ABOUT COVER

Editorial Board Member of *World Journal of Psychiatry*, Sujita Kumar Kar, MD (Psychiatry), Additional Professor, Department of Psychiatry, King George's Medical University, Lucknow-226003, UP, India. drsujita@gmail.com

AIMS AND SCOPE

The primary aim of *World Journal of Psychiatry* (*WJP*, *World J Psychiatry*) is to provide scholars and readers from various fields of psychiatry with a platform to publish high-quality basic and clinical research articles and communicate their research findings online.

WJP mainly publishes articles reporting research results and findings obtained in the field of psychiatry and covering a wide range of topics including adolescent psychiatry, biological psychiatry, child psychiatry, community psychiatry, ethnopsychology, psychoanalysis, psychosomatic medicine, *etc.*

INDEXING/ABSTRACTING

The *WJP* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Current Contents/Clinical Medicine, Journal Citation Reports/Science Edition, PubMed, PubMed Central, Reference Citation Analysis, China National Knowledge Infrastructure, China Science and Technology Journal Database, and Superstar Journals Database. The 2022 Edition of Journal Citation Reports® cites the 2021 impact factor (IF) for *WJP* as 3.500; IF without journal self cites: 3.313; 5-year IF: 7.380; Journal Citation Indicator: 0.62; Ranking: 89 among 155 journals in psychiatry; and Quartile category: Q3.

Abstract

An important factor in the course of daily medical diagnosis and treatment is understanding patients' emotional states by the caregiver physicians. However, patients usually avoid speaking out their emotions when expressing their somatic symptoms and complaints to their non-psychiatrist doctor. On the other hand, clinicians usually lack the required expertise (or time) and have a deficit in mining various verbal and non-verbal emotional signals of the patients. As a result, in many cases, there is an emotion recognition barrier between the clinician and the patients making all patients seem the same except for their different somatic symptoms. In particular, we aim to identify and combine three major disciplines (psychology, linguistics, and data science) approaches for detecting emotions from verbal communication and propose an integrated solution for emotion recognition support. Such a platform may give emotional guides and indices to

the clinician based on verbal communication at the consultation time.

Key Words: Physician-Patient relations; Emotions; Verbal behavior; Linguistics; Psychology; Data science

Core Tip: In the context of doctor-patient interactions, we focus on patient speech emotion recognition as a multifaceted problem viewed from three main perspectives: Psychology/psychiatry, linguistics, and data science. Reviewing the key elements and approaches within each of these perspectives, and surveying the current literature on them, we recognize the lack of a systematic comprehensive collaboration among the three disciplines. Thus, motivated by the necessity of such multidisciplinary collaboration, we propose an integrated platform for patient emotion recognition, as a collaborative framework towards clinical decision support.

INTRODUCTION

In order to establish a therapeutic relationship between physician and patient, it is necessary to have knowledgeable practitioners in various specialties as well as an effective interaction and communication between physician and patient which starts with obtaining the patient's medical history and continues to convey a treatment plan[1,2]. Doctor-patient communication is a complex interpersonal interaction where different types of expertise and techniques are required to understand this relationship completely in verbal and nonverbal forms, especially when trying to extract emotional states and determinants during a medical consultation session[3]. Doctor-patient communication is a complex interpersonal interaction which requires an understanding of each party's emotional state. In this paper, our focus is on physicians' understanding of patients' emotions. When patients attend medical consultation, they generally convey their particular experiences of the perceived symptoms to physicians. They interpret these somatic sensations in terms of many different factors including their unique personal and contextual circumstances. Motivated by the illness experience, they generate their own ideas and concerns (emotions), leading them to seek out consultation[4-6]. Generally, patients expect and value their doctors caring for these personal aspects of their experience[7,8]. During interactions and conversations with patients, physicians should be able to interpret their emotional states, which can help build up trust between patients and them[9,10]. This will ultimately lead to better clinical outcomes. Also, identifying and recording these states will help complete patients' medical records. Many diseases that seem to have physical symptoms are, in fact, largely intertwined with psychological variables, such as functional somatic syndromes (FSS)[11]. Increasingly, physicians have realized that recognizing the psychological state of patients with FSS will be very effective in providing an appropriate treatment. For example, the ability to accurately understand sound states may help interpret a patient's pain. Thus, the presence of information about patients' mental states in their medical records is essential.

Emotion detection accuracy, *i.e.*, the ability to detect whether a patient is expressing an emotion cue, has consequences for the physician–patient relationship. The key to patient-centered care is the ability to detect, accurately identify, and respond appropriately to the patient's emotions[12-15]. Failure to detect a patient's emotional cues may give rise to an ineffective interaction between doctor and patient, which may, in turn, lead to misdiagnosis, lower recall, mistreatments, and poorer health outcomes[16,17]. Indeed, if the emotion cue is never detected, then the ability to accurately identify or respond to the emotion never comes into play. Doctors who are more aware of their patients' emotions are more successful in treating them[13]. Patients have also reported greater satisfaction with such physicians[18-22]. Recognizing the emotions and feelings of patients provides the ground for more physician empathy with patients[23,24]. The academic and medical literature highlights the positive effects of empathy on patient care[25]. In this regard, the medical profession requires doctors to be both clinically competent and empathetic toward the patients. However, in practice, meeting both needs may be difficult for physicians (especially inexperienced and unskilled ones)[26]. On the other hand, patients do not always overtly express these experiences, feelings, concerns, and ideas. Rather, they often communicate them indirectly through more or less subtle nonverbal or verbal "clues" which nevertheless contain

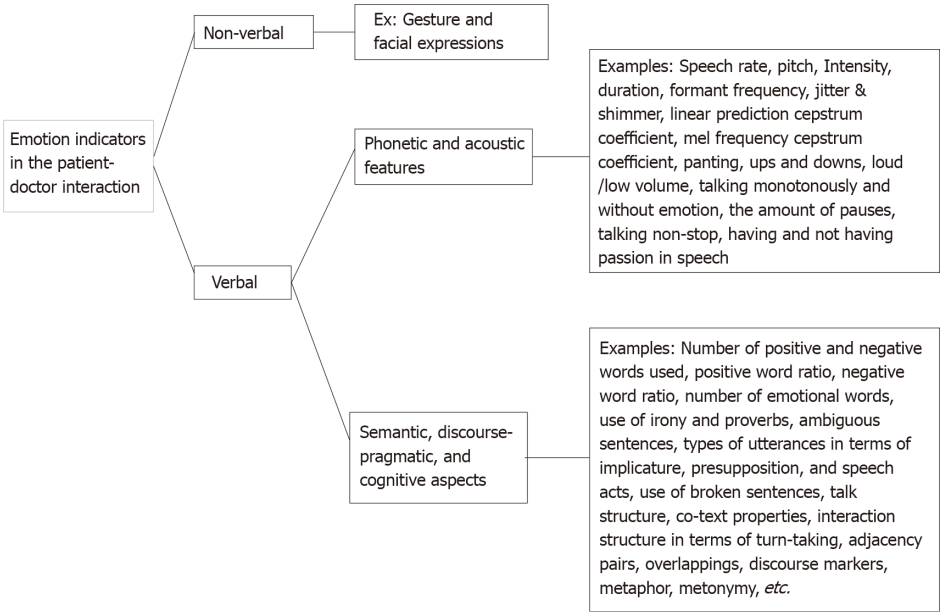
interesting clinical information which can be defined as "clinical or contextual clues"[27-29]**.** They do not say, ‘‘Hey doctor, I’m feeling really emotional right now; or do you know whether I’m angry or sad?’’ Thus, emotional cues are often ambiguous and subtle[30-33].

On the other hand, patients' emotional audiences (*i.e.*, physicians) are often inexperienced in detecting emotions. One of the most important problems physicians face in the development of this process is the difficulty of capturing the clues that patients offer and failing to encourage them to expose details about these feelings[34]. Research indicates that over 70% of patients’ emotional cues are missed by physicians [34]. It is unclear whether missed responses were the result from physicians detecting an emotional cue and choosing not to respond, or from failing to detect the cue in the first place. Indeed, these emotional cues present a challenge to doctors who often overlook them, as clinical information and therefore opportunities to know the patient's world are lost[34-37]. Physicians vary in their ability to recognize patients' emotions, with some being fully aware of the significance of understanding emotions and capable of identifying them. They also range from high emotional intelligence to low emotional intelligence. Another argument often heard from physicians is that they do not have time for empathy [38].

Despite the importance of such issues, this aspect remains grossly overlooked in conventional medical training. This comes from the fact that training emotion skills in medical schools is variable, lacks a strong evidence- base, and often does not include the training of emotion processing[39].

In the preceding paragraphs, four reasons were offered as to why physicians have failed to detect and interpret patients’ emotional states, and hence why we need to find a solution for this problem. These reasons could be summarized as follows. First, detecting patients’ emotions can contribute to healing them, as well as to increasing their satisfaction. Secondly, emotional cues are mostly indirectly found in patients’ speech. That is, emotional cues can be very subtle and ambiguous. Further, many physicians do not possess enough experience to detect patients’ emotions or even when they are skilled and experienced enough to do so, they do not have time to deal with it. In addition, training doctors to detect patients’ emotions has been thoroughly overlooked in routine medical training. Thus, if a solution can be found to help physicians recognize patients' emotions and psychological states, this problem can be overcome to a large extent.

One strategy is to develop and employ a technology that can provide information about the patient’s emotions, feelings, and mental states by processing their verbal and non-verbal indicators (Figure 1). In the present manuscript, we focus on verbal communication. Human speech carries a tremendous number of informative features, which enables listeners to extract a wealth of information about speakers’ identity. These features can range from linguistic characteristics through extralinguistic features to paralinguistic information, such as the speaker’s feelings, attitudes, or psychological states [40]. The psychological states (including emotions, feelings, and affections) embedded in people's speech are among the most important parts of the verbal communication array humans possess. As with other non-verbal cues, they are under conscious control much less than verbal cues. This makes speech an excellent guide to a human’s “true” emotional state even when he/she is trying to hide it.



In order to design and present such technology, the first step is to know which indicators in speech can be used to identify emotions. Psychologists, psychiatrists, and linguists have done extensive research to identify people's emotions and feelings, and have identified a number of indicators. They believe that through these markers, people's emotions and feelings can be understood.

THE PSYCHOLOGICAL APPROACH

Psychologists and psychiatrists pay attention to content indicators and acoustic variables to identify people's emotions through their speech. Scholarly evidence suggests that mental health is associated with specific word use[41-43]. Psychologists and psychiatrists usually consider three types of word usage to identify emotions: (1) Positive and negative emotion words; (2) standard function word categories; and (3) content categories. They distinguish between positive (“happy”, “laugh”) and negative (“sad”, “angry”) emotion words, standard.

Function word categories (*e.g.*, self-references, first, second, and third person pronouns) and various content categories (*e.g.*, religion, death, and occupation). The frequent use of “You” and “I” suggests a different relationship between the speaker and the addressee than that of “We”. The former suggests a more detached approach, whereas the latter expresses a feeling of solidarity. Multiple studies have indicated that the frequent use of the first-person singular is associated with negative affective states[44-48], which reveals a high degree of self-preoccupation[49]. People with negative emotional states (such as sadness or depression) use second and third person pronouns less often[38-40]. These people have a lower ability to express positive emotions and express more negative emotions in their speech[44-48]. Also, people with negative emotional states use more words referring to death[44].

In addition to the content of speech, psychologists and psychiatrists also look at several acoustic variables (such as pitch variety, pause time, speaking rate, and emphasis) to detect emotions. According to the research in this area, people with negative emotional states typically have a slower speaking rate [50-54], lower pitch variety[55,56], produce fewer words[57], and have longer pauses[53,54,58].

Figure 1 Emotion indicators in the patient-doctor interaction.

THE LINGUISTIC APPROACH

Within linguistics, various approaches (*e.g.*, phonetic, semantic, discourse-pragmatic, and cognitive) have been adopted to examine the relationship between language and emotion[56,59,60]. As far as the phonetic and acoustic studies are concerned, emotions can be expressed through speech and are typically accompanied with physiological signals such as muscle activity, blood circulation, heart rate, skin conductivity, and respiration. This will subsequently affect the kinematic properties of the articulators, which in turn will cause altered acoustic characteristics of the produced speech signals of the speakers. Studies of the effects of emotion on the acoustic characteristics of speech have revealed that parameters related to the frequency domain (*e.g.*, average values and ranges of fundamental frequency and formant frequencies), the intensity domain of speech (*e.g.*, energy, amplitude), temporal characteristics of speech (*e.g.*, duration and syllable rate), spectral features Mel frequency cepstral coefficients, and voice quality features (*e.g.*, jitter, shimmer, and harmonics-to-noise-ratio are amongst the most important acoustically measurable parameters for correlates of emotion in speech. For instance, previous studies have reported that the mean and range of fundamental frequency observed for utterances spoken in anger situations were considerably greater than the mean and range for the neutral ones, while the average fundamental frequency for fear was lower than that observed for anger[61] (Figure 2 and Table 1).

Past research has produced many important findings to indicate that emotions can be distinguished by acoustical patterns; however, there are still a multitude of challenges regarding emotional speech research. One of the major obstacles that must be tackled in the domain of emotion recognition relates to variable vocalization which exists within speakers. Voices are often more variable within the same speaker (within-speaker variability) than they are between different speakers and it is thus unclear how human listeners can recognize individual speakers' emotion from their speech despite the tremendous variability that individual voices reveal. Emotion is sensitive to a large degree of variation within a single speaker and is highly affected by factors such as gender, speakers, speaking styles, sentence structure in spoken language, culture, and environment. Thus, identifying what specific mechanisms motivate variability in acoustic properties of emotional speech and how we can overcome differences arising from individual properties remain major challenges ahead of the emotion recognition field.

With regard to investigations in the area of pragmatics (in its continental notion which encompasses discourse analysis, sociolinguistics, cognitive linguistics, and even semantics), we observe a flourishing trend in linguistics focusing on the emotion in language[59,62]. These studies have examined important issues related to referential and non-referential meanings of emotion. In semantics, the focus has been on defining emotional and sentimental words and expressions, collocations and frames of emotion[63,64], field semantics[62], as well as lexical relations including semantic extensions. However, more pragmatic and discourse-oriented studies have looked at issues in terms of emotion and cultural identity[65,66]; information structure/packaging (*e.g.* topicalization and thematicization[67] and emotion, emotive particles and interjections[68-70], emotional implicatures, and emotional illocutionary acts, deixis, and indexicality (*e.g.* proximalization and distalization[71,72], conversational analysis and emotion (*e.g.* turn-taking and interruption)[73,74], *etc.*

Table 1 Acoustic differences related to prosody and spectral features of the word (sahar) produced by a Persian female speaker in neutral and anger situations

	Neutral	Angry
Prosody features		
Mean Fundamental frequency (F0)	200 Hz	225 Hz
Minimum of the fundamental frequency	194 Hz	223 Hz
Maximum of the fundamental frequency	213 Hz	238 Hz
Mean intensity	60 dB	78 dB
Spectral features		
First formant frequency (F1)	853 Hz	686 Hz
Second formant frequency (F2)	2055 Hz	1660 Hz
Third formant frequency (F3)	3148 Hz	2847 Hz
Fourth formant frequency (F4)	4245 Hz	3678 Hz

Cognitive linguists use other methods to recognize emotion in speech. The cognitive linguistic approach to emotion concepts is based on the assumption that conventionalized language used to talk about emotions is a significant tool in discovering the structure and content of emotion concepts[75]. They consider a degree of universality for emotional experience and hold that this partial universality arises from basic image schemas that emerge from fundamental bodily experiences[76-79]. In this regard, the cultural model of emotions is a joint product of (possibly universal) actual human physiology, metonymic conceptualization of actual human physiology, metaphor, and cultural context [77]. In this approach, metaphor and metonymy are used as conceptual tools to describe the content and structure of emotion concepts.

Conceptual metaphors create correspondences between two distinct domains. One of the domains is typically more physical or concrete than the other (which is thus more abstract)[76]. For example, in the Persian expression *gham dar delam* â*shiyâneh kardeh* 'sadness has nested in my heart', *gham* 'sadness' is metaphorically conceptualized as a bird and *del* 'heart/stomach' is conceived of as a nest. The metaphor focuses on the perpetuation of sadness. The benefit of metaphors in the study of emotions is that they can highlight and address various aspects of emotion concepts[75,76]. Metonymy involves a single domain, or concept. Its purpose is to provide mental access to a domain through a part of the same domain (or vice versa) or to a part of a domain through another part in the same domain[80]. Metonymies can express physiological and behavioral aspects of emotions[75]. For example, in *she was scarlet with rage*, the physiological response associated with anger, *i.e.*, redness in face and neck area, metonymically stands for anger. Thus, cognitive linguistics can contribute to the identification of metaphorical and metonymical conceptualizations of emotions in large corpora.

Although speech provides substantial information about the emotional states of speakers, accurate detection of emotions may nevertheless not always be feasible due to challenges that pervade communicative events involving emotions. Variations at semantic, pragmatic, and social-cultural levels present challenges that may hinder accurately identifying emotions *via* linguistic cues. At the semantic level, one limitation seems to be imposed by the "indeterminacy of meaning", a universal property of meaning construction which refers to "situations in which a linguistic unit is underspecified due to its vagueness in meaning"[81]. For example, Persian expressions such as *ye juriam* or *ye hâliam* roughly meaning 'I feel strange or unknown' even in context may not explicitly denote the emotion(s) the speaker intends to convey, and hence underspecify the conceptualizations that are linguistically coded. The other limitation at the semantic level pertains to cross-individual variations in the linguistic categorization of emotions. Individuals differ as to how they linguistically label their emotional experiences. For example, the expression *tu delam qoqâst* 'there is turmoil in my heart' might refer to 'extreme sadness' for one person but might suggest an 'extreme sense of confusion' for another. Individuals also reveal varying degrees of competence in expressing emotions. This latter challenge concerns the use of emotion words, where social categories such as age, gender, ethnic background, education, social class, and profession could influence the ease and skill with which speakers speak of their emotions. Since emotions perform different social functions in different social groups[82], their use is expected to vary across social groups.

Language differences are yet another source of variation in the use and expression of emotions, which presents further challenges to the linguistic identification of emotions. Each language has its own specific words, syntactic structures, and modes of expressions to encode emotions. Further, emotions are linked with cultural models and reflect cultural norms as well as values[83]. Thus, emotion words cannot be taken as culture-free analytical tools or as universal categories for describing emotions[84].

DOI: 10.5498/wjp.v13.i1.1 **Copyright** © The Author(s) 2023.

Figure 2 Spectrograms of the Persian word (sahar) pronounced by a Persian female speaker in neutral (top) and anger (down) situations. Figure 2 shows spectrograms of the word (sahar), spoken by a native female speaker of Persian. The figure illustrates a couple of important differences between acoustic representations of the produced speech sounds. For example, the mean fundamental frequency in anger situations is higher (225 Hz) than that observed for neutral situations (200 Hz). Additionally, acoustic features such as mean formant frequencies (*e.g.* F1, F2, F3, and F4), minimum and maximum of the fundamental frequency, and mean intensity are lower in neutral situations. More details are provided in Table 1.

Patterns of communication vary across and within cultures. The link between communication and culture is provided by a set of shared interpretations which reflect beliefs, norms, values, and social practices of a relatively large group of people[85]. Cultural diversity may pose challenges to doctors and health care practitioners in the course of communicating with patients and detecting their emotions. In a health care setting, self-disclosure is seen as an important (culturally sensitive) characteristic that differentiates patients according to their degree of willingness to tell the doctor/practitioner what they feel, believe, or think[86]. Given the significance of self-disclosure and explicitness in the verbal expression of feelings in health care settings (Robinson, ibid), it could be predicted that patients coming from social groups with more indirect, more implicit, and emotionally self-restrained styles of communication will probably pose challenges to doctors in getting them to speak about their feelings in a detailed and accurate manner. In some ethnic groups, self-disclosure and intimate revelations of personal and social problems to strangers (people outside one's family or social group) may be unacceptable or taboo due to face considerations. Thus, patients belonging to these ethnic groups may adopt avoidance strategies in their communication with the doctor and hide or understate intense feelings. People may also refrain from talking about certain diseases or use circumlocutions due to the taboo or negative overtones associated with them. Further, self-restraint may be regarded as a moral virtue in some social groups, which could set a further obstacle in self-disclosing to the doctor or healthcare practitioner.

Overall, it is seen that these linguistically-oriented studies reveal important aspects of emotion in language use. In particular, they have shown how emotion is expressed and constructed by speakers in discourse. Such studies, however, are not based on multi-modal research to represent a comprehensive and unified description of emotion in language use. This means that, for a more rigorous and fine-

grained investigation, we need an integrative and cross-disciplinary approach to examining emotions in language use.

THE DATA SCIENCE APPROACH

From the data science perspective, speech emotion recognition (SER) is a machine learning (ML) problem whose goal is to classify the speech utterances based on their underlying emotions. This can be viewed from two perspectives: (1) Utterances as sounds with acoustic and spectral features (non-verbal); and (2) Utterances as words with specific semantic properties (verbal)[87-91]. While in the literature, SER typically refers to the former perspective, the latter is also important and provides a rich source of information, which can be harvested in favor of emotion recognition *via* natural language processing (NLP). Recent advances in the NLP technology allow for a fast analysis of text. In particular, word vector representations (also known as word embeddings) are used to embed words in a high dimensional space where words maintain semantic relationships with each other[92]. These vector representations, which are obtained through different ML algorithms, commonly capture the semantic relations between the words by looking into their collocation/co-occurrence in large corpora. In this way, the representation of each word and the machine's understanding of that partially reflect the essential knowledge that relates to that word, thus capturing the so-called frame semantics. The problem of SER can thus be tackled by analyzing the transcript of the speech by running various downstream tasks on the word vectors of the given speech.

As for the former perspective, different classifiers have so far been suggested for SER as candidates for a practically feasible automatic emotion recognition (AER) system. These classifiers can be put broadly into two main categories: Linear classifiers and non-linear classifiers. The main classification techniques/models within these two categories are: (1) Hidden Markov model[93-96]; (2) Gaussian mixture model[97,98]; (3) K-Nearest neighbor[99]; (4) Support vector machine[100,101]; (5) Artificial neural network[94,102]; (6) Bayes classifier[94]; (7) Linear discriminant analysis[103,104]; and (8) Deep neural network[102-107].

A review of the most relevant works within the above techniques has recently been done in[108]. We have provided a short description of the above techniques in Appendix. One of the main approaches in the last category, *i.e.*, deep neural networks, is to employ transfer learning. Recently[109] has reviewed the application of generalizable transfer learning in AER in the existing literature. In particular, it provides an overview of the previously proposed transfer learning methods for speech-based emotion recognition by listing 21 relevant studies.

The classifiers developed for SER may also be categorized in terms of their feature sets. Specifically, there are three main categories of speech features for SER: (1) The prosodic features[110-114]; (2) The excitation source features[110,111,115,116]; and (3) The spectral or vocal tract features[117-120].

Rosodic features, also known as continuous features, are some attributes of the speech sound such as pitch or fundamental frequency and energy. These features can be grouped into the following subcategories[104,105]: (1) Pitch-related features; (2) Formant features; (3) Energy-related features; (4) Timing features; and (5) Articulation features. Excitation source features, which are also referred to as voice quality features, are features which are used to represent glottal activity, such as harshness, breathiness, and tenseness of the speech signal.

Finally, spectral features, also known as segmental or system features, are the characteristics of various sound components generated from different cavities of the vocal tract system that have been extracted in different forms. The particular examples are ordinary linear predictor coefficients[117], one-sided autocorrelation linear predictor coefficients[113], short-time coherence method[114], and least squares modified Yule–Walker equations[115].

Table 2 summarizes the three discussed approaches to recognizing emotional indicators in speech 1.

Given the breadth and complexity of emotion detection indicators in psychology and linguistics, it is difficult to establish a decision support system for a doctor's emotional perception of patients. This requires a comprehensive and multidisciplinary approach. In order to build such a system, an application will be very useful. When a person experiences intense excitement, in addition to a reduction in his/her concentration, his/her mental balance is also disturbed more easily and quickly. This is also used as a strategy in sociology to take hold of people's minds.

Under unstable conditions, reasoning and logical thinking (and thus more effective and active behavior), which emerge in response to the activity of new and higher parts of the brain, are dominated by older parts of the brain, which have more biological precedents (several thousand *vs* millions of years). Thus, these older parts act impulsively or reactively.

Working in an emergency environment and sometimes even in an office has special conditions, such as excessive stress due to medical emergencies, pressure from patient companions, patient's own severe fear, as well as the impact of the phenomenon of "transference" and "countertransference" between physician and patient or between physician and patient companion. These can impair a physician's ability to reason and think logically. Thus, use of such an intelligent system can enhance doctors' efficiency, increase their awareness, and make it easier for them to manage the conditions.

Table 2 Different approaches to recognizing the emotional indicators in speech

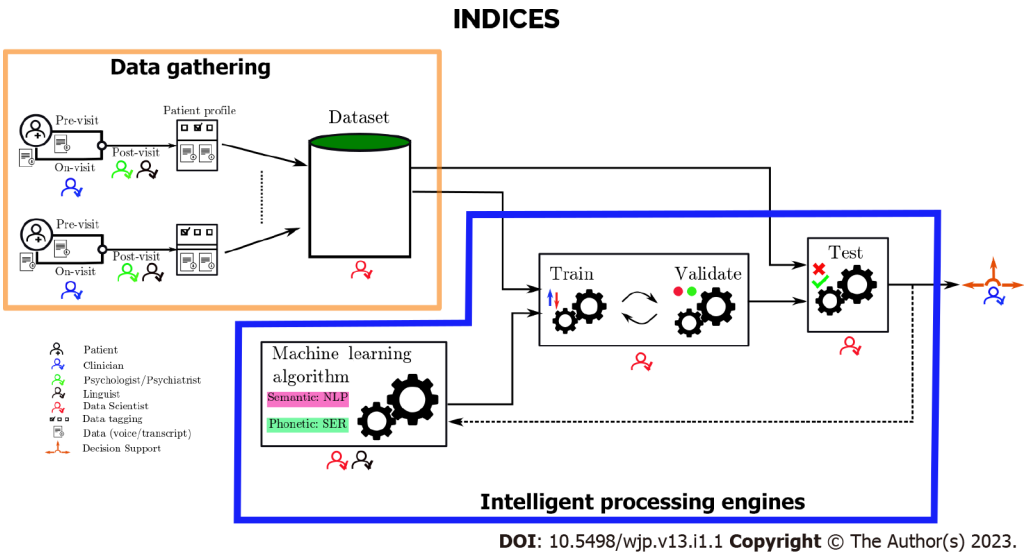
Approaches	Emotional indicators
Psychological	(1) Positive and negative emotion words; (2) Standard function word categories; (3) Content categories; (4) The way of pronoun usage; and (5) Acoustic variables (such as pitch variety, pause time, speaking rate and emphasis)
Linguistic	(1) Phonetic: Spectral analysis, temporal analysis; (2) Semantic & Discourse-pragmatic: Words, field, cultural identity, emotional implicatures, illocutionary acts, deixis and indexicality; and (3) Cognitive: Metaphor, metonymy
Data science	(1) SER: Looking at sounds with acoustic and spectral features; and (2) NLP: Looking at words with specific semantic properties, word embedding

SER: Speech emotion recognition; NLP: Natural language processing.

THE PROPOSED SOLUTION

In the previous sections, the problem of SER was viewed from its three main perspectives: Psychology/psychiatry, linguistics, and data science, and the key elements within each perspective were highlighted. One way to integrate these three sides and benefit from their potential contributions to SER is through developing an intelligent platform. In what follows, focusing on SER in the context of doctor-patient interactions, we propose a solution for such integration.

The proposed solution consists of two key components: (1) The intelligent processing engine; and (2) The data-gathering platform.



The intelligent processing engine, at the algorithmic level, is based on NLP, speech processing, and in a wider context, behavioral signal processing methods. While it is clear that the processing engine will serve as the brain of the proposed intelligent platform, and is indeed a place where the novelty, creativity, and robustness of implemented algorithms can make a great difference, it will not practically function desirably without a well-thought, flexible data-gathering platform. Thus, despite the genuine algorithms which are to be developed at the core of the platform, and the undeniable impact they will have on the performance of the system, we believe it is the data-gathering platform that will make the solution very unique. One idea is to develop a cloud-based multi-mode multi-sided data gathering platform, which has three main sides: (1) The patient side; (2) The physician side; and (3) The linguistic/psychologist side.

Regarding the functioning of the platform, three modes can be considered: (1) The pre-visit mode; (2) The on-visit mode; and (3) The post-visit mode.

The pre-visit mode will include the patient's declaration of his/her health-related complaints/conditions and concerns, which will be automatically directed to the cloud-based processing engine, and labeled *via* a SER algorithm. This mode is reinforced *via* receiving additional multi-dimensional data from the patient through filling various forms and questionnaires. Also, it is possible for the patient to submit text to accompany his/her speech. This allows one to perform additional classification/clustering tasks such as sentiment analysis or patient segmentation on the provided text, using biomedical NLP methods. The on-visit mode enables the recording of the visiting session and the clinician-patient conversations. Finally, the post-visit mode of the application provides an interface for the psychiatrist/psychologist as well as the linguist to extract and label the psychological and linguistic features within the patient's speech. Such tagging of the data by a team of specialists will in the long term lead to a rich repository of patient speech, which is of great value in training the ML algorithms in the processing engine. The proposed platform, which we have named INDICES, is depicted in Figure 3.

Although the proposed platform is to be designed such that it scales up at the population level in order to benefit from the diversity of the gathered data, it will also serve every individual as a customized personalized electronic health record that keeps track of the patient's psycho-emotional profile. As for the implementation of the platform, it is practically possible to tailor it to various devices (cell phones, tablets, PCs, and Laptops) *via* android/macOS, and web service applications

Note that emotion is essentially a multifaceted concept and no matter how sophisticated the proposed signal processing and data mining technology is, it would eventually face limitations in grasping all of its aspects. For instance, cultural aspects of expressing emotions can be a serious challenge to the technological system. Extracting the appropriate measurable features for correctly interpreting the cultural indices of emotion in speech can be a challenge, which nonetheless adds to the beauty of the problem. Further, as mentioned earlier, not all emotional indicators are embedded in the speech. Indeed, facial expressions and body gestures play important roles in expressing one's emotions as well. Hence, since the technology considered in our proposed method is focused merely on speech signals, it will of course have *blind spots* such as the visual aspects of emotion which are not exploited. This can be thought of as a main limitation that bounds the performance of the proposed emotion recognition system. However, with the same pattern that technology has always emerged throughout history, the proposed method can similarly serve as a baseline to which further improvements and additional capabilities can be added in future. We must also note that in capturing the different aspects of emotion, we are faced with

DOI: 10.5498/wjp.v13.i1.1 **Copyright** © The Author(s) 2023.

Figure 3 Integrated platform for patient emotion recognition and decision support. It consists of the data gathering platform and the intelligent processing engines. Each patient's data, in the form of voice/transcripts is captured, labeled, and stored in the dataset. The resulting dataset feeds the machine language training/validation and test engines. The entire process of intelligent processing may iterate several times for further fine tuning. It is crucial to have collaboration among the three relevant expertise in different parts of the proposed solution.

a tradeoff between computational complexity and performance. In particular, depending on the required accuracy of the system, one may need to customize the aspects of emotion which are to be examined *via* technology, taking into account the computational burden they would impose on the system.

We shall finally end this section with two remarks. First, it is important to note that despite all integrations and optimizations involved in the design and training of the proposed intelligent platform, it would still have the intrinsic limitations of a machine as a decision-maker, some of which were mentioned above. Thus, the proposed solution would eventually serve as a decision aid/support (and not as a decision replacement). Secondly, while the proposed solution provides a global framework, it invites for a series of methodologies and solutions, which are to be adapted and customized to each language and culture setting for local use.

APPENDIX

We provide Table 3, which includes a brief description of each of the data science techniques and models mentioned earlier, along with reference sources in which further technical details of the methods can be found.

CONCLUSION

In the context of doctor-patient interactions, this article focused on patient SER as a multidimensional problem viewed from three main aspects: Psychology/psychiatry, linguistics, and data science. We reviewed the key elements and approaches within each of these three perspectives, and surveyed the relevant literature on them. In particular, from the psychological/psychiatric perspective, the emotion indicators in the patient-doctor interaction were highlighted and discussed. In the linguistic approach, the relationship between language and emotion was discussed from phonetic, semantic, discourse-pragmatic, and cognitive perspectives. Finally, in the data science approach, SER was discussed as a ML/signal processing problem. The lack of a systematic comprehensive collaboration among the three discussed disciplines was pointed out. Motivated by the necessity of such multidisciplinary collaboration, we proposed a platform named indices: An integrated platform for patient emotion recognition and decision support. The proposed solution can serve as a collaborative framework towards clinical decision support.

Table 3 A brief description of some data science models/methods

Method/Model	Short description	Ref.
HMM	A HMM is a statistical model that can be used to describe the evolution of observable events that depend on internal factors, which are not directly observable. The observed event is called a 'symbol' and the invisible factor underlying the observation is called a 'state'. A HMM consists of two stochastic processes, namely, an invisible process of hidden states and a visible process of observable symbols. The hidden states form a Markov chain and the probability distribution of the observed symbol depend on the underlying stateVia this model, the observations are modeled in two layers: One visible and the other invisible. Thus, it is useful in classification problems where raw observations are to be put into a number of categories that are more meaningful to us (Supplementary Figure 1)	[121, 122]
Gaussian mixture model	A Gaussian mixture model is a probabilistic model that assumes all data points are generated from a mixture of a finite number of Gaussian distributions with unknown parameters (Supplementary Figure 2)	[123]
KNN	KNN is a type of supervised learning algorithm used for classification. KNN tries to predict the correct class for the test data by calculating the distance between the test data and all training points. The algorithm then selects the K number of points which are closest to the test data. The KNN algorithm calculates the probability of the test data belonging to the classes of 'K' training data where the class that holds the highest probability (by majority voting) will be selected (Supplementary Figure 3)	[123]
SVM	The SVM is an algorithm that finds a hyperplane in an N-dimensional space (N: The number of features) that distinctly classifies the data points in a way that the plane has the maximum margin, *i.e.*, the maximum distance between data points of the two classes. Maximizing this margin distance would allow the future test points to be classified more accurately. Support vectors are data points that are closer to the hyperplane and influence the position as well as orientation of the hyperplane (Supplementary Figure 4)	[123]
Artificial neural network	An artificial neural network is a network of interconnected artificial neurons. An artificial neuron which is inspired by the actual neuron is modeled with inputs which are multiplied by weights, and then passed to a mathematical function which determines the activation of the neuron. The neurons in a neural network are grouped into layers. There are three main types of layers: – Input Layer – Hidden Layer(s) – Output Layer. Depending on the architecture of the network, outputs of some neurons are carried along with certain weights as inputs to some other neurons. By passing an input through these layers, the neural network finally outputs a value (discrete or continuous) which can be used to perform various classification/regression tasks. In this context, the neural network first has to learn the set of weights *via* the patterns within the so called training dataset, which is a sufficiently large set of input data labeled with their corresponding correct (expected) output (Supplementary Figure 5)	[124]
Bayes classifier	Bayes classifier, which is based on Bayes' theorem in probability, models the probabilistic relationships between the feature set and the class variable. Based on the modeled relationships, it estimates the class membership probability of the unseen example, in such a way that it minimizes the probability of misclassification	[123]
Linear discriminant analysis	Linear discriminant analysis is a method used in statistical machine learning, to find a linear combination of features that characterizes or separates two or more classes of objects or events. The resulting linear combination can be used as a linear classifier, or, as a means to dimension reduction prior to the actual classification task	[124]

HMM: Hidden markov model; KNN: K-nearest neighbor; SVM: Support vector machine.

Abstract

BACKGROUND

Recommendations for psychotherapy have evolved over the years, with cognitive behavioral therapy (CBT) taking precedence since its inception within clinical guidelines in the United Kingdom and United States. The use of CBT for severe mental illness is now more common globally.

AIM

To investigate the feasibility and acceptability of a culturally adapted, CBT-based, third-wave therapy manual using the Comprehend, Cope, and Connect approach with individuals from a diverse population presenting to primary and secondary healthcare services.

METHODS

A pilot study was used to assess the feasibility and acceptability of the manualised intervention. Outcome measures were evaluated at baseline, post-intervention and 12 wk-follow up. 32 participants with mental health conditions aged 20-53 years were recruited. Assessments were completed at three time points, using Clinical Outcomes in Routine Evaluation (CORE), Hospital Anxiety and Depression Scale (HADS), Bradford Somatic Inventory and World Health Organization Disability Assessment Schedule 2.0 (WHODAS). The Patient Experience Questionnaire was completed post-treatment.

RESULTS

Repeated measures of analysis of variance associated with HADS depression, F (2, 36) = 12.81, P < 0.001, partial η^2 = 0.42 and HADS anxiety scores, F (2, 26) = 9.93, P < 0.001, partial η^2 = 0.36; CORE total score and WHODAS both showed significant effect F (1.25, 18.72) = 14.98, P < 0.001, partial η^2 = 0.5. and F (1.29, 14.18) = 6.73, P < 0.001, partial η^2 = 0.38 respectively.

CONCLUSION

These results indicate the effectiveness and acceptability of the culturally adapted, CBT-based, third-wave therapy manual intervention among minoritized groups with moderate effect sizes. Satisfaction levels and acceptability were highly rated. The viability and cost-effectiveness of this approach should be explored further to support universal implementation across healthcare systems.

Key Words: Cognitive behavioral therapy; Comprehend; Cope; Connect; Ethnicity; Culture

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: This study explores the relevance of a cultural cognitive behavioral therapy manual to manage mental health and wellbeing in primary and secondary care settings in the United Kingdom. Specificity and adaptability are key to demonstrating the relevance as well as the cost-effectiveness of mental health management approaches. Results show the effectiveness of the proposed intervention, with high levels of acceptability and participant satisfaction.

INTRODUCTION

Cognitive behavioral therapy (CBT) was developed by Beck *et al*[1] with the aim of reducing cognitive biases and dysfunctional behaviors in order to alleviate symptoms of psychopathology. CBT was developed in an ethnocentric environment however, recent research has enabled adaptations to be made to CBT in various aspects[2]. Changes to treatment goals, assigned homework, and types of coping mechanisms taught are some of the adjustments that have been made to this intervention to make it more applicable to different psychological conditions[3,4]. Currently, adaptations to CBT to ensure relevancy and accessibility to ethnic minority groups are also being implemented such as introducing family involvement, use of appropriate language terms, and developed understanding of psychopathology from a culture viewpoint[5,6]. Social constructs and determinants play a vital role in the psychotherapies developed, driven by varying cultural factors of those within developed country-based populations. This is often identified with dysfunctions such as inadequate health policies, transparency in healthcare access and accountability mechanisms, and democratic deficits of global governance systems due to persistent global political determinants of health that have a negative impact. As such, the inclination for cultural factors and sociological constructs to influence the delivery of evidence-based therapeutics would be a logical consensus.

Few CBT adaptations employ surface changes to the intervention, which involve general and practical adaptations, such as increased awareness of cultural issues, aligning therapy with public service messages, or translating materials[7-9]. Most studies used cognitive behavioral strategies and included a variety of ethnic minority samples[6,10-15]. These studies also found that culture-specific values related to interpersonal relationships, family, and spirituality could play a significant role when providing therapy to culturally diverse patients[6,12,13,16]. Specifically, treatments that carefully accommodated cultural values resulted in improved outcomes, especially when adaptions ensured that therapy was problem-focused and direct, supports arguments that culturally diverse individuals may struggle with open-ended and non-directive therapy[17-20].

The implementation of Improving Access to Psychological Therapies (IAPT) initiatives within the United Kingdom increased the development and delivery of psychology treatments for depression and anxiety to be jointly provided with primary care services[21]. IAPT services operate through a 5-stage model, which enable adequate adjustments to be made to ensure beneficial treatment outcomes[22]. Minority ethnic groups face difficulties with accessing mental health services and it is common for them to have unfavorable experiences[23]. Hence, IAPT implemented the BAME Service User Positive Practice Guide which outlines core elements needed in IAPT service provision in order for ethnic minority groups to receive equitable treatments and outcomes[24]. One change currently active within IAPT services is ability to self-referral, removing to obstacle of organizational discrimination for many groups[24]. This has seen an increase in recovery rates from 43.8% to 50% among Black and Asian populations between Quarter 4 2015/16 and Quarter 1 2021/22 data[25]. This being said, there is still a huge gap in culturally-accommodating interventions within IAPT service provision.

Interestingly, National Health Service (NHS) Digital reported that the service users of IAPT were primarily Caucasian patients (78.2%) while only 16.4% were from ethnic minority background[26]. This may indicate a lack of acceptability of IAPT treatments in their current form and it could be argued that the accessibility of IAPT services to diverse populations may still be limited. Although these initial findings have highlighted the need for adaptation of therapy for patients from diverse ethnic minority backgrounds, concerns around the adaptation of CBT for every ethnic group have been raised from a pragmatic perspective, due to limitations within scalability and sustainability[27]. In the past few years, there has been a huge shift towards personalised mental health care services, highlighting the need to consider the individual and any interplaying factors when implementing services[27,28]. Culture is an entity which has significant effects on the psychopathology and help-seeking behavious of individuals hence should be accounted for when implementing interventions[6]. It is common for interventions and assessment tools to be translated to endless languages[29,30], and adaptations in accordance to culture should be accepted on the same terms. This being said, the translatability of interventions to other languages raises socio-economical issues for healthcare systems and policymakers alike yet, not considering translatability could exacerbate health inequality concerns and the same goes for adaptations to cultures. For these reasons, the authors developed a therapy manual that uses a generic third-wave approach, taking into consideration the above factors as well as sensitive forms of therapy in recognition of cultural bias in psychological therapies[15,23,31-35]. CBT and Comprehend, Cope, and Connect (CCC) interventions can be adapted to treat various psychological illnesses but there is also scope for these treatments to be adjusted in accordance to culture[36]. CCC has been chosen due to its universal applicability to levels of processing as it does not require specific adaptation for different ethnicities[37], and indeed the current study included individuals from African, Caribbean, South Asian, and Chinese backgrounds among others. Many Western therapies were developed through an individualistic approach but CCC lends itself to involving family and significant others within the intervention, incorporating aspects of mindfulness, spirituality, and faith. Third-wave approaches to CBT moved the focus towards interpersonal impacts on psychopathology and treatments such as relationships, values, acceptance, and beliefs[38]. Acceptance of different faiths and beliefs are equally important to ensure clinically optimal, yet culturally sensitive diagnostic and treatment approaches are rendered to all patients. Previous literature reports on the increased efficacy of third wave treatments, such as mindfulness-based cognitive therapy or acceptance and commitment therapy, compared with standard interventions across all populations and this paper aims to add to current understandings[39-41].

CCC is a third-wave cognitive behavioral approach based on a collaboratively arrived at, emotion focused, strengths based and trauma informed formulation that leads naturally to the identification of vicious cycles. It is evident at this stage that breaking the cycles is necessary, and skills such as mindfulness, arousal management and emotion management, as well as behavior change are identified and encouraged[42]. The development of the culturally adapted CBT based third-wave CCC manual offers high replicability of this study and the potential for a larger sample and introduction of a control group for comparison. High feasibility for further research using this manualized therapy is also indicated by the good recovery and retention rates, as well as positive patient experience questionnaire (PEQ) scores, which significantly indicated high levels of satisfaction and experience.

MATERIALS AND METHODS

Study design

An uncontrolled pilot study was conducted to explore the feasibility, acceptability, and effectiveness of culturally adapted, a third-wave based cognitive behavioral approach using CCC as a therapeutic intervention for patients with common mental disorders and emotional problems. The study was conducted within IAPT and secondary adult mental health services at an NHS Foundation Trust in the United Kingdom as CCC training has been implemented across both services.

Recruitment of participants

The recruitment of participants was through Community Mental Health Team (CMHT) services and IAPT's iTalk service at NHS Trust. The study was advertised through posters in CMHT and iTalk services. Recruiting participants for this study was difficult despite inclusion across both IAPT and CMHT services.

Potential participants could also contact the study therapist if they were interested in taking part. All potential participants were screened for eligibility before joining the study to ensure they met the inclusion criteria. Permission to approach potential participants was obtained from the treating clinicians. Participants who agreed to be approached were contacted and provided with an ethically approved participant information sheet. The researcher met participants in person to discuss the study in detail and obtain informed consent if interested in taking part. Participants were given a minimum of 48 h to decide if they would like to participate in the study. All participants who consented were informed that they could withdraw from the study at any time.

Eligibility

Participants with moderate to severe mental health problems were identified from IAPT services and secondary care services within the NHS Trust. Our target population was adult patients, aged 18 years and above, with moderate to severe mental illness as confirmed by specialist psychiatric services and documented in the electronic health records (F32: Depressive episode; F20: Schizophrenia; F41.1: Generalised anxiety disorder; F40.1: Social phobia; F43.1: Post-traumatic stress disorder; F42: Obsessive-compulsive disorder; F41.8: Mixed depression and anxiety). All patients from ethnic minority backgrounds were included following written informed consent. However, participants with an organic illness or a primary diagnosis of substance misuse and those experiencing acute psychotic symptoms were excluded from the study. Overall, 32 participants met the inclusion criteria and consented to take part in the study (Figure 1).

Ethics statement

The study was approved by the Health Research Authority London-Camden & Kings Cross Research Ethics Committee, reference number: 16/LO/1899.

Intervention

In terms of simultaneous interventions, CMHT patients were provided this intervention alongside standard treatment whilst IAPT patients were offered the adapted intervention. The CCC intervention was first evaluated within Acute Mental Health services[39-41] and developed for delivery in primary care IAPT services for complex cases[43]. Within primary care, the programme consisted of four individual sessions in which the collaborative emotion and trauma-focused formulation is agreed followed by a 12-wk group and skills-based interventions targeting emotion management and behaviour change (Tables 1 and 2). One or two review sessions concluded the programme. The CCC manual was culturally adapted by the authors using the cultural adaptation framework published elsewhere[23]. A full account of the intervention outlining the theory and applicability of CCC is published elsewhere[44]. Although this is aside from the focus of this study, research on acute services and CCC has also been published[43].

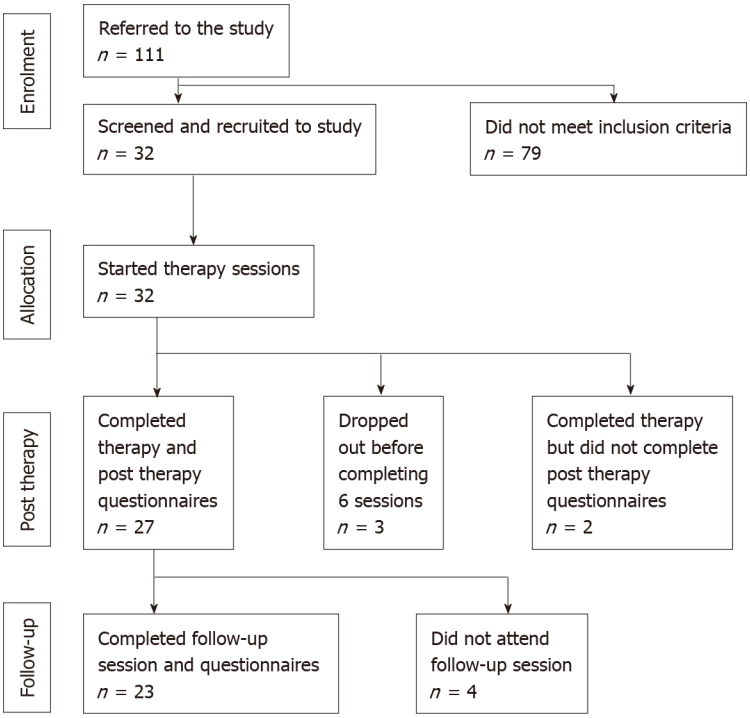
The adaptation facilitated the inclusion of family members and careers to be involved in the therapy; allowed for the somatic conceptualisation of emotional issues and teaching stories Spirituality and religion, where relevant, are integral to all versions of CCC. The manual developed this aspect further to meet the needs of a diverse population. In many ethnic minority cultures, the family is the nucleus within households and communities, so incorporating this core value with ensure more efficacious treatment outcomes. Families are able to provide support within therapy sessions, at home with homework tasks, but also within the wider community promoting positive outcomes for the patient and acceptance of such interventions and services in the wider community[12,14]. Similarly, ethnic minority groups hold various spiritual and religious values which greatly impact understanding of psychopathology and influence help-seeking behaviors[6,45-48]. It is important to understand these elements as they greatly impact values and beliefs, and these are the concepts of wellness explored within therapy[37]. Culturally-adapted CCC used in the current study is an abridged version of standard CCC offered in IAPT therapy at the moment.

Table 1 Comprehend, Cope, and Connect schedule of sessions

Session no	Activity
1-4	Listening; introducing the states of mind; introducing mindfulness and/or breathing
	Collaboratively creating the formulation diagram
	Negotiating goals for therapy based on what is needed to break the vicious circles
	Sharing the draft compassionate summing up letter and looking forward to what to work on through the group programme
5-12	Goals based interventions aimed at breaking the cycles. Mindfulness is the core intervention, and the following are employed as indicated by the formulation
	Arousal management, including relaxation breathing and lifestyle adjustment to reduce chronic stress
	Behavioural activation
	Emotion management includes facing, expressing and letting go of emotion self-compassion
	Aspects of self; mindfulness managed subpersonality work. Relationship management including assertiveness building a new relationship with the past
	Follow-up at 12 wk post-therapy

Table 2 Principal interventions post formulation

Intervention
Mindfulness is the core intervention; it informs the application of the others
Arousal management (relaxation breathing *etc*.)
Behavioral activation
Facing, expressing and letting go of emotion
Self-compassion
Positive anger work
Aspects of self (mindfulness managed subpersonality work)
Relationship management including assertiveness
Building a new relationship with the past



A collaborative and compassionate conceptualisation was completed within the first four sessions (Figure 2). The process starts with open-minded listening and starts with the individual's internal state and how this has been affected by recent circumstances and past adversities. The impact of the past on the present is explained. Strengths, potential values, faith, or spiritual connections are identified before the vicious cycle, representing the current management of the internal state, are tracked. Finally, a compassionate letter summing up the formulation is shared, and the intervention phase of the therapy comprises new skills to break the vicious cycles.

Modifications to the manual

Refining the manual was a key aim of the study in light of new learning arising from the challenges that emerged during therapy delivery. Adherence to the manual was monitored by an independent experienced clinician, where key cultural issues were identified and addressed accordingly. Adaptations followed the cultural adaptation framework already published elsewhere[6]. Some of the modifications included the following: (1) Allowing somatic conceptualisation of emotional challenges; (2) Managing faith issues where this impacts mental health; (3) Managing the balance between family and system expectations of the individual and their own needs; and (4) Cultural differences in attitudes to assertiveness and anger.

Outcome measures

Use of clinical outcome measures varies across primary, secondary and tertiary services. The measures used in this study were not adapted to diverse communities. This is acknowledged in the discussion section under limitations. IAPT participants in the current study also completed standard IAPT measures as this was a service requirement. The study specific outcome measures are listed below:

Socio-demographic measures: A case report form was developed and used to collect this information from the participants. This included the following variables: Date of birth, gender, primary diagnosis, ethnicity, education, and employment history.

Hospital Anxiety and Depression scale: Hospital Anxiety and Depression Scale (HADS) is a 14-item self-report measure of anxiety and depression. It is scored on a 4-point Likert scale. It has good internal consistency[47,48] and good concurrent validity[49].This measure was designed for a nonclinical population but has recently been validated for a mental health population and the reliability estimates have shown that the Cronbach's alpha for HADS (all items), HADS-Anxiety subscale (HADS-A) and HADS-Depression subscale (HADS-D) was 0.91, 0.90 and 0.80 respectively[45,47].

The Bradford Somatic Inventory: Bradford Somatic Inventory (BSI) is used to measure somatic symptoms. It has 45 items[50]. Scores above 21 indicate depression. It was developed from symptom reports by psychiatric patients in Pakistan and Britain with clinical diagnoses of common mental health problems. The BSI enquires about a wide range of somatic symptoms during the previous month, and if the subject has experienced a particular symptom, whether the symptom has occurred on more or less than 15 d during the month (scoring 2 or 1, respectively).

World Health Organization Disability Assessment Schedule 2.0: World Health Organization (WHO) Disability Assessment Schedule 2.0 (WHODAS) was developed by the WHO to measure disability due to physical and psychological problems and has been used extensively in research[51]. The scale covers 6 domains of functioning, including cognition, mobility, self-care, getting along, life activities, and participation. Responses are on a Likert scale of 0-4.

Clinical outcomes in Routine Evaluation: Clinical outcomes in Routine Evaluation (CORE) is a self-report questionnaire designed to be administered before and after therapy[52]. The participants were asked to respond to 34 questions about how they have been feeling over the last week, using a 5-point scale ranging from 'not at all' to 'most or all of the time'. The 34 items of the measure cover four dimensions: (1) Subjective well-being; (2) Problems/symptoms; (3) Life functioning; and (4) Risk/harm. The responses are designed to be averaged by the practitioner to produce a mean score to indicate the level of current psychological global distress (from 'healthy' to 'severe').

PEQ: Participant therapy satisfaction will be measured using the post-treatment PEQ, an 11-item self-administrated questionnaire[53]. Items 1-10 ask respondents to indicate whether their needs were met using either a two-point scale (1 being yes and 2 being no) or a five-point scale (ranging from 0 = 'not satisfied' to 5 = 'very satisfied with services'). Item 11 will capture qualitative data with any recommendations for improvement.

Statistical analysis

Frequency and descriptive commands were used to measure descriptive statistics, and an explore command was utilised to measure the normality of the data, using histograms and the Kolmorogov-Smirnov test. For each questionnaire score, an analysis of variance (ANOVA) and analysis of covariance (ANCOVA) were used. Factors used for the covariates included age, gender, diagnosis, psychiatric medication, living with someone or alone, ethnic group, having higher education or not having a partner or not, duration of mental illness, being under care of a CMHT or IAPT, history of the previous admission, use of additional services and employment status. However, because of the small sample size, these were individually entered into the analysis.

PEQ measured patient satisfaction with the intervention. It had an ordinal structure, with some items having three or more levels and others having only two levels. A correlation was carried out between PEQ and other outcome scales to investigate whether satisfaction with the intervention was related to other outcomes. Kendal's Tau was calculated where PEQ items had three or more levels, and Sommer's D was calculated where PEQ items had two levels. The statistical package IBM SPSS v20 was used to analyse the data.

RESULTS

Overall characteristics of participants

Demographic data was collected and coded between 29th March 2017 and 4th September 2019. A total of 32 participants (n = 27) female were included in the final sample. Nine participants were from Back African, Black Caribbean and Black Other ethnic groups. Thirteen participants were from either Indian, Bangladeshi, Chinese or Other Asian groups. Ten participants were from Other/Mixed groups. Baseline demographic characteristics are detailed in Table 3. It is worth noting that most participants in this study presented with a high proportion of such complexity and history of trauma (Table 4).

ANOVA results

Change in HADS depression using repeated measures ANOVA: HADS depression score was significantly different when all three time points were compared simultaneously: F (2, 36) = 12.81, P < 0.001, partial eta squared = 0.42 (Figure 3A). However, Bonferroni-adjusted pairwise comparisons

Table 3 Demographic characteristics

Characteristics	Total sample, (*n* = 32)
Gender (*n*, %)	
Male	5 (16)

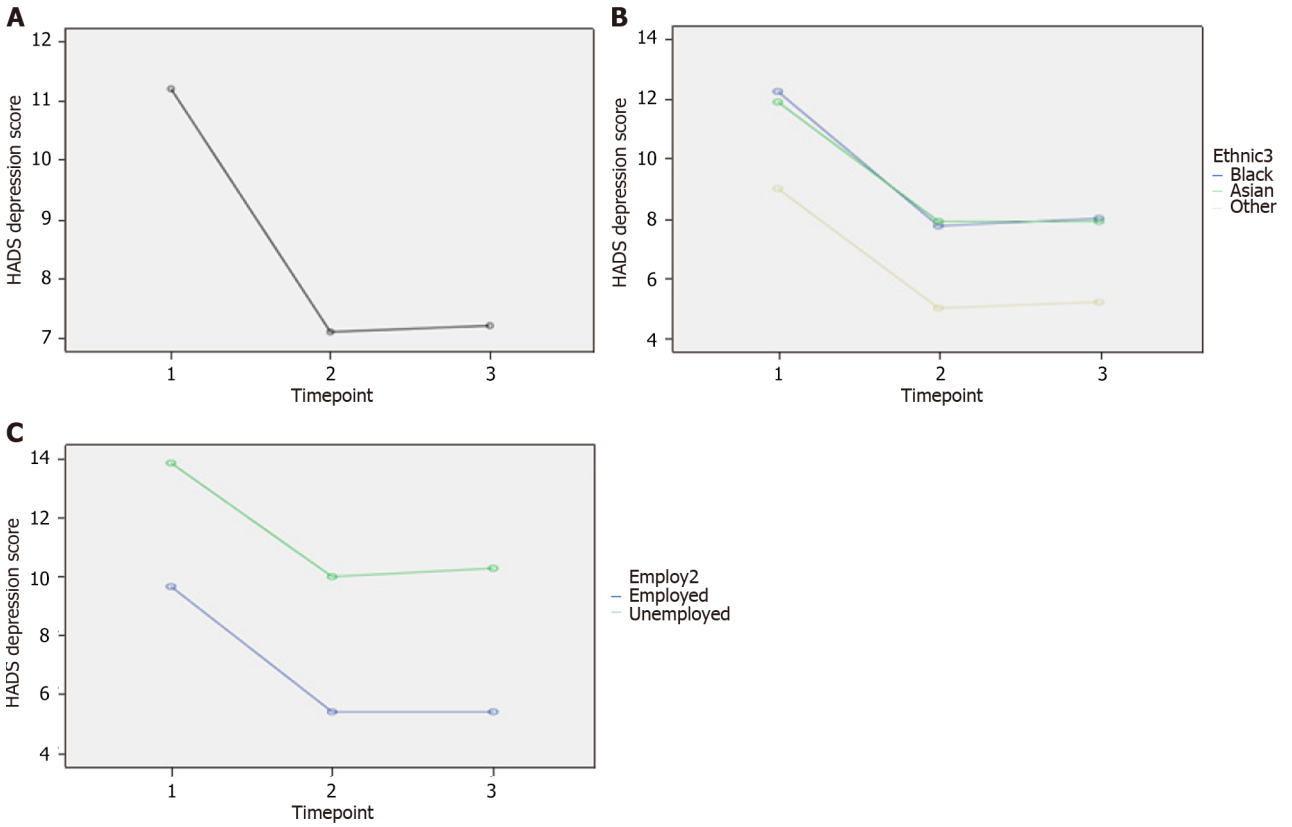
showed that HADS depression significantly reduced from baseline to post-treatment and baseline to follow-up, but there was no significant difference between posttreatment and follow-up (Table 5). This meant that there was a benefit at post-treatment and that the benefit was maintained at follow-up.

No difference between ethnic groups meant that the intervention showed similar effect in the groups (Figure 3B). However, the effect of employment status as a covariate on HADS depression was significant: F (1, 17) = 9.73, P = 0.006, eta squared = 0.36 (Figure 3C). Employed people showed lower HADS depression mean scores at all three time points. Interaction of employment with timepoint was not significant.

Table 4 Presentation information and strategies used



Participant	Earlier life experiences (traumatic context)	Presenting problem and impact of past	Specific CCC coping, strategies in addition to mindfulness
1	Childhood abuse (by a close family member), age 4 yr, and neglect; judgmental mother - unrealistic academic expectations	Acquiring physical disability (fibromyalgia and chronic pain), triggers sadness, anger, shame and anxiety, and feeling useless	Building a new relationship with the past: Self compassion
2	Childhood abuse. Domestic violence from partners	Anger and cannot cope when feeling unsupported, let down in the present. Unassertiveness	Building a new relationship with the past: Self-compassion; positive; anger work
3	Over-looked academically as a girl; sense of injustice. Sexual abuse by older brother told not to tell (approx 7 years old) told mother, who blamed and chastised her for the act	Unacknowledged in current family leading to disproportionate depression and anger	Emotion management; selfcom-passion
4	Punishing and neglectful mother. Anxious childhood	Inability to deal with emotions. Avoidant of relationships	Self-compassion; emotion management
5	Childhood trauma. Father nearly died in car crash when 9 years old. Family preoccupied with impact on sibling	Obsessional thoughts regarding harm to daughter. Avoidance	Arousal management; aspects of self[1]; self compassion
6	Extreme childhood fear engendered by tales of black magic	Post-natal fears for safety of son. High anxiety. Compensates with controlling pre-emptive and perfectionist behaviors	Arousal management; building a new relationship with the past; emotion management
7	Neglectful and chaotic childhood. Alcoholic father	Avoidance of emotion leading to constant activity and chronic stress. Alcohol	Arousal management; emotion management
8	Multiple deaths of family members coming close together	Obsessive health anxiety	Arousal management; self-compassion; relationship management[2]
9	Shamed within family as teen for (culturally unacceptable) homosexuality. Physical and emotional abuse by mother. Father left when 3 years old	Envy, anger, relationship and career difficulties. Loneliness copes with perfectionist ideas but behavioral inactivity (fear of failure)	Emotion management; relationship management[2]
10	Sister preferred. Sexual abuse by ex-partner. Experienced racism at work	Low self-esteem. Perfectionism leading to high stress	Positive anger work; aspects of self; relationship management
11	Childhood trauma - mother left. Sex abuse by a parent at 12 yr. Abusive childhood. Adult trauma - loss of daughter in a road traffic accident. Impact of road traffic accident - reduced memory, increased emotionality and impulse control	Flashbacks. Dissociation. Low self-esteem. Problems with emotions and relationships	Building a new relationship with the past; emotion management; relationship management[2]
12	Childhood trauma - loving family, experienced war conflict while in Turkey during Kurdish and Turkish conflict - witnessed village members being tortured by soldiers. 'Reported seeing 'Jinns', dead bodies and evil spirits' - hallucinations? Adult trauma - illegal immigrant for 14 yr - experienced extreme anxiety and feeling under attack from others	Panic, hypervigilance, avoidance of crowds and exercise	Arousal management; emotion management
13	Mental, physical and sexual abuse	Avoidance of emotion. Avoidance of intimacy	Building a new relationship with the past; relationship management[2]; emotion management; aspects of self[1]
14	Childhood sexual abuse by a parent between 5 to 12 yr. Experienced 13 yr of mental and physical abuse from husband	Emotionally overwhelmed. Withdrawal and unmotivated, or dysregulated anger	Arousal management; relationship management; self-compassion
15	Emotionally abusing and criticising childhood	Dissociation. Emotional overwhelm and relationship difficulties	Positive anger work; emotion management;self-compassion
16	Migration age 19 yr of age; hostile in-laws. Major health difficulties severely impact marriage	Suicidal and self-harm. Low mood	Arousal management; relationship management; self compassion[2]
17	Unhappy childhood; migration distress. Breast cancer	Obsessive anger at neighbours leading to conflict	Arousal management positive anger work; emotion management
18	Diagnosed with Autism. Early childhood developmental problems	Social avoidance	Arousal management; behavioral activation;

			relationship management[2]
19	Ran away from home age 11 yr. 'Kicked out' of family home at the age of 19 yr. Loss of young sibling and felt excluded	Suicidal. Avoidant of emotion	Building a new relationship with the past; self compassion; emotion management
20	Long exploitative and abusive marriage plus racial bullying at work	Stress, chronic hypertension. Relationship difficulties	Arousal management; emotion management; positive anger work; aspects of self[1]

[1]Aspects of self is mindfulness managed subpersonality work.

