summarized in Figures 1-4. As shown in Figure 1A, there was a sharp effect of extremely low temperature, although, in Figure 1B, the overall low temperature had no positive effect on RR. Figure 2 shows the mild effect of AP on RR, which is close to zero. Figure 3 shows a larger effect of low WS and a smaller effect of high WS. As shown in Figure 4, both moderate and high RH appeared to have relatively small effects.

To provide more certainty and precision in the estimates, we further investigated the effect of each meteorological factor by calculating and plotting the RRs by these factors at lags 0-7, as shown in Figures 5-8. The results for AT showed significant increases at lags 0-2 and 5-6. Figure 5 shows that an extremely low temperature (-29.0 ℃) at lag 0 increased daily hospital admissions for depressive disorders by 1.53 times (95%CI: 1.23-1.89) relative to median temperature (7.8 ℃), which was the largest effect of AT. As shown in Figure 6, the effect of AP was significant only at lags 5 and 6. A moderately high AP (762 mmHg) at lag 5 increased the number of admissions by 1.13 times (95%CI: 1.00-1.27) relative to the median AP (748.9 mmHg). Figure 7 shows that WS had a significant effect at lags 2-7. The largest effect was at lag 7, where an extremely low WS (0.4 m/s) increased the number of admissions by 1.58 times (95%CI: 1.07-2.31) relative to the median WS (2.6 m/s). Relatively high RHs at lags 4-7 had statistically significant effects, and the largest effect of RH

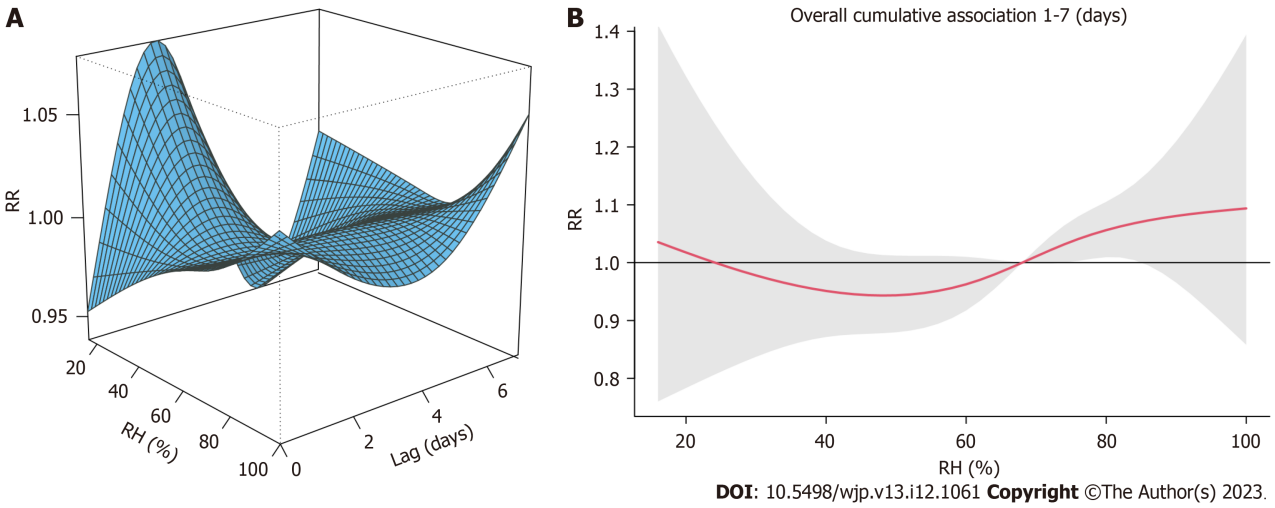
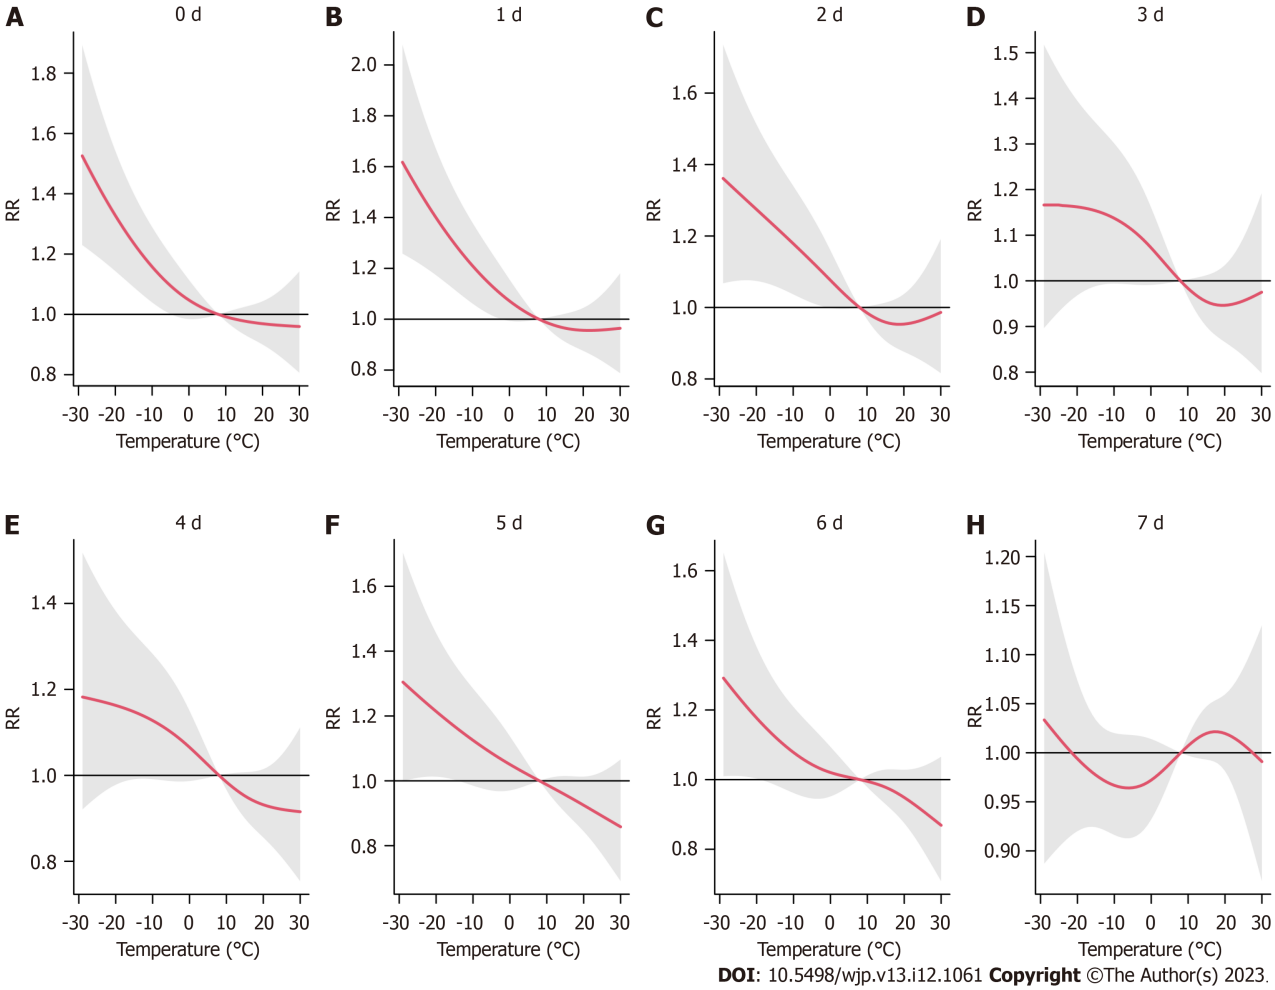
Figure 2 Effects of atmospheric pressure on hospital admissions for depressive disorder. A: 3D plot of relative risk (RR) along atmospheric pressure (AP) and lags, with reference to the median AP of 748.9 mmHg; B: Overall RR of lags 1-7 by atmospheric pressure, with reference at 748.9 mmHg. RR: Relative risk; AP: Atmospheric pressure.



DOI: 10.5498/wjp.v13.i12.1061 **Copyright** ©The Author(s) 2023.

Figure 3 Effects of wind speed on hospital admissions for depressive disorder. A: 3D plot of relative risk (RR) along wind speed (WS) and lags, with reference to the median WS of 2.6 m/s; B: Overall RR of lags 1-7 by wind speed, with reference at 2.6 m/s. RR: Relative risk; WS: Wind speed.

resulted from a moderately high RH (86%) at lag 7, which increased the number of admissions by 1.09 times (95%CI: 1.01-1.17) relative to the median RH (67.9%), as shown in Figure 8.



Next, the concentrations on the same day (lag 0) and 1-7 d ago (lag 1-7) of the six air pollutants were included in the time-series model. The results are shown in Figure 9. Among these air pollution variables, only NO_2 showed significant effects, and the effects of concentration increases in NO_2 at lags 0-7 were all statistically significant, despite their weakness. The cumulative exposure to air pollution was also modeled and plotted, as shown in Figure 10. Consistent with the non-cumulative results, only NO_2 exhibited a significant cumulative effect. As NO_2 accumulated, the exposure effect on daily hospital admissions for depressive disorders increased slightly and smoothly, reaching its highest value at lag 7, where RR = 1.0047 (95%CI: 1.0024-1.0071).

A bivariate response surface model was generated to analyze the interactions between environmental factors. AT significantly interacted with all pollutants included in this study, except for NO_2. As shown in Figure 11, extremely low ATs combined with high concentrations of $PM_{2.5}$ and PM_{10} increased the number of admissions for depressive disorders. Combination of low temperature, low SO_2, and of high temperature and high SO_2 affected hospital admissions. Extremely low temperatures at any CO concentration increased the admission rate. When hot, a low CO concentration had an increasing effect, whereas a high CO concentration did not. Low temperatures and high O_3 concentrations had decreasing effects. Figure 12 shows the interactions between the AP and air pollutants. The interactions between the AP and $PM_{2.5}$, CO, NO_2, and O_3_8h were statistically significant. Low APs combined with low CO, low NO_2, or high O_3 had increasing effects, whereas high APs combined with high $PM_{2.5}$, high CO, or low O_3 increased hospital admissions for depressive disorders. The interaction patterns of AP and $PM_{2.5}$/CO/NO_2 were similar; however, the pattern between AP and O_3 was the opposite. The interactions between WS and air pollutants are shown in Figure 13. SO_2 had the only significant

interaction effect with WS, indicating that most single effects of air pollutants were consistent at different levels of WS. Generally, when high WS and high concentrations of pollutants coexisted, hospital admissions for depressive disorders did not increase. Finally, the interactions between RH and air pollutants were analyzed, and the results are plotted in Figure 14. No significant interaction effects were found between any pair, indicating that the effects of air pollution were relatively stable across different levels of RH.

DISCUSSION

Based on daily hospital admission data for depressive disorders from 2015 to 2022 in a hospital in Harbin, China, we obtained environmental data for the same period, including meteorological and ambient air pollution data, and conducted a time-series analysis to investigate the short-term exposure effects of these environmental factors on depressive disorders. Our results showed that meteorological factors, including AT and WS, could sharply influence daily hospital admissions, while AP, RH, and air pollutant NO_2 (immediate, lagged, or cumulatively lagged) had significant but moderate or small effects. We modeled the relationship between meteorological factors and air pollution and found significant interaction effects between AT and $PM_{2.5}$/PM_{10}/SO_2/CO/O_3_8 h, AP and $PM_{2.5}$/CO/NO_2/O_3_8 h, and WS and SO_2.

Specifically, we found that the risk of depressive disorder admission increases by 53% when an extremely low temperature (-29 ℃, for Harbin) occurs. This finding was consistent with the results of a previous study conducted in Europe[8], but contrary to most similar studies[5,14,33-35], where increased or high AT was associated with increased depressive symptoms or higher hospital admissions. This inconsistency may have resulted from regional differences in the areas of interest selected by each study. Harbin City (45°25′-45°30′N, 126°20–126°25′E) is located in Northeast China and has a typical continental monsoon climate. The highest temperature in the study period was 30.6 ℃, indicating that it is never excessively hot in Harbin, unlike in Hong Kong[5] or Shanghai[33]. From reference[6], we know that both low and high temperatures might be important drivers of morbidity in mental disorders and that lower temperatures may have a more general and widespread effect on cause-specific morbidity. The result in Europe[8] even showed a protective

impact of a higher AT (> 14.2 ℃), which may serve as a reference for explaining the zero effects of a higher temperature in Harbin. A famous nickname for Harbin City is "Ice City," indicating its freezing coldness in winter. Studies have shown that exercise interventions[15] and frequent visits to outdoor green spaces[17] effectively improve depression symptoms. Therefore, extremely low temperatures can negatively affect depressive symptoms by limiting outdoor exercises and visits to green spaces. Furthermore, low temperatures usually co-exist with insufficient sunlight in winter, and reduced sunlight exposure, both in intensity and duration, is related to an increased risk of depression, according to previous studies[22,36]. Despite this inconsistency with most similar studies, this study confirmed the importance of AT in depressive admissions.

In addition, we found a 58% increase in depressive disorder admissions when the WS approached zero. We propose two possible mechanisms underlying the effect of low WS. First, as coal-fired heating in the cold period always causes severe air pollution in Harbin[37,38], low WS would worsen the air pollution. Air pollution-induced inflammation of the respiratory airways is associated with depression in vulnerable individuals[39]. Severe air pollution may also decrease outdoor activities and sunlight exposure, thereby increasing the risk of depressive disorder[40]. Hence, low WS during cold winters may be associated with depressive symptoms caused by severe air pollution. Second, a previous study showed that during warmer periods, warm and dry winds have an increasing effect on the concentration of positive ions in the atmosphere, which increases blood and brain serotonin levels[8]. Low WS may not provide this improving effect on depressive symptoms.

We also found relatively small effects of AP, RH, and the air pollutant NO_2. These results are consistent with previous studies, where high RH levels seem to be pertinent to suicide risk[41] and nitrogen oxides increase the risk of mental health problems, probably *via* mechanisms of inflammation and neuronal injury[35].

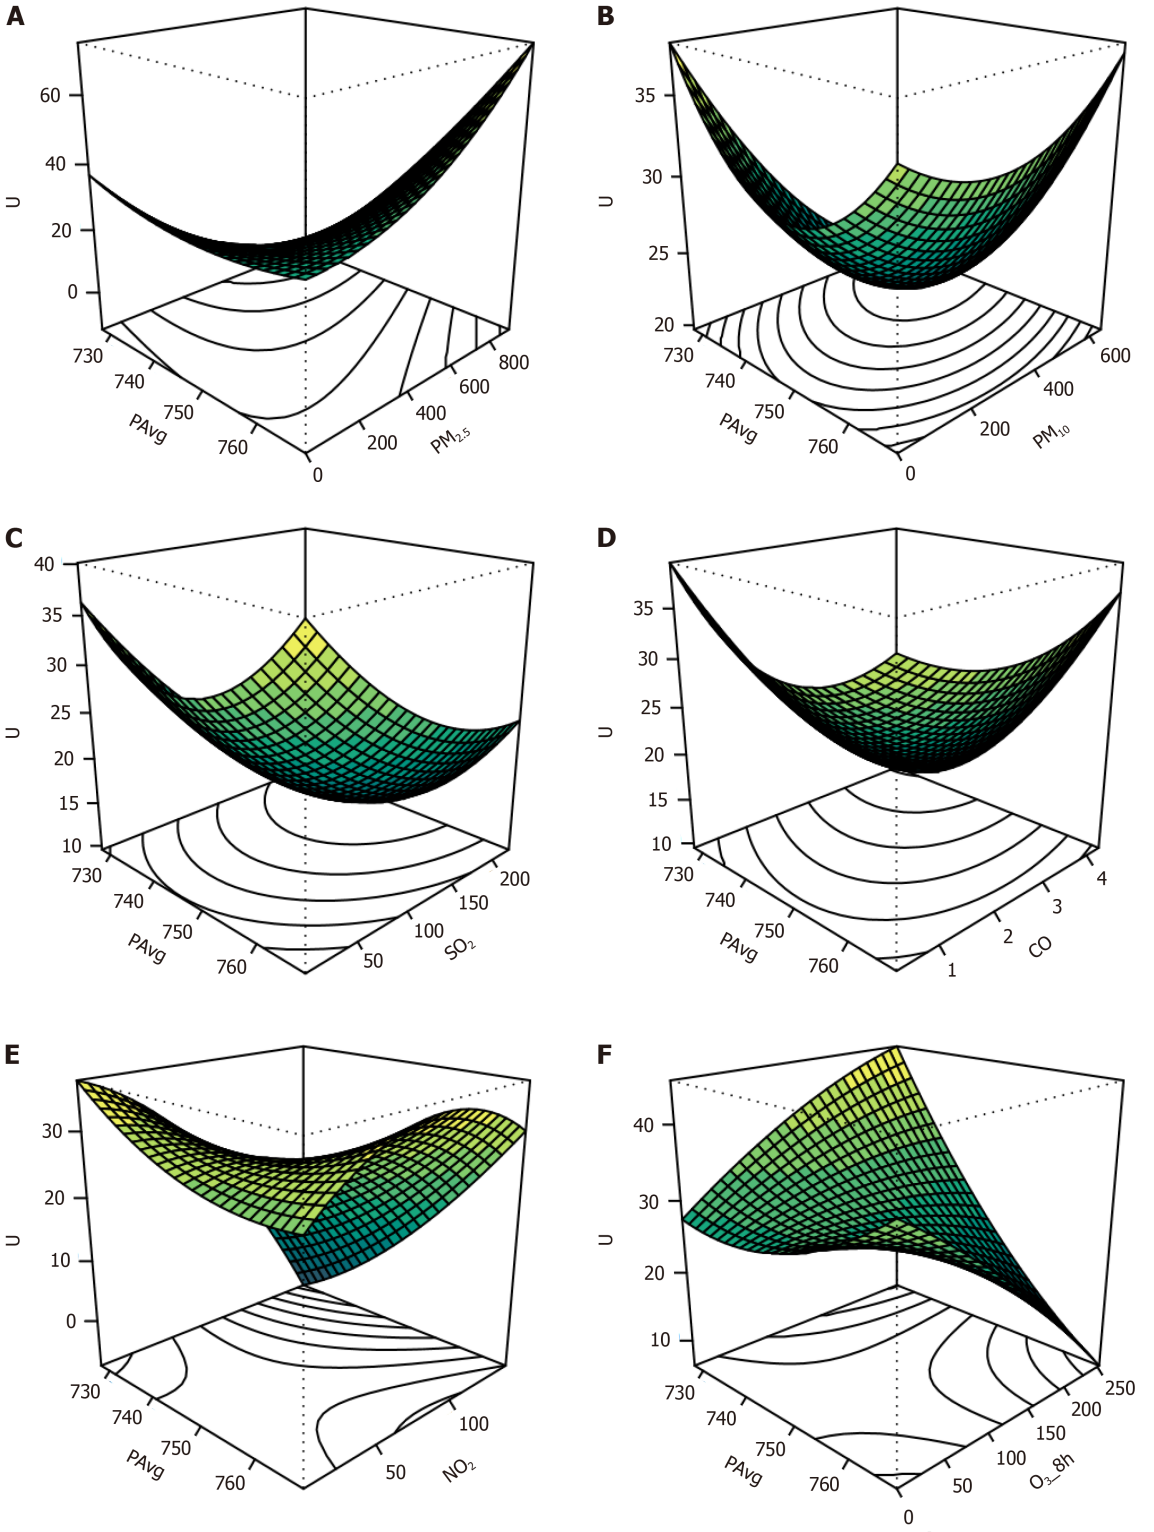
A: Relative risk (RR) by cumulative fine particles concentrations at lags 0-7; B: RR by cumulative inhalable particles concentrations at lags 0-7; C: RR by cumulative sulfur dioxide concentrations at lags 0-7; D: RR by cumulative carbon monoxide concentrations at lags 0-7; E: RR by cumulative nitrogen dioxide concentrations at lags 0-7; F: RR by cumulative maximum 8-h average concentration of ozone concentrations at lags 0-7. $PM_{2.5}$: Fine particles; PM_{10}: Inhalable particles; SO_2: Sulfur dioxide; CO: Carbon monoxide; NO_2: Nitrogen dioxide; O_3_8h: Maximum 8-h average concentration of ozone; RR: Relative risk.