[2]Relationship management includes assertiveness.

Mindfulness is the core intervention; it informs the application of the others. Arousal management includes relaxation breathing and lifestyle adjustment emotion management includes facing, expressing and letting go of emotion. CCC: Comprehend, Cope, and Connect.

Figure 3 Hospital Anxiety and Depression Scale Scores. A: Hospital Anxiety and Depression Scale (HADS)-depression scores; B: HADS-depression scores by ethnic groups; C: HADS-depression scores by employment states. HADS: Hospital Anxiety and Depression Scale.

Change in HADS anxiety using repeated measures ANOVA: HADS anxiety score was significantly different when all three time points were compared simultaneously: F (2, 36) = 9.93, $P < 0.001$, partial eta squared = 0.36 (Figure 4). However, Bonferroni-adjusted pairwise comparisons showed that HADS anxiety significantly reduced from baseline to post-treatment and baseline to follow-up, but there was no significant difference between post-treatment and follow-up (Table 5). This meant that there was a benefit at post-treatment and that the benefit was maintained at follow-up.

Change in WHO disability scale using repeated measures ANOVA: WHO disability scale was significantly different when all three time points were compared simultaneously: F (1.29, 14.18) = 6.73, $P < 0.016$, partial eta squared = 0.38 (Figure 5A). However, Bonferroni-adjusted pairwise comparisons showed that the WHO disability scale significantly reduced from baseline to post-treatment and baseline to follow-up, but there was no significant difference between post-treatment and follow-up (Table 5). This meant that there was a benefit at post-treatment and that the benefit was maintained at follow-up. However, the effect of living alone as covariate on WHO disability scale was significant: F (1, 10) = 8.99, $P = 0.013$, eta squared = 0.47 (Figure 5B). Those who were living alone had higher mean score at all three times. Interaction of living with timepoint was not significant. In addition, the effect of

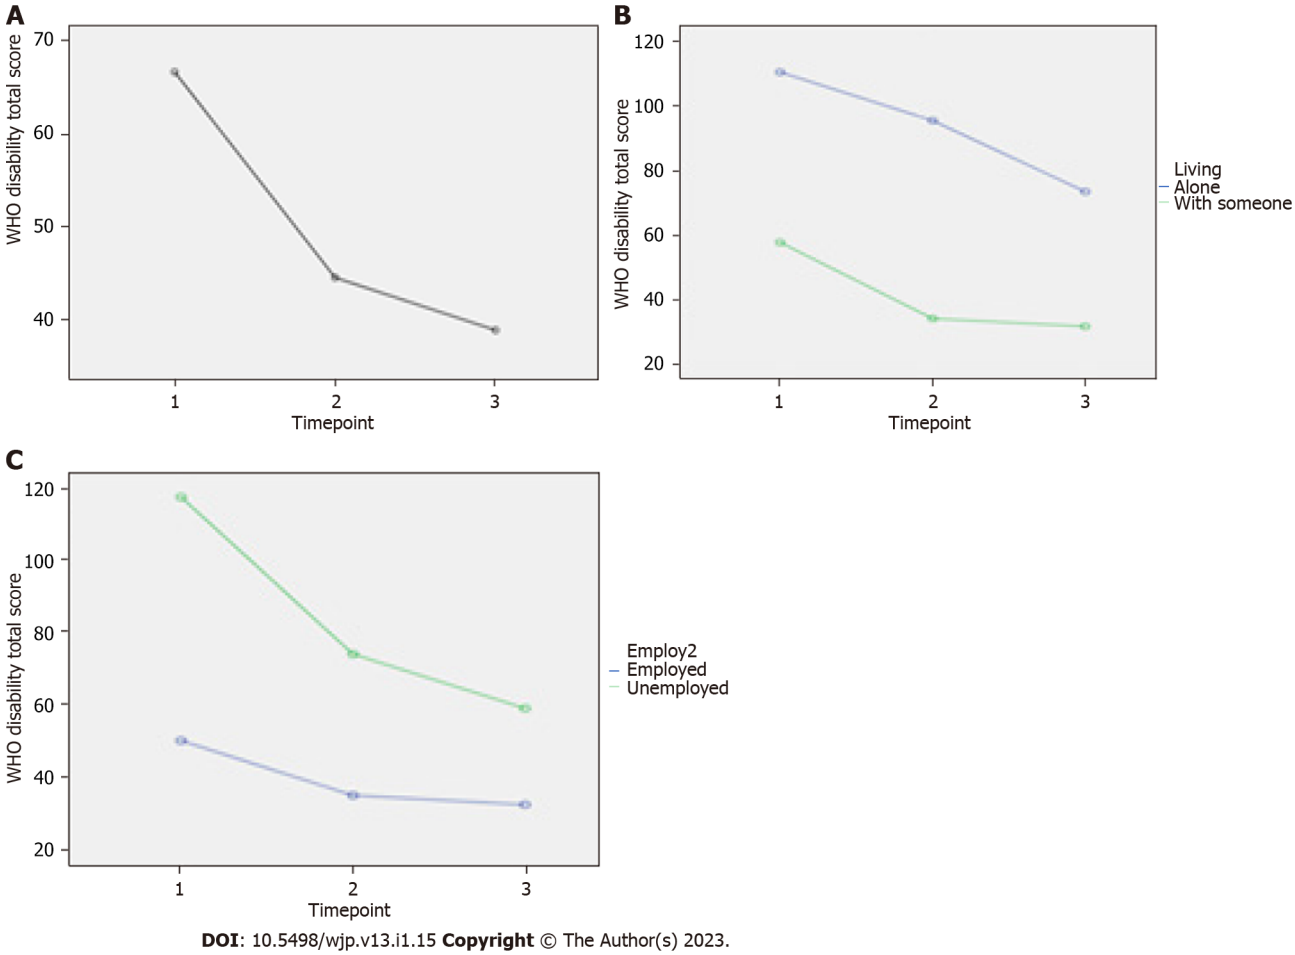
Figure 4 Hospital Anxiety and Depression Scale Anxiety Scores. HADS: Hospital Anxiety and Depression Scale.

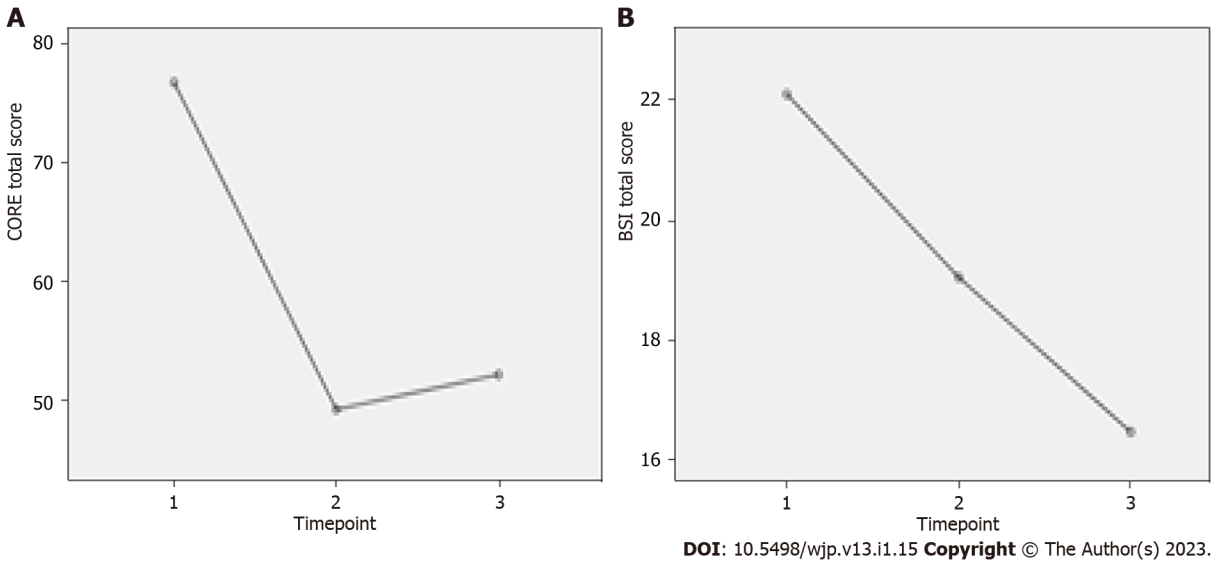
employment status as a covariate on WHO disability scale was significant, F (1, 10) = 8.68, $P = 0.015$, eta squared = 0.47 (Figure 5C). Employed people showed lower WHO disability scale mean score at all three time points. Interaction of employment with timepoint was not significant.



Change in CORE total score using repeated measures ANOVA: The CORE total score was significantly different when all three time points were compared simultaneously: F (1.25, 18.72) = 14.98, $P = 0.001$, partial eta squared = 0.5 (Figure 6A). However, Bonferroni-adjusted pairwise comparisons showed that CORE total score significantly reduced from baseline to post-treatment and baseline to follow-up, but there was no significant difference between post-treatment and follow-up (Table 5). This meant that there was a benefit at post-treatment and that the benefit was maintained at follow-up.

Change in CORE total mean to risk using repeated measures ANOVA: The CORE total mean with risk was significantly different when all three time points were compared simultaneously: F (1.25, 18.72) = 14.98, $P = 0.001$, partial eta squared = 0.5. However, Bonferroni-adjusted pairwise comparisons showed that the CORE total mean with risk significantly reduced from baseline to post-treatment and baseline to follow-up; but there was no significant difference between post-treatment and follow-up (Table 5). This meant that there was a benefit at post-treatment and that the benefit was maintained at follow-up.

The effect of the following covariates on the HADS, WHODAS, and CORE total mean with risk was not significant: Age, gender, diagnosis, psychiatric medication, living with someone or alone, ethnic group, having higher education or not, having a partner or not, duration of mental illness, being under care of CMHT or IAPT, history of previous admission, use of additional services and employment status. No difference between ethnic groups meant that the intervention showed similar effects in the groups.



Change in CORE total mean without risk using repeated measures ANOVA: The CORE total mean without risk was significantly different when all three time points were compared simultaneously: F (1.24, 18.66) = 16.58, $P < 0.001$, partial eta squared = 0.53. However, Bonferroni-adjusted pairwise comparisons showed that the CORE total mean without risk significantly reduced from baseline to post-treatment and baseline to follow-up; but there was no significant difference between post-treatment and follow-up (Table 5). This meant that there was a benefit at post-treatment and that the benefit was maintained at follow-up.

Change in CORE risk mean using repeated measures ANOVA: The CORE risk mean was not significantly different when all three time points were compared simultaneously: F (2, 36) = 11.83, $P = 0.175$, partial eta squared = 0.09. Furthermore, Bonferroni-adjusted pairwise comparisons showed that the CORE risk mean was not significantly different in any of the three-way comparisons (Table 5). This

Figure 6 Clinical Outcomes in Routine Evaluation and Bradford Somatic Inventory scores at three timepoints. A: Clinical Outcomes in Routine Evaluation; B: Bradford Somatic Inventory scores. CORE: Clinical Outcomes in Routine Evaluation; BSI: Bradford Somatic Inventory.

meant that this measurement did not change significantly between the three time points. Thus, no covariates were entered in this analysis.

Change in CORE symptoms mean using repeated measures ANOVA: The CORE symptom mean was significantly different when all three time points were compared simultaneously: F (2, 32) = 91.10, P < 0.001, partial eta squared = 0.54. However, Bonferroni-adjusted pairwise comparisons showed that the CORE symptom mean significantly reduced from baseline to post-treatment and baseline to follow-up; but there was no significant difference between post-treatment and follow-up (Table 5). This meant that there was a benefit at post-treatment and that the benefit was maintained at follow-up.

Changes in CORE functioning mean using repeated measures ANOVA: The CORE functioning mean was significantly different when all three time points were compared simultaneously: F (1.25, 91.92) = 7.26, P = 0.01, partial eta squared = 0.31. However, Bonferroni-adjusted pairwise comparisons showed that the CORE functioning mean significantly reduced from baseline to post-treatment and baseline to follow-up; but there was no significant difference between post-treatment and follow-up (Table 5). This meant that there was a benefit at post-treatment and that the benefit was maintained at follow-up.

Changes in CORE wellbeing mean using repeated measures ANOVA: CORE wellbeing mean was significantly different when all three time points were compared simultaneously, F (2, 36) = 20.41, P = 0.01, partial eta squared = 0.53. However, Bonferroni-adjusted pairwise comparisons showed that CORE wellbeing mean significantly reduced from baseline to post-treatment and baseline to follow-up; but there was no significant difference between post-treatment and follow-up (Table 5). This meant that there was a benefit at post-treatment and that the benefit was maintained at follow-up.

Change in BSI total using repeated measures ANOVA: The BSI total was significantly different when all three time points were compared simultaneously: F (2, 36) = 6.50, P = 0.008, partial eta squared = 0.26 (Figure 6B). However, Bonferroni-adjusted pairwise comparisons showed that the BSI total did not reduce significantly from baseline to post-treatment and but did so from baseline to follow-up; there was also a significant difference between post-treatment and follow-up (Table 5). This meant that there was no benefit at post-treatment but there was at follow-up.

ANCOVA results

Compared with ANOVA, ANCOVA further analysed the outcomes adjusted by certain covariates. This allowed us to examine the sensitivity of the findings in ANOVA towards certain covariates. If the significant results in ANOVA changed tremendously to unsignificant, the reliability of the results in ANOVA should be doubted. Such covariates could be influencing the outcomes in an undetected way and thereby contribute to the differences between groups. Therefore, we further analysed the significant model in ANOVA. After adding covariates, the P-value in ANOVA changed from less than 0.05 to larger than 0.05 in ANCOVA, thus these covariates were the key variables we should pay attention to. If the significant results in ANOVA remained significant in ANCOVA, *i.e.*, no drastic changes in the P-value, it would consolidate our finding in ANOVA by evidencing the insensitivity of the result towards the covariate.

Change in HADS depression using mixed factorial ANCOVA: With Timepoint and Employment being factor, HADS depression score adjusted by gender was not significantly different when all three time points were compared simultaneously: F (2, 42) = 0.158, P = 0.855. Also, when adjusted by age, HADS depression score did not show significant difference across three time points: F (2.42) = 0.595, P = 0.556 (Table 6). This suggested part of the differences of HADS depression scores across three timepoints could be explained by gender. Bonferroni-adjusted pairwise comparisons had the similar results to those of ANOVA.

In addition to this, other covariates, such as psychiatric medication, living with someone or alone, having higher education or not, having a partner or not, duration of mental illness, being under care of a CMHT or IAPT, history of previous admission and use of additional services, didn't change the results of the ANOVA analysis. Therefore, with factors living alone and employment, differences in questionnaire scores at three timepoints were not caused by these covariates.

Change in HADS anxiety using repeated measures ANCOVA: Results in ANOVA showed that HADS anxiety score was significantly different through three timepoints with a P-value less than 0.001 (Table 6). While HADS anxiety score adjusted by gender was not significantly different when all three time points were compared simultaneously: F (2, 44) = 0.014, P = 0.986 (Table 6). This suggested part of the difference of HADS anxiety score across three time points could be explained by gender. Bonferroni-adjusted pairwise comparison kept the similar results with those of ANOVA analysis.

Change in WHO disability scale using mixed factorial ANCOVA: Based on the results of ANOVA, model with factors employment and living alone had a P-value of 0.016 between three timepoints (Table 6). In ANCOVA analysis, with the same two factors, WHO disability scale adjusted by gender was not significantly different when all three time points were compared simultaneously: F (1.24, 22.38) = 0.354, P = 0.704 (Table 6). This meant that part of the difference of WHO disability scale across three time points could be explained by gender. With the same factors, using covariates age or higher education respectively resulted in a small increase in the P-value of time-point: From P = 0.016 (Table 5)

Table 6 Results of repeated measures analysis of covariance for outcome variables

Dependent variable	Covariate	Independent variable	Degrees of freedom	F value	*P* value	Bonferroni adjusted pairwise comparisons		
HADS depression	Gender	Timepoint (within subjects)	2, 42	0.158	0.855	Baseline (mean 11.77 SD 0.78) *vs* post-treatment (mean 7.75, SD 0.73), *P* = 0.003	Baseline *vs* follow-up (mean 7.55, SD 0.89), *P* < 0.001	Post treatment *vs* follow-up, *P* = 1.0
		Employment (between subjects)	1, 21	9.788	0.005	Employed *vs* unemployed mean difference[1] -3.96 (95%CI: -6.60 to -1.33); employed have lower mean score at all three time points		
	Age	Timepoint (within subjects)	2, 42	0.595	0.556	Baseline (mean 11.85 SD 0.77) *vs* post-treatment (mean 7.78, SD 0.74), *P* = 0.002	Baseline *vs* follow-up (mean 7.62, SD 0.89), *P* < 0.001	Post treatment *vs* follow-up, *P* = 1.0
		Employment (between subjects)	1, 21	11.266	0.003	Employed *vs* unemployed mean difference[1] -4.33 (95% CI: -7.02 to -1.65); employed have lower mean score at all three time points		
HADS Anxiety	Gender	Timepoint (within subjects)	2, 44	0.014	0.986	Baseline (mean 14.54 SD 0.77) *vs* post-treatment (mean 10.33, SD 0.75), *P* < 0.001	Baseline *vs* follow-up (mean 10.38, SD 0.86), *P* < 0.001	Post treatment *vs* follow-up, *P* = 1.0
WHO disability scale total	Gender	Timepoint (within subjects)	1.24, 22.38[2]	0.354[2]	0.704[2]	Baseline (mean 85.32 SD 8.72) *vs* post-treatment (mean 65.83, SD 7.42), *P* = 0.143	Baseline *vs* follow-up (mean 53.59, SD 8.26), *P* = 0.014	Post treatment *vs* follow-up, *P* = 0.016
		Living alone (between subjects)	1, 18	8.288	0.010	Living alone *vs* with someone mean difference[1] 37.82 (95%CI: 10.22 to 65.42); living alone have higher score at all three timepoints		
		Employment (between subjects)	1, 18	10.674	0.004	Employed *vs* unemployed mean difference[1] -30.52 (95%CI: -50.14 to -10.89); employed have lower mean score at all three time points		
	Age	Timepoint (within subjects)	1.25, 22.41[2]	3.631[2]	0.062[2]	Baseline (mean 84.69 SD 8.62) *vs* post-treatment (mean 65.47, SD 6.89), *P* = 0.138	Baseline *vs* follow-up (mean 53.30 SD 7.41), *P* = 0.011	Post treatment *vs* follow-up, *P* = 0.013
		Living alone (between subjects)	1, 18	8.167	0.010	Living alone vs with someone mean difference[1] 34.92 (95%CI: 9.25 to 60.59); living alone have higher score at all three timepoints		
		Employment (between subjects)	1, 18	14.555	0.001	Employed *vs* unemployed mean difference[1] -35.13 (95%CI: -54.47 to -15.78); employed have lower mean score at all three time points		
	Higher Education	Timepoint (within subjects)	1.22, 20.78[2]	3.506[2]	0.068[2]	Baseline (mean 84.60 SD 8.89) *vs* post-treatment (mean 65.38, SD 7.64), *P* = 0.165	Baseline *vs* follow-up (mean 52.48, SD 8.31), *P* = 0.014	Post treatment *vs* follow-up, *P* = 0.008
		Living alone (between subjects)	1, 17	7.318	0.015	Living alone *vs* with someone mean difference[1] 36.75 (95%CI: 8.09 to 65.41); living alone have higher score at all three timepoints		
		Employment (between subjects)	1, 17	10.370	0.005	Employed *vs* unemployed mean difference[1] -31.02 (95%CI: -51.34 to -10.70); employed have lower mean score at all three time points		
CORE total	Gender	Timepoint	1.47, 32.30[2]	0.028[2]	0.938[2]	Baseline (mean 73.88, SD 4.56) *vs* post-treatment (mean 47.42, SD 5.11), *P* < 0.001	Baseline *vs* follow-up (mean 48.04, SD 5.25), *P* < 0.001	Post treatment *vs* follow-up, *P* = 1.0
	Age	Timepoint	1.47, 32.23[2]	0.975[2]	0.364[2]	Baseline (mean 73.88, SD 4.48) *vs* post-treatment (mean 47.42, SD 4.95), *P* < 0.001	Baseline *vs* follow-up (mean 48.04, SD 5.15), *P* < 0.001	Post treatment *vs* follow-up, *P* = 1.0
BSI total	Age	Timepoint	2, 46	0.285	0.753	Baseline (mean 22.64, SD 2.06) *vs* post-treatment (mean 18.60, SD 2.06), *P* = 0.041	Baseline *vs* follow-up (mean 16.60, SD 2.09), *P* = 0.001	Post treatment *vs* follow-up, *P* = 0.406
	Gender	Timepoint	2, 46	1.027	0.366	Baseline (mean 22.64, SD 2.03) *vs* post-treatment (mean 18.60, SD 2.09), *P* = 0.026	Baseline *vs* follow-up (mean 16.60, SD 2.07), *P* = 0.001	Post treatment *vs* follow-up, *P* = 0.411
	Higher education	Timepoint	2, 44	2.811	0.071	Baseline (mean 22.58, SD 2.19) *vs* post-treatment (mean 18.21, SD 2.15), *P* =	Baseline *vs* follow-up (mean 16.75, SD 2.11), *P* = 0.003	Post treatment *vs* follow-up, *P* = 0.661

					0.028			
	Marital status	Timepoint	2, 46	3.146	0.052	Baseline (mean 22.64, SD 2.05) *vs* post-treatment (mean 18.60, SD 2.08), P = 0.040	Baseline *vs* follow-up (mean 16.60, SD 2.08), P = 0.002	Post treatment *vs* follow-up, P = 0.434

[1]This is the difference in average means across all three time-points.

[2]Greenhouse-Geisser value given due to significant Mauchly's test of sphericity.

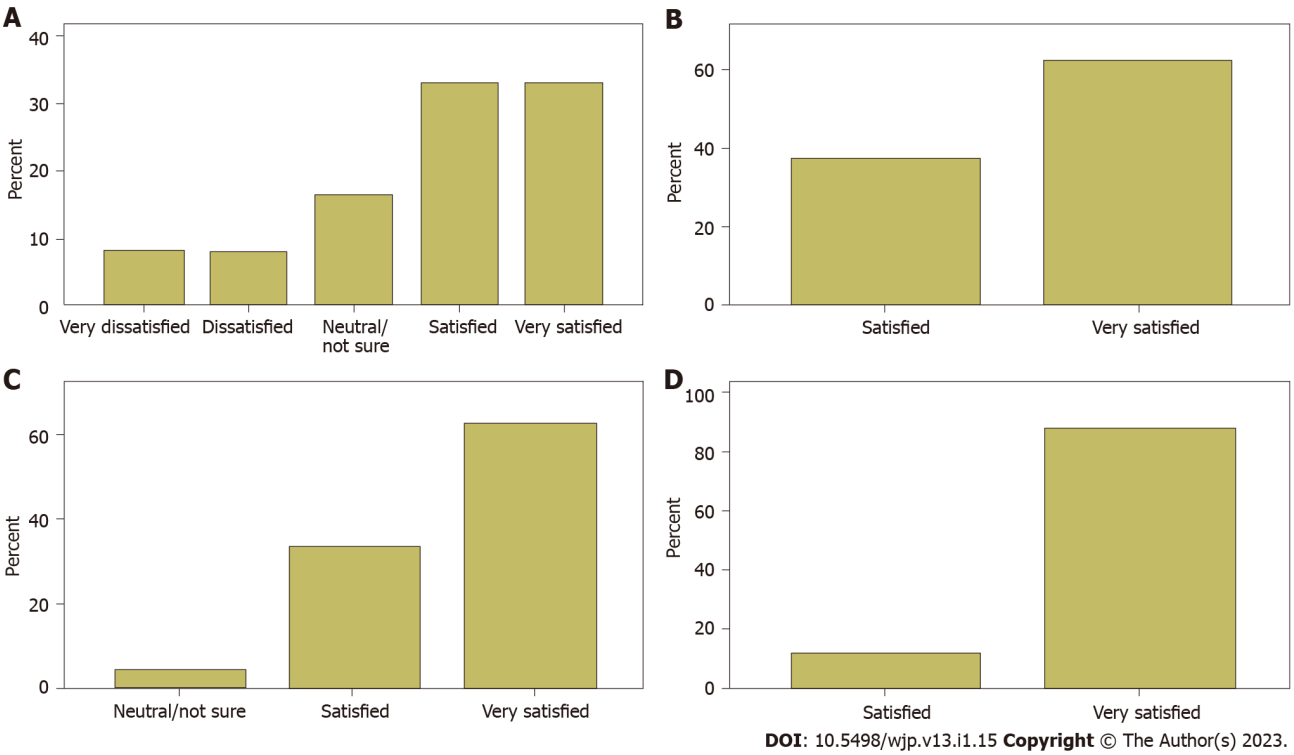
CI: Confidence interval; NA: Not available; WHO: World Health Organization; CORE: Clinical Outcomes in Routine Evaluation; HADS: Hospital Anxiety and Depression Scale; BSI: Bradford Somatic Inventory.

to P = 0.062 and P = 0.068 (Table 6). It was evident from the results that the changes to the WHO disability scale between three time points was not easily explained by age or higher education. Bonferroni-adjusted pairwise comparison failed to show significant reduction of the WHO disability scale from baseline to post-treatment. However, our results showed a significant reduction of the WHO disability scale from baseline to follow-up and from post-treatment to follow-up.

Change in CORE total score using repeated measures ANCOVA: The CORE total score adjusted by gender and age respectively was not significantly different when all three time points were compared simultaneously: F (1.47, 32.30) = 0.028, P = 0.938 and F (1.47, 32.23), P = 0.364 (Table 6). After adding these two covariates respectively, the differences of scores between three timepoint were not that much, which suggested part of the difference of CORE total score across three time points could be explained by gender and age. Bonferroni-adjusted pairwise comparison result did not change.

Change in BSI total using repeated measures ANCOVA: The BSI total adjusted by age and gender respectively was not significantly different when all three time points were compared simultaneously: F (2, 46) = 0.285, P = 0.753 and F (2, 46), P = 0.366 (Table 6). As for the covariate higher education, it showed a small increase in the P-value of timepoint from ANOVA results to ANCOVA results: From P = 0.008 (Table 5) to P = 0.071 (Table 6). This suggested part of the difference of BSI total across three time points could be explained by age and gender. Bonferroni-adjusted pairwise comparison result was the same as ANOVA results.

Analysis of BSI items 45 and 46



BSI item 45 asked only at baseline 'Have felt that you have been passing urine in the semen?' A total n = 6 men answered "no". BSI item 46 asked at all three time points, 'Have you had difficulty getting a full erection?' All n = 6 male respondents answered "no" at baseline, while post-treatment (n = 4) responded "no" and (n = 1) said "yes", while 1 did not respond. At follow-up timepoint, (n = 4) responded "no" and (n = 2) did not respond.

PEQ post-treatment results

PEQ analysis involved descriptive data on each item relating to the patient experience and satisfaction of the intervention. Figures 7A-D display a graphical presentation of the PEQ items 1, 3, 5, and 10. A total of 24 out of 32 participants completed the questionnaire. There was a significant positive correlation between PEQ item 8 and CORE risk mean (Somers D = 0.5); between PEQ item 8 and HADS Depression (Somers D = 0.67); and between PEQ item 8 and CORE functioning mean (Somers D = 0.69). This meant that the people who had worse scores on risk, functioning, and depression were more engaged with the treatment. However, all other correlations were not significant. Therefore, overall, the experience of treatment was independent of the changes in the outcome scales.

DISCUSSION

Our feasibility study sought to explore how some of the cultural barriers could be addressed with a manual that adapts the CBT based, third-wave based, CCC therapy- for diverse ethnic minority groups. Of the 32 participants within our sample, 3 dropped out before completing a total of 6 sessions. Thus, there is a positive notion for acceptability and adherence to the intervention. Given the ethnic diversity within the study sample, our manual appears to have relevance to operate cross-culturally. Significant improvement on anxiety/depression (HADS, anxiety and depression, BSI, and CORE) and overall quality of life (WHODAS) is suggested within the study sample. Developing the manual in response to challenges posed by the therapy in supervision raised interesting issues that were resolved within the CCC framework. Therefore, the development of CBT approaches built around mindfulness, commonly referred to as the third-wave, promotes a reflective space between the individual's thoughts and feelings, in contrast to the direct challenge, which makes it more acceptable to ethnic minority groups.

Figure 7 Patient Experience Questionnaire Items. A: How satisfied are you with the amount of time you had to wait for your first appointment? B: How satisfied are you with the type of treatment that you received? C: How satisfied are you with the overall experience of using this service? D: How satisfied are you with the therapist that treated you?

CCC avoids much of the complexity of other therapies by drawing on its roots in cognitive science to target the universal human need to establish a tolerable internal state. Attempts to regain equilibrium where this state is not tolerable led to behaviors and experiences that are then labelled as symptoms.

In addition, difference in cultural attitudes where assertiveness and anger proved amenable to the controlled expression of emotion with a mindfulness approach, which is similar to previous research conducted[18,37]. This could also be an intervention that could aid managing family expectations' to highly sensitive subject matter[6]. Issues that raised religious and cultural sensitivity, such as sexual abuse, required both validation of the individual's experience and acceptance of the limitation of open acknowledgement by the wider group. The relational nature of the interacting cognitive subsystems-based model of the person opens the way to the discussion of religious and faith issues that sidestepped contentious dogmas. CCC enables deep reflection by accommodating cultural adjustments, it makes this process of therapy more applicable and relevant. At present, four studies on CCC have been published looking at acute psychology which is different to the intervention used in this study[43,54-56], while demonstrating the ability of the approach to engage a challenging population. Three more studies are in preparation. Research into CCC is sparse at the moment and this pilot study is preliminary research into the CCC intervention, hence currently lacks any research comparators. The findings of this study are largely in line with previous research on culturally adapted CBT. Previous research found that adaptations in core elements, such as family, therapy delivery, and religious/spiritual views, enabled for the most efficacious outcomes for ethnic minority groups[14,15].

The recognized role of childhood or adult trauma in the development of psychological stress needing clinical management and psychological input is fully incorporated into CCC. The participant characteristics highlight the spectrum of trauma and past adversity contributing to current mental health difficulties across a primary care sample not selected for trauma. In the United Kingdom, National Institute for Health and Care Excellence guidelines provide an important consideration for clinicians who have such patients. Therefore, it is essential that primary, secondary, and tertiary care health professionals are fully aware of such issues to ensure patients receive optimal short, medium, and long-term care that is detrimental to reducing distress and improving their quality of life. Similarly, emotional, and general wellbeing, should be considered as an undercurrent to this intervention that requires to be kept at proximity, when managing ongoing care for these patients. Equally, in the event, potential patients have underlying chronic long-term comorbidities, the correlational aspect should be considered at the time of introducing this intervention and measuring its outcome longitudinally.

The main limitation of this study was that it was an uncontrolled pilot study to assess the feasibility of the manualized intervention. Therefore, the sample size remained sizable to demonstrate an effect size. The sample used was skewed towards female participants (84.4%) and outcome measures were not

adapted accordingly. Future studies should consider gender accountability. The emphasis was on learning from individual therapies with individuals who presented to an IAPT service and a CMHT with a wide range of problems and from diverse ethnicities. In relation to using both primary and secondary care samples, results have shown that both groups accepted in intervention and participant satisfaction was significant. As such, it represents the normal clinical practice in its complexity, making generalization more difficult. However, within these limitations, the results are promising and should merit a more extensive and definitive phase three randomized controlled interventions in the future.

In terms of future research, it would be ideal for a comprehensive randomized study design to be implemented. It would be insightful to include a much larger sample size with proportionate participant numbers from each ethnic group included. This would allow for stronger statistical outputs and more generalizable conclusions regarding the impact of this CaCBT-based third-wave therapy manual.

CONCLUSION

The culturally adapted CBT third-wave based manual intervention showed significant improvement in symptoms (HADS, anxiety and depression and CORE) and overall quality of life (WHODAS) from baseline to post-treatment. The study therapists reported that the adapted CCC formulation was simple, effective, and validated the patients' experiences well. This study adds to the body of knowledge supporting cultural adaptations of evidence-based therapies for diverse and minoritized ethnic groups.

ARTICLE HIGHLIGHTS

Research background

Currently, cognitive behavioral therapy (CBT) is one of the most common interventions implemented to treat symptoms of psychopathology of various illnesses. Standardised CBT manuals may not be completely relevant to all populations for several reasons including cultural and psychosocial variations.

Research motivation

Culturally adapted CBT could be beneficial to individuals of minority ethnic backgrounds as the contextual relevance may elevate the therapeutic benefit. Hence, this paper proposes a CaCBT-based third-wave therapy manual based on the Comprehend, Cope and Connect model.

Research objectives

This study aimed to test the feasibility, acceptability and adherence of the proposed intervention within ethnic minority participants who are currently engaged in Improving Access to Psychological Therapies' iTalk and Community Mental Health Team services that are part of the United Kingdom's National Health Service.

Research methods

In order to test the intervention, an uncontrolled feasibility study was deployed with 32 participants. Various outcome measures were recorded at three time points (baselines, post-intervention, and 12-wk follow-up).

Research results

A repeated measures analysis of variance revealed significant improvements in symptoms across Hospital Anxiety and Depression Scale depression and anxiety scores as well as the Clinical Outcomes in Routine Evaluation total score and World Health Organization Disability Assessment Schedule 2.0 measures.

Research conclusions

The results of this feasibility study reported that the CaCBT-based third-wave therapy was effective. Our results also showed significant adherence and acceptability among minority ethnic participants. Moderate effect sizes were reported with high participant satisfaction levels although a wider clinical trial will be required to fully assess the efficacy and effectiveness of the manual in the future.

Research perspectives

It would be important to further explore a randomised controlled trial as well as its' cost-effectiveness, overall benefit and scalability to a more diverse sample within the United Kingdom. This would aid in conducting wider global clinical trials to better understand the suitability of this adapted intervention.

ACKNOWLEDGEMENTS

The authors would like to thank all participants who contributed to the study. The authors would like to thank Matthew McNought and Carmen Caro Morente for their contributions as research therapists in the project and Sana Sajid and Joanna Pang for their administrative support.

ABOUT COVER

Editorial Board Member of *World Journal of Psychiatry*, Tsang Wing Hong Hector, PhD, OTR, Cally Kwong Mei Wan Professor in Psychosocial Health, Chair Professor and Head, Department of Rehabilitation Sciences, The Hong Kong Polytechnic University, Hung Hom, Hong Kong, China. hector.tsang@polyu.edu.hk

AIMS AND SCOPE

The primary aim of *World Journal of Psychiatry* (*WJP*, *World J Psychiatry*) is to provide scholars and readers from various fields of psychiatry with a platform to publish high-quality basic and clinical research articles and communicate their research findings online.

WJP mainly publishes articles reporting research results and findings obtained in the field of psychiatry and covering a wide range of topics including adolescent psychiatry, biological psychiatry, child psychiatry, community psychiatry, ethnopsychology, psychoanalysis, psychosomatic medicine, *etc*.

INDEXING/ABSTRACTING

The *WJP* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Current Contents/Clinical Medicine, Journal Citation Reports/Science Edition, PubMed, PubMed Central, Reference Citation Analysis, China National Knowledge Infrastructure, China Science and Technology Journal Database, and Superstar Journals Database. The 2022 Edition of Journal Citation Reports® cites the 2021 impact factor (IF) for *WJP* as 3.500; IF without journal self cites: 3.313; 5-year IF: 7.380; Journal Citation Indicator: 0.62; Ranking: 89 among 155 journals in psychiatry; and Quartile category: Q3.

Abstract

BACKGROUND

Major depressive disorder (MDD) is a common and serious mental illness. Many novel genes in MDD have been characterized by high-throughput methods such as microarrays or sequencing. Recently, noncoding RNAs (ncRNAs) were suggested to be involved in the complicated environmental-genetic regulatory network of MDD occurrence; however, the interplay among RNA species, including protein-coding RNAs and ncRNAs, in MDD remains unclear.

AIM

To investigate the RNA expression datasets downloaded from a public database and construct a network based on differentially expressed long noncoding RNA (lncRNAs), microRNAs (miRNAs), and mRNAs between MDD and controls.

METHODS

Gene expression data were searched in NCBI Gene Expression Omnibus using the search term "major depressive disorder." Six array datasets from humans were related to the search term: GSE19738, GSE32280, GSE38206, GSE52790, GSE76826, and GSE81152. These datasets were processed for initial assessment and subjected to quality control and differential expression analysis. Differentially expressed lncRNAs, miRNAs, and mRNAs were determined, Gene Ontology and Kyoto Encyclopedia of Genes and Genomes enrichment analyses were performed, and protein-protein interaction network was generated. The results were analyzed for

their association with MDD.

RESULTS

After analysis, 3 miRNAs, 12 lncRNAs, and 33 mRNAs were identified in the competing endogenous RNA network. Two of these miRNAs were earlier shown to be involved in psychiatric disorders, and differentially expressed mRNAs were found to be highly enriched in pathways related to neurogenesis and neuroplasticity as per Gene Ontology and Kyoto Encyclopedia of Genes and Genomes enrichment analyses. The expression of hub gene fatty acid 2-hydroxylase was enriched, and the encoded protein was found to be involved in myelin formation, indicating that neurological development and signal transduction are involved in MDD pathogenesis.

CONCLUSION

The present study presents candidate ncRNAs involved in the neurogenesis and neuroplasticity pathways related to MDD.

Key Words: Major depressive disorder; Noncoding RNA; Competing endogenous RNA; Bioinformatics; Data mining

Core Tip: Competing endogenous RNAs (ceRNAs) are novel regulatory molecules involved in a wide range of biological processes and diseases. This study explored the potential ceRNA networks (ceRNETs) involved in the pathogenesis of major depressive disorder (MDD) using bioinformatics data mining. A ceRNET comprising 3 miRNAs, 12 lncRNAs, and 33 mRNAs was constructed based on two public datasets obtained from the Gene Expression Omnibus database. Elucidating the correlation of the ceRNET with MDD opens new avenues to discover specific diagnostic biomarkers for MDD and expands our knowledge about this disease.

INTRODUCTION

Major depressive disorder (MDD), characterized by persistent and intense feelings of sadness for extended periods, is one of the most common causes of morbidity and mortality worldwide[1], yearly affecting approximately 5% of adults worldwide[2]. The exact cause of MDD remains unknown; however, the occurrence of MDD is widely believed to involve crosstalk between genetic, environmental, social, and developmental vulnerabilities and resilience factors[2,3]. Numerous risk factors for MDD have been identified from three major perspectives: medical, social, and substance[4,5]. Available treatment options primarily include pharmacotherapy, psychotherapy, and lifestyle changes. However, prevention and treatment of this disease remain difficult because of varying presentations, unpredictable course and prognosis, and variable responses to treatment[6]. Therefore, further studies are needed to determine the biological mechanisms underlying MDD to develop better patient therapies.

The increasing popularity of high-throughput microarray technologies has facilitated the identification of genome variations in MDD, improving the understanding of its pathogenesis and development, and revealing promising biomarkers. Gao *et al*[7] identified 241 differentially expressed genes (DEGs) in the hippocampus (hip), 218 DEGs in the prefrontal cortex (pfc), and 327 DEGs in the striatum (str) from patients with MDD. These DEGs were enriched in glycan biosynthesis, RIG-I-like receptor signaling, and pyrimidine metabolism pathways, which significantly contribute to MDD pathogenesis. Additionally, the DEGs AR, PTK2, IRAK1, IL12A, GALNT12, GALNT2, CD19, and PTDSS2 were identified as novel therapeutic targets[7,8]. Moreover, Segman *et al*[9] found 73 DEGs between patients with postpartum major depression and controls using peripheral blood cells; the immune response, transcriptional effects on cell proliferation, and DNA replication and repair were significantly enriched in these patients. Although novel genes have been discovered and well-studied, genetic predisposition to MDD only partly explains the occurrence of this illness. With the development of epigenetic theory and technology, non-coding RNAs (ncRNAs) have been identified to help explain the interaction between genetics and the environment. Li *et al*[10] found an inverse relationship between serum brain-derived neurotrophic factor (BDNF) levels and miR-132/miR-182 levels in depression, supporting the

notion that miR-182 is a putative regulatory microRNA (miRNA) of BDNF. Zhou *et al*[11] found that miRNAs act as key regulators of synaptic plasticity in MDD pathogenesis. Liu *et al*[12] detected four long non-coding ribonucleic acids (lncRNAs) related to the expression of mRNAs associated with MDD. Although ncRNAs have been proposed to play important roles in MDD, the regulatory network among RNA species remains unclear.

The competing endogenous RNA (ceRNA) network proposed by Salmena *et al*[13] has been verified in an increasing number of studies. This complicated post-transcriptional regulatory network plays a critical role in the progression and pathogenesis of various illnesses, including cancer. However, to date, no ceRNA network has been proposed for MDD. Here, we investigated RNA expression datasets downloaded from the Gene Expression Omnibus (GEO) database and constructed a network based on differentially expressed lncRNAs, miRNAs, and mRNAs between MDD and controls. This network was used to mine for functional ncRNAs that may contribute to the epigenetic mechanism underlying MDD pathogenesis and may be useful as potential therapeutic targets and biomarkers for MDD.

MATERIALS AND METHODS

Data resources and preprocessing

Gene expression data were searched in NCBI GEO using the search term "major depressive disorder". Six array datasets from humans were related to the search term: GSE19738 (expression profiling by array, n = 42; MDD, 21; control, 21), GSE32280 (expression profiling by array, n = 24; MDD, 8; subsyndromal symptomatic depression, SSD, 8; control, 8), GSE38206 (expression profiling by array, n = 18; MDD, 9; control, 9), GSE52790 (expression profiling by array and ncRNA profiling by array, n = 22; MDD, 10; control, 12), GSE76826 (expression profiling by array, n = 22; MDD, 10; control, 12), and GSE81152 (ncRNA profiling by array, n = 50; MDD, 31; control, 19). These datasets were processed for initial assessment; if they met the requirements, they were subjected to quality control and differential expression analysis.

Identification of differentially expressed lncRNAs, miRNAs, and mRNAs

The differentially expressed mRNAs, lncRNAs, or miRNAs were determined based on the threshold criteria of $|\log2 \text{(fold-change)}| \geq 1$ and an adjusted P value < 0.05 using the R limma package (version 3.40.6). The differentially expressed lncRNAs (DE_lncRNAs) obtained from GSE76826 were entered into the miRcode database (http://www.mircode.org/) that provides an integrated, searchable map of putative target sites of miRNAs, to predict the interactions of DE_lncRNAs and DE_miRNAs. Only DE_lncRNAs for which miRNAs were successfully predicted were selected for ceRNA network construction. The miRNAs obtained were overlapped with differentially expressed miRNAs obtained from GSE81152, and the overlapping miRNAs were identified as a differentially expressed miRNA (DE_miRNA). The name of the DE_miRNA was entered into the miRDB (http://mirdb.org/) and TargetScan (http://www.targetscan.org/vert_72/) databases, both of which are online databases used to predict miRNA targets. The mRNAs obtained above were overlapped with differentially expressed RNAs identified from GSE76826. The DE_lncRNAs, DE_miRNAs, and DE_mRNAs obtained in the manner described above were used for ceRNA network construction.

DE_lncRNA/DE_miRNA/DE_mRNA network construction

Cytoscape 3.4.0 was used to visualize the DE_lncRNA/DE_miRNA/DE_mRNA network construction.

Gene Ontology function and Kyoto Encyclopedia of Genes and Genome pathway enrichment analysis

To help identify the potential biological functions of these genes in the MDD ceRNA network, Gene Ontology (GO) functional and Kyoto Encyclopedia of Genes and Genome (KEGG) pathway enrichment analyses were performed using the clusterProfiler package in R. GO terms have three categories; biological process, cellular compartment, and molecular function. $P \leq 0.05$ indicated a significant difference in GO terms and KEGG pathways.

Construction of the protein interaction network

The protein interaction (PPI) network was constructed to evaluate the interactions among genes. The DE_mRNAs were selected to construct a PPI network based on Search Tool for the Retrieval of Interacting Genes/Proteins (STRING) ver.11.0 (https://string-db.org/). In the PPI network, a node represents a gene; the undirected link between two nodes is an edge, representing the interaction between two genes, and the degree of a node corresponds to the number of interactions of a gene with other genes in the network.

RESULTS

Quality control and differential expression analysis

The workflow of the analysis is shown in Figure 1. Because the GSE19738 dataset lacks documents to annotate gene symbols and the GSE32280 dataset uses peripheral blood mononuclear cells rather than whole blood, both these datasets were excluded from analysis at the first stage. Next, sample-level quality control was performed using principal component analysis to ensure that the cases and controls were well-separated and to identify sample outliers. After removing the outliers, there were 10 controls and 8 MDD cases in GSE52790, 12 controls and 9 MDD cases in GSE76826, and 10 controls and 23 MDD cases in GSE81152. The four remaining datasets, GSE32280, GSE52790, GSE76826, and GSE81152, were utilized to identify differentially expressed mRNAs, lncRNAs, and miRNAs using the limma R package with the threshold set to an adjusted P value < 0.05 and $|\log2 \text{(fold-change)}| \geq 1$. A hierarchical cluster heatmap showing the expression patterns of the DEGs between MDD and controls is shown in Figure 2. As no DEGs were found in GSE32280, this dataset was excluded from subsequent analysis. A total of 125, 373, and 54 DEGs were identified in the GSE52790, GSE76826, and GSE81152 datasets, respectively. There were 112 upregulated and 13 downregulated genes among the 125 DEGs in GSE52790, 109 upregulated genes (including 89 mRNAs and 10 lncRNAs) and 264 downregulated genes (including 198 mRNAs and 66 LncRNAs) in the 373 DEGs of GSE76826, and 51 upregulated and 3 downregulated genes in the 54 DEGs of GSE81152.

Construction of a ceRNA network for MDD

To better understand the effect of lncRNAs on mRNAs mediated by combinations with miRNAs in MDD, we constructed a ceRNA network based on the GSE76826 and GSE81152 data. Eighty-six differentially expressed lncRNAs from GSE76826 were retrieved and entered into the miRcode database to predict the potential interacting miRNAs. Eighty-four miRNAs (645 LncRNA-miRNA pairs) were identified in the miRcode database. Next, we overlapped these 84 miRNAs to the differentially expressed miRNAs identified in GSE81152, generating 3 shared miRNAs (the corresponding lncRNAs were reduced to 12) (Table 1). Thereafter, we entered these 3 miRNAs into the miRDB and TargetScan databases to identify their potential target mRNAs and combined the results from these two databases to achieve high true-positive coverage. A total of 1,868 mRNAs was generated from the two databases; when the 287 differentially expressed mRNAs identified from GSE76826 were overlapped, 33 shared mRNAs were identified (Table 2). Finally, we assembled all identified ceRNA pairs to generate an mRNA-miRNA-lncRNA network in MDD (Figure 3).

Gene set enrichment analysis

Enrichment analysis indicated that the 33 differentially expressed mRNAs were significantly associated with the GO terms for 887 biological process, 105 molecular function, and 55 cell component terms. For the KEGG pathways, the only significant pathway was the mammalian target of rapamycin (mTOR) signaling pathway. Table 3 and Figure 4 list the top 10 most significant biological processes, molecular functions, and cellular components from the GO terms.

PPI network construction

A total of 33 DEG mRNAs were entered into the STRING database to build a PPI network. Gene nodes with the highest W values in the network were *ACVR1C*, *ELOVL4*, *fatty acid 2-hydroxylase* (*FA2H*), *INHBB*, *NIPAL4*, and *UGT8* (Figure 5).

DISCUSSION

Considerable progress has been made in understanding the pathophysiology of MDD; however, no single model or mechanism can fully explain all aspects of the disease[6]. MDD is believed to involve the following: Reduced levels of monoamines, changes in the hypothalamic-pituitary-adrenal axis, inflammation, limited neurogenesis, changes in brain structure and function, heredity factors, environmental milieu, and epigenetics[6]. Epigenetics, a field focusing on gene-environment interactions, has gained attention over the past decades. The recent application of microarray-based genome-wide expression analysis has enabled the identification of MDD-associated genes, including novel ncRNAs. Although numerous studies have demonstrated that ncRNAs play important roles in MDD pathogenesis, the mechanisms of how these genes regulate MDD have not been well-characterized[14, 15]. Thus, we performed ceRNA network analysis by data mining to determine the potential regulatory mechanisms of MDD.

Multiple GO terms were identified in enrichment analysis, reflecting the complexity of the disorder. We observed that protein-coding genes in the network were highly correlated with cellular growth and developmental differentiation, including the activin receptor signaling pathway, peripheral nervous system development, G protein-coupled receptor internalization, receptor-ligand activity, hormone

activity, growth factor activity, and cellular growth. The term "signaling by activins" in our results is consistent with previous studies showing that activin can modulate depression and anxiety-related behavior[16-21]. Activins are members of the transforming growth factor-β superfamily that are expressed in various tissues, including neuronal cells, and are involved in proliferation, differentiation, metabolism, homeostasis, apoptosis, immune response, and tissue repair. Postnatal neurogenesis, which leads to the production of new neurons in the adult brain, can influence the replacement of damaged neurons, stress responses, memory formation, and depression, among others[22]. Previous studies have reported that the activin activity in the adult forebrain influences locomotor activity, anxiety-related behavior, and hippocampal neurogenesis, which is also associated with age-related cognitive decline [23]. Additionally, consistent with our results, utilizing a genome-wide association study, Smeeth *et al* [23] suggested a complex relationship among reproductive hormones, hippocampal neurogenesis, and depression. Based on transcriptome array results analysis of Chinese patients with MDD, Liu *et al*[12] reported the enrichment of differentially expressed coding genes in the signal transduction pathway and basic metabolic process associated with neurodevelopmental disease[12,13]. Our KEGG results also showed that the mTOR signaling pathway is a part of the regulatory network of MDD. This agrees with previous studies which showed that the mTOR signaling pathway, which senses and integrates diverse extracellular stimuli to promote cellular growth or limit catabolic processes, contributes to normal neuronal growth and is associated with neurogenesis[24]. Notably, the mTOR signaling pathway has become an important target for treating depression using drugs such as ketamine[25,26].

The use of ncRNAs as biomarkers of psychological disorders is gaining momentum. In the ceRNA network developed in this study, there were 12 lncRNAs, 3 miRNAs, and 33 mRNAs specific to MDD. Consistent with our results, hsa-mir-137, as a brain-enriched miRNA, was earlier confirmed as a gene related to MDD, bipolar disorder, schizophrenia, and Parkinson's disease susceptibility[27-30], whose underlying mechanisms regulate synaptic plasticity. Moreover, Zhao *et al*[31] detected significantly lower hsa-miR-137 Levels in the brain and peripheral blood in post-stroke depression rats, and Kim *et al* [32] found that it can be used as a diagnostic marker for methamphetamine withdrawal syndrome. Similarly, hsa-miR-125b-5p in the peripheral blood is highly expressed in Alzheimer's disease compared with that in controls.

In addition to genetic components, different epigenetic mechanisms play an important role in the occurrence and development of MDD. A previous study revealed that the non-protein-coding RNA repressor of NFAT, human accelerated region 1, transcribed antisense of rheelin, and B-secretase-1 are associated with cognitive function, potentially contributing to MDD, and the lncRNA BDNF-AS was reportedly related to synaptic plasticity and potentially associated with MDD[33-36]. In a recent study, Abedpoor and colleagues reported that the lncRNA network could play an indispensable role in regulating depression-like behaviors in mice[37]. Furthermore, two studies reported lower RMRP expression in a mouse model of depression and MDD relative to normal subject samples[14]. In another

study, Issler *et al*[38] observed that LINC00473 was downregulated in the prefrontal cortex of depressed females. Collectively, these results suggest that lncRNAs are potential diagnostic and prognostic biomarkers. Our results revealed 12 different lncRNAs involved in the MDD ceRNA network, suggesting the existence of a regulatory network in MDD.

Figure 4 Gene Ontology functional enrichment analysis.

In the present study, FA2H was highlighted in the PPI network. FA2H encoded by *FA2H* is highly expressed in the human brain and is involved in the formation of 2-hydroxy galactosylceramides and 2-hydroxy sulfatides in myelin[39,40]. The FA2H gene appears to be related to lipid metabolism and is one of the 10 candidate genes identified in an inherited neurologic disorder known as neurodegeneration with brain iron accumulation and is also involved in hereditary spastic paraplegia SPG35 and leukodystrophy[41,42]. Mutations in FA2H have been identified in autism spectrum disorders[43]. The function of FA2H does not appear to be limited to the brain since elevated FA2H expression has also been found in hepatocellular carcinoma and lung adenocarcinoma involving UGT8[44,45]. However, there have been no reports of FA2H in MDD and thus, this is the first study to suggest that FA2H is related to MDD. Considering its role in myelin formation, this gene may contribute to MDD pathogenesis *via* impacting neurological development and modulating signal transduction.

Elongation of very long-chain fatty acids-4 (ELOVL4) was another protein of interest identified in the PPI. This protein is essential for the synthesis of very long-chain polyunsaturated (VLC-PUFA) and saturated fatty acids (VLC-SFA) of chain lengths greater than 26 carbons[46]. The VLC-PUFAs play an important role in maintaining neural tissue homeostasis. Studies have suggested that dysregulated

DOI: 10.5498/wjp.v13.i2.36 **Copyright** ©The Author(s) 2023.

Figure 5 Protein interaction network construction. FA2H: Fatty acid 2-hydroxylase.

ELOVL4 expression may be involved in the lipid alterations observed in neuroblastoma, and mutations in the ELOVL4 gene could cause several distinct neurodegenerative diseases, including stargardt-like macular dystrophy, spinocerebellar ataxia 34, and a neuro-ichthyotic syndrome with severe seizures and spasticity[47,48]. However, like FA2H, none of the studies so far have linked ELOVL4 and MDD, and therefore, future validation benchmark experiments are needed.

There were some limitations to our study. The potentially important genes associated with MDD lack gene expression and functional validation, and hence, further *in vivo* and *in vitro* studies are required. Furthermore, the two datasets were not from the same platform, which may have resulted in a few deviations. However, the present study provides novel insight into MDD pathogenesis.

CONCLUSION

To date, MDD diagnosis mainly depends on the patient's subjective expression, which may be misinterpreted by clinicians. Therefore, identification of a reliable biomarker that can be used to diagnose MDD and guide its treatment is imperative. In conclusion, the present study revealed that hsa-miR-4465, hsa-miR-137, and hsa-miR-125b-5p may be useful genetic biomarkers for MDD as they are potentially involved in the neurogenesis and neuroplasticity pathways in MDD. These results require further validation in future studies.

ARTICLE HIGHLIGHTS

Research background

Major depressive disorder (MDD) is a common and serious mental illness. Many novel genes in MDD have been characterized by high-throughput methods such as microarrays or sequencing. Recently, noncoding RNAs (ncRNAs) were suggested to be involved in the complicated environmental-genetic regulatory network of MDD occurrence.

Research motivation

The interplay among RNA species, including protein-coding RNAs and ncRNAs, in MDD remains unclear.

Research objectives

To investigate the RNA expression datasets and construct a network based on differentially expressed long noncoding RNA (lncRNAs), miRNAs, and mRNAs between MDD and controls through data mining method.

Research methods

Gene expression data were searched and downloaded from NCBI Gene Expression Omnibus database. Six array datasets from humans were related to the search term: GSE19738, GSE32280, GSE38206, GSE52790, GSE76826, and GSE81152. These datasets were processed for initial assessment and subjected to quality control and differential expression analysis. Differentially expressed lncRNAs, miRNAs, and mRNAs were determined, Gene Ontology and Kyoto Encyclopedia of Genes and Genomes enrichment analyses were performed, and protein-protein interaction network was generated. The results were analyzed for their association with MDD.

Research results

After analysis, 3 miRNAs, 12 lncRNAs, and 33 mRNAs were identified in the ceRNA network. Two of these miRNAs were earlier shown to be involved in psychiatric disorders, and differentially expressed mRNAs were found to be highly enriched in pathways related to neurogenesis and neuroplasticity as per Gene Ontology and Kyoto Encyclopedia of Genes and Genomes enrichment analyses. The expression of hub gene fatty acid 2-hydroxylase was enriched, and the encoded protein was found to be involved in myelin formation, indicating that neurological development and signal transduction are involved in MDD pathogenesis.

Research conclusions

The present study presents candidate ncRNAs involved in the neurogenesis and neuroplasticity pathways related to MDD.

Research perspectives

Bioinformatic data mining method can be an cost-effective way to explore potential biomarkers for complicated diseases. However, benchmark experiment is needed in the future to validate the results.

Abstract

BACKGROUND

Depression is the most common mental illness in postpartum mothers, and the etiology of postpartum depression remains poorly understood. Over the past several decades, studies have reported that postpartum depression is caused by multiple factors, such as genetic, psychological, pregnancy, and environmental factors, with the family environment being an important environmental factor. The theory of family cohesion and adaptability put forward by Olson is a classic model that describes the level of family function. However, to date, this model has not been examined regarding its applicability to patients with postpartum depression.

AIM

To investigate the relationship between family cohesion and adaptability and the risk of postpartum depressive symptoms.

METHODS

We retrospectively analyzed 1446 patients admitted to the postpartum healthcare clinic of the Affiliated Foshan Maternity and Child Healthcare Hospital from April 2021 to December 2021. Patients were grouped according to whether postpartum depression symptoms were reported (symptoms, n = 454; no symptoms, n = 992). All patients completed the Edinburgh Postpartum Depression Scale and the Chinese version of the Family Cohesion and Adaptability Assessment Scale II. Baseline and clinical data were compared between groups. Univariate regression analysis was used to investigate the association between different types of family cohesion and postpartum depressive symptoms and the association between different family adaptability types and postpartum

depressive symptoms.

RESULTS

After adjusting for age, education, occupation, gravidity, parity, and mode of delivery, disengaged [adjusted odds ratio (AOR) = 3.36, 95%CI: 1.91–5.91], and separated (AOR = 1.97, 95%CI: 1.34–2.90) family cohesion types showed a higher risk of postpartum depression than the connection type, whereas the enmeshed type (AOR = 0.38, 95%CI: 0.28–0.51) protected against postpartum depressive symptoms. Rigid (AOR = 4.41, 95%CI: 3.02–6.43) and structured families (AOR = 1.88, 95%CI: 1.34–2.63) had a higher risk of postpartum depressive symptoms than flexible families, whereas chaotic families (AOR = 0.35, 95%CI: 0.24–0.51) protected against postpartum depressive symptoms.

CONCLUSION

Family cohesion and adaptability are influencing factors for postpartum depressive symptoms, with higher family cohesion and adaptability being associated with a lower risk of postpartum depressive symptoms.

Key Words: Family cohesion; Adaptability; Postpartum depressive symptoms; Cross-sectional study

Core Tip: Postpartum depression is the most common mental illness in postpartum mothers; studies have reported that postpartum depression is caused by multiple factors. This study analyzed the family environments of 1446 postnatal women, showing that high family cohesion and adaptability prevented the development of postpartum depressive symptoms. Further, we observed a linear relationship between family cohesion, adaptability, and postpartum depressive symptoms, where higher family cohesion and adaptability scores were associated with a risk of postpartum depressive symptoms.

INTRODUCTION

Postpartum depression is the most common mental illness in postpartum mothers. In high-income countries, more than 10% of postpartum women experience postpartum depression, and the prevalence is higher in low-income countries[1,2]. Postpartum depression is a leading cause of death for postpartum women, and numerous studies have suggested that postpartum depression in mothers affects the developmental processes of their children, including cognitive and language delays, behavioral problems, unsafe attachment, decreased academic performance, and increased risk of depression in adulthood[3,4]. Postpartum depression places heavy burdens on families and society. Therefore, early detection and intervention of postpartum depressive symptoms are crucial for prevention and treatment.

The etiology of postpartum depression remains poorly understood. Over the past several decades, studies have reported that postpartum depression is caused by multiple factors, such as genetic, psychological[5], pregnancy[6], and environmental factors[7-10]. Guan *et al*[11] found that a poor family environment contributes to the development of postpartum depression, and family communication, emotional responses, and other related factors influence the development of postpartum depression. A study conducted in Japan found that women who live with family members who have a high level of perception and participate in parenting have a low risk of postpartum depression[12]. In addition, Kızılırmak reported a significant negative correlation between Edinburgh Postnatal Depression Scale (EPDS) scores and the total scores for spousal, emotional, social, and physical support in postpartum women[13]. In terms of marital satisfaction, pregnant women who are unsatisfied with the quality of their marriage are more likely to suffer from postpartum depression[14]. A large retrospective study on the correlation between postpartum depression and domestic violence among Asian mothers found that women who experience domestic violence from their partners are at high risk of developing postpartum depression. Moreover, violence and intimidation by other family members are associated with the incidence of postpartum depression, and domestic violence increases the risk of suicidal ideation in patients with postpartum depression[15].

The theory of family cohesion and adaptability put forward by Olson is a classic model that describes the level of family function[16,17]. Family cohesion reflects the robustness of family members' emotional ties and refers to the ability of family members to support each other, unite, and overcome difficulties when dealing with family difficulties. Family adaptability reflects the flexibility of families to deal with changes and is based on the ability to change family power structures or roles in the process of family development. However, to date, this model has not been examined regarding families of patients with postpartum depression. In this study, we conducted a cross-sectional survey among postpartum women in China to explore the effects of family cohesion and adaptability on postpartum depressive symptoms and provide a reference for treatment.

MATERIALS AND METHODS

Participants

We retrospectively analyzed 1446 patients admitted to the postpartum healthcare clinic of the Affiliated Foshan Maternity and Child Healthcare Hospital from April 2021 to December 2021. According to whether postpartum depression symptoms were reported, patients were divided into a postpartum depression symptoms group and a no postpartum depression symptoms group. The inclusion criteria were: (1) Postpartum women of Han ethnicity (self-reported) in China aged 18–45 years; (2) no cognitive, intellectual, or behavior disorders; (3) voluntary participation in the study and ability to independently complete the questionnaires; (4) no serious complications during pregnancy and childbirth and no postpartum child death; and (5) an Apgar score of 8–10. The exclusion criteria were: (1) Postpartum women with major traumatic stress events in the last month, such as spouse death, divorce, and domestic violence; (2) severe or unstable somatic disease; and (3) previous diagnosis of schizophrenia, depression (including postpartum depression), bipolar disorder, obsessive-compulsive disorder, generalized anxiety disorder, panic attacks, or epilepsy.

Postpartum depressive symptoms

The EPDS was used to measure postpartum depressive symptoms. The EPDS was developed in 1987 and is used specifically for screening for postpartum depression. The scale has good reliability and validity. The total score of the scale ranges from 0 to 30, where a higher score indicates greater severity of depression. The Chinese version of the EPDS has been shown to have good reliability and validity [18]. In the Chinese version, the demarcation of depressive symptoms is divided into nine points.

Family adaptability and cohesion

Family cohesion and adaptability were measured using the Family Cohesion and Adaptability Scale (FACES II-CV). FACES II-CV was developed by Olson in 1982 and translated into Chinese by Fei *et al* [19]. The scale evaluates the cohesion and adaptability of families across a total of 30 items, which are scored on a 5-point Likert scale. A higher score indicates better family cohesion and adaptability. Family cohesion is divided into four types based on the total subscale score: disengaged (< 55.9), separated (55.9–63.9), connected (63.9–71.9), and enmeshed (> 71.9). Family adaptability is divided into four types: rigid (< 44.7), structured (44.7–50.9), flexible (50.9–57.1), and chaotic (> 57.1). We only used the section on actual family status, and Cronbach's alpha for this section was 0.93.

Covariates

Age[20], occupation[20], education[21], mode of delivery[22,23], gravidity, and parity[24] have previously been reported to be associated with postpartum depressive symptoms. Therefore, we included them as covariates in this study. The occupation was divided into "unit head", "professional and technical personnel", "clerks", "business and service personnel", "unemployed/housewife", and "other". Educational level was defined by participants' highest level of education, and responses included "junior high school or below", "senior high school", and "college or university". The mode of delivery was divided into "vaginal delivery" and "cesarean section".

Statistical analysis

The cohesion and adaptability of women with and without postpartum depressive symptoms are represented as mean ± SD and were compared using the Student's *t*-test. Age, occupation, educational level, mode of delivery, gravidity, and parity are described using frequency and rate and were compared using χ^2 tests. Logistic regression was performed to assess the association between postpartum depressive symptoms, family cohesion, and adaptability, and odds ratios (ORs) and 95%CIs were calculated. In model 1, the associations between family cohesion, adaptability, and postpartum depressive symptoms were assessed without adjusting for covariates. Subsequently, variables that were significant in the univariate analysis or those that have been reported in previous studies as confounding factors were adjusted for in model 2. A two-tailed $P < 0.05$ was considered significant. All analyses were performed using Statistical Analysis System software (version 9.2; SAS Institute, Inc.,

Cary, NC, USA).

RESULTS

Characteristics and postpartum depressive symptoms of participants

As shown in Table 1, the age range of participants was 19–49 years, with an average age of 30 ± 4.30 years. Postpartum depressive symptoms were reported in 454 postpartum women for a prevalence rate of 31.4%. There were no significant differences between women with and without postpartum depressive symptoms in age ($\chi^2 = 2.07$, $P = 0.354$), education level ($\chi^2 = 2.65$, $P = 0.448$), mode of delivery ($\chi^2 = 0.177$, $P = 0.674$), gravidity ($\chi^2 = 4.004$, $P = 0.261$), or parity ($\chi^2 = 6.107$, $P = 0.107$). However, there was a significant difference in occupation between the two groups ($\chi^2 = 11.26$, $P = 0.046$).

Family cohesion and adaptability of postpartum women

The total scores for family cohesion and adaptability were significantly lower in the postpartum depressive symptoms group than in the group without postpartum depressive symptoms ($P < 0.001$; Table 2).

Association between different types of family cohesion and postpartum depressive symptoms

As shown in Table 3, the results of the univariate regression analysis showed that different types of family cohesion were associated with postpartum depressive symptoms (model 1, $P < 0.001$). In model 2, after adjusting for age, educational level, occupation, gravidity, parity, and mode of delivery, the disengaged type [adjusted OR (AOR) = 3.36, 95%CI: 1.91–5.91] and separated type (AOR = 1.97, 95%C: 1.34–2.90) had a higher risk of postpartum depressive symptoms than the connection type, whereas the enmeshed type (AOR = 0.38, 95%CI: 0.28–0.51) was a protective factor of postpartum depressive symptoms.

Association between different family adaptability types and postpartum depressive symptoms

The results of the univariate regression analysis showed that different family adaptability types were associated with postpartum depressive symptoms (Table 4, model 1, $P < 0.001$). After adjusting for age, educational level, occupation, gravidity, parity, and mode of delivery, rigid (AOR = 4.41, 95%CI: 3.02–6.43) and structured families (AOR = 1.88, 95%CI: 1.34–2.63) had a higher risk of postpartum depressive symptoms than flexible families, whereas chaotic families (AOR = 0.35, 95%CI: 0.24–0.51) protected against postpartum depressive symptoms.

DISCUSSION

We found that the prevalence of postpartum depressive symptoms was 31.6%, which is consistent with previous studies[15]. This indicates that postpartum depressive symptoms are an important perinatal mental health problem among. Furthermore, the levels of family cohesion and adaptability in the postpartum depressive symptoms group were significantly lower than those in the non-postpartum depressive symptoms group, which suggested that, when families are in the transition period between pregnancy and birth, high levels of cohesion and adaptability can enable family members to join forces, adjust strategies, and jointly help the mother cope with the various difficulties involved in raising children and the increase in costs. This, in turn, reduces the psychological pressure on women and lowers the risk of postpartum depressive symptoms. Previous studies have similarly found that higher family cohesion and adaptability reduce the prevalence of psychological disorders. For example, a survey conducted in 100 patients with terminal illnesses admitted to a palliative care ward in South Korea found that higher family adaptability reduced anxiety and depression in patients, whereas higher family cohesion resulted in lower rates of depression[25]. In a study of family cohesion and adaptability in youth at high clinical risk for psychosis, the youth and their mothers were reported to have lower adaptability and cohesion than their healthy control counterparts[26]. Moreover, a study on anger traits and somatization in junior college students in Shanghai, China, found that a high level of family cohesion and adaptability played a protective role, reducing the effects of anger characteristics on physical symptoms. They suggested that intervention measures that combine family cohesion, adaptive training, and depression treatment may be effective for patients with a high level of anger characteristics [27]. Taken together, we suggest that, to prevent and treat postpartum depressive symptoms, mental health workers specializing in women's mental health should focus on improving maternal family cohesion and adaptability.

Olson's theory of families, called "The Circumplex Model", suggests that family cohesion and adaptability have a curvilinear relationship with psychological and behavioral disorders. Excessively high or low cohesion and adaptability in the family are considered dysfunctional, and moderate cohesion and adaptability in the family model are regarded as beneficial[16,28]. Inadequate cohesion

FACES II-CV: Family Cohesion and Adaptability Scale.

leads to alienation and poor communication among family members, whereas excessive cohesion leads to family members lacking a sense of boundary and self-space. Furthermore, families with insufficient adaptability have more rigid family rules and an inability to adapt to environmental changes, whereas an excessive level of adaptability leads to confusion around family rules and a lack of organizational

guidance, which is not conducive to the physical or mental health development of family members[29]. However, this model has also been questioned and criticized by some scholars, and several studies have reported inconsistent results. In a study conducted in South Korea on the correlation between adolescent behavioral problems and family cohesion and adaptability, results showed that the relationship between family cohesion, adaptability, and adolescent behavioral problems was linear rather than curvilinear. The study found that higher scores of family cohesion and adaptability were associated with a lower incidence of adolescent behavioral problems[30]. In addition, in a study on the relationship between psychological stress and family cohesion and adaptability in infertile couples, results showed that the relationship between family cohesion, adaptability, and psychological stress was also linear rather than curvilinear. They found that higher scores of family cohesion and adaptability were associated with less psychological pressure in couples with infertility[31].

We observed a linear relationship between family cohesion, adaptability, and postpartum depressive symptoms, where higher family cohesion and adaptability scores were associated with a lower risk of postpartum depressive symptoms. We speculate that this difference is related to the specific physiological stage of the postpartum period. Postpartum women often have poor self-functioning and are dependent on their surrounding environment[32,33]. Moreover, pregnant women in China often follow the custom of "confinement"[34,35], where postpartum women are taken care of at home for one month after giving birth and are not permitted to do housework or leave the house. High levels of cohesion and adaptability enable family members to offer crucial help to pregnant women, reducing psychological pressure and preventing the development of postpartum depression. The present findings are in line with the abovementioned studies. The findings here of a linear relationship rather than a curvilinear relationship between family cohesion, adaptability, and psychological and behavioral disorders may be related to the study population. Previous studies reporting curvilinear relationships were mainly conducted in general populations[16,36], whereas those reporting linear relationships were mainly focused on specific groups, such as adolescents, couples with infertility, and postpartum women. These groups often have weaker self-functioning and high dependence on their external environment and require significant support from their families to meet their needs to maintain psychological balance and prevent psychological and behavioral problems.

Limitations

The sample size of the present study was large, and we controlled for potential confounding factors. For example, interviews were conducted in the hospital by trained nurses, and a scale specifically developed for speakers of Mandarin was used for assessment, which offered reliability of the results.

However, the study also had limitations. For example, this was a single-center study. Furthermore, we used the EPDS to assess depressive symptoms without using the Diagnostic and Statistical Manual of Mental Disorders (Fifth Edition) interviews to confirm diagnoses of depression. Indeed, research has suggested that self-reporting methods produce higher EPDS scores[37]. In addition, although we adjusted for several confounding factors, we did not control for other factors related to postpartum depressive symptoms, such as breastfeeding[38-40], intimate partner violence[5,15], and marital relationships[41,42]. We aim to include these factors in future studies using a hierarchical approach.

CONCLUSION

The present research showed that high family cohesion and adaptability prevented the development of postpartum depressive symptoms. For familial treatment of postpartum depression, family therapists may need to consider the physical and mental characteristics, customs, and cultures of postpartum women and appropriately adjust and enhance family cohesion and adaptability as much as possible to help prevent pregnant women from developing postpartum depression.

ARTICLE HIGHLIGHTS

Research background

Postpartum depression is the most common mental illness of mothers after childbirth, and the family environment is an important environmental factor affecting postpartum depression. Olson's theory of family cohesion and adaptability is a classic model to describe the level of family function. However, this model has not been tested in families of patients with postpartum depression.

Research motivation

The main focus was to explore the relationship between family cohesion/adaptability and postpartum depression symptoms. The key problem to be solved was how to investigate family cohesion and adaptability and postpartum depression symptoms and how to study the relationship between them. This research has great significance for future explorations into reducing the risk of postpartum depression.

Research objectives

The purpose of this study was to explore the relationship between family cohesion and adaptability and the risk of postpartum depressive symptoms.

Research methods

The clinical data of 1446 postpartum women with and without depressive symptoms were analyzed retrospectively. The Edinburgh Postpartum Depression Scale and the Chinese version of the Family Cohesion and Adaptability Scale II were used to evaluate depressive symptoms and family cohesion, respectively. Univariate regression analysis was used to evaluate the correlation between family cohesion and postpartum depression symptoms.

Research results

The prevalence of depression in postpartum women was 31.4%, and the family cohesion scores of this population were low. Univariate regression analysis showed that the risk of postpartum depression in detached and separated families was higher than that in connected families, while cohesion was a protective factor for postpartum depression. In addition, rigid and structured families had a higher risk of postpartum depression than flexible families, while chaotic families could prevent postpartum depression.

Research conclusions

This study showed that the prevalence of depression in postpartum women was 31.4%, and the family cohesion scores of this group were low. The higher the scores of family cohesion and adaptability, the lower the risk of postpartum depressive symptoms. Disordered families and cohesive families can prevent postpartum depression.

Research perspectives

Future research should investigate differences in family cohesion and adaptability in different types of families and their influence on postpartum depression according to the age, education, and the annual income of postpartum women.

Abstract

BACKGROUND

The existing literature indicates that psychotherapeutic treatment, especially exposure and response prevention (ERP) is efficacious in treating obsessive-compulsive disorder (OCD). The coronavirus disease 2019 pandemic adversely impacted many patients with OCD and disrupted their usual treatment. Moreover, the pandemic forced a global switch to telemental health (TMH) services to maintain the standards and continuity of care. Consequently, clinicians are increasingly using TMH-based psychotherapeutic treatments to treat OCD. However, several challenges have made it difficult for them to implement these treatments in the changed circumstances imposed by the pandemic.

AIM

To describe the formulation, implementation, feasibility, and usefulness of videoconferencing-based ERP (VC-ERP) treatment for OCD during the coronavirus disease 2019 pandemic.

METHODS

This prospective, observational study was conducted in the psychiatric unit of a multi-specialty hospital in north India over 12 mo (July 2020-June 2021). All patients with OCD were assessed using the home-based TMH services of the department. The VC-ERP protocol for OCD was the outcome of weekly Zoom meetings with a group of clinicians involved in administering the treatment. After a systematic evaluation of the available treatment options, an initial protocol for delivering VC-ERP was developed. Guidelines for clinicians and educational materials for patients and their families were prepared. The protocol was implemented among patients with OCD attending the TMH services, and their progress was monitored. The weekly meetings were used to upgrade the protocol

to meet the needs of all stakeholders. Feasibility and efficacy outcomes were examined.

RESULTS

All patients were diagnosed with OCD as a primary or a comorbid condition according to the International Classification of Diseases, 10th version criteria. Out of 115 patients who attended the services during the study period, 37 were excluded from the final analysis. Of the remaining 78 patients, VC-ERP was initiated in 43 patients. Six patients dropped out, and three were hospitalized for inpatient ERP. Eleven patients have completed the full VC-ERP treatment. One patient completed the psychoeducation part of the protocol. VC-ERP is ongoing in 22 patients. The protocol for VC-ERP treatment was developed and upgraded online. A large proportion of the eligible patients (n = 34/43; 79%) actively engaged in the VC-ERP treatment. Drop-out rates were low (n = 6/43; 14%). Satisfaction with the treatment was adequate among patients, caregivers, and clinicians. Apart from hospitalization in 3 patients, there were no other adverse events. Hybrid care and stepped care approaches could be incorporated into the VC-ERP protocol. Therefore, the feasibility of VC-ERP treatment in terms of operational viability, service utilization, service engagement, need for additional in-person services, frequency of adverse events, and user satisfaction was adequate. The VC-ERP treatment was found to be efficacious in the 11 patients who had completed the full treatment. Significant reductions in symptoms and maintenance of treatment gains on follow-up were observed.

CONCLUSION

This study provided preliminary evidence for the feasibility and usefulness of VC-ERP in the treatment of OCD. The results suggest that VC-ERP can be a useful option in resource-constrained settings.

Core Tip: The coronavirus disease 2019 pandemic adversely impacted many patients with obsessive-compulsive disorder (OCD), compelling clinicians to increasingly use telemental health-based options rather than conventional psychotherapeutic treatments for OCD. This study described the implementation of a videoconferencing-based exposure and response prevention treatment protocol developed by an online group of clinicians during the pandemic. On prospective follow-up, 34 patients had either completed or were undergoing the treatment. The preliminary results showed that videoconferencing-based exposure and response prevention was a feasible and efficacious mode of treatment and may be a useful option for OCD, even in low-resource settings.

INTRODUCTION

The existing literature regarding the treatment of obsessive-compulsive disorder (OCD) indicates that exposure and response prevention (ERP) or cognitive behavior therapy (CBT) that includes ERP is more effective in treating OCD than any other control or active psychotherapeutic treatment[1-5]. Moreover, the evidence also suggests that ERP is more efficacious than medication treatment of OCD, and the gains from treatment last longer. Nevertheless, combined treatment with medications and psychotherapy is more effective for severe OCD and is commonly used in routine clinical practice. However, despite the availability of evidence-based and effective psychotherapeutic treatments, very few patients have ready access to them. The rates of treatment-seeking are low among patients due to poor awareness, stigma, and inadequate engagement. The provision of ERP is also hampered by the shortage of professionals trained in administering ERP and skepticism among clinicians about ERP. Other hurdles include the longer duration and greater costs of ERP and the need to travel long distances for treatment. It has been proposed that telemental health (TMH) treatments may help in overcoming many

of these limitations of conventional ERP[3,4,6-8].

TMH-based psychotherapy has been used to treat OCD for more than three decades[6-10]. The older forms of such TMH treatments for OCD included computerized CBT and telephone-based CBT with or without therapist support. These methods were followed by videoconferencing-based ERP (VC-ERP) or CBT, with the earliest trials of these interventions starting to appear by the 1990s. The latest development in this field has been the advent of online psychotherapeutic interventions including internet-based CBT, web-based self-help groups, virtual reality-based ERP, and smartphone-based interventions. The existing evidence shows that TMH-based ERP/CBT for OCD leads to significant symptom reduction and improved functioning[9,11-14]. Treatment gains are often maintained for several months[8,9,11-13]. These treatments are feasible, acceptable, and cost-effective[8,10,12,14,15]. There appears to be no difference in efficacy between the TMH-based and in-person treatments[6,9,11,13,14], but this is not a consistent finding[7,8,10,16]. However, the evidence for these findings is relatively scarce and hampered by methodological inadequacies among the constituent studies[7,8,11,13,14]. Moreover, there are concerns about technological obstacles such as connectivity, safety, privacy, and confidentiality[7,10,17]. Lastly, clinicians are particularly dissatisfied with the inadequate treatment alliance and dropouts in TMH treatments[6,9,16].

The onset of the coronavirus disease 2019 pandemic negatively affected many patients with OCD[18-21]. There was an increase in patients with new-onset OCD and exacerbation of symptoms in those already suffering from OCD. However, studies have differed in their estimation of the impact of the pandemic on OCD. It seems that around two-thirds of the patients have been unaffected, whereas about one-third of patients have worsened[22]. The delivery of in-person ERP was also adversely affected because of the disruption in mental health services during the pandemic. While some studies found that ERP services were curtailed or that clinicians found it difficult to adapt to the changed circumstances[19,23], others reported no difference between the pre-pandemic and post-pandemic phases[22]. Nevertheless, the forced switch to TMH-based services during the pandemic in several countries[24] has meant that many clinicians are using TMH-based rather than conventional ERP for OCD[22,23,25].

A major lacuna in the existing literature on TMH-based psychotherapy for OCD is that most of the studies have been conducted in Western countries[13,14]. This applies to studies of internet-based CBT, VC-ERP, and other online interventions. Only a few studies of these interventions from Japan[26,27], Korea[28], and the Middle East[29] could be identified. In general, research on the efficacy of TMH in the treatment of psychiatric disorders from developing countries is limited, and reviews of the subject have not included trials on TMH-based treatment of OCD[30-32]. Apart from the lack of evidence, cultural acceptability of TMH-based treatments, their efficacy, and engagement with these treatments are also quite different in these countries. The situation in India is similar. Though VC-based TMH services were used in India before the pandemic and there was an upsurge in these services during it, there were large gaps in the delivery of these services[33,34]. Controlled trials on TMH-based psychotherapy of OCD are not available. Therefore, a new beginning had to be made. This study described the formulation and implementation of VC-ERP treatment for OCD during the pandemic and its current status in terms of feasibility and usefulness.

MATERIALS AND METHODS

This report followed the Strengthening the Reporting of Observational Studies in Epidemiology (STROBE) guidelines for reporting observational studies.

Setting

The VC-ERP protocol was developed in the psychiatric unit of a multi-specialty hospital in north India. Patients with OCD attending the unit were already being treated with in-person ERP mostly on an inpatient basis. Inpatient ERP was associated with good short-term outcomes, but the long-term outcomes were unclear because of the high dropout rate after discharge[35]. Similar outcomes for inpatient ERP had been reported from another Indian center[36]. The department had also been running a home-based TMH service on a smaller scale since September 2018. This service was used for VC-based follow-up of patients who had completed in-person ERP. Following the shutdown of the outpatient clinics in March 2020, the home-based TMH service was upgraded and scaled up to cater to all outpatients. The features of this service have been described elsewhere[37]. This expanded platform allowed the delivery of VC-ERP based on the treatment protocol for in-person ERP.

VC-ERP for OCD

The in-person ERP protocol was modified to allow it to be delivered through the VC platform using the Zoom software. The use of VC was supplemented by WhatsApp video calls and messaging, phone calls (landline or smartphones), and e-mail. Virtual prescriptions sent by WhatsApp messages were used to convey advice regarding investigations and medications. The use of multiple digital modes of patient-clinician communication was consonant with the hybrid model of care, which had been recommended particularly during the pandemic[38]. This improves the flexibility and versatility of TMH-based care

and maintains its continuity by switching between different modes when one of them fails.

The modified VC-ERP protocol was developed based on feedback from a weekly Zoom group of clinicians actively involved in VC-ERP treatment for OCD. The group consists mainly of trainee psychiatrists, (post-MD) senior residents, and a consultant psychiatrist. Apart from group supervision of the trainees administering the treatment, the activities undertaken by this group have included carrying out a detailed review of the literature on ERP for OCD, TMH-based treatment options, and VC-ERP for OCD. Standardized guidelines for VC-ERP were prepared, and clinicians adhered to these standards of care. Educational materials for patients and their families were also prepared. The final protocol for VC-ERP is shown in Tables 1 and 2.

Differences between VC and in-person ERP

The differences between ERP by VC or by in-person treatment and the difficulties encountered during VC-ERP were the primary focus of many group discussions. The consensus views on this aspect are included in Table 3. These considerations provided the basis for the modifications made in the VC-ERP treatment protocol.

Modifications in technique required for conducting VC-ERP

Introductory education sessions with the patients and their caregivers were felt to be essential to improve their understanding and motivation for ERP. Although detailed psychoeducation sessions were carried out as a part of the ERP later, during this phase the objective was to provide enough information to ensure patient and caregiver cooperation with the process of assessment[39]. The contents of the brief information leaflet used for this purpose are depicted in Table 2.

A structured procedure for assessment was used. The clinician-administered version of the Yale-Brown Obsessive Compulsive Scale (YBOCS) was used to screen for different obsessions/compulsions as well as to rate the severity of obsessive-compulsive symptoms. The YBOCS is the most commonly used instrument for this purpose because of its reliable psychometric properties[1,4,13]. Standardized procedures such as those by Hawton *et al*[40] were used to conduct the behavioral analysis in the ABC format (antecedents, behaviors, consequences). Subjective units of distress were used to rate the severity of behaviors and also construct an ascending hierarchy of problem behaviors. The construction of the hierarchy was a key step in the process of planning for VC-ERP. Inputs were actively solicited from patients and caregivers during this stage. They were asked to keep a daily record of symptoms for about a week to make the hierarchy as comprehensive as possible. Google sheets or WhatsApp messages that could be regularly updated were used for this purpose. The assessment process often took up to 2 wk, but a prolonged and comprehensive assessment had many advantages such as increasing awareness about symptoms among the patients and caregivers, reducing their distress, and acquainting them with the VC-ERP treatment to follow. Finally, the hierarchies made were continuously upgraded during treatment based on the new information provided by patients or caregivers. Therefore, the process of assessment continued throughout the treatment.

A five-step approach to VC-ERP was used. These five steps of ERP were based on standard protocols of ERP or CBT[1,39,41-43]. Benson's relaxation technique[44] was the preferred mode of teaching relaxation exercises. The only other modification was that "processing" was used instead of cognitive restructuring. Processing involved discussing the patients' experiences and understanding of ERP and how this matched their expectations of the treatment[13,42]. Processing also allowed for discussions on the reality of the patient's beliefs, explanations about neutralization strategies, and suggestions about using more adaptive coping strategies. Modifications to the other components of the ERP are summarized in Table 4.

Outcomes of VC-ERP

The main focus of this study was on the feasibility outcomes including operational viability, service utilization, service engagement, need for additional services, frequency of adverse events, and treatment satisfaction and treatment preferences among patients, caregivers, and clinicians. The information about treatment engagement and the dropout rate was obtained from the medical records of patients who were offered ERP and either consented or refused the treatment. For all other outcomes, only patients who had agreed to undertake ERP and those who had completed or were actively engaged in the treatment were included. Patients were not interviewed separately for this part. Rather, the information was obtained from their treatment records. Therefore, any patient with incomplete treatment records was excluded. For the efficacy outcomes, only the 11 patients who had completed the entire VC-ERP were considered. Pre- and post-treatment YBOCS scores were extracted from their records to determine the efficacy of VC-ERP treatment. Information about the maintenance of gains post-treatment over 13 mo was also extracted from the treatment records.

Statistical analysis

The sample was characterized by using frequencies, means, and standard deviations. Loss to follow-up at any time was considered a dropout. Pre- and post-treatment comparisons were carried out using the Wilcoxon signed rank test.

Table 1 The treatment protocol for videoconferencing-based exposure and response prevention treatment for obsessive-compulsive disorder

Components	Details
Detailed assessment	Establishing the diagnosis based on history and mental state examination Relevant investigations. Formulating a management plan consisting of medications and psychosocial treatment. The decision to start ERP was made following this assessment
Introductory psychoeducation[1]	Brief introductory education sessions with patients and designated caregivers with the help of a two-page written information leaflet for them
Standardized assessments	(1) YBOCS screening (2) YBOCS rating (3) Standardized behavioral analysis, *e.g.*, by Hawton *et al*[40] (4) Construction of ascending hierarchy of symptoms (according to the subjective units of distress on a 0%-100% scale)
Five-step ERP[2]	Psychoeducation, symptom monitoring, relaxation exercises, exposure and response prevention, and processing
Conduct of VC sessions[3]	All VC-ERP sessions were conducted at home, supervised by the clinician, and attended by the caregiver. WhatsApp messages or phone calls were used to convey advice regarding details of sessions, investigations, and medications
Additional strategies	Incorporation of additional techniques, *e.g.*, thought stopping with ERP for those with predominant obsessions
Relapse prevention	Continued follow-up through VC with constant re-emphasis on all components of the ERP. Booster sessions, if required upon completion of the initial VC-ERP treatment
Caregiver involvement	A family member designated as the primary caregiver was involved in the entire process of the VC-ERP treatment. The caregiver conducted homework sessions
Hybrid care	Hybrid treatment had two components (1) Employing a combination of VC-ERP sessions at home and in-person ERP sessions at the outpatient department (2) Employing multiple modes of patient-clinician communication such as VC, mail, text messages, and phones to augment in-person care

[1]Details in Table 2.

[2]These five steps of exposure and response prevention (ERP) were based on standard protocols of ERP or cognitive behavior therapy[1,39,41-43]. Psychoeducation imparted more detailed information about obsessive-compulsive disorder (OCD) including a cognitive-behavioral model of OCD. Apart from providing basic information about OCD, it attempted to correct common misconceptions. Psychoeducation also involved providing a clear rationale for ERP, information about the components and procedure for ERP, conduct of videoconferencing-based ERP sessions, and how ERP was expected to help. Patients and caregivers were taught to objectively monitor symptoms, thoughts, and distress during sessions and during the course of treatment. Standard formats for monitoring during videoconferencing sessions were developed. Google sheets or text messages that could be regularly updated were exchanged between clinicians and patients. The clinician carried out his/her own assessments, and feedback about progress of treatment was provided to the patient. Relaxation exercises, preferably using Benson's relaxation technique[44] were taught. It involved muscle relaxation, deep breathing, and the use of relaxation as a coping strategy. It was used to reduce anxiety and improve motivation for treatment. Standard techniques of ERP were used with certain modifications as explained in Table 4. During processing, the patients' experience of the sessions was discussed to enhance their understanding of ERP, examining the reality of their beliefs, and discussing more adaptive ways of coping[13,42].

ERP: Exposure and response prevention; VC-ERP: Videoconferencing-based exposure and response prevention; YBOCS: Yale-Brown Obsessive-Compulsive Scale.

Ethical considerations

This observational study was a part of a larger study on home-based TMH services for all patients[37]. The protocol was approved by the institute's ethics committee. Due to the restrictions imposed by the pandemic, verbal informed consent over the phone was allowed. As explained above, data regarding outcomes were obtained only from patients who had verbally consented to undertake ERP and had actively engaged in the process of treatment. However, patients were not contacted or assessed separately to determine these outcomes. Rather, all data regarding outcomes were extracted from routine medical and treatment records. Patient identities have not been revealed. Therefore, written informed consent from patients was not obtained for information about treatment outcomes. All the methods followed the guidelines of the Declaration of Helsinki for medical research involving human subjects.

Table 2 Content of the brief introductory education session for videoconferencing-based exposure and response prevention treatment for obsessive-compulsive disorder

Content
1 What is OCD? What are obsessions and compulsions in OCD?
2 How common is OCD?
3 How does the patient feel while experiencing the symptoms of OCD?
4 Why do patients develop OCD?
5 What are the types of treatment available?
6 What is the role of medications in treating OCD?
7 What is ERP and how does it work?
8 What is the need for ERP?
9 How will the VC-ERP sessions be conducted?
10 How long will the treatment take?

ERP: Exposure and response prevention; OCD; Obsessive-compulsive disorder; VC-ERP: Videoconferencing-based ERP for OCD.

Table 3 Problems with videoconferencing-based exposure and response prevention treatment for obsessive-compulsive disorder and in-person and proposed solutions

	Difficulties with VC-ERP	Suggested solutions
Understanding and motivation of patients and caregivers	It was harder to explain the procedure to patients/caregivers. Motivation to engage in VC-ERP was often low. As a result, treatment engagement was variable	Early initiation of psychoeducation and the more frequent use of hybrid treatment
Difficulties faced during the assessment	The initial assessment took longer. Frequent interruptions due to poor network connectivity and the need to restart the process several times were common. Patients/caregivers often complained about the long period of assessment. Some patients became more anxious during the process	Educate patients/caregivers about the likely timeframes for assessment and treatment during the introductory psychoeducation sessions. Additional in-person sessions and administering benzodiazepines for short periods could help control anxiety
Conducting ERP sessions-patient-related and caregiver-related difficulties	These included variable cooperation, discomfort and hesitation, worry about confidentiality, indulging in neutralization strategies during sessions, preference for in-person visits, and problems with the timing and duration of the sessions	Shorter VC-ERP sessions (minimum of 30 min) and flexible scheduling of sessions (every 7-14 d). Ongoing education of patients and caregivers to ensure realistic expectations from VC-ERP
Conducting ERP sessions-clinician-related difficulties	Clinicians faced problems in sustaining their motivation, dealing with the additional burden of VC sessions and the need to adjust to a new medium	Training, supervision, and support for clinicians through regular group meetings
Technological difficulties	Poor connectivity, unavailability of proper equipment, user's unfamiliarity with technology, and time constraints	Modifications to the ERP procedure to make it more compatible with VC
Disadvantages	Group members conducting VC-ERP sessions rated it about three times as difficult compared to in-person ERP because of the problems encountered	A structured treatment package incorporating modifications in the treatment, ongoing education, and support for all users
Advantages	Group members agreed that VC-ERP had advantages such as greater access, convenience of carrying out sessions at home, and lesser likelihood of late disengagement if motivation could be ensured	The consensus was that though conducting VC-ERP may be more difficult than in-person ERP, the basic procedures and their implementation were similar

ERP: Exposure and response prevention; VC-ERP: Videoconferencing-based exposure and response prevention.

RESULTS

Participants

During the period of this study (July 2020-June 2021), the home-based TMH service was used to treat 3442 new and 12126 old patients. Of these, 115 new patients (3%) had a diagnosis of OCD as a primary or a comorbid condition according to the International Classification of Diseases, 10th version criteria. During subsequent follow-up, 1 patient whose diagnosis was changed from OCD to personality disorder was excluded; 28 patients had dropped out of treatment, and details regarding the status of 8 patients were not available. Therefore, 78 patients were included in the final analysis.

Table 4 Modifications in technique required for conducting videoconferencing-based exposure and response prevention treatment for obsessive-compulsive disorder

VC-ERP components	Modifications made to the VC-ERP
Detailed psychoeducation	Carried out using manuals in English and the local language for clinicians, patients, and caregivers. The content was simple, brief, and provided clear explanations. Psychoeducation sessions continued throughout the treatment
Monitoring of symptoms and progress	Simultaneous monitoring was carried out by the patients, caregivers, and clinicians through VC sessions, Google sheets, or WhatsApp messages that were regularly updated. Constant feedback about the progress of treatment was provided to the patient
Relaxation exercises	Benson's relaxation technique was preferred because of its brief and simple format. Autogenic training or modified Jacobson's progressive muscular relaxation exercises were taught if required. Written instructions in English and the local language and audio-visual aids for teaching were available for clinicians, patients, and caregivers
Duration of VC-ERP sessions	Though prolonged exposure is the goal because of its greater efficacy, it was quite difficult to have VC sessions of more than 30 min. Thus, the minimum duration was set at 30 min with the opportunity to prolong the sessions according to the patient's convenience
Frequency of VC-ERP sessions	The frequency of sessions varied from weekly sessions to one session every 10-14 d. Flexibility was essential in deciding the duration and frequency of sessions. Several other factors were considered, particularly patient/caregiver preferences, the stage of ERP, the severity of symptoms, and the availability of clinicians
Supervision of VC-ERP sessions	The patient's camera was not only focused on the patient but also covered a significant portion of the room so that clinician could detect any surreptitious compulsions or neutralizing acts. The camera was never switched off during the sessions
Engaging patients during the VC-ERP sessions	Clinicians, patients, and caregivers were all actively involved during the VC-ERP sessions. Every effort was made to minimize distractions. Neutralizing acts were noted and discussed later during processing. The clinician engaged with the patients at regular intervals to make sure that they were focusing on the treatment and to check the level of anxiety during sessions. However, constant talking was avoided because this might distract the patient
Ensuring patients' tolerance of anxiety	Patient comfort with the level of exposure and their ability to tolerate anxiety was of overriding importance. They were never forced to engage in something that made them uncomfortable during the ERP sessions. Rather, each step was undertaken after proper education and fully ensuring the patient's agreement and cooperation
The slower pace of VC-ERP	VC-ERP was expected to progress at a much slower pace than in-person ERP. This was explained to the patients and caregivers and usually did not present a problem
Privacy and confidentiality	Privacy was essential, and patients were informed about the people present in the room (*e.g.*, technicians) when the session was being conducted. The patient was only accompanied by the designated caregiver at home. Any recording was done only with the patient's explicit consent. All material relating to the treatment was stored securely
Safety	Patients were required to be accompanied by caregivers during the sessions. Anxiety levels were constantly monitored, and sessions were terminated if the patient was uncomfortable. If there were other concerns about the safety of the patient (*e.g.*, risk of self-harm or violence), closer monitoring was instituted for such highrisk situations. Caregivers were also educated to manage such high-risk situations. For persisting safety concerns including symptom exacerbations during VC-ERP, patients and family members were helped to attend outpatient or emergency services
Treatment of comorbidities	Other modalities such as medications or occasionally ECT were used to treat primary or secondary comorbidities. The VC-ERP was adapted to meet the needs of patients with comorbid symptoms. Techniques utilized included temporarily suspending the sessions when comorbid symptoms increased, offering increased support at this time using the VC platform, promoting greater involvement of caregivers, and combining VC sessions with in-person sessions
Using hybrid modes of treatment	Hybrid care involved conducting some of the initial ERP sessions on an in-person basis and the later sessions by utilizing VC. Similarly, for each new step of the hierarchy, the initial session was an in-person one followed by VC sessions. This often mitigated the problems of poor understanding and variable motivation noted in exclusive VC-ERP treatment. Requests from patients and caregivers for in-person sessions were catered to as far as possible
Self-exposure	In exceptional instances when caregivers were not available, therapist-guided self-exposure was tried. A greater level of patient motivation was required for self-exposure and the pace of ERP was slower

ERP: Exposure and response prevention; VC-ERP: Videoconferencing-based exposure and response prevention. ECT: Electroconvulsive therapy.

Patient profiles

Out of 78 patients, 38 were men and 40 were women. In general, patients seen during the pandemic were more likely to be older, married, better educated, and from higher-income families living near the hospital[37]. However, many patients were barely literate, impoverished, and from distant, rural locations. Three patients had late-onset OCD. Twenty-one patients had a comorbid psychiatric illness. OCD as a primary condition included the following comorbidities: single depressive episode (n = 6), recurrent depressive disorder (n = 4), dysthymia (n = 1), agoraphobia (n = 1), hypochondriasis (n = 1), and impulse control disorder (n = 1). OCD as a secondary comorbidity was present in schizophrenia (n = 3), bipolar disorder (n = 2), dementia (n = 1), and traumatic brain injury (n = 1). Most patients were on pharmacological treatment for OCD and comorbid conditions.

VC-based ERP for OCD: feasibility, acceptability, and efficacy

Tables 5 and 6 provide these details.

VC-ERP was considered in the majority of patients with OCD, but because of different reasons only about half of them (55%) started VC-ERP. Of the 43 patients who started VC-ERP, 6 dropped out early and 3 had to be hospitalized for inpatient ERP. Thus, a large proportion of the eligible patients (n = 33/43; 77%) had completed the full treatment (n = 11) or were currently undergoing VC-ERP (n = 22). One patient improved following the initial sessions and did not have to complete the entire treatment. Hybrid treatment was more commonly used by many of these patients (n = 20) once the outpatient services resumed. Most patients and caregivers considered this to be a better option and preferred hybrid care.

Feasibility outcomes among the 34 patients engaged in VC-ERP showed that it was possible to implement the treatment in usual clinical settings. Drop-out rates were low (n = 6/43; 14%). Apart from the 3 patients (9%) with severe OCD who did not respond to VC-ERP and required hospitalization, there were no other adverse events. The number of patients treated with VC-ERP in a year was more than those who had received inpatient ERP for a year during the pre-pandemic period. Satisfaction with the treatment was adequate among patients, caregivers, and clinicians. Therefore, the feasibility of VC-ERP treatment in terms of operational viability, service utilization, service engagement, need for additional in-person services, frequency of adverse events, and user satisfaction was adequate.

The 11 patients who completed the entire treatment had moderate levels of OCD for several years. VC-ERP led to significant reductions in the YBOCS scores on completion. Treatment gains have been maintained in these patients on follow-up for a year after completing the VC-ERP. More than half of them (54%) had comorbid conditions, but this did not affect their improvement with VC-ERP.

DISCUSSION

TMH-based services are efficacious and suitable alternatives to in-person care and have proved to be particularly useful during the pandemic. By promoting ready access to psychiatric care, they can remove several barriers associated with conventional services, enhance satisfaction among users, and empower the underserved population from remote areas[24,31,32].

The efficacy, advantages, and disadvantages of VC-based ERP for OCD

Several reviews[6-10] and meta-analyses[11,13] of TMH-based treatments for OCD have found that VC-based treatment is useful, but they have only included a few trials of VC-ERP for OCD. Similarly, meta-analyses[25,45,46] and reviews[17,47-50] that have found VC-based treatments to be effective for psychiatric disorders have included a limited number of VC-ERP studies of OCD. This is not surprising because there are only three randomized-controlled trials (RCTs) of VC-ERP in OCD[51-53]. A fourth RCT of VC treatment for anxiety and mood disorders included 4 patients with OCD[54]. These RCTs have shown that VC-ERP is more efficacious than neutral or active control treatments and equal in efficacy to in-person ERP. Treatment gains are maintained for several months, and VC-ERP had a more positive impact on the treatment alliance and patient engagement. Open trials have similarly shown that VC-ERP is an effective, feasible, acceptable, and cost-saving treatment, which can be used to supplement in-person ERP[27,55-58]. However, the RCTs have small sample sizes and are of brief duration. Therefore, without properly conducted RCTs with non-inferiority or equivalence designs, the current evidence in favor of VC-ERP for OCD cannot be considered adequate[59].

Like other TMH-based treatments, VC-ERP has several advantages compared to in-person ERP[7,13,17,50,52]. It leads to wider dissemination of ERP and greater patient access to evidence-based ERP. Home-based ERP allows greater flexibility, greater involvement of family members in ERP, and more opportunities to address the negative attitudes or accommodations by the family. It can be cost-effective because it reduces travel costs and absence from work. Since patients receive treatment at home, the stigma associated with seeking psychiatric treatment is lessened. However, VC-ERP has its challenges. It is heavily dependent on external factors such as technological infrastructure, internet penetration and affordability, network connectivity, and the user's familiarity with technology. Patient and family motivation might be poor, forging effective treatment alliances may be difficult, and supervision and monitoring may not be optimal[50,52,56].

VC-based ERP for OCD vs internet-based CBT

Currently, there seems to be a greater emphasis on delivering online or internet-based ERP or CBT for OCD particularly in high-income countries[9]. The two types of treatment have their advantages and disadvantages. Internet-based CBT has a broader evidence base and the number of trials including RCTs is much more than those of VC-ERP[10,11-14]. Its efficacy is comparable to in-person CBT. Internet-based CBT is particularly useful as an initial option for mild or moderate OCD. Moreover, it is more readily accessible and offers a wider choice of techniques and varying levels of clinician assistance. The treatment is efficacious and cost-effective even with low levels of clinician support[15]. Moreover, greater levels of clinician support can help minimize dropouts, and treatment gains are usually

Table 5 Details of videoconferencing-based exposure and response prevention treatment for obsessive-compulsive disorder

Patients	Number	Comments/details
Patients with OCD attending the home-based TMH services during the study-period	115	This was 3% of all new outpatients and represented an increase in the number of such patients compared to the period before the pandemic
Patients available for analysis	78	ERP not considered (n = 17; 15%); improved with medications and did not require ERP (n = 2); refused ERP (n = 3); VC-ERP yet to be initiated (n = 13)
Patients in whom VC-ERP was initiated/early dropouts	43	Six patients dropped out from VC-ERP treatment. (Dropout rate 14%)
Improvement after initial treatment	1	One patient improved after initial psychoeducation and regular relaxation exercises and was not required to complete the entire VC-ERP treatment
Transition to hybrid care	20	Hybrid care became easier once the outpatient services resumed in December 2021
Transition to inpatient ERP	3	VC-ERP was followed by inpatient-based ERP because of severe OCD and non-response to VC-ERP.
Patients who have undergone/are undergoing VC-ERP	33	VC-ERP has been completed in 11 patients and is ongoing in 22 patients

ERP: Exposure and response prevention; OCD: Obsessive-compulsive disorder; VC-ERP: Videoconferencing-based exposure and response prevention; TMH: Telemental health.

Table 6 Efficacy of videoconferencing-based exposure and response prevention treatment for obsessive-compulsive disorder

Age	Sex	Marital status	Residence	Comorbidity	Duration of OCD	Baseline YBOCS score	YBOCS score at completion
Mean: 31.27 (SD: 9.65) yr, range: 22-56 yr	Men: 9; Women: 2	Single: 8; Married: 3	Urban: 9; Rural: 2	OCD primary disorder: 7 (depressive disorder: 2); OCD secondary disorder: 4 (schizophrenia: 3; bipolar disorder: 1)	Mean: 6.90 (SD: 6.48) yr, range: 1-25 yr	Mean: 25.45 (SD: 5.63), range: 17-36	Mean: 4.27 (SD: 4.22)[1], range: 0-13

[1]Significant reduction in Yale-Brown Obsessive-Compulsive Scale scores; Z = 2.936; P < 0.01 (using the Wilcoxon signed rank test).
OCD: Obsessive-compulsive disorder; YBOCS: Yale-Brown Obsessive-Compulsive Scale; SD: Standard deviation.

enduring.

Despite these advantages, there is no difference in efficacy between VC-ERP and internet-based treatments[13]. Indeed, some of the evidence seems to indicate that VC-ERP may be more efficacious than internet-based treatments[45,60]. Moreover, VC-ERP resembles the "gold-standard" in-person ERP more closely than internet-based ERP[13,16,17,45,46]. Since VC-ERP is conducted at home, it has the advantage of greater convenience, more chances of the behavioral gains generalizing to natural settings, increased involvement of the family, and a better insight into the patient's home environment[6,16,17,45,50]. Some reviews also suggest that VC-ERP is more suitable for those with severe OCD[8,9] and patients from remote locations[16,45-47,50], whereas internet-based treatments are more useful in milder OCD and for people with better access to the internet[8-10]. Lastly, the main advantage of VC-ERP seems to be the greater therapeutic contact it provides particularly in comparison to internet-based treatments with minimal therapist contact. There is considerable evidence to indicate that higher levels of therapeutic contact are associated with greater efficacy of TMH-based treatments for OCD[7,9,14,61,62].

The choice of VC-ERP in this study was influenced by these considerations along with the prior experience of in-person ERP in the department, the availability of a home-based platform for VC-ERP, and the unavailability of internet-based treatments.

Findings of the present study and its limitations

Being a preliminary report, this study had several obvious limitations. It was largely a descriptive account of the development and implementation of VC-ERP for OCD from a relatively under-resourced setting. The number of patients who had completed the treatment was very small, and all data related to the efficacy of VC-ERP are therefore prone to a high risk of bias. This risk is increased further because patients were not randomized to VC-ERP treatment, and there was no control group. A selection bias toward better-motivated patients is also possible. Since this was a naturalistic observational study, it was not possible to control for confounding factors such as the effect of pharmacological treatment or comorbid conditions.

Nevertheless, some of the findings were encouraging and could have some implications for further efforts in this area. The principal focus of this study was to describe the process of developing a protocol for VC-ERP treatment of OCD during the pandemic. Due to the restrictions imposed by the pandemic the entire process of development and subsequent implementation had to be carried out online. The primary aim of the study was to examine the operational viability and feasibility of conducting VC-ERP according to the treatment protocol developed in this study. The examination of these outcomes among 34 patients who had completed the treatment or were actively engaged in it indicated that the VC-ERP protocol was a feasible and viable means of treating OCD.

The VC-ERP treatment provided access to a larger number of patients who could benefit from ERP. Dropout rates were low and adverse events were relatively rare. The treatment was acceptable to patients, caregivers, and clinicians, and the levels of satisfaction were adequate. Since this was a naturalistic observation study among patients from routine care settings, these results can be generalized to other patients from similar clinical settings. Moreover, since the treatment was conducted in a low-resource setting of a developing country like India, these results could be particularly relevant for countries with similar resource constraints. Although the treatment was mostly conducted during the pandemic, the findings showed that it was feasible to implement the treatment even after the pandemic had subsided. Moreover, such naturalistic studies also fulfil the pressing need to conduct VC-ERP trials for OCD in real-world settings[9,16,60].

Its findings corresponded to the recent studies of OCD, which indicated that VC-ERP may be equally effective in routine treatment settings[22,63,64]. The use of hybrid treatment both in terms of multiple platforms for hosting VC-ERP and combining it with in-person care offers a greater degree of flexibility and has the potential for greater effectiveness[15,16,38,45,50]. Similarly, this study found that hybrid care was considered to be more advantageous and preferred by patients, caregivers, and clinicians. Another unexpected gain of the VC-ERP treatment was the opportunity to incorporate stepped care into the treatment protocol. Stepped care refers to the use of low-intensity treatments such as internet-based CBT for patients with less severe OCD with the option to transition to more intensive treatments if the illness is more severe. It has been advocated for a long time but is being re-emphasized because of the wide range of TMH-based treatments currently available for OCD[7,9,13,14,16]. In this study patients with milder OCD improved after the initial sessions, while many with more severe OCD moved on to hybrid care, and a few with the most severe illnesses could move on to inpatient ERP when VC-ERP failed. This was consistent with the stepped care approach.

The findings regarding the efficacy of VC-ERP among 11 patients who had completed the full treatment were very preliminary and had several limitations that have been listed above. Nevertheless, they did suggest that the VC-ERP treatment of this study was an effective means of managing OCD in terms of significant symptom reduction and maintenance of gains post-treatment. The extent of improvement was similar to other Indian studies of inpatient ERP for OCD[35,36]. However, the long-term outcome of VC-ERP was likely to be better because of the improved treatment engagement and follow-up with the treatment. These results were also in line with much of the existing evidence on the efficacy of VC-ERP from RCTs[51-54] and open trials[27,55-58]. Lastly, the findings suggested that VC-ERP treatment could be useful for a population with moderately severe OCD and high rates of comorbidity. Though most of the evidence appears to indicate that VC-ERP is ineffective in treating comorbid depression[7,11,22], some studies have shown that it is equally effective in those with comorbid conditions[22,64].

CONCLUSION

In conclusion, the present study has shown that despite many barriers it is possible to develop a structured form of VC-ERP for OCD that is feasible and acceptable to the users. The findings, though preliminary, suggest that VC-ERP could be a viable option for the treatment of OCD in low- and middle-income countries where the treatment gap for OCD is greater and TMH services are relatively underdeveloped. However, much more will need to be done to improve this treatment and prove its efficacy before it can be integrated into the wider system of mental healthcare in these countries.

ARTICLE HIGHLIGHTS

Research background

The existing literature indicates that exposure and response prevention (ERP) is efficacious in treating obsessive-compulsive disorder (OCD). However, despite the availability of such effective psychotherapeutic treatments, very few patients have ready access to them. Telemental health (TMH) treatments may help in overcoming these limitations of conventional ERP.

Research motivation

The coronavirus disease 2019 pandemic adversely impacted many patients with OCD, compelling clinicians to increasingly use telemental health-based options rather than conventional psychotherapeutic treatments for OCD. However, research on the efficacy of TMH in the treatment of psychiatric disorders from developing countries is limited, and trials on TMH-based treatment of OCD are rare. This study from India described the formulation and implementation of videoconferencing-based ERP (VC-ERP) treatment for OCD during the pandemic and its current status in terms of feasibility and usefulness.

Research objectives

To describe the formulation of a treatment-protocol for VC-ERP developed by an online group of clinicians, to describe the implementation of the protocol, and to examine the feasibility and usefulness of the VC-ERP treatment for OCD during the pandemic and after it.

Research methods

This prospective, observational study was conducted in the psychiatric unit of a multi-specialty hospital in north India over 12 mo (July 2020-June 2021). All patients with OCD were assessed using the home-based TMH services of the department. The VC-ERP protocol for OCD was the outcome of weekly Zoom meetings with a group of clinicians involved in administering the treatment. The protocol was implemented among patients with OCD attending the TMH services and upgraded to meet their needs. Feasibility and efficacy outcomes were examined.

Research results

One hundred and fifteen patients with OCD attended the TMH services during the study period; 37 of these were excluded. Of the remaining 78 patients, VC-ERP was initiated in 43 patients. Six patients dropped out, and 3 patients were hospitalized for inpatient ERP. Eleven patients have completed the full VC-ERP treatment. One patient improved following the initial sessions and did not have to complete the entire treatment. VC-ERP is ongoing in 22 patients. The feasibility of VC-ERP treatment in terms of operational viability, service utilization, service engagement, need for additional in-person services, frequency of adverse events, and user satisfaction was adequate. Significant reductions in symptoms and maintenance of treatment gains on follow-up were observed in 11 patients who completed the entire treatment.

Research conclusions

This study provided preliminary evidence for the feasibility and usefulness of VC-ERP in the treatment of OCD. It suggested that VC-ERP could be a viable option for the treatment of OCD in low- and middle-income countries with a greater treatment gap for OCD and underdeveloped TMH services.

Research perspectives

Further research is needed to improve the VC-ERP treatment and prove its efficacy before it can be integrated into the wider system of mental healthcare.

ACKNOWLEDGEMENTS

We wish to thank B. Sai Chaitanya Reddy, Aarzoo Suman, and all the residents who have taken part in the group for VC-ERP. Their active and invaluable contribution to the group has made all this possible.

FOOTNOTES

Author contributions: Kathiravan S and Chakrabarti S were involved in preparing the study protocol and conducting the review of the literature; Kathiravan S collected the data about patient treatment; Kathiravan S and Chakrabarti S were both involved in analyzing the data and preparing the manuscript; All authors have approved the final version of the manuscript for submission.

Institutional review board statement: This observational study was a part of a larger study on home-based TMH services for all patients[37]. The protocol was approved by the institute's ethics committee. Due to the restrictions imposed by the pandemic, verbal informed consent over the phone was allowed. Copies of the approval from the ethics committee have been uploaded.

Informed consent statement: This observational study was a part of a larger study on home-based TMH services for all patients[37]. The protocol was approved by the institute's ethics committee. Due to the restrictions imposed by the pandemic, verbal informed consent over the phone was allowed. As explained above, data regarding outcomes were

obtained only from patients who had verbally consented to undertake exposure and response prevention and had actively engaged in the process of treatment. However, patients were not contacted or assessed separately to determine these outcomes. Rather, all data regarding outcomes were extracted from routine medical and treatment records. Patient identities have not been revealed. Therefore, written informed consent from patients was not obtained for information about treatment outcomes. All the methods followed the guidelines of the Declaration of Helsinki for medical research involving human subjects.

Conflict-of-interest statement: None of the authors have any potential conflicts of interest to report. Details have been provided in the conflict-of-interest statement format.

Data sharing statement: Data regarding the study are available from the corresponding author (subhochd@yahoo.com) upon reasonable request.

STROBE statement: The authors have read the STROBE Statement—checklist of items, and the manuscript was prepared and revised according to the STROBE Statement—checklist of items. The checklist has been included.

Abstract

BACKGROUND

Major depressive disorder (MDD) is the most frequent reason of disabled people in the world, as reported by the World Health Organization. However, the diagnosis of MDD is mainly based on clinical symptoms.

CASE SUMMARY

The clinical, genetic, and molecular characteristics of two Chinese families with MDD are described in this study. There were variable ages of onset and severity in depression among the families. Both Chinese families had a very low prevalence of MDD. The mitochondrial genomes of these pedigrees were sequenced and indicated a homoplasmic T3394C (Y30H) mutation, with the polymorphism located at a highly conserved tyrosine at position 30 of *ND1*. The analysis also revealed unique sets of mitochondrial DNA (mtDNA) polymorphisms originating from haplogroups M9a3 and M9a.

CONCLUSION

This finding of the T3394C mutation in two unrelated depressed patients provides strong evidence that this mutation may have a part in the etiology of MDD. However, In these two Chinese families having the T3394C mutation, no functional mtDNA mutation was observed. Therefore, T3394C mutations are related with MDD, and the phenotypic manifestation of these mutations may be affected by changes in nuclear genes or environmental factors.

INTRODUCTION

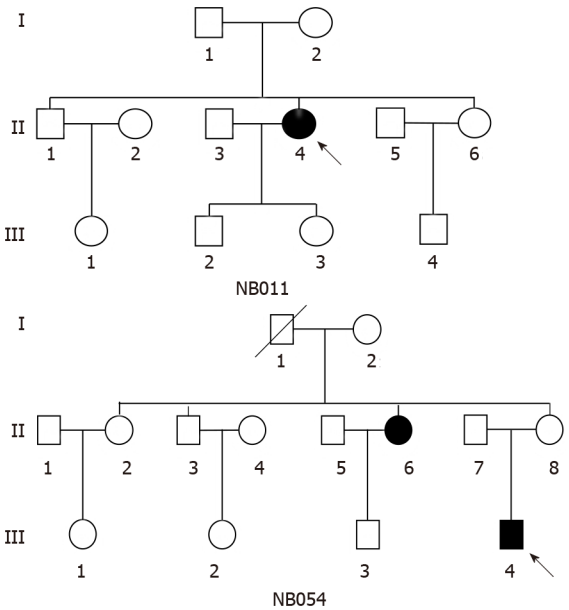
Major depressive disorder (MDD) is a frequent dangerous human disease, which severely impairs the normal life and work of patients and causes a heavy burden on their family and society. In 2008, the World Health Organization rated it as the third leading cause of worldwide disability, and by 2030, it is expected to lead the list[1]. Despite its high incidence and prevalence, clinical symptoms are the primary basis for a diagnosis of MDD, and there is little evidence at the molecular level[2]. In addition, current drug therapy for MDD is not effective, with only 27% of patients in remission after the first treatment and 67% in remission after four complete treatments[3]. These considerations imply that the currently available antidepressants that target the monoaminergic system are insufficient for therapeutic use. In evaluating new therapeutic approaches, specific biomarkers should be identified that objectively determine the pathology involved in MDD, and relevant molecular targets might be revealed[4].

Mitochondrial DNA (mtDNA) is a 16.6 kb circular molecule that is maternally transferred and found within the mitochondrion[5]. Mitochondria can be considered "power generators" because they transform oxygen, energy substrates (proteins, carbohydrates, and lipids), and other substances into adenosine triphosphate[6]. In major psychiatric diseases, significant changes in the mitochondrial count, shape and electron transport activity in neurons are accompanied by an increase in mitochondrial DNA polymorphism, deletion and mutation, suggesting that defects in the mitochondria might be a primary cause of MDD[7,8]. Munakata *et al*[9] sequenced the whole mitochondrial genome of white blood cells from a family in which a proband was suspected of maternal inheritance of borderline personality disorder, MDD, suicide and other psychiatric disorders. The patient was identified as having both MDD and epilepsy. Comparing the proband sequence to the standard human mtDNA sequence, the authors identified 34 base changes. From the mtDNA sequence, it is possible to detect comprehensive subhaplogroups, new mutations, and common single nucleotide polymorphisms. It is also possible to determine private mutations in mtDNA through resequencing, especially if they are homoplasmic, which contributes to the variance between individuals in mtDNA composition[10].

This study aimed to characterize clinical, genetic, and molecular characteristics of two Chinese families with possible maternally transmitted MDD. The T3394C mutation in the *ND1* gene in these Chinese families was identified through molecular analysis. We employed polymerase chain reaction (PCR) amplification of fragments covering the full mitochondrial genome and subsequent DNA sequence analysis to shed insight on the significance of the mitochondrial haplotype in the phenotypic expression of the T3394C mutation in two Chinese families.

CASE PRESENTATION

Chief complaints



We ascertained two Han Chinese families (Figure 1) through the Psychiatric Clinic of Ningbo Kangning Hospital, Zhejiang. The Ningbo Kangning Hospital Ethics Committee approved the protocol, and obtaining clinical assessments and collecting blood samples from all family members required informed consent. In-depth interviews were conducted with members of these pedigrees to discover family and personal medicinal records of major depressive disorder and other medical abnormalities. To check for mtDNA alterations, we collected 167 DNA samples from healthy Chinese people who served as controls.

In family NB011, as shown in Table 1, the proband (II-4) complained of depression and visited the Psychiatric Clinic at Ningbo Kangning Hospital at the age of 62. She struggled with MDD approximately 12 years prior. The Hamilton depression rating scale (HDRS) showed a score of 24 and no

history of suicide attempt. She exhibited the classic clinical features of MDD. The psychiatric examination found no other abnormalities. In addition, no further significant medical background was discovered. The family was from East China's Zhejiang Province. None of the remaining seven matrilineal relatives displayed MDD.

In the NB054 pedigree, the proband (III-4) visited the Psychiatric Clinic at Ningbo Kangning Hospital upon reaching the age of 20. He struggled with MDD 8 years prior. The HDRS showed a score of 39 and a history of suicide attempt. Thus, he had classic symptoms of clinical features of MDD. no further significant medical background was discovered. The family was also from Zhejiang Province in Eastern China. Clinical testing and additional research into II-6's family history confirmed that she had MDD. Other matrilineal relatives did not show signs of MDD.

History of present illness

In addition, there was no indication that any member of these families had an alternative recognized etiology for MDD.

History of past illness

Comprehensive family medical histories of these individuals showed no other clinical abnormalities existed in these people's families, such as diabetes, hearing loss, or vision problems.

Psychiatric examinations and evaluation by the Hamilton depression rating scale

The diagnosis of MDD for the probands was developed by utilizing structured clinical interviews[11] and was confirmed by a separate diagnostic examination conducted by a licensed psychiatrist. Depressive symptom intensity in patients with MDD was measured by the HDRS[12]. The probands with MDD got a minimum HDRS score of 17 on 17 items. The severity of MDD was determined by HDRS as follows: normal < 7; mild = 7-17; moderate = 17-24; severe > 24. The probands of MDD were not included if they had any of the following conditions according to DSM-IV: (1) Abuse of alcohol or drugs within the previous six months; (2) bipolar disorder; and (3) post-traumatic stress disorder or a history of an eating disorder within the previous month of study enrollment.

Laboratory examinations

Mitochondrial genome mutational analysis: Utilizing Puregene DNA Isolation Kits (Gentra Systems), genomic DNA was extracted from the subjects' entire blood. As previously stated, L- and H-strands oligonucleotide primer sets were used to amplify the whole mitochondrial genomes of the two probands by PCR in 24 overlapping fragments[13]. Each purified fragment was examined using direct sequencing on an ABI 3100 automated DNA sequencer utilizing a Big Dye Terminator Cycle sequencing reaction kit. Consensus Cambridge sequence was matched to these sequence findings (GenBank accession number: NC 012920)[14]. The Seqweb program GAP (GCG) was used for DNA and protein sequence alignments. Genomic DNA from Chinese controls were used as templates, we amplified segments spanning the required sites by PCR and sequenced the resulting PCR products to determine the allele frequency of the T3394C mutation in the *ND1* gene.

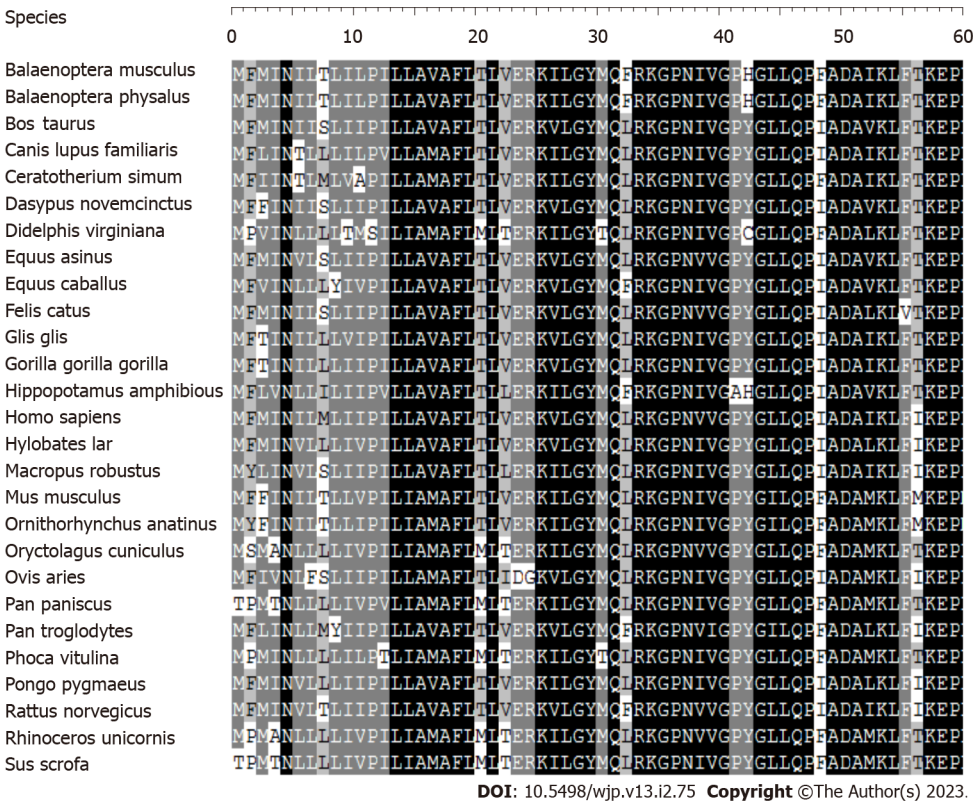
Phylogenetic analysis and haplogroup analyses: Homo sapiens[14], mouse[15], bovine[16], and Xenopus laevis[17] mitochondrial DNA sequences were utilized in the interspecific study. By comparing the four animals, the conservation was evaluated. The complete mtDNA sequences of the two Chinese probands with the T3394C mutation were allocated to the Asian mitochondrial haplogroups as per the nomenclature of mitochondrial haplogroups[18,19].