The distinctive results of this study were the interactions between AT and $PM_{2.5}$/PM_{10}/SO_2/CO/O_3_8 h, AP and $PM_{2.5}$/CO/NO_2/O_3_8 h, and WS and SO_2. After carefully inspecting the patterns of these interactions, we assumed that most interactions corresponded to the relationship between the increased risk of depressive disorder and severe air pollution caused by coal-fired heating. In most significant interactions, typical meteorological factor levels in winter (including low AT and high AP) combined with high levels of air pollutants were associated with depressive symptoms. The interaction between WS and SO_2 was the same, as both high WS plus low SO_2 and low WS plus high SO_2 seemed unfavorable for outdoor activities and sunlight exposure. The increasing effect of low WS plus low SO_2 may appear during warmer periods, as low WS does not improve serotonin levels. The cases of O_3 were different from those of the others. We assumed that the reason for this inconsistency between O_3 and other air pollutants was seasonal differences. The O_3 concentration is typically high in the summer, whereas the concentrations of other pollutants are high in the winter.

The strength of our study lies in the precise effects we modeled and measured, especially the interaction between meteorological factors and ambient air pollution. Although our results indicate the effects of environmental factors on hospital admissions for depressive disorders, they are inconsistent with most similar studies and need to be replicated in other methodologically superior studies. The results cannot be generalized to the entire population of China because the sample came from only one northeastern city and urban population. Patient information was insufficient, which limited further analyses.



CONCLUSION

Our study suggests that meteorological factors and the air pollutant NO_2 affect daily hospital admissions for depressive disorders and that interaction effects exist between meteorological factors and ambient air pollution. Clinicians and

patients are encouraged to pay more attention to the environmental effects on depressive symptoms. More stringent air quality control measures may be helpful to protect public mental health. Further studies involving more cities in China and a larger sample should be conducted to enable generalization. Thorough studies into the underlying mechanisms for environment impacting mental health are also warranted.

ARTICLE HIGHLIGHTS

Research background

Environmental factors have been shown to affect individual mental health; however, the relationships and effects of different environmental factors in relatively cold areas have not yet been clarified.

Research motivation

We studied the effects of environmental factors, including their interaction effects, on daily hospital admissions for depressive disorders, aiming to discover the patterns of interaction between various environmental factors and provide regional references for this research field.

Research objectives

To investigate the single and interaction effects of environmental factors, we modeled, measured, and plotted these potential effects and added evidence to explore the complex relationship between environmental factors and human mental health.

Research methods

We performed a retrospective study using data from Harbin, China between 2015 and 2022, including daily hospital admissions for depressive disorders, meteorological data, and air pollution data. A time-series analysis was conducted using generalized additive models with quasi-Poisson regression to measure the effect of each single factor on depression. A bivariate response surface model was used to model the interaction effects of different factors. Our data came from a higher-latitude area, offering an opportunity to investigate regional differences in relationship patterns and the effects of environmental factors.

Research results

Our results showed that air temperature and wind speed influenced daily hospital admissions. Extremely low temperatures and wind speeds could increase daily hospital admissions for depressive disorders by approximately 50%. atmospheric pressure, relative humidity, and the air pollutant nitrogen dioxide had significant but moderate effects. Interaction effects between three meteorological factors and six air pollutants were discovered.

Research conclusions

Meteorological factors and air pollutants have single and interaction effects on daily hospital admissions for depressive disorders, and the effect pattern may be related to coal-fired heating in winter.

Research perspectives

Specific mechanisms behind the complex relationships of environmental factors are to be studied.

Abstract

BACKGROUND

Changes in China's fertility policy have led to a significant increase in older pregnant women. At present, there is a lack of analysis of influencing factors and research on predictive models for postpartum depression (PPD) in older pregnant women.

AIM

To analysis the influencing factors and the construction of predictive models for PPD in older pregnant women.

METHODS

By adopting a cross-sectional survey research design, 239 older pregnant women (≥ 35 years old) who underwent obstetric examinations and gave birth at Suzhou Ninth People's Hospital from February 2022 to July 2023 were selected as the research subjects. When postpartum women of advanced maternal age came to the hospital for follow-up 42 d after birth, the Edinburgh PPD Scale (EPDS) was used to assess the presence of PPD symptoms. The women were divided into a PPD group and a no-PPD group. Two sets of data were collected for analysis, and a prediction model was constructed. The performance of the predictive model was evaluated using receiver operating characteristic (ROC) analysis and the Hosmer-Lemeshow goodness-of-fit test.

RESULTS

On the 42nd day after delivery, 51 of 239 older pregnant women were evaluated with the EPDS scale and found to have depressive symptoms. The incidence rate was 21.34% (51/239). There were statistically significant differences between the PPD group and the no-PPD group in terms of education level (P = 0.004), family relationships (P = 0.001), pregnancy complications (P = 0.019), and mother–infant separation after birth (P = 0.002). Multivariate logistic regression analysis showed that a high school education and below, poor family relationships, pregnancy

complications, and the separation of the mother and baby after birth were influencing factors for PPD in older pregnant women ($P < 0.05$). Based on the influencing factors, the following model equation was developed: Logit (P) = 0.729 × education level + 0.942 × family relationship + 1.137 × pregnancy complications + 1.285 × separation of the mother and infant after birth -6.671. The area under the ROC curve of this prediction model was 0.873 (95%CI: 0.821-0.924), the sensitivity was 0.871, and the specificity was 0.815. The deviation between the value predicted by the model and the actual value through the Hosmer-Lemeshow goodness-of-fit test was not statistically significant ($\chi^2 = 2.749$, $P = 0.638$), indicating that the model did not show an overfitting phenomenon.

CONCLUSION

The risk of PPD among older pregnant women is influenced by educational level, family relationships, pregnancy complications, and the separation of the mother and baby after birth. A prediction model based on these factors can effectively predict the risk of PPD in older pregnant women.

Key Words: Older pregnant women; Postpartum depression; Influencing factors; Prediction model

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Older pregnant women are more likely to develop postpartum depression (PPD) than younger pregnant women. PPD can harm the physical and mental health of pregnant women, offspring development, and family and social harmony. Here, we investigated the PPD status of 239 older pregnant women. Based on whether the older pregnant women experienced depression 42 d postpartum, we divided them into a PPD group and a no-PPD group. By conducting statistical analysis on two sets of data and constructing a prediction model, we examined the issue of how medical personnel can effectively assess the PPD risk of older pregnant women.

INTRODUCTION

Postpartum depression (PPD) is a postpartum mental condition characterized by anxiety, irritability, and extreme depression. In severe cases, hallucinations or suicidal tendencies may occur[1]. PPD not only harms the physical and mental health of pregnant women but also has adverse effects on offspring development, families, and society[2]. Related research reports show that the incidence of PPD among younger pregnant women in China is 14.7%. The incidence of PPD in older pregnant women (≥ 35 years old) is as high as 36.9%[3]. There are some recent studies on PPD in pregnant women, but they are all based on analyses of mental illness history, family relationships, and other aspects[4,5]. There is a lack of exploration on pregnancy complications and the separation of mothers and babies after birth. This results in inadequate clinical measures to prevent PPD, and there is a lack of reporting on predictive models. This study combined the overall situation before, during, and after childbirth to understand the influencing factors of PPD in older pregnant women and construct a risk prediction model to provide guidance for obstetricians in predicting the risk of PPD in older pregnant women and developing treatment measures.

MATERIALS AND METHODS

Patient characteristics

Adopting a cross-sectional survey research design, 239 older pregnant women (≥ 35 years old) who underwent obstetric examinations and gave birth in our hospital from February 2022 to July 2023 were selected as the research subjects. According to the Edinburgh PPD Scale (EPDS), the presence or absence of PPD symptoms was measured at 42 d postpartum, and the older pregnant women were divided into a PPD group and a no-PPD group. This study was approved by the Medical Ethics Committee of Suzhou Ninth People's Hospital.

Inclusion and exclusion criteria

The inclusion criteria were as follows: (1) Women with a gestational age ≥ 37 wk at delivery, a single birth, and natural conception; (2) women with normal consciousness and intelligence; (3) women without adverse pregnancy outcomes (stillbirth, abortion, deformity); (4) women who were informed of this study and signed an informed consent form; and (5) women who were evaluated with the EPDS at 42 d postpartum. The exclusion criteria were as follows: (1) Women with comorbid malignant tumors; (2) women with trauma or infection before delivery; (3) women diagnosed with

depression during any depression screening during pregnancy (early, middle, late) or the prenatal period (prior to delivery)[6]; and (4) women with past mental illness.

Survey methods

General information: By creating a general data collection form, age, education level, birth history, pregnancy complications (pregnancy-induced hypertension, pregnancy-induced diabetes, *etc.*), delivery mode, separation of the mother and infant after birth (referring to the newborn needing to be admitted to the neonatal department for treatment after birth), neonatal feeding mode and other information of the older pregnant women were collected.

Family relationships: The Chinese version of the Family Adaptability Cohesion Environment Scale II-CV[7] was used to evaluate the family relationships of the older pregnant women. This scale mainly evaluates intimacy and adaptability. Intimacy refers to the emotional connection between a mother and her family members. Adaptability refers to the ability of a mother to adapt to the different developmental stages of her family and family situation. This scale consists of 30 items. The total score ranges from 30 to 150 points, and items are scored using a 5-point likert-type (1-5 points) scoring method. The higher the score is, the better the family relationship. In this study, a score of ≤ 70 indicates a lack of harmonious family relationships; a score of > 70 indicates a harmonious family relationship.

PPD diagnosis: At each pregnant woman's follow-up visit at our obstetric clinic on the 42nd day postpartum, we evaluated whether she had PPD symptoms using the EPDS. The scale consists of 10 items, and the total score is 30 points. When the EPDS score of an older mother is ≥ 9 points, it indicates the presence of PPD symptoms[8].

Statistical procedure

Using SPSS 25.0 software for data analysis, the counting data are expressed in terms of the rate and composition ratio [*n* (%)]. The two groups were compared and subjected to the χ^2 test. The influencing factors of PPD in older pregnant women were analyzed through multiple logistic regression analysis, and predictive model equations were built based on the influencing factors.

The area under the receiver operating characteristic (ROC) area under curve (AUC) was used to evaluate the predictive efficiency of the model, and the Hosmer-Lemeshow goodness-of-fit test was used to evaluate whether the prediction model showed an overfitting phenomenon. $P < 0.05$ indicated that the difference was statistically significant.

RESULTS

The incidence and univariate analysis of PPD in older pregnant women

On the 42nd d after delivery, 239 older pregnant women who attended their outpatient follow-up were included, and 51 were found to have depressive symptoms (PPD group) after evaluation with the EPDS. The incidence rate was 21.34% (51/239); 188 women (no-PPD group) had no depressive symptoms. The comparison between the PPD group and the no-PPD group showed statistically significant differences in terms of education level ($\chi^2 = 8.290$, $P = 0.004$), family relationships ($\chi^2 = 10.672$, $P = 0.001$), pregnancy complications ($\chi^2 = 5.520$, $P = 0.019$), and mother–infant separation after birth ($\chi^2 = 9.681$, $P = 0.002$) (Table 1).

Multivariate logistic regression analysis of PPD in older pregnant women

The dependent variable was whether the older pregnant women had symptoms of PPD at 42 d postpartum (0 = no; 1 = yes). Features with statistical significance in univariate analysis (education level, family relationships, pregnancy complications, and the separation of the mother and infant after birth) were included as independent variables, and the assigned values are shown in Table 2. After multiple factor logistic regression analysis, it was found that a high school education and below, poor family relationships, pregnancy complications, and the separation of the mother and baby after birth were the influencing factors for PPD in older pregnant women ($P < 0.05$) (Table 3).

Construction of a risk prediction model for PPD in older pregnant women

The prediction model was constructed based on the regression coefficients and constant terms shown in Table 2 to obtain the following equation: Logit (P) = 0.729 × education level (0 = college or higher; 1 = high school and below) + 0.942 × family relationships (0 = harmony; 1 = disharmony) + 1.137 × pregnancy complications (0 = no; 1 = yes) + 1.285 × separation of the mother and infant after birth (0 = no; 1 = yes) -6.671. Using the predicted probability value of the model as the test variable, the state variable was the presence or absence of PPD in the older mothers. ROC curves were drawn to analyze and predict the performance of the model. The AUC area under the ROC curve of the prediction model was 0.873 (95%CI: 0.821-0.924), the sensitivity was 0.871, and the specificity was 0.815, which indicates that the model has good differentiation ability (Figure 1). The deviation between the predicted value of the model and the actual value through the Hosmer-Lemeshow goodness-of-fit test was not statistically significant ($\chi^2 = 2.749$, $P = 0.638$), indicating that the model showed no overfitting phenomenon.

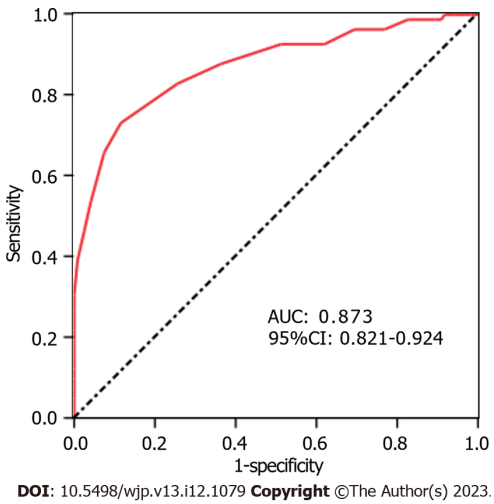
Variable	Description of valuation
Education level	0 = college or higher; 1 = high school and below
Family relationships	0 = harmonious; 1 = disharmony
Pregnancy complications	0= no; 1= yes
Separation of the mother and infant after birth	0= no; 1= yes



DISCUSSION

China's fertility policy is open, which has resulted in a significant increase in the number of older pregnant women[9]. The incidence of PPD among older pregnant women is relatively high. Some influencing factors for the occurrence of PPD in older pregnant women were identified, and a model was constructed to predict the PPD risk of older pregnant women early, help to take early preventive measures, and reduce the incidence of PPD in older pregnant women.

Table 3 Multivariate logistic regression analysis results of postpartum depression in older pregnant women

Variable	β	SE	Wald χ^2	*P* value	OR (95%CI)
High school and below	0.729	0.279	6.827	0.009	2.073 (1.199-3.582)
Incompatible family relationships	0.942	0.349	7.285	0.007	2.565 (1.294-5.083)

Figure 1 Receiver operating characteristic curve evaluation of the postpartum depression risk prediction model for older pregnant women. AUC: Area under curve.

An analysis of the Chinese PPD population showed that the incidence of PPD was highest within 6 wk after delivery (the postpartum period)[10]. This study found that the incidence of PPD in older pregnant women at 42 d postpartum was 21.34%, which is within the scope of literature reports[11,12]. PPD symptoms in older pregnant women may be caused by various factors. This study further found that a high school education and below, poor family relationships, pregnancy complications, and the separation of the mother and baby after birth were all factors affecting PPD in older pregnant women. Some possible reasons are as follows: (1) Studies have shown that pregnant women with low education levels are prone to fear of childbirth[13]. When a mother has the psychological characteristics of fea, poor cognitive integration, a lack of proactive ways to seek help, and is extremely prone to negative emotions, if she cannot find a positive way to alleviate her fear, she may have a low self-evaluation of postpartum care for her newborn, have an increased psychological burden, and develop PPD. Additionally, a low education level and a poor living environment and family economic situation may also affect PPD risk to some extent[14]. The pressure of raising young children is high [15], quality of life is affected[16], and it is easy to generate negative emotions, which triggers PPD symptoms; (2) family relationships play an important role in the family[17]. A woman usually needs care and attention from her mother-in-law after childbirth[18]; differences in cognition between the two generations may result in differences of opinion regarding the care of the newborn and even conflicts. This invisibly causes psychological pressure and burdens for the new mother [19]. As a result, the family environment is not harmonious, which often increases the mental burden on mothers[20]. Severe cases may result in the mother not receiving sufficient family support, thus increasing her risk of PPD occurrence; (3) older pregnant women tend to have diabetes and hypertension during pregnancy[21]. Research shows that, women diagnosed with pregnancy induced hypertension were more likely to have depressive symptoms than their normotensive counterparts[22]. These pregnancy complications not only increase the risk of PPD[23] but also increase the risk of complications such as postpartum infections and bleeding[24]. Studies have shown that puerperal infection events are significantly correlated with PPD[25]. Which increases the risk of PPD and affects the physical recovery of the mother. Therefore, pregnancy complications are an important factor in increasing PPD; and (4) the health status of newborns is a key concern for mothers and their families. Previous studies have shown that infant health is a contributing factor to PPD in postpartum women[26]. This may be due to the combination of other diseases at birth and the need for a newborn to be transferred to a neonatal department for relevant monitoring and treatment[27], increase maternal concerns about the health status of their children, causing psychological storage of certain negative information, aggravate psychological stress, making it easy for mothers to be emotionally affected by these negative information, increase the risk of

postpartum PPD. At the same time, when the newborn is complicated with diseases, the family has to bear a large amount of medical expenses and increase the family burden[28], which significantly increases the probability of PPD in the maternal.