Mitochondrial DNA analysis: The mitochondrial genome of these probands for mutations was analyzed to determine the molecular basis of MDD. PCR was used to amplify the whole genome fragments of mitochondria that were then sequenced from the samples of these probands. Substances with MDD have been shown to carry a T-to-C transition at position 3394 (T3394C) in the *ND1* gene, which causes the amino acid tyrosine to be replaced by histidine (Y30H) at position 30[20]. Figure 2 shows that the tyrosine at ND1 position 30 is significantly preserved across 27 different species. Leber's hereditary optic neuropathy (LHON) has been linked to this mutation in 3 Chinese families[21] and 1 Finnish family[22], as well as metabolic diseases[23], and deafness[24] in 1 Chinese family. From a sample of 167 unrelated Chinese control people, we know that one (20-year-old man) carries the T3394C mutation based on allele frequency analysis.

Besides the identical T3394C mutation (Table 2), these individuals displayed unique mtDNA polymorphisms. Other nucleotide variations in these mitochondrial genomes include 12 documented variations in the D-loop, three recognized variations in the *12S rRNA* gene, 1 recognized variation in the *16S rRNA* gene, 14 recognized silent variants, and 11 (2 novel/9 known) nonsense mutations in the polypeptide-encoding genes. These nonsense mutations are T4216C (T304H) in the *ND1* gene; G4491A (V8I) in the *ND2* gene; A8701G (T59A), TG8728T (T68G), A8860G (T112A) and A9136G (I204V) in the *A6* gene; A10398G (T114A) in the *ND3* gene; A14417G (V86A) in the *ND6* gene; and C14766T (T7I) and A15326G (T194A) in the *Cytb* gene. There were 31 mutations that were carried by both probands. Phylogenetic analysis of these RNA and polypeptide variations and sequences from other taxa, such as mice[15], cattle[16], and Xenopus laevis[17], was used to assess these variants further. Nevertheless, with the exception of T3394C, none of these variations shown evolutionary conservation. The mtDNA sequence variants of two Chinese relatives were used to identify their haplogroup affiliation of each mtDNA using the nomenclature of mitochondrial haplogroups[18,19]. The mtDNA of pedigrees NB011 and NB054 correspond, respectively, to the Eastern Asian haplogroups M9a3 and M9a.

FINAL DIAGNOSIS

The described patients are all ultimately diagnosed with MDD.



DISCUSSION

In this investigation, the clinical, genetic, and molecular characteristics of two Chinese families with MDD were determined. MDD had a distinct clinical phenotype and solely existed in the maternal lineage in the two families, prompting us to speculate that mtDNA may be the molecular foundation of MDD. Complete mitochondrial genome sequence study of the two pedigrees revealed different mtDNA polymorphisms except for the same T3394C (Y30H) mutation in the *ND1* gene. The *ND1* gene is the central component of the 45 subunits of complex I, and the T3394C mutation caused a shift from tyrosine to histidine (Y30H) at position 30[25,26]. Actually, the hydroxyl group on Y30 of ND1 interacts electrostatically with the side chain of E4 and the carbonyl group on M1 of NDUFA1[26,27]. Consequently, the T3394C mutation may disturb the interactions among ND1 and NDUFA1, consequently affecting the structure and function of complex I[28]. Leber's optic neuropathy[21,22], metabolism disorders[23] and deafness[24] are only some of the additional clinical problems linked to the T3394C mutation.

Figure 2 Alignment of partial *ND1* polypeptides from different species. The arrow indicates the tyrosine at position 30 (Y30) at the N-terminus of the *ND1* polypeptide, corresponding to the T3394C mutation.

Although both families had typical clinical manifestations of major depressive disorder, there were differences in penetrance, age at onset, and severity. The penetrance of the two families was 8.3% and 14.3%, respectively. This relatively low penetrance of MDD in two Chinese families having the T3394C mutation and its presence in one out of 167 controls suggests that, similar to previous mutations[29,30], the T3394C mutation alone is inadequate to induce the clinical manifestation. Therefore, the T3394C mutation requires modifying variables, such as nuclear histories, additional external variables, and mitochondrial haplotypes for phenotypic expression. Particularly, it has been demonstrated that mitochondrial haplotypes alter the penetrance and expressivity of MDD linked with primary mtDNA mutations[31]. The mtDNA of pedigrees NB011 and NB054 correspond, respectively, to the Eastern Asian haplogroups M9a3 and M9a.

The homogenous mutation T3394C was found in MDD families with different genetic backgrounds. The minimal penetrance of MDD among families with this mutation suggests that the T3394C mutation is a molecular base for the pathogenesis of MDD, but the mutation alone is not sufficient to cause phenotypic expression of MDD. This suggests that other mediators played a synergistic role in the pathophysiology of these families. Furthermore, the whole mitochondrial genome of the two families did not carry other highly conserved and functional mutation sites, indicating that polymorphic sites related to mitochondrial haplomorphism may not have a significant impact in the pathophysiology of two MDD families with the T3394C mutation. Moreover, mtDNA epigenetics may be involved in the occurrence of MDD, but research on the role of mtDNA epigenetics in diseases and therapeutic targets is insufficient. Therefore, nuclear-modified genes or external variables have a function in the phenotypic expression of MDD related T3394C mutations in these Chinese individuals. In conclusion, the *ND1* T3394C mutation may be a mitochondrial gene mutation site associated with MDD.

CONCLUSION

This observation of the T3394C mutation in two genetically unrelated individuals who suffer from depression strongly indicates that the current mutation might contribute to developing MDD. However, in these two Chinese families having the T3394C mutation, no functional mtDNA mutation was found. Therefore, the phenotypic manifestation of T3394C mutations linked to MDD may be affected by nuclear changed genes or environmental factors.

ACKNOWLEDGEMENTS

We thank the participants for their contributions to this study. We thank the Genetics Institute of Zhejiang University for its help in mitochondrial sequencing.

ABOUT COVER

Editorial Board Member of *World Journal of Psychiatry*, Henriette Löffler-Stastka, MD, Associate Professor, Dean, Department of Psychoanalysis and Psychotherapy, and Postgraduate Unit/Teaching Center, Medical University of Vienna/General Hospital of Vienna, Vienna 1090, Austria. henriette.loeffler-stastka@meduniwien.ac.at

AIMS AND SCOPE

The primary aim of *World Journal of Psychiatry* (*WJP*, *World J Psychiatry*) is to provide scholars and readers from various fields of psychiatry with a platform to publish high-quality basic and clinical research articles and communicate their research findings online.

WJP mainly publishes articles reporting research results and findings obtained in the field of psychiatry and covering a wide range of topics including adolescent psychiatry, biological psychiatry, child psychiatry, community psychiatry, ethnopsychology, psychoanalysis, psychosomatic medicine, *etc*.

INDEXING/ABSTRACTING

The *WJP* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Current Contents/Clinical Medicine, Journal Citation Reports/Science Edition, PubMed, PubMed Central, Reference Citation Analysis, China National Knowledge Infrastructure, China Science and Technology Journal Database, and Superstar Journals Database. The 2022 Edition of Journal Citation Reports® cites the 2021 impact factor (IF) for *WJP* as 3.500; IF without journal self cites: 3.313; 5-year IF: 7.380; Journal Citation Indicator: 0.62; Ranking: 89 among 155 journals in psychiatry; and Quartile category: Q3.

Abstract

Attention-deficit/hyperactivity disorder (ADHD) often co-occurs with substance use (SU) and/or substance use disorder (SUD). Individuals with concurrent ADHD and SU/SUD can have complex presentations that may complicate diagnosis and treatment. This can be further complicated by the context in which services are delivered. Also, when working with young people and adults with co-existing ADHD and SU/SUD, there is uncertainty among healthcare practitioners on how best to meet their needs. In February 2022, the United Kingdom ADHD Partnership hosted a meeting attended by multidisciplinary experts to address these issues. Following presentations providing attendees with an overview of the literature, group discussions were held synthesizing research evidence and clinical experience. Topics included: (1) A review of substances and reasons for use/misuse; (2) identification, assessment and treatment of illicit SU/SUD in young people and adults with ADHD presenting in community services; and (3) identification, assessment and treatment of ADHD in adults presenting in SU/SUD community and inpatient services. Discussions highlighted inter-service barriers and fragmentation of care. It was concluded that a multimodal and multi-agency approach is needed. The consensus group generated a table of practice recommendations providing guidance on: identification and assessment; pharmacological and psychological treatment; and multi-agency interventions.

Key Words: Attention-deficit/hyperactivity disorder; Substance use; Pharmacokinetics; Assessment; Treatment; Comorbidity

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Attention-deficit/hyperactivity disorder (ADHD) often co-occurs with substance use (SU) and/or substance use disorder (SUD). The co-occurrence of ADHD and SU/SUD is associated with earlier onset and faster transition to more serious SUD, and reduced treatment effectiveness. This manuscript is the product of a consensus meeting of experts from ADHD and/or SUD services, across a range of clinical, academic, educational, occupational, and service-user sectors. A consensus was reached offering practical guidance to support practitioners working with young people and adults with ADHD and SU/SUD with recommendations for identification and assessment, pharmacological treatment, psychological treatment, and multi-agency interventions.

INTRODUCTION

Attention-deficit/hyperactivity disorder (ADHD) is a neurodevelopmental disorder characterized by age-inappropriate levels of inattention and/or hyperactivity and impulsivity that interfere with functioning across multiple life domains (*e.g.*, personal, academic, work, family, social)[1,2]. Previously only considered a childhood disorder, the persistence of ADHD symptoms into adulthood is now recognised[3,4]. Meta-analyses estimate the prevalence of ADHD to fall between 5% and 7% in children and adolescents[5,6], and between 2.5% and 5% in adults[7,8].

Alongside physical comorbidities[9-11] psychiatric comorbidity is common in the ADHD population [12,13], with 75% reporting to have at least one other diagnosis[14]. One of the most common and impairing comorbidities is substance use disorder (SUD)[15-17]. Meta-analyses have shown that childhood ADHD is significantly associated with later substance use (SU) and SUD during adolescence and young adulthood[18,19]. ADHD is also highly prevalent among individuals with SUD[20-22]; a meta-analysis revealed around 23% of treatment-seeking individuals with SUD met DSM criteria for comorbid ADHD[23]. Accurately identifying ADHD in SUD contexts may be difficult due to high drop-out rates between screening and diagnostic assessments and/or possible unreliable historical information. This is further complicated by presenting symptoms that may be common to both ADHD and SUD, such as inattention, impulsivity and executive dysfunction[24,25].

Hence, the presentation of individuals with comorbid ADHD and SUD is complex. This may complicate identification and treatment[12]. Individuals with a dual diagnosis show more chronic patterns of SU, including earlier onset of SU and a more rapid transition to serious SU[26-28]. They are more likely to engage in polysubstance use[4,29] and experience greater difficulty remaining abstinent [30]. They demonstrate severe functional impairments across several life domains. These include increased risk of depression and suicide attempts[21], reduced quality of life[31], greater psychiatric comorbidity[32], accidents and crime[33,34]. When accompanied by comorbid oppositional defiant disorder (ODD) and conduct disorder (CD), there is an increased risk of premature death[35]. Research indicates poor treatment outcomes[36], with severity of SUD being a predictive factor for treatment outcome[37,38]. In those with a dual diagnosis, pharmacotherapy is less effective for treatment of ADHD when using standard dose, necessitating higher doses of medication[39].

Within the literature, the benefits of treating ADHD and comorbid SUD have been investigated, albeit with mixed findings. A meta-analysis of observational studies published in 2003 showed a significant reduction in risk of SUD in youths treated with stimulants compared with those who did not receive stimulants[40]. More recent observational studies have demonstrated a similar protective effect on later development of SUD[41,42]. Other studies, however, found comparable outcomes between children with and without medication treatment history[43].

Methodological issues with observational studies result in uncertainty regarding conclusions drawn as there may be baseline differences across groups. A meta-analysis of within-individual design studies, which are less prone to bias (although they cannot control totally for temporal effect), demonstrated a reduction of severity of SUD during periods when individuals were receiving medication, compared to periods when they did not[44].

A recent analysis of randomized controlled trials (RCTs) found a range of beneficial effects in the stimulant arm compared with placebo, including reduction of SU, increased abstinence, reduced craving, reduced frequency of ADHD symptoms, improved management of withdrawal symptoms, and decrease in the severity of ADHD symptoms[45]. This contrasts with a previous meta-analysis of 13 RCTs evaluating the effect of ADHD medication on outcomes in individuals with dual diagnosis which found a small to moderate reduction of ADHD symptoms but no beneficial effect for SU, drug abstinence or treatment discontinuation[39]. Carpentier and Levin[46] proffered some possible explanations for negative findings in their systematic review. These included high prevalence of polydrug use, presence of psychiatric comorbidity (additional to ADHD and SUD), possibility of suboptimal dosing of stimulant medication, generally low treatment retention, and influence of concurrent treatment (primarily cognitive behavioral therapy; CBT)[47].

There is increasing recognition of the need to identify and treat inappropriate use of substances by individuals with ADHD; and equally to identify and treat comorbid ADHD among those with SU or SUD. It is understood that treatment for those with concurrent ADHD and SUD may be complicated by the context in which services are being delivered. In the United Kingdom (as for many countries) individuals with ADHD are rarely able to access effective psychological treatments for their SU unless

this is associated with a level of impairment considered to be a 'disorder'[48]. Many young people do not fit within this criterion. Unfortunately, many healthcare practitioners do not feel they have the knowledge and skills to prevent this escalation, as intervention is commonly limited to specialist SUD services. Equally, expertise in treating ADHD within SUD services is rare. Uncertainty among practitioners on how to meet the needs for this complex group motivated the United Kingdom ADHD Partnership (UKAP) to convene a meeting attended by multidisciplinary experts to consider the complexities and challenges of working with young people and adults with concurrent ADHD and SU/SUD with the aim of providing helpful guidance and recommendations.

METHOD

Specialists in the fields of ADHD and SUD convened in London (United Kingdom) on 4th February 2022 for a meeting hosted by the UKAP. Meeting attendees included experts from ADHD and/or SUD services across a range of disciplines. Thirteen participants had medical qualifications/appointments, five had psychological qualifications/appointments and nine had academic qualifications/appointments. There was also representation by a service-user and an educational/occupational specialist.

The consensus group incorporated evidence from a broad range of sources. However, this largely reflects clinical practice and legislature in the United Kingdom, which may differ in other countries.

The meeting commenced with detailed presentations, providing an overview of the literature regarding the relationship between ADHD and SU/SUD. Following this, attendees separated into three breakout groups. Each group was tasked with providing a framework of guidance relevant to their assigned topic. Discussions were facilitated by a nominated group member and summarized by note-takers. Group participants drew on their clinical experience and research evidence, with discussions covering the following overarching topics: (1) Substances and reasons for use; (2) Identification, assessment, and treatment of illicit SU/SUD in young people and adults with ADHD presenting in community services; and (3) Identification, assessment, and treatment of ADHD in adults presenting in SU/SUD community and inpatient services.

Presentations and debate amongst attendees were audio-recorded and transcribed. A note-taker was allocated to each breakout group and following the meeting these notes were circulated to breakout group participants for review and approval. At the end of the meeting breakout groups presented respective conclusions and recommendations for debate, discussion, and approval by all attendees. All materials (transcriptions, electronic slide presentations and breakout group notes) were synthesized by the medical writer (KC) into a draft manuscript. Further drafts were produced by the lead author (SY) working in collaboration with the medical writer (and with consultation with some authors where necessary). A draft was then circulated to all authors for review and revisions; this did not generate any disagreements between authors. Following further revisions, a final draft was circulated to all authors for agreement and approval.

The consensus is based on published research, but it also reflects the views of the authors based on their practical experience. Acknowledging that children, adolescents, adults, and older adults experience different challenges and treatment demands[49,50], the consensus group considered differences in biopsychosocial needs across age groups.

RESULTS AND CONSENSUS OUTCOME

Substances and reasons for their use by people with ADHD

Alcohol and nicotine are the most commonly used recreational substances used among adolescents and adults with ADHD but cannabis is the most used illicit substance[18,19,38,51,52]. Stimulants such as cocaine, amphetamines and methamphetamine (Ice) are also common[53,54]; a meta-analysis reported the prevalence of cocaine use in adults with ADHD to be around 26%. Ten percent had cocaine use disorder[55].

Various reasons have been proposed for SU among individuals with ADHD. Individuals with ADHD often claim that, prior to their diagnosis, they used substances as a form of self-medication to attenuate ADHD symptoms and associated impairments. However, there is no robust empirical evidence to support this proposal[56,57]. Individuals report using substances frequently to help them to sleep, manage fluctuations in mood, and improve attention and executive functioning[58-60]. It has also been posited that individuals with ADHD may be more susceptible to using substances due to impulsivity (behavioral inhibition hypothesis)[61]. This, together with immediate gratification and reward-seeking behaviour may collectively impact on the positive and negative reinforcement of substances and their potency.

Adolescents and adults with ADHD have high rates of comorbidity with other conditions, many of which are associated with increased risk of SU. CD and ODD may explain the association[62-64]. Other

studies have shown that depression, bipolar disorder, and antisocial personality disorder all convey an elevated risk for SU/SUD among individuals with ADHD[32,62,65-68]. Other potential reasons include increased exposure to psychosocial risk factors (*e.g.*, parental SU/SUD, peer pressure, predatory grooming and exploitation, financial, family and work-related stressors, chronic low self-esteem, feelings of demoralization and failure, trauma and fear responses)[14,59].

Table 1 shows key aspects of the pharmacology of several commonly used recreational drugs that might be used by people with ADHD. The primary molecular targets and neurotransmitters that are impacted by interactions of different drugs are shown, most of these are not dopamine.

Biological factors such as speed of brain entry of stimulants may influence which substances are used [69]. Figure 1 shows three examples of drugs with accelerated brain entry.

The consensus group agreed that there is a complex interplay between an array of factors, which results in individuals with ADHD initiating use of illicit substances. Across the lifespan, motivation for using these substances may transition across several phases towards dependency[48,70,71].

Identification, assessment, and treatment of illicit SU/SUD in young people and adults with ADHD presenting in community services

When to refer individuals with ADHD for support for their SU/SUD: There was extensive debate regarding what would be considered a 'red flag' indicative of a SU problem developing in young people and adults with ADHD. Experimental drug use is common, with the highest level of experimental use usually occurring during adolescence. This in itself may not necessarily be a cause for concern. The threshold for what may be considered concerning or problematic is likely to vary; a person, parents, family members, teachers and employers may all have differing perspectives. It was agreed that 'red flags' should be understood in relation to the person's community, social, economic, religious, and cultural circumstances. This includes contexts where SU may be normalized within the immediate environment the person inhabits. The boundary between use and misuse is likely to be influenced by what is normative within the individual's immediate social network (family, peer group and wider neighborhood). It may also be influenced by politics and sociocultural values.

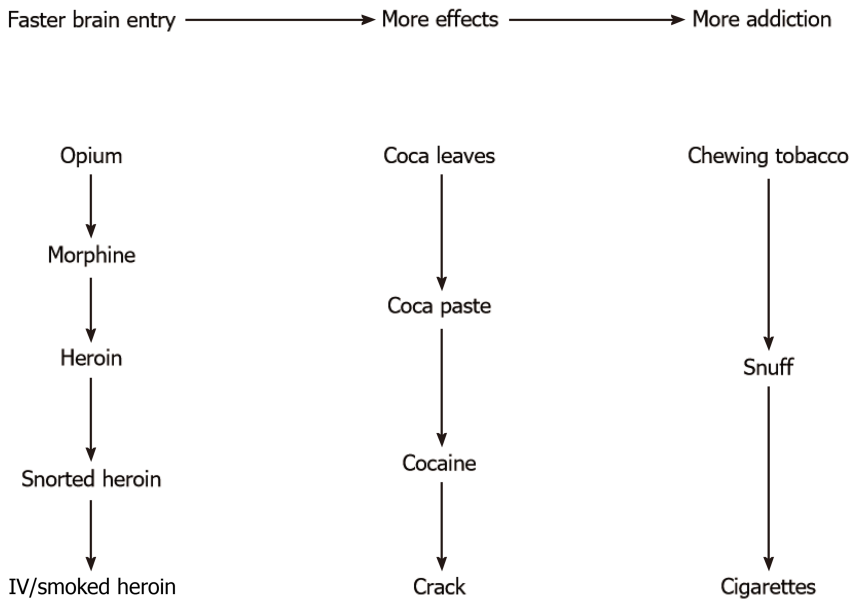
When considering 'red flags' (indicating possible SU/SUD), one should focus on any changes in presentation that are out of character for the person. Typically, this is a decline in self-care, physical and/or mental health, and daily functioning, often associated with social and occupational problems. Table 2 details several markers that may prompt concern; however, these are also markers of other evolving mental health and/or social problems. Thus it is the clustering of multiple markers together across various life domains that is informative. The key message is to ensure that SU/SUD is not disregarded as a potential explanatory factor for change in presentation.

The decision to refer to addiction services should be determined by level of impairment and distress and the wishes of the individual (and parents/caregivers/partner), if appropriate. It was noted that the legal class of substance (*e.g.*, Class A drugs which are most likely to result in the most serious harm, compared with Class B and C drugs) and method of use (*e.g.*, injecting) may determine the level of concern and/or the level of impairment due to associated harm to user.

The way in which the referral is made may depend on how the concern has developed; whether the individual has disclosed their use and/or expressed concerns, or whether it has been uncovered by other means (*e.g.*, found on them/urine testing), and whether there are attempts to deny use. The consensus group agreed that it is important to spend time building rapport with the individual and to develop a shared understanding of SU and how it fits in within a broader context.

Referral pathways are different across regions dependent on commissioning and funding. Anecdotal accounts from the consensus group emphasized reduction/closure of young people's addiction services, resulting in young people being 'bounced around' between different services in order to find appropriate support. Some consensus group members reported that some child and adolescent mental health services and adult services do not accept referrals for individuals with SU difficulties. Exclusion criteria may differ according to type of substance and methods used. Later in adolescence, young people may be referred early to adult addiction services, depending on region.

The consensus group agreed that ADHD services should have an agreed procedure for dealing with concurrent SU/SUD, taking into consideration regional available resources (health, social and third sector).



Assessing people with undiagnosed ADHD: Assessment of ADHD and SU/SUD can be challenging, particularly when ADHD has not previously been diagnosed. Like other diagnoses, the diagnosis of ADHD, with or without SU/SUD requires careful and comprehensive clinical assessment. This should include a full developmental history, mental health history and current mental state examination, medical history, educational/employment history, social history, and, when helpful, assessment of cognitive executive functioning difficulties. It is also important to consider family history of ADHD and SU/SUD, and other psychiatric and neurological problems. Gender differences in presentation should be considered (*e.g.*, symptom severity for hyperactive-impulse symptoms may be lower in females) which may result in missed diagnosis or misdiagnosis[72].

Table 1 Pharmacology of commonly used recreational drugs that might be used by people with attention-deficit/hyperactivity disorder

Drug type	Primary target	Main effects/transmitters	Other actions	Antagonists/blockers
Opiates	Mu opiate receptors		Kappa and delta opiate receptors	Naltrexone Naloxone Nalmefene
Stimulants				
Cocaine	DAT	Inc. Dopamine	Local anesthetic Inc. 5HT	[BP-897 partial agonist]
Amphetamines	DAT	Inc. Dopamine		Mecamylamine
Nicotine	Nicotinic ACH receptor	Inc. Dopamine		Varenicline
Sedatives				
Ethanol	GABA/glut	Inc. GABA	[1]Inc. Dopamine	No
Benzos	GABA	Dec. glutamate		Flumazenil
GHB	GABA	Inc. GABA		No
Solvents	N/A			No
Cannabis	CB1 receptors	[1]Dopamine		Rimonabant
Ecstasy	5HT transporter	Inc. 5HT	Some DA release	[1]SSRIs
LSD	5HT 2 receptors	Stimulate 5HT		5HT2 receptor antagonists

[1]Postulated but not proven.

Column 2 lists the primary molecular targets for the different pharmacological classes of drugs. Column 3 lists the neurotransmitters that are impacted by the interactions listed in column 2. Column 4 lists other molecular targets that these drugs can influence. Column 5 lists antagonists or blockers that can be used to stop or reverse the effects of the drugs. DAT: Dopamine transporter; GABA: Gamma-amino-butyric acid; inc: Increased; dec: decreased.

Figure 1 Examples of drug modification to accelerate brain entry. Brain entry escalates with the downward direction of the arrows.

Assessment of ADHD with comorbid SU/SUD involves careful examination of symptom severity and frequency, chronicity, pervasiveness, degree of impairment across life domains, and childhood onset. A useful tool to assess impairment may be the Weiss Functional Impairment Rating Scale[73]. Nevertheless, while rating scales are useful aids for clinical assessment, the consensus group emphasized the importance of services not rigidly adhering to thresholds and cut-offs as this may lead to high proportions of false positives and negatives.

Table 2 Markers of potential concern for substance use/substance use disorder

Life domain	Markers
Physical	Declining physical health including nausea and abdominal pain
	Looks fatigued
	Disheveled
	Unexplained weight loss
	Dilated pupils, redness in eyes
	Muscle in-coordination
	Poor personal hygiene
	Sniffing
	Administration scars (needle entry marks)
Daily functioning	Unaccountable increase in expenditure
	Difficulty managing daily living tasks (including budgeting, staying on top of household tasks)
	Poor punctuality
	Possession of substances, hiding substances
	Accessing of prescription drugs in the home
	Difficulty managing underlying health conditions (*e.g.*, epilepsy, diabetes)
Home life	Absconding from home (adolescents)
	Receiving packages in the post which they are eager to intercept
	Driving offences
	Accidental injuries, including road traffic accidents
	Increased risk of injury and assault (both to self and others)
	Difficulties fulfilling chores and/or parenting responsibilities
	Social services involvement
	Debts
	Gambling
	Housing problems and homelessness
Educationand work	Truancy/absence from school/college or work
	Deterioration in academic/work performance
	School detention, suspension, expulsion
	High turnover of short-term employment
	Official warnings and disciplinary procedures at work
Social	Social withdrawal
	Social exclusion
	Marginalized
	Sudden change in social groupings
	Part of a 'bad crowd' (gangs, friends much older than peers)
	Friendship and intimate relationship problems
	Domestic violence
Mental health	Apparent deterioration in mental state and health
	Signs of emotional or physical withdrawal from others
	Paranoia
	'Unexplained' onset and/or change of mood swings

	Presenting as exhilarated or with excessive confidence
	Low mood and depression
	Irritability, agitation
	Anxiety
	Paranoia
	Confusion, delusions and/or hallucinations
	Emotional lability
	A&E admissions due to mental health condition
Behaviour	Early use of experimentation with drugs including early onset vaping/smoking (*e.g.*, under 12 yr)
	Excessive use of energy drinks
	'Unexplained' onset of behaviour that seems 'out of character'
	Change in personality/demeanor
	Lack of constructive interests and activities
	Disengagement of 'healthy' leisure activities (change in interest)
	Increased energy, restlessness and disinhibition
	Conduct problems and/or oppositional behaviour
	Irritable, agitated, aggressive and/or violent behaviour
	Risk taking behaviour (shoplifting, theft from home and/or others)
	Risky/compulsive sexual behaviour (promiscuity, risk of pregnancy, sexually transmitted infections)
	Solitary drug use
	Missing appointments
	Parenting issues leading to safeguarding concerns
	Self-harming behaviors
Speech and cognition	Changes in cognitive functioning at different times of the day
	Difficulty sustaining concentration
	Increased alertness
	Confusion
	Memory problems and loss
	Change in usual speech presentation (*e.g.*, slurred, rapid or rambling speech)
	Reference to 'needing' substances (*e.g.*, to help sleep, improve confidence) rather than use for fun or enjoyment
	Unexplained improvements in functioning

It is essential to determine if ADHD or SU/SUD, or both can best explain the presenting symptoms. One key consideration is whether ADHD is masked by SU/SUD. Some individuals report that substances have a countering effect on their ADHD symptoms (*e.g.*, the consensus group shared anecdotal accounts of experiencing patients who report stimulant use has a calming effect rather than an elating effect). Examining the temporal course of ADHD-like symptoms and SU/SUD is crucial. Assessment must be conducted by qualified healthcare professionals with training and expertise in assessing dual disorders so that differential diagnosis can be considered[22]. It is not advisable to conduct an assessment when an individual is under the influence of substances at the time of the assessment and/or when at a stage of withdrawal[24].

Assessing people with diagnosed ADHD: Individuals who already have a primary diagnosis of ADHD should be carefully monitored for SU. This might include alcohol, tobacco, caffeine, study drugs (*i.e.*, accessing prescription stimulants to help focus and/or stay awake). It is important to obtain information regarding the age of initiation for each substance, frequency of use, methods of administration, the social context in which use takes place, the effects of the substance on the person's cognitive, psychological, physiological, and behavioral functioning, the medical, educational/employment, social and medical problems attributable to SU, and any previous treatment. An association between problematic video gaming and nicotine, alcohol and cannabis use has been reported, so asking about these factors

(and internet use more broadly) may be helpful[74].

When conducting the assessment with young people, it is important to consider the role of parents/caregivers (and taking account of the wishes and needs of the young person). There may be additional physical, criminogenic, and safeguarding risks associated with SU which will need to be addressed. Like other assessments, the person should be informed of the confidentiality of information shared and circumstances in which this will be breached.

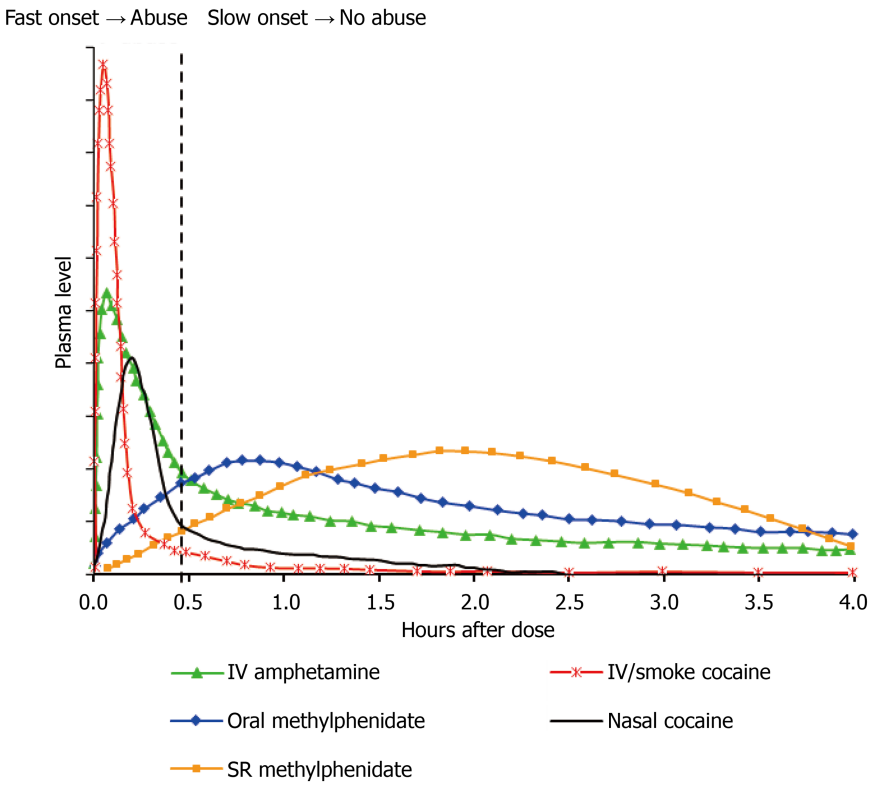
The utility of SU/SUD screening assessments as an indicator for further assessment was discussed. A commonly used screening tool recommended by the consensus group for young people is CRAFFT. This is an acronym generated from six core questions relating to the experience of young people: (1) Have you ever ridden in a CAR driven by someone (including yourself) who was "high" or had been using alcohol or drugs? (2) Do you ever use alcohol or drugs to RELAX, feel better about yourself, or fit in? (3) Do you ever use alcohol/drugs while you are by yourself, ALONE? (4) Do you ever FORGET things you did while using alcohol or drugs? (5) Do your family or FRIENDS ever tell you that you should cut down on your drinking or drug use? and (6) Have you gotten into TROUBLE while you were using alcohol or drugs?[75].

The authors suggest that young people who complete the CRAFFT before seeing their healthcare practitioner are more likely to answer honestly[76]. Completed self-administered copies can then be used by practitioners to guide discussions about SU.

For adults, commonly used screening tools include the Drug Use Disorders Identification Test[77], Drug Abuse Screening Tool (DAST)[78] and Alcohol Use Disorders Identification Test (AUDIT)[79]. The DAST and AUDIT have demonstrated acceptable reliability and validity among adults seeking ADHD clinical evaluation[80].

For young people and adults alike, it is important to identify the substances the person is using, and to discern the intended (*i.e.*, function) and unintended consequences of use. This may differ for different substances. This can be explored in relation to the five-stage pathway (experimental, social, instrumental, habitual, dependent) (refer to Young and Bramham[81] and/or Young and Woodhouse[48] for more information). Individuals should be encouraged to acknowledge the adverse consequences of their SU across physical health, mental health, personal functioning, risky behaviour, interpersonal relationships, ability to study or work, and contact with criminal justice system (CJS).

However, many people with ADHD have difficulty engaging in consequential thinking processes, requiring them to be empathically guided through the process. It can be helpful to start by first acknowledging the benefits of SU before considering disadvantages.



Understanding how SU and ADHD have interacted in the past and present can help services and the individual to understand internal and contextual motivational mechanisms which increase or attenuate risk of SU. This will be helpful in identifying treatment areas. One assessment method involves a functional analysis of behaviour which systematically assesses the antecedents and consequences of specific behaviors. For SU associated behaviors, this involves the assessment of internal and external factors that trigger SU, including factors of positive reinforcement (*e.g.*, euphoria) and negative reinforcement (*e.g.*, numbing of feelings). In turn, the analysis is a helpful strategy for identifying targets for intervention.

Generating chronological timelines can be a helpful technique to record and identify potential interactions between important aspects of ADHD symptomatology (*e.g.*, periods of heightened/lower symptoms, periods of deterioration/functional improvement) and SU (*e.g.*, onset, drug free periods, escalation of use, serious difficulties including episodes of drug-induced psychosis). Mapping these out in this way can be helpful to discern associations concerning onset and maintenance of use, triggers of risk and optimal management.

Pharmacological treatments

Historically there have been concerns regarding prescribed stimulant medications' abuse potential, addictive nature, or that they may worsen pre-existing SU/SUD. These concerns are unfounded[43,82-86]; the formulations that are used are not addictive. Tolerance effects are not clear. Some clinicians have noted a reduced benefit from stimulants over time in some patients, although this is not a universal problem. Neuroimaging studies (*e.g.*, PET studies[87]) point to an increase in dopamine reuptake receptors in adults with ADHD treated for up to 12 months with stimulants. This evidence suggest that tolerance may happen during treatment with psychostimulants. However, the experience of consensus group members was that individuals are more likely to be poorly compliant with stimulant medication or choose to stop taking it, rather than seek higher doses.

Nevertheless, for individuals with comorbid SU/SUD, long-acting preparations are recommended rather than immediate release due to their lower abuse potential (immediate release stimulants are more likely to be crushed to a powder and snorted or used intravenously)[88]. The time course of common stimulants taken *via* different routes is shown in Figure 2. Speed of plasma peaks determines abuse ability. The intra-venous route produces the fastest brain entry and highest peak concentration with intra-nasal cocaine somewhat behind. These effects explain the high propensity for liking and hence abuse of these. Oral methylphenidate peaks at about one hour and slow-release forms even later; a similar profile is seen for lisdexamfetamine. In general, drugs with a low peak concentration and where

DOI: 10.5498/wjp.v13.i3.84 **Copyright** ©The Author(s) 2023.

Figure 2 Speed of plasma peaks for different types of stimulants. IV: Intravenous; SR: Slow release.

the peak occurs after 30 minutes shows low abuse liability. Notably, lisdexamfetamine is a pro-drug (rather than a slow-release preparation) that has to be metabolized in the blood to release the active ingredient (dexamfetamine). This metabolic step explains why even after intra-venous injection lisdexamfetamine does not produce a noticeable 'high' hence providing a low abuse liability[69].

The consensus group emphasized that pharmacological treatment nihilism is not appropriate. It is essential that individuals with ADHD and SU/SUD are not deprived of effective medications. However, short-acting preparations should be reserved for a very circumscribed group (*e.g.*, in contexts where there is possibility for supervised consumption).

Medication should be informed not only by the effectiveness of the medication but also by safety and tolerability (*i.e.*, to physical and mental health).

There was agreement that non-stimulant medicines should generally be reserved as a second line treatment option (even in dual diagnosis cases) as research has shown that, on average (*i.e.*, at the group level) they are less effective than stimulants[89] raising risks of non-compliance. Compared with stimulant medications, where the benefits can be very quick (sometimes within a few days), non-stimulant medications take several weeks to have a therapeutic effect[53]. An exception to this, may be for those misusing alcohol; atomoxetine may reduce alcohol cravings[90].

There was debate about whether voluntary drug testing should be used to monitor use of substances. Drug testing is generally used to monitor compliance with drug rehabilitation programs where there may be suspicions of non-adherence. The overarching view was that where clinicians have concerns about severity of SU, support from specialist SUD services should be sought.

Research has shown that heart rate and/or blood pressure increases in individuals with ADHD treated with stimulants[91,92]. Small but persistent increases in heart rate and/or blood pressure over a sustained period has raised concerns. Meta-analyses however have found no significant link between ADHD medication and serious cardiovascular outcomes such as sudden death, stroke, or myocardial infarction[93,94], though this evidence reports at a group-level, so it is not informative at an individual level. Where there are concerns regarding cardiovascular risk, a cardiologist should be consulted. This is considered particularly important when there is a personal or family history of cardiovascular conditions (*e.g.*, premature sudden/unexpected death in children or young adults, clinically important arrhythmias, prolonged QT syndrome, hypertrophic cardiomyopathy, and Marfan syndrome). For safety[95], the group stressed that heart rate and blood pressure should be measured before initiating medications and routinely during treatment, and titration should be slow. It is also worth being aware that people with ADHD may be more sensitive to the effects of or dependence on sedatives such as alcohol.

Treatment with ADHD medication, especially stimulants, may increase the health risks from the concurrent use of recreational drugs[96]. These are presented in Table 3. In general, there are few specific hazards from the interactions of ADHD medication with recreational drugs with the exception of other powerful stimulants (especially cocaine/crack) which add to the burden on dopamine and noradrenaline neurotransmitter effects and the potential for cardiac events and seizures[96].

Considering when to commence ADHD medication was an area of intense debate. Consensus participants acknowledged that ADHD symptoms and associated impairments make it more difficult to treat SU difficulties, and vice versa. The consensus group agreed that ideally SU would be stabilized (*e.g.*, by the individual demonstrating a level of improved functioning with life not being primarily organized around substances) before initiating medication for ADHD. When this is not possible, services may need to be pragmatic, with decisions informed by an individual risk assessment. There was agreement that abstinence is not necessary for individuals to benefit from ADHD medication.

In the United Kingdom there are lengthy waiting lists for an assessment of ADHD (some being two years and over)[97]. Hence individuals may have stabilized SU at point of referral but relapse whilst waiting. It was agreed that there may be a role for prioritization of those with SUD within ADHD services. This is done for other groups across other health services (*e.g.*, pregnant women, veterans, those with long-term conditions).

Prescribing issues for certain groups were highlighted in discussions. Evidence indicates that adherence to medication declines in teenage years. This has been attributed to adverse effects, sub-optimal response, reduction in parent supervision, increased need for autonomy, comorbid conditions, and social stigma associated with ADHD diagnosis and taking medication[98]. The consensus group noted that this may be of particular concern, acknowledging that young people may be vulnerable at this time to misuse substances to manage their symptoms[61]. Research suggests that treatment with ADHD medication may protect against SU/SUD, but only if the medication is taken continuously[40,86,99,100].

It is imperative to provide psychoeducation to encourage young people to understand and take ownership of their treatment[101]. Provision of developmentally appropriate healthcare within services may also be of benefit[102], a summary of which is provided in Table 4[103].

The consensus group acknowledged the complexity of prescribing and monitoring medication among adults. As individuals get older, they are likely to be prescribed other medications to treat comorbid mental health and physical health conditions. Practitioners should refer to summaries of product characteristics when considering prescribing needs and potential interactions with other medications. Cardiac risk increases with increasing age, which should be considered when prescribing. Monitoring of weight may also be appropriate for adults who are misusing substances, as aside from the potential of stimulant related suppression of appetite, they may prioritize buying drugs over food.

ADHD is associated with working in unskilled occupations (*i.e.*, those not requiring formal education)[104]. Anecdotal accounts from consensus group members discussed individuals working in unskilled occupations with varying shift patterns who use substances chronically. This disrupts sleep patterns and makes monitoring and review of pharmacological treatment problematic, for example, setting specific times-a-day prescriptions, and difficulties attending clinic appointments, especially if they need to attend multiple services (ADHD and SUD).

Psychological interventions

Multi-modal treatments are emphasized for young people and adults with comorbid ADHD and SU/SUD[105]. Several RCTs investigating pharmacological interventions for individuals with co-occurring ADHD and SU/SUD have demonstrated few group differences between medication and placebo group. These studies have had adjunct psychological therapies such as CBT or motivational interviewing (MI), leading to some authors positing that observed improvements may be attributed to the psychological therapy. The design of these studies prevents firm conclusions being drawn, although suggests that psychological therapy is a useful intervention for treating SU/SUD among those with ADHD[59].

Psychological approaches vary across the lifespan and the content of the treatment should be tailored to meet individual need[81]. Specific assessment and treatment techniques for young people and adults with ADHD and SU/SUD can be found in Young and Bramham and/or Young and Woodhouse[48,106]. The consensus group agreed that the following adjustments and psychological interventions will be helpful.

Adjustments to treatment: Executive functioning and memory deficits are commonly reported in individuals with ADHD[107,108]. In addition, chronic use of substances has been found to be associated with visuospatial and memory deficits[109]. Such difficulties can make engaging in therapy and sticking to long-term goals challenging[110]. It is important to accommodate for deficits associated with ADHD and/or SU/SUD. Where neuropsychological testing has been conducted, the strengths and weaknesses profile can be used to inform adaptations to the treatment process. Some specific adjustments to traditional treatment approaches that should be considered include: using text and/or email reminders to reduce non-attendance due to forgetfulness, adapting language and behaviour (implicit rather than explicit conversational approach), adjusting the pace of introducing new elements in treatment, making the treatment more concrete, using material that is easy to understand, greater use of supplementary

Table 3 Potential increased risks from use of recreational drugs in people treated with attention-deficit/hyperactivity disorder medication

Substance	Risks	Risk level	Antidotes
Alcohol	Intoxication, dependence	++	
Cannabis (d9THC)	Anxiety, paranoia	+	Benzodiazepines
Cocaine	Cardiac problems, seizures	+++	b-blockers – benzodiazepines
LSD/psychedelics	Paranoia	+	Risperidone/olanzapine
Ketamine	Dependence, bladder damage	++	
MDMA	Cardiac problems	++	b-blockers
Methamphetamine	Dependence, paranoia	++	Risperidone/olanzapine
Nitrous oxide	Intoxication, neuropathy	+	Vitamin B12
Opioids	Respiratory depression, dependence	++	Naloxone naltrexone
Sedatives	Intoxication, ataxia	+	Flumazenil (for benzos)
Spice/synthetic cannabinoids	Cardiac problems, seizures	+++	Rimonabant

+: Moderate risk; ++: Considerable risk; +++: High risk; LSD: Lysergic acid diethylamide; MDMA: Methylenedioxymethamphetamine.

visual materials, repetition and consolidation of core concepts, a high level of structure, shorter and/or more frequent sessions, mid-session breaks, and identify support between sessions for homework tasks.

It is recommended that individuals are provided with a notebook which they should be encouraged to bring to sessions. This serves as a record of the treatment, including the strategies and techniques they have found most helpful and later becomes a resource when treatment has ended. Any handouts summarizing key information should be secured in the notebook. Exercises should be completed in the person's own writing and their own words (with careful guidance from the practitioner, as needed) to facilitate 'ownership' of the problem, and in turn responsibility and action. For individuals who prefer to keep electronic records, handwritten notes can be scanned for storage on electronic devices.

MI: Motivation is an important predictor of treatment outcome[111]. However, motivation to stop misusing substances may be especially challenging when individuals perceive themselves to use them to self-medicate. MI is a client-centered method for enhancing motivation to change by exploring and resolving ambivalence[112] and it may be an effective model to work for adults with ADHD and coexisting SU/SUD[113]. MI techniques involve expressing empathy, supporting self-efficacy, rolling with resistance, and developing discrepancy. A central tenet of MI is to avoid confrontation as this is posited to incite resistance. Individuals who misuse substances go through several stages in a 'transtheoretical model of change' (precontemplation, contemplation, preparation, action, maintenance)[112,114]. MI is suggested to be particularly helpful in the initial motivational stages (precontemplation and contemplation)[48].

Different MI techniques can be used depending on what stage of the 'transtheoretical model of change' the person is in (*i.e.*, readiness to change). An individual's readiness to change is dependent on many factors (*e.g.*, environmental factors such as friends being drug users and/or living in an area where drugs are frequently offered, psychological factors such as beliefs that they are unable to function adequately without using substances), and thus it is important to consider a biopsychosocial perspective. Stages are cyclical (not linear), and it is common for individuals to oscillate between stages. Practitioners need to be aware of the persons current motivational stage and should monitor interest to engage in treatment, adapting treatment interventions as needed. Helpful tools to explore ambivalence and encourage change include use of dissonance charts and decisional balance sheets (please refer to Young and Bramham[106] for further details about these techniques). The group considered that it may be helpful for MI techniques to be employed more broadly by key frontline contacts within services, which may necessitate further training.

Formulation: Formulation (or case conceptualization), beyond diagnosis[115] is central to intervention planning. Within the formulation it is important to consider the bidirectional relationship between ADHD and SU/SUD. Formulation can help both the practitioner and individual make sense of the individual's experience in a flexible and systematic manner. One framework that may be useful is the Five Ps model[116,117]. This is an idiographic-based framework which enables systematic and holistic examination of multifaceted and complex subjects such as comorbid ADHD and SU/SUD. The Five Ps model organizes information into five sections: (1) Presenting problem; (2) predisposing factors; (3)

Table 4 Developmentally appropriate healthcare dimensions and examples of implementing them into practice

Dimensions of DAH	In practice
Biopsychosocial development and holistic care	Assess wider aspects of young person's life using approaches such as HEEADSSS tool (Home, Education, Eating, Activities, Drugs, Sexuality, Suicide, Safety)
	Consider stage young person is at in their development rather than chronological age
Acknowledgement of young people as a distinct group	Opportunity for young person to be seen independently (for some or all of the consultation)
	Flexible access to service (*e.g.*, outside school/college hours)
	Dedicated clinics and space (*e.g.*, age-banded clinics, appropriately sized seating, magazines/posters of relevance and interest)
	Consideration of different ways young person can contact the service (*e.g.*, digital technologies rather than letters/phone calls)
	Explain confidentiality and rights; display confidentiality policy in waiting room
Adjustment of care as the young person develops	Communication to be adjusted in line with cognitive development
	Appointment letters addressed directly to young person in addition to parents/caregivers, when needed; language used is clear
	Use of simple self-assessment tools which may feel less awkward for young person
	Record contact details for both young person and parents/caregivers
Empowerment of the young person by embedding health education and promotion	Psychoeducation provided to young person and parents/caregivers
	Shifting emphasis and supporting family to move from shared-care to self-management as the young person gets older
	Check out with young person how they would like parents/caregivers to be involved
	Involve parents/caregivers in treatment decisions in ways that have been agreed with young person
	Sign-posting young person to local services, as appropriate
	Discuss with young person their confidence and independence in making appointments, managing medication, *etc.*
Working across teams and organizations	Workforce training in developmentally appropriate healthcare, including strength-based approaches such as solution-focused and motivational interviewing
	Adult service included in transitioning planning prior to transfer (*e.g.*, multi-disciplinary team meetings with adult and child teams present, adult services copied into correspondence)
	Transition planning to start early (aged 13-14)
	Opportunity for young person to visit adult service prior to transfer; provide information leaflet about service to be transferred to
	Young people issues are considered in service policies and guidelines; consistency of policies in child and adult services
	Young people's participation at all levels of delivery

DAH: Developmentally appropriate healthcare.

precipitating factors; (4) perpetuating factors; and (5) protective factors.

Practitioners may find it helpful to rename these using more accessible language for individuals, particularly young people. This may be current (what is happening now?), past (what has happened in the past that may be important?), triggers (what sets things off? what was happening when difficulties started?), what keeps things stuck (things that keep difficulties going and/or make change difficult), and positives (positives in life, including own strengths and support from others). These Five Ps should include biological, cognitive, environmental/systemic and personality considerations and the relationships between factors should be explored.

Psychoeducation: Psychoeducation is an important part of treatment that facilitates treatment engagement. Psychoeducation may be provided more generally to family members, but it is important that key information is also directed to the young person in the absence of family members. This is because without 'buy-in' from the individual there is a risk they will just go through the motions to keep people happy or drop out of treatment. It also facilitates informed decision-making and may improve medication adherence and outcomes[118].

Psychoeducation should not be considered a one-off event but rather a process which should be returned to as needed. Psychoeducational interventions are particularly important at key points of service and/or personal transition, with differing topics covered specific to changing biopsychosocial needs and demands. For children and adolescents there may be misconceptions about medication. Discussions should include basic information about ADHD, the purpose and benefits of medication and the long-term consequences of SU. The latter should include legal consequences (*e.g.*, providing substances to a friend can result in supply charges, in turn affecting ability to apply to law or medical schools and travel to destinations such as the United States). For older adolescents and adults, psychoeducation should include discussion about driving including the increased risk of accidents, and legal penalties if convicted of driving under the influence of alcohol or drugs (*e.g.*, losing driving license, a fine, imprisonment, and a criminal record). Both accidents and convictions are likely to substantially increase insurance costs (in the United Kingdom convictions have increased since the introduction of roadside drug testing). Psychoeducation should also include information regarding misconceptions around medication increasing the likelihood of addiction, safety of medication when using substances (*e.g.*, increased risk when binging) and how with age risk significantly increases.

When approaching the care of young people with co-occurring ADHD and SU/SUD, engagement and support of families/carers is critical. Societal connotations about SU can be disparaging and group workshops are helpful in negating feelings of shame through sharing experiences in a supportive environment. Given the heritability for ADHD[108], some parents/caregivers are likely to also have ADHD (possibly unrecognized) and it is important the psychoeducational interventions are facilitated in a manner that aids understanding and engagement. Discussion topics may include the increased risk of SU/SUD for those with ADHD; potential signs and symptoms to be aware of; when and how to seek treatment; treatment options; value of adherence to ADHD medication; how to support a young person (dos and don'ts); refuting myths and misconceptions; dispelling stigma and feelings of shame; and coping skills for parents/caregivers.

CBT: The content of CBT interventions should be adapted to meet individual needs associated with cognitive and emotional functioning of individuals with ADHD and SU/SUD. Individuals with concurrent ADHD and SU/SUD may find it difficult to envisage the potential for change; their impulsivity, together with physiological and/or psychological SU dependency, may leave them perceiving they have little choice and/or will. Agreeing realistic goals is essential and should be based on the individual's presentation and needs (ADHD symptomatology, severity and complexity of SU/SUD, physical health, mental health, internal and external resources, social and cultural systems, and the person's motivation). To increase motivation, goal selection should be a collaborative effort and the goal concrete and relevant. When considering level of functioning (emotional, behavioral and cognitive), it is often necessary to help guide the person in 'fine tuning' treatment goals. Goals which are abstract and/or unrealistic are less likely to be achieved and in turn are likely to negatively affect motivation, confidence, and self-esteem, which may already be fragile[119,120]. Hence goal negotiation is a process and to do this effectively it is important that a good therapeutic alliance has been developed.

Individuals should be invited to use self-reinforcement techniques as useful reminders of their goals, which can help nudge them toward achieving them. These should have some personal meaning. Examples may include mobile phone screensaver with an important word or phrase or symbol, brightly colored sticker on the strap of a wristwatch or the back of a mobile phone, written message in the 'notes' app of a mobile phone, flashcards that are carried in a wallet. A reward system should also be incorporated to motivate new behaviour. Individuals with ADHD struggle to delay gratification; teaching individuals to give themselves rewards on a 'little and often' basis may help to satisfy immediate gratification need and reinforce new behaviour. One form of reward is encouraging 'self-talk' (*e.g.* by giving self-praise, encouraging and motivating statements). It may however be that individuals prefer more material/tangible rewards. Small rewards may be awarded for achieving small steps, with larger rewards introduced at the end of longer periods of sustained behaviour. The person should also be encouraged to share their success and progress with their support network (who will respond positively). This will help to maximize motivation and encouragement.

When working with young people, behavioral-oriented interventions may be more of a focus than cognitive interventions (due to the abstract nature of thinking required). It is important that individuals learn behavioral skills that can be applied on a long-term basis. This should encompass developing skills and confidence to manage potentially high-risk situations such as being offered substances and/or when there is peer pressure. One of the best methods of acquiring new behaviors is to practice in role-plays, where individuals can learn and practice strategies that involve problem-solving, planning, and impulse control. The aim is to learn specific skills that can be automatically applied, minimising cognitive load during real-life stressful situations. Overt rehearsal has been found to enhance treatment effects[106]. In-session practice is considered particularly important for individuals with a dual diagnosis of ADHD and SU/SUD as it is expected they may have difficulty completing practice exercises outside of session.

Individuals should be made aware of emotional and physical states that are likely to increase risk of SU, including when they are most likely to be sensitive to cravings, urges and withdrawal. Identifying and engaging in scheduled activities during 'risk periods' as part of a wider structured timetable can

help young people to maintain abstinence when they are likely to be at their most vulnerable. They should also be guided to use replacement techniques (*i.e.*, replacing substances with something that is less harmful) to assuage cravings and urges. Methadone is commonly prescribed as a replacement for heroin, and nicotine patches, gum, lozenges and vapes/electronic cigarettes as substitutes for cigarettes. Similarly, drinking fizzy drinks may help to alleviate urges to misuse alcohol.

Cognitive interventions should be introduced, as appropriate, to meet the developmental needs of the individual. One such program is the manualized R&R2ADHD program, which is suitable for young people and adults. It covers topics of relevance to both ADHD and SU/SUD, including the development of prosocial competence skills, cognitive and executive functioning skills, critical reasoning, consequential thinking, emotional control, negotiation and assertiveness skills, and social problem-solving skills[61,121-123].

Relapse and prevention: Miller and Rollnick[112] state that individuals with SU/SUD are likely to oscillate between the stages of change several times before abstinence is achieved. Relapse is common for those without ADHD, and those with comorbid ADHD may be at an increased risk[124]. This understanding needs to be built into the expectations of treatment for both the service, individual and family/carers to avoid a sense of disappointment and failure. Services can help prepare individuals for relapse incidents by helping them to develop an action plan. This should include a list of warning signs and triggers for relapses and setbacks, and strategies that they have found helpful over the course of treatment which they can use to help prevent relapse. It is advisable that individuals make a note of these strategies as they progress through treatment. Acknowledging the likelihood of relapse, the plan should include compassionate messages designed to reassure and help motivate the person to get back on track, such as "I am human, we all make mistakes, I can move forward". Contact information for personal and professional networks to access support should also be included in the plan. This may include family, friends, local support groups, nominated mentors and/or 'buddies', occupational health services and confidential services. Information contained in the plan should be in the person's handwriting using their own words as this will help them to 'own' the plan. Individuals with concurrent ADHD and SU/SUD may require 'booster' sessions after treatment has concluded[124].

Identification, assessment and treatment of ADHD in adults presenting in SU/SUD community and inpatient services

Identification: Those working in SUD services should be vigilant to ADHD as a possible comorbid diagnosis, given the high prevalence of adult ADHD among those with SUD. The inherent challenges of accurately assessing ADHD in SUD services was highlighted in group discussions. A major problem is the overlap of ADHD symptoms with intoxication and withdrawal states (*e.g.*, agitation, restlessness, impulsive behaviour, concentration difficulties) and common outcomes between the two conditions (*e.g.*, job loss, poor school performance). These factors often result in ADHD being overlooked with symptoms and impairments in functioning erroneously attributed to SU[125]. High rates of comorbidity with other conditions (*e.g.*, anxiety, depression, bipolar disorder, personality disorders and autism) may further complicate diagnosis (see Table 5). Practitioners need to be aware that identification is further complicated by individuals with ADHD developing compensatory strategies that mask symptoms and/or that limit the (negative) impact on their functioning[126].

Assessment: The consensus group recommended screening for ADHD in adults with SUD. Research suggests that the Adult ADHD Self-Report Scale (ASRS)[127] could be a viable option for screening ADHD in those with SUD in terms of its sensitivity[110]. However, research indicates a lower specificity when compared to general population data[128], resulting in higher probability of false positives. This is likely to be explained by higher prevalence of comorbid psychiatric conditions as well as deficits associated with SUD[129]. Thus, the ASRS may serve as a guide to identify individuals with SUD at high risk for ADHD diagnosis, but this should be interpreted with caution and always followed up with a comprehensive clinical evaluation to differentiate findings from associated psychopathology.

Whilst screening is recommended for everyone accessing SUD services, the consensus group noted that this is not current practice. Observable markers were considered that may trigger screening, noting that some individuals appear to function better than others under SU. In particular, some substances may have a paradoxical effect for those with ADHD (*e.g.*, illicit stimulant use has shown improvement in attentional capacity and lower psychomotor activity rather than an elating effect[130]). Discussing the reasons for use (*e.g.*, to calm, dampen hyperactivity, intrusive thoughts, sleep) may be helpful, although this may be a factor associated with several psychiatric conditions and not solely ADHD. Other markers include presenting behaviors that appear beyond SU (*e.g.*, impulsivity; evidence of chaotic SU; frequent contact with the CJS and/or from an early age; gambling and other addictions, including caffeine; rapid relapse after de-toxification, transition from in-patient or other structured environments and difficulties in engaging with services and/or maintaining treatment). Importantly, for those in the care of institutional settings, their current presentation may be misleading due to high levels of structure and routine that are typical of these environments.

Table 5 Overlapping symptoms between attention-deficit/hyperactivity disorder, substance use/substance use disorder and other psychiatric disorders

Symptom	ADHD	SU/SUD	Other psychiatric comorbidity[1]
Agitation	√	√	√
Anxiety	√	√	√
Hyperactivity	√		√
Impulsivity	√	√	√
Inattention	√	√	√
Intolerance to frustrations	√	√	√
Mood instability	√	√	√
Poor concentration	√	√	√
Poor memory	√	√	√
Restlessness	√	√	√
Risk-taking behavior	√	√	√
Sleep difficulties	√		√

[1]Anxiety, depression, bipolar disorder, personality disorders.
ADHD: Attention-deficit/hyperactivity disorder; SU: Substance use; SUD: Substance use disorder.

When assessing suspected ADHD in individuals with SUD, it important to bear in mind that substances can mimic the symptoms of ADHD (negatively affecting concentration, organization, and impulsivity)[131]. Huntley and colleagues[24] found a clinically significant reduction in self-rated ADHD symptoms when comparing evaluations a few days after admission to a detoxification unit with evaluations one week later, when individuals had been detoxified or stabilized on long-term medication. This resulted in 40% of participants no longer meeting screening criteria for ADHD. Thus, in settings that prioritize rapid detoxification and discharge, screening may not provide meaningful results. Screening in addiction services should not occur at reception/upon admission but a few weeks later as it is important to obtain a stable baseline for functioning. Should screening at reception/upon admission be service policy, it is recommended that this be followed up with a second screen. Aside from factors associated with SU or its withdrawal hampering assessment, individuals may be reluctant to divulge information and reveal vulnerabilities. They may not trust how information will be used [132].

Ideally, clinical evaluations for ADHD are best conducted during a period of sustained abstinence, or once detoxification or stabilization for substance dependency has been completed. Some authors recommend at least one month of abstinence in order to assess for ADHD symptoms reliably and accurately[133]. The group however acknowledged that this recommendation may be difficult to implement in community contexts, particularly where ADHD symptoms and associated impairments in functioning may be hindering individuals from effectively engaging with SUD services. The consensus group highlighted potential risks associated with detoxification if ADHD remains untreated, including chaotic relapses. In these cases, it is important to guard against diagnosing ADHD-like symptoms that arise because of SU in the absence of underlying ADHD.

Consensus group members noted that for both inpatient and community settings, the assessment content will be the same, although the process is likely to differ, with potentially a slower paced assessment within community settings, accounting for environmental context and time to build relationships in the community.

As discussed previously, assessment must rely on a detailed developmental history for differential diagnosis. This should include a focus on drug and alcohol-free periods of the individual's life (*e.g.*, checking whether ADHD symptoms are present during periods of abstinence and/or at time prior to onset of SU) to establish if these symptoms are primary or drug induced. It is common for adults with ADHD to have other concurrent conditions including depression, anxiety, antisocial personality disorder, emotionally unstable personality disorder, and bipolar disorder. These conditions are also highly prevalent among adults with SUD. They also share many common symptoms with ADHD. For example, emotionally unstable personality disorder and ADHD share impulsivity characteristics. It is therefore imperative that as part of a comprehensive differential diagnosis assessment, the process also looks to exclude other conditions that could better explain presenting ADHD-like symptoms. Assessing individuals with SUD for ADHD requires specific expertise in psychiatric evaluation to enable differentiation between ADHD and other psychiatric disorders. Group members highlighted the risk of

diagnostic overshadowing especially with personality disorder, when practitioners are not well-versed in neurodevelopmental disorders, indicating a need for improved training in psychiatric services.

There may be a small number of individuals with SUD who present for ADHD assessment to access prescribed stimulant medication. As highlighted in the earlier section discussing the pharmacokinetics of stimulant medication for ADHD, long-acting preparations have low abuse liability. Should individuals be seeking stimulant medication for misuse purposes, it is likely that they will be dissatisfied with the effect, as they will not obtain the 'high' that they anticipate. Practitioners should ascertain the individual's expectations of diagnosis and treatment and be mindful that for a small number of individuals, symptoms may be exaggerated and/or feigned for perceived external gain[48].