The development of a good prediction model lies in screening effective indicators. This study analyzed the influencing factors of PPD in older pregnant women through multiple logistic regression analysis and built a prediction model based on influencing factors. After analysis, it was found that the area under the ROC curve of the prediction model was 0.873, which indicated that the model has high predictive performance. Some reasons for this are as follows: The model was tested with independent samples in this article, irrelevant indicators were filtered out, related indicators were included, information complementarity was realized, and the predictive performance of the model was enhanced. The difference between the value predicted by the model and the actual value through the goodness-of-fit test was not statistically significant, indicating that there was no overfitting in the model, which is suitable for clinical promotion and application. Therefore, building a model based on the various influencing factors of PPD in older pregnant women can effectively predict PPD risk, providing a new approach for medical personnel to assess high-risk populations early to develop personalized management measures. For example, strengthening psychological counseling and health education for high-risk populations, advising family members to provide material and spiritual support to new mothers, helping mothers relieve stress, guiding mothers and their families in the care of newborns, enhancing maternal feeding confidence, and reducing the incidence of depressive symptoms are some possible management measures.

However, our study still has some limitations: (1) This was a single-center study with a single source of patients, and the representativeness is relatively limited; and (2) the sample size was small, which may lead to biased results. More participants need to be included to validate the conclusion.

CONCLUSION

The risk of PPD among older pregnant women is closely related to their educational level, family relationships, pregnancy complications, and the admission of newborns to the neonatal department after birth. A PPD risk prediction model for older postpartum women with good discrimination should be constructed.

ARTICLE HIGHLIGHTS

Research background

Postpartum depression (PPD) is a mental illness that can be caused by multiple factors, including the process of physical recovery in the postpartum period, newborn health, psychological stress, *etc*. The physiological functions of older pregnant women are far inferior to those of younger women. The process of physical recovery in the postpartum period is slow, and the decrease in a mother's own physiological stress ability makes them more prone to mental and psychological disorders.

Research motivation

Exploring the influencing factors of PPD in older pregnant women and constructing predictive models will provide guidance for the clinical evaluation of PPD risk in older pregnant women and the development of relevant measures.

Research objectives

This study aimed to identify the influencing factors of PPD in older pregnant women and construct a prediction model based on the influencing factors of PPD in older pregnant women.

Research methods

This study used a cross-sectional survey to investigate the PPD status of older pregnant women in our hospital and collected their data for analysis.

Research results

The incidence of PPD in older pregnant women at 42 d postpartum was 21.34%. Among these older pregnant women, a high school education and below, poor family relationships, pregnancy complications, and the separation of the mother and baby after birth were all influencing factors for PPD. A prediction model built based on these factors had high prediction efficiency.

Research conclusions

The risk of PPD among older pregnant women is closely related to their educational level, family relationships, pregnancy complications, and the admission of newborns to the neonatal department after birth. Constructing a PPD risk prediction model for older postpartum women based on the above factors can enable medical staff to perform early assessment of PPD risk for older pregnant women.

Research perspectives

The influencing factors of PPD in older pregnant women were identified, and a predictive model was constructed based on these influencing factors to determine the risk of PPD in older pregnant women in the future.

Abstract

BACKGROUND

Most of the recent research on nightmare distress and depressive symptoms has focused on adolescents and students, with less research on the nurse population. Emergency department nurses are at high risk for nightmare distress and depressive symptoms, but no studies have been conducted to explore the relationship between the two; thus, further investigation is needed.

AIM

To understand the relationship between nightmare distress and depressive symptoms among emergency department nurses in China.

METHODS

A convenience sampling method was used to select 280 emergency department nurses from nine provinces, including Jiangxi, Sichuan, Jiangsu, and Shanxi Provinces. The Chinese version of the Nightmare Distress Questionnaire and the Center for Epidemiological Studies Depression Scale (CES-D) were administered.

RESULTS

Emergency department nurses' nightmare distress scores were positively associated with depressive symptom scores (r = 0.732), depressed affect (r = 0.727), somatic symptoms (r = 0.737), and interpersonal difficulty (r = 0.647). Further multiple linear regression analyses showed that education level, work pressure, self-reported health, and CES-D scores were factors that influenced nightmare distress among Chinese emergency department nurses ($P < 0.05$).

CONCLUSION
Nightmare distress is closely associated with depressive symptoms in Chinese emergency department nurses, and early intervention is recommended for professionals with this type of sleep disorder to reduce the occurrence of depressive symptoms.

Key Words: Nightmare distress; Emergency department nurses; Depressive symptoms; Workplace violence; Observational study; China

Core Tip: Understanding the relationship between nightmare distress and depressive symptoms in emergency department nurses and adopting effective interventions could reduce their incidence in this population. Currently, most studies on nightmare distress and depressive symptoms have focused on adolescents or students, and fewer have examined emergency department nurses. This study is the first to examine the relationship between nightmare distress and depressive symptoms among emergency department nurses, providing a theoretical basis for developing effective interventions.

INTRODUCTION

The International Classification of Diseases, 10th Revision[1] defines a nightmare as an extremely disturbing and memorable dream, that is, recurring dreams that involve danger to the health, survival, and dignity of the individual while he or she sleeps. Nightmares are a fearful and distressing experience; when individuals wake after a nightmare, the content of the dream is clearly recalled, and they have difficulty falling asleep[2]. Studies have shown that nightmares not only affect an individual's sleep quality, including insomnia and difficulty falling asleep[3], but are also a major risk factor for suicide, depression, and posttraumatic stress disorder[3-5]. A large sample survey showed that people with nightmare distress are more likely to have depressive symptoms than healthy groups[6]. Most of the recent studies on nightmare distress and depressive symptoms have focused on adolescents and students[2,3,6], but fewer studies have been conducted on the nurse population. Nurses are a high-risk group for nightmare distress[7], especially emergency department nurses, possibly because they often witness patient deaths and severe trauma[8]. Furthermore, due to the special nature of the work environment, these professionals are often subjected to threats, verbal violence, and even physical violence from patients and families[9,10]. Therefore, the aim of this study was to explore the relationship between nightmare distress and depressive symptoms among Chinese emergency department nurses through a cross-sectional survey and to inform interventions to improve the working environment of emergency department nurses globally and reduce the occurrence of nightmare distress and depressive symptoms in this population.

MATERIALS AND METHODS

Participants and research design

This study had a multicenter cross-sectional design. In March to April 2023, a convenience sampling method was used to select emergency nurses from tertiary hospitals in nine Chinese provinces (Jiangxi, Sichuan, Jiangsu, Shanxi, Guangdong, Hebei, Zhejiang, Hainan, and Shaanxi). The inclusion criteria were as follows: (1) Employment as an emergency department nurse; and (2) Voluntary participation in this study. The exclusion criteria for nurses were as follows: (1) On leave during the survey period; (2) Trainees; or (3) Receiving further training from the hospital. The rejection criteria were as follows: (1) Completed the questionnaire incompletely; or (2) Had answers to the questionnaire that were obviously repeated. The study was approved by the Ethics Committee of the First Affiliated Hospital of Nanchang University (ethics number: IIT2023196).

Sample

This study collected sociodemographic data and work-related data, and a total of 19 independent variables were included. According to the calculation formula[11], the necessary sample size was 5-10 times that of the number of independent variables; considering the possibility of 20% invalid samples, a minimum of 114 participants were needed. A total of 300 questionnaires were distributed in this study; of these, 280 were finally included in the analysis after excluding invalid responses. The questionnaire return efficiency was 93.33%.

Measures

General information: Custom-designed questionnaires were based on published studies in the field[12,13] and expert opinions. The questionnaires covered mainly sociodemographic characteristics (such as sex, age, and marital status) and work-related factors (title, years of work, number of night shifts per month, work pressure, and frequency of violence in the workplace).

Nightmare distress: Nightmare distress was measured using the Chinese version of the Nightmare Distress Questionnaire (NDQ-CV)[14], which is an adaptation of the Nightmare Distress Questionnaire (NDQ)[15]. The NDQ-CV includes a total of 14 items in two dimensions: General nightmare distress and daytime reality perception. Each item is rated on a 5-point scale from 1 (never) to 5 (always), and the total score of the scale ranges from 14 to 70, with higher scores associated with higher levels of nightmare distress. The Cronbach's a coefficient for the total scale in this study was 0.942, and the Kaiser-Meyer-Olkin value was 0.951 ($P < 0.05$), indicating good reliability.

Depressive symptoms: Depressive symptoms were measured using the Center for Epidemiological Studies Depression Scale (CES-D). The CES-D was developed by Radloff[16] and translated into Chinese by Zhang *et al*[17]. The scale includes four dimensions: Depressed affect, positive affect, somatic symptoms, and interpersonal difficulty. It has 20 items, four of which are reverse scored. Each item is rated on a scale from 0 to 3, for a total score ranging from 0 to 60. The higher the score, the more severe the depressive symptoms. A score ≥ 20 indicates significant depressive symptoms. In this study, the Cronbach's a coefficient of the total scale was 0.866, and the KMO value was 0.956 ($P < 0.05$), indicating good reliability.

Quality control

In this study, 20 emergency department nurses were randomly selected for a pilot survey in a tertiary hospital in Jiangxi Province, and the self-report questionnaire section was modified according to the problems that emerged from the pilot survey. Before the questionnaires in the formal experiment were completed, the purpose and importance of this study and the precautions for completing the questionnaires were explained by professionals, and the questionnaires were distributed after obtaining the informed consent of the study subjects. After the questionnaires were collected, the researcher reviewed the content of the completed questionnaires, and two researchers entered the data using Excel software to ensure the accuracy of the data.

Data analysis

The data were analyzed using SPSS 25.0 statistical software. Continuous data that conformed to a normal distribution are expressed as the mean ± SD, and categorical data are expressed as frequencies and percentages. Independent sample *t* tests were used to detect differences between two groups, and one-way ANOVA was used to compare multiple groups. Pearson correlation analysis was used to explore the relationship between nightmare distress and depressive symptoms; linear regression analysis was used to explore the factors influencing the emergence of nightmare distress among nurses in the emergency department. A threshold of $\alpha = 0.05$ (two-sided) was used to indicate significant differences.

RESULTS

Descriptive statistics and correlations

A total of 280 emergency department nurses (54 men and 226 women) were included in the study. Among these nurses, most were 26-35 years old (44.3%), had a bachelor's degree (76.1%), had more than 10 years of experience (39.6%), and were married (63.2%). Additionally, most of the nurses were the nurse-in-charge (37.9%), had a monthly income of 5000 to 10000 yuan (62.5%), worked 6 to 10 shifts per month (46.4%), had high pressure (44.6%), and frequently suffered from workplace violence (46.1%). Among those included, 47.5% rated their health as average, 62.5% did not regularly exercise, and the majority were from the emergency departments of Jiangxi Province (31.1%). Further details are shown in Table 1. Using nightmare distress scores as the dependent variable and sociodemographic characteristics as independent variables, comparisons were conducted. The influence of dichotomous variables (*e.g.*, sex) was tested using independent sample *t* tests, and that of variables with multiple categories (*e.g.*, education level) were examined by one-way ANOVA to compare nightmare distress scores among emergency department nurses with different characteristics. The results of the univariate analysis showed that nightmare distress scores of emergency department nurses significantly differed according to sex, education level, working years, monthly income, work pressure, self-reported health, and province ($P < 0.05$; Table 1).

Correlation of nightmare distress with depressive symptoms

Pearson correlation analysis showed that nightmare distress total score and subscale scores were positively correlated with depressive symptom total score, depressed affect, somatic symptoms, and interpersonal difficulties and negatively correlated with positive affect ($P < 0.01$), as shown in Table 2.

Multivariate regression of nightmare distress

Multiple linear regression analysis with the NDQ-CV total score as the dependent variable and sex, education level, years of work, monthly income, work pressure, self-reported health, province, and CES-D total score as the independent variables (assignments are shown in Table 3) showed that education level, work pressure, self-reported health, and CES-

Table 3 Independent variables in multivariate regression analysis

Independent variable	Code
Gender	Male = 1, female = 2
Education level	Associate degree = 1, bachelor's degree = 2, graduate degree or above = 3
Years of work	< 1 year = 1, 1-5 years = 2, 6-10 years = 3, > 10 years = 4
Monthly income	< 5000 = 1, 5000-10000 = 2, > 10000 = 3
Work pressure	None = 1, mild = 2, moderate = 3, severe = 4
Self-reported health	Poor = 1, average = 2, good = 3
Province	Jiangxi = 1, Sichuan = 2, Jiangsu = 3, Shanxi = 4, Guangdong = 5, Shaanxi = 6, Hainan = 7, Zhejiang = 8, Hebei = 9

D scores were the factors influencing nightmare distress among emergency department nurses ($P < 0.05$; Table 4).

DISCUSSION

The results of this study showed a positive correlation between nightmare distress scores and depressive symptom scores, indicating that higher levels of nightmare distress among emergency department nurses are associated with more severe depressive symptoms, which is consistent with the results of previous studies[2,3,18]. Studies have shown that the amygdala, medial prefrontal cortex, hippocampus, and anterior cingulate cortex differ between patients with nightmare

distress and healthy individuals[18,19]. Among these areas, the amygdala is the main area involved in negative emotions such as fear and depression and is the central part responsible for emotions; the anterior cingulate cortex plays a major role in regulating emotions and selective attention; and the hippocampus is the main area supporting memory. The anterior cingulate cortex, prefrontal cortex, and amygdala exhibit high activity in patients with nightmare distress, while the hippocampus is biased toward remembering negative emotions, increasing the risk of depressive symptoms[19]. Chen and Li[20] showed that the hypothalamic-pituitary-adrenocortical axis exhibits abnormal activation in patients with nightmare distress, with altered levels of cortisol and melatonin. Changes in the circadian rhythm of melatonin secretion are closely associated with a variety of alterations in individuals; disruption of melatonin homeostasis (lower melatonin levels) is a pathological basis for the induced symptoms of depression in patients. Mahar *et al*[21] showed that chronic stress leads to attenuation of cell proliferation and neurogenesis, phosphorylation of extracellular signal-regulated kinase, substantial attenuation of 5-hydroxytryptamine (5-HT) levels and 5-HT auto-receptor sensitivity, and reduction of hippocampal inhibition of the hypothalamus-pituitary-adrenal axis, which induces depressive symptoms in nightmare-plagued patients. In addition, sleep disorders caused by nightmare disturbances lead to an abnormal increase in inflammatory factors and impairment of autophagy. Li *et al*[22] showed that the levels of inflammatory factors such as NLRP1, tumor necrosis factor-α, and interleukin-1β in the hippocampus of sleep-disturbed mice were markedly increased, and the levels of the autophagy proteins Atg5 and Atg7 were significantly reduced, thus inducing neuroinflammation and consequently depressive symptoms. Levin and Nielsen[23] showed that patients with nightmare distress are more likely to have neurotic, stress-related symptoms and that patients with high levels of nightmare distress have stronger memories of their nightmares because they recollect the dream content during waking hours as a coping mechanism, thus increasing their risk of developing depressive symptoms[18].

In the present study, multiple regression analysis showed that education level, work pressure, self-reported health, and depressive symptoms are independent factors that influence nightmare distress among emergency department nurses. The higher the education level and work pressure, the higher the nightmare distress score of emergency department nurses, possibly because a higher education level is associated with higher self-esteem and higher levels of perceived stress, which in turn increase the risk of nightmare distress[2,24]. Emergency department nurses with poorer self-reported health have lower immunity, and sleep quality decreases when they are overworked, resulting in shorter bouts of deep sleep and increased time in light sleep stages, which are more susceptible to external stimuli, leading to insomnia and nightmare distress[25]. Studies have shown that patients with depressive symptoms have altered sleep structure and significantly impaired sleep quality[25]; impaired sleep is an important factor contributing to nightmare distress. In addition, patients with depressive symptoms exhibit long-term states of sadness and uneasiness, which affects the normal regulatory function of the cerebral cortex, thus increasing the risk of nightmare distress[3]. Therefore, it is recommended that hospital administrators should optimize the management of the emergency department, conduct regular psychological symposiums to alleviate the workplace pressure of emergency department nurses, and provide emergency department nurses with spiritual and material support to bolster their sense of professional identity. Emergency department nurses themselves should increase their exercise levels and improve physical health; those with more severe nightmare distress and depressive symptoms should seek psychotherapy treatment, such as cognitive-behavioral therapy [26], imagery rescripting, and imaginal exposure[27], to improve their mental health and psychological resilience, alleviate nightmare distress and depressive symptoms, and improve their quality of life.

Strengths and limitations

This study has several strengths. First, the sample consisted of emergency department nurses from multiple provinces, and the findings have strong generalizability. Second, this is the first study to explore the relationship between nightmare distress and depressive symptoms among Chinese emergency department nurses; our findings can inform intervention guidelines for reducing nightmare distress and depressive symptoms among emergency department nurses and even other nurses worldwide. Finally, this study adopted an anonymous survey method, which was conducive to obtaining real information about the participants and improved the reliability of its results.

Likewise, this study has some limitations. First, this was a cross-sectional study that only explored the correlation between nightmare distress and depressive symptoms among emergency department nurses; future longitudinal studies are needed to elucidate the causal relationship between the two variables. Second, the assessment instruments used were all self-report questionnaires. Self-report data are highly subjective and may contain information bias, and future studies are needed to verify the relationship between nightmare distress and depressive symptoms among emergency department nurses in conjunction with more specialized diagnostic methods. Finally, emergency department nurses were

selected from only one hospital in some provinces included this study, which may lead to selection bias, and larger sample sizes should be used in future research.

CONCLUSION

This study analyzed the relationship between nightmare distress and depressive symptoms among Chinese emergency department nurses and concluded that nightmare distress and depressive symptoms were positively correlated among these professionals. The results of the current analysis showed that emergency department nurses' nightmare distress was influenced by a variety of factors. In the future, researchers should conduct randomized controlled studies of the relationship between nightmare distress and depressive symptoms among emergency department nurses and explore related interventions to reduce the severity of nightmare distress and depressive symptoms among emergency department nurses.