Where possible, obtaining collateral information from other sources will help to reduce the risk of misdiagnosis. Obtaining informant data on ADHD symptoms for this population however can prove difficult due to the strained interpersonal relationships that many individuals with SUD have with family and friends[24]. The person may also be reluctant to share contact information. In clinical practice, the diagnostic assessment of ADHD for persons with SU/SUD may primarily rely on self-report, despite the fact that cognitive impairments associated with SUD can compromise the reliability of retrospective recall[129]. Nonetheless, where only self-report is available, research indicates that for most cases this may be sufficient, with moderately high correlations identified between informant and self-report ratings[24]. This is increased for individuals with good insight into the condition[134]. The absence of collateral information should not delay or prevent assessment.

SUD may exacerbate ADHD symptoms by as much as 30%[90] and this may alleviate with successful SUD treatment. To prevent misdiagnosis, it is important to follow-up and continue to monitor symptoms. Within adult inpatient contexts and custodial environments, it is possible to observe individuals over a prolonged period (24/7) and record degree of restlessness, inattentiveness, impulsiveness, poor emotional regulation, and problems with self-organization. Within community settings it is similarly important to be aware of behavioral observations during appointments, although quality of information may be comparatively limited due to the environmental constraints.

Pharmacological treatment: NICE guidelines suggest that appropriately qualified healthcare professionals can, with adequate training, acquire the necessary knowledge of ADHD to support assessment and/or treatment[135]. However, the experiences of the consensus group were that in the United Kingdom some healthcare practitioners with the appropriate skills to prescribe are prevented from doing so by local commissioning arrangements and guidelines[97]. Constraining prescribing to scarce and over-stretched specialist services is unnecessarily limiting and does not reflect the range of services involved in the care of individuals with concurrent ADHD and SUD. In accordance with NICE guidelines, the consensus group agreed that expanding local commissioning parameters to allow prescribing more widely would streamline care. In turn this would help individuals to access the support they need and reduce clinical burden on specialist services, allowing them to manage more complex cases.

Some practitioners outside ADHD specialist services may be concerned about assuming responsibility for prescribing ADHD medication. For example, primary care practitioners have voiced concerns about stimulants being 'controlled drugs' and the risk of potential misuse and diversion[136] (see previous section on pharmacological treatment in the community and Figure 2 which discusses the pharmacokinetics of stimulant medication that refute this perspective). Facilitating confidence in prescribing was considered crucial with specialist SUD services deemed to have a role in providing readily available specialist advice and guidance *via* remote clinics (telephone or online). This was considered particularly important for this population where complexity issues with poly-pharmacy are likely to be encountered. Research suggests that clear protocols and clearer advice from specialist services may help to change some hesitant practitioners' views on prescribing[137]. The effectiveness of integrated care between primary care and specialist services has been demonstrated in other conditions (*e.g.* heart failure). This has shown to be associated with improved coordination between services, General practitioners (GPs) feel more confident in supporting patients, specialist services receiving more detailed feedback from primary care, and patients receiving more streamlined and holistic care[138].

When considering prescribing pharmacological treatments for this population, discussions centered on risk assessment regarding compliance and safety. In clinical practice this must be considered on an individual case by case basis (rather than categorically), and a decision made following an individual risk-benefit analysis which should be documented. Consensus group members agreed that active users of substances should still be offered pharmacological treatment if shown to be motivated to change and engaged, subject to appropriate risk assessments. Contraindications to stimulant pharmacotherapy may include current abuse of prescription stimulants or a clear indication that the medication would be sold or diverted. In addition there may be concerns regarding cardiovascular safety. Factors such as prior history of misusing stimulant medication and overall clinical stability should be considered. Practitioners should give appropriate weight to the efficacy of stimulant medication when balancing concerns regarding risk of misuse or diversion.

When considering concerns regarding misuse or diversion, the overarching opinion was that long-acting forms of stimulant medication should be prescribed. Despite lowered risk, it nevertheless remains important to be vigilant of any signs of misuse or diversion. Signs which may indicate possible

misuse or diversion include: a repeated pattern of requests to replace alleged missing or lost prescriptions; requests for dose increases (not clinically indicated); early re-ordering of prescriptions; demands for immediate release preparations or claims that long-acting prescriptions are not effective; and symptoms associated with heavier use or intoxication[89]. Individualized risk assessment should incorporate clinical management; careful monitoring is likely to detect non-therapeutic use of stimulant medication, enabling treatment plans to be modified appropriately.

Supervised consumption and interval dispensing was recommended in inpatient and custodial settings as options available to minimize risk. These should correspond with dispensing arrangements for prescribed methadone (commonly at weekly or six times per week dispensing frequencies). Consensus group members also noted that in environments which enable supervised consumption, lisdexamfetamine (a long-acting prodrug formulation) may be preferred as it can be dissolved in a drink, limiting potential for misuse or diversion. Furthermore, lisdexamfetamine has to be hydrolyzed by red blood cells to work. This means that when ingested by other routes (*e.g.*, intravenously or intranasally), the abuse potential is significantly limited. Oral and intravenous studies have shown no differences in subjective effects, likeability or blood pressure[53].

It was agreed that emphasis should be placed on adherence to the prescribed medication regimen which will facilitate optimal response. Individuals should be discouraged from binge using substances due to increased toxicity.

The consensus group highlighted the importance of ensuring that the person is part of the treatment planning process. They should feel that treatment is their choice rather than feeling it has been imposed. Educating individuals about the available treatment options including benefits and risks was considered important in helping them to develop a stake in the treatment.

Psychological interventions: Psychological treatment should address the specific difficulties experienced by adults with comorbid ADHD and SUD[139]. This involves using the same interventions discussed previously, including MI, formulation, psychoeducation, CBT, and relapse prevention approaches. The focus of treatment should include emotional liability/dysregulation, education and employment problems, interpersonal difficulties and development of prosocial competence, self-harm, dysfunctional coping strategies, and comorbid conditions such as anxiety and depression.

Psychological interventions are likely only to be effective following detoxification (*i.e.*, the individual no longer needs pharmacological treatment for withdrawal symptoms) and once the individual is stabilized[59,110]. Longer psychological support and treatment may be required for those who use opiates. It was noted that it is not uncommon for service-users to lack support of family members and/or friends due to strained relationships; these individuals may require enhanced supportive scaffolding from healthcare and service-user services.

Multi-agency interventions

Individuals with both ADHD and SUD present with complex problems and often inter-agency working is needed for the successful provision of care.

Multi-agency interventions for young people: Young people and adults with concurrent ADHD and SU/SUD may require access to coordinated ongoing support from a wide variety of agencies. Yet in the United Kingdom, there are local and regional idiosyncrasies in referral and treatment pathways for young people with ADHD that can make it difficult to access care. Some GPs are unable to refer young people suspected of having ADHD directly for an ADHD assessment. For individuals with coexisting SU/SUD (who may be or who say they are self-medicating) the problem may be exacerbated. Referrals may be managed through schools but in some cases before this can take place, parents/caregivers must complete a parenting program. If then deemed appropriate by the school, a referral for an ADHD assessment can be made. Consensus group members acknowledged that some parents who themselves have ADHD, possibly undiagnosed, (heritability of ADHD is reported to range between 70-80%[108]) may have difficulties completing a parenting program. There are potential issues with schools being gatekeepers, particularly for those with ADHD and SU, as the focus may be on the SU. As a result of this, vulnerable young people do not receive the support and/or reasonable adjustments they need (and are entitled to) in order to optimize learning and development in educational settings. This may be further complicated by the mediating role of conduct disorder[64] with young people drifting into an antisocial peer group where substance misuse is common.

Young people with ADHD are at increased risk of being suspended or expelled and dropping out of school[140]. This may be exacerbated for those with SU. If ADHD is unrecognized and undiagnosed, the possibility that these individuals may be attempting to self-medicate (deliberately or unwittingly) may not be considered. All schools should have a drugs policy establishing the ways the school will deal with drugs on school property. This needs to balance the needs of the pupils with the wider school community. In some schools this involves the establishment of a drugs contract which aims to act as a deterrent and incentive to healthy habits and decision-making. The contract is signed by the pupil and their parents or carers on a voluntary basis. Typically, the contract includes a random drug testing regime and sets prescribed sanctions for default from the contract. However, this may present a dilemma for the pupil and parents/carers regarding consent and/or ambivalence over their level of

support and co-operation with its implementation.

Community social interventions (*e.g.* such as Premier League Kicks[141] and Oasis Charitable Trust [142]) have an important role in supporting vulnerable individuals, including those with SU problems. Individuals should be signposted to services which can provide routes into education, training, employment, and steer young people away from a harmful trajectory.

Multi-agency interventions for adults: ADHD in adulthood is associated with work-related problems including impaired work performance and difficulties gaining and maintaining jobs[104]. The impairments associated with ADHD indicate that it should be regarded as a disability under the United Kingdom Equality Act 2010[143], affording individuals with certain rights and access to services. Individuals with ADHD may be entitled to reasonable adjustments in the workplace. Reasonable adjustments are assessed and provided on an individual basis. Some examples of reasonable adjustments include alterations to the workspace to reduce distractions in the environment, work schedule changes, frequent breaks, and use of technology assistance. Individuals may benefit from support in disclosing their ADHD diagnosis, particularly when they experience fear regarding occupational stigma.

However, commencing and sustaining new patterns of behaviour in an occupational setting can be difficult. From the experience of the consensus group, work-related problems may result in individuals using substances as a coping strategy which can further compound workplace difficulties. This is particularly relevant for people with ADHD who have executive functioning difficulties in planning, organizing, initiating, and completing tasks[107].

Relationships can be a useful 'vehicle for change' to help with this challenge; for example, a mentor or 'buddy' in the workplace can make it easier to facilitate completion of tasks. This principle is in Alcoholics and Narcotics Anonymous programs, where individuals are partnered with a sponsor who can offer help and guidance and provide accountability. Individuals should be sign-posted to formal groups of this nature for support with their treatment goals. In the United Kingdom, individuals may also benefit from a referral to social prescribing services. Social prescribing link workers adopt a holistic approach to wellbeing and can connect individuals to community groups and statutory services for both practical and emotional support.

The consensus group discussed anecdotal accounts of clinicians being asked to attend 'team around the family' meetings. This arises when concerns have been raised by other key professionals involved in the care of the family, resulting in clinicians being asked to complete parenting assessments. The consensus group experience was that these requests relate to a lack of awareness and stigma associated with ADHD, and this is further compounded when SU/SUD is present. This led to discussions where it was agreed that ADHD should not be considered a diagnosis that debars individuals from parenting (although severe and/or chronic substance dependency might).

Criminal justice system (CJS): ADHD and comorbid SU/SUD may increase risk that people will have contact with the CJS[144]. Research suggests that ADHD is likely to adversely impact an individual's pathway through the CJS, leading to further negative sanctions[145]. The consensus group noted that this may be particularly relevant for community treatment options, such as the Community Sentence Treatment Requirement (CSTR) program (available in England). Where a CSTR service operates, it gives magistrates and judges a sentencing option, whereby a community sentence with one or a combination of three treatment requirements can be applied: drug rehabilitation requirements (DRRs), alcohol treatment requirements (ATRs), and/or mental health treatment requirements[146]. From consensus group members' clinical experiences, individuals with ADHD may find it difficult to comply with DRRs and ATRs. This may result in individuals being in breach of requirements and in some cases lead to incarceration. Non-compliance with community options may be associated with symptoms of ADHD (*e.g.*, forgetfulness), but this may be disregarded if it is perceived that ADHD symptoms and resultant impairments in functioning represent 'bad behavior' rather than unmet needs[146]. A National Neurodiversity Lead for CSTRs has been in place, increasing awareness of ADHD and other neurodevelopmental conditions, and has demonstrated examples of good practice for reasonable adjustments which would be of value more broadly across the CJS.

It is important to ensure communication between in-reach and out-reach healthcare services working across CJS services, and improvement in the flow of medical information across these services is likely to enhance safe and effective care for those with comorbid ADHD and SU/SUD.

DISCUSSION

The co-occurrence of ADHD and SU/SUD is common. The presence of both conditions exacerbates difficulties greater than that of either condition alone and is associated with reduced treatment effectiveness. The identification and assessment of ADHD and SU/SUD is complicated not only by overlapping symptoms across the two conditions but by other highly comorbid conditions. Given the high prevalence of ADHD and SU/SUD comorbidity, the consensus highlighted that those working in SUD services should be vigilant to ADHD as a possible comorbid diagnosis, and those working in

ADHD services should be vigilant to signs of SU/SUD. Where ADHD or SU/SUD is suspected, assessment should be conducted by practitioners experienced in differential diagnosis. There is a risk of diagnostic overshadowing where practitioners are not well-versed in neurodevelopmental disorders, and vice versa, SU/SUD.

The use of psychostimulant medications in the treatment of concurrent ADHD and SU/SUD is complex. There is no published evidence of abuse of sustained release preparations, but caution is advisable when prescribing immediate release stimulant preparations[88]. This is not because appropriate use can give a high, but because immediate release stimulants are more likely to be crushed to a powder and snorted or used intravenously. Early treatment of ADHD may protect against later SU/SUD and can be useful in reducing ADHD symptoms without worsening pre-existing SU/SUD. Practitioners are encouraged to pharmacologically treat both ADHD and SU/SUD simultaneously, where practicable.

A multi-modal approach combining pharmacological treatment with psychological interventions is recommended, commensurate with studies which suggest that psychological therapy may be a useful strategy to treat SU among those with ADHD. Further research in this area is needed. Psychological interventions should adopt a transdiagnostic approach, targeting difficulties common to both ADHD and SU/SUD and should be adapted to meet the biopsychosocial needs and demands of the person.

Consensus meeting discussions continually highlighted existing inter-service barriers and fragmentation of care. In the United Kingdom, recent legislation has established integrated care systems which are partnerships that bring together local health and care organizations with the aim of providing better coordinated care to meet the needs of the people who live in the area. The consensus group stressed a need for re-evaluation of commissioning arrangements and pathways for those with coexisting ADHD and SU/SUD, offering opportunities for joint working and shared care, in turn resulting in better continuity of care.

Transition planning was considered a primary focus with group members noting that, with increasing age, biopsychosocial demands tend to increase whilst support declines. There is a stark notion that individuals 'fall off a cliff' when they turn 18. An emphasis on preventing drop out from services, especially when transitioning from child to adult services, may help prevent onset and/or escalation of SU. The provision of consistent, coordinated care over this important transitional period is vital. Developmentally appropriate healthcare provides an individualized integrated care approach which is responsive to the multiple and changing impacts of health conditions upon the individual and their goals[103]. Whilst currently primarily adopted for those with long-term health conditions, it is recommended more widely, including those with concurrent ADHD and SU/SUD.

Empowering general services was deemed vital. Training is an important step to ensure adequate knowledge and competencies for services to support monitoring and continuation of treatment under shared care arrangements. Access to foundational awareness training in ADHD (that is equivalent to the current provision of autism awareness training) was recommended. Ideally, this should be delivered to healthcare professionals including those in third sector mental health services, educational professionals, employment services, CJS workers, police, housing and homeless services, social workers, youth center workers, and GPs. It was also suggested that a similar level of awareness across services may be required for SUD.

It is hoped that this consensus can be used by practitioners across a range of disciplines to support the effective identification and treatment of individuals with concurrent ADHD and SU/SUD in order to achieve optimal outcomes. The consensus recommendations for practice are summarized in Table 6.

We need early and accurate identification and treatment of SU/SUD among young people in ADHD services, and vice versa. The delivery of appropriate interventions is likely to facilitate promising rather than harmful trajectories, leading to better outcomes at both individual and community levels. In the United Kingdom, systemic changes in commissioning arrangements, service delivery, workforce education and training are necessary if we are to effectively meet the needs of this complex group.

CONCLUSION

This review of the relevant current literature, combined with the diligence of the consensus group, has identified the most salient vulnerabilities of individuals with combined ADHD and SU. Furthermore, the consensus statement provides a structure within which the pertinent vulnerabilities can be best identified, treated, and managed by clinical and multi-agency interventions. The statement provides an important readily accessible contribution to the literature for practice, research, and evaluation of treatment effectiveness for young people and adults with combined ADHD and SU/SUD.

Table 6 Overview and practice recommendations

Recommendations
Identification and assessment
Due to the level of complexity, assessments should only be conducted by qualified healthcare professionals with appropriate training and expertise in assessing dual disorders. This may require foundation training in ADHD and SUD across the two services and/or assessments being made jointly by experts in different areas
It is critical to examine the temporal course of ADHD-like symptoms and SU/SUD. A focus on drug and alcohol-free periods may help with differential diagnosis
Symptoms of ADHD and SU/SUD may be masked for many reasons including overlapping of symptoms between disorders, other comorbid conditions (*e.g.*, personality disorder, bipolar disorder, anxiety, depression), and the individual may have developed compensatory strategies
Substances may have a countereffect for individuals with ADHD. Where individuals appear to be functioning better under SU, this may indicate possible underlying ADHD
Assessors should be aware that for those in institutional settings, current presentation may be misleading due to structure and routine minimising deficits in functioning
A comprehensive assessment should include a full developmental history, mental health history and current mental state examination, medical history, educational/employment history, social history, cognitive executive functioning difficulties, family history of ADHD and SU/SUD, in addition to other psychiatric and neurological problems. Perceived sex differences in presentation should be considered which may result in missed or misdiagnosis
Rating scales are not diagnostic. If used to screen, services should not rigidly adhere to cut-offs as this is likely to lead to high proportion of false positives and negatives
Young people presenting with an initial diagnosis of ADHD should be continually monitored through development for SU/SUD, given high rates of ADHD and SU/SUD comorbidity
ADHD assessment should not be conducted when an individual is under the influence of substances at the time of the assessment and/or when in a stage of withdrawal. Ideally, ADHD clinical evaluations are best conducted during a period of sustained abstinence or following detoxification or stabilization
When conducting the assessment with young people, it is important to consider how parents/caregivers are involved commensurate with the wishes and needs of the young person
The assessment may need to address additional physical, criminogenic, and safeguarding risks associated with SU. The person should be informed of the confidentiality of information shared and circumstances in which this will be breached
There are high rates of comorbidity associated with both ADHD and SU/SUD; the assessment should look to exclude other conditions that could better explain presenting symptoms
Follow-up and continued monitoring of symptoms is advised to prevent misdiagnosis
Practitioners should be aware of the risk of diagnostic overshadowing, which may require improved training in mental health services
Whenever possible, collateral information should be obtained from independent sources. For those with SUD, this may be difficult due to poor/strained relationships; the absence of collateral information should not unduly delay or prevent assessment
Pharmacological treatment
A nihilistic attitude to pharmacological treatment is not appropriate; active users of substances should be offered ADHD medication, subject to appropriate risk assessment
Long-acting stimulant preparations are recommended as first line treatment. Generally non-stimulants should be reserved as a second line due to relative effectiveness and concerns regarding non-compliance
Short-acting stimulant preparations are advised for a very circumscribed group (*e.g.*, in contexts where there is possibility for supervised consumption)
Abstinence of substance use is not necessary for individuals to benefit from ADHD medication, though SU should ideally be reduced/stabilized before initiating ADHD medication
For those with primary alcohol use, atomoxetine may be of specific consideration in light of research indicating effectiveness in reducing alcohol cravings
Prescribing needs to consider interactions between ADHD medication and other medications for comorbid conditions, where applicable
Practitioners should be aware of personal and family history of cardiovascular conditions. Where there are concerns regarding cardiovascular risk, a cardiologist should be consulted prior to prescribing stimulant medication
Heart rate, blood pressure and weight should be measured before initiating medications and routinely monitored during treatment; titration should be slow. Include height monitoring in CYP
Individuals with SU/SUD at time of stabilization should be considered for prioritization for assessment in ADHD services
Provision of developmentally appropriate healthcare (DAH) within services may be of benefit
Commissioning arrangements should permit prescribing beyond specialist services
In spite of lowered risk of misuse or diversion with long-acting stimulant preparations, practitioners should still be vigilant of signs including pattern of losing prescriptions, early re-ordering of prescriptions, demands for immediate release preparations or claims that long-acting prescriptions are not effective, and symptoms associated with heavier use or intoxication

Supervised consumption and interval dispensing should be considered as options to minimize risk. ADHD medication dispensing arrangements should correspond with prescribed methadone, where applicable

Psychoeducation on pharmacological treatment may help to improve adherence and engagement

Psychological treatment

Where neuropsychological testing has been conducted, the strengths and weaknesses profile should be used to inform adaptations to the treatment process

Email/text reminders from service should be used to reduce likelihood of non-attendance. Sessions may require increased frequency of sessions, with greater structure, being delivered at a slower pace in shorter duration and/or including mid-session breaks, with repetition and greater use of supplementary visual material

Individuals should be provided with a notebook which serves as a record of strategies learnt. This should be completed in the person's own writing to facilitate 'ownership', responsibility, and action

Motivational interviewing (MI) is more suitable for older adolescents and adults and is particularly helpful in the initial motivational stages (precontemplation, contemplation, preparation)

Practitioners need to be aware of the individual's current motivational stage and should monitor interest to engage in treatment throughout, adapting treatment interventions as necessary

Functional behavioral analysis should be used to help identify constructive or functional alternatives to substance use

Psychoeducation should be provided as an important part of the treatment process and should be returned to at regular intervals over the course of treatment, including key points of service and/or personal transition

Psychoeducational programs should differ for children, adolescents, and adult populations in relation to changing biopsychosocial needs and demands. They should be provided to both the young person and their family. Topics should include basic information about ADHD, the purpose and benefits of medication and non-pharmacological interventions, long-term consequences of SU (including legal consequences, misconceptions around medication increasing the likelihood of addiction, how and where to access local support

Societal connotations about SU can be disparaging; parent/carer group interventions provide a supportive environment where they can share experiences (common humanity) and assuage feelings of shame

Clear and realistic goals should be collaboratively identified and monitored using the SMART framework

Individuals should be invited to use self-reinforcement techniques (which hold personal meaning) as reminders of their goals

Reward systems should be incorporated into treatment to motivate new constructive behaviour

Cognitive behavioral therapy interventions should be adapted commensurate with cognitive and emotional functioning; there may need to be more of a focus on behavioral-oriented interventions when working with young people

Young people and adults may benefit from the R&R2ADHD program which adopts a transdiagnostic approach targeting difficulties common to both ADHD and SU/SUD

Psychological treatment should include a relapse and prevention action plan, with follow-up 'booster' sessions provided, as needed

Multiagency interventions

Signposting to services which provide routes into education, training, employment, can help to steer people away from a harmful trajectory and prevent relapse

Practitioners should be aware that individuals may lack support networks due to strained interpersonal relationships, requiring enhanced supportive scaffolding from healthcare and service-user services

Schools should have a drugs policy establishing clearly how schools will deal with SU, where appropriate, this may include a drugs contract. If deemed appropriate, schools should also screen and refer young people for assessment of ADHD

Educational and employment support services should be aware of potential challenges for individuals. Reasonable adjustments to education/workplace may be required to help individuals manage demands and prevent harmful trajectories

Healthcare services to make reasonable adjustments through offering combined appointments

Individuals to be sign-posted to alcoholics/drug addicts anonymous for support with treatment goals

Referral to social prescribing services may be helpful in connecting people with community groups and statutory services for practical and emotional support

Transition planning between child and adult services should commence early and be a primary focus

Services should not work in silos. Foundational awareness training in ADHD and SU/SUD (as individual and comorbid conditions) should be provided to key professionals across health and social care, education and justice services and third sector organizations

ADHD: Attention-deficit/hyperactivity disorder; SU: Substance use; SUD: Substance use disorder.

FOOTNOTES

Author contributions: Young S was responsible for the planning and scientific input of this consensus statement; all authors attended the consensus meeting; Cocallis K completed the first draft of the manuscript; It was substantially

revised by Young S with further input from Nutt D, Mason P and Mukherjee R; The second draft was revised and circulated by Young S and Cocallis K to all authors for comment and endorsement of the consensus; Following further feedback and amendments by Young S and Cocallis K, the final draft was circulated once more; all authors have read and approved the final manuscript.

Conflict-of-interest statement: Young S, Abbasian C, Cubbin S, Branney P, Colley B, Deeley Q, Hill P, Hollingdale J, Judge D, Lewis A, Mason P, Johnson J and Woodhouse E are affiliated with consultancy firms/private practices. Over the past five years Young S has received honoraria for consultancy and educational talks years from Janssen, Medice and Takeda. She is author of the ADHD Child Evaluation (ACE) and ACE+ for adults; and lead author of R&R2 for ADHD Youths and Adults. Hill P received honoraria for consultancy and educational talks from Takeda and Flynn Pharma. Cortese S declares honoraria and reimbursement for travel and accommodation expenses for lectures from the following non-profit associations: Association for Child and Adolescent Central Health (ACAMH), Canadian ADHD Alliance Resource (CADDRA), British Association of Pharmacology (BAP), and from Healthcare Convention for educational activity on ADHD. Mason P has received honoraria for consultancy and educational talks from Takeda, Flynn Pharma and Lily. Nutt D has received honoraria for educational talks from Takeda and Janssen. Lewis A has received honoraria for consultancy to the Association for Child & Adolescent Mental Health (ACAMH) and Takeda and for educational talks to Forensic Treatment Division, Ministry of Justice, Republic of Korea. Mukherjee R has received honoraria for consultancy and talks related to ADHD from Takeda, Flynn Pharma and Janssen. Johnson J has received honoraria for consultancy and educational talks for Flynn Pharma, Takeda and Janssen. The remaining authors (Gudjonsson GH, Cocallis K, Roberts J, Al-Attar Z, Robinson F) declare that the meeting was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.

Abstract

BACKGROUND

Sleep breathing, one of the basic human needs, is a physiological need that affects cardiac functions, body temperature, daily vitality, muscle tone, hormone secretion, blood pressure, and many more. In the international literature, studies reported that patients have had sleep problems in the hospital since the 1990s, but no measurement tool has been developed to determine the causes of hospital-acquired insomnia in individuals. These findings suggest that sleep remains in the background compared to activities such as nutrition and breathing. Although patients generally experience hospital-acquired sleep problems, there is no measurement tool to determine hospital-acquired sleep problems. These features show the originality of the research.

AIM

To develop a measurement tool to determine the sleep problems experienced by patients in the hospital.

METHODS

A personal information form, hospital-acquired insomnia scale (HAIS), and insomnia severity index (ISI) were used to collect research data. The study population consisted of patients hospitalized in the internal and surgical clinics of a research hospital in Turkey between December 2021 and March 2022. The sample consisted of 64 patients in the pilot application stage and 223 patients in the main application stage. Exploratory factor analysis and confirmatory factor analysis (CFA) analyses were performed using the SPSS 20 package program and the analysis of moment structure (AMOS) package program. Equivalent forms method used.

RESULTS

The HAIS consisted of 18 items and 5 subscales. The Cronbach alpha values of the subscales ranged between 0.672 and 0.842 and the Cronbach alpha value of the overall scale was 0.783. The scale explained 58.269% of the total variance. The items that constitute the factors were examined in terms of content integrity and named as physical environmental, psychological, safety, socioeconomic, and nutritional factors. CFA analysis of the 5-factor structure was performed in the AMOS package program. The fit indices of the obtained structure were examined. It was determined that the values obtained from the fit indices were sufficient. A significant correlation was determined between the HAIS and the ISI, which was used for the equivalent form method.

CONCLUSION

The HAIS is a valid and reliable measurement tool for determining patients' level of hospital-acquired insomnia. It is recommended to use this measurement tool to determine the insomnia problems of patients and to adapt it in other countries.

Key Words: Insomnia; Sleeplessness; Sleep disorder; Scale development; Hospital; Hospital housekeeping

Core Tip: Sleep, which is one of the basic human needs, is a physiological need that affects heart functions, hormone secretion, mood, psychological state and many more. Although there are studies in the international literature reporting that patients have sleep problems in the hospital since the 1990s, a measurement tool has not been developed to determine the causes of hospital-acquired insomnia in individuals. Determination of hospital-acquired insomnia causes of individuals; It will provide many benefits such as increasing the quality of care, improving mood, reducing stress levels, increasing the effectiveness of treatment, and increasing psychological resilience. In this research, a measurement tool was developed to identify the causes of hospital-acquired insomnia and to identify the causes of insomnia in hospitals or inpatient health institutions by focusing on the vital sleep activity. A measurement tool consisting of 18 items and 5 factors was developed. In addition, the literature on the factors that cause hospital-acquired insomnia was reviewed and some recommendations were made.

INTRODUCTION

Sleep breathing, one of the basic human needs, is a physiological need that affects cardiac functions, body temperature, daily vitality, muscle tone, hormone secretion, blood pressure, and many more. With these properties, sleep is the basic need for human survival[1-3]. Some conditions such as pregnancy, stress, menopause, physical diseases, and hospitalization increase the need for sleep[1,4]. Sleep plays an important role in maintaining health and recovering diseases[1,3]. Moreover, sleep is a need that people are most vulnerable to deprivation and must inevitably be replaced[2].

Insomnia can be defined as difficulty falling asleep, maintaining or ending sleep, and situations in which individuals do not feel rested or ready for the new day because they do not sleep enough or for a sufficient time[1,2]. Insomnia can occur independently or due to other problems. Temporary insomnia, which may arise from reasons such as stress, is a common problem, including in hospitals. Studies show that 33% to 69% of patients experience sleep deprivation in the hospital[5-7].

Insomnia is a common patient complaint during hospitalization[8-12]. While in the hospital, patients may experience sleep problems due to many reasons such as hospitalization, not getting used to the bed, being away from the family, a foreign environment, disease anxiety, surgical interventions, sound, light, noise, inability to meet the needs of daily living, and deterioration in body image[13,14]. In addition, it is stated that some factors such as the high number of patients in the room, room temperature, implementations made at sleep time, and the obligatory sleeping positions affect sleep patterns in the hospital[15]. It is stated that the reasons such as the stuffiness of the room, smell, reasons arising from the bedding, inconvenience of the bed and the pillow, pain, lack of information, drugs, tubes such as drains-catheters, hunger-fullness also cause sleep problems among hospitalized patients [16]. In another study, it was stated that in intensive care units, sleep is affected by factors originating from intensive care (noise, patient care, and treatment practices) and disease-related factors (pain,

anxiety, disease severity, drugs, mechanical ventilation)[17].

Individuals resort to medication since insomnia creates stress and anxiety in individuals. However, in this process, it will be a more effective method to determine the cause of insomnia, take precautions, eliminate the cause, make necessary arrangements for sleep, plan the nursing care accordingly, and use medication as a last resort[2,18,19]. The ability of a nurse to solve this problem is associated with his/her ability to evaluate sleep and the appropriateness of the measurement tools used.

According to the literature, scales such as the Epworth sleepiness scale[20], Pittsburg sleep quality index[21], DSM-5 sleep-wake disorders module[22], Richard-Campbell sleep questionnaire[23], postpartum sleep quality scale[24], sleep quality scale[25], Jenkins sleep scale[26], sleep hygiene index [27], sleep assessment scale for children with cancer[28] are used to determine sleep-related problems in our country. In addition, the form of factors affecting sleep[29] is used to evaluate sleep in terms of quantity and quality. As can be understood from the names of the scales, there is no measurement tool to measure the causes of hospital-acquired insomnia. In the international literature, studies reported that patients have had sleep problems in the hospital since the 1990s, but no measurement tool has been developed to determine the causes of hospital-acquired insomnia in individuals. These findings suggest that sleep remains in the background compared to activities such as nutrition and breathing. This research focuses on the activity of sleep, which is vital and aimed to develop a measurement tool to reveal the causes of hospital-acquired insomnia and determine the causes of insomnia in hospitals or inpatient health institutions. In addition, literature on the factors that cause hospital-acquired insomnia was reviewed and some recommendations were made. These features show the originality of the research.

MATERIALS AND METHODS

Research type

The research was designed as a methodological study.

Research place and time

The study was conducted with patients hospitalized in surgical and internal medicine clinics in a research hospital in Turkey between December 2021 and March 2022.

Research population and sample

The population of the study consisted of patients hospitalized in Turkey. During the pilot application of the study, 64 patients were reached. It is stated that the sample size should be at least 5 times the number of scale items (10 times if possible) in scale adaptation studies[30]. The main application stage started with 42 items. For this reason, it was predicted that the sample size should have been at least 210 or 420. Therefore, 223 patients were reached during the main application stage. The data were filled in using the face-to-face interview method. It took 20-30 min to fill in the data of each patient. The study was completed with a total of 287 patients.

Inclusion criteria of research

(1) Not having any sleep problems before hospitalization; and (2) Being hospitalized for at least three days.

Data collection tools

The data were collected using a personal information form and the hospital-acquired insomnia scale (HAIS)-draft form.

Personal information form: This form consists of questions about gender, age, education level, social security, and previous hospitalization of the participants.

Insomnia severity index: The index was developed by Bastien *et al*[31] in 2001 and was validated in Turkish by Boysan *et al*[32] in 2010. The 7-item index was developed in a 5-point Likert type in order to measure the degree of insomnia of individuals. Items are scored between 0-4; the lowest score obtainable from the scale is 0 and the highest score is 28. In scoring, a score of 0-7 indicates clinically insignificant insomnia; 8-14 indicates insomnia lower threshold; 15-21 indicates clinical insomnia (moderately severe); 22-28 indicates clinical insomnia (insomnia) (severe). Insomnia severity index (ISI) was used to determine the concurrent validity of the scale. Concurrent validity is the comparison of the findings obtained from a measurement tool that is desired to be developed with a scale, whose validity and reliability has been proven, on a similar subject. A correlation is expected between the data obtained from both measurement tools[33].

HAIS: First stage: The relevant literature was examined in depth. Interviews were held with 2 patients, 2 patient relatives, and 4 nurses about the causes of hospital-acquired insomnia. After the literature

review and interviews, a conceptual infrastructure on the subject was created. An item pool of 150 items considered suitable for the scale was prepared. The item pool was reviewed 4 times and some items were eliminated. The item pool was finalized with 66 items for expert opinion.

Second stage: The item pool consisting of 66 items was presented to 11 experts (2 Turkish language experts, 9 field experts) and the content validity was evaluated. The items in the scale were revised in line with expert opinions. Then, the suitability of the scale items was evaluated, the Turkish language validity was established, and the revisions were completed. 10 items were removed from the scale. The scale was finalized for the pilot application with 56 items. The Cronbach alpha value of the data of 56 items was determined as 0.882. In the pilot application stage, 14 items (i4, i6, i9, i12, i14, i19, i22, i26, i29, i30, i32, i35, i36, i43) with an item correlation value of less than 0.20 were removed from the item pool. The Cronbach alpha value was determined to be 0.913 with 42 items. Main application stage started with 42 items.

Third stage: Validity and reliability analysis of the HAIS was performed. The sample of the study consisted of 223 patients. In the analyses, it was determined that the scale is a valid and reliable measurement tool consisting of 18 items and 5 subscales. The scale was developed as a 5-point Likert scale (1: Strongly disagree - 5: Strongly agree). Scoring for the subscales and the overall scale was based on the item score average. The lowest score obtainable from the scale and its subscales is 1 and the highest score is 5. There is no reverse item on the scale. As the scale score increases, hospital-acquired insomnia increases. There is no cut-off point in the scale. The Cronbach alpha value for the overall scale was determined to be 0.783.

Pilot application

In scale adaptation studies, it is necessary to reach a sample size of more than 50; the internal consistency of the scale should be 0.70 and above; it should be checked whether the item-total correlation value is below 0.30[34]. In this study, the pilot application was carried out with 64 patients. In the pilot application stage, 14 items with an item correlation value below 0.20 were removed from the item pool. The Cronbach alpha value was determined to be 0.913 with 42 items and the main application stage was initiated.

Main application

The patients were visited in their rooms and their informed consent was obtained. After their consent was taken, the data of the study were collected by the face-to-face method. The scale items were asked to the patients one by one by the researcher (BÇ) and their answers were marked. At this stage, the HAIS and the ISI, which is thought to be a parallel form, were used. In the main application, 223 patients were reached. At this stage, validity and reliability analyses, two criteria that a scale should have, were performed[35].

Statistical analysis

SPSS 20 package program and analysis of moment structure (AMOS) 20 package program" were used for data analysis. Frequency and percentage were used to indicate the sociodemographic characteristics of the patients. Exploratory factor analysis (EFA) and confirmatory factor analysis (CFA) were used to ensure scale validity. In the EFA, item score averages and standard deviations, Kaiser-Meyer-Olkin (KMO), Bartlett's test of sphericity, item-total correlation value was used. Scree plots chart and eigenvalue were used to determine the factor structures of the scale[34,36,37].

KMO and Bartlett's sphericity tests were performed to check the suitability of the sample size and the suitability of the data set for analysis. The fact that the KMO test was greater than 0.60 and the *P* value of the Barlett's sphericity test was significant showed the adequacy of the sample and the suitability of the data set[34,38,39].

EFA was performed to ensure construct validity. During the EFA, there should be no overlapping items. In addition, the item eigenvalue of the scale items should be at least 1 and the item load should be at least 0.30[34,40]. Varimax rotation, which is a vertical rotation method preferred in scale development studies, was used to ensure construct validity[34,36]. The presence of multicollinearity problem was tested with linear regression [variance inflation factors (VIF) < 10, C-index (CI) < 30, tolerance > 10][38]. If an item has a loading value of more than 0.32 in more than one dimension and the difference between factor loadings in these dimensions is less than 0.10, these items were accepted as overlapping items[34].

In CFA, fit indices and path diagram were used. The Cronbach alpha value of the items, factors and total scale was used to determine the reliability level of the scale. In addition, split half analysis was performed. Retest method was used to determine the invariance of the scale against time. The following criteria were taken as basis: a minimum KMO value of 0.60, a Bartlett's test of sphericity *P* value being significant, an eigenvalue of at least 1, a Cronbach alpha value of at least 0.7 for factors and the scale, a split half Cronbach alpha value of at least 0.7. The values suggested by Bae *et al*[41], Woo *et al*[42] were taken into account in the fit indices [χ^2/SD value, goodness of fit index (GFI), adjusted GFI, comparative fit index, root mean square error of approximation, standardized root mean square residual fit indices] [41,42].

In the analyzes related to reliability, a Cronbach alpha value of 0.70 and above was taken as the basis [43-45].

Ethical aspects and permissions

Ethics committee approval dated 16.08.2021 and numbered 20028 was obtained from the Muş Alparslan University Scientific Research and Publication Ethics Committee. Institutional permission was obtained from Atatürk University Research Hospital in order to carry out the study. Patients were informed about the purpose and method of the study and that the research was based on volunteerism in detail. Consent was taken from the patients participating in the study. The individuals participating in the research were informed that their data would not be shared.

RESULTS

Of the patients, 52% were famale; 47.1% were aged between 51-70; 49% were primary school graduates; 69.5% had social security; 30.9% had a history of 1-2 wk-hospitalization; the sleep quality of 31.8% was between 7 and 8 (Table 1).

Validity findings

EFA: Reliability analysis was performed to determine whether the items had appropriate values. Therefore, 11 items were removed before starting the EFA. EFA was performed to ensure construct validity. In order to determine the items to be included in the scale, it was taken into account that there was no overlapping item, the item eigenvalue was 1, and the item load value was at least 0.30. The Cronbach alpha value of the remaining 31 items was determined to be 0.783. The analysis was continued with 31 items. Varimax axis rotation, a vertical rotation method preferred in scale development studies, was used in order to ensure construct validity.

Before performing exploratory and CFA for the scale, KMO and Bartlett's sphericity tests were performed to check the suitability of the sample size and the suitability of the data set for analysis. In addition, the anti-image test, which is one of the sampling criteria, was applied. The KMO value was determined as 0.663. Bartlett's sphericity test was found to be significant (χ^2 = 3019.015; P = 0.001) (Table 2). As a result of the anti-image test, it was determined that there was no value below 0.50. These results showed that the sample size and data set were suitable for analysis.

Items i4, i5, i6, i13, i18, i19, i20, i23, i24, i28, i30, i39, and i40 were excluded from the scale since they were overlapping items. In the EFA performed with 18 items, it was determined that the KMO value was 0.741 and that Bartlett's sphericity test was significant (χ^2 = 1704.892, P = 0.001). The anti-image test was examined and it was found that there was no value below 0.50. These findings showed that the data were suitable for factor analysis. As a result of the Varimax analysis, it was determined that the scale items were gathered under 5 factors. The scree plot also confirmed that the scale has a 5-factor structure. In light of this information, CFA was performed with 5 factors and 18 items (Figure 1).

When the analysis results were examined, it was found that factor 1 consists of 5 items, i22, i26, i29, i31, i32, and explained 22.345% of the total variance. This factor was named physical environmental factors.

Factor 2 consists of 4 items, i7, i14, i15, i16, and explained 18% of the total variance. This factor was named psychological factors.

Factor 3 consists of 3 items, i41, i42, i43, and explained 11.016% of the total variance. This factor was named safety factor.

Factor 4 consists of 3 items, i10, i11, i12, and explained 8.580% of the total variance. This factor was named socioeconomic factors.

Factor 5 consists of 3 items, i1, i2, i3, and explained 5.788% of the total variance. This factor was named nutritional factors.

When the 18-item scale was analyzed as a whole, it was determined that it has a 5-factor structure and that the common factor loads of 18 items varied between 0.407 and 0.886. It was determined that 5 factors explained 66.25% of the total variance. These values showed that the scale is sufficient to explain the hospital-acquired insomnia problems of patients (Table 3).

CFA: The structure obtained from EFA was tested with CFA. In line with the modification recommendations made with CFA, it was deemed appropriate to make modifications between items i10-i12 and i22-i29. After modification, improvements were observed in the χ^2 value. Information on the fit indices obtained as a result of CFA is given in the table. Fit values were evaluated considering the reference values stated. (Table 4) The items were considered important for the factors in which they were included. The path diagram was examined and it was determined that the obtained values were appropriate in terms of the item-factor agreement (Figure 2).

Reliability findings

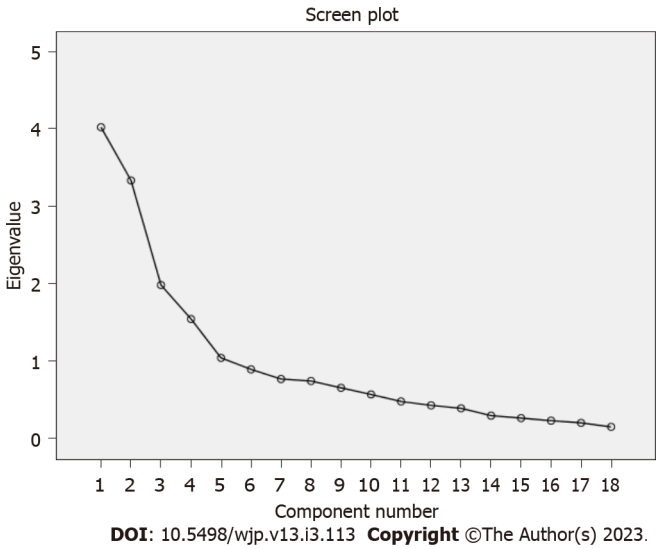
Internal consistency (Cronbach alpha) coefficients: The Cronbach alpha coefficient was calculated to

Table 1 Distribution of patients by sociodemographic characteristics (*n* = 221)

Characteristics	Variables	*n*	%
Sex	Famale	116	52
	Male	107	48
Age	18-30	16	7.2
	31-50	50	22.4
	51-70	105	47.1
	71 and above	52	23.3
Educational status	Illiterate	45	20.2
	Primary school	110	49.3
	Middle school	20	9
	High school and above	48	21.5
Social security	Yes	155	69.5
	No	68	30.5
Hospitalization	No	44	19.7
	Less than 1 wk	57	25.6
	1-2 wk	69	30.9
	2-3 wk	23	10.3
	1 mo and more	15	13.4
Sleep quality with 1 lowest 10 highest	1-2	21	9.4
	3-4	38	17.1
	5-6	49	22
	7-8	71	31.8
	9-10	44	19.8

Table 2 Cronbach's alpha, Kaiser-Meyer-Olkin values and Bartlett's test results for data sets

Tests		Test results
Kaiser-Meyer-Olkin sampling adequacy		0.663
Bartlett's test of sphericity	χ^2	3019.015
	Standard error	465
	P value	0.001



determine the reliability analysis of the 18 items of the finalized scale. The Cronbach alpha values were 0.672 for the nutritional factors subscale including items i1, i2, and i3; 0.677 for the socioeconomic factors including items i10, i11, i12; 0.804 for the psychological factors subscale including items i7, i14, i15, and i16; 0.842 for the physical environmental factors subscale including items i22, i26, i29, i31, i32; 0.786 for the safety factors subscale including i41, i42, and i43. The Cronbach alpha value for the overall scale was 0.783. These values show that the scale is reliable.

Split half confidence coefficient: As a result of the split half reliability analyses of the 18-item final version of the scale, it can be said that the Spearman-Brown correlation value (r = 0.670) and the Guttman split half coefficient value (r = 0.60) of the scale have sufficient values and that the Cronbach alpha reliability coefficients for the split halves are sufficient. The split half reliability coefficients are given in the table (Table 5). The results of the split half reliability analyses showed that the scale is reliable (Table 5).

The item score means were determined to be 1.06 ± 032 for F1, 1.57 ± 0.90 for F2, 1.12 ± 0.46 for F3, 1.41 ± 0.77 for F4, and 1.08 ± 0.27 for F5. The item score mean of HAIS was 1.25 ± 0.35. The mean total ISI score was determined to be 10.35 ± 7.76 (Table 6).

Figure 1 Scree plot factor structure.

It was determined that there was a positive and significant correlation between the mean ISI score and the mean scores on F2, F3, F4, and HAIS. A statistically significant correlation was found between HAIS and F1, F2, F3, F4, and F5. These findings show that the scale is an adequate tool to measure the hospital-acquired insomnia levels of patients (Table 7).

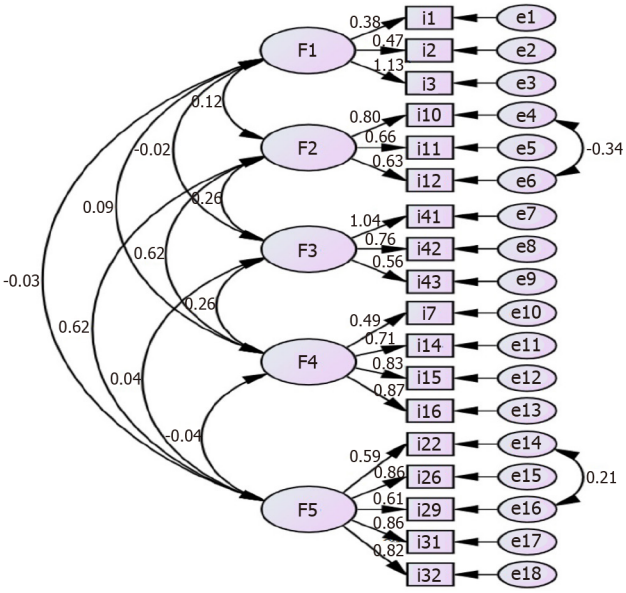
Total hospital-acquired insomnia scale	1.25	0.35	1.00	3.06
Insomnia severity index	10.35	7.76	0	28

DISCUSSION



In order to create the conceptual structure of the scale and prepare the item pool, the literature was reviewed and in-depth interviews were conducted with 2 patients, 2 patient relatives, and 4 nurses. An item pool of 150 items was created. The item pool was reviewed 4 times and an item pool of 66 items was created to be presented to experts. Two Turkish language experts and 9 field experts were consulted. In line with the recommendations of 11 experts, 11 items were removed from the item pool and the pilot application started with 56 items. During the pilot application stage, 64 patients were reached. In line with the data obtained from 64 patients, 14 items were excluded since the total correlation value was low and the main application stage was initiated with 42 items.

During the main application stage, 223 individuals were reached. Reliability analyses were performed in line with the data obtained from 223 individuals and 11 items with low item correlation values were

Figure 2 Clinical application readiness scale confirmatory factor analysis diagram.

eliminated from the analysis. As a result of the EFA performed with 31 items, 13 items were excluded from the analysis one by one since they were overlapping. While each item was removed from the analysis one by one, KMO, Bartlett's sphericity test, and anti-image test were checked. The overlapping status was checked and items were removed accordingly. Bartlett's sphericity test, KMO value, and anti-image test were checked with the remaining 18 items. Bartlett's sphericity test ($P < 0.05$), KMO value (0.741), and anti-image test for 18 items were found to be suitable for analysis[33-35]. As a result of the EFA of 18 items, a 5-factor structure was created. Scree plot also showed that the structure consisted of 5 factors. The items that constitute the factors were examined in terms of content integrity and named as physical environmental, psychological, safety, socioeconomic, and nutritional factors. CFA analysis of the 5-factor structure was performed in the AMOS package program. The fit indices of the obtained structure were examined. It was determined that the values obtained from the fit indices were sufficient. These results revealed that the scale is valid and reliable.

With the keywords "sleep" and "insomnia", national and international literature was first searched on the Turkish measurement tools index and Google scholar. 20 relevant scales were reached. Eight scales were found to be regarding adult patients or associated with the hospital. The names of these scales were as follows; Pittsburgh sleep quality index[21], Epworth sleepiness scale[20], insomnia severity index[31], Richard-Campbell sleep questionnaire[23], DSM 5 sleep-wake disorders scale[22], Thought control questionnaire-insomnia revised[46], insomnia catastrophizing scale[47]. All scales were examined one by one and it was determined that there was no tool to determine hospital-acquired sleep problems. In addition, the subscales of the scales in question and the subscales of the hospital-acquired insomnia scale, which is the subject of the research, were examined and no similarity was detected. This shows the originality of the scale. It was determined that the Cronbach alpha values of the subscales ranged between 0.672 and 0.842 and the Cronbach alpha value for the overall scale was 0.783. It was

determined that the scale explained 58.269% of the total variance.

Practice implications

It is stated that patients who do not have sleep problems in their daily routine at home have problems after hospitalization, such as waking up frequently, having difficulty falling asleep, decreased sleep time, not feeling rested when they wake up, and inability to sleep. A new environment, the severity of the underlying disease, underlying psychiatric conditions, pain, room light, sharing a room with others, being away from the family, changes in sleep-wake-up times, pain, bad condition of the roommate patient, worrying about the disease, inadequate physical activity, frequent entries to the room, medications, and infections.

Hospital-acquired insomnia is usually treated symptomatically at the time of hospitalization. However, misuse or overuse of sedatives/hypnotics is thought to be associated with complications in this population of acute patients. The use of a scale to determine the causes and severity of insomnia before resorting to pharmacological methods is one of the indicators of quality nursing care. Prevention of hospital-acquired insomnia, which is evaluated with the scale, with simple and applicable nursing interventions will contribute to the prevention of unnecessary use of medications.

CONCLUSION

In conclusion, the scale consists of 18 items and 5 subscales: Physical environmental factors, psychological factors, safety factors, socioeconomic factors, and nutritional factors. The subscale of physical environmental factors consists of 5 items; psychological factors consist of 4 items; safety factors, socioeconomic factors, and nutritional factors subscales consist of 3 items. There is no reverse item on the scale. The item score average is used in the calculation of the scale score. The lowest score obtainable from the scale and 5 subscales is 1 and the highest score is 5. There is no cut-off point in the scale. As the scale score increases, the hospital-acquired insomnia level increases. The scale explains 66.250% of the total variance. In the light of this information, it can be said that the hospital-acquired insomnia scale is a valid and reliable measurement tool.

ARTICLE HIGHLIGHTS

Research background

Insomnia is a major problem for people. Many causes of insomnia have been reported. One of these reasons is hospital-acquired insomnia. Although it has been stated in many studies that patients experience hospital-acquired insomnia, it has been determined that there is no valid and reliable measurement tool that measures hospital-acquired insomnia problems of individuals.

Research motivation

Insomnia, which affects individuals physiologically, psychologically and therapeutically, is a serious problem in the hospital. Hospital-induced insomnia affects the quality of treatment and care. For this reason, healthcare professionals need a measurement tool that can measure the hospital-acquired insomnia levels of patients.

Research objectives

In this study, it was aimed to develop a valid and reliable measurement tool that can determine the hospital-acquired insomnia levels of patients.

Research methods

This research is scale development research consisting of a pilot application and a main application. First of all, an item pool was created for the scale and presented to expert opinion. After the expert opinion, the scale items were made ready for pre-application. In the preliminary application, data were obtained from 64 individuals. During the main application phase, 223 patients were reached. Exploratory factor analysis, confirmatory factor analysis and reliability analyzes were performed with the obtained data. Analyzes were performed using SPSS 20 package program and analysis of moment structure package program.

Research results

As a result of data analysis, it was determined that the scale consisted of 5 sub-dimensions and 18 items. The total Cronbach alpha value of the scale was determined to be 0.783.

Research conclusions

It was determined that the scale, which consists of 5 sub-dimensions and 18 items, is a valid and reliable measurement tool in determining the hospital-acquired insomnia levels of the patients.

Research perspectives

It is recommended to use this measurement tool to determine the insomnia problems of patients and to adapt it in other countries.

ACKNOWLEDGEMENTS

We thank the patients for taking part in the study.

Abstract

BACKGROUND

Tardive sensory syndrome (TSS) is a subtype of tardive syndrome (TS), and its etiology is still uncertain. Lurasidone is an atypical antipsychotic that has high affinity for dopamine D2- and serotonergic 5HT2A- and 5-HT7-receptors.

CASE SUMMARY

A 52-year-old woman, previously diagnosed with schizophrenia, and with no history of movement disorders and no sensory paresthesia, had taken lurasidone, initiate dose 40 mg daily then up titration to 120 mg daily, since March 2021, and developed mandibular sensory (pain) paresthesia after 3 mo of administration. After switching from lurasidone to quetiapine, she reported obvious improvement in her mandibular pain.

CONCLUSION

It is noteworthy that TSS is a rare subtype of TS, and lurasidone, an atypical antipsychotic, usually has a lower risk of causing TS. In light of the temporal relationship, it is therefore concluded that use of lurasidone might have caused TSS in this patient. We reported this rare case as a reminder that clinicians should adopt a cautious approach when prescribing atypical antipsychotics, so as to prevent TS.

INTRODUCTION

Tardive syndrome (TS) is an iatrogenic condition resulting from exposure to chronic dopamine receptor blocking agents (DRBA), and is a more expansive phenomenological spectrum that encompasses tardive dyskinesia (TD), tardive dystonia, tardive akathisia, tardive sensory syndrome (TSS), tardive parkinsonism, and tardive tics[1]. TS is a distressing adverse effect of medication that might impair patients' quality of life and even increase the risk of suicide[2]. Lurasidone is an atypical antipsychotic that exerts its effects through high affinity for dopamine D2- and serotonergic 5HT2A- and 5-HT7-receptors[3]. To our knowledge, there is no report of TSS as a side effect of lurasidone in the literature. Here, we describe a patient with schizophrenia who had been treated with lurasidone for 3 mo, and later developed TSS.

CASE PRESENTATION

Chief complaints

A 52-year-old female developed mandibular sensory paresthesia and pain after 3 mo of lurasidone administration, without orofacial dyskinesia, hands tremor, limbs rigidity, bradykinesia, axial dystonia, retrocollis, torticollis, or blepharospasm.

History of present illness

A 52-year-old female had been diagnosed with schizophrenia since April 2001, and was treated with various antipsychotics, including risperidone 1 mg/d, amisulpride 200 mg/d, quetiapine 200 mg/d, ziprasidone 40 mg/d, and clozapine 125 mg/d, with a duration of a few months, respectively. The most long duration of main regimen was olanzapine 10-25 mg daily (June 2013-March 2021), which was fully effective, but was discontinued due to the adverse side effect of weight gain. Consequently, the main regimen was shifted to lurasidone, initiate dose 40 mg/d then up titration to 120 mg/d since March 2021. However, she developed mandibular sensory paresthesia and pain after 3 mo of lurasidone administration, without orofacial dyskinesia, hands tremor, limbs rigidity, bradykinesia, axial dystonia, retrocollis, torticollis, or blepharospasm.

History of past illness

A 52-year-old female with no history of medical disease, movement disorders or sensory paresthesia had been diagnosed with schizophrenia since April 2001.

Personal and family history

The patient had no developmental delay, and had elementary school education level with poor academic performance. She had introverted personality as premorbid personality and poor interpersonal relationship. She could keep her occupational function as a cleaner since young adult until now. She got married at her 20's and divorced at her 32' while she was diagnosed of schizophrenia. The patient denied psychiatric family history.

Physical examination

We also consulted a dentist to rule out oral infection or other lesions. Both the aforementioned laboratory tests and dental consultation showed negative findings. Due to the defining features, TSS was suspected[4]. Severity was evaluated on the basis of an Extrapyramidal Symptom Rating Scale (ESRS) score of 18 points[5] before we changed antipsychotics to quetiapine monotherapy.

Laboratory examinations

A series of laboratory tests including complete blood count, liver function, renal function, diabetes mellitus lipid profile, copper, ceruloplasmin, thyroid function, rheumatoid factor, antinuclear antibody, immunoglobulin (Ig)A, IgG, anti-2 glycoprotein 1Ab, anticardiolipin Ab IgG, anticardiolipin Ab IgM. Anti-ENA, a venereal disease research laboratory test, HBs antigen, hepatitis C virus antibody, cryoglobulin identification, a homocysteine test and brain computed tomography (CT), were performed to rule out a secondary organic etiology. We also consulted a dentist to rule out oral infection or other lesion. The aforementioned laboratory tests and dental consultation both showed negative findings.

Imaging examinations

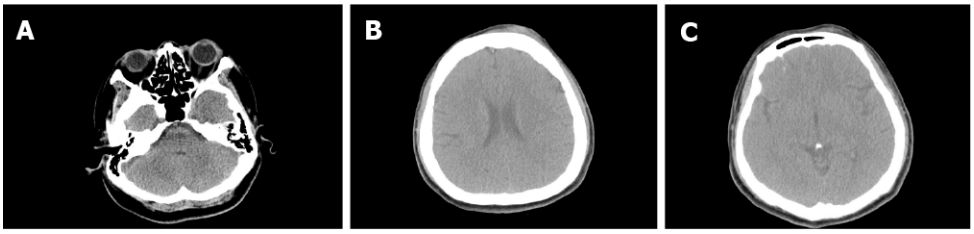
The brain CT image and report are demonstrated in Figure 1. Technique of examination: Axial brain CT with 5 mm section from vertex to skull base without contrast enhancement; normal ventricular size; normal appearance of cerebral fissures, cisterns & sulci; no evidence of intracranial hemorrhage; no midline deviation; no abnormal parenchymal attenuation change; no definite bony fracture; well pneumatization of bilateral mastoid cells; unremarkable of paranasal sinus; symmetrical and smooth contours of nasopharynx; and left frontal scalp swelling. There is no evidence of intracranial hemorrhage.

FINAL DIAGNOSIS

Due to the defining features, TSS was suspected[4] (see Video).

TREATMENT

After lurasidone was switched to quetiapine 300 mg/d, the aforementioned sensory discomfort was significantly ameliorated, and remission was achieved.



OUTCOME AND FOLLOW-UP

After 1 mo, the ESRS scores improved by 65% (from 18 to 6); at the outpatient clinic follow-up, the visual analog scale scores for pain measurement decreased to 0/10 after 6 mo in remission.

DISCUSSION

TSS, manifested with unpleasant, burning or pain sensation in the oral or genital regions, is a chronic and specific type of TS. However, the pathophysiology of TSS remains uncertain[6]. D2 hypersensitivity alone seems to be insufficient to account for TS, or TSS. One theory has been proposed to elucidate the pathophysiology of TS; some atypical agents (clozapine and quetiapine in particular) have a relatively low affinity for D2 receptors that loosely bind to postsynaptic D2 receptors in the striatum then dissociate quickly, but some DRBAs act as binding tightly and have long-lasting effects on the receptors [7], which may explain why remission of TS is achieved after cross-shifting of lurasidone to quetiapine, as in our case. Another explanation for TS is that TS is attributed to defective adaptation of 5-HT2A, vesicular monoamine transporter type 2 levels, metabotropic and N-methyl-D-aspartatic acid receptors in the striatum, that as demonstrated in effect of antipsychotic drugs on nonhuman primates[7]. In addition, both pro- and antinociceptive effects of 5-HT2A receptor activation likely appear in other studies, but converging evidence underscores that peripheral 5 HT-2A receptors have an excitatory role in acute, sub-chronic and chronic pain transmission[8,9].

That then is another reasonable explanation why the remission of TS was achieved after cross-shifting of lurasidone to quetiapine in this case. A similar explanation may have been offered in a previous report of TSS related to trazodone which is a potent serotonin 5-HT2A and 5-HT2C receptors antagonist and a weak serotonin reuptake inhibitor that results in more dopamine release[10]. An alternative hypothesis, supported by human and animal neuropathological studies, indicates that TS is a neurodegenerative disorder involved in striatal interneurons damaged by oxidative stress. This theory assumes that dopaminergic receptor blockade may lead to elevated turnover rates of dopamine and free radical produced by monoamine oxidase[6]. Eleven cases of TSS associated with antipsychotic drugs have been reported, and each case suffered from profound pain distress that required treatment[11]. This symptomatic syndrome is chronic and affects predominantly older women, according to unmodifiable patient-related and disease-related risk factors for TD[12]. In general, for mild to moderate TS, it is recommended to reduce the dose of neuroleptics, switch to atypical medications, or discontinue

Figure 1 Axial cranial computed tomography without contrast enhancement. A: No lesion within maxillary sinus, pons, and cerebellum; B: No lesion within bilateral basal ganglia; C: No infection sign, such as brain abscesses.

antipsychotic treatment altogether in the hope of promoting remission[13]. Lurasidone, classified as a second-generation antipsychotic, has few adverse side effects pharmacologically related to TS. To date, a 4-patient study has indicated lurasidone as a potential cause of tardive dystonia and tardive akathisia [14]. That the TSS seen in our case was related to lurasidone can be indicated by the temporal relationship. Even though this temporal relationship suggests that our patient's TSS was mainly related to the use of lurasidone, we could not rule out the effects of the previous use of other antipsychotics[13].

CONCLUSION

To our knowledge, this might be the first report to indicate that TSS occurred during lurasidone treatment. It is important that clinicians should adopt a cautious approach when prescribing atypical antipsychotics to prevent the development of TS, although these medications have a lower risk of causing TS.

ABOUT COVER

Editorial Board Member of *World Journal of Psychiatry*, Yuan-Pang Wang, MD, MSc, PhD, Associate Research Scientist, Doctor, Research Associate, Senior Scientist, Department of Psychiatry, School of Medicine, University of São Paulo, Sao Paulo 01060-970, Sao Paulo, Brazil. gnap_inbox@hotmail.com

AIMS AND SCOPE

The primary aim of *World Journal of Psychiatry* (*WJP*, *World J Psychiatry*) is to provide scholars and readers from various fields of psychiatry with a platform to publish high-quality basic and clinical research articles and communicate their research findings online.

WJP mainly publishes articles reporting research results and findings obtained in the field of psychiatry and covering a wide range of topics including adolescent psychiatry, biological psychiatry, child psychiatry, community psychiatry, ethnopsychology, psychoanalysis, psychosomatic medicine, *etc*.