ARTICLE HIGHLIGHTS

Research background

Emergency department nurses are at high risk for nightmare distress and depressive symptoms. Understanding the relationship between nightmare distress and depressive symptoms and adopting appropriate interventions can alleviate nightmare distress and depressive symptoms among emergency department nurses. Therefore, this study was conducted to explore the correlation between nightmare distress and depressive symptoms among emergency department nurses through a cross-sectional survey.

Research motivation

Mental health issues are increasingly pronounced among emergency department nurses. This study aimed to elucidate the relationship between nightmare distress and depressive symptoms among emergency department nurses and to suggest effective interventions to improve their mental health.

Research objectives

This study investigated emergency department nurses in several provinces in China to explore the relationship between nightmare distress and depressive symptoms in this population.

Research methods

In this study, 280 emergency department nurses in nine provinces were selected using a convenience sampling method. They completed the Chinese version of the Nightmare Distress Questionnaire and the Center for Epidemiological Studies Depression Scale. SPSS 25.0 statistical software was used to analyze the collected data.

Research results

The results of this study showed that more severe nightmare distress among emergency department nurses was associated with more pronounced depressive symptoms and that the severity of nightmare distress in this population was influenced by factors such as education level, work stress, and self-reported health.

Research conclusions

The severity of nightmare distress in emergency department nurses is positively correlated with depressive symptoms. Nightmare distress can cause serious psychological problems, and early interventions for this population can alleviate depressive symptoms. This study provides a theoretical basis for developing effective interventions.

Research perspectives

This study investigated emergency department nurses in only China; future studies could include those in multiple countries to achieve a comprehensive understanding of the relationship between nightmare distress and depressive symptoms among emergency department nurses and to promote mental health in this profession.

ACKNOWLEDGEMENTS

All authors of this study express sincere gratitude to all editors and reviewers who have worked hard to improve the quality of the manuscript.

Abstract

BACKGROUND

Stroke patients often experience psychological distress, which can impact their intimate relationships with spouses, subsequently influencing their treatment and recovery. Physical activity is considered a key rehabilitation method for stroke patients. This paper aims to analyze whether psychological distress affects intimate relationship between spouses through physical activity.

AIM

To explore the mediating effect of physical activity between psychological distress and intimate relationship in stroke patients.

METHODS

A total of 256 stroke patients who underwent treatment at the First People's Hospital of Shangqiu between July 2021 and July 2022 were enrolled in this study. The participants completed questionnaires, including the Kessler Psychological Distress Scale (K10), the Quality of Relationship Index (QRI), International Physical Activity Questionnaire, and a general information questionnaire. Data analysis were performed using SPSS 23.0. The Harman test was employed to detect common method deviations, and Spearman correlation was used for correlation analysis. The mediating effect was assessed using Process 3.4.1, with significance testing of the regression coefficients conducted using the bias-corrected percentile Bootstrap method (5000 iterations, 95% confidence interval). Statistical significance was set at $P < 0.05$.

RESULTS

The results showed that patients scored an average of 21.61 ± 6.44 points on the K10, 32.40 ± 6.19 points on the QRI; the median physical activity level according to the International Physical Activity Questionnaire was 1861 (566, 2846)

MET·min/w. The level of physical activity (the physical activity intensity of the patients reflected by the International Physical Activity Questionnaire-Long Form scale) negatively correlated with psychological distress and intimacy ($P < 0.05$), and positively correlated with each other ($P < 0.05$), with the correlation stronger at lower physical activity levels compared to higher ones. The mediating effect of physical activity between psychological distress and intimate relationship was calculated to be 40.23%. Bootstrap analysis further validated the results. The mediating effect of psychological distress on intimate relationships through physical activity level was -0.284, with a confidence interval of -0.409 to -0.163, excluding 0, confirming a significant mediating effect of psychological distress on intimate relationships.

CONCLUSION

Physical activity significantly affects relationship between psychological distress and intimate relationships among stroke patients. Addressing the role of physical activity may have implications for improving patient outcomes and rehabilitation strategies.

Key Words: Stroke; Cross-sectional study; Psychological distress; Intimate relationship; Mediating effect; Physical activity level

Core Tip: Psychological distress is prevalent among stroke patients and can significantly impact their intimate relationships with spouses. Physical activity plays a crucial role in stroke prevention and rehabilitation. This study successfully identified a mediating effect of physical activity on psychological distress and intimate relationships, among stroke patients, confirmed through the Bootstrap test. These findings provide a robust foundation for promoting stroke patient rehabilitation and addressing relationship challenges between spouses.

INTRODUCTION

Stroke is not simply a singular disease; rather, it encompasses a group of conditions resulting from impaired brain function caused by cerebrovascular disease[1]. With its high incidence, disability, mortality and recurrence rate, stroke has become a global health concern, leading to numerous disabilities and deaths in China[2]. During the post-stroke treatment and rehabilitation process, patients often face stigma and significant psychological distress due to disabilities and disruptions in their self-image[3]. Intimate relationships, characterized by communication that fosters intimacy and cooperation within an interdependent framework, play a crucial role in the lives of stroke patients and their spouses[4]. Spouses of stroke patients endure long-term care and economic burdens and experience multiple psychological pressures from family and society, which can negatively impact their relationship and mutual happiness[5]. Research indicates that regular physical activity is a vital preventive measure against stroke, attributed to its potential to improve vascular function and reduce stroke-related risk factors[6]. Therefore, physical activity can potentially aid patient rehabilitation, delay deterioration of their condition, alleviate psychological distress, and mitigate the adverse effects of negative emotions on the relationship between stroke patients and their spouses. However, there is a lack of research on the interplay among physical activity level, psychological distress, and intimacy in the context of stroke patients, both domestically and globally. Therefore, this study aimed to investigate whether the level of physical activity acts as a mediating factor between psychological distress and intimacy in stroke patients. By exploring this relationship, the study seeks to provide novel insights into alleviating the strains within the spousal relationships among stroke patients.

MATERIALS AND METHODS

Patient characteristics

This cross-sectional survey involved 256 patients who received stroke-related treatment at the First People's Hospital of Shangqiu between July 2021 and July 2022. Inclusion criteria were as follows: (1) Patients meeting the diagnostic criteria of stroke and diagnosed with stroke through head computed tomography or magnetic resonance imaging; (2) Age under 80 years; (3) Married and cohabitating with a spouse; and (4) Stable condition, clear consciousness, and no obvious language comprehension and expression disorders. Exclusion criteria included: Severe heart, liver or kidney dysfunction, respiratory failure and malignant tumors. The study received ethical approval from the First People's Hospital of

Shangqiu (2021-125-29), and all participants provided informed consent voluntarily.

Research tools

Figure 1 illustrates the study process. The following research tools were utilized: (1) General information questionnaire: A self-designed questionnaire capturing demographic data (*e.g.*, age, gender) and disease-related information (*e.g.*, stroke attack, stroke course); (2) The Kessler Psychological Distress Scale (K10)[7]: Used to assess the mental health status of individuals, comprising ten items scored on a five-level scale (score range: 10-50). Higher scores indicate poorer mental health status (Cronbach's α = 0.896); (3) The Quality of Relationship Index (QRI)[8]: Evaluates satisfaction with intimate relationships using six items rated on a 7-level scale (score range: 6-42). Higher scores indicate higher satisfaction with intimate relationships (Cronbach's α = 0.943); and (4) International Physical Activity Questionnaire-Long Form (IPAQL)[9]: Measures patients' health-related physical activity over the past week and calculates metabolic equivalents. The questionnaire covers physical activities (work-related, transportation, daily life, sports, and leisure), sedentary behavior, and sleep. Among them, four types of physical activities were evaluated for walking, moderate and severe physical activities, with a total of 27 items. The total metabolic equivalent was used to evaluate the overall physical activity level. Higher scores indicate better physical activity levels (Cronbach α = 0.827). For analysis, the total metabolic equivalent scores were sorted from small to large, and the first 50% and the last 50% were divided into two groups: Lower activity group and higher activity group.

Quality control

A sample size of 256 patients was deemed sufficient, meeting the requirement of seven times the number of research variables (based on the largest number of items in the International Physical Activity Questionnaire, 27 items) with a consideration of a 20% missing rate. The investigators, designated by the hospital, distributed and collected the questionnaires on-site with unified guidance. If respondents were unable to complete the questionnaire themselves, investigators assisted them in filling it out based on the their inputs. Missing items were addressed promptly to ensure complete and accurate information was obtained. Double entry and verification of data were conducted to ensure the validity, accuracy and integrity of data entry.

Statistical analysis

Data processing was performed using SPSS 23.0 (IBM Corp., Armonk, N.Y., United States). Normally distributed measurement data are presented as mean ± SD, while skewed distribution data are expressed as median (M) and quartile (P_{25}, P_{75}). Count data are expressed as cases (%). The Harman single factor test was used to test for common method bias. Spearman correlation analysis was used for correlation analysis. The mediating effect was tested by Process 3.4.1 (Designed by Andrew F. Hayes based on SPSS), and the significance of regression coefficients was assessed using the bias-corrected percentile Bootstrap method (5000 iterations, 95% confidence interval). Statistical significance was set at $P < 0.05$.

RESULTS

Clinical characteristics

A total of 260 questionnaires were distributed, and 256 valid questionnaires were collected, yielding an effective response rate of 98.46%. Among the participants, 195 were male (76.17%) and 61 were female (23.83%). The age distribution was as follows: 28 patients (10.94%) were younger than 45 years, 132 patients (51.56%) were between 45 and 60 years, and 96 patients (37.50%) were older than 60 years. The proportion of patients with junior high school education was the largest (40.23%), and the college or higher had the lowest proportion (14.84%). More than ninety percent of the patients had a year of marriage of more than 20 years (92.19%), and only 7.81% (20/256) of the patients had less than 20 years. There are 71.88% (184/256) of the patients were a first-ever stroke. The type of stroke in 3.52% (9/256) of patients were hemorrhagic, 94.14% (241/256) were ischemic, and 2.34% (6/256) were hybrid. About 7 percent of the patients had self-care ability and did not need to rely on others for activities, 65.24 % of the patients had mild dependence, and 27.73 % of the patients had moderate and heavy dependence (Table 1).

Common method bias

To address potential common method bias, quality control measures were implemented during the investigation. Factor analysis of the questionnaires was conducted, and the Harman test showed that the eigenvalue of two factors exceeded 1, accounting for a maximum of 34.59% (< 40%), indicating no significant common method deviation.

Comparison of K10 and QRI scores

The study found that the average K10 score of the 256 patients was 21.61 ± 6.44 points, while the average QRI score was 32.40 ± 6.19 points. Significant differences in K10 and QRI scores were observed among patients with different physical activity levels ($P < 0.05$) (Figure 2).

Correlation analysis

Correlation analysis was performed among psychological distress (K10), intimate relationship (QRI), and metabolic equivalent (IPAQL) in patients with different physical activity levels. In the lower activity group, psychological distress

exhibited negative correlations with intimacy and metabolic equivalent (r = -0.523, P < 0.001; r = -0.528, P < 0.001), while intimate relationship positively correlated with metabolic equivalent (r = 0.631, P < 0.001). In the higher activity group, psychological distress showed negative correlations with intimate relationship and metabolic equivalent (r = -0.481, P < 0.001; r = -0.265, P < 0.001), and a positive correlation between intimate relationship and metabolic equivalent (r = 0.476, P < 0.001) was observed (Figure 3).

Mesomeric effect

The mediating effect analysis revealed that psychological distress significantly influenced intimate relationships in the first step (b = -0.734, P < 0.001), indicating a total effect. In the second step, psychological distress had a significant effect on physical activity level (b = -0.650, P < 0.001). In the third step, both psychological distress and physical activity level significantly affected intimate relationships (b = -0.439, P < 0.001; b = 0.454, P < 0.001), establishing a partially mediated model through activity level (Table 2).

The results were further validated through Bootstrap analysis. It was found that: (1) The total effect of psychological distress on intimate relationships was -0.706, with a confidence interval of -0.786 to -0.625, indicating a significant total effect; (2) The direct effect of psychological distress on intimate relationships was -0.422, with a confidence interval of -0.514 to -0.330 also signifying a significant direct effect; and (3) The mediating effect of psychological distress on intimate relationships through physical activity level was -0.284, with a confidence interval of -0.409 to -0.163, excluding 0, confirming a significant mediating effect of psychological distress on intimate relationships (Table 3).

The level of physical activity was found to act as a mediating factor between psychological distress and intimacy, and the mediating model was established. The psychological distress-physical activity level-intimacy relationship exhibited a partial mediating effect, accounting for 40.23% of the total effect (Figure 4).

DISCUSSION

Stroke patients often experience language impairment and motor dysfunction, leading to reduced self-care ability and social adaptability, which can result in psychological distress for both the patients and their partners[10]. As the main caregivers in the family, partners' attitudes and caregiving abilities directly influence the patient's mood and rehabilitation progress[11]. Importantly, alleviating psychological distress can enhance the relationship between patients and partners, foster open communication, and improve marital happiness and overall quality of life for spouses[12]. Previous studies have identified hypertension, diabetes, dyslipidemia, and obesity as risk factors associated with stroke, and physical activity can have a positive impact on these risk factors[13,14]. Physical activity can positively impact these risk factors by improving vasodilation, reducing diabetes, hypertension, dyslipidemia, obesity, and depression risk, thus

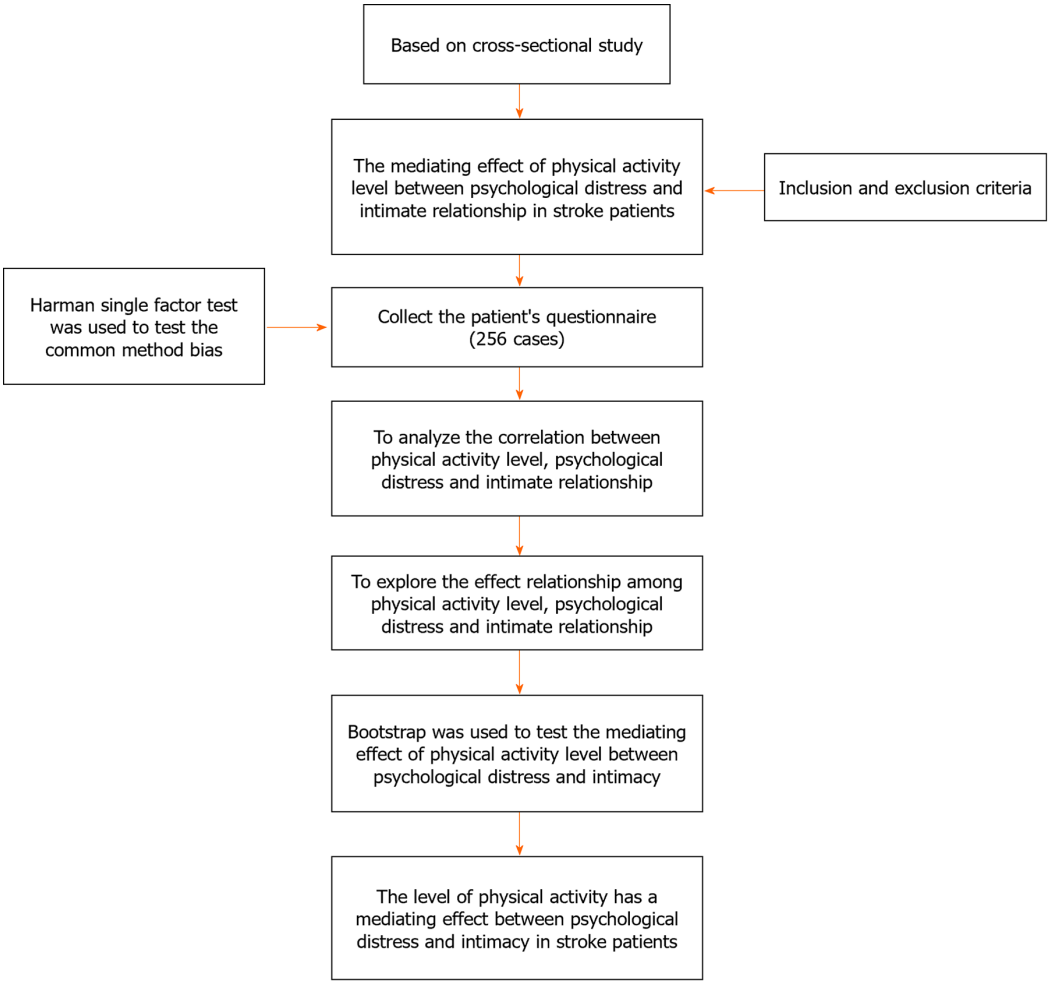

Table 2 Process method to test the mediating effect

Procedure	Dependent variable	Independent variable	R^2	β	*F* value	*t* value	*P* value

Figure 3 Correlation analysis of patients' psychological distress, intimate relationship satisfaction, and physical activity level. A: Lower activity level group, the correlation between psychological distress [the Kessler Psychological Distress Scale (K10)] and intimate relationship satisfaction [the Quality of Relationship Index (QRI)]; B: Lower activity level group, the correlation between psychological distress (K10) and physical activity level [International Physical Activity Questionnaire-Long Form (IPAQL)]; C: Lower activity level group, the correlation between intimate relationship satisfaction (QRI) and physical activity level (IPAQL); D: Higher activity level group, the correlation between psychological distress (K10) and intimate relationship satisfaction (QRI); E: Higher activity level group, the correlation between psychological distress (K10) and physical activity level (IPAQL); F: Higher activity level group, the correlation between intimate relationship satisfaction (QRI) and physical activity level (IPAQL). K10: The Kessler Psychological Distress Scale; QRI: The Quality of Relationship Index; IPAQL: International Physical Activity Questionnaire-Long Form.

promoting stroke recovery and delaying deterioration. Therefore, moderate physical activity can aid stroke patients' recovery, reduce their psychological distress, and help restore and improve the relationship between patients and their partners.