INDEXING/ABSTRACTING

The *WJP* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Current Contents/Clinical Medicine, Journal Citation Reports/Science Edition, PubMed, PubMed Central, Reference Citation Analysis, China National Knowledge Infrastructure, China Science and Technology Journal Database, and Superstar Journals Database. The 2022 Edition of Journal Citation Reports® cites the 2021 impact factor (IF) for *WJP* as 3.500; IF without journal self cites: 3.313; 5-year IF: 7.380; Journal Citation Indicator: 0.62; Ranking: 89 among 155 journals in psychiatry; and Quartile category: Q3.

Abstract

Medical practitioners' duties are highly stressful and performed in a particularly challenging and competitive work environment. Stress and burnout among physicians have emerged as a worldwide public health problem in recent years. A high level of distress and burnout can lead to clinically significant behavioral health problems, such as stress-related psychiatric disorders. Mounting evidence shows that physicians have higher risks of insomnia, anxiety, and depression than the general population, especially during the coronavirus disease 2019 pandemic. However, the behavioral health problems of these vulnerable healthcare professionals are noteworthy for being underrecognized and undertreated. In this mini-review, we summarize the current progress of studies on the prevalence and determinants of distress and stress-related psychiatric disorders among physicians and their healthcare-seeking behaviors. We discuss future research directions and the clinical approach that may maximize self-awareness and promote prompt and adequate treatment for clinically significant behavioral health problems of physicians.

Key Words: Physician; Depression; Anxiety; Insomnia; Healthcare-seeking behavior; Undertreatment

Core Tip: Physicians are experiencing unprecedented stress and distress. They face major risks of distress and burnout, which can subsequently cause stress-related psychiatric disorders, such as insomnia, anxiety, and depression. Nevertheless, many of these vulnerable healthcare professionals do not seek medical help. There is a clear need for further research to evaluate the determinants of underrecognition and undertreatment of stress-related psychiatric disorders, how to enhance early detection and management of these mental health problems, and how to eliminate obstacles to the use of mental health services in this population.

INTRODUCTION

Healthcare professionals are well known to bear a heavy burden of high job strain and workplace challenges[1]. High-pressured working environments, with excessive workloads, extended working hours, high levels of time pressure, limited resources, and restricted autonomy, have been acknowledged as factors causing mental health issues of healthcare professionals. In addition to these issues, medical practitioners may also have to deal with medical disputes and hospital evaluations in addition to the challenges of their clinical practice[2]. Distress and burnout, regarded as the exhaustion of emotional or physical strength as a result of prolonged frustration or stress, are common among physicians[3-6]. In a Medscape survey, 56% of physicians said they experienced burnout and attributed it to excessive bureaucracy combined with other causal factors, including long working hours, increasing computerization of practice, lack of respect from colleagues, lack of clinical autonomy, and insufficient compensation[7].

The issue of physicians' wellness has been gaining attention in recent years, and how to measure physicians' wellbeing and mental health is crucial[8]. A lot of literature reports physicians' distress or mental illness in terms of fatigue, burnout, emotional exhaustion or withdrawal, anxiety, depression, suicide, substance abuse, or functioning impairment. Additionally, there are existing instruments that can evaluate physician wellness. For instance, Arnetz[9] used a standardized questionnaire, *i.e.*, the quality of work competence survey, to evaluate core elements of organizational and staff wellbeing. These included mental energy, skills development, work-related exhaustion, work climate, work tempo, leadership, and organizational efficacy.

The high level of occupational stress, distress, and burnout of physicians affects not only their physical and mental well-being, but also the quality of patient care and the overall efficiency and costs of the healthcare system[8,10,11]. Firth-Cozens[11,12] called attention to stress, depression, alcoholism, and suicide among doctors in the United Kingdom in the 1990s. Since then, multiple epidemiological studies and several systematic reviews have been conducted worldwide[13-17]. Their findings are broadly similar as are the causal relationships between rates of stress and stress-related mental disorders, including anxiety, depression, insomnia, and substance use.

The distress, burnout, and subsequent behavioral health problems of healthcare professionals may be aggravated during special circumstances, such as pandemics. For instance, the coronavirus disease 2019 (COVID-19) pandemic has completely altered the lives of millions of people globally, putting an enormous strain on society and healthcare systems[18]. It is anticipated that the mental health problems of healthcare professionals would be exacerbated due to persistent stress and long-term sequelae following COVID-19[19-23].

Doctors' well-being and stress-related behavioral health problems are becoming a global public health issue. However, studies also show that healthcare professionals are passive seekers of help to deal with their mental health problems[24-26]. In this review, we focus on the distress and behavioral health problems of physicians. We extract data from the relevant literature and follow the progress of the latest studies on the prevalence and influential factors of distress and subsequent stress-related psychiatric disorders among physicians. Furthermore, we discuss physicians' healthcare-seeking behaviors and suggest strategies for intervention.

EPIDEMIOLOGY OF STRESS-RELATED PSYCHIATRIC DISORDERS AMONG PHYSICIANS

An increasing body of literature shows that distress and burnout among medical practitioners can lead

to clinically significant behavioral health problems, especially stress-related psychiatric disorders, including depression[15-17,27,28], anxiety[29,30], insomnia[31], substance use[32,33], and even suicide [33-37]. In 2015, a landmark meta-analysis and systematic review analyzed data from 54 cross-sectional and longitudinal studies involving 17560 resident physicians from 18 countries[38]. Results showed that the overall pooled estimate of depression or depressive symptoms was 28.8% [95% confidence interval (CI) = 25.3-32.5]. A review by Yates[3] highlighted that 42% of United States physicians participating in a large-scale online survey in 2018 stated that they experienced burnout. The survey repeated in 2019 showed similar results, with 44% "feeling burned out" and 14% reporting suicidal thoughts. A recent survey of doctors in Hong Kong revealed that 16.0% of the respondents screened positive for depression and 15.3% reported suicidal ideation[28]. In the Canadian Physician Health Study, almost one quarter of physicians reported a period of depression lasting at least two weeks[15], and the rate of depression was higher among female physicians. A study evaluating the levels of an association between occupational stress and depression in Taiwanese physicians found a depression rate (13.3%), which was more than three times higher than that of the general population (3.7%) in Taiwan[16]. The authors also found that gender was not independently correlated with depression, but that the interaction between job control and gender was independent of depression. In a national crosssectional survey of Japanese physicians, depressive symptoms were noted in 8.3% of men and 10.5% of women[37], and 5.7% of men and 5.8% of women exhibited suicidal ideation. Another national study performed before the COVID-19 pandemic revealed that 6.5% of US doctors had suicidal thoughts in the previous year[36]; this rate exceeded the prevalence of suicidal ideation among United States workers in other fields.

Fewer studies have surveyed anxiety disorders in physicians, with early surveys using validated scales suggesting rates of anxiety disorder as high as 24%[39] and post-traumatic stress disorder ranging between 4% and 15%[39,40]. One Canadian study using the posttraumatic stress disorder (PTSD) Checklist-Civilian Version (PCL-C) found a prevalence of probable PTSD of 4.4%[40]. For probable PTSD, no gender differences were observed, but possible PTSD was more common in males (47.3% *vs* 20.4%, $P = 0.001$). Additionally, mean scores were higher for men than for women (30.4 *vs* 25.4, 95%CI = 1.4-8.5, $P = 0.006$). A recent systematic review by Pougnet *et al*[29] found that 7.8%-48.0% of hospital doctors had mood disorders, 2.2%-14.6% had post-traumatic stress disorder, and 10.5%-19.3% had anxiety disorders. In a study of sleep patterns of physicians in Japan, 21.0% of men and 18.1% of women [31] suffered from insomnia.

RISK FACTORS

Several factors are associated with the risks of distress and stress-related psychiatric disorders. Studies investigating the impact of gender on the mental health of physicians found that females were more vulnerable to stress-related psychiatric disorders and suicide[15,37,41,42]. For example, data from the Canadian Physician Health Study indicated that depression was more prevalent among female physicians[15]. Furthermore, more than a quarter of the physicians reported that mental health concerns made it difficult to manage their workload, a problem more common among female physicians. The Norwegian Physicians' Survey indicated that mental health problems were related to low work control (autonomy), time pressure, and demanding patients[24]. There is little gender difference early in the career, but more female doctors than male doctors seem to experience problems in the later years. Schernhammer and Colditz[42] web-based survey showed that female physicians' suicide rate was disproportionately higher than that of male physicians. They reported that the suicide rates of female and male physicians were 2.3 times (95%CI = 1.90-2.73) and 1.4 times (95%CI = 1.21-1.65) higher compared to that of the general population, respectively.

Age and work experience of doctors may also matter[36,41,43]. More experienced and older physicians report lower burnout or psychological distress than younger physicians[43]. This result may due to experienced and older physicians' independence afforded by experience accumulated over time and ever-changing work conditions and the development of protective defenses in their interaction with patients. A study by the British Medical Association revealed that junior physicians reported the highest rate of diagnosis of a mental health condition[41].

Other factors may also contribute to distress and stress-related psychiatric disorders in doctors. For instance, physicians working longer hours seem to be more vulnerable to psychological disturbance [41]. A narrative review found that distress and suicide risks are affected by a lack of positive feedback, emotional exhaustion to the brink of burnout, a lack of support networks, and workplace isolation[44]. Furthermore, risks may be aggravated by long working hours, strained family relationships, and poor work-life balance, as well as organizational and systemic issues. A recent systematic review by Saade *et al*[27] summarized the work-related risk factors of depression, including skill utilization; decision authority; physical and psychological demands; number of hours worked; work schedule (regular/irregular; daytime/nighttime); social support from coworkers, supervisor, and the family; job promotion and recognition; job security; and bullying.

THE IMPACT OF THE COVID-19 PANDEMIC

In several ways, the COVID-19 pandemic has profoundly altered social and occupational environments. There are many factors that influence the mental health of the general population as well as healthcare providers, including fear of infection, social distancing policies, mandatory lockdowns, and isolation periods, as well as suspension of production activity, loss of earnings, and anxiety about the future, together influence the mental health of the general population and healthcare providers. The possibility of high infection rates during the pandemic period added to the stress of healthcare professionals. This included using protective equipment, implementing new medical procedures, long working shifts, staying away from family, *etc*[20].

The distress, burnout, and stress-related psychiatric disorders of medical practitioners seemed to have been exacerbated during the COVID-19 pandemic[20,45-47]. A recent systematic literature review of the symptoms of burnout syndrome in physicians revealed that the overall burnout rate ranged from 14.7% to 90.4% during the outbreak of the COVID-19 pandemic[20]. In addition, the review highlighted that the high prevalence of burnout symptoms was associated with stress, anxiety, and depression; the factors that contributed to burnout included the violent issues related to organizational health as well as the lack of personal protective equipment.

An umbrella review of systematic reviews by Fernandez *et al*[47] found a 17.0%-19.8% rate of anxiety and a 40.4% rate of depression among physicians during the COVID-19 pandemic. In an umbrella review involved 44 meta-analyses[45], 26.7% (95%CI = 19.8-33.6) of hospital doctors reported anxiety and 30.9% (95%CI = 24.9-36.9) reported depression symptoms, while 37.2% (95%CI = 32.61-41.86) suffered from insomnia during the COVID-19 pandemic. In a recent systematic review and meta-analysis by Johns *et al*[46], the pooled prevalence of anxiety and depression was 25.8% (95%CI = 20.4%-31.5%) and 20.5% (95%CI = 16.0%-25.3%), respectively. The authors argued that a significant proportion of physicians experienced high levels of anxiety and depression symptoms during the COVID-19 pandemic, although not conclusively more so than before the pandemic.

A recent study of health professionals' help-seeking behavior during the COVID-19 pandemic in Spain reported a notable increase (29.4%) in the number of referrals to the special clinical unit during the pandemic, especially among physicians compared to nurses[48]. The most prevalent major diagnoses at admission remained similar before and during the pandemic: Adjustment disorders, mood disorders, anxiety disorders, and substance use disorders.

HELP-SEEKING BEHAVIORS AND UNDERTREATMENT OF PHYSICIANS

Although evidence shows that medical practitioners are at high risk of clinically significant behavioral health problems that may require treatment, they tend to be reluctant to seek treatment for mental health problems[25,28,36,41,49]. A recent survey exploring United States doctors' suicidal ideation and attitudes to seeking help found that 1 in 15 doctors reported having suicidal thoughts in the previous 12 mo[36]. Most doctors (72.9%) disclosed that they would seek professional help if they had a serious emotional problem. However, doctors with suicidal ideation were less likely to state that they would seek help (64.2%) than those without suicidal ideation. Earlier research data from the Canadian Medical Association showed that of the 18% of physicians who were recognized as depressed, only a quarter considered seeking help and only 2% actually did[25]. A European study revealed that 78.3% of distressed physicians had never sought professional help for burnout or depression[49]. In a study conducted by the British Medical Association, junior doctors and medical students reported the highest rate of being formally diagnosed with a mental illness, but junior doctors were the least likely to know how to access support or help[41]. A recent survey of physicians in Hong Kong also found that among the cases positive for depression (16.0%), less than half reported having a formally diagnosed mood disorder[28].

Studies using objective data echo the findings of self-report surveys on the help-seeking behaviors of doctors[33,50]. Gold *et al*[33] used data from the National Violent Death Reporting System to explore suicide among United States physicians. They found that although mental illness was a critical comorbidity in doctors who committed suicide, postmortem toxicology testing showed low rates of antidepressants. We also conducted a study using a nationwide population-based database of the National Health Insurance program in Taiwan to explore the actual risk of stress-related psychiatric disorders among healthcare-seeking doctors[50]. A total of 15150 doctors and 45450 matched controls were included, and the results showed that the adjusted odds ratios for treated depression, anxiety, and insomnia in the physicians enrolled were 0.716 (95%CI = 0.630-0.813), 1.103 (95%CI = 1.020-1.193), and 2.028 (95%CI = 1.892-2.175), respectively. In other words, doctors have a higher likelihood of being treated for insomnia and anxiety but a lower likelihood of being treated for depression than the general population. Moreover, we found that undertreatment was more common in female doctors for anxiety; in age groups > 35 years for depression; in surgery and OBS/GYN specialties for anxiety; as well as in surgery and internal specialties for depression.

Doctors' own attitudes may be the reason for their hesitancy in seeking professional help for psychological or behavioral health problems. A survey of United States female physicians revealed that almost 50% believed that they fit the criteria for mental illness although they had not sought treatment[51]. The main reasons for avoiding care included limited time, the belief that diagnosis was embarrassing or shameful, fear of reporting to a medical licensing board, and a belief that they could independently manage their illness. A recent study of Australian physicians' help-seeking for depression found that the most common barrier to help-seeking was "confidentiality/privacy"[52]. In addition to the fear of professional consequences, *e.g.*, the impact on the medical license[53], physicians identified barriers such as limited time to seek medical treatment and the stigma attached to mental illness[54]. Previous studies have suggested that physicians are reluctant to see another professional, especially if the problem is psychological[26,55]. Doctors become used to coping with their distress or psychological problem through avoidance and denial, although the effect is doubtful[11,56,57]. Instead, most doctors tend to use self-prescribed medications and self-treatment for their own psychological distress or medical illness[24,49,58,59].

Doctors' attitudes can hinder their access to proper health care for themselves. Physicians are not used to the role of being the patient and fear that their need for help may be seen as a mark of their inability to cope or weakness[55,60,61]. Such a perceived stigma is associated with resistance to help-seeking. In an anonymous survey of 1401 academic physicians in the United States, 12% reported moderate to severe depressive symptoms in the previous two weeks[62], but of these, less than half reported that they were likely to seek treatment for a mental health problem. More than half the doctors endorsed survey items about the stigma attached to mental illness. It is worth noting that the fear of being stigmatized can develop as early as when the doctors are students[63-65]. In a survey of students at six medical schools in the United States, only a third of the respondents with burnout sought help for a mental health issue in the last 12 mo[63]. The authors concluded that negative personal experiences, perceived stigma, and the hidden curriculum may lead to the majority of students not seeking the help they needed.

RECOMMENDED MANAGEMENT AND INTERVENTION STRATEGIES

As physicians' mental health problems have been globally recognized as a health crisis, an increasing number of researchers have proposed action plans and intervention strategies in recent years, although not all of them are validated. Interventions to deal with this problem can be divided into two categories: Those focusing on the individual; and those addressing the work environment[3,66]. Individual-focused programs frequently comprise instruction in mindfulness, exercise, and nutrition, while programs on dealing with the work environment focus mainly on stressors such as productivity pressures, electronic health records, and the administrative burden.

In a recent review focusing on physician stress and burnout, Yates[3] proposed a number of solutions, including decreasing the amount of time physicians spend on non-clinical tasks, organizational changes to improve usability of electronic medical record systems, the adoption of scribes, personal resilience methods focused on self-care, and programmatic approaches to promoting physician well-being. Other authors also recommend specific interventions such as meditation, mindfulness training, and individualized professional coaching and groups for stress management[67-70]. Posluns and Gall[68] focused on the role of self-care in promoting well-being and suggested self-care practices including awareness, balance, flexibility, social support, physical health, and spirituality. Furthermore, they suggested integrating self-care practice into clinical training programs and the quality assurance courses of professional associations in the field of mental health.

A number of interventions have been established to improve the well-being of junior physicians and resident doctors[71-74]. For example, a recent study assessed an educational program, the Resident Physician Burnout and Peer Communication Curriculum, aimed at promoting a strong informational and emotional social support system[73]. The course used peer roleplaying to establish self-awareness and social support, enhance communication skills, and inform about available mental health resources, thus encouraging intervention. The author concluded that roleplaying provided an effective, low-cost method of destigmatizing *via* encouraging discussion of burnout, educating about signs and symptoms, and learning about available resources. In their recent review, Krishnan *et al*[71] identified three main types of interventions in the United Kingdom: Mentorship, clinical preparation interventions, and mindfulness. Most of the studies reviewed showed positive outcomes of interventions, suggesting them to be advantageous in reducing stress levels and anxiety, and thereby improving the well-being of young doctors. However, a study evaluating a suicide screening and treatment referral program for faculty and residents at an academic medical center in the United States highlighted the challenges of engaging the professionals in the program, although the minority who successfully participated in the treatment referral program were satisfied with the outcomes[74].

Medical residents and doctors often find it inconvenient to receive professional counseling owing to concerns about cost, time, confidentiality, and stigma. The distress and mental health problems of frontline physicians exacerbated by the COVID-19 pandemic emphasize the need for accessible psycho-

Table 1 Summary of recommended management and intervention strategies

Individual	Work environment	Program	Ref.
Personal resilience methods focused on self-care	Decreasing the amount of time physicians spend on non-clinical tasks, organizational changes to improve usability of electronic medical record systems, the adoption of scribes	Programmatic approaches to promoting physician well-being	[3]
Meditation, mindfulness training, and individualized professional coaching and groups for stress management			[67-70]
Self-care practices including awareness, balance, flexibility, social support, physical health, and spirituality		Integrating self-care practice into clinical training programs and the quality assurance courses of professional associations	[68]
Peer roleplaying to establish self-awareness and social support, enhance communication skills, and inform about available mental health resources, thus encouraging intervention	A strong informational and emotional social support system	Resident physician burnout and peer communication curriculum	[73]
Mindfulness	Mentorship	Clinical preparation interventions	[71]
	Providing confidential, free, and individual on-site counseling and medication management	RFWP	[76]
	A novel smartphone app offering a digital-first mental health resource		[75]
Normalizing depression as a medical disorder, decreasing the stigma of mental disorders, and encouraging faculty and physicians to seek treatment			[72]

RFWP: Resident and Faculty Wellness and Peer Support Program.

logical support for medical professionals. There are novel approaches to reducing barriers[75,76]. For instance, the Resident and Faculty Wellness and Peer Support Program at Oregon Health and Science University has sought to reduce these obstacles by providing confidential, free, and individual on-site counseling and medication management[76]. During the COVID-19 pandemic, all appointments *via* this program were shifted to a telehealth service and many doctors were grateful for the opportunity to talk through their apprehensions and strengthen their coping ability. Another study investigated a novel smartphone app offering a digital-first mental health resource to young physicians[75]. It contained psychoeducational material, information on common work stressors, cognitive behavioral modules, guided meditation, and a section on help-seeking options for mental health problems through workplace and private routes. Results showed that anxiety and depressive symptoms significantly decreased between the pre- and post-assessment points; however, doctors' safety concerns about COVID-19 significantly increased.

In a special article aiming to reduce the stigma associated with mental illness and encourage medical students to seek treatment, Brower[72] suggested that faculty attitudes toward mental health problems, including unwillingness to acknowledge having such issues, may be transmitted to medical students educated by them and keep depression concealed *via* the hidden curriculum. In addition, the fear of mental illness is manifested as privileging applications and licensing under the guise of patient safety, leading to a culture of shame and silence. Brower[72] appealed to medical faculty and physicians, as founders and executors of this professional culture, to be the ones to start changing it. The article also provides suggestions for normalizing depression as a medical disorder, decreasing the stigma of mental disorders, and encouraging faculty and physicians to seek treatment (Table 1).

CONCLUSION

Healthcare providers' mental wellness has become a worldwide public health concern. The literature on stress-related mental health conditions of these vulnerable professionals and their determinants was limited until a few years ago. Although recent research has begun to focus on action plans and intervention strategies, few mention the barriers to help-seeking and the impacts of doctors' mental health problems on patient care[77]. The present review highlights that physicians have high risks of distress, burnout, and subsequent stress-related psychiatric disorders, which may be further exacerbated during the COVID-19 pandemic. However, at-risk physicians are still notably underrecognized and undertreated. Doctors' reluctance to seek help may be largely due to their own attitudes,

especially the stigma attached to mental illness. Our review is limited by its focus on qualitative analysis without quantitative analyses, such as the effectiveness of mental health interventions in doctors.

We hope that this review encourages a number of future considerations. Firstly, improved awareness of the significance of physician wellness, both organizationally and individually, is needed by physicians, their employers, and their patients. Inclusion of physician wellness as an indicator of quality of organizations might be the first step that can lead to a shift in the culture of care for physicians' wellness. Thus, health systems and organizations should routinely measure physician wellness and the level of distress and burnout, establish evidence-based intervention strategies, and discuss the challenges related to their implementation. Secondly, educating physicians themselves, especially medical students and future doctors, about the impact of mental health problems, how to develop self-awareness and help-seeking, and how to eliminate the stigma is crucial. Finally, more prospective and longitudinal studies are needed to explore the causes, manifestations, impacts, and determinants of distress, burnout, and subsequent stress-related psychiatric disorders in physicians. Moreover, research on health care-seeking behaviors of physicians, as well as the possible barriers, both individual and organizational, to their use of mental healthcare resources is necessary. Accordingly, assessment of comprehensive management and novel intervention methods, such as telehealth, digital medicine, groups, and other outreach treatments, and their efficacy is also highly recommended.

Abstract

Serotonin deficiency in major depressive disorder (MDD) has formed the basis of antidepressant drug development and was originally attributed to induction of the major tryptophan (Trp)-degrading enzyme, liver Trp 2,3-dioxygenase (TDO), by cortisol, leading to decreased Trp availability to the brain for serotonin synthesis. Subsequently, the serotonin deficiency was proposed to involve induction of the extrahepatic Trp-degrading enzyme indoleamine 2,3-dioxygenase (IDO) by proinflammatory cytokines, with inflammation being the underlying cause. Recent evidence, however, challenges this latter concept, as not all MDD patients are immune-activated and, when present, inflammation is mild and/or transient. A wide range of antidepressant drugs inhibit the activity of liver TDO and bind specifically to the enzyme, but not to IDO. IDO induction is not a major event in MDD, but, when it occurs, its metabolic consequences may be masked and overridden by upregulation of kynurenine monooxygenase (KMO), the gateway to production of modulators of immune and neuronal functions. KMO appears to be activated in MDD by certain proinflammatory cytokines and antidepressants with anti-inflammatory properties may block this activation. We demonstrate the ability of the antidepressant ketamine to dock (bind) to KMO. The pathophysiology of MDD may be underpinned by both the serotonin deficiency and glutamatergic activation mediated respectively by TDO induction and N-methyl-D-aspartate receptor activation. Inhibition of TDO and KMO should be the focus of MDD pharmacotherapy.

Key Words: Major depressive disorder; Indoleamine 2,3-dioxygenase; Kynurenine monooxygenase; Proinflammatory cytokines; Serotonin deficiency; Tryptophan 2,3-dioxygenase

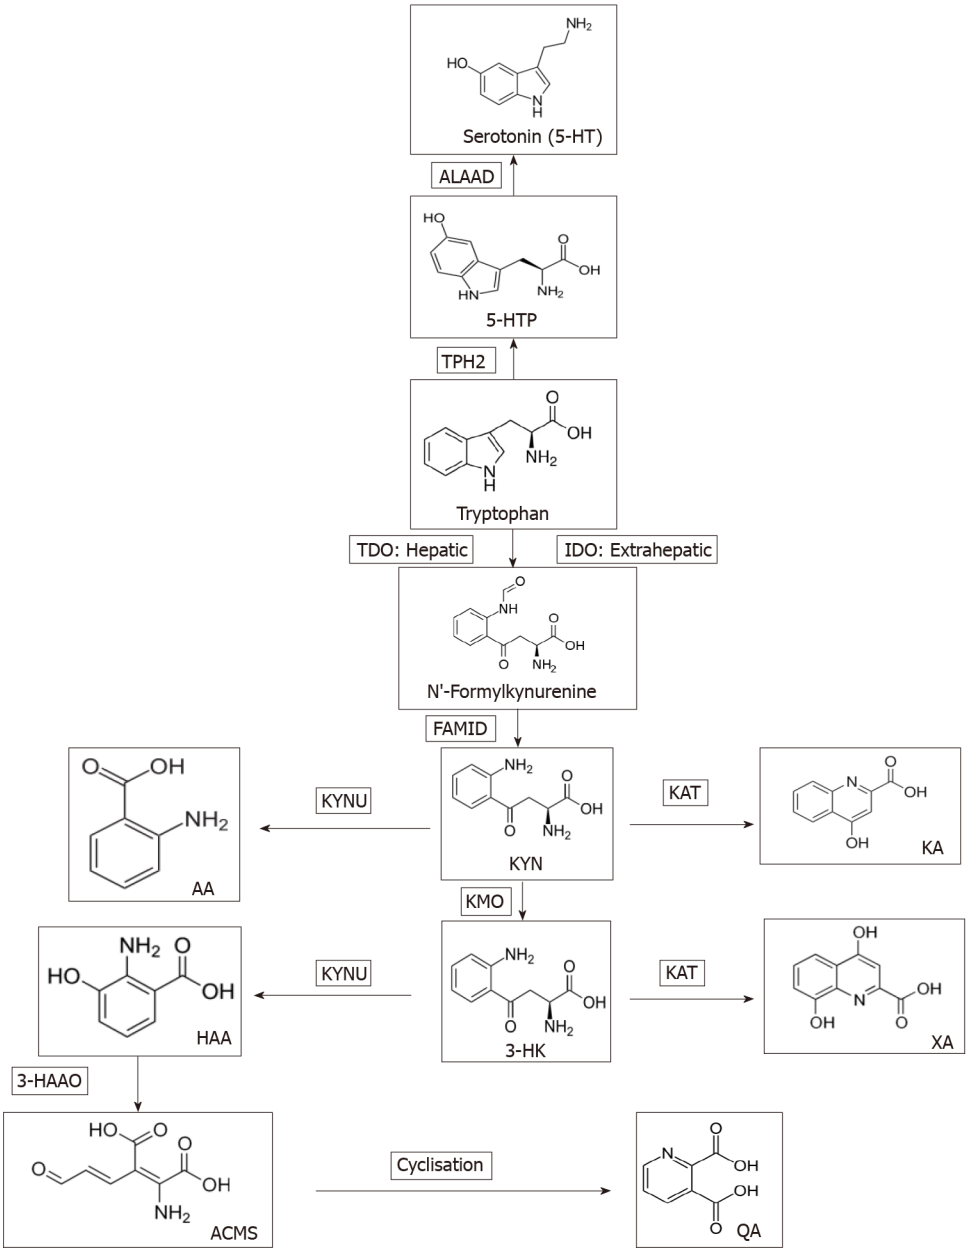
INTRODUCTION

Serotonin deficiency in major depressive disorder

Antidepressant drug development has been based on the monoamine hypothesis of affective disorders that postulates a deficiency of one or more monoamines and the need to develop agents that can inhibit either their breakdown (monoamine oxidase inhibitors) or their reuptake and subsequent degradation [tricyclic antidepressants (TCAs), serotonin-specific and serotonin-noradrenaline reuptake inhibitors]. The serotonin deficiency was originally suggested from observations by Curzon and Bridges[1] that patients with depression exhibit raised cortisol levels that can induce the synthesis of liver tryptophan 2,3-dioxygenase (TDO; formerly Trp pyrrolase) resulting in accelerated peripheral Trp degradation and hence a decrease in its availability to the brain for 5-HT synthesis. Brain (Trp) is the major determinant of 5-HT synthesis, because Trp hydroxylase exists partially (≤ 50%) saturated with its Trp substrate[2]. Depriving the brain of Trp by the acute Trp depletion test reverses antidepressant-induced remission in depressed patients[3].



Inhibition of liver TDO by antidepressant drugs

Curzon[4] suggested that TDO is a biochemical factor in depressive illness and Samsonova and Lapin were the first to demonstrate TDO inhibition by some TCAs[5]. Subsequently, a wide range of antidepressant drugs of various structures and pharmacological profiles were shown to inhibit TDO activity in rat liver *in vitro* and after administration[6-13]. TDO inhibition occurs with doses as small as 0.5 mg/kg body weight[7] and involves prevention of conjugation of the inactive apoenzyme with its heme activator and cofactor. TDO inhibition by antidepressants therefore depends on extent of the heme saturation of the apoenzyme and also of its glucocorticoid induction by cortisol, with some antidepressants being better inhibitors of heme-activated TDO, whereas others are better inhibitors of cortisol-induced TDO[13]. Ability of antidepressants to lower raised cortisol levels is another determinant of TDO inhibition[13].

Further evidence of the targeting of TDO by antidepressant drugs was provided by our group, using molecular docking *in silico*: A technique for screening potential inhibitors of target proteins[14,15], but is also useful to confirm known inhibitors. We demonstrated high docking scores (strong binding) of many antidepressants, including amoxapine, citalopram, fluoxetine, fluvoxamine, moclobemide, paroxetine, seproxetine, sertraline[16], tianeptine and venlafaxine, but not the non-antidepressant drugs pargyline and mefenamic acid[17] to the crystal structure of TDO, but no docking to that of the extrahepatic IDO. Thus, antidepressants target TDO and this could explain their ability to restore serotonin homeostasis, at least in part, by reversing the defective serotonin synthesis. As TDO is the first and rate-limiting enzyme of the kynurenine (Kyn) pathway (KP), a description of this pathway and its intermediates may be useful at this point (Figure 1).

The KP of Trp metabolism

The KP is the major pathway of Trp degradation, accounting for 95% of dietary Trp metabolism, with the hepatic pathway contributing 90% and the extrahepatic pathway the remaining 5%, though contribution of the latter pathway is significantly increased by immune activation of IDO by interferons and other proinflammatory cytokines[18]. The liver contains all the enzymes leading to NAD^+ synthesis, whereas other tissues express fewer enzymes[18]. Production of Trp metabolites in extrahepatic tissues including immune cells will therefore depend on the enzymes present. In the absence of TDO or IDO induction, the Kyn produced in liver or IDO-containing tissues can be transported elsewhere for further

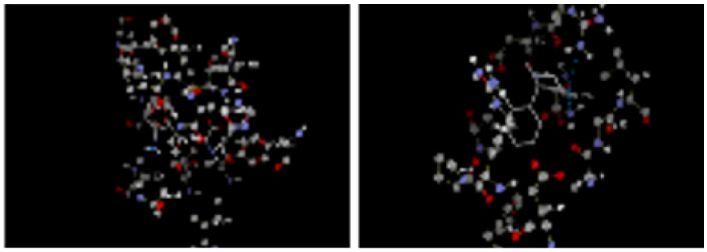
metabolism. Activity of the KP controls plasma Trp availability for cerebral serotonin synthesis and results in production of a range of Kyn metabolites that influence immune and neuronal functions[18].

Control of plasma Trp availability

Control of plasma Trp availability to tissues including the brain is primarily the function of liver TDO. Thus, deletion of the *tdo2* gene in mice increases plasma (Trp) by up to 12.7-fold[19,20] and brain (Trp) by 10.6-fold[21]. The increase in brain (Trp) is associated in increased 5-HT synthesis[21]. By contrast, deletion of the *IDO1* or *IDO2* gene does not alter Trp availability to the brain or 5-HT synthesis[21]. Trp availability for cerebral 5-HT synthesis is therefore determined by hepatic TDO activity in the first place, but also, secondarily, but more immediately, by 2 other determinants: albumin binding of plasma Trp and extent of competition for entry into the brain from a group of large neutral or competing amino acids (CAA), mainly Val Leu, Ile, Phe and Tyr. The best predictor of likely change in brain Trp and hence 5-HT synthesis is the ratio in plasma of Trp/CAA[13]. Plasma Trp exists largely (90%-95%) bound to albumin, with 5%-10% being freely available for tissue uptake. Binding is determined by levels of

albumin and of the physiological displacers of bound Trp, nonesterified fatty acids (NEFAs). Free Trp can therefore be easily altered by dietary, hormonal and pharmacological factors that influence Trp binding[22]. Under certain conditions wherein displacement of bound Trp is strong and sustained, the rise in free Trp will be associated with a decrease in total Trp, due to the rapid equilibration between the free and total fractions. Investigators should be careful in interpreting the changes in Trp disposition under these conditions[22], and whereas most investigators measure the ratio of total Trp/CAA, the ratio of free Trp/CAA is a more accurate measure in situations other than after acute Trp depletion or loading, as these are associated with parallel changes in both free and total Trp.

Neuronal and immune properties of KP metabolites



Neuronal activity is influenced by the cytoprotective kynurenic acid (KA) and excitotoxic quinolinic acid (QA) as antagonist and agonist respectively of the N-methyl-D-aspartate (NMDA) receptors of the excitatory amino acid glutamate[23], with the balance between QA and KA determining the level of neuronal excitability. Immune function is influenced by several Kyn metabolites. 3-hydroxykynurenine (3-HK), 3-hydroxyanthranilic acid (3-HAA) and QA are the main proinflammatory metabolites that undermine T-cell function[18], whereas picolinic acid (PA) is anti-inflammatory. KA is dually acting [24]. KMO is the gateway for production of these metabolites and the pathway favours Kyn oxidation by KMO to 3-HK and hydrolysis of the latter to 3-HAA by KYNU, because of the relatively high affinity of both enzymes towards their respective substrates[18]. 3-HAA 3,4-dioxygenase is the most active of KP enzymes, hence the rapid conversion of 3-HAA to an unstable intermediate that cyclises non-enzymically to QA[18]. Affinity of Kyn aminotransferase (KAT) towards its Kyn and 3-HK substrates is much weaker, hence the relatively low production of KA and xanthurenic acid, formation of both of which requires increased levels of the KAT substrates[18]. KMO gene deletion in mice decreases plasma 3-HK and QA by about 86% and 92% respectively and increases concentrations of Kyn, KA and AA by 15-, 133- and 4-fold respectively[25]. Thus, KMO inhibition diverts Kyn metabolism towards the cytoprotective KA. By contrast, activation of KMO can enhance the conversion of Kyn to 3-HK leading to decreased Kyn levels: An effect that will neutralise the rise in Kyn expected with TDO and/or IDO induction. This may explain the frequent observation that the reported increase in the Kyn/Trp ratio after mild immune activation is mostly due to the decrease in Trp, rather than an increase in Kyn[26]. These aspects may help explain some of the KP changes in MDD and their modulation by antidepressants (see below). Investigators use the plasma Kyn/Trp ratio to express indirectly IDO activity. While this may apply correctly in *in vitro* culture or cell systems, this ratio is not specific for IDO in *in vivo* situations, as other factors also alter it, including TDO activity, flux of plasma free Trp down the KP and activities of KMO and KYNU[26].

Inflammation and glutamatergic activity in major depressive disorder

The involvement of inflammation in major depressive disorder (MDD) was first proposed following the observation[27] that hepatitis C patients treated with interferon-alpha (IFN-α) become depressed. As this cytokine is an IDO inducer, the concept that serotonin deficiency in MDD is underpinned by IDO induction secondarily to inflammation was born. Extrapolating from hepatitis C to MDD was however unwise, given that Trp metabolism is already compromised by this virus and the use of IFN-α can only potentiate the effect of the virus on Trp metabolism, in particular IDO induction[17]. Although many studies of the immune status in MDD followed, recent studies suggested that not all MDD patients are immune-activated and, when present, inflammation is mild and/or transient and its reversal does not reflect clinical outcome[28,29]. Elevation of proinflammatory cytokines in some patients is not associated with an inflamed subgroup, but is due to a right shift of the immune marker distribution[30]. In MDD, reports of changes in the Kyn/Trp ratio used to express IDO activity are contradictory, partly because of the non-specificity of this ratio[26]. Whereas considerable evidence exists for liver TDO inhibition leading to elevation of plasma and brain Trp and enhanced serotonin synthesis in rats by a broad range of antidepressant drugs[6-8], and emerging evidence for inhibition of the accelerated Trp degradation in MDD by escitalopram causing an increase in plasma Trp[31], little is known about potential IDO inhibition by antidepressants. The absence of docking of antidepressants to IDO[17] suggests that this extrahepatic enzyme does not play a role in MDD antidepressant therapy and this notion is supported by the observations that the Kyn/Trp ratio does not link inflammation with depressive symptoms[32], and that IDO expression in monocytes of MDD patients is not different from that in healthy controls[33], though this may reflect patient heterogeneity.

Antidepressants and KP enzymes

As stated above, antidepressant drugs inhibit and target liver TDO, but not extrahepatic IDO[17]. Even when IDO is induced in some MDD patients by proinflammatory cytokines, it is most likely that the effect of this induction (as well as that of TDO) will be masked, superseded or overridden by changes in subsequent KP enzymes, notably KMO. KMO activation in MDD is gaining ground and may be another important biochemical event in the pathophysiology of this disorder. KMO activation can result in decreased levels of the Kyn substrate and consequently in the Kyn transamination product KA, as has been reported in unmedicated MDD patients[34,35]. While many antidepressants have previously been

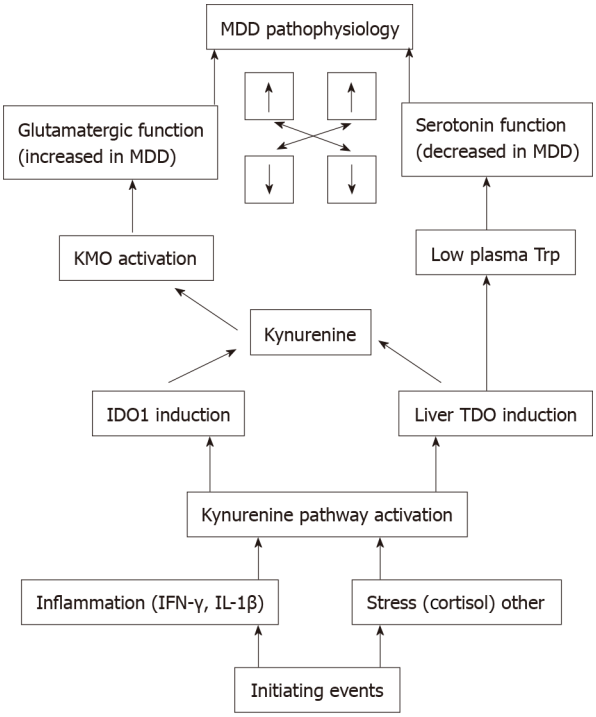
Figure 2 Molecular docking of kynurenine and ketamine to kynurenine monooxygenase. Docking was performed using the Molegro virtual Docker software as described previously[16,17], but with kynurenine monooxygenase. With kynurenine (top), the best scored docking solution of 5y66 with the reference ligand, amino acids in the active site are presented in ball and stick with element colour and ligand is presented in thick lines with element colour (where carbon is grey, oxygen is red, nitrogen is blue, sulphur is yellow and hydrogen is white). Blue lines represent the hydrogen bonds in between the ligand and the active site of 5y66. Docking parameters were as follows: Kynurenine: Molecular weight (207.206), docking score (-95.4662), re-rank score (-81.6652), root mean square deviation (RMSD) (2.19513), torsion (4), H-bond (-6.03152). Amino acid residues at the kynurenine monooxygenase (KMO) active site are: Gly321, Ile224, Phe319, Met373, His320, Ala56, Leu226, Phe319, ligand binding amino acid residues are: Tyr404, His320, and Leu226. With ketamine (bottom), molecular weight (237.725), docking score (-81.8059), re-rank score (-65.0284), RMSD (zero), torsion (2), H-bond (-0.0342033). Amino acid residues at the KMO active site are: Asp112, Arg39, Gly16, Ala15, Glu37, Phe131, Arg111, Arg100, ligand binding amino acid residues are: Asn 115, Arg111. KMO: Kynurenine monooxygenase; KYN: Kynurenine.

proposed to act by reducing inflammation and hence inhibition of IDO induction, it is more likely that they act by inhibiting KMO activation by cytokines, notably, interleukin-1β and IFN-γ[36], as has been demonstrated with ketamine[29], escitalopram[31] and sertraline[37]. Additionally, whereas ketamine does not dock to either TDO or IDO and so is unlikely to inhibit either enzyme[17], we demonstrate here for the first time its strong docking to KMO (Figure 2), that is comparable with that of the reference ligand Kyn itself, and suggest that KMO inhibition is likely to be one mechanism of action of ketamine.

The role of anti-inflammatory drugs in MDD therapy



Current evidence suggests that anti-inflammatory strategies have not met with the anticipated success in MDD therapy and that only MDD patients with chronic inflammation may benefit from such therapy, while other patients with low-grade inflammation may experience harm[38]. Of 6 non-steroidal anti-inflammatory drugs tested, only salicylic acid (the active aspirin metabolite) docks to TDO[17] and aspirin appears to be an effective single or adjunctive therapy of MDD if given in relatively small doses and for short- to medium-term durations, but not for long-term use, which does not protect against depression and can actually induce it[18]. Mechanisms of these opposite effects of aspirin involve modulation by salicylate of Trp metabolism and disposition in opposite direction[17].

Serotonin and glutamate interactions

KMO activation leads to production of the excitotoxic Kyn metabolite and NMDA receptor agonist QA. Glutamatergic activity can therefore be enhanced in at least some MDD patients. Mutual interactions between serotonergic and glutamatergic activities are well established and may be important determinants of MDD pathophysiology. Thus, serotonin modulates glutamate neurotransmission in several brain regions, especially those involved in cognition, motor function and nociception, with raphe neurons being immune-positive for glutamate[39]. The cognitive and emotional disorders in MDD due to defective serotonin function can in part be due to disruption of the serotonin control over glutamate and gamma-aminobutyric acid neurotransmission[40,41]. On the other hand, NMDA receptors may regulate behavior by modulating serotonin and dopamine function[42,43]. Though complex in nature, this mutual interaction can be viewed simplistically as low serotonin losing control over glutamate neurotransmission and inhibition of the latter facilitating serotonin function (Figure 3).

CONCLUSION

We hypothesized that the KP is at the center of MDD pathophysiology and a target of antidepressant therapy. Figure 3 outlines the potential role of the KP in MDD and emphasizes the importance of TDO and KMO, the inhibition of which is likely to become the focus of pharmacotherapy of MDD. Studies on the frequency of KMO enhancement and its mechanism(s) in MDD are needed. Effects of antidepressants other than ketamine and escitalopram on enzymes and metabolites of the KP should be investigated. KMO inhibition therapy could be explored in MDD. We suggest that lowering glutamatergic activity by KMO inhibition can restore serotonin function and should be recognized as a new mechanism of antidepressant action, perhaps exemplified by ketamine. The rapid and novel mode of action of ketamine should encourage the search for safer and longer-acting alternatives. The requirement of normal serotonin levels in the antidepressant-like efficacy of ketamine in rodent models

Figure 3 Schematic representation of the proposed role of the kynurenine pathway in the pathophysiology of major depressive disorder. Mutual interactions between serotonergic and glutamatergic functions are indicated by the bidirectional arrows for increased or decreased function. MDD: Major depressive disorder; KMO: Kynurenine monooxygenase; Trp: Tryptophan; IDO: Indoleamine 2,3-dioxygenase; TDO: Tryptophan 2,3-dioxygenase; IFN: Interferon; IL: Interleukin.

[44] may explain in part the transient efficacy of the drug in humans. Furthermore, studies with the two ketamine enantiomers suggest that NMDA receptor antagonism is not the sole mechanism of the drug's antidepressant action[45]. KMO inhibition and blockade of progress of the KP to QA formation is thus far a potential mechanism of ketamine action. Addressing the above issues may provide a way forward in the search for the ideal MDD pharmacotherapy.

Abstract

This brief overview highlights the global crisis of perinatal psychiatric illness (PPI). PPI is a major contributor to many adverse pregnancy, childbirth, and childhood development outcomes. It contributes to billions of dollars in spending worldwide each year and has a significant impact on the individual, their family, and their community. It is also highly preventable. Current recommendations for intervention and management of PPI are limited and vary considerably from country to country. Furthermore, there are several significant challenges associated with implementation of these recommendations. These challenges are magnified in number and consequence among women of color and/or minority populations, who experience persistent and negative health disparities during pregnancy and the postpartum period. This paper aims to provide a broad overview of the current state of recommendations and implementation challenges for PPI and layout a framework for overcoming these challenges. An equity-informed model of care that provides universal intervention for pregnant women may be one solution to address the preventable consequences of PPI on child and maternal health. Uniquely, this model emphasizes the importance of managing and eliminating known barriers to traditional health care models. Culturally and contextually specific challenges must be overcome to fully realize the impact of improved management of PPI.

Key Words: Perinatal psychiatric illness; Postpartum depression; Equity-oriented care; Minority populations; Maternal mortality; Pregnancy

Core Tip: Perinatal psychiatric illness is a major contributor to maternal mortality and morbidity rates, especially among women of color. This paper explores the ways in which current standard of practice is failing to address these disparities and offers an alternative framework for consideration.

INTRODUCTION

Rates of maternal morbidity and mortality are a global health crisis. In 2017, 295000 women worldwide perished due to maternal causes[1]. Global maternal mortality rates are estimated at 211 maternal deaths per 100000 live births. The lifetime risk of maternal mortality for a 15-year-old girl is estimated at 1 in 190[1]. Mortality rates are more than 40 times higher in underdeveloped countries compared to developed geographic areas such as Europe and Australia[1]. There are major differences in rates of maternal mortality and morbidity. Differences can be seen between countries, with sub-Saharan Africa and Southern Asia accounting for approximately 86% of all estimated global maternal deaths in 2017[1]. Differences based on minority status can also be seen within countries. In the United States, Black women are 2.5 times more likely to die in childbirth than White women[2]. In the United Kingdom, Black and Asian women are more likely to die of maternal-related causes than White women[3]. Ethnic minorities (*e.g.*, non-Han women) in China have higher maternal mortality rates than non-minority populations (*e.g.*, Han women[4]). In Brazil, non-white women are 3.5 times more likely to die from obstetric deaths than White women[5]. In Australia, Indigenous women have a maternal mortality rate 4.6 times higher than non-Indigenous women[6]. These trends are consistent worldwide.

Maternal Mortality Review Committees have determined that 11% of pregnancy-related deaths are due to perinatal psychiatric illness (PPI), and these deaths are 100% preventable[7]. PPI is the most common morbidity in pregnancy and the leading cause of mortality during the perinatal period in developed nations[8]. PPI is a significant contributor to poor outcomes throughout pregnancy, childbirth, and postpartum. Rates of PPI in high-income countries range from 7%-15%, while the prevalence ranges from 19%-25% in low- and middle-income countries[9]. Women of color are especially at risk for PPI. In the United States, Black, Asian/Pacific Islander and Hispanic/Latinx women report experiencing PPI at 2-5 times the rates of White women[10,11]. In the United Kingdom, non-White (especially Asian) women experience PPI at higher rates than White women[12]. In Norway, the prevalence of PPI in women of underrepresented ethnicities was almost 3 times that of Western Europeans[13]. Research on racial disparities is limited. Many studies combine all racial and/or ethnic minorities together, which disregards important differences between races and cultures.

PPI refers to any psychiatric illness experienced from the beginning of pregnancy up to 1 year postpartum. A landmark study of 10000 mothers found that of women who screened positive for depression, 27% reported being depressed before pregnancy and 33% reported that their depression began during pregnancy[14]. Though many primarily think of postpartum depression when referring to PPI, there are several psychiatric illnesses that are prevalent and related to negative outcomes during the perinatal period. Perinatal depression is indeed common, occurring in around 25% of women[15]. It refers to the occurrence of a major depressive episode in the perinatal period, marked by low mood, low energy, sleep problems (apart from caring for the infant), and sometimes suicidal thoughts. This is differentiated from what has been called the "baby blues" or the "maternity blues", which refers to a transient affective disturbance that usually peaks within 5 d after childbirth[16]. PPI also refers to psychiatric symptoms beyond depression. Perinatal anxiety presents with symptoms such as excessive and uncontrollable worries about the baby and motherhood, fear of childbirth, and intrusive thoughts of the baby being harmed or dying[17]. It may occur at higher rates than perinatal depression[18]. Perinatal obsessive-compulsive disorder is more common than obsessive-compulsive disorder in the general population and is marked by obsessions and compulsions related to the baby[19]. Obsessions are generally related to fears of contamination and harming the baby and compulsions may include avoidance of child-rearing tasks and mental rituals[19]. Perinatal post-traumatic stress disorder (PTSD) refers either to a recurrence of PTSD brought on by major life changes during pregnancy and postpartum or to new onset PTSD secondary to traumas experienced during pregnancy or childbirth. Symptoms include nightmares, avoidance of stimuli associated with the trauma, and negative

appraisals of self and others related to the trauma[20]. Finally, perinatal psychosis, though relatively rare, is an emergent situation. It typically occurs within 2-3 d of childbirth, though emerging evidence suggests that some women may even experience it prenatally. It is most common in women with a history of bipolar disorder or with a first-degree relative with schizophrenia or bipolar disorder[21].

PPI is associated with a range of negative outcomes. Women experiencing PPI tend to initiate prenatal care later and miss more appointments. Both factors are highly associated with poor childbirth outcomes[22-24] and are targets for appropriate intervention like psychoeducation and enhanced awareness of PPI. PPI is also associated with pregnancy and delivery complications (such as high blood pressure, gestational diabetes premature labor, low infant APGAR score, low birth weight[25]). Specific findings stratifying risk by ethnicity and race are limited. One United States study found that non-Hispanic Black and Asian women have higher levels of risk for preterm birth while depressed than White women, and Hispanic women were not at higher risk for preterm birth when depressed[26].

Women with PPI and their babies also experience postpartum comorbidities associated with psychiatric illness. Women with PPI have more trouble bonding with their baby, and mental health concerns can be seen 4-5 years postpartum in 30%-40% of women[22,27,28]. The children of women with untreated psychiatric distress go on to have higher rates of psychiatric illness, behavioral problems, and academic difficulties[29]. To illustrate, a French study showed increased externalizing and internalizing behavior and poor motor and regulation skills in 1-year-old children of mother with perinatal depression[30]. These findings were replicated in a large (n = 2698) study out of the Netherlands examining internalizing behavior in 3-year-old children of women with perinatal anxiety and depression[31]. Studies of teenagers (aged 16 to 17-years-old) in Finland and the United Kingdom demonstrated increased risk for depression and low social competence when their mother had experienced perinatal depression[32,33].

Risk factors for PPI are myriad and many are quite common. Individual risk factors include unwanted pregnancy (50% of pregnancies), primiparity (*i.e.*, first pregnancy), and fertility difficulties [34]. Social determinants of health related to PPI include childhood maltreatment, especially childhood sexual violence, which affects up to 25% of girls from low-income and middle-income countries[9]. Other social determinants that increase risk for PPI and are disproportionately experienced by women of color and underrepresented ethnicities are poverty, poor nutrition, lower levels of educational attainment, low social support, gender discrimination and gender-based violence, and previous mental health conditions[9,34,35]. Again, studies stratifying risk for PPI by race and ethnicity are extremely limited, though there is evidence for the deleterious impact of immigration and race-based discrimination on mental health (*i.e.*, increased risk for PPI) in the perinatal period[36]. Adversity more commonly observed in underrepresented populations, such as intimate partner violence, childhood trauma and military deployment, is also associated with greater risk for mental health outcomes[36].

Untreated PPI can have devastating consequences for mothers, their partners, their children, their workplaces, and their communities. At the population level, PPI is associated with increased healthcare costs, inappropriate use of healthcare (*i.e.*, excess- and under-utilization as well as increased use of emergent care), child abuse, family dysfunction, and, at worst, suicide, homicide, and infanticide[22,37]. At the individual level, PPI impacts the mother's health, attachment with their child, the infant's health, and can lead to suicide or homicide[38,39]. At an economic level, the cost of PPI is significant. Though research on exact costs worldwide are limited, studies out of Canada and South Africa suggest that women with PPI utilize services costing roughly 2 times those of women without PPI[40,41]. In the United States, PPI costs an estimated $14 billion per year, including cost estimates of loss of productivity and direct healthcare[42]. Even when strictly examining medical costs in the United States, PPI costs 5 times as much as other pregnancy concerns like gestational diabetes or postpartum hemorrhage[43].

Given the regular touchpoints between pregnant women and providers during the prenatal period and the onset of many psychiatric concerns during the prenatal period, pregnancy offers an optimal time for early detection and intervention for perinatal mental health problems[44]. The American College of Obstetricians and Gynecologists recommends 13 care appointments during the prenatal period[45]. Evidence suggests that prenatal mental health interventions are effective at improving health outcomes and preventing psychiatric distress, but PPI is significantly under-identified and largely under-treated[46].

CURRENT RECOMMENDATIONS

In response to mounting concerns related to PPI and its impact on women and communities, initiatives to improve care have focused on universal screening. In the United States, the following organizations all recommend at least one screening for perinatal depression with a validated measure during the perinatal period: American College of Obstetricians and Gynecologists, American Academy of Pediatrics, United States Preventive Services Task Force (USPSTF), Centers for Medicare and Medicare Services, Council on Patient Safety in Women's Health Care[47-50]. The USPSTF specifies that screenings should only occur when there are significant resources for effective treatment and follow-up [51]. In the United Kingdom, universal screening is recommended by the National Institute for Health

and Care Excellence, though again, only when there are resources available for treatment and follow-up [52]. This is consistent with guidelines suggested by the World Health Organization in 2022[34] which suggested a stepped-care approach to the integration of perinatal mental health services into maternal health care. In Canada, universal screening is not recommended by the Canadian Task Force on Preventive Healthcare due to paucity of evidence for its benefits[53].

FOUR CHALLENGES ASSOCIATED WITH CURRENT RECOMMENDATIONS

Though there are some benefits to universal screening, including the low cost and low provider burden of having patients complete the forms, at least four major challenges have arisen with the current recommendations for universal screening in the perinatal period. Each challenge impacts all pregnant women, and each is also uniquely impactful in the outcomes of women of color.

Universal screening is not universally implemented

Unfortunately, screening has not been universally and systematically implemented in prenatal care, with estimates of screening by OB/GYN providers ranging from 39-72%[44,54,55]. Providers often do not assess for psychiatric illness for a number of reasons, including: (1) Lack of education regarding efficient measurement tools; (2) uncertainty regarding how to respond if a pregnant person endorses signs of perinatal psychiatric illness (PPI, and whether they will then be liable if negative outcomes occur); (3) lack of guidance regarding availability of appropriate treatment; (4) lack of time in short visits; and (5) lack of financial incentive for clinicians to screen[56,57].

There are notable racial disparities in the decision whether to screen for psychiatric distress. Women of color are 5%-10% less likely to be asked about psychiatric distress than White women[58,59], and without screening, women of color are less likely to spontaneously offer information regarding psychiatric distress due to discomfort and stigma[60].

Pregnant women underreport distress on psychiatric screenings

When screening does occur, many pregnant women underreport psychiatric distress. A qualitative review found that across several studies, many women reported that they did not have knowledge about PPI and were unaware that they would likely meet criteria given their current symptoms[61]. Other women who did recognize that they had symptoms of PPI reported being unable or unwilling to disclose feelings due to fear of burdensomeness, fear of giving their family a "bad name", and fear of losing their baby[61]. Many women had previously had symptoms dismissed or over-normalized (*i.e.*, described as normal aspects of the pregnancy period, a "rite of passage") and thus declined to disclose symptoms[62]. Other reasons to underreport symptoms include fear of disclosure outcomes, worry about being judged to be a bad mother, and lack of continuity of care[44,63]. Importantly, one study linked discomfort with being screened with higher scores on a depression scale, highlighting the relationship between experience of symptoms and discomfort with reporting them[64].

Limited data exist on differences in reporting of symptoms among pregnant women of different racial groups. However, women of color underreport psychiatric distress in non-pregnant samples, so it can be assumed they likely underreport symptoms during pregnancy[65].

Referrals are inconsistent

Women who do screen positive for psychiatric distress may or may not be given a referral to care, based on the clinic's access to resources and information. One program successfully engaged 80% of women who screened positive for depression symptoms in care, while another saw fewer referrals to care after universal screening was implemented than before[56,66].

Women of color who screen positive for psychiatric distress are not referred when appropriate as often as are White women. In one study, White women who disclosed psychiatric distress were referred for treatment twice as often as Asian and Black women[59]. In another, Hispanic/Latinx and Black women who met full criteria for depression were less likely to receive a depression diagnosis, limiting referrals[67]. Some studies show a 10% referral to treatment rate when women of color screen positive for psychiatric distress[68].

Follow-up after referrals is inconsistent

If they are given a referral to care, pregnant women do not follow up with treatment. In a study of referral rates, only approximately 40% of women referred attended even one visit[69]. Primary reasons for lack of follow-up include practical concerns (*e.g.*, perceived insufficient time, the inconvenience of attending appointments), perceived stigma (*e.g.*, feeling that needing help makes one a bad mother), and displeasure with how symptoms were handled by their provider (*e.g.*, feeling minimized, dismissed, or humiliated[61,62]). Pharmacological hesitancy is also noted in failure to follow-up, with many women worried about addiction, side effects, and stigma[62].

When resources might be available, women of color have significantly lower utilization rates of psychiatric services (*e.g.*, attendance at appointments, continued care and follow-up, medication management) than White women, even when controlling for age, type of psychiatric condition, and socioeconomic status[70-74]. Some researchers identify mental illness stigma as a potential contributor to these differences[75], as Black women perceive greater overall depression stigma than White women, regardless of personal experience with depression[76]. Furthermore, prior experiences with mental health treatment likely play a role in the attitudes of Black women seeking treatment during periods of psychological distress[77].

Though screening all women is the suggested standard of care in response to the mental health crisis in pregnant and postpartum women, these data demonstrate that universal screening is not sufficient for improving outcomes. Universal screening may even paradoxically serve as a barrier to care when delivered in its most common form (attached as a form to check-in paperwork). Without an explanation as to how the answers will be used, women (especially women of color) underreport symptoms to avoid negative outcomes[78].

In short and consistent with the Canadian Task Force on Preventive Healthcare, the current recommendations for universal screening are not effective for improving outcomes.

EQUITY-ORIENTED CARE

The above-described challenges inherent to universal screening reflect profound health inequities for pregnant women and especially pregnant women of color. Current standards of care (*e.g.*, universal screening and referral) were developed using the traditional medical framework, within which health inequities are increasing worldwide[79-81]. Even countries that provide universal health services to their citizens demonstrate major inequities based on race and ethnicity in their perinatal care. For example, in a large study in the United Kingdom examining over 600000 women who gave birth, Black African, Asian, and White non-British women had significantly lower access to outpatient mental health services than White British women[82]. Moving the needle on PPI and thus maternal mortality and morbidity will require approaches that are fundamentally aware of and responsive to health inequities in a way that traditional healthcare is not.

Equity-oriented care is positioned as an alternative to traditional care. It has been previously defined as "an approach that aims to reduce the effects of structural inequities, *etc.*; the impact of multiple and intersecting forms of racism, discrimination, and stigma (*e.g.*, related to mental illness, chronic illnesses, non-conforming gender and sexual identities, *etc.*) on people's access to services and their experiences of care; and the frequent mismatches between dominant approaches to care, *etc.*, and the needs of people who are most affected by health and social inequities"[83]. An equity-oriented framework is trauma-informed (recognizing the higher rates of trauma and violence in communities of color), culturally safe (explicitly addressing power dynamics and historical mistrust in the medical system), and contextually tailored (highlighting skills and education relevant to the medical system and community)[84].

Therefore, a successful perinatal mental health intervention would deviate from the traditional model of screening to refer and would follow an equity-oriented model. This model would specifically address mental health stigmatization and work to reduce systemic racism in the medical context while addressing practical barriers to accessing care. A direct way to meet both needs is to move away from universal screening and toward universal intervention.

UNIVERSAL INTERVENTION IN THE PRENATAL PERIOD

A universal intervention approach to psychiatric distress in pregnancy may eliminate known barriers to appropriate psychiatric management, thus improving trajectories for all pregnant women, and especially for women of color. Rather than losing women at every step of the screening-to-referral pipeline, provision of a universal intervention in the prenatal period ensures that evidence-based tools for prevention of PPI are delivered. Providing this intervention to all women is a novel approach to management of PPI.

Based on the accumulation of evidence regarding the most impactful interventions in the perinatal period, equity-oriented prenatal universal intervention should be trauma-informed[85] and limited to one 45-min session. This model is consistent with research suggesting that even one childbirth educational session is effective for improving outcomes and that requiring more sessions creates a barrier to psychiatric care[86,87]. It should be delivered in the prenatal period as either an adjunct to a standing prenatal appointment or as a separate appointment. It can be delivered by a mental health professional (*e.g.*, contracted, embedded, or other) or potentially by a trained OB/GYN provider (*e.g.*, nurse, MA, or other). Based on previous research regarding barriers to effective care as well as what is most helpful for women during the prenatal period, the universal intervention should include the following components: (1) Brief education about pregnancy and the childbirth process; (2) brief discussion of perinatal psychiatric issues in plain language; (3) discussion of trust and potential

discomfort with providers; (4) explanation of skills for maximizing healthcare appointments; and (5) list of free and low cost resources available throughout pregnancy and after childbirth. Components 1-4 could be created and disbursed as relevant for all pregnant women while component 5 needs to be individualized to the clinic based on location and institutional/community resources.

Brief education about pregnancy and the childbirth process

Various psychological techniques and theories suggest the importance of understanding stressors that lie ahead and managing them proactively (*i.e.*, stress inoculation training[88], dialectical behavior therapy[89]). Consistent with these theories, education should be provided regarding both the normal course of the pregnancy and childbirth process (including medically normal but potentially psychologically stressful situations such as transvaginal ultrasounds, manual cervical checks, and childbirth) as well as non-normal but still common situations (*e.g.*, gestational diabetes, preeclampsia, emergency c-sections). A respectful and informative overview of the pregnancy and childbirth phases will provide patients with an understanding of their course as well as allowing for prophylactic distress tolerance for the different situations.