The prevalence of psychological distress among stroke patients in China is high, with post-stroke depression and anxiety reported at 84.51% and 75.63%, respectively[15]. Psychological distress significantly hampers treatment, rehabilitation, long-term function, and quality of life for stroke patients, increasing the risk of stroke recurrence and mortality [16]. Physical activity refers to bodily movements that requires energy expenditure, primarily achieved through skeletal muscle contraction. It encompasses both structured and physical exercises as well as daily activity[17]. After illness,

Figure 4 Patient physical activity mediation model.

patients may have reduced self-care ability and fear of exercise, leading to low physical activity levels. In this study, patients with lower physical activity levels had higher scores for psychological distress (K10) and a lower scores for intimate relationship satisfaction (QRI), consistent with previous research findings[18-20]. Unimproved conditions, poor prognosis, and uncertainty about the illness cause psychological problems that lead to patient self-closure and reluctance to express thoughts and feelings to their partners, affecting the intimate relationship between them. Correlation analysis revealed significant associations among psychological distress (K10), intimate relationship satisfaction (QRI), and physical activity levels (IPAQL) in patients with different physical activity levels. Patients with lower physical activity levels showed stronger correlations, suggesting that lower physical activity levels were associated with more distress and reduced communication with spouses, leading to a greater impact on intimate relationships. Unpleasant emotional experiences can disrupt the maintenance of intimate relationships between spouses.

The mediating effect analysis indicated that physical activity levels significantly mediated the relationship between psychological distress and intimate relationship satisfaction, accounting for 40.23% of the total effect. This suggests that physical activity can alleviate the patients' psychological distress and indirectly influence the intimate relationship with their spouses. Several studies have highlighted the correlation between psychological distress and physical activity level [21]. Prolonged exposure to severe and complex stress, exceeding an individual's coping abilities, can not only affect the patient's emotional responding, but also impact their partner's well-being and marital satisfaction. Increasing physical activity, such as participating in sports, can help reduce the risk of adverse psychological states, anxiety and depression during such challenging times. In fact, stroke patients often use physical activity as part of their rehabilitation treatment. This approach can stimulate nerve and limb function recovery, regulate the sympathetic nervous system to alleviate anxiety and depression levels, enhance physical functionality, decrease disability rates, and improve daily living activities [22]. However, it is important to note that in this study, physical activity level represents only one of the mediating factors between psychological distress and intimate relationship satisfaction. This implies that physical activity plays a partial role in mediating these factors. To effectively address patients' psychological distress, a comprehensive consideration of other contributing factors is necessary. Medical professionals play a crucial role in supporting patients during their treatment journey. Encouraging patients to manage their illness correctly, guiding them and their spouses to adopt positive behaviors, and fostering effective coping strategies are essential steps to alleviate psychological distress. Furthermore, enhancing patient cooperation and strengthening the intimacy between spouses can help mitigate both the psychological and physical burdens faced by the couple.

CONCLUSION

In summary, patients' psychological distress significantly affects their intimate relationship with their spouses, and the level of physical activity serves as a crucial factor between psychological distress and intimate relationship satisfaction. Therefore, it is imperative to focus on improving patients' physical activity levels to reduce psychological distress pressure, enhance communication between spouses, and provide mutual support to foster a stronger sense of intimacy and well-being.

ARTICLE HIGHLIGHTS

Research background

The psychological distress experienced by stroke patients can significantly impact their intimate relationships with their partners.

Research motivation

The strain in spousal relationships can further exacerbate the psychological distress of stroke patients and imped their recovery process.

Research objectives
This study aims to investigate whether the level of physical activity in stroke patients influences their psychological distress and subsequently affects the quality of their intimate relationships with their spouses.

Research methods
Data was collected through questionnaires, and the presence of common method bias was verified using Harman test. The mediating effect analysis was conducted to explore the relationships between psychological distress, intimacy, and physical activity levels. The significance of the regression coefficient was verified using Bootstrap.

Research results
The findings indicate that the physical activity level of stroke patients has an impact on their psychological distress, which, in turn, influences the quality of their intimate relationships with their partners.

Research conclusions
This study has shed light on the interplay between psychological distress, intimate relationships, and physical activity levels among stroke patients, offering new insights to improve the bond between couples in such situations.

Research perspectives
As a single-center study, this research has certain limitations, and other factors may also influence the outcomes. To enhance the generalizability and validity of the findings, further expansion and external validation are warranted.

Abstract

BACKGROUND

The coronavirus disease 2019 (COVID-19) epidemic disrupted education systems by forcing systems to shift to emergency online leaning. Online learning satisfaction affects academic achievement. Many factors affect online learning satisfaction. However there is little study focused on personal characteristics, mental status, and coping style when college students participated in emergency online courses.

AIM

To assess factors related to satisfaction with emergency online learning among college students in Hebei province during the COVID-19 pandemic.

METHODS

We conducted a cross-sectional survey of 1600 college students. The collected information included demographics, psychological aspects of emergent public health events, and coping style. Single factor, correlation, and multiple linear

regression analyses were performed to identify factors that affected online learning satisfaction.

RESULTS

Descriptive findings indicated that 62.9% (994/1580) of students were satisfied with online learning. Factors that had significant positive effects on online learning satisfaction were online learning at scheduled times, strong exercise intensity, good health, regular schedule, focusing on the epidemic less than one hour a day, and maintaining emotional stability. Positive coping styles were protective factors of online learning satisfaction. Risk factors for poor satisfaction were depression, neurasthenia, and negative coping style.

CONCLUSION

College students with different personal characteristics, mental status, and coping style exhibited different degrees of online learning satisfaction. Our findings provide reference for educators, psychologists, and school administrators to conduct health education intervention of college students during emergency online learning.

Key Words: COVID-19; Emergency online leaning; Online learning satisfaction; College students; Mental status; Coping style; Distance education; Psychiatric status

Core Tip: We evaluated satisfaction with online learning and its associated factors, specifically demographic variables, mental status, and coping style of Chinese college students who participated in emergency online courses during the coronavirus disease 2019 pandemic. Little study has been focused on online acceptance of education. Our findings provide reference for educators, psychologists, and school administrators to conduct health education intervention.

INTRODUCTION

The SARS-CoV-2 [hereafter referred to as coronavirus disease 2019 (COVID-19)] pandemic disrupted the educational, economic, and social systems of many countries[1]. To reduce the spread of the virus, countries adopted diverse control strategies such as lockdown and social distancing. COVID-19 hampered education by disrupting student learning goals in many disciplines[2]. The Chinese Ministry of Education suggested "suspending classes without suspending learning". Students across the nation were required to stay at home, and emergency online learning was widely practiced in February 2020[3]. College students urgently turned to distance education to minimize the pandemic's negative impacts on health[4]. Teachers and students were suddenly thrust into an unplanned, unwanted, uncharted, online learning experiment during COVID-19-mandated confinement. This transition increased workload, altered curricula, and eliminated hands-on experiences. In online education, students had to act more autonomously and take more responsibility for their learning[5]. Students from various backgrounds and places were required to adapt to new environmental, technological, and psychological learning conditions that may have affected academics[4,6,7]. The COVID-19 pandemic impacted a cascade of detrimental effects on college student academic performance[8]. Online learning may have been an approach to ensure student knowledge and practice in this special period, although consideration of student satisfaction is mandatory to improve academics[9].

Learning satisfaction reflects how students view their learning experiences, a crucial indicator of online learning effectiveness that is related to academic achievement[10]. The effect of online learning quality on student performance was strongly mediated by satisfaction with online learning, and ensuring student satisfaction can increase the academic success of both the institution and the student[11]. Surveys of online learning satisfaction during the COVID-19 pandemic show conflicting results. Yekefallah *et al*[10] reported that 59% of college students had poor satisfaction with online learning. Arain *et al*[12] found that the level of satisfaction was only 30% among medical students. Wilhelm *et al*[13] found that undergraduate students reported lower levels of learning, engagement, and confidence with the course materials during remote teaching compared with the face-to-face portion of the class. Conversely, Eansor *et al*[14] showed that online learning had high satisfaction levels, and student knowledge scores and self-confidence were raised because of rich online educational resources and the ability to support asynchronous and synchronous communication between students and teachers and between the students themselves[15]. These differing findings make it necessary to clarify satisfaction with online learning and factors that affect satisfaction to provide effective and targeted interventions for academics and mental and physical health.

Student factors, instructor performance, system quality, and course evaluations all affect online learning satisfaction. Mohammed *et al*[16] found that student factors and system quality were the main elements that influenced student satisfaction. Online learning satisfaction during the COVID-19 lockdown has been assessed by self-efficacy and teacher attitude towards technology integration[17], the interaction between learners and content and lecturers and learners[18], higher education teacher emotional experiences[19], internet connectivity[20], curriculum arrangement[16], and learning environment[21]. Furthermore, the COVID-19 pandemic and related restrictions could impact mental health; college students and young adults had a high prevalence of anxiety, depression, sleep problems, and suicidal ideation[22]. Ionescu *et al*[23] reported that the higher the psychopathology scores, the less online learning satisfaction. Self-directed learning was negatively associated with negative emotions[24]. In addition, University period is a critical time for shaping a student's personality and developing talents; college students have unique psychological characteristics[25]. However, it is not clear which personal characteristics (demographic variables) and which emotions, *e.g.*, depression, fear, neurasthenia, compulsive anxiety or hypochondria, exerted important effects in online learning satisfaction early in the epidemic. Furthermore, coping style is a cognitive and behavioral feature that individuals adopt when facing stressful situations and events. Coping style has a positive and a negative dimension[26]. Positive coping helps individuals to actively manage adversity, which involves asking for advice and finding solutions to adjust to stressors quickly and maintain mental well-being. Negative coping includes social withdrawal and avoidance. Negative coping can increase anxiety and depression and increase the degree of procrastination, which have a negative effect on academic performance [27]. Positive coping is a protective factor for mental health[28]. Nevertheless, factors associated with emergency online learning satisfaction such as coping style have not been adequately defined for the specific pandemic period. Thus, we measured the influence of different characteristics of college students, their psychological state and coping style on their learning satisfaction. Our findings will provide references for colleges to conduct accurate mental health education for students and ensure student satisfaction with online courses. Also, our findings provide understanding of the challenges to fostering a productive learning environment threatened by epidemic outbreak and economic uncertainty.

MATERIALS AND METHODS

Study design

This study was a cross-sectional investigation. An online questionnaire was generated by Wenjuanxing. Wenjuanxing is a web-based, widely used, open questionnaire platform which was developed by the Changsha Ranxing Information and Technology Limited Company. A General Information questionnaire, Psychological questionnaire for Emergent Events of Public Health, and a Simplified Coping Style Questionnaire (SCSQ) were used to measure online satisfaction with learning and associated factors, particularly personal characteristics, mental status, and coping style.

Participants and data collection

Study participants were undergraduates from four colleges and universities, Hebei Medical University, Hebei Normal University, Hebei Academy of Fine Arts, and Shijiazhuang Information Engineering Vocational College. Convenience sampling was used to select participants. Data collection was conducted between March 23, 2020 and April 9, 2020. Because of the pandemic, the students remained at home in different cities and received electronic questionnaires by WeChat. The questionnaire was distributed by school administrators or teachers.

Ethics statement

The study protocol was approved by the Ethics Committee of Hebei General University and complied strictly with ethical requirements. Ethics Review No. (2020) scientific ethics No. (30). All participants provided prior informed consent. Participants were informed that they were free to withdraw at any time. Participants were asked to respond on their own merits and complete survey items in accordance with standardized guidelines. Participant identities were anonymous.

General information questionnaire

The questionnaire was designed to investigate mainly demographic and sociological data, *i.e.*, gender, age, current role, grade, nationality, family location, academic year, monthly household income, parents' education, online status, average daily time paying attention to the epidemic, and whether bored at home for long time. In addition, online learning satisfaction, exercise intensity, and health status scores during the epidemic were rated 1-10 from "very dissatisfied or weak or poor" to "very satisfied, strong, good". Satisfaction scores were defined as poor (1-3), general (4-6), and good (7-10) for online courses.

Psychological Questionnaire for Emergent Events of Public Health

Mental status was assessed with Psychological Questionnaire for Emergent Events of Public Health[29]. This questionnaire is composed of 25 items of five subscales, depression, neurasthenia, fear, compulsion-anxiety, and hypochondria. Each item is scored according to a four-point Likert scale (0 = seldom to 3 = severe) or (0 = seldom to 3 = always). The higher the score of a dimension, the more serious the emotional reaction. The prompt "Possible attitude or practice toward COVID-19" was set to match the actual situation of this survey. The Cronbach's α of the questionnaire for this assessment was 0.776.

SCSQ

Coping styles were assessed with the SCSQ[30]. This questionnaire reflects the attitudes and practices adopted when one experiences setbacks or difficulties. The questionnaire included 20 items in 2 dimensions: Positive coping styles (12 items, *e.g.*, try to look on the bright side, find different ways to solve a problem) and negative coping styles (8 items, *e.g.*, relieve troubles by smoking and drinking, imagine a miracle will come). A 4-point scale was used for each item (0 = never, 1 = seldom, 2 = often, and 3 = always). The total score of the positive coping subscale was from 0 to 36, and the total score of the negative coping subscale was from 0 to 24. High scores reflected high levels of the indicated coping style. The internal consistency coefficients of the positive and negative coping subscale were 0.890 and 0.680, respectively.

Data analysis

Quantitative data were analyzed with descriptive and exploratory methods. First, the skewness and kurtosis values were used to determine whether the data were normally distributed. Data were skewed, continuous variables were expressed as median (interquartile range) and were assessed by Mann–Whitney test or Kruskal-Wallis H test. Second, the correlation of variables was represented by Pearson's and Spearman's coefficients based on the type of data. Third, multiple linear regression was performed to identify predictors of online learning satisfaction. All statistical analysis was performed using SPSS 22.0 (IBM Corporation). All tests were within the 95% confidence interval. When the confidence interval did not include zero, the mediating effect was significant at $P < 0.05$. A two-tailed P value of less than 0.05 was considered statistically significant.

RESULTS

Descriptive statistics

We collected 1600 questionnaires, of which 1580 (98.6%) were effective. The average answer time was 294 ± 165 S. The average age of the participants was 19.9 years (range 17-29 years). There were 342 men (21.6%) and 1238 women (78.4%). There were 191 (12.1%) medicine and 799 (50.6%) and 590 (37.3%) arts and science students. Online learning satisfaction was poor for 3.9% (61/1580) of participants, general for 33.2% (525/1580), and good for 62.9% (994/1580).

Demographic characteristics and single factor analysis

Table 1 lists demographic characteristics and single factor analysis. In the online learning satisfaction dimension, we found statistical significance ($P < 0.05$) for age, major, academic year, family location, online status, average time attention to epidemic, whether following a regular schedule, whether bored at home, health condition, and exercise intensity.

Correlation analysis of online learning satisfaction, mental status, and personal characteristics

We assessed the correlation matrix for all study variables (Table 2). Correlation analyses showed that fear, compulsion-anxiety, positive coping style, father's education, online status, exercise intensity, health condition, whether on a regular schedule, and whether bored at home were positively associated with online learning satisfaction. However, depression, neurasthenia, hypochondria, negative coping style, age, and average time of attention to the epidemic were negatively correlated with online learning satisfaction.

Multiple linear regression of online learning satisfaction

To avoid interaction and multicollinearity, we constructed three models. The dependent variable was learning satisfaction, after confounding factors were excluded. Online learning at schedule, strong exercise intensity, good health, regular schedule, paying attention to epidemic less than one hour, and not bored at home had positive effects ($P < 0.05$) on online learning satisfaction (Table 3). There was no statistical significance for other independent variables. Depression and neurasthenia had significant negative effects on online learning satisfaction, whereas fear positively affected online learning satisfaction ($P < 0.05$; Table 4). Positive coping had a significant positive effect on satisfaction with online courses, whereas negative coping had a significant negative effect ($P < 0.05$; Table 5).

DISCUSSION

The COVID-19 epidemic disrupted education systems, and college students had to turn to distance education quickly. Online learning satisfaction affected academic achievement. As such, it is critical to assess online learning satisfaction, and we need to be aware of some implications. In this study, we showed a relation between online learning satisfaction, personal characteristics, mental status, and coping style. We propose recommendations and solutions to enhance student online learning satisfaction.

We found that online learning satisfaction was reported good by 62.9% (994/1580) of study participants, but nearly half of college students were less satisfied with their studies. Similarly, Maqableh and Alia[31] found that more than a third of surveyed undergraduate students were dissatisfied with the online learning experience. Our results might suggest that emergency online learning could be an optional approach when surviving the shift during the COVID-19 pandemic. On the basis of similar studies, we suggest that a more plausible explanation is that online learning laid a good foundation for promoting interest, effective in learning because of its unlimited access, ease of use, flexibility, innovation,

Table 1 Demographic characteristics and single factor analysis among college students during coronavirus disease 2019 [median (interquartile range)], (*n* = 1580)

repeatedly watching for the future and review, and online learning was effective, applicable and acceptable in education [32]. However the challenge is to find the associated factors and take measures to improve satisfaction according to those factors.

Our findings indicated that college students who participated in online learning at schedule were more satisfied than students who could not get online either because of a lack of a schedule or no network accessibility. That is to say, online learning satisfaction may be related to the degree of participation. Similarly, Hensley *et al*[33] found that students who were able to participate in online courses at schedule had greater learning satisfaction and were more likely to complete their courses successfully. Also, mobile connections and the quality of internet were main factors related to student negative emotions that associated with the quality, performance, and timeliness of study obligations[34]. We suggest forming a home-school joint mechanism, constructing more and improving existing networks, and urging students to attend classes at schedule, to enhance participation and increase online learning satisfaction.

We found that strong exercise intensity, good health, and regular schedule were positively associated with learning satisfaction. Zhang *et al*[35] reported that college students who participated in physical activity < 3 d/wk had symptoms of depression compared with students who exercised ≥3 d/wk. There was also an interaction between long screen use,

less physical activity, and symptoms of depression. High levels of depression were associated with difficulty in paying attention to academics[36] and ultimately deficient learning satisfaction. A poor physical condition leads to lack of energy, which directly affects learning satisfaction. College students who work and sleep irregularly often use the screen too long before going to bed; this behavior can cause sleep deprivation and sleep rhythm disorder, increased sleep-related disorders[37], induced adverse emotions such as anxiety and depression[38], affected cognitive function and learning [39], and eventually poor learning satisfaction. Also, sleep disturbance predicts the development and persistence of posttraumatic stress disorder and depression[40] which impair health and academic performance. Therefore, we suggest that a network interactive platform of individual-family-school-society should be established as an effective linkage mechanism to make sports and exercise programs congenial and encourage college students to participate in sports and exercise at home, or receive exercise prescription teaching to mobilize student initiative, enthusiasm, an consciousness,

and to expand personalities[41]. As well, students need to keep regular bedtimes and wake-up times to promote physical and mental health and ensure online learning satisfaction.

Our data suggest that low levels of online learning satisfaction were more likely to be reported by students who spent more than one hour per day looking for information about COVID-19. Previous studies have been focused on the relation between depression, anxiety, and online learning satisfaction. Wong *et al*[42] reported that students who had poor online learning satisfaction were more likely to experience stress. Kecojevic *et al*[36] found that students who spent more than an hour a day searching for information about COVID-19 were more likely to report higher levels of anxiety, depression, and somatization. These findings demonstrate that excessive attention to the epidemic was associated with high levels of anxiety, depression, and difficulty paying attention to academics, which led to low academic satisfaction. Additionally, there should be organized learning about COVID-19 to improve protection skills and avoid gossip and information overload.

Our findings indicate that college students who were bored staying at home for a long time were more likely to experience poor online learning satisfaction. Giusti *et al*[43] reported that students who studied at home either alone or with classmates were nearly three times more likely to have poor academic performance. Li *et al*[44] found that college students who lived at home for a long time tended to lack social interaction and support, and they felt lonely; family dysfunction, low social support, and low physical exercise have negative impacts on mental status. Similarly, Wissing *et*

al[45] mentioned that perceived peer support can promote collaborative learning and improve medical student learning satisfaction and participation. Therefore, in a special period of limit, we suggest that relevant organizations guide college students to increase contact and interaction with teachers and classmates and provide social and family support to promote positive feelings of long-term home confinement.

We found that high levels of depression and neurasthenia and negative coping styles had negative effects on online learning satisfaction, whereas positive coping styles had positive effects. On the basis of the control-value theory, investigators consider academic emotion to be an important factor that affects student learning satisfaction and academic performance in online learning context; negative adaptive coping strategies are associated with depression and anxiety [46]. Loneliness causes depression and anxiety, whereas procrastination completely mediates the effect of depression on academic performance[47]. Neurasthenia did not disappear; it continues to enjoy a marginal life in international classification schemes and is a common diagnosis in China[48]. Also, International Classification of Diseases (ICD)-11 Bodily Distress Disorder encompasses Neurasthenia which in the ICD-10 was classified in the grouping of "Other neurotic disorders"[49]. Huang *et al*[50] reported that 23.5% of adolescents were prone to anxiety, of which 1.7% had severe anxiety, and 26.3% of adolescents were prone to depression, of which 1.4% had severe depression. Therefore, on the basis of a study by Liu *et al*[51], we suggest that college students who experienced depressive disorders not only need support and personalized interventions from educators and school administrators, but also they need professional interventions such as cognitive behavioral therapy and online medication therapy from psychologists and psychiatrist. College student personality and psychology are still in a period of maturation. The coping styles of college students are closely related to their psychological health and learning satisfaction. Positive, mature coping is a protective factor of mental health, and it promotes developing individual adaptation. Negative, immature coping has a negative effect on mental health. To alleviate symptoms of depression, young adults who experience stressful life events may need to reinforce problem-focused coping and minimize emotion-focused coping strategies[52]. Therefore, we suggest that educators train student positive coping styles when conducting psychological intervention and educate and help students to adopt positive coping styles such as self-adjustment, help-seeking, and problem-solving. Doing so will improve college student mental health and online study satisfaction.

Our study may have some limitations. Considering differences in individual physical quality and endurance, we choose the ten grades of exercise intensity and did not use the sports scale. A standardized exercise intensity scale can be used to further refine our study. Interestingly, we found that fear was positively related to online learning satisfaction. As is well known, moderate anxiety or fear of failure in learning can motivate, and high fear of COVID-19 may have kept college students alert, promoted study of relevant topics, and mobilized their subjective initiative to respond positively, which may have increased online learning satisfaction. However, Al-Nasa'h *et al*[53] reported that fear of COVID-19 diminished the satisfaction of online learning. This difference may be related to differences in scales, sample sizes, and regions used in each study. We enrolled a large number of participants located in one metropolis of China. Hence, samples from other contexts are needed to assess the generality of our findings.

CONCLUSION

Our findings enrich our understanding about the impact of the COVID-19 pandemic on satisfaction of the college population toward emergency online learning. Although there was high online learning satisfaction, online education is still an imperfect substitute for in-person learning. College student online learning satisfaction was affected by whether it was scheduled and by depression, neurasthenia, fear, exercise intensity, attention to the epidemic, emotion at home, and coping style during the early stage of COVID-19. We suggest that college students with different characteristics should receive attention at different levels. Psychological intervention should be conducted, publicity and knowledge about COVID-19 should be strengthened, interaction between teachers and students and classmates should be strengthened when teaching online, and support from family and school should be enhanced to alleviate bad emotions that affect online learning satisfaction. Additionally, online group or individual psychological assistance, even psychotropic drugs for high-risk groups, should be made available. Students should adjust coping style and strengthen psychological defense skills. Students, families, schools, and the community can establish a joint mechanism. Related institutions can form mental health guidelines to promote safe and effective learning and a healthy life.

ARTICLE HIGHLIGHTS

Research background

The coronavirus disease 2019 (COVID-19) pandemic disrupted all facets of everyday life. Students turned to online education to minimize the pandemic's spread and negative impacts on health. Students from various backgrounds and places were required to adapt to new learning conditions. Student learning satisfaction is a crucial indicator of the effectiveness of online learning that is related to academic achievement.

Surveys of online learning satisfaction during the COVID-19 pandemic show inconsistent results. Some studies showed that the higher the psychopathology scores, the less online learning satisfaction. University period is a critical time for shaping a student's personality and developing talents, they have unique psychological characteristics. However, it is not clear which personal characteristics (demographic variables) and which emotions, e.g., depression, fear, neurasthenia, compulsive anxiety or hypochondria, had important effects in online learning satisfaction early in the pandemic.

Furthermore, coping style is a cognitive and behavioral feature that individuals adopt when they face stressful situations and events. Coping style has a positive and a negative dimension. Positive coping helps individuals to actively manage adversity. Negative coping includes social withdrawal and avoidance. Negative coping can increase anxiety and depression and increase the degree of procrastination, which have negative effects on academic performance. Positive coping is a protective factor for mental health. Nevertheless, factors associated with emergency online learning satisfaction such as coping style have not been adequately defined for the specific pandemic period.

Research motivation

Our study will clarify satisfaction with online learning and identify personal characteristics and the emotions that had important effects on online learning satisfaction early in the pandemic. Furthermore, this study will clarify which coping style was associated with emergency online learning satisfaction in the specific period. Our findings will provide references for colleges to conduct accurate mental health education and ensure student satisfaction with online courses for a good quality academic experience and metal health.

Research objectives

Our objective is to provide references for colleges to conduct accurate mental health education for students and ensure their satisfaction with online courses. In addition, we will explain challenges to fostering a productive learning environment threatened by epidemic outbreak and economic uncertainty.

Research methods

We measured the influence of college student psychological states and coping styles on their learning satisfaction. Measurements were based on questionnaires designed to investigate mainly demographic and sociological data, *i.e.*, gender, age, current role, grade, nationality, family location, academic year, monthly household income, parents' education, online status, average daily time paying attention to the epidemic, and whether bored at home for long time. Mental status was assessed with the Psychological Questionnaire for Emergent Events of Public Health (PQEEPH). The PQEEPH scale is specially designed for public health emergencies; it is composed of 25 items of five subscales, *i.e.*, depression, neurasthenia, fear, compulsion-anxiety, and hypochondria that describe emotional status precisely and in detail. Coping styles were assessed with the Simplified Coping Style Questionnaire. Quantitative data were analyzed with descriptive and exploratory methods. First, the skewness and kurtosis values were used to determine whether the data were normally distributed. Data were skewed, continuous variables were expressed as median (interquartile range) and were assessed by Mann–Whitney test or Kruskal-Wallis H test . Second, the correlation of variables was represented by Pearson's and Spearman's coefficients based on the type of data. Third, multiple linear regression was performed to identify predictors of online learning satisfaction. All statistical analysis was performed using SPSS 22.0 (IBM Corporation). All tests were within the 95% confidence interval.

Research results

We collected 1600 questionnaires, of which 1580 (98.6%) were effective. Online learning satisfaction was poor for 3.9% (61/1580) of participants, general for 33.2% (525/1580) participants, and good 62.9% (994/1580). Demographic characteristics and single factor analysis showed statistical significance ($P < 0.05$) for age, major, academic year, family location, online status, average time attention to epidemic, whether following a regular schedule, whether bored at home, health condition, and exercise intensity. Correlation analysis of online learning satisfaction, mental status, and personal characteristics showed that fear, compulsion-anxiety, positive coping style, father's education, online status, exercise intensity, health condition, whether on a regular schedule and whether bored at home were positively associated with online learning satisfaction. Depression, neurasthenia, hypochondria, negative coping style, age, average time of attention to the epidemic were negatively correlated with online learning satisfaction. Multiple linear regression of online learning satisfaction showed online learning at schedule, strong exercise intensity, good health, regular schedule, paying attention to epidemic less than one hour, and not bored at home had positive effects ($P < 0.05$) on online learning satisfaction. Depression and neurasthenia had significant negative effects on online learning satisfaction, whereas fear had positive effects ($P < 0.05$). Positive coping had a significant positive effect on satisfaction with online courses, whereas negative coping had a significant negative effect ($P < 0.05$).

Research conclusions

The new theory is that this study assessed factors especially on personal characteristics, mental status, and coping style related to satisfaction with emergency online learning among college students during the COVID-19 pandemic. Little study has been focused on online acceptance of education in early time of COVID-19 pandemic. Our findings provide reference for educators, psychologists, and school administrators to conduct health education intervention.

The new method we used is the PQEEPH. This scale is specially designed for public health emergencies, it is composed of 25 items of five sub scales, depression, neurasthenia, fear, compulsion-anxiety, and hypochondria which describe the emotional status detailed and precisely.

Research perspectives

On the basis of our methods and findings concerning factors that affect online learning satisfaction, we suggest that it will be possible to assess the effects of psychological intervention for college students during the next emergency online learning period and then formulate corresponding and mature programs.

Abstract

BACKGROUND

Physical education is pivotal in our country's education reform. Urban schools have notably enhanced the intensity of physical education in recent years. However, the effects of physical education on students' anxiety, depression, and self-esteem levels, as well as their interrelations, remain unexplored.

AIM

To analyze the influence of physical education on students' anxiety, depression, and self-esteem.

METHODS

This study employed a cross-sectional design. A stratified cluster sampling method was used to select 478 first-year university students. Self-administered questionnaires were used to investigate the physical education status and basic information of college students. We used the Physical Activity Rank Scale-3 (PARS-3), Self-Rating Anxiety Scale (SAS), Self-Rating Depression Scale (SDS), and Self-Esteem Scale (SES) to assess the level of exercise, anxiety, depression, and self-esteem. Multiple Logistic regression was used to analyze the factors influencing anxiety, depression, and low self-esteem. The receiver operating characteristic curve and area under the curve (AUC) were used to evaluate the predictive ability of PARS-3 scores for anxiety, depression, and low self-esteem. Spearman's correlation was used to analyze the correlations among the PARS-3, SAS, SDS, and SES.

RESULTS

Compared with the domestic norms, SAS and SDS scores were higher, and SES scores were lower ($P < 0.05$). Among the participants, 210 (43.93%) had PARS-3 scores below 20, 94 (19.67%) had scores of 20-42, and 174 (36.40%) had scores above 42. After adjusting for daily sleep time, gender, being an only child, major, father's educational background, mother's educational background, and family

residence, PARS-3 scores were independent influencing factors for anxiety, depression, and low self-esteem (P < 0.05). The AUC of PARS-3 scores predicting anxiety, depression, and low self-esteem were 0.805 (0.760-0.849), 0.799 (0.755-0.843), and 0.831 (0.788-0.874), respectively. The sensitivities were 0.799, 0.801, and 0.748, and the specificities were 0.743, 0.716, and 0.814, respectively. PARS-3 was negatively correlated with SAS and SDS scores (r = -0.566, -0.621, both P < 0.001) and positively correlated with SES scores (r = -0.621, P < 0.001). SES scores were negatively correlated with SAS and SDS scores (r = -0.508, r = -0.518, both P < 0.001).

CONCLUSION

The amount of physical activity is negatively correlated with anxiety and depression degree and positively correlated with self-esteem degree.

Key Words: Physical education; Student; Anxiety; Depression; Self-esteem; Influence

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: This study establishes a negative correlation between physical activity levels and the degree of anxiety and depression while demonstrating a positive correlation with self-esteem. This provides substantial evidence for the impact of physical education on anxiety, depression, and self-esteem of college students.

INTRODUCTION

University physical education aims to promote students' holistic development and cultivate students' comprehensive quality through sports activities[1]. Physical activity is a reliable way to develop healthy behaviors, sports abilities, morality, and other qualities among students[2]. College students are under pressure from various aspects, such as college entrance, interpersonal conflict, and job search competition. Moreover, they are prone to psychological problems, such as anxiety and depression, which may lead to violent injuries and even suicide[3]. Self-esteem refers to confidence in one's worth, abilities, and morals[4]. Self-esteem is a positive psychological quality and psychological capital for college students' growth and success[5]. College students are an important part of young people, and their physical and mental health have an important influence on personal development and long-term national planning. Research has shown that individuals with low self-esteem are prone to anxiety, depression, and other negative emotions[6]. However, individuals with high self-esteem have varying mental health levels[7]. Appropriate physical activity reduces anxiety and depression among college students[8] and effectively improves their self-esteem[9]. However, studies on the effects of physical education on anxiety, depression, and self-esteem are scant. Therefore, we used college students to analyze the influence of physical education on anxiety, depression, and self-esteem to provide a reference for improving their physical and mental health.

MATERIALS AND METHODS

Object of study

We conducted a cross-sectional survey. We selected university students using stratified cluster sampling. The participants were based on major, including humanities and social sciences, science and engineering, and medical sciences. Three majors were selected to obtain a sufficient sample size.

We determined the sample size using a formula (quantitative variable)[10] for cross-sectional studies: $n = (\frac{Z_{1-\alpha/2}\times\sigma}{\delta})^2$, where: n represents the sample size of each group; $Z_{1\text{-alpha}/2}$ = 1.96; δ represents the allowable error, which is the half-width of the confidence interval; and sigma is the standard deviation. Based on δ = 5 and σ = 30, we calculated n to be 139. Considering a 10% withdrawal rate, we estimated that the study required 459 participants [139 × 3 × (1 + 10%)].

The survey object recruitment methods were as follows: Buy some small gifts, such as carbon pens, cartoon erasers, post-it notes, and other small prizes, for each person willing to participate in the survey. The students included in the survey have the spirit, consciousness, ability, and a WeChat account to complete the questionnaire independently. They knowingly and voluntarily agree to participate in this study. We excluded the students who could not complete the questionnaire for any reason. To protect privacy, we ensure the questionnaire results and data are only known by the research team and destroy the questionnaire after obtaining the relevant data analysis conclusions. We established a WeChat group of survey participants and, after obtaining informed consent, sent questionnaire links to the group for the

questionnaire survey. Participation was voluntary. We sent 500 questionnaires, and 486 were returned (97.2% recovery rate). After excluding the invalid questionnaires such as missing or multiple pages, incomplete filling, respondents not meeting the requirements, obviously wrong or incorrect answers, or recalled deadlines, we included 478 effective questionnaires (95.6%) in the analysis.

Questionnaire survey and quality control

We used original questionnaires that were reviewed and tested by experts. The audit includes the completeness, standardization, consistency, authenticity, effectiveness, feasibility, and scientificity of the questionnaire. A test is a form of survey used to obtain preliminary information and understand respondents' opinion before conducting a formal survey. The questionnaire obtained information on the participants, their parents, and their peers. The survey included questions regarding sociodemographic factors, physical activity, anxiety, depression, and self-esteem. The survey was conducted from February to May 2023.

The investigators in this study were members of a research group that had undergone unified training and assessment. They managed the research data and survey results. Participants who were unable to participate in the survey during the set period were contacted by the investigators within two weeks and requested to complete the questionnaire using the same procedure as the set survey to reduce the number of invalid questionnaires.

Sociodemographic factors

Based on a review of the relevant literature, we designed a sociodemographic questionnaire under the guidance of epidemiologists. The questions included student number, gender, being an only child, major, parents' educational background, family residence, and average daily sleep time over the last month.

Sports activities

We employed the Physical Activity Rank Scale-3 (PARS-3)[11] to calculate the participants' physical activity in the past month. In previous studies, the scale's internal consistency and reliability were 0.86 and 0.82, respectively. The scale contains three dimensions: time, intensity, and frequency of exercise. Items were rated on a five-point Likert scale (1 = light exercise; 5 = competitive exercise). Among them, exercise time was rated 0 to 4 points, and exercise intensity and frequency grades were 1 to 5 points. Exercise was calculated as time × intensity × frequency; the score range was 0 to 100 points. Exercise classification criteria were as follows: ≤ 19 points = low exercise, 20-42 points = moderate exercise, ≥ 43 points = high exercise.

Anxiety and depression

We used the Self-Rating Anxiety Scale (SAS) and Self-Rating Depression Scale (SDS)[12] to detect anxiety and depression, respectively. The SAS contains 20 items (15 positive and 5 reverse scores). Similarly, the SDS contains 20 items (11 positive and nine reverse scores). Items were rated on a four-point Likert scale (1 = occasional; 4 = persistent). The sum of the scores for each item was the approximate score of anxiety or depression. The standard or final score of anxiety or depression was calculated as 1.25 times the score of anxiety or depression rounded to a whole number. The criteria for identifying anxiety were an SAS score of > 50 points while depression was an SDS score of > 53 points.

Self-esteem

We employed the Self-Esteem Scale (SES)[13] to evaluate college students' self-esteem. The scale's internal consistency was 0.87 in previous studies. This scale contains ten items (five positive and five negative). Items were rated on a four-point Likert scale (1 = strongly disagree; 4 = strongly agree). The total self-esteem score was the sum of all entries. Higher SES scores indicated higher self-esteem.