Brief discussion of perinatal psychiatric issues in plain language

The average medical communication requires a level of health literacy (*i.e.*, ability to read and use medical information) that is higher than that of the average patient[90]. Improving mental health literacy, or knowledge about specific mental health conditions including early detection, has been suggested as a way to intervene earlier in the experience of psychiatric illness[91]. For this intervention, this would include providing patients with a plain language description of various PPI, including how they might experience them (in contrast to education for providers, which focuses more on how the provider might perceive symptoms).

Discussion of trust and potential discomfort with providers

Because limitations to screening include the likelihood of underreporting symptoms due to discomfort with and lack of trust in providers, an intervention should include a candid and humble discussion of this issue. Discussing common barriers to effective collaboration with providers (*e.g.*, experience of racism, fear of how shared knowledge will be used, previous traumatic medical experiences) may elucidate individual biases and difficulties that can be managed.

Explanation of skills for maximizing healthcare appointments

Patient empowerment is a crucial component of good medical care, and it is especially critical for vulnerable populations that tend to engage more passively in medical care[92]. Empowering women to utilize their medical appointments in the ways that they find most helpful can be done through providing simple skills and providing permission for their use. Skills should include bringing in questions written down ahead of time, recording appointments (with permission from provider), and asking for time for questions at the start of the appointment[93]. Skills also include emotion regulation skills to use when feeling anxious in the appointment.

List of free and low-cost resources available throughout pregnancy and after childbirth

A list of virtual and in-person options should be provided if the patient is interested in pursuing further behavioral health resources.

This method is equity-oriented in that it is trauma-informed, culturally safe (by explicitly addressing trust and discomfort with providers), and contextually tailored (discusses skills in plain language and ways to maximize healthcare appointments). It does not rely on women to overcome systemic barriers, fear and mistrust to risk disclosing painful experiences; rather, it offers information and education from a place of cultural humility and openness.

This method may confer a number of benefits over universal screening

Reduction of stigma: By delivering the intervention to all women, the information and education are considered standard components of prenatal care (similar to education about gestational diabetes) rather than specialized referrals based on problematic or unique disclosures. We expect that providers may see an increase in scores on screenings and in PPI diagnoses due to increased comfort with disclosing.

Increased preparation: The information provided within a universal psychological intervention should highlight events during the pregnancy and childbirth periods that may be uniquely stressful with an emphasis on identifying methods of coping in advance. This normalizes the potential reactions the pregnant person may have and allows them to prepare appropriately.

Increased mental health literacy: This intervention will provide general education about mental health concerns, which increases mental health literacy and reduces stigma.

Table 1 Advantages and disadvantages of universal screening and universal intervention

	Advantages	Disadvantages
Universal screening	Low cost; low provider burden	Patients likely to under-disclose; disparities in referrals and follow-ups; disparities in who receives resources and psychoeducation; reflects traditional model of healthcare; higher levels of care not always available if needed
Universal intervention	All patients receive psychoeducation and resources; mental healthcare is integrated into prenatal care; all patients have opportunity to discuss mental health concerns; will likely reduce costs long-term	Higher immediate cost; need for additional practitioners; higher levels of care not always available if needed

Increased comfort with help-seeking: By destigmatizing PPI and clearly explaining the importance of treating PPI, pregnant women may feel more comfortable seeking access to mental healthcare.

These interventions should be standard of care for all pregnant women.

CHALLENGES OF THIS MODEL

This model is not without its challenges. Systems-level barriers continue to exist, whether healthcare is privatized or nationalized. In low-, middle-, and high-income countries, challenges include low levels of funding afforded to mental health services, inequalities in levels of access to mental health care, and shortages of mental health providers[94,95]. Decisions will need to be made in clinic as to whether the intervention should be delivered by an embedded mental health professional (MHP) or by an OB/GYN provider. Benefits of delivery by an MHP are need for limited training, ability to provide ongoing care in clinic, and reduced burden on an already overburdened OB/GYN staff. Benefits of delivery by an OB/GYN provider are the low resources needed for implementation and reduction in the likelihood that the provider will divert responsibility for mental health management fully to the MHP, a frequent occurrence when MHPs are embedded in primary care[66]. Finally, this model does not address the major shortage of psychiatrists and mental health practitioners, both of whom are necessary when ongoing care is needed for more serious PPI management.

UNIVERSAL INTERVENTION *VS* UNIVERSAL SCREENING

As discussed above, universal intervention may address many of the concerns with universal screening. In summary, Table 1 discusses the advantages and disadvantages of universal screening (current state in many countries) and universal intervention (proposed model).

CONCLUSION

The application of a universal intervention model may de-stigmatize psychiatric care and address many of the barriers that continue to contribute to health disparities for women and especially women of color. Delivering a universal intervention to all patients, regardless of psychiatric distress within the context of prenatal care may improve individual and community outcomes for women by reducing stigma, increasing preparation, providing a connection to a psychiatric professional and improving mental health literacy. For women with psychiatric distress, a universal intervention may also provide a basic stress inoculation for pregnancy process, individualized referral to services if needed, and updated resources. If successful on a large scale, this intervention could contribute to changes in major international guidelines regarding the appropriate course of prenatal care.

Abstract

In recent years, epidemiological and genetic studies have shown an association between autoimmune diseases and psychosis. The question arises whether patients with schizophrenia are more likely to develop multiple sclerosis (MS) later in life. It is well known that the immune system plays an important role in the etiopathogenesis of both disorders. Immune disturbances may be similar or very different in terms of different types of immune responses, disturbed myelination, and/or immunogenetic predispositions. A psychotic symptom may be a consequence of the MS diagnosis itself or a separate entity. In this review article, we discussed the timing of onset of psychotic symptoms and MS and whether the use of corticosteroids as therapy for acute relapses in MS is unfairly neglected in patients with psychiatric comorbidities. In addition, we discussed that the anti-inflammatory potential of antipsychotics could be useful and should be considered, especially in the treatment of psychosis that coexists with MS. Autoimmune disorders could precipitate psychotic symptoms, and in this context, autoimmune psychosis must be considered as a persistent symptomatology that requires continuous and specific treatment.

Key Words: Multiple sclerosis; Psychosis; Schizophrenia; Corticosteroids; Antipsychotics

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Immunological perturbations in multiple sclerosis (MS) can lead to the development of psychotic symptoms. The use of corticosteroids and antipsychotics might prove beneficial and in patients with MS-related psychosis and outweigh their adverse effects.

INTRODUCTION

Multiple sclerosis (MS) is an autoimmune disorder of the central nervous system (CNS) that is characterized by neuroinflammation, demyelination, axonal loss and neurodegeneration[1]. It is one of the most common neurologic disorders and the most common cause of acquired neurological disability in young adults, that has an effect on 2.5 million people worldwide[2]. MS patients are two to three times more likely than the general population to suffer from mood and mental disorders[3,4].

Neurological and psychiatric diseases often overlap and co-occur[5,6]. Psychiatric symptoms may occur at any time during a neurological autoimmune disease, but they may also be an initial clinical manifestation and precede the onset of typical neurological symptoms[7]. The initial or early presence of these symptoms may complicate the establishment of a correct diagnosis, hinder the early recognition of the underlying brain disorder, and lead to inadequate treatment and a poorer prognosis[8,9]. Furthermore, the presence of various psychotic symptoms in neurological diseases additionally compromises these conditions and has an impact on individual functioning and overall disease burden [10]. The prevalence of psychosis/psychotic disorders is approximately 4.3%[11].

Mental disorders in neurological diseases may have different underlying causes[12]. In MS patients, the onset of psychiatric symptoms may be a consequence of the MS diagnosis itself[13]. Brain lesions, physical disabilities, symptoms of MS and pharmacological treatments may cause psychopathological manifestations[14].

There is limited scientific evidence that could be useful for clinical decision-making in the resolution of psychotic symptoms in patients with MS. Recent data by Sabe and Sentissi have confirmed our clinical observations[15]. There is a lack of data considering MS and psychosis, especially schizophrenia (SCH), simultaneously. We might think that this is due to a lack of interest in the field, but it is also possible that these disorders do not exist at their full capacity simultaneously. In this mini-review, we aim to resolve some clinical dilemmas. First, we discuss the timing of the onset of psychotic symptoms and MS. Second, whether the use of corticosteroids is unfairly neglected and whether a more aggressive treatment approach is warranted. And third, whether antipsychotics may be of benefit as adjunctive therapy is discussed. Immune disturbances may be similar or very different in terms of different types of immune responses, disturbed myelination, and/ or immunogenetic predispositions.

This mini-review was conducted through a systematic electronic search of the PubMed, Cochrane, and Web of Science databases to identify cases of MS with psychotic symptoms. The terms used were "multiple sclerosis"; "psychosis"; "schizophrenia"; "neurodegeneration"; "neuroinflammation"; "corticosteroids"; and "antipsychotics." We searched for studies published in English, with no restriction on year of publication. Experimental studies, randomized or nonrandomized clinical trials, cohort studies, and case-control studies were included. We have assessed the abstracts of potentially relevant titles and reviewed the full text of potentially eligible studies. In this mini-review, we attempted to select and focus on only up-to-date and clinically relevant data.

NEUROIMMUNOLOGICAL ASPECTS OF MS AND PSYCHOSIS

Genetic predisposition, individual and environmental factors, and specific immune responses had a significant impact on disease onset and clinical presentation. This suggests that the same etiological factors and pathophysiological pathways may influence the association between MS and psychosis. It raises the question of whether patients with SCH might also suffer from MS later in life. The genetic basis of MS is supported by the fact that the risk of disease is higher in MS family members than in the general population, that certain racial and ethnic groups have a lower illness tendency, and that the concordance rate is higher in monozygotic twins[16]. Previous genetic studies have shown that the predisposition to develop MS depends on several independent polymorphic genes and their interaction. No single gene variant is necessary or sufficient to cause MS, but each one increases the overall risk of the disease in an additive manner[17]. Genome-wide association studies (GWAS), which examine gene polymorphisms in the whole genome, suggest that over 200 gene loci that have different immune

functions are responsible for the development of MS[18,19]. The risk genes control the differentiation and state of these cells through their function in specific cellular processes in immune cells. In addition, recent evidence indicates that many immune cell populations are highly heritable, raising the possibility that MS risk genes define differences of immune cell populations that could also be involved in the pathogenesis of illness[18].

It is well known that the immune system plays an important role in the etiopathogenesis of MS and SCH[20,21]. Some authors assign them to the same group of neuroinflammatory and neurodegenerative properties, but with marked differences in the immune response. From the clinician's point of view, this fact could mean that these disorders are mutually exclusive. We have already considered confronting results of the prevalent immune responses in MS and SCH as prototypes of disorders of type 1 *vs* type 2 immune responses, respectively[22,23]. In recent years, growing epidemiological evidence has suggested a bidirectional association between autoimmune diseases and increased risks with SCH[24]. A family history of autoimmune disease has been shown to be related to an increased risk of psychotic disorders and vice versa[25]. In addition, having a first-degree relative with SCH increases the risk of autoimmune diseases by 6%[26]. Previous studies have found that patients with MS are at an increased risk of developing SCH[27]. SCH and other psychotic disorders have been associated with genetic markers of immune activation, suggesting a possible etiological link between MS and psychosis[28]. GWAS emphasized the significant overlapping of genes, noted the involvement of similar HLA alleles, and identified 21 independent loci associated with SCH and also associated with MS. In these diseases it seems that the major histocompatibility complex is responsible for the genetic overlap[29,30]. A possible additional role of genetics in this association could be an inherited susceptibility to common risk factors for infections or a predisposition to abnormal immune responses that further increases the risk of autoimmune reactions[31]. Despite the contrasting nature of these diseases, some common features have been identified. Risk factors for both MS and SCH include an interaction between genetic and environmental factors[32,33]. Infection is one of the most important triggers for the development of both diseases[34,35]. In the last decade, considerable attention has been paid to the gut microbiome as a possible etiological factor in the pathophysiology of MS and SCH[36]. It has been suggested that the composition of the intestinal flora plays an important role in CNS and immune system development [37]. Dysbiosis of the microbiome has been shown to affect the Th1/Th2 balance and the ratio of regulatory T cells to Th17 cells, which affects the immune response to pathogens[38,39]. Dysbiosis has been found to affect T cell-mediated inflammation in MS and SCH patients[40,41].

In SCH, it has been previously hypothesized that inflammation in the microvasculature persists as chronic, low-grade inflammation and does not disseminate in whole brain parenchyma as in acute encephalitis[21]. This organic substrate could be related to the soft neurological signs, observed in patients with SCH[42]. Similar to SCH, the clinical manifestations in MS may be the result of acute or chronic neuroinflammation. In the acute stage, the peripheral immune system is involved, and T cells, B cells, and macrophages enter into CNS and cause acute inflammation in the brain[21]. In addition, these mechanisms have no influence on the chronic phase. Recently, a concept of "compartmentalization" of the inflammatory process in the brain has been postulated, in which a local immune response in the CNS occurs separately from the peripheral immune system[43]. This hypothesis is supported by the fact that disseminated activation of microglial cells is the primary characteristic of the chronic phase of the illness[44]. There is ample evidence of biomarkers indicating a link between immunological processes, psychotic disorders and MS. Elevated levels of different inflammatory markers have been found in the blood and cerebrospinal fluid (CSF) of patients with psychosis and MS, with particularly high levels in patients with first-episode psychosis or acute relapse[45,46]. Dysregulation of regulatory T cells and Th17 cells may be essential for immunological homeostasis and play a role in the development of both diseases[47,48]. In recent years, much attention has been paid to B cells and their role in the autoimmune pathology of MS and psychosis[49,50]. Oligoclonal bands (OCBs) in CSF have been detected in approximately 90% of patients with MS[51]. In up 12.5% of patients with SCH were found OCBs[45]. It is important to keep in mind that there are other possible triggering and contributing factors besides the specifics of the immune response in MS and psychosis. Within the new concept of nomothetic network psychiatry and causal models, perhaps the identification of these transdiagnostic classes could even be presented as new nosological categories[52].

CLINICAL ASPECTS OF MS AND PSYCHOSIS

In clinical practice, it is important to distinguish whether psychosis precedes the onset of MS, coincides with MS, or is observed in the later stages of this somatic disease. We remind that these psychotic symptoms could be integral to SCH, a schizoaffective disorder, affective disorders, or even delirium. Also, we must point out that psychosis should be considered as a much broader concept than SCH. This information is important for the choice of future MS treatment.

Symptoms and signs of MS include ataxia, loss of coordination, hyperreflexia, spasticity, loss of visual acuity, sphincter incontinence, fatigue, anxiety, depression, and cognitive deficits[53]. Most patients have a relapsing-remitting form of the disease which is characterized by progression of symptoms in

relapse and possible further deterioration over time[53].

Neuropsychiatric symptoms were previously reported as a rare manifestation of MS. Recently, the most commonly observed behavioural disturbances preceding the onset of MS have been summarized. Symptoms described include lack of insight, delusions, auditory and visual hallucinations, mood disturbances, behaviour disorder, and confusion[15]. Psychotic symptoms reported in MS patients also include irritability/agitation, sleep disturbances, grandiosity, blunted affect, and rare symptoms such as catatonia and transient catalepsy[4,14].

In a recent systematic review of case reports and case series, the authors pointed out that psychotic symptoms preceded or accompanied the MS diagnosis in half of the cases, with a mean time to MS diagnosis of 0.8 ± 1.4 years, whereas 15.1% of MS diagnoses were discovered after isolated psychiatric symptoms. They observed a significant delay considering MS treatment initiation between initial psychotic symptoms and MS diagnosis (2.73 ± 3 years), and in patients with the first episode of psychos and MS diagnosis (0.8 ± 1.2 years)[15]. Another important observation in their analysis was that typical MS white matter lesions were found in a small group of patients with psychiatric disorders[54]. Finally, they pointed out that resistance or poor response to antipsychotics was associated with excellent improvement of both psychiatric and neurological symptoms with corticosteroids in most cases[15]. Autoimmune psychosis must be considered as a persistent symptomatology that requires continuous treatment[55].

Pathological changes in white and grey matter structures may play an important role in the pathogenesis of MS-related psychosis. Neuroimaging studies revealed that MS patients with psychotic symptoms have a higher total lesion score, especially in periventricular areas[56]. Psychotic symptoms in MS are correlated with a higher number or volume of lesions in the temporal or frontal lobes, cerebellum, and corpus callosum[57,58]. In addition, the presence of soft neurological signs in patients with sudden or acute psychotic symptoms without a prior personal or family history of psychosis is an indication for neurological exploration[15,59].

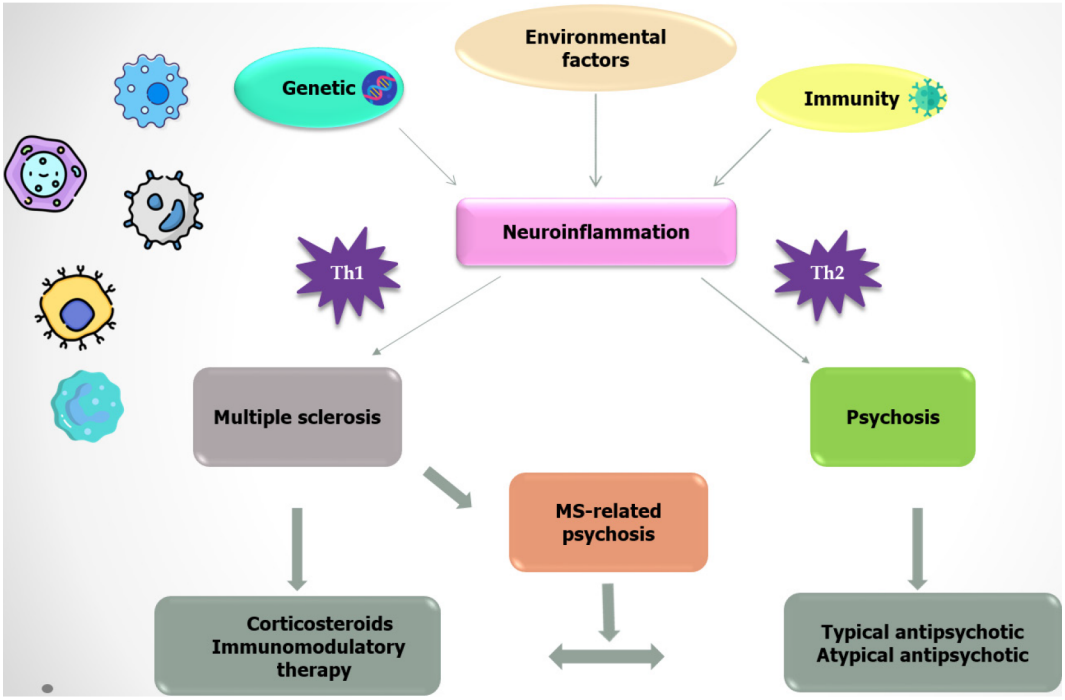
KNOWN FACTS AND TREATMENT CHALLENGES IN MS-RELATED PSYCHOSIS

Immunomodulatory medications for the treatment of MS could be useful to achieve remission of the disease, but in some cases may have a direct effect on the development of psychotic symptoms, although the mechanisms are poorly understood. This effect also occurs after initiation of corticosteroids or could be related with interferon beta (IFN-β) treatment. The study of 11 cases confirmed severe depression with suicidality in patients with MS, who were taking IFN-β and had no psychiatric history [60]. These patients also had phobic, aggressive, behavioural, psychotic, and manic symptoms, indicating the presence of a complex mood-behaviour disorder associated with IFN-β use. Complete remission of psychiatric complications was observed after discontinuation of IFN-β. Glatiramer acetate was generally not associated with deterioration of mood[61]. Gasim *et al*[62] conducted a systematic review to investigate whether the use of disease-modifying therapies is associated with adverse psychiatric effects in MS patients. This study included natalizumab, fingolimod, dimethyl fumarate, teriflunomide, and alemtuzumab and showed that their use do not increase risk of adverse psychiatric effects in MS, and some of them, such as fingolimod, even reduced the incidence of depressive symptoms. In addition, Krivinko *et al*[63] recently demonstrated that fingolimod treatment attenuated psychosis-associated behavioural deficits in rodents.

The standard MS treatment for acute exacerbations is pulse therapy with systemic glucocorticoids. Intravenous methylprednisolone at a dose of 1000 mg/d for 3 or 5 days or oral prednisone with or without tapering dose is usually used[64]. Administration of high-dose corticosteroids (HDC) may be repeated, depending on the MS course and disease activity[65]. Pulsed regimens of corticosteroid administration in the short term in MS have been reported to be well tolerated and safe, with only minor transient and dose- dependent side effects such as palpitations, hot flashes, dyspepsia, insomnia, and virulent taste[65].

An important clinical question is whether the use of corticosteroids, which are regularly used to treat MS relapses, can induce psychiatric symptoms. Several reports suggest that psychiatric side effects may occur with HDC use, including hypomania/mania, depression, psychosis, and suicidal ideation[66-71]. Mood changes, particularly (hypo)mania and depressive symptoms could be potentiated by HDC treatment[72]. In patients with MS, depression and mood disorders have been associated with pulse steroid therapy, suggesting that the risk may be related to the patient's psychiatric history[73].

Steroid-induced psychosis is a well-documented phenomenon[74]. In clinical practice, there are different approaches to corticosteroid treatment for MS-related psychosis. The literature on the treatment of corticosteroid-induced psychosis is very scarce and limited to MS reports and small-sample size studies. In our country, the prevailing opinion is that patients with psychosis should not be treated with corticosteroids because they may exacerbate psychosis. Moreover, nearly 30% of patients in the acute phase of their psychotic symptoms were successfully treated with corticosteroid therapies[75]. The question arises whether it is more beneficial for the patient to keep the psychosis under control or to treat the acute relapse, act on the inflammation, and prevent further disease progression and



neurological disability. The Maudsley guideline indicates that the benefits of corticosteroid therapy may outweigh its adverse effects[76]. To date, however, few studies have explored the impact of corticosteroid therapy on psychosis in people affected by MS, and the specific risk factors predictive of psychiatric changes remain unclear[72,77]. Chronic consumption of corticosteroids and increase in their dose and duration of treatment are associated with these adverse effects[78]. As frequently mentioned, a general therapeutic strategy for corticosteroid-induced psychiatric symptoms should begin with dose reduction or discontinuation of the drug whenever possible[69,79].

Corticosteroid-induced hypomania, mania, and mixed mania showed to be successfully treated with a typical antipsychotic or mood stabilizer, most commonly haloperidol, haloperidol plus lithium, quetiapine, risperidone, olanzapine, olanzapine with valproate, carbamazepine, lithium, lamotrigine plus clonazepam, or clonazepam alone when lithium was ineffective[68]. In some cases, a combination of an antipsychotic and a benzodiazepine was needed[68]. In the case of medication-induced psychosis, adjustment of the MS drug should be considered and treatment with an antipsychotic should be initiated. There are few practical guidelines for the choice of antipsychotic drug and dosage, but there is evidence of good results with the use of clozapine, risperidone, ziprasidone, low-dose chlorpromazine, or the prophylactic use of lithium along with corticosteroid therapy[80]. In patients with steroid-induced psychosis, use of the antipsychotic quetiapine resulted in decreased irritability, reduced psychological distress, and improved sleep[81]. Atypical antipsychotics remain the treatment of choice in these patients because they have a more favourable tolerability profile, as they are less likely to affect the extrapyramidal system and reduce the risk of developing pseudoparkinsonism and catalepsy[82, 83]. Researchers also presumed that patients with MS had an unexpected sensitivity to antipsychotic drugs[84]. MS is closely related to various movement disorders[85]. However, clinicians should be aware that movement disorders can also represent adverse drug reactions caused by chronic antipsychotic therapy[86], especially in cases of polypharmacy.

The anti-inflammatory potential of antipsychotics could be useful and should be considered especially in the treatment of psychosis that coexists with MS. Patients with SCH have been found to have decreased intracortical myelination, whereas certain antipsychotic agents may restore this defect. Patergnani *et al*[87] showed that human and experimental MS induce a mitochondrial deficit leading to activation of autophagy and mycophagy. These phenomena play a causal role in MS as their inhibition by antipsychotic drugs such as haloperidol and clozapine may prevent demyelination, induce remyelination, and reverse MS behavioural deficits[87]. In addition, Stamoula *et al*[88] argued that the atypical antipsychotics clozapine, risperidone, quetiapine, and olanzapine dramatically reduce the severity of experimental autoimmune encephalomyelitis and delay its onset by downregulating the production of pro-inflammatory cytokines and chemokines and attenuating T-cell infiltration, myeloid cell activation, and upregulation of T regulatory cells.

CONCLUSION

Psychotic symptoms could represent an acutisation of MS, considering the specific localization of the lesions. In this context, it can be assumed that causal therapy of MS also leads to resolution of psychosis. It is also important to exclude somatic comorbidities to make the diagnosis of SCH. Autoimmune disorders could precipitate psychotic symptoms, and in this context, special attention should be paid to patients with the first psychotic episode and soft neurological signs, sudden cognitive decline, and unsatisfactory response to antipsychotic treatment. Only when all of the previously mentioned facts have been ruled out can one conclude that psychosis is a separate entity (Figure 1). Physicians treating patients with MS and psychosis should assume, first and foremost, that the psychotic syndromes are related to MS and not triggered by medication. Based on the literature data, it is extremely important for clinicians to perform accurate screening of psychiatric status in patients with MS before initiating HDC treatment and to note that HDC should be used with caution in patients with an acute MS exacerbation. The properties and indications of available immunomodulatory drugs need to be better understood, and the therapeutic approach should be adjusted with careful consideration of the individual's unique constellation of symptoms. The mechanism of action and pharmacokinetics of the antipsychotic drug, the safety and efficacy profile from clinical trials, and knowledge of potential side effects should also be incorporated into the therapeutic strategy.

ORIGINAL ARTICLE

Observational Study

Relationship between perceived social support and post-traumatic growth in coronavirus disease 2019 patients discharged from the hospital

Meltem Şirin Gök, Bahar Çiftçi

Specialty type: Psychiatry

Provenance and peer review: Invited article; Externally peer reviewed.

Peer-review model: Single blind

Peer-review report's scientific quality classification

Grade A (Excellent): 0
Grade B (Very good): B
Grade C (Good): 0
Grade D (Fair): D
Grade E (Poor): 0

P-Reviewer: Hua Z, China; Xie Y, China

Received: December 29, 2022
Peer-review started: December 29, 2022

Abstract

BACKGROUND

The coronavirus disease 2019 (COVID-19) pandemic has affected mental health and physical health negatively in some individuals. Examining perceived social support and post-traumatic growth (PTG) in COVID-19 patients could facilitate our understanding of how patients maintain their mental health.

AIM

To examine the relationship between the level of perceived social support and PTG in COVID-19 patients discharged from the hospital.

METHODS

This descriptive study was carried out between August and September 2022 with patients who were hospitalized due to COVID-19 in a university hospital in Erzurum and who were discharged at least 3 mo prior to the beginning of the study. The study was completed by 196 patients. Study data were collected face-to-face using a personal information form, multidimensional scale of perceived social support and PTG inventory.

RESULTS

The total mean score of the multidimensional scale of perceived social support was 63.82 ± 15.72. The PTG inventory total mean score was 47.77 ± 19.85. In addition, a direct significant correlation was found between perceived social support in COVID-19 patients and PTG.

CONCLUSION

The study results showed that perceived social support variables affected PTG

significantly. Therefore, it is recommended for healthcare professionals to implement interventions to promote social support from healthcare professionals and the patient's family and friends. Considering the negative effects of the ongoing COVID-19 pandemic, it is very important and necessary to implement effective public health interventions to promote PTG to reduce mental health problems.

Key Words: COVID-19 patients; Perceived social support; Post-traumatic growth; COVID-19

Core tip: Since post-traumatic growth (PTG) includes development at the level of psychosocial functionality, it can contribute to personal development by positively affecting psychological and social factors after traumatic events. Social support positively affects an individual's mental health and PTG. The results of this study remarkably showed that there is a significant relationship between perceived social support and PTG. More studies are needed to confirm this observation.

INTRODUCTION

The symptoms are variable in individuals diagnosed with coronavirus disease 2019 (COVID-19). Some individuals were asymptomatic, while the disease may progress from mild pneumonia to severe and fatal acute respiratory failure[1]. This disease affects the physical, psychological and social well-being of individuals[2]. Fear of death, hospitalization in the intensive care unit, endotracheal intubation, pain, limited communication, environmental stress, insomnia, impaired comfort, quarantine measures, feeling of loneliness, loss of control and stigmatization are among the different stressors of the COVID-19 pandemic[3]. A diagnosis of COVID-19 and hospitalization are considered the greatest of these stressors and accepted as a traumatic life experience[4]. While traumatic events cause serious mental problems such as anxiety, depression and post-traumatic stress disorder in some individuals[5], they may result in post-traumatic growth (PTG) in some[6]. PTG is defined as positive psychological changes as a result of a major life crisis or struggle with a traumatic event[7]. These changes occur in areas of improved interpersonal relationships, new opportunities, a greater sense of personal power, a greater appreciation of life and spiritual change[7].

The rapid increase in the number of COVID-19 cases and deaths has been reported to cause stress, fear, anxiety and depression in many people[8]. However, as individuals try to understand negative experiences and adapt to difficulties, positive reactions may also occur[9]. After the diagnosis of a severe disease, most survivors experience various positive changes that reflect useful psychological adaptation and positive personal development processes that enable them to better cope with the disease[7]. In a qualitative study, it was found that patients with severe COVID-19 showed negative emotional reactions in the early periods of the disease, while the disease resulted in psychological growth over time. The patients met the problems gratefully by cherishing their lives and their families[3]. Since PTG includes development at a psychosocial functionality level, it may contribute to personal development by positively affecting psychological and social factors after traumatic events[10]. In this context, social support is a source of resilience that positively affects individual mental health and facilitates PTG[11-13].

Measures taken during the COVID-19 pandemic, such as quarantine and social distancing, have led to differentiation in many areas of life. For this reason, individuals could not socialize at desired levels, and they faced problems such as social isolation and loneliness[14]. Similarly, in one study, social support was determined to be a psychological factor that made patients stronger[3]. Social support often refers to the care or support individuals receive from others or the feeling of belonging to a social network that provides mutual help[13]. To date social support has been broadly construed in two ways: perceived social support and received social support[15]. Perceived social support concerns the subjective evaluation of how individuals perceive friends and family members as available to provide material, psychological and overall support during times of need, whereas received support relates to the actual quantity of support received. This distinction between these two types of support is important for two reasons[15].

Social support in the face of stress can act in two different ways. In the buffer effect model, it is reported that social support reduces or balances the damaging effects of stress on physical and mental health as a buffer, especially in protecting physical and psychological health of people who are exposed to stressful experiences. In the basic impact model, social support has an effect independent of the level of stress, and there is a direct relationship between social support and health[16]. According to this approach, social support can increase life satisfaction and prevent or reduce stressful life events by providing a sense of belonging. Thus, with this effect of social support, the person experiences fewer physical and psychological problems[17]. Looking at the models that explain the relationship between psychological problems and social support, it is emphasized in the social causality model that lack of social support causes psychological symptoms. According to the social choice model, the individual's psychological symptoms cause the sources of social support to change. Finally, in the mutual effect model, while social support is effective on psychological well-being, the psychological state of the individual is also effective on accessing adequate social support. In other words, there is a bidirectional relationship between social support and psychological symptoms[18].

During COVID-19 treatment, the importance of psychosocial intervention is emphasized in both recovery and reducing psychological problems[13]. Studies conducted have reported that social support has an effect on improving psychological problems[12]. Psychological effects of contagious diseases may continue or develop over time. It has been found that individuals with high social support perception have fewer negative psychological consequences[11]. Social support is thought to be important for mental health in the post-discharge follow-up of COVID-19 survivors. Nurses, who are continuous interacting with patients, have important responsibilities in identifying traumatized individuals, increasing the support they need and empowering them in this process. Since the COVID-19 pandemic has negatively affected mental health and physical health, examining PTG and social support in COVID-19 patients will facilitate our understanding of how patients protect their mental health[19].

On the other hand, it is widely believed that high perceived social support predicts high PTG[15,20,21]. Given that several studies have reported that people often feel isolated and alienated and have difficulty accessing social support when diagnosed with COVID-19[22], there is a need to further clarify the role of perceived social support within PTG during COVID-19. In light of all this information, the aim of this study was to examine the relationship between the level of perceived social support and PTG in COVID-19 patients discharged from the hospital.

Research questions

What are the perceived social support levels of COVID-19 patients discharged from the hospital?

What are the PTG levels of COVID-19 patients discharged from the hospital?

Is there a relationship between perceived social support and PTG in COVID-19 patients discharged from the hospital?

MATERIALS AND METHODS

Study design

This study was conducted with a descriptive and a cross-sectional design.

Place and time of the study

The study was conducted at Atatürk University Research Hospital between August 2022 and September 2022.

Population and sample of the study

The population of the study consisted of patients who were discharged after receiving COVID-19 treatment at Atatürk University Research Hospital. Before starting the study, a sufficient number of sample was calculated for correlation analysis with the G Power 3.1.9.7. Package program. Since no similar study was found in the literature, priori power analysis was performed based on a moderate effect size (0.3). In the power analysis based on alpha of 0.05 and power of 0.99, it was determined that the sample size should be 195. For this reason, the study was completed with 196 patients.

Inclusion criteria

(1) Patients who were treated in the hospital with a diagnosis of COVID-19 and who had been discharged at least 3 mo prior to study enrollment; (2) Patients older than 18 years of age; and (3) Patients who did not have cognitive disabilities.

Data collection tools

Study data were collected by using a personal information form, multidimensional scale of perceived social support and PTG inventory.

Personal information form: This form was prepared by the researchers to find out the demographic characteristics of discharged COVID-19 patients and COVID-19-related characteristics. This form consisted of questions such as age, sex, educational status, marital status, number of children and level of income.

Multidimensional scale of perceived social support: The scale was developed by Zimet *et al*[23]. A Turkish validity and reliability study of the scale was conducted by Eker *et al*[24]. The scale is a 7-point Likert type self-report consisting of 12 items and 3 subscales. The subscales are family support, friend support and significant other support. Each item is evaluated between 1 and 7. The minimum possible score from the scale is 12, while the maximum possible score is 84. A higher score means higher perceived social support. Internal consistency of the scale is between 0.80 and 0.95 for the total scale and the subscales[24]. Cronbach's alpha value was 0.93 for the present study.

PTG inventory: The inventory was developed by Tedeschi *et al*[5]. The scale consists of a total of 21 items and 5 factors. The scale factors are improved relationships, new possibilities, personal strength, spiritual growth and appreciation for life. Internal consistency coefficient of the original scale is 0.90, while internal consistency coefficients of the factors vary between 0.67 and 0.85[5]. PTG inventory was adapted into Turkish by Dürü *et al*[25]. The scale is a 6-point Likert type scale. Scoring system is between 0 (I did not experience this change) and 5 (I experienced this change to a very great degree). It was stated in the Turkish adaptation that the 5-factor structure was preserved, and this structure explained 67.84% of the total variance. Score range of the scale is between 0 and 105. Higher scores from the scale mean higher PTG. Cronbach's alpha was 0.93 in the Turkish adaptation study[25]. Cronbach's alpha was 0.94 in the present study.

Data collection

Study data were collected with the face-to-face interview technique. After the purpose of the study was explained, the questions in the data collection tools were asked one by one, and the answers of the patients were recorded. Data collection lasted approximately 15 min for 1 patient. Consent was given by the patient prior to data collection.

Data assessment

Data analysis was performed using SPSS version 22.0. Frequency, percentage, mean and standard deviation measurement were used for descriptive statistics. Normality distribution of the data was analyzed with skewness and kurtosis coefficients. Pearson's correlation analysis was used for the examination of the comparison between the two scales. Cronbach's alpha was evaluated to test the reliability of the scales. A P value of 0.05 was considered statistically significant. Post-traumatic effect of perceived social support was analyzed with a simple linear regression analysis.

Ethical considerations

Ethical approval was obtained from the Ethics Committee of Atatürk University Faculty of Medicine to conduct the study. Written institutional permission was also obtained from Atatürk University Research Hospital for data collection. Oral and written informed consent was obtained from the patients.

Limitations of the study

The first limitation of the study was the collection of data with self-report scales. Another limitation was that PTG symptoms were not evaluated by a mental health professional but by the self-reports of the patient. Since the results depended on data collected from COVID-19 patients discharged in the Eastern Anatolia region of Turkey, it is not suitable for the results to be generalized to COVID-19 patients from other regions.

RESULTS

Mean age of the patients was 50.05 ± 19.19. It was found that 57.1% of the patients were male, 73.0% were married, 75.0% had children, 66.8% had nuclear family, 60.7% lived in a city center, and 59.2% were primary education graduates. It was found that 45.9% of the patients were unemployed and 57.7% had income equal to expenditure. It was found that 70.4% of the patients were treated in the COVID-19 clinic, treatment lasted for an average of 13.22 ± 10.46 d, 52.6% received oxygen therapy, and an average of 12.67 ± 5.93 mo passed after being discharged. We observed that 63.3% of the patients did not have a chronic disease, and 78.1% were not hospitalized for any other reason after discharge from COVID-19. In addition, it was found that 55.6% of the patients lost a close friend due to COVID-19, 93.3% did not receive psychological help from any expert due to COVID-19, and 87.2% had been vaccinated for COVID-19 (Table 1).

[2]Housewife and those who do not work in another job.
COVID-19: Coronavirus disease 2019.

The total mean score of the multidimensional scale of perceived social support was 63.82 ± 15.72. The mean subscale scores of the multidimensional scale of perceived social support were 20.22 ± 6.27 for family support, 20.85 ± 5.80 for friend support and 22.74 ± 4.71 for significant other support.

PTG growth inventory total mean score was 47.77 ± 19.85. When the factors were examined, the mean scores were 13.87 ± 5.57 for improved relationships, 8.52 ± 3.82 for new possibilities, 8.81 ± 4.71 for personal strength, 9.20 ± 4.35 for spiritual growth and 7.34 ± 3.43 for appreciation for life (Table 2).

A weak, yet significant, positive correlation was found between family support and improved relationships, new possibilities, personal strength and total PTG scale ($P < 0.05$). In the significant other subscale of perceived social support, no significant correlation was found between total PTG scale and subfactors ($P > 0.05$). A weak, yet significant, positive correlation was found between perceived social support total score of the patients and improved relationships, new possibilities, personal strength and total PTG scale ($P < 0.05$) (Table 3). According to the results of the simple linear regression analysis, it was found that perceived social support significantly and positively predicted the PTG levels of the discharged COVID-19 patients (β = 0.159, $P < 0.05$). According to the model, perceived social support explained 2.5% of the total variance in PTG ($R^2 = 0.025$ F = 5.026, $P < 0.05$) (Table 4).

DISCUSSION

In this study, which examined the relationship between the perceived social support level of COVID-19 patients discharged from the hospital and PTG, it can be seen that the patients had a good level (63.82 ± 15.72) of perceived social support (between 12 and 84) (Table 2). Social support was defined as the support available to the individual through social relationships with others. Social support from health professionals and health institutions is an effective factor in this regard[26]. A study by Moodi *et al*[27] showed that patients' perceived social support scores were high. Zhang *et al*[28] found increased support from friends and family during the COVID-19 outbreak. Thompson *et al*[29] found that social support increased in discharged COVID-19 patients. In the study of Kandeğer *et al*[30], COVID-19 patients were found to have high perceived social support. Alnazly *et al*[31] concluded that patients had high social support levels.

Health personnel became an important source of support for patients due to lack of direct communication between the patient and family members during their hospitalization. In addition to the support of family members, patients also receive support, such as education and counselling, from the health system. All these services may have played an important role in the formation of perceived social support. Increased perceived social support may subsequently positively influence PTG. Positive developments during the pandemic, such as the development and dissemination of the vaccine, may have helped to eliminate the negative emotions of COVID-19 patients and to create positive coping styles of the patients.

Table 2 Multidimensional scale of perceived social support and post-traumatic growth scale sub-scale and mean, minimum and maximum values of total score averages

Scales	Minimum and maximum scores that can be obtained from the scale	Minimum and maximum scores taken from the scale	mean ± SD
MSPSS			
Family support	4-28	4-28	20.22 ± 6.27
Friend support	4-28	7-28	20.85 ± 5.80

In this study, it was found that the individuals had moderate (47.77 ± 19.85) PTG (between 0 and 105) (Table 2). Although there are few studies on PTG in COVID-19 patients who have survived after admission to the intensive care unit, these results are in line with previous studies. Therefore, the present study showed that PTG may be important in patients treated in an intensive care unit for COVID-19. In another study, it was found that patients hospitalized in the intensive care unit with a

COVID-19 diagnosis experienced PTG close to a moderate level after treatment[32]. In a study conducted on discharged COVID-19 patients, Thompson *et al*[29] showed moderate PTG. The most important step for post-traumatic development is that individuals do not see themselves as trauma victims but as post-traumatic survivors. Tedeschi *et al*[5] suggested that initial stress is induced by traumatic events, which encourages individuals to challenge and rebuild (existing) schemas and assumptions, which then results in positive changes. However, one of the important points is that the evaluation of PTG symptoms by the patient's own reports, not by a mental health professional, may have affected this result. For this reason, the importance of the findings of this study will be emphasized, and the evaluation of the patient by both their own PTG and mental health experts will strengthen the results.

According to Tedeschi *et al*[5], social support plays an important role in the transition from trauma to growth since it activates the cognitive processes that support PTG. It can be especially valuable for COVID-19 patients to have the opportunity to express themselves in a supportive environment and to get help in any adversity they experience. Social support is associated with better physical and psychological health. The correlation between patients' perceived social support and PTG and the factors of improved relationships, new possibilities and personal strength was found to be positive but weak (Table 3). In the study by Gökahmetoğlu *et al*[33], no correlation was found between perceived social support and PTG. In a study conducted by Hill *et al*[34] on cancer patients, it was concluded that social support was not a predictive variable in PTG. In a study conducted on patients with different traumatic experiences, Dürü *et al*[25] found that social support did not have an effect on PTG.

On the other hand, perceived social support and PTG were found to be positively correlated in our study. In the study by Sun *et al*[3], it was stated that during quarantine periods individuals benefited from the emotional support they received from their families as well as the support provided by their colleagues and neighbors. Similarly, in a study conducted with individuals diagnosed with COVID-19 and discharged in China, it was determined that social support systems were positively related to PTG [29]. In a study examining the quarantine experiences of COVID-19 patients, it was stated that the social support patients received from their families and friends made a significant contribution to coping with negative emotions[35]. In a study by Lohiniva *et al*[36], some patients mentioned some positive developments such as feeling closer to their spouses and spending more time as a family during the quarantine period. A high level of perceived social support affects the individual's ability to provide a sense of having a safe environment, to emphasize their sense of belonging, to act as a buffer against stress, to provide new meanings and to create more positive perceptions that support growth. While perceived social support facilitates adaptation to cognitive processes, it also supports individuals to effectively manage coping strategies in identifying positive situations for their personal development.

Being diagnosed with COVID-19, physical symptoms caused by the disease and quarantine practices can cause many changes in individuals, especially spiritually. It is thought that the uncertainty about the disease and the treatment process, the fact that the disease can be fatal and the restrictions on daily life cause personal changes in individuals. Especially in this process, it has been observed that individuals experience many personal changes such as changes in life philosophy and perspective, changes in life priorities, strengthening in self-perception and appreciating and being grateful for what they have. It is thought that the differences between study results are due to the scales used, inclusion criteria and the way individuals perceive and evaluate social support. This positive change experienced by individuals may have led them to emerge stronger from the crisis created by the pandemic. Findings showed that increasing perceived social support can contribute to PTG.

Another remarkable finding is that the most significant growth in PTG was in the spiritual subdimension (Table 2). A sample of parents in Portugal during the pandemic found high rates of PTG, particularly in the areas of appreciation for life and improved relationships[37]. In the study by Liu *et al* [38], some patients stated that COVID-19 supported their personal development and motivation for a better life in the future. It is thought that this difference is due to Turkish culture, religious differences and customs. In this context, COVID-19 diagnosis may cause an individual change and empowerment in patients. In the present study, it was suggested that patients' life priorities and philosophies have changed and that they will prioritize their health.

CONCLUSION

In the present study, which examined the relationship between perceived social support level of COVID-19 patients discharged from the hospital and PTG, it was found that patients had a good level of perceived social support and a moderate level of PTG. A significant correlation was also shown between perceived social support of the patients and PTG. Since there are few studies examining the relationship between these variables in the literature, it is important to conduct more studies to confirm these findings. It may be useful to repeat the research with larger samples. Prospective and longitudinal studies are recommended to further confirm the versatility of the findings and to elucidate the factors influencing PTG. Since these findings include subjective evaluations of patients, it is recommended to plan new studies in which the results are also evaluated objectively by mental health professionals.

Relevance for clinical practice

It is known that a large number of people have been affected by the COVID-19 pandemic, especially patients in the intensive care unit. The high impact of the traumatic event, although at least 3 mo have passed after being discharged from the intensive care unit due to COVID-19, may be associated with the continuation of the pandemic process and the increase in the number of patients. Therefore, considering the adverse mental health impacts of the ongoing COVID-19 pandemic, it is crucial to implement effective public health interventions to promote PTG and reduce mental health issues.

ARTICLE HIGHLIGHTS

Research background

The coronavirus disease 2019 (COVID-19) pandemic has affected the mental health of individuals. There is a controversial relationship between perceived social support and post-traumatic growth (PTG).

Research motivation

There are few studies that show the relationship between perceived social support and PTG in COVID-19 patients.

Research objectives

To examine the relationship between the level of social support perceived and PTG.

Research methods

This descriptive study was carried out between August and September 2022 with patients who were hospitalized due to COVID-19 and who were discharged at least 3 mo prior to the beginning of the study. The study was completed by 196 patients. Study data were collected face-to-face using a personal information form, multidimensional scale of perceived social support and PTG inventory.

Research results

It was found that patients had a good level of perceived social support and a moderate level of PTG.

Research conclusions

Perceived social support positively affects PTG.

Research perspectives

Further research is needed to confirm these results. In the future, mental health specialists should evaluate individuals for PTG.

ACKNOWLEDGEMENTS

We thank the participant for taking part in the study.

Abstract

BACKGROUND

Physical exercise is an underutilized tool for the management of mental disorders. New technologies have made a breakthrough in health care, and one of its possible applications (apps) could be that of customizing exercise programs for special populations, such as patients with mental disorders. However, the app of the so-called e-health to mental health care is still limited.

AIM

To know the efficacy of apps to promote physical activity in patients with mental disorders.

METHODS

We conducted a systematic review of the PubMed and Embase databases with the aim of exploring the use of new technologies for the enhancement of physical exercise in patients with a psychiatric illness. Following the selection process, 10 articles were included in the review.

RESULTS

The most commonly used devices in this type of intervention are wearable devices and web platforms. Good results in terms of effectiveness and acceptability were obtained in most of the studies.

CONCLUSION

Our findings suggest that the use of new technologies in mental health represents a feasible strategy with great potential in clinical practice.

Key Words: e-health; m-health; Physical exercise; Mobile applications; Wearable device

Core Tip: Physical exercise is an underutilized tool for the management of mental disorders. New technologies have made a breakthrough in health care, and one of its possible applications (apps) could be that of customizing exercise programs for special populations, such as patients with mental disorders. Apps that aim to improve and increase physical activity in patients diagnosed with the disease have shown good results in terms of efficacy and acceptability, so they should be known by clinicians in order to offer them to patients who meet a good profile.

INTRODUCTION

Mental illness is one of the major global public health problems[1]. People with severe mental disorders are in poorer health, with more cardiovascular risk factors and high morbidity and mortality rates. Factors associated with this poorer health status include a greater tendency to lead a sedentary lifestyle and high comorbidity with chronic physical illnesses[2-4]. Furthermore, mental disorders often do not access the health care they require and, even when they do, treatment is often inadequate[5].

The relationship between physical health and mental illness can also be harnessed to our advantage and contribute to closing the gap in the treatment of these disorders: Numerous studies show the benefits of physical exercise on mental state[6-14]. In a recent population-based survey in Spain, physical exercise was inversely associated with major depressive disorder (MDD), irrespective of body mass index[6]. Several studies have investigated the therapeutic potential of physical exercise in other mental disorders such as anxiety, post-traumatic stress disorder, or even psychotic disorders[7-12]. Finally, several randomised clinical trials agree on the antidepressant effect of physical exercise[13,14].

However, it is difficult to inculcate physical exercise habits in people with psychiatric symptoms, especially in the acute phases of the illness. New technologies can make this task easier. Digital medicine, also called e-health, is opening new horizons in the management of a multitude of diseases, including MDD[15]. The enhancement of physical activity is one of the most exploited functions by this type of technology that is based on applications (apps) and software programmes managed through various platforms, such as websites, wearable devices, smartphones, or social networks. Some of these devices have sensors that allow continuous measurement of physical activity, mainly through accelerometers[16].

Physical activity promotion programmes show better results when they take into account the particularities of each population. Apps and other electronic interventions therefore have been designed for focusing on promoting physical activity in different patient populations, such as people with diabetes or cancer[17,18]. However, the role played by digital medicine in the management of mental illness is more limited, despite the fact that these populations could benefit from the advantages of new technologies. Several studies demonstrate the interest shown by psychiatric patients in the use of mobile technology to improve their mental health[15,19-21]. It is therefore crucial that the large offer available on the digital market is screened by clinicians and researchers.

Nursing professionals have sown a prominent interest in e-health interventions and can play a key role in the app of new technologies to mental health care, as they are often the closest link to the patient [22]. For example, patients often prefer to ask nurses for advice on mobile apps they can use[23]. The continuous development of new technologies, however, is progressing significantly faster than the research conducted to empirically test these advances[24]. A review of the evidence on these tools is crucial to provide the best evidence-based knowledge conducive to good use of this technology. The aim of this paper is to systematically review the available evidence on mobile apps for physical activity enhancement in patients with mental illness.

MATERIALS AND METHODS

Registration

This systematic review was conducted in accordance with the Preferred Items for Reporting of Systematic Reviews and Meta-Analyses recommendations[25]. The protocol for this systematic review was registered in the PROSPERO database (registration number: CRD42021242258).

Search strategy

We conducted a systematic literature search in the PubMed and Embase databases to identify studies on e-health interventions for the enhancement of physical activity in people with mental illness. The concept of "enhancement" encompassed both the outcomes of increased physical activity and the results obtained because of this activity (such as weight loss or improvement in other health parameters).

The inclusion criteria were as follows: (1) Original articles; (2) Published in the last ten years 10 years (November 15, 2012 to November 15, 2022); (3) Peer-reviewed journals; (4) Language: English or Spanish; (5) Exploring mobile apps for physical activity promotion in individuals with mental illness; (6) Adult population; and (7) Providing measurable outcomes, either in terms of effectiveness or feasibility.

The search terms used in PubMed were as follows: (physical[Title/Abstract] OR exercise[Title/Abstract]) AND (psychiatr*[Title/Abstract] OR mental disorder*[Title/Abstract] OR mental illness*[Title/Abstract] OR schizophreni*[Title/Abstract] OR anxiety[Title/Abstract] OR bipolar[Title/Abstract] OR depressi*[Title/Abstract]) AND (phone[Title/Abstract] OR device[Title/Abstract] OR app[Title/Abstract] OR web[Title/Abstract] OR social media[Title/Abstract] OR virtual reality[Title/Abstract] OR new technologies[Title/Abstract] OR digital[Title/Abstract] OR e-health[Title/Abstract] OR m-health[Title/Abstract]).

A similar search strategy was employed for the Embase database, such as: "(physical OR exercise) AND (psychiatr* OR mental disorder* OR mental illness* OR schizophreni* OR anxiety OR bipolar OR depressi*) AND (phone OR device OR app OR web OR social media OR virtual reality OR new technologies OR digital OR e-health OR m-health)".

Selection and extraction process

Two researchers (Guerrero-Jiménez M and Ruiz M) independently analysed the eligibility of the studies. Critical appraisal tools checklists were used to assess the quality of the articles[26]. When there was no agreement between the reviewers, the decision rested with the senior investigator. The variables of interest collected from the articles were: (1) Scientific content and technical characteristics of the apps; (2) Effectiveness; (3) Acceptability (level of approval by users); (4) Level of satisfaction; and (5) Outcome measures.

Quality assessment

Two reviewers (Guerrero-Jiménez M and Ruiz M) assessed independently the quality of the articles (this is described in Supplementary Table 1). Discrepancies between reviewers were resolved by discussing and reaching a consensus. We assessed several aspects, including methodological design, risk of bias, and reporting quality. For randomized clinical trials, Cochrane Collaboration's tool for assessing risk of bias was used.

RESULTS

Figure 1 shows the flow chart of the literature search. The initial search yielded 6257 results (PubMed = 5970; EMBASE = 302) of which 9 were finally included in the review, characteristics and main findings of the studies are recorded (Table 1)[27-35]. With the exception of two studies[28,34], the reviewed articles worked with sample sizes of less than 50 participants. All studies had positive results following intervention with mobile technologies. Acceptability was generally high, as was participation in the studies. The different studies reviewed can be divided according to the intervention tool used. Our review includes about 400 participants with different psychiatric illness as bipolar disorder and MDD.

Mobile apps

The pilot study by Macias *et al*[30] found that the use of the app promoted longer walks in obese patients with mental illness, in addition to obtaining good adherence and user satisfaction with the platform (Table 2).

Wearables

Studies such as those by Macias *et al*[30] and Naslund *et al*[31] or Aschbrenner *et al*[27] used wearables in the intervention with patients with mental illness, obtaining positive results in weight loss, and in one of the studies, improvement in physical condition.

Table 1 Characteristics and main findings of the studies

Ref.	Device	Features	Design	Sample	Measures and scales	Main findings
Aschbrenner *et al*[27], 2016	Wearable device (Fitbit Zip)	Accelerometer, step and distance registration	Pilot study pre-post	13 patients with overweight and psychiatric disorders	Satisfaction questionnaire 6-MWT; weight (kg)	At 6 mo 45% of the participants were underweight and 45% improved their physical condition
Haller *et al* [28], 2018	Internet platform	Heart rate monitor and resistance bands	RCT	20 patients with MDD (moderate and severe)	Depression scales: (1) QIDS; (2) Self-efficacy, quality of life and physical activity; and (3) General health status SF-36	Feasible and effective in patients with moderate to severe depressive symptoms, improving quality of life and decreasing depressive symptoms
Lambert *et al* [29], 2018	eMotion (Web)	Accelerometer. Weekly module course. Interactive worksheets	RCT	62 patients with at least moderate depressive symptoms and anxiety	PHQ-8. Vigorous physical activity	Depression levels were lower in the intervention group than in the control group
Macias *et al* [30], 2015	WellWave	Digital library with readings, personal messages and a variety of activities	Pilot study	10 patients with obesity and mental illness (schizophrenia, MDD or BD)	Self-assessments. Number of steps and walking time	Seven of the ten participants increased the number and duration of weekly walks. High app participation
Naslund *et al* [31], 2016	Wearable device (Fitbit Zip)	Accelerometer. Podometer. Progress Log	Prospective	34 patients with psychiatric disorders (various diagnoses)	Weight (kg). 6-MWT	Higher average daily steps were associated with greater weight loss
Naslund *et al* [32], 2016	Wearable device (Fitbit Zip)	Accelerometer. Podometer. Progress Log	Exploratory study	11 patients with severe mental illness and obesity	Quantitative usability and satisfaction questionnaire. Interviews	The use of the app motivates participants to engage in physical exercise
Naslund *et al* [33], 2018	Facebook	Messages, posting of posts, photos	Exploratory study	25 patients with mental illness (MDD, BD and schizophrenia, obesity under pharmacological treatment)	FB Interactions. 6-MWT. Weekly group attendance	Participants who actively contributed to the Facebook group have a higher weight loss
Pfirrmann *et al*[34], 2018	Web	Forum, psychoeducation	Analysis of four clinical trials	5 participants with oesophageal carcinoma, 5 with liver disease, 5 with MDD and 5 with cystic fibrosis	-	Efficacy as an exercise enhancer in all pathologies
Young and Morgan[35], 2018	SHED-IT	Measuring tape, pedometer	Pre-post study	209 male patients with overweight and depressive symptoms	PHQ-8. Weight (kg)	Reduction of weight and depressive symptoms, with a high level of engagement and satisfaction

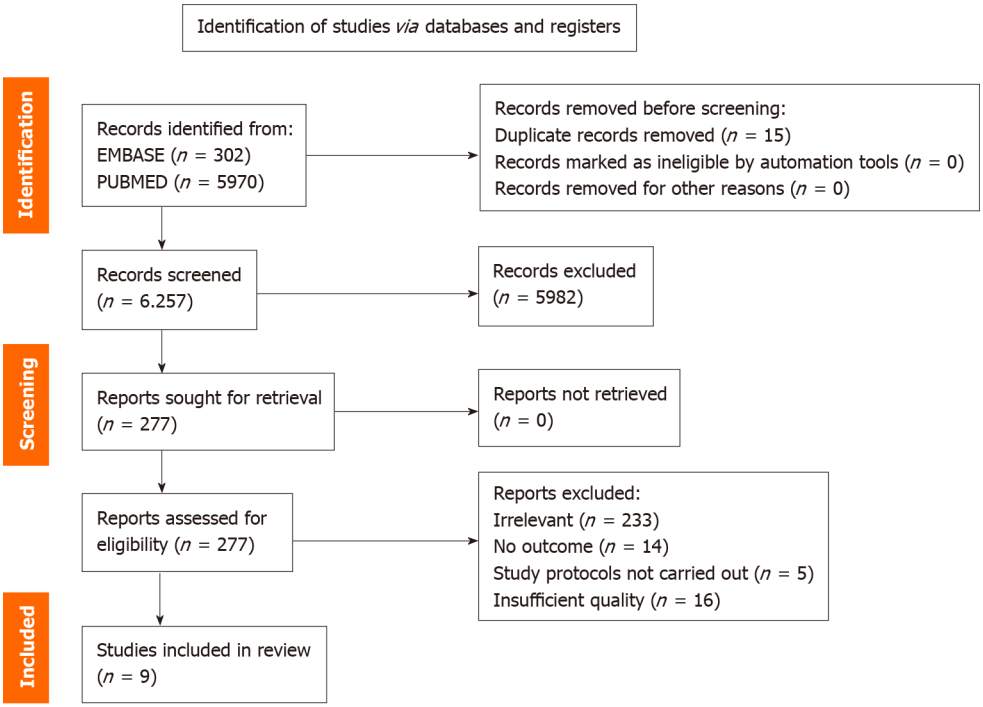
6-MWT: 6-minute walk test; BD: Bipolar disorder; FB: Facebook; MDD: Major depressive disorder; MINI: Mini international neuropsychiatric interview; PANSS: Positive and negative syndrome scale; SCID: Structured clinical interview for axis-I DSM-IV disorders; RCT: Randomized controlled trial; PHQ: Patient health questionnaire.

Social networks

Naslund *et al*[32] explored the use of the social network Facebook in intervention with patients diagnosed with mental illness and obesity. They found that the use of this social platform prompted patients to greater motivation for weight loss, with participants with the highest number of interactions having lost the most weight.

Other digital interventions

Other studies used web-based platforms, where their effectiveness was observed, both in various pathologies[33] and in the reduction of depressive symptomatology, which was greater in the intervention group compared to the control group[28].



DISCUSSION

However, most of the studies focus their interventions on pathologies other than mental health, which is

Table 2 User satisfaction with the different device

Ref.	Device	Positive	Negative	Suggested improvements
Macias *et al*[30], 2015	WellWave	Personal messages, reading library	-	Test whether learning how to use the app can increase personal satisfaction
Naslund *et al* [31], 2016	Wearable device	Self-monitoring	Difficulties of use	Make tutorials on the use of the device
Naslund *et al* [32], 2016	Wearable device	Self-monitoring	Difficulties of use	Make tutorials on the use of the device. Participants are satisfied with the use of the app
Aschbrenner *et al* [27], 2016	Wearabledevice	Self-monitoring	Difficulties of use	Make tutorials on the use of the device before. High level of satisfaction
Haller *et al*[28], 2018	Web platform	Easy to use, self-monitoring	Does not include follow-up	Include monitoring as web-based apps show a trend towards non-use over time. Show a trend towards non-use over time
Lambert *et al*[29], 2018	eMotion	Self-monitoring	Not assessed	Not assessed
Naslund *et al* [33], 2018	Facebook	Accessibility, facilitates communication between people in the same condition. Allows information sharing and feedback	Not assessed	Not assessed
Pfirrmann *et al* [34], 2018	Web	Forum. Unspecific information	Not assessed	Not assessed
Young and Morgan[35], 2018	SHED-IT	Self-monitoring	Not assessed	Longer-term programme of longer duration

apps: Applications.

Figure 1 Flow chart of the literature search.

why, despite the large amount of literature published on the subject, only 9 studies were conducted on the population to be studied and included in this review[27-35].

Discussion of effectiveness

Our findings suggest that physical exercise may be a useful tool in the management of mental disorders, and that the delivery of these interventions through e-health platforms may increase adherence and accessibility to treatment. The therapeutic effect of physical exercise can be explained by several

mechanisms. Physical activity may have neuroregenerative properties and increase brain-derived neurotrophic factor (BDNF)[36,37] although a recent meta-analysis did not find that physical exercise significantly increased BDNF in patients with depression[38].

The immune system may also be involved in this association. Inflammatory pathways are thought to play a key role in the neurobiological basis of mental illnesses such as MDD, which would explain the bidirectional association that has been found between certain mental illnesses and inflammation[39,40]. Exercise has been shown to have anti-inflammatory properties[41], and this reduction in inflammation and oxidative stress may explain the beneficial effects of exercise on mental health. This effect may be mediated by changes in the neuroimmune system, such as induction of the release of interleukin-10 and other anti-inflammatory cytokines[42,43].

Comparisons with prior reviews

Many barriers to the adoption of e-health in clinical practice remain despite the great potential of new technologies. Qualitative survey results of investigation involving patients and professionals provide some insight into the challenges that remain to be overcome for the adoption of e-health[44]. While patients appear open to using e-health, their interest differs from actual use. A 2019 survey of veterans with depression found that while 73.1% of them were interested in mental health apps, only 10.7% actually used any of them[45].

Among the most important barriers is precisely the lack of integration in public health systems, which leads to mistrust between users and professionals. In this respect, the United Kingdom is a pioneer in trying to integrate new technologies into its healthcare system[46]. Another barrier is the concern for privacy when using tools with internet access, as there is a risk of dissemination of highly sensitive data [47,48]. The absence of privacy policies is a frequent drawback when creating and using apps. Privacy is an issue of concern to users, and one of the main features they value in this type of media is that there is a method of protecting sensitive information by passwords, for example[49].