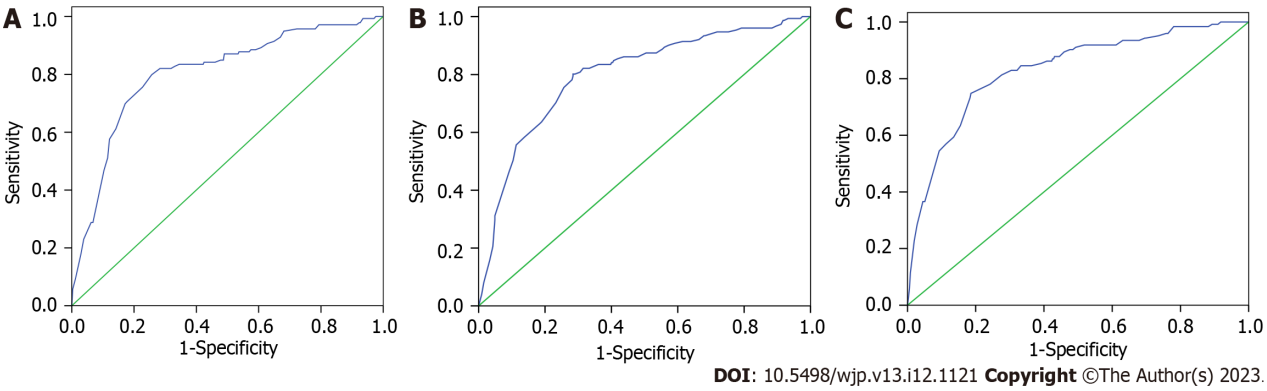
Statistical analysis

We used SPSS 20.0 to process the data and expressed the measurement data as mean ± SD. Comparisons between two sets of data were performed using the *t*-test, and comparisons between three sets of data were performed using a one-way analysis of variance (ANOVA) and Bonferroni. Count data are represented as *n*.

We classified low self-esteem by subtracting one standard deviation from the domestic norm average of SES[14]. Anxiety (anxious = 1, not anxious = 0), depression (depressed = 1, not depressed = 0), and self-esteem (low self-esteem = 1, regular/high self-esteem = 0) were the dependent variables, whereas PARS-3 scores and sociodemographic indicators were the independent variables. A multivariate logistic regression model was used for the analysis. The predictive ability of the receiver operator characteristic curve (ROC) and area under the curve (AUC). Spearman's correlation analysis was used to explore the correlation between PARS-3 scores and SAS, SDS, and SES scores. A *P* value less than 0.05 means that the difference is statistically significant.

RESULTS

SAS, SDS, and SES scores



The participants' SAS and SDS scores were higher and SES scores were lower than the domestic norms [SAS: (29.78 ± 10.07) points, SDS: (33.46 ± 8.55) points][15,16] ($P < 0.05$; Table 1).

Table 1 Self-Rating Anxiety Scale, Self-Rating Depression Scale and the Self-Esteem Scale scores (*n* = 478)

Items	SAS	SDS	SES
Participants	46.39 ± 7.26	48.22 ± 10.24	26.35 ± 4.31
Domestic norm	29.78 ± 10.07	33.46 ± 8.55	28.75 ± 4.86
t^1	53.067	37.365	-12.184
P value	< 0.001	< 0.001	< 0.001

[1]Single sample *t*-test.

Influence of sociodemographic factors on PARS-3 scores

Among the participants, 210 (43.93%) had PARS-3 scores ≤ 19, 94 (19.67%) scored 20-42, and 174 (36.40%) scored ≥ 43. Among the participants with PARS-3 scores ≤ 19, the PARS-3 scores of only children were higher than those who were not only children. The PARS-3 scores of college students with an average daily sleep time > 8 h were higher than those with an average daily sleep time of 6-8 h and those with an average daily sleep time of < 6 h (all $P < 0.05$; Table 2).

Influence of sociodemographic factors on SAS, SDS, and SES scores

The SDS scores of college students whose fathers' education was at or above the graduate level were higher than those of those whose fathers' education was less than the graduate level, and their SES scores were lower than those of those whose fathers' education was below the graduate level ($P < 0.05$; Table 3).

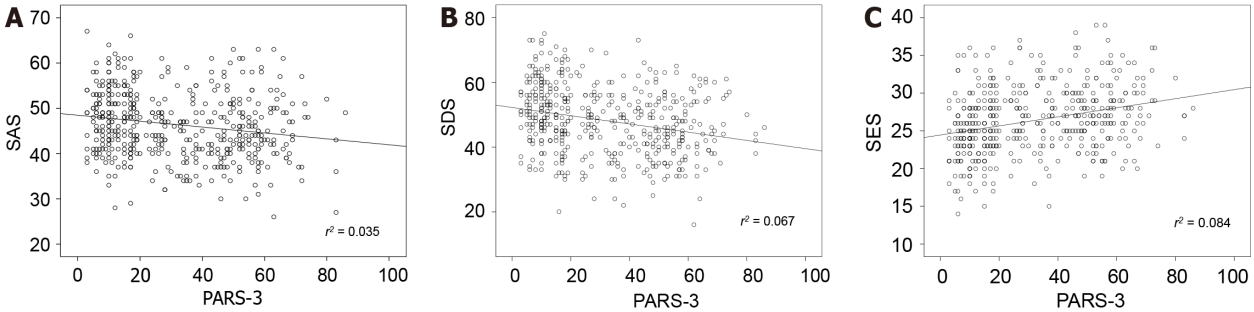
Factors influencing anxiety, depression, and low self-esteem

Anxiety (anxious = 1, not anxious = 0), depression (depressed = 1, not depressed = 0), and self-esteem (low self-esteem = 1, regular/high self-esteem = 0) were the dependent variables, whereas PARS-3 scores and sociodemographic indicators were the independent variables. A multivariate logistic regression model was used for the analysis (Table 4). The results showed that after adjusting for daily sleep time, gender, being an only child, major, father's educational background, mother's educational background, and family residence, PARS-3 scores were independent influencing factors for anxiety, depression, and low self-esteem ($P < 0.05$; Table 5).

Predictive ability of PARS-3 scores

The AUC of the PARS-3 scores predicting anxiety, depression, and low self-esteem were 0.805 (0.760-0.849), 0.799 (0.755-0.843), and 0.831 (0.788-0.874), respectively. The sensitivities were 0.799, 0.801, and 0.748 and the specificities were 0.743, 0.716, and 0.814, respectively (Figure 1, Table 6).

Correlation analysis between PARS-3 scores and SAS, SDS, and SES scores



PARS-3 scores were negatively correlated with SAS and SDS scores (r = -0.566, -0.621, both $P < 0.001$) and positively correlated with SES scores ($r = -0.621$, $P < 0.001$). SES was negatively correlated with SAS and SDS scores ($r = -0.508$, $r = -0.518$, both $P < 0.001$; Figure 2, Table 7).

DISCUSSION

Self-esteem affects how individuals deal with stressful events; individuals with high self-esteem are more inclined to adopt positive coping strategies to deal with stress[17]. Understanding the link between physical education and anxiety, depression, and self-esteem helps guide and intervene to promote students' holistic physical and mental development.

The amount of exercise, also known as exercise load, refers to the physical load, psychological load, and calories consumed by the human body during physical activity. Exercise load determines the intensity, duration, accuracy, and characteristics of the exercises. This study revealed anxiety, depression, and low self-esteem among college students, which require attention. The proportion of students with low physical activity was lower than that reported by Sheng *et al* [18]. However, the overall situation is not positive, and the potential impact of low physical activity on the physical and mental health of college students should be monitored. This may be due to the wide use of electronic products, such as smartphones and tablet computers. Several college students are addicted to mobile phones and the internet, reducing their willingness to participate in sports activities[19]. Some researchers have proposed that the lack of exercise among college students is related to a lack of good exercise habits due to academic pressure in middle school[20]. Students in middle school did not develop good exercise habits, and their bad exercise habits after college cannot be corrected in time, resulting in less exercise. Moreover, our findings suggest that college students with high physical activity levels have a lower risk of anxiety, depression, and low self-esteem. Furthermore, our results indicate that higher amounts of exercise are associated with reduced anxiety and depression and improved self-esteem among college students. Participation in sports activities can affect anxiety and depression levels in many ways. Sports activities can increase communication between college students and their peers and release negative emotions, thereby reducing anxiety and depression. Additionally, regular participation in sports activities can improve college students' sense of self-efficacy, thus enhancing their subjective support levels, problem-solving ability, and positive evaluation of volitivity and self-confidence[21]. Therefore, college students who are more active and proactive in coping with pressure have fewer negative emotional experiences and more positive emotional experiences, thus reducing anxiety and depression levels [22]. Moreover, physical exercise increases the relative content of metabolites 4-hydroxyphenyl lactate and dihydro thymine and decreases the relative content of glutamine in the human body, thus affecting the regulatory pathways related to negative emotions, such as coenzyme Q biosynthesis, tyrosine metabolism, and pyrimidine metabolism[23]. In addition, physical exercise can change the composition of the human intestinal flora, affecting the secretion of a series of substances that regulate neural activity, such as serotonin, and improving the level of anxiety and depression in individuals[24]. Therefore, we suggest that schools encourage college students to participate actively in physical exercise. Psychological education departments should pay attention to the mental health status of college students with low daily physical activity and implement effective intervention measures to prevent anxiety and depression.

This study found that higher amounts of exercise are associated with higher self-esteem among college students, which was in line with Zayed's findings[25]. Previous research has shown that physical exercise can improve self-esteem by reducing loneliness. Moreover, physical activity enhances self-esteem[26]. Activity time, frequency, and intensity may be the key factors that produce positive psychological benefits for self-esteem. Our findings indicated that lower self-esteem

was associated with being more prone to depression, which was in line with extant studies[27]. College students with high self-esteem are confident, self-reliant, rational, and peaceful. Their self-evaluation is generally positive; they can rationally face the negative evaluation of others and effectively filter negative information. In addition, college students with high self-esteem have a better sense of control over their environment, can accept and adapt to the existing environment, and are willing to change themselves. When facing stressful events, they can effectively use their current social support to provide a buffer for themselves and reduce the negative impact of stressful events[28]. This effectively reduces the occurrence of anxiety and depression among college students. Therefore, individuals with high self-esteem can self-regulate their depression and solve general psychological problems under stressful conditions. The correlation scatter plot suggests that exercise significantly impacts anxiety, depression, and self-esteem. However, the goodness of fit

is low, indicating that exercise alone is not the sole factor affecting these aspects in college students. Ramón-Arbués *et al* [29] demonstrated that anxiety, depression, and self-esteem of college students were also related to Internet use, smoking, and insomnia.

Anxiety, depression, and low self-esteem are contemporary college students' main mental health problems. The detection rate of anxiety and depression in Chinese college students is rising. College students urgently need an intervention method that can effectively relieve their anxiety, depression, and low self-esteem. This study demonstrates that increasing physical activity decreases anxiety and depression thereby boosting self-esteem in college students. It indicates the value of incorporating appropriate physical activities for promoting college students' psychological well-being and development. Moreover, a significant correlation exists between anxiety, depression, and self-esteem. Low self-esteem can contribute to the development of anxiety and depression. Therefore, regardless of the specific psychological changes in anxiety, depression, and self-esteem, one must be vigilant to any abnormal psychological development. Due to the limited information collected in this study, it was impossible to investigate the correlation between the amount of physical activity and sedentary behavior, video time, and other behaviors, which needs to be supplemented by future studies with large samples. Moreover, this cross-sectional survey design introduces potential problems such as uncertain time sequencing, external factor interference, data quality impact, and potential factor uncertainty, making it challenging to establish causality. Therefore, other research methods such as randomized controlled studies should be employed in the future to verify the results of this study.

CONCLUSION

Physical activity decreases anxiety and depression and increases self-esteem among college students. Colleges and universities should promote active participation in sports and implement scientifically balanced exercise routines. This can alleviate anxiety and depression, improve self-esteem, and enhance the overall physical and mental well-being of college students, ultimately contributing to their holistic development.

ARTICLE HIGHLIGHTS

Research background

College students experience varying levels of anxiety, depression, and self-esteem. As this reflects the quality of education reform in China, the correlation between physical activity and students' anxiety, depression, and self-esteem must be explored.

Research motivation

This study aimed to identify the factors related to anxiety, depression, and self-esteem among college students, and provide guidelines for interventions. Considering the influence and adjustability of physical activity in students, we speculated that the amount of physical activity among college students may be related to anxiety, depression, and self-esteem.

Research objectives

To analyze the influence of physical activity on anxiety, depression, and self-esteem among college students.

Research methods

We investigated 478 first-year college students using the Physical Activity Rank Scale-3 (PARS-3), Self-Rating Anxiety Scale (SAS), Self-Rating Depression Scale (SDS), and Self-Esteem Scale (SES). A multivariate logistic regression model, receiver operating characteristic curve (ROC), area under the curve (AUC), and Spearman's correlation analysis were employed to determine the correlation between PARS-3 and SAS, SDS, and SES scores.

Research results

PARS-3 was negatively correlated with SAS and SDS scores (r = -0.190, -0.267, both P < 0.001) and positively correlated with SES scores (r = 0.313, P < 0.001). SES was negatively correlated with SAS and SDS scores (r = -0.125, P = 0.016; r = -0.143, P = 0.002).

Research conclusions

Physical activity was negatively correlated with anxiety and depression and positively correlated with self-esteem.

Research perspectives

Based on the multi-factor logistic regression model, ROC, AUC, and Spearman's correlation analysis, we comprehensively analyzed the correlation between college students' PARS-3 scores and SAS, SDS, and SES scores. We demonstrated that college students' PARS-3 scores were negatively correlated with SAS and SDS scores and positively correlated with SES scores. This could guide future interventions to reduce anxiety, depression, and low self-esteem among college students.

Abstract

BACKGROUND

In the information age, the use of the internet and multimedia tools has large effects on the life of middle school students. Improper use of the internet may result in internet addiction (IA). Thus, actively exploring the factors influencing adolescent and the mechanism of addiction as well as promoting adolescent physical and mental health and academic development are priorities that families, schools, and society urgently need to address.

AIM

To explore the effect of childhood trauma on adolescent IA and to consider the roles of loneliness and negative coping styles.

METHODS

A total of 11310 students from six junior high schools in Henan, China, completed the child trauma questionnaire, IA test, loneliness scale, and simple coping style questionnaire. In addition, data were collected from 1044 adolescents with childhood trauma for analysis with IBM SPSS 26.0 and AMOS 28.0; we examined the relationships among childhood trauma, IA, loneliness, and negative coping styles.

RESULTS

We found that childhood trauma not only directly affected adolescents' IA but also affected IA through loneliness and negative coping styles.

CONCLUSION

Therefore, this study has theoretical implications regarding adolescent mental health and may inform interventions for IA.

Key Words: Addictive behavior; Mental health; Coping styles; Trauma; Loneliness

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: This study is concluded: (1) Childhood trauma has a positive predictive effect on teenagers' internet addiction (IA); (2) Childhood trauma has a negative psychological and behavioral impact on teenagers; (3) Loneliness and negative coping styles play a chain intermediary role in the influence of childhood on IA among teenagers; and (4) IA.

INTRODUCTION

In the information age, the use of the internet and multimedia tools has a large effect on the lives of middle school students. Improper use of the internet may result in internet addiction (IA). IA is often defined as problematic, compulsive internet use (for gaming, social networks, pornography, *etc.*) that results in severe impairment of an individual's functioning in all aspects of life over a long period[1,2]. Worldwide, the current prevalence rate of IA is 7.02%; alarmingly, the age of IA onset is dropping, and the prevalence rate is increasing[3]. From 2004 to 2019, a questionnaire survey of 92171 middle school students in Shanghai, China, reported that the prevalence rate of IA was 4.3%, that students with high levels of loneliness exhibited IA, and that academic pressure aggravated IA[4]. Studies have shown that IA causes mental health problems in individuals and impairs psychosocial functioning, such as an inability to concentrate for long periods, isolation, anxiety, social withdrawal, depression, interpersonal avoidance, and sleep disorders[5-8]. Physical health problems such as dry eye, mouse hand, and cervical and lumbar spine pain can also occur [9,10]. Moreover, some studies have shown that IA is related to non-suicidal self-injury and suicide in adolescents[11-13]. Thus, actively exploring the factors influencing adolescent IA and the mechanism of addiction as well as promoting adolescent physical and mental health and academic development are priorities that families, schools, and society urgently need to address.

Childhood trauma and IA

Childhood trauma is often described as serious adverse childhood experiences, mainly involving neglect and abuse[14], which have a series of negative effects on physical and mental health[15,16]. Unfortunately, childhood trauma is very common. According to Koenen *et al*[17], 38.48% of children have been exposed to at least one traumatic event before the age of 13. Childhood trauma is associated with the development of various addictive behaviors, which have become an increasingly serious public health problem[18-20]. For example, a study proved that childhood trauma is an important predictor of gambling disorder; physical neglect is the single trauma subtype that significantly increases the incidence of gambling disorder in adulthood[21]. It remains unclear whether childhood trauma is common among adolescents with IA. Therefore, we hypothesized that childhood trauma positively predicts adolescent IA (H1).

The potential mediating role of loneliness

Loneliness refers to complex feelings when the intimate relationship and social needs of individuals are not fully satisfied and are often accompanied by negative emotional experiences such as isolation, helplessness, and pain[22,23]. Abuse and neglect are severe childhood traumatic events and are lonely experiences. It is difficult for people without the same experience to truly understand these feelings. The traumatized person may have friends who support him or her, but because the friends cannot understand these feelings, the traumatized person may not be willing to share his or her experiences[24]. Therefore, even with the support of friends, they may feel lonely after the trauma. According to the social compensation hypothesis, lonely people may compensate for emotional or social needs through self-disclosure, self-catharsis, and interpersonal communication through the internet[25]. Adolescents with high levels of loneliness have a higher risk of IA[26,27]. However, it is unclear whether childhood trauma affects IA through loneliness. We hypothesized that loneliness influences the impact of childhood trauma on IA (H2).

The potential mediating role of negative coping styles

Coping styles are the cognitive and behavioral styles adopted by individuals in the face of setbacks and pressures. They are usually divided into positive coping styles (problem-solving, cognitive reassessment, social support, *etc.*) and negative coping styles (avoiding or denying problems or attributing solutions to external factors)[28,29]. Childhood is an important period of development, and traumatic experiences during this period will have a long-term impact on cognition and emotion regulation[30]. Some studies have shown that adolescents with childhood trauma mainly exhibit negative coping styles[31,32]. A reasonable explanation for using a negative coping style is that continuous exposure to childhood trauma

may lead to changes in one's neurobiology that lead to increased vigilance and perceived environmental threat, thus changing one's perceived stress[33]. Traumatic events will result in negative coping styles, which is consistent with the stress response model[34]. Some studies have indicated that addictive behaviors are closely related to the selected coping style, especially negative coping styles[35-37]. Adolescents may exhibit negative coping methods on the internet such as venting, avoiding, or denying difficulties encountered in reality[38]. Based on previous theories and studies, we propose that negative coping styles mediate the relationship between childhood trauma and IA (H3).

Moreover, some studies have shown that loneliness affects coping styles[39,40], and negative coping styles positively predict IA[41,42]. However, few studies have shown that negative coping styles play an intermediary role in the relationship between loneliness and IA. In this study, we proposed that negative coping styles may mediate between loneliness and IA, and loneliness and negative coping styles have a chain mediating role in the relationship between childhood trauma and IA (H4).

Study framework

Childhood trauma, IA, loneliness, and negative coping styles interact with each other. Nevertheless, it remains unclear how these variables interact to lead to IA in adolescents. In this study, we proposed the conceptual framework shown in Figure 1. From the perspective of adolescents, we discuss the influence of childhood trauma on IA and investigate the role of loneliness and negative coping styles to provide empirical support and guidance for related research and interventions for adolescent mental health.

MATERIALS AND METHODS

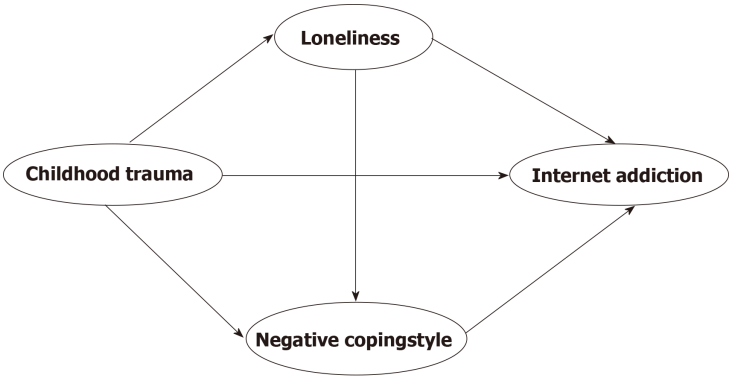
Data collection and ethical considerations

From May to June 2023, volunteers were recruited from six junior and senior high schools in Henan Province, China, using a convenient sampling method. The inclusion criteria were as follows: (1) Enrolled in secondary school; and (2) Provided informed consent and volunteered to participate in this study. The exclusion criterion was the failure to complete all of the questionnaires, regardless of reason. This study was approved by the Institutional Review Committee of Henan Provincial Key Laboratory of Psychology and Behavior (20230516001), and all participants signed informed consent forms.

Questionnaire

General demographic data: We collected sociodemographic information including gender, age, parental marital status, only-child status, left-behind child status, family residential location, and relationships with teachers and classmates.

Childhood trauma questionnaire: We used the childhood trauma questionnaire compiled by Bernstein *et al*[43] and revised by Zhao *et al*[44]. The questionnaire consists of 28 questions, of which 3 are validity items designed to detect false-negative trauma reports. The questionnaire assesses five dimensions of childhood maltreatment. Each question is answered on a Likert scale, from 1 "never correct" to 5 "often correct". A higher overall score indicates a greater severity of trauma. The Cronbach's α coefficient of this study scale was 0.817.



IA test: The IA test is a self-report scale compiled by young that contains 20 items[45]. Each entry is scored according to the degree of compliance on a scale of 1-5, and the total score range is 20-100 points. The higher the score is, the more severe the IA. A score ≥ 50 points indicates the presence of IA. The Cronbach's α coefficient was 0.909 in this study.

Loneliness scale: We used the University of California-Los Angeles Loneliness Scale compiled by Russell *et al*[46] in 1978. The scale consists of 20 items with 4 response options, 11 questions, and 9 reverse-scored questions. The higher the score is, the stronger the individual's experience of loneliness. The Cronbach's α coefficient in this study was 0.815.

Coping styles scale: Coping styles were evaluated with the simple coping style questionnaire, which was compiled by Xie[47] based on the Chinese context. It consists of two dimensions, positive response, and negative response, with a total of 20 items. Items are rated on a 4-point Likert scale (1 = not used, 4 = frequently used). This study focused on the negative response scale, which consists of 8 items and focuses on the characteristics of negative responses. The scale in this study had a Cronbach's α coefficient of 0.728.

Statistical analysis

All data were analyzed using IBM SPSS 26.0 and Amos 28.0 in this study. First, the frequency and percentage are reported for the demographic characteristics of participants. In addition, we used Harman's single-factor test to test for possible common method deviations. Normality tests were performed on continuous variables to detect skewness and kurtosis. If IA, loneliness, childhood trauma, and negative coping styles followed a normal distribution, we used Pearson's correlation analysis to explore the relationships among these variables. Otherwise, we used Spearman correlation analysis. We then used structural equation modeling to examine the mediation effects. In this study, IA was the dependent variable, childhood trauma was the independent variable, and loneliness and negative coping styles were the mediating variables. Based on previous item parceling studies[48], we used a "project-building balance" approach to package entries on loneliness and coping styles. Finally, bootstrapping was used to test the mediation effect, and if $P < 0.05$, the mediation effect was considered significant.

Figure 1 Conceptual framework.

RESULTS

Sample results

We recruited a total of 11310 participants. Of these, 190 dropped out halfway and 11120 questionnaires were returned. After excluding questionnaires with incomplete data, we finally obtained 10819 valid questionnaires. Then, 9775 false-negative trauma reports were excluded. Finally, we analyzed the data of 1044 adolescents with childhood trauma, constituting 9.3% of the total number of participants in the survey, as shown in Figure 2. Bentler and Chou[49] proposed that the sample size should be more than 10 times the number of observed variables; therefore, 1044 samples met the requirements for testing the hypothesized model.

The demographic characteristics of the 1044 adolescents are shown in Table 1. Among them, 612 were male (58.6%), and 432 were female (41.4%). The students were in junior high school or high school, and the age range was 12-18 years. Among the sample, 937 were from two-parent families, and 105 were from single-parent families. A total of 70 (6.7%) students were only children, and the remaining 89.8% had siblings. In this survey, there were 458 (43.9%) left-behind children (students living with their grandparents, attending boarding school, or living alone), and there were 586 (56.1%) children living with their parents. Of these children, 56.6% were from rural areas, and the remaining 43.4% were from urban areas. A total of 48.8% of the students reported that they had a good relationship with their classmates, and 31.5% of the students reported that they had a good relationship with their teachers.

Bias test of common method

Because all data were collected with questionnaires, we used Harman's single-factor test to test for possible common method bias. The test results showed that there were 19 variables with eigenvalues greater than 1. The first variable explained 14.85% of the total variation, which is below the critical standard of 40%[50]. Hence, there were no serious common methodological biases in this study.

Descriptive statistics and correlations among variables

SPSS was used to examine the distributions of these variables, and all continuous variables had normal distributions. Therefore, we used Pearson correlation analysis to assess the correlations between variables. Means, standard deviations, and Pearson correlation coefficients of each variable are shown in Table 2. In this exploratory analysis, correlations between variables were examined with Pearson correlation analysis; there were significant correlations between each variable in this analysis at the significance level of 99%. Regarding the correlation coefficients, the r values were greater than 0. Thus, there was a significant positive correlation between the four dimensions of childhood trauma and each variable. The independent-sample t test results showed that there was a significant influence of parental marital relationship on IA (t = -4.252, P < 0.001). One-way ANOVA was used for variables with homogeneity of variance. The results showed that there were significant differences in IA among different ages (F = 16.86, P < 0.001). In addition, there were significant differences in IA according to relationships with peers and teachers (F = 9.837, P < 0.001). Considering that parent martial relationship (harmonious/disharmonious), age (12-18 years old), and relationship with teachers (poor/average/good) may influence IA, we decided to control for these variables in the subsequent mediation analysis.

SEM of factors influencing IA

Parents' marital relationship, age, and relationship with teachers were selected control variables because IA is significantly affected by these three variables. The model fit results are shown in Table 3; in accordance with Hu and Bentler [51], we provide several representative model fit indices. The CMIN/DF value of the model (4.616) was less than 5. The root mean square error of approximation value (0.059) was less than 0.08, and the root mean square residual value (0.040) was less than 0.05. In addition, the comparative fit index and goodness of fit index test results indicated excellent fit (0.9 or more). Therefore, the results of this analysis show that the SEM of factors influencing IA was satisfactory.

Table 1 Sample characteristics (*n* = 1044)

Variable	Option	*n*	*n*
Gender	Male	612	58.6
	Female	432	41.4

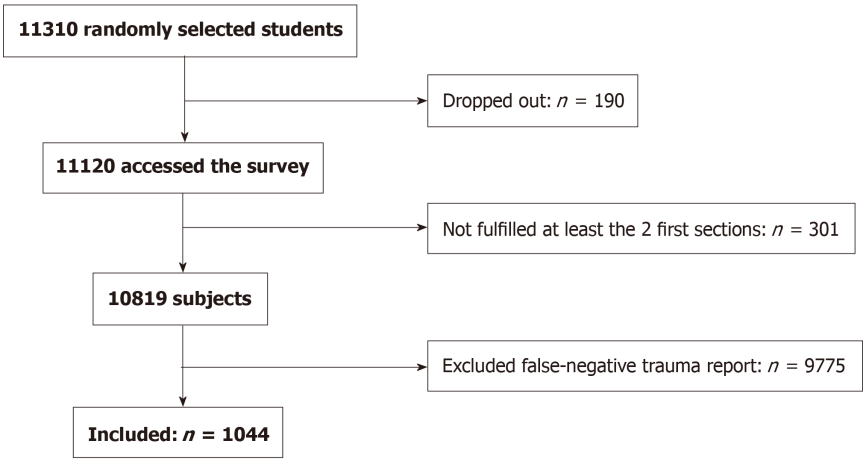
EN: Emotional neglect; PaEB: Physical and emotional abuse; SB: Sexual abuse; BN: Body neglect; NCS: Negative coping style; IA: Internet addiction.



Factors hypothesized to influence IA

According to the results shown in Figure 3, childhood trauma positively predicted loneliness ($\beta = 0.50$, $P < 0.001$), childhood trauma positively predicted negative coping style ($\beta = 0.25$, $P < 0.001$), loneliness positively predicted negative coping style ($\beta = 0.21$, $P < 0.001$), loneliness positively predicted IA ($\beta = 0.14$, $P < 0.001$), negative coping style positively predicted IA ($\beta = 0.30$, $P < 0.001$), and childhood trauma positively predicted IA ($\beta = 0.17$, $P < 0.001$).

Figure 3 The SEM of factors influencing internet addiction. EN: Emotional neglect; PaEB: Physical and emotional abuse; SB: Sexual abuse; BN: Body neglect; L1-L4: Four items of loneliness; IA1: Tolerability and time management; IA2: Compulsivity and prominence; IA3: Interpersonal, study and health; IA4: Abstinence reaction; NCS1-NCS3: Three items of negative coping style; MS: Marital status; RwT: Relationship with teachers.

Finally, we used 5000 bootstrap samples to determine the 95% confidence interval, and assessed the mediating effects of loneliness and negative coping style on the relationship between childhood trauma and IA. The results are shown in Table 4; loneliness mediated in the relationship between childhood trauma and IA. Negative coping styles also mediated the relationship between childhood trauma and IA. In addition, loneliness and negative coping styles had a chain mediating role in the relationship between childhood trauma and IA. In short, childhood trauma not only directly affected IA but also indirectly affected IA through loneliness and negative coping style in a chain mediation effect

Table 4 Structural equation modeling results

Effect	Path	Estimate	*P* value
Ind2	IA < loneliness < childhood trauma	0.093	0.005
Ind2	IA < negative coping style < childhood trauma	0.104	0.001

(Table 4).

DISCUSSION

Among the 1044 adolescents with childhood trauma, there were 473 (45.6%) students with IA, and the prevalence rate was as high as 45.6%, which is higher than the Hu *et al*[52] reported. Among these participants, 75 had severe IA. This may be related to the unique study population (adolescents with childhood trauma). We explored the relationship between childhood trauma and IA in adolescents. The mediating roles of loneliness and negative coping styles were determined through a chain mediation model. To address IA in adolescents with childhood trauma, it is of practical and theoretical importance to study the relationships among these variables.

Childhood trauma and IA

The results of this study revealed a direct relationship between childhood trauma and IA, suggesting that physical and emotional neglect/abuse in childhood are important predictors of adolescent IA, which is consistent with previous findings and supports H1. Studies have shown that childhood trauma can lead to poor behavior in adolescents[53,54]. For example, childhood trauma can directly predict adolescent mobile phone addiction as well as IA[55,56]. The present study showed that childhood trauma is significantly associated with IA, which is consistent with previous research results[57]. Importantly, this study also showed that adolescents with IA accounted for 45.6% of the sample, which differs from previous findings, suggesting that adolescents with childhood trauma are more likely to have IA. Traumatic childhood experiences have various adverse effects on adolescents in physical, psychological, emotional, and behavioral dimensions. Studies have shown that children who have experienced childhood trauma are often in a clinical or subclinical psychological state, and they will be more inclined to use the internet to express their sadness, depression, and other psychological states and obtain comfort[58]. Thus, we should pay attention not only to the health and academic needs of adolescents but also to their psychological and emotional needs. School-based health care centers and education systems are key resources for adolescent trauma interventions. Schools can identify students with childhood trauma through screening, focusing on their health. This will be more conducive to adolescents' healthy growth and reduce problem behaviors such as IA.

Mediation through loneliness

This study explored the mechanism underlying the association between childhood trauma and adolescent IA and showed that loneliness plays a mediating role in this relationship, supporting hypothesis 2. The results showed that childhood trauma significantly predicted adolescent loneliness, which is consistent with previous studies[59,60]. Loneliness is a common experience in adolescence. According to a survey, 11%-20% of those aged 12-15 years reported that they felt lonely at least "sometimes"[61]. Childhood trauma aggravates adolescents' depression and inferiority complexes, limits their social communication, and thus aggravates loneliness. Moreover, loneliness is a negative emotional state and is closely related to some mental disorders. For example, loneliness and depression are associated[62]. This study showed that loneliness has an impact on adolescent IA, which is consistent with previous research results[63]. Adolescents with high levels of loneliness tend to use the internet instead of offline social interactions to meet the need to belong[64]. However, IA aggravates the loneliness of adolescents. Therefore, we suggest that schools organize more recreational activities for spare time to meet the social needs of adolescents. We should also prioritize the identification of students with communication barriers, emphasize the restoration of interpersonal relationships with time, help students actively integrate into the community, and prevent or reduce adolescent loneliness.

Mediating effect of negative coping styles

This study showed that negative coping styles have a mediating role in the effects of childhood trauma on IA, supporting hypothesis 3. The family risk factor model suggests that living in abusive or neglectful family environments can exacerbate or impose risks of poor self-perception, negative emotions, and coping styles as they adapt to social environments[65,66]. The results of this study are consistent with the family risk model, showing that childhood trauma positively predicts negative coping styles. Coping styles play an important role as mediating variables in an individual's

stress process[67-69]. Positive coping styles are conducive to regulating negative emotions when facing difficulty. In contrast, individuals with negative coping styles are more likely to choose to avoid difficulties. The results of this study also showed that negative coping styles positively predict adolescent IA behavior, which is consistent with previous studies[70]. However, IA can lead to additional stressful events, increased mental health problems, and decreased academic performance. Therefore, negative coping styles and IA form a negative cycle. At schools, we should guide adolescents to select positive and healthy coping styles, which are highly important for preventing or reducing adolescent IA.

Chain mediating effect of loneliness and negative coping styles

This study also indicated that loneliness can positively predict negative coping styles, which is consistent with previous studies[39,71]. In addition, we found that loneliness and negative coping style act as chain mediators of the relationship between childhood trauma and IA, supporting hypothesis 4. Adolescents with childhood trauma will inevitably have some negative emotions[72-74]. The coping style selected reflects the emotion regulation strategies of adolescents facing difficulty. Adolescents with negative coping styles tend to internalize their emotions with self-blame and avoidance. Engaging in internet use is a way of venting after trauma. Previous studies have shown that high levels of loneliness and negative coping styles are more likely to produce IA problems[75,76]. Overall, childhood trauma can predict loneliness, and loneliness can predict IA by influencing negative coping styles. Importantly, loneliness and coping styles can be changed. We can formulate intervention measures focusing on alleviating loneliness and cultivating positive coping styles, especially among adolescents with childhood trauma. We can help students enhance their mental health and psychological adjustment, develop a healthier and positive coping style, learn to reduce loneliness, and reduce the occurrence of IA among adolescents.

Limitations

First, this study investigated only six schools in one province, which somewhat reduces the generalizability of the conclusions. A study with a nationally representative sample and a multicenter design is needed. Second, this study used self-report data, which may have some problems, such as recall bias. Although no common method bias was found in this study, more objective assessments should also be considered in subsequent studies. Finally, this study had a cross-sectional design, and further longitudinal studies are needed to investigate causality.

CONCLUSION

This study constructed a chain mediation model from the perspective of adolescents to explore the process and mechanisms by which childhood trauma influences IA. Childhood trauma had a positive predictive effect on adolescent IA, and loneliness and negative coping styles had a chain mediating role in the influence of childhood on IA among adolescents. The path of childhood trauma® loneliness® negative coping styles® IA in adolescents was confirmed. This study provides empirical support and guidance for research and interventions for adolescent IA. In addition, it provides important insights into the mental health of middle school and the development of harmonious school life.

ARTICLE HIGHLIGHTS

Research background

Internet addiction (IA) refers to a compulsive or excessive use of the internet that interferes with daily life activities, relationships, and overall well-being. It is characterized by an individual's inability to control or limit their online behavior, leading to negative consequences.

Research motivation

This study aimed to explore the effect of childhood trauma on adolescent IA and to consider the roles of loneliness and negative coping styles.

Research objectives

The study hypothesized that childhood trauma would be positively associated with adolescent IA, and this relationship would be partially mediated by loneliness and negative coping styles. Negative coping styles refer to maladaptive strategies used to deal with stress, such as avoidance, substance use, and self-blame.

Research methods

This study constructed a chain mediation model from the perspective of adolescents to explore the process and mechanisms by which childhood trauma influences IA. Childhood trauma had a positive predictive effect on adolescent IA, and loneliness and negative coping styles had a chain mediating role in the influence of childhood on IA among adolescents.

Research results

The results showed that childhood trauma was positively associated with both loneliness and negative coping styles. Moreover, loneliness and negative coping styles were found to mediate the relationship between childhood trauma and adolescent IA. The findings suggest the importance of addressing childhood trauma and its subsequent impact on mental health and addictive behaviors.

Research conclusions

This study provides empirical support and guidance for research and interventions for adolescent IA, and it also provides important insights into the mental health of middle school and the development of harmonious school life.

Research perspectives

This study used self-report data, which may have some problems, such as recall bias. Although no common method bias was found in this study, more objective assessments should also be considered in subsequent studies.