Mental disorder may act as a barrier in itself, as shown by a study in which veterans with posttraumatic stress disorder (PTSD), despite demanding more mental health services, were less willing to participate in mental health apps than their peers without PTSD[50]. The lack of confidence of medical professionals themselves in the reliability of e-health interventions sometimes slows down the adoption of mental health in clinical practice. In addition, there is a markedly smaller number of studies evaluating these interventions than the number of devices and apps available on the market[51]. Users often seek advice from their healthcare professionals, such as doctors or nurses. Training doctors, nurses and other healthcare professionals in the use of new technologies is therefore a crucial element in accelerating the adoption of these interventions in clinical practice[52,53].

CONCLUSION

Digital medicine represents a tool of great potential in clinical practice. Thanks to their great versatility and acceptance among users, new technologies can open up new fields in mental health care. In the specific case of physical exercise enhancement in mental health patients, new technologies can facilitate adherence to exercise programmes and increase their personalization. However, there are still wide-ranging barriers to the adoption of these interventions on a day-to-day basis. One of the steps needed to advance research is the development of new apps and tools, and their testing in exploratory articles with larger sample sizes.

Another of the fronts to be explored is the field known as machine learning. From the huge amount of data that these devices can collect, we can detect behavioural patterns characteristic of each person and thus optimise interventions to individual needs. This is a step towards participatory medicine, a paradigm shift that has been pursued for years[53], in which the integration of multidisciplinary treatment teams would also be an important point.

ARTICLE HIGHLIGHTS

Research background

Mobile applications (apps) have proven to be very useful in improving physical health in numerous medical illnesses.

Research motivation

We want to know if apps have proven to be useful in patients with mental illness.

Research objectives

The main objective of the present systematic review is to know the efficacy of apps to increase physical

activity in patients suffering from mental illness.

Research methods

We have carried out a systematic review, following the Preferred Items for Reporting of Systematic Reviews and Meta-Analyses recommendations, of the last 10 years, selecting articles that have studied the efficacy of apps in increasing physical activity in patients with mental illness. The quality of the selected studies was also analyzed.

Research results

From 6257 initial articles we included finally 9 articles that met the criteria for inclusion. We resume the principal studies that have showed an improvement in reduction of weight and depressive symptoms and an increase of level of satisfaction and physical exercise in patients that are suffering a mental disease.

Research conclusions

Apps can be a good strategy to improve the physical health of patients with mental illness.

Research perspectives

In the future, digital tools should be developed to analyze clinical efficacy using multivariate analysis, larger samples, including different psychiatric diseases and more specific treatments using artificial intelligence (machine learning).

Abstract

BACKGROUND

The coronavirus disease 2019 (COVID-19) pandemic produced changes in intensive care units (ICUs) in patient care and health organizations. The pandemic event increased patients' risk of developing psychological symptoms during and after hospitalisation. These consequences also affected those family members who could not access the hospital. In addition, the initial lack of knowledge about the virus and its management, the climate of fear and uncertainty, the increased workload and the risk of becoming infected and being contagious, had a strong impact on healthcare staff and organizations. This highlighted the importance of interventions aimed at providing psychological support to ICUs, involving patients, their relatives, and the staff; this might involve the reorganisation of the daily routine and rearrangement of ICU staff duties.

AIM

To conduct a systematic review of psychological issues in ICUs during the COVID-19 pandemic involving patients, their relatives, and ICU staff.

METHODS

We investigated the PubMed and the ClinicalTrials.gov databases and found 65 eligible articles, upon which we commented.

RESULTS

Our results point to increased perceived stress and psychological distress in staff, patients and their relatives and increased worry for being infected with severe acute respiratory syndrome coronavirus-2 in patients and relatives. Furthermore, promising results were obtained for some psychological programmes aiming at improving psychological measures in all ICU categories.

CONCLUSION

As the pandemic limited direct inter-individual interactions, the role of interventions using digital tools and virtual reality is becoming increasingly important. All considered, our results indicate an essential role for psychologists in ICUs.

Key Words: COVID-19; Intensive care unit; Psychological interventions; Pandemic; Mental health; Health care professionals

INTRODUCTION

Intensive care unit (ICU) utilisation during the coronavirus disease 2019 (COVID-19) pandemic accounted for around 25% of patients hospitalised during the February 2020 to September 2021 period in 21 United States Healthcare systems[1]. The COVID-19 pandemic has produced changes in ICUs both in patient care and in hospital care organization. On the one hand, the high burden of stress that patients usually experience in the ICU, has been exacerbated by the fear of the virus and the need to isolate, especially from family members. The pandemic has consequently increased the patient's risk of developing important psychological symptoms during and after hospitalization[2-4]. In addition, family members also experienced psychological symptoms due to the lack of access to the hospital, as this keeps them away from their loved ones and made it more difficult to exchange information with health workers[5]. Psychological symptoms associated with the COVID-19 pandemic, despite being more severe in the patient population, match those of relatives[6]. Finally, the lack of knowledge about the virus and its management, the climate of fear and uncertainty, increased workload, and the risk of becoming infected and infecting loved ones, had a great impact on staff[7-9]. This highlighted the importance of interventions aiming to provide psychological support to the treatment team, to reorganise the daily routine, and to characterise the role of the professionals working in an ICU.

With the awareness that the COVID-19 emergency is not over, the aim of this review was to highlight the changes and developments occurring in ICUs during the pandemic, knowing that many of its characteristics and changes are still important and will probably be in the future. The need to monitor the psychological phenomena taking place in ICUs during the COVID-19 period and to implement adequate interventions in the same structures has already been stressed in neonatal/paediatric[9,10-13] and adult age[14]. A review focused on the role of the psychologist in paediatric ICUs[15], and other two in adults were systematic reviews, one on informational and educational interventions in ICUs[16], the other on bereavement support[17], while one study identified three areas of utility of a psychologist in an ICU, namely, attention to patients at the ICU, attention to family members or caregivers, and work with health personnel[18]. There are currently no studies collecting experiences and evidence of effectiveness of psychological interventions during the COVID-19 pandemic. Hence, through this review we intend to investigate the psychological characteristics of ICU admission during the pandemic, through the assessment of the perspectives of the various involved individuals, *i.e.*, patients, family members, and staff members, and on the interventions that the psychologist, along with the medical team, enforced to deal with the health emergency.

We will start by describing patients' most frequent psychological repercussions of ICU admission and stay. Subsequently, we will summarise the elements of the main psychological characteristics of patients, family members, and caregivers during the COVID-19 pandemic.

As the pandemic limited direct, person-to-person interindividual interactions, with a concomitant rise in the use of digital homework, we found it interesting to dedicate a section of this review to interventions with digital tools. During the pandemic, these tools proved to be very effective (besides being the only available) in facilitating communication at various levels. Within this framework, we also highlight the role of virtual reality (VR) used in intensive care to treat the psychological consequences and promote the well-being of patients hospitalised with COVID-19 (and their relatives).

MATERIALS AND METHODS

To identify evidence of psychological issues and interventions in ICUs, we searched the PubMed database adopting the following search strategy: COVID-19 AND ("Intensive Care Unit" OR ICU) AND psychol* AND (implicat* OR intervent*), which produced on September 30, 2022, 214 results. We also searched the ClinicalTrials.gov database using the strategy Condition or disease: COVID-19 and Other terms: intensive care unit AND psychological, which produced 41 results on the same date. Eligibility depended on being an experimental work having data, either epidemiological or interventional. Excluded were reviews (and meta-analyses as well as guidelines; n = 25), case reports and series (n = 5), opinion articles (n = 16, editorials, comments on other articles, and reports without data), protocols of future studies (n = 17), articles not reporting on psychological outcomes or interventions, not involving ICUs, or not involving COVID-9 (collectively labelled as outcome, n = 52), studies not providing results (n = 38), studies lumping ICU data with data from other wards without providing separate data for ICUs (n = 6), studies with overlapping populations (n = 1, in which case only the article with the higher sample size would have been selected, provided it was higher in quality than others), studies with inadequate design to obtain the desired results (n = 16), unfocused articles (n = 12), papers unrelated to the subject matter (n = 5), *post mortem* studies (n = 0), and animal studies (n = 0).

RESULTS

Reviews/meta-analyses and guidelines were excluded but we thoroughly searched their reference lists for studies that possibly eluded our database searches. Duplicates were also to exclude if occurring in both searched databases (n = 0). When adding records concerning ClinicalTrials.gov to those of PubMed, we took care to substitute those that had their NCT number published within PubMed with the published article and rate it as appropriately. One ClinicalTrials.gov record produced four additional articles published with its NCT number, thus amounting to a grand total of 259 records. ClinicalTrials.gov added 1 eligible article; the 64 identified by PubMed. PubMed results did not overlap with those of ClinicalTrials.gov. We found no duplicates in our searches. Of the records identified by our ClinicalTrials.gov search, 19 were completed, but only 1 of them had results (and was not eligible, record 29 in Supplementary Material), 9 were still recruiting, 7 were active, but not recruiting, 1 was not yet recruiting, 3 had unknown status, and 2 were terminated (one in Malaysia for logistical problems/administrative issues, the other in Turkey, due to technical reasons). Most projects were based in France (n = 19, 1 in its extra-European territories), other 9 in Northern Europe and British isles (5 Belgium, 2 the Netherlands, 1 Denmark, and 1 United Kingdom), 6 in Southern Europe (3 Spain, 2 Turkey, and 1 Italy), 5 in the Americas (3 United States, 1 Brazil, and 1 Colombia), 1 in Asia (Malaysia), and 1 in Africa (Egypt) (Supplementary Material). The first was first-posted on June 19, 2019, the last on June 16, 2022, indicating early and enduring interest in the subject. Qualitative analyses were included if they adequately assessed psychological outcomes, but unfortunately, most did not. We assessed eligibility by reaching consensus among five authors (Monti L, Tranquilli S, Mazza M, Marconi E, and Kotzalidis GD) through Delphi rounds; no more than two were necessary to establish it. The results of the search are shown in Figure 1[19]. The list of studies considered is in the Supplementary Material in a Table, where reasons for exclusion are provided for each study (Supplementary Material). The final number of included studies was 65, spanning from July 2, 2020 to September 23, 2022. A summary of their results is provided in Table 1.

DISCUSSION

Psychological implications of being hospitalised in an ICU: ICU admission

Admission to the ICU often has significant consequences for patients and their caregivers and family members[20]. It is an event with traumatic potential. In fact, it involves a high stress charge due to invasive and painful procedures, sleep deprivation, unnatural noises and lights, inability to communicate, feeling of helplessness, and especially imminent threat of death[21]. The most frequent negative experiences reported by patients were thirst, loss of control, and noise[22].

During the COVID-19 pandemic, patients reported increased stress, probably related to the increased preventive and personal protective measures and the increased isolation from family, friends, and caregivers[20]. Indeed, many patients recall traumatic and loneliness elements in their ICU experience and many of them were admitted to the ICU during the pandemic while family members were in critical, sometimes fatal, conditions[23]. ICU admission often renders patients psychologically vulnerable; in fact, patients frequently report high levels of anxiety and depression[24]. Such symptoms may affect treatment plans and outcomes[25]. Psychological distress and psychiatric symptoms should be taken into account to prevent worsening of the quality of life after leaving the ICU[26].

Psychological implications of being hospitalised in an ICU: During ICU hospital stay

People who are admitted to ICUs may already have or not have psychological distress; ICU admission may worsen pre-existing psychological distressed, expressed as a variety of psychiatric symptoms which resemble post-traumatic stress disorder (PTSD), depression, excessive worrying, insomnia, and anxiety, or may induce newly developed psychological distress. An Italian study found that ICU admission may be associated with increased depression levels and suicidal ideation in a small, but clinically significant proportion of patients with COVID-19, and may worsen pre-existing depression [27]. A Turkish study showed depression may be mediated by restricted visits to the ICU patient, while anxiety was mediated by ICU admission itself[28]. In this study, ICU admission and visit restriction were independent risk factors; positive polymerase chain reaction for COVID-19 and female gender were associated with both anxiety and depression, as assessed with the Hospital Anxiety and Depression (HAD) scale. Another Turkish study examined the quality of sleep using the Pittsburgh Sleep Quality Index and depression and anxiety with the HAD in ICU patients with COVID-19; poor sleep quality was associated with depression and longer ICU hospitalisation[29]. The authors concluded that through improving sleep quality would help reducing duration of ICU stay.

Clozapine is a second-generation antipsychotic agent that is reserved to severe, treatment-resistant cases of schizophrenia and bipolar disorder due to potentially life-threatening agranulocytosis. Because of this, it is associated with worse pulmonary outcomes, namely pneumonia[30]. Although the use of second-generation antipsychotics is generally associated with reduced odds of getting a COVID-19 infection[31], it has been suggested that patients on clozapine may be at higher risk of COVID-19

Table 1 Summary of eligible studies on coronavirus disease 2019 in intensive care units

Ref.	Type	Population	Design	Outcomes and assessments	Results	Conclusions and observations
Sayde *et al* [138], 2020	C-S survey	265 ICU patients recruited, 20 refused, 185 excluded, 35 included: 17: Intervention group, (16 female, 11 male); 18 patients control group (15 female,13 male)	Diary and questionnaire administered 1 (BL), 4, 12, and 24 wk after ICU discharge (September 2017 to September 2018) in New Orleans, Louisiana, United States	Psychological distress, (IES-R), Anxiety and Depression (PHQ-8; HADS; GAD-7)	Controls had a significantly greater decrease in PTSD, hyperarousal, and depression symptoms at week 4 compared to the intervention group. No significant differences in other measures, or at other follow-ups. Both study groups exhibited clinically significant PTSD symptoms at all timepoints after ICU discharge	Diary increased awareness of the psychological support available to ICU survivors and family members
Huang *et al* [139], 2020	C-S online survey	6523 people with contact history, completed the survey, 260 were excluded, 6261 included. 3585 female (57.3%), 2676 male (42.7%)	Online questionnaire sent to participants of Hubei province and outside Hubei province, China, from February 10 to 15, 2020	Tested depression (PHQ-9) and public perceptions in response to the COVID-19 outbreak	Most people endorsed preventive and avoidance behaviours. People from Hubei, with contact history, and people who were infected or whose family members were infected by COVID-19, had a much higher prevalence of depression and anxiety	Assessing public response, perception, and psychological burden during the outbreak may help improving public health recommend-ations and deliver timely psychological intervention
Leng *et al*[140], 2021	C-S survey	90 ICU nurses; 65 female (72.2%), 25 male (27.8%)	Tests administered to ICU Wuhan (China) nurses, from 11 to 18 March 2020	PTSD (PTSD Checklist-Civilian and PSS), related to demographic survey and 2 open questions	Nurses have elevated PTSD levels. Nurses' stress and PTSD symptoms were positively correlated. Isolated environment, concerns about personal protective equipment shortage and usage, physical and emotional exhaustion, intensive workload, fear of being infected, and insufficient work experiences with COVID-19 were a major stress source	Even highly skilled and resilient nurses experienced some degree of mental distress, such as PTSD symptoms and perceived stress
Lasater *et al* [80], 2021	C-S analyses	ICU nurses and ICU patients: First sample 4298 medical-surgical nurses; second sample 2182 ICU nurses	Staffing data collected from registered nurses in New York and Illinois using HCAHPS and AHA, between 16-12-2019–24-2-2020	Information on patient satisfaction, hospital characteristics	Over half the nurses experienced high burnout. Half gave their hospitals unfavourable safety grades and two-thirds would not definitely recommend their hospitals. One-third of patients rated their hospitals less than excellent and would not definitely recommend it to others	Hospital nurses had burn-out and were working in understaffed conditions in the weeks prior to the first wave of COVID-19 cases, thus increasing public health risks
Jain *et al*[81], 2020	C-S online survey	512 Indian anaesthesiologists, 227 female (44.3%), 285 male (55.7%)	Online questionnaire sent to anaesthesi-ologists across India from 12-5-2020 to 22-5-2020	Anxiety (GAD-7) and Insomnia (ISI)	Elevated COVID-19-related anxiety and insomnia levels of anaesthesiologists. Age < 35 yr, female sex, being married, resident doctors, fear of infection to self or family, fear of salary deductions, increase in working hours, loneliness due to isolation, food and	Anaesthesiologists on COVID-19 duty suffer from anxiety and insomnia

					accommodation issues and posting in COVID-19 duty were risk factors for anxiety. < 35 yr, unmarried, those with stress due to COVID-19, fear of loneliness, issues of food and accommodation, increased working hours favour insomnia	
Kirolos *et al* [82], 2021	LS	41 families with a baby at NICU	Multicentre service evaluation in five United Kingdom neonatal care units, between July and November 2019	Surveys contained quantitative (9-point Likert scale, or closed-ended yes/no responses) and qualitative items (open comment boxes)	In post-implementation surveys (n = 42), 88% perceived a benefit of the service on their neonatal experience. 71% (n = 55) felt the service had a positive impact on relationships with families	Asynchronous video supports models of family integrated care and can mitigate family separation
Lasalvia *et al* [83], 2020	C-S online survey	2195 ICU HCWs; female 539 (24.7 %), male 1647 (75.3)	All healthcare and administrative staff of Verona University Hospital (Veneto, Italy) from April to May 2020	Psychological distress (IES-R), Anxiety (SAS) and mental health (PHQ-9)	63.2% of participants reported COVID-related traumatic experiences at work; 53.8% showed symptoms of post-traumatic distress; 50.1% showed symptoms of clinically relevant anxiety; 26.6% symptoms of moderate depression	The psychological impact of the COVID-19 pandemic on healthcare staff working in a highly burdened north-east Italy is high and to some extent higher than that reported in China
Ou *et al*[84], 2021	C-S study	92 nurses in isolation ward, female 85 (92.4%); male 7 (7.6%)	Test was administered to nurses in isolation ward, the Guangdong Province of China, in February 2020	Resilience and psycho-pathological symptoms (CD-RISC2; SCL-90)	Total resilience score was 87.04 ± 22.78. SCL-90 score ranged 160-281 (202.5 ± 40.79). Only 8.70% of nurses (n = 8) scored > 160 on the SCL-90, suggesting positive symptoms. Most nurses had 0 to 90 positive self-assessment items (median 14); 19.57% (n = 18) had > 43 positive items to CD-RISC 2	High resilience promotes physical and mental health, and may be improved by training, psycho-logical interventions, and full use of hospital resources
Vlake *et al*[69], 2020	Case report	One COVID-19 patient (male), age: 57 yr	Test for evaluating COVID-19 ICU-VR intervention in one Dutch man with COVID-19	Anxiety and depression (HADS) and psycho-logical distress (IES-R)	One week after receiving ICU-VR, levels of PTSD, anxiety, and depression had normalised and stayed normal 6 mo after discharge	Virtual realty improved psycho-logical rehabilitation outcomes, hence they should be considered by clinicians for the treatment of ICU-related psychological sequelae after COVID-19
Fernández-Castillo *et al* [85], 2021	C-S survey	17 nurses: 6 male, 11 male	17 nurses of a tertiary teaching hospital in Southern Spain, from 12-30 April 2020	Semi-structured videocall interviews	Four main themes emerged from the analysis and 13 subthemes: "providing nursing care", "psychosocial aspects and emotional lability", "resources management and safety" and "profes-sional relationships and fellowship"	Nursing care has been influenced by fear and isolation, making it hard to maintain humanisation of health care
Writing Committee for the COMEBAC Study Group *et al*[86], 2021	C-S telephone survey	834 eligible COVID-19 survivors: 478 evaluated (201 male, 277 female)	Survivors of COVID-19 in France underwent telephone assessment 4 mo after discharge, between July and September 2020	Respiratory, cognitive, and functional symptoms (Q3PC cognitive screening questionnaire, symptom Checklist and 20-item Multidimensional	244 patients (51%) declared at least 1 symptom absent before COVID-19: Fatigue in 31%, cognitive symptoms in 21%, and new-onset dyspnoea in	4 mo after hospital-isation for COVID-19, a cohort of patients frequently reported previously absent symptoms

				Fatigue Inventory; SF-36; cognitive impairment (MoCA)	16%. The median 20-item Multidimensional Fatigue Inventory score (n = 130) was 4.5 for reduced motivation and 3.7 for mental fatigue. The median SF-36 score (n = 145) was 25 for the subscale "role limited owing to physical problems". Among 94 former ICU patients, anxiety, depression, and PTSD symptoms were observed in 23%, 18%, and 7%, respectively. The left ventricular ejection fraction was < 50% in 8 of 83 ICU patients (10%)	
Stocchetti *et al* [87], 2021	C-S online study	Of 271 medical staff working in this ICU, 136 included: 84 nurses (62%) and 52 physicians (38%)	Nurses and physicians working in this ICU participated to online survey in January 2021	Burnout (MBI), anxiety (HADS); resilience (RSA) and Insomnia (ISI)	60% of participants show high burnout level: Nurses reported significantly higher scores of anxiety and insomnia levels. 45 % reported symptoms of depression, and 82.4% of the staff showed moderate-to-high levels of resilience	The COVID-19 pandemic can have a significant impact on ICU staff. Effective interventions needed to maintain healthcare professionals' mental health and relieve burnout
Kirk *et al*[12], 2021	C-S online study	430 of 458 paediatric HCWs, concluded the online survey	Online survey administered to paediatric HCWs in the emergency, ICU and infectious disease units from April 28 to May 5 2020	Depression and Anxiety symptoms (DASS-21)	168 (39.1%) of respondent showed depression, 205 (47.7%) anxiety and 106 (24.7%) symptoms of stress. Depression reported in the mild (47, 10.9%), moderate (76, 17.7%), severe (23, 5.3%) and extremely severe (22, 5.1%) categories. Anxiety (205, 47.7%) and stress (106, 24.7%) were reported in the mild category only	A high prevalence of depression, anxiety and stress was reported among frontline paediatric HCWs during the COVID-19 pandemic
Yang *et al*[88], 2021	C-S online study	Of 1075 contacted individuals, 1036 front-line HPCD completed the online survey: Female 755 (72.9%), male 288 (27.1). 874 (84.4%) nurses, 162 (15.6%) physicians	1036 front-line HPCDs exposed to COVID-19 were tested online from 5 to 9 March 2020 in Wuhan, China	Sleep, insomnia, emotional regulation (RESE)	543 (52.4 %) reported symptoms of sleep disorders. HPCD for patients with COVID-19 in China reported experiencing sleep disturbance burdens, especially those having exposure experience and working long shifts	RESE is an important resource for alleviating sleep disturbances and improving sleep quality
Moradi *et al* [89], 2021	C-S survey	17 nurses in ICUs: 5 males and 12 females	Semi-structured face-to-face interviews were administered to nurses in ICUs of Urmia, Iran	Semi-structured face-to-face interviews	Four challenges throughout the provision of care for COVID-19 patients: 'organization's inefficiency in supporting nurses', 'physical exhaustion', 'living with uncertainty' and 'psychological burden of the disease	A profound understanding of ICU nurses' challenges while caring for COVID-19 patients is needed to increase healthcare quality
Bruyneel *et al* [90], 2021	C-S online survey	1135 ICU nurses: Female 892 (78%); male 243 (22%)	Nurses in the French-speaking part of Belgium completed a web-based survey, April 21-May 4, 2020	Burnout (MBI)	68% burnout level. 29% of ICU nurses were at risk of depersonalisation, 31% of reduced personal accomplishment, and 38% of emotional exhaustion	Burnout risk requires monitoring and implementation of interventions to prevent it and manage it

Shariati *et al* [91], 2021	LS online survey	67 family members of COVID-19 patients admitted to the ICU	Longitudinal pre-post intervention online survey of 67 family members of COVID-19 ICU patients in three hospitals in Iran; May to August 2020	Stress symptoms (PSS-14)	Mean PSS-14 post-intervention significantly lower in the intervention group than in the control group ($P < 0.001$)	Use of web-based communication between nurses and family members was effective in reducing perceived stress
Kok *et al*[92], 2021	LS survey	Open cohort of ICUs professional: BL survey 252 respondents, response rate: 53%, male 66 (26.2%), female 186 (73.8%); and follow-up 233 respondents, response rate: 50%, male 65 (27.9%), female 168 (72.1%)	BL survey collected in October-December 2019 and follow-up survey sent in May-June 2020 to a university medical centre and a large teaching hospital in the Netherlands	Semi-structured interview form	The prevalence of burnout symptoms was 23.0% before COVID-19 and 36.1% after, with higher rates in nurses (38.0%) than in physicians (28.6%). Post-COVID-19 incidence rate of new burnout cases among physicians was higher (26.7%) than among nurses (21.9%). Higher prevalence of burnout symptoms after the beginning of the pandemic	Overburdening of ICU healthcare personnel during an extended period leads to burnout symptoms
Kürtüncü *et al* [93], 2021	C-S survey	18 COVID-19 patients: 4 females and 14 males	Telephone-conducted semi-structured interview of 18 ICU patients in Turkey; March-September, 2020	Semi-structured interview form	Interventions in ICUs are able to promote communication with patients and are essential for achieving positive circumstances	Families of missing patients may benefit from interventions of nurses aimed at working-through the loss and providing family support and care during their critical illness
Martillo *et al* [94], 2021	C-S online survey	45 COVID-19 ICU patients: Male 33 (73.3%), female 10 (22.2%)	Single-centre descriptive cohort study of ICU patients at Mount Sinai Hospital, New York; April 21 to July 7, 2020	Insomnia (ISI), mental health (PHQ-9), QoL (EQ-5D-3L), PTSD (PCL-5), telephone cognitive assessment (MoCA)	22 patients (48%) reported psychiatric impairment, and four (8%) had cognitive impairment. 38% at least mild depression, and 18% moderate-to-severe depression. 8% PTSD. 9% had impaired cognition	Severe COVID-19-related symptoms associated with high risk of developing PICS. Planning needed for appropriate post-ICU care
Donkers *et al* [95], 2021	C-S online survey	355 nurses, 108 supporting staff and 41 ICU physicians from 84 ICUs: 124 males, 380 females	Online questionnaire sent by email to Dutch ICU nurses and supporting staff from 7 April to 11 June, 2020	MD for HCWs (MMD-HP), Ethical Decision-Making (EDMCQ)	MD levels higher for nurses than others; "Inadequate emotional support for patients and their families" was the highest-ranked cause of MD for all participants; all participants judged positively the ethical climate regarding the culture of mutual respect, ethical awareness, and support	Targeted interventions on MD are important for improving the mental health of critical care professionals and the quality of patient care
Fteropoulli *et al* [96], 2021	C-S online survey	1071 healthcare personnel: 73% females, and 27% males	Anonymous online survey administered. May 25 to October 27, 2020, in Cyprus	QoL (WHOQOL-Brief), anxiety (GAD-7), depression (PHQ-8), burnout (CBI), and coping (Brief COPE)	27.6% moderate and severe anxiety, 26.8% depression. Being female, nurse or doctor, working in frontline units, perceptions of inadequate workplace preparation to deal with the pandemic and using avoidance coping were risk factors	There are several risk factors for psychological distress during the pandemic, which may be individual, psychosocial, and organisational
Peñacoba *et al* [97], 2021	C-S online survey	308 intensive care nurses: Female 268 (87%) and male 40 (13%)	Online form used to collect data from surgical and general critical care units in a public Spain Hospital, March 2020 to June 2020	Stress subscale (depression, anxiety, and stress in Spanish DASS-21), physical and mental health-related QoL (SF-36), GSES, and resilience (RS-14)	Greater perception of self-efficacy related to lower perception of stress and greater resilience, while higher resilience was linked to greater physical and	Stress is related to physical and mental health factors which are linked to QoL through self-efficacy and resilience

					mental health	
Wozniak *et al* [98], 2021	C-S online study	3461 HCWs of 352 ICU	Online data collected from May 28 to July 7, 2020, at HUG, Switzerland	Socio-demographic data, lifestyle changes, anxiety (GAD-7; PHQ-9), psychological distress (PDI; WHO-5)	145 (41%) reported poor well-being, 162 (46%) anxiety, 163 (46%) depression, 76 (22%) peritraumatic distress. Working in ICU more than other departments changes eating habits, sleeping patterns, and alcohol consumption ($P < 0.01$)	High prevalence of anxiety, depression, peritraumatic distress and poor well-being during the first COVID-19 wave among HCWs, especially in ICU
Li *et al*[99], 2021	C-S survey	78 ICUs nurses: Female 4 (17.95%), male 64 (82.05%)	Data from 78 ICU nurses in Beijing COVID-19 hospital during March 2020	Depression (SDS), stress (PPS)	44.9% ($n = 35$) reported depressive symptoms, stress perception; work experience in critical diseases, and education are risk factors for depression	Work experience in critical illness is linked to depression. Psychological intervention may reduce it
Manuela *et al* [100], 2021	C-S survey	34 females, mothers of premature infants born before 32 wk of gestational age; 20 pre-COVID-19 period *vs* 14 during COVID-19 pandemic	20 mothers of premature infants recruited at HUG, CH, January 2018 to February 2020 before COVID-19 *vs* 14 mothers from November 2020 to June 2021	Postnatal depression (EPDS); (PSS:NICU), attachment (MPAS)	No significant differences for depression, stress, and attachment between the two groups; "trend" towards increase of depression symptoms in mothers during the COVID-19 pandemic; depression correlated with attachment and stress scores	Protective family-based actions and appropriate interventions to support parents during the COVID-19 pandemic can reduce depression and stress of mothers of premature infants
Nijland *et al* [76], 2021	LS survey	Of 326 ICU nurses, 138 (42.33%) participated; 86 VRelax users, male 13 (15%), female 73 (85%) and 52 non-users, male 9 (17%), female 43 (83%)	VRelax intervention investigated in Dutch ICU nurses in May, 2020	Single-question VAS-stress scale	VR reduced stress by 36% (mean difference = 14.0 ± 13.3, $P < 0.005$). 62% of ICU nurses rated VRelax as helpful to reduce stress	VRelax is effective in reducing immediate perceived stress
Scheepers *et al* [101], 2021	LS survey	Of 203 ICU and internal medicine staff, 103 residents (50.1%) participated	ICU and Internal medicine staff of AMC, Amsterdam, The Netherlands tested during the first wave of COVID-19, March 15 to June 30, 2020	Explored residents' perceptions of well-being (well-being survey), and their perceived support of the well-being program during the COVID-19 pandemic	Residents working in the ICU reported significantly lower levels of mental well-being than internal medicine residents	Well-being programmes for ICU staff need to address ICU-specific stressors, enhancing supervision and peer support
Liu *et al*[102], 2021	Study 1: LS survey; study 2: LS survey	Study 1: Of 268 ICU nurses and 26 head nurses, 258 completed the survey: Female 220 (85.27%), male 38 (14.73%). Study 2: 64 ICU medical professionals: Female 40 (65.57%), male 24 (34.43%)	Study 1: ICU nurses of major Chengdu hospital, China, recruited. Retested after 3 wk for work engagement and rated by head nurses for taking-charge behaviour after further 3 wk. Study 2: ICU medical staff of same Chinese hospital completed scales on early March, 2020 and 2 wk later	Studies 1-2: Perceived COVID-19 crisis strength and work meaningfulness assessed with 5-point Likert scales, and demographic data. Self-rating of work engagement and clinician rating of taking-charge behaviour	Study 1: Health worker'sperceived COVID-19 crisis strength exerted a more negative effect on his or her work engagement and taking charge at work. Study 2: The interventions significantly decreased perceived COVID-19 crisis strength and increased work meaningfulness for medical staff in an ICU	Study 1: Frontline health workers worldwide have regarded the COVID-19 crisis as an extraordinarily stressful event. Study 2: Interventions are important for reducing stress during COVID-19 pandemic
Carmassi *et al* [103], 2021	C-S survey	265 frontline HCWs: Male 84 (31.7%), female 181 (68.3%)	Data was recruited in a sample of frontline HCWs at a major university hospital in Pisa, Italy, April 1 to May 1, 2020	PTSS (IES-R), anxiety (GAD-7), depression (PHQ-9), assess work and social Functioning (WSAS)	Subjects with acute PTSS have higher levels of PTSS, depressive symptoms, and moderate-to-severe anxiety symptoms	More long-term studies are needed to evaluate the impact of psychopathology on the socio-occupational functioning of health professionals
Secosan *et al* [104], 2021	C-S survey	Of 200 frontline HCWs, 126, 63% (32 nurses and 94 physicians)	Data collected from Romanian frontline HCWs, March to April 2020	Psychological capital (PsyCap) (PCQ) related to anxiety and depression (DASS-21),	High anxiety predicts lower emotional exhaustion and a low level of mental health	PsyCap is may decrease the impact of anxiety and depression on

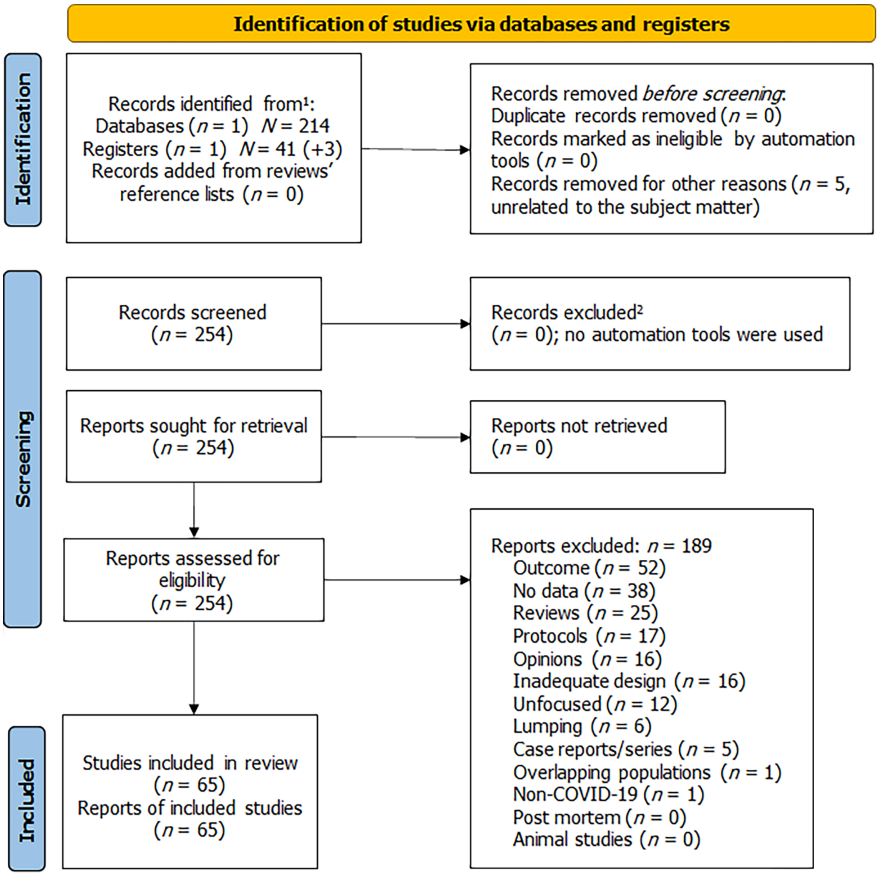
		participated; male 35.7%, female 64.3%; 42.8% single, 52.3% married, 4.7% divorced		burnout (MBI)	complaints about healthcare professionals when PsyCap is high	psychological outcomes in frontline HCWs. Psychological interventions can help ICUs staff
Scarpina *et al* [105], 2021	C-S survey	60 patients who survived COVID-19 infection: Male 58.3%, female 41.7%	Participants had been recruited at the COVID-19 post-ICU, from May 2020 to January 2021, in Italy	Fearful facial expressions recognition, perceived psychological functioning, Empathy (4-point Likert scale questionnaire)	Altered detection and recognition of fearful expressions and altered processing of fearful expressions in individuals who survived COVID-19 infection	Altered emotional face recognition could represent psychological distress; psychological interventions in rehabilitative settings can be helpful
Kapetanos *et al* [106], 2021	C-S survey	381 HCWs: 72.7% nurses (202 males, 75 males) 12.9% physicians (28 males, 21 males), 14.4% other occupations (18 males; 7 males)	Data on mental health status of HCWs collected from healthcare professionals from all over Cyprus from May to June 2020	64-item, self-administered questionnaire, which included DASS21 and MBI	Prevalence of 28.6% anxiety, 8.11% stress, 15% depression, and 12.3% burnout. Environmental changes included increased working hours, isolation, and separation from family	Also the second wave of the pandemic impaired psychological health of HCWs
Manera *et al* [107], 2022	C-S survey	152 COVID-19 patients: 101 males, 51 females	Retrospective assessment of post-infectious SARS-CoV-2 patients at Maugeri Scientific Clinical Institutes, Northern Italy, May 2020 to May 2021	Cognitive measures (MMSE) as related to disease severity (at-risk *vs* not at-risk: Neuro+ *vs* Neuro-)	Mild-to-moderate patients (26.3%) showed impaired MMSE performances; ICU patients made less errors (P = 0.021) on the MMSE than non-ICU patients. Age negatively influenced MMSE performance. For Neuro-patients, steroidal treatment improved MMSE scores (P = 0.025)	Mild-to-moderate patients, with mechanical ventilation who however are not admitted to an ICU, are more likely to suffer from cognitive deficits, independently from their aetiology
Mollard *et al* [108], 2021	C-S survey	885 postpartum women, 82.3% married	English-speaking adult postpartum women who gave birth in US hospitals from 1 March to 9 July 2020 participated in survey between 22 May to 22 July 2020	Demographic and health variables measured with self-report questionnaires; stress (PSS-10), Mastery (PM), and resilience (CD-RISC2)	Post-pandemic participants showed higher stress and lower resilience, high levels of depression, anxiety, and stress compared to a pre-pandemic normative sample. Women with an infant admitted to a NICU had higher stress. High income, full-time employment, and partnered relationships lowered stress. Lower stress increased mastery and resilience. Non-white women showed higher stress and lower resilience	Postpartum women are susceptible to stress, depression, and anxiety
Pappa *et al* [109], 2021	C-S survey	464 HCWs: Female 68%, male 32%; 43% nurses, 49% married	Six COVID-19 reference hospitals in Greece, from May 2020 to June 2020	Levels and risk factors of anxiety (GAD-7), Depression (PHQ-9), traumatic stress (IES-R), burnout (MBI) and fear (NFRS)	30% moderate/severe depression, 25% anxiety, 33% traumatic stress. 65% of respondents scored moderate-severe on EE, 92% severe on DP, and 51% low-moderate on PA. Predictors: Fear, perceived stress, risk of infection, lack of protective equipment and low social support	Need for immediate organisational and individual interventions to enhance resilience and psychological support for HCWs
Meesters *et al* [110], 2022	C-S online survey	25 parents (16 mothers, 9 fathers) of infants at NICU	Data collected at Rotterdam NICU from April to June 2020	Sociodemographic questions related to stressor (PSS:NICU) and COVID questionnaire	Most important sources of stress were being separated from, not being able to always hold their infant, and other family members	NICU staff can support psychologically parents during hospital isolation and reduce the effect of

					not allowed to visit	restrictive measures
Piscitello *et al* [111], 2022	LS survey	Of 78 eligible, 33 ICU nurses (42%) completed survey: Female 29 (50.9%), male 28 (49.1)	Data collected November to December 2020 at Rush University	Nurse MD (MMD-HP)	Results pre and post intervention were not statistically different	Further research required to identify interventions that could improve nurses' MD
Sezgin *et al* [112], 2022	C-S online survey	10 ICU nurses: 2 males and 8 females	Data collected by online survey in 10 ICUs of 7 hospitals in İstanbul, Turkey, October to December 2020 using the snowball method to recruit	Followed the Consolidated Criteria for Reporting Qualitative Research; 32-item checklist to identify major themes	'Death and fear of death', 'impact on family and social lives', 'nursing care of COVID-19 patients', 'changing perceptions of their own profession: empowerment and dissatisfaction', and 'experiences and perceptions of personal protective equipment and other control measures' are the major themes identified	There is need to improve working conditions and develop nursing standards in ICU
Rodriguez-Ruiz *et al*[113], 2022	LS online survey	HCW in ICU: 1065 in first time and 1115 in second time	Spanish ICUs in October to December 2019 and September to November 2020	MD (MMD-HP-SPA)	During the pandemic, nurses reported higher MD levels compared to the prepandemic period. ICU physicians reported significantly higher MD levels than ICU nurses during the prepandemic period, but not during the pandemic period	In Spain, during the COVID-19 pandemic, there is an increase of MD among ICU HCPs
Vlake *et al* [114], 2022	LS survey	89 post COVID patients: Male 63 (70%) and female 26 (39%)	VR efficacy data from Dutch post-ICU patients, June 2020 to February 2021; participants followed-up for 6 consecutive months	Psychological distress (IES-R) and QoL related to anxiety and depression (HADS)	High psychological distress levels in all groups. ICU-VR group showed improved ICU satisfaction with respect to the control group. 81% of patients reported a higher ICU quality, which was linked to virtual reality	ICU-VR is an innovative strategy to enhance satisfaction with ICU and improves ICU ratings aftercare, adding to its perceived quality
Fumis *et al* [115], 2022	C-S survey	Of 62 ICU physicians, 51 participated: Male 60.8%, female 39.2%; 76% married	Burnout investigated in ICU physicians during the second COVID-19 wave in São Paulo, Brazil, from December 10 to December 23, 2020	Questionnaire with demographic and occupational variables, and information on the impact of the COVID-19 pandemic on daily life (insomnia, lack of appetite, irritability, decreased libido, fear of being infected, fear of infecting loved ones, overspending) and MBI	19 (37.2%) showed high burnout, *i.e.*, 96.1% low PA, 51.0% high DP, and 51.0% high EE. Conflicts between the ICU physicians and other physicians were 50%	ICU staff have high burnout level
Levi and Moss [116], 2022	C-S survey	10 ICU nurses: 9 females and 1 male; 3 married and 7 single	ICU nurses completed psychological stress survey during the COVID-19 pandemic in southeastern United States from August to September 2020	Psychological Stress and PTSD Symptoms (PTSD Checklist), job satisfaction (a Likert-type scale), demographic information	The survey revealed 6 recurring themes: Change in Practice, Emotion, Patient's Family, Isolation, Job Satisfaction, and Public Reaction. 7 of 10 ICU nurses reported PTSD symptoms; 6 of 10 wanted to quit their jobs	Critical care nurses during the COVID-19 pandemic are highly subjected to PTSD; its early identification may prevent other related health deteriorating problems
Righi *et al*[117], 2022	C-S survey	465 long COVID patients: 54% male and 46% female; 51 % hospitalised	Patients > 18 yr with SARS-CoV-2 infection at Verona University Hospital during February 29 to May 2 2020, followed for 9 mo	Duration and predictors of symptom persistence (symptom questionnaire), physical health and psychological distress (K10)	37% of patients had at least 4 symptoms; 42% had symptom lasting more than 28 d. 19% showed psychological distress after 9 mo. Female and symptom persistence at day 28 were risk factors for psychological distress	Patients with advanced age, ICU stay, and multiple symptoms were more likely to suffer from long-term symptoms, with negative impact on both physical and mental wellbeing

Gilmartin *et al* [118], 2022	C-S survey	22 post COVID-19 patients: Male 15 (68%), female 7 (32%)	A prospective cohort study through establishing a PICS follow-up clinic at Tallaght University Hospital in October 2020 for patients who had been admitted to their ICU	PICS investigated by psychological assessment for ICU (IPAT), PTSD (PCL-5), cognitive impairment (MoCA)	IPAT score was 6.6 ± 4.6 with a PCL-5 score of 21.1 ± 17.5 and a MoCA score of 24 ± 8.4, suggestive of mild cognitive impairment	Patients have a high burden of physical and psychologic impairment 6 mo following ICU discharge for post-COVID-19 pneumonia
Guttormson *et al*[119], 2022	C-S online survey	485 ICU nurses: Female 430 (88.1%), male 56 (11.5%)	Participants recruited from national United States sample of ICU nurses, through AACCN newsletters and social media during the COVID-19 pandemic, October 2020 to January 2021	Measure of MD (MMD-HP), burnout (PROQOL-5), PTSD symptoms (TSQ), anxiety, and depression (PHQ-ADS)	Nurses reported moderate-high levels of MD and burnout; 44.6% reported depression symptoms and 31.1% had anxiety symptoms, while 47% of participants showed risk for PTSD	United States ICU nurses had high levels of anxiety and depression and higher risk for PTSD
Likhvantsev *et al*[120], 2022	C-S survey	Of 403 eligible COVID-19 patients in Russian ICUs (Moscow), 135 participated	Prospective cohort study investigated patients admitted in COVID-19 ICUs, March to June 2020	QoL (SF-36 questionnaire)	Heparin treatment in the ICU proved to be the only modifiable factor associated with an increase in the physical component of QoL	Heparin treatment enhanced QoL during COVID-19 patient recoveries at ICUs
Shirasaki *et al* [121], 2022	C-S survey	54 family members (68.5% female, 31.5% male) of 85 patients (16.7% female, 83.3% male) with COVID-19 admitted to ICU participated	PICS-F was investigated between March 23, 2020, and September 30, 2021, in Japan	PICS-F related to Psychological distress (IES-R), anxiety, and depression (HADS), and PTSD (FS-ICU)	Family members had 24% of anxiety, 26% depression and 4% PTSD	One-third of family members of COVID-19 patients admitted to the ICU had symptoms of PICS-F
Amiri Gooshki *et al*[122], 2022	C-S survey	152 patients with COVID-19: Male 55 (36.2%), female 97 (63.8%); 98 (64.47%) married	Psychological consequences of COVID-19 were investigated at hospitals in south-eastern Iran in 2020	Demographic and background information, Depression, Anxiety (DASS-21), psychological distress (IES-R)	73% of patients showed severe PTSD, 26.3% moderate depression and 26.3% severe anxiety	Higher psychological load is enhanced by ICU admission, divorce, illiteracy, and retirement
Omar *et al* [123], 2022	C-S survey	445 HCWs (physicians, nurses, and respiratory therapists): 171 ECMO-ICU, 274 non ECMO-ICU; male 239 (53.7%), female 206 (46.3%)	HCWs grouped by ECMO service (ECMO-ICU *vs* non-ECMO-ICU) and burnout status (burnout *vs* no burnout), in 8 tertiary-care hospital ICUs in Qatar, January 1 to June 30, 2021	General and demographic questions, burnout (MBI-HSS)	288 HCWs reported burnout and 158 did not. PA lower among ECMO-ICU personnel compared with those in a non-ECMO-ICU (42.7% *vs* 52.6%, P = 0.043)	High burnout in both ECMO-ICU and non-ECMO-ICU personnel
Arshadi Bostanabad *et al* [124], 2022	C-S online survey	207 ICU nurses: Male 60 (29%), female 147 (71%); 51.7% married	Psychological empowerment was investigated in Iran, from February 2021 through April 2021	Psychological empowerment questionnaire, demographic information	Positive relationship between clinical competencies and psychological empowerment (r = 0.55, P < 0.001) and between clinical competencies and work experiences (r = 0.17, P = 0.01)	Clinical competency is linked to nurse health and quality of care
Zhang *et al*[9], 2022	C-S online survey	Of 3055 eligible PICUs HCWs, 2109 HCWs completed the survey: Female 1793 (85.2%) and male 316 (14.98%); 35.04% doctors and 64.96% nurses; 1456 (69.04%) married	Online survey was administered to HCWs in the paediatric ICUs of 62 hospitals in China on March 26, 2020	General information, PTSD (IES-R), anxiety and depression (DASS-21)	970 HCWs (45.99%) reported PTSD symptoms; 39.69% had severe depression, 36.46% anxiety and 17.12% high level of stress. Married HCWs showed higher risk of PTSD than unmarried. PTSD was influenced by marital status, intermediate professional titles and exposure history; while professional titles and going to work during the epidemic were a	During public health emergencies, HCWs need specialised support

					risk factor for depression	
Kılıç and Taşgıt [125], 2023	C-S survey	93 parents who were not allowed to see their NICU babies as a response to the COVID-19 pandemic: 52 mothers (55.91%) and 41 fathers (44.09%)	Data collected between March and October 2021, in the NICU of a public hospital in Ankara, Turkey	Descriptive questionnaire, anxiety, depression, and stress (DASS-42), and Coping Style (CSS)	Depression subscale was 13.69 ± 8.86, Anxiety subscale 12.11 ± 8.37, and stress subscale 19.09 ± 9.24. CSS "self-confident" scale was 2.71 ± 0.65, "optimistic" 2.57 ± 0.59, "helpless" 2.29 ± 0.62, "submissive coping" 2.25 ± 0.49, and "seeking of social support" 2.38 ± 0.52. Participants who received information about their babies' condition by nurses had lower mean CSS "helpless" and "submissive" subscale scores than others	For parents of NICU patients need use psychological empowerment programs to help them adopt active coping strategies to deal with challenges in times of crisis
Pappa *et al* [126], 2022	C-S online survey	464 self-selected HCWs: 68% female, 32% male; nurses (43%), married (49%)	Online questionnaire sent to ICU HCWs in Greece, from May 2020, to June 2020	Depression (PHQ-9), anxiety (GAD-7) and traumatic stress (IES-R) related to burnout (MBI) and level of fear (NFRS)	Depression was 30%, anxiety 0 25% and traumatic stress 33%. Burnout was high: 65% of HCWs scored moderate-severe on EE, 92% severe on DP and 1% low-moderate on PA	Need for interventions to enhance resilience and support wellbeing in pandemic
Vranas *et al* [127], 2022	C-S survey	Of 36 eligible intensivists, 33 participated: Female 12 (36%), male 21 (64%)	Semi-structured interviews conducted on ICUs of six United states between August and November 2020	Four S (space, staff, stuff, and system) semi-structured interview, related to MD, Burnout and Fear of Becoming Infected	Restricted visitor policies and their perceived negative impacts on patients, families, and staff enhanced MD. Burnout symptoms in intensivists were enhanced by experiences with patient death, exhaustion, and perceived lack of support from colleagues and hospitals	COVID-19 pandemic reduced ICU workers' well-being, increased burnout and MD
Voruz *et al* [128], 2022	C-S survey	102 COVID-19 patients: 26 anosognosic, and 76 nosognosic patients	Tests administered by clinical psychologists and questionnaires online to patients at HUG	Neuropsychological battery (TMT, Stroop task, verbal fluency and GREFEX, backward digit span43 and backward Corsi test, Test for Attentional Performance, Rey-Osterrieth Complex Figure test, BECLA battery, WAIS-IV, QPC, BRIEF-A), psychiatric (ERQ, BDI-II, STAI, API, PTSD Checklist, GMI, DES, PSS, ESS) olfactory (Sniffing Sticks test battery), dyspnoea (self-report questionnaire), and QoL (SF-36)	Patients with anosognosia for memory dysfunction scored significantly lower on objective cognitive and olfactory measures compared with nosognosic patients; but reported significantly more positive subjective assessments of their QoL, psychiatric status, and fatigue. The number of patients exhibiting a lack of consciousness of olfactory deficits was significantly higher in the anosognosic group. Significantly more patients with lack of consciousness of olfactory deficits were in the anosognosic group, as confirmed by connectivity analyses	Cognitive disorders like anosognosia are related to different COVID-19 symptoms
Green *et al* [129], 2023	LS survey	24 ICU HCWs: 67% female, 33% male; 79% nurses	At Cedars-Sinai Medical Center (CSMC) in Los	Administered tests were: SAQ, TC, resilience (BRS),	Positive feedback paradigm enhanced resiliency and improve	Need to improve TC and resiliency. A messaging interface

			Angeles, CA, United States, over a 6-wk period from June 2020 to July 2020	burnout (BSI)	attitudes toward a TC	to exchange mutual positivity can be a simple, low-cost intervention to provide an effective peer-to-peer support system
Wozniak *et al* [130], 2022	C-S survey	3461 HCWs. 352 ICU HCWs: Female 23 (66.5%), male 118 (33.5); 242 (68.7%) married. 3109 no-ICU HCWs: Female 2327 (74.9%), male 779 (25.1%); 1973 (63.5%) married	Mental health outcomes and lifestyles change in ICU HCWs and non-ICU HCWs; the study was carried out at HUG and 8 public hospitals in Switzerland, between May to July 2020	Anxiety (GAD-7), depression (PHQ-9), distress (PDI) and Well-Being (WHO-5)	ICU HCW: 41% showed low well-being, 46% symptoms of anxiety, 46% depression and 22% peritraumatic distress. ICU HCWs scored higher than non-ICU HCWs on all tests ($P < 0.01$). Working in ICU rather than in other departments, being a woman, the fear of catching and transmitting COVID-19, anxiety of working with COVID-19 patients, work overload, eating and sleeping disorders can enhance worse mental health outcomes	High prevalence of anxiety, depression, peritraumatic distress and low well-being during the first COVID-19 wave among HCWs, especially ICU HCWs
Tariku *et al* [131], 2022	C-S survey	402 of 423 eligible participants, responded to survey: Male 233 (58.0%), female 169 (42.0%); 137 (34.1%) married	HCWs mental disease was investigate in Ethiopia, during the coronavirus disease 2019	Survey assessing the presence of common mental disorders (SRQ-20)	22.6% of mental disorders in HCWs. Being female, married, having had direct contact with COVID-19 patients, working in COVID-19 treatment centres and ICU, having any symptoms of COVID-19, and poor social support were a risk factor for mental disorders in HCWs	On-fourth to one-fifth of Ethiopian HCWs have a mental disorder during COVID-19 pandemic
Wang *et al* [132], 2021	C-S telephone survey	Of 267 eligible patients, 199 COVID-19 patients participated in the survey; male 93 (46.7%), and female 106 (53.3%); age 42.72 ± 17.53; 163 ± 81.9 married	PTSD symptoms in COVID-19 survivors investigated with telephone survey 6 mo after hospital discharge in 5 hospitals of 5 Chinese cities, August to September 2020	Somatic symptoms after discharge (PHQ-15), PTSD (PTSD-8)	7% of participants having PTSD; socio-demographic status, hospitalization experiences, post-hospitalization experiences, and psychological status enhanced PTSD symptom	Effects of COVID-19 on survivors can also involve psychological aspects and last for many months after recovery
Moll *et al*[133], 2022	LS survey	Pre-pandemic survey, 1233 HCWs, of which 572 responded (46.5%): Female 408 (71.3%), male 127 (24.9%). Pandemic survey: Of 1422 clinicians, 710 (49.9%) responded to survey; female 529 (74.5%), male 146 (20.5%)	Burnout data collected March to May 2017 and June to December 2020, during the pandemic at Emory University, Atlanta (Georgia)	Burnout (MBI)	46.5% (572 respondents) in 2017 and 49.9% (710 respondents) in 2020 shown higher burnout symptoms. Nurses' burnout prevalence increased with pandemic from 59% to 69% ($P < 0.001$), with increased EE and DP, and decreased PA. Other HCWs showed no differences in burnout levels between 2017 and 2020	Nurses are more at risk for burnout after the beginning of the COVID-19 pandemic
Groenveld *et al* [134], 2022	LS survey	Of 48 post-COVID-19 patients, 40 completed the survey: Female 68%, male 32%; median age 54 yr	Feasibility of virtual reality exercises at home for post-COVID-19 condition was investigated, between July 2020 and February 2021, in the southeast of the Netherlands	VR platform to reduce stress and anxiety and promote cognitive functioning	70% of participant report an advertising event during VR, but only 25% recall these events. 75% reports VR as having a positive influence on their recovery	VR physical exercises at home is feasible and safe with good acceptance
Lovell *et al*	LS online	240 nursing staff, 8	A before-and-after	PERMA-Profiler,	Well-being scores after	Study findings may



[135], 2023	Survey	permanent ICU consultants, 32 rotational registrars, 10 allied health staff members, and a team of 10 administrative and 20 operational support staff members of ICUs	interventional online study was conducted over a 2-yr period, between 2019 and 2021, in a 30-bed level-3 ICU within an Australian metropolitan teaching hospital	questionnaire to assess overall well-being (1 item), negative emotions (3 items: Sadness, anger, and anxiety), loneliness (1 item), and physical health (3 items)	the intervention were not statistically different from BL. There are three key categories: Boosting morale and fostering togetherness, supporting staff, and barriers to well-being	inform strategies for improving ICU staff members' well-being
Sun *et al*[136], 2022	C-S online survey	524 ICU nurses provided 340 valid questionnaires (64.89% actual rate); 313 females, 27 males; 229 (67.35%) married	Online questionnaire sent to ICU nurses of 15 Chinese provinces, December 2020 to January 2021	Tested calling (BCS) and resilience (BRCS) as related to thriving at work (TWS) and ethical leadership (ELS)	All variables strongly and positively correlated with each other. The high resilience group was closely associated with calling after adjusting for age, gender, marital status, and other factors	Nurses' resilience underlies their promptness to stick to their duty and calling
Chommeloux *et al*[137], 2023	LS survey	Of 80 eligible patients, 62 patients supported by ECMO for severe ARDS were included in the study	Psychological disorders of ICU patients assessed at 6 and 12 mo after ECMO onset, March to June 2020 in 7 French ICUs	Anxiety, depression, PTSD, and QoL	Mental health is one of the most impaired domains: 44% of patients had significant anxiety, 42% had symptoms of depression and another 42% were at risk of PTSD, one year after admission to an ICU	Despite partial physical recovery one year after COVID-19, psychological function remains impaired

Calling, commitment to one's duties due to internal or external value system prompts (must serve society and others, because of a supreme entity recommends so or because of one's own beliefs). infection[32]. However, ICU patients with COVID-19 on clozapine did not differ for outcome from those receiving other antipsychotics[33].

Psychological implications of being hospitalised in an ICU: ICU post-discharge

As previously mentioned, the ICU exposes patients to stressful experiences with potential long-term repercussions. People who overcome a critical phase of illness and ICU admission can develop a post-intensive care syndrome (PICS), a cluster of physical, cognitive, and mental impairments observed after ICU hospitalisation; this shares clinical features with depression, anxiety, and PTSD[34]. The main risk factors for developing PICS can be classified as interventional, environmental, and psychological factors, including treatments such as mechanical ventilation, unfamiliar environment, and severe stress

DOI: 10.5498/wjp.v13.i4.191 **Copyright** ©The Author(s) 2023.

Figure 1 Results of our database searches for psychological consequences of the coronavirus disease 2019 pandemic on intensive care units and possible psychological interventions according to the recommendations of the Preferred Reporting Items for Systematic Reviews statement. [1]Consider, if feasible to do so, reporting the number of records identified from each database or register searched (rather than the total number across all databases/registers). [2]If automation tools were used, indicate how many records were excluded by a human and how many were excluded by automation tools. COVID-19: Coronavirus disease 2019.

experienced during hospitalisation[26,35].

The emergence of the COVID-19 pandemic has increased the number of patients exposed to risk factors of PICS and who require intensive care and aftercare[20]. Furthermore, a COVID-19 patient in the ICU who develops acute respiratory failure, is likely to be exposed to increased use of sedation and limited physical therapy in addition to mechanical ventilation. Therefore, critically ill COVID-19 patients have high chances of developing PICS[23]. Patients with COVID-19 who were treated in the ICU and survived have higher risk due to visit restriction, prolonged mechanical ventilation, higher sedative exposure, and reduced availability of physical therapy[36], but they are also at risk of developing prolonged cognitive dysfunction[37]. Generally, after ICU hospitalisation, mental health problems are very common and often impact health-related quality of life. These include anxiety, depression, and PTSD, as well as guilt, reduced libido, social isolation, irritability, and low confidence [38].

During the pandemic, PTSD appears to have a high incidence, of about 30%[39], characterised by symptoms such as hypervigilance, avoidant behaviour, and re-living the traumatic experience. In particular, hypervigilance may result in panic responses, irritability, and altered sleep-wake cycle, or in overconfident behaviour or, as in the case of COVID-19 patients, with concern about contagion and re-exposure[23]. Sometimes patients may present with disturbing and intrusive memories related to hospitalisation. Specific stimuli, such as smells, images, and sounds, may also activate memories. In addition, some patients may be inclined to avoid any medical environment after ICU admission[23].

COVID-19 and its complications, long hospital stay, and side effects of medications lead to reduced physical capacity that can affect mood. Recent literature has shown that both patients with COVID-19 and those without have high rates of post-hospitalisation depression[40], as well as anxiety and insomnia[41]. However, ICU patients with COVID-19 and ICU patients without COVID-19 did not differ on psychological distress, *i.e.*, cumulative symptoms of PTSD, anxiety, and depression three months after discharge, thus suggesting not to focus exclusively on COVID-19-positive patients[42].

During the COVID-19 pandemic, another major problem was social stigma[43]. In some cases, patients experienced guilt or shame for passing the disease on to others, with ensuing difficulty in

returning to their customary daily lives[23]. Multidisciplinary critical care, in addition to preventing imminent death, lays the foundation for improving patients' overall long-term survival experience[44].

Interventions aiming at addressing the psychological implications of COVID-19: Interventions with patients

In general, in patients admitted to the ICU, it is important to consider not only physical health but also mental health. This was especially important in COVID-19 patients, as high mortality and unpredictability had peculiar psychological meanings and consequences[45]. Attention is also due to patients with a previous history of mental disorder, as social isolation and estrangement can make the individual particularly vulnerable to psychopathological breakdown events. For this reason, during the pandemic, healthcare personnel has worked closely with psychologists to monitor the psychological condition of patients[45]. In this study, an in-person psychological intervention aimed at preventing unpleasant outcomes was encouraged in the most severe cases, which can result in aggression, self-injurious behaviour, and suicide attempts. Psychological support, taking care to use individual precautions aiming at reducing the risk of infection, was based on the assessment of the patient's prior state of mental health (traumas, previous episodes of self-harm, *etc.*) and his/her social and family environment. It is also important to take into account the potential impact of COVID-19 on the patient's socio-economic status[45].

In some ICUs, interventions such as music therapy or meditation were performed to mitigate the anxiety and distress of patients[46]. The addition of available technological devices such as TV, laptop, or radio may alleviate the patient's sense of isolation[46]. Sometimes psychological support for COVID-19 patients in ICU has been conducted remotely, through the use of digital tools. In particular, phones and the internet have proven to be effective in treating psychological issues[45]. Technology has also allowed ICU patients to keep in touch with their relatives, with tablets and mobiles provided for this purpose[46]. As mentioned above, patients may experience psychological sequelae even after discharge from the ICU. Early psychological interventions can support the patient in regaining ordinary daily routine. To treat PTSD, anxiety, worry, and panic reactions the use of cognitive behavioural therapy or metacognitive therapy could be given a trial, as these techniques have shown some efficacy in all these conditions[47,48]. In this framework, psychoeducational interventions are used to teach the patient to manage possible stress reactions[49]. Online support groups led by a psychologist can help COVID-19 survivors to share emotions related to the period experienced in the ICU[23].

Interventions aiming at addressing the psychological implications of COVID-19: Interventions with family members

Family members of patients admitted to the ICU are at high risk of developing psychological disorders. Anxiety, depression, PTSD, and other trauma-related reactions are the most common. In the literature, this clinical condition is called PICS-family[26,50]. During the COVID-19 pandemic, these symptoms can exacerbate due to the isolation family members suffer and the impossibility to get into direct contact with their loved ones. In addition, family members are often positive for COVID-19 and isolated at home, and this generates a sense of helplessness and loneliness in patients[45,51]. Relatives play a fundamental role, especially when the patient is dying because they have to make decisions for him, or to defend his/her interests[50].

For these reasons, it is important to design interventions that help preventing psychological dysfunctions among family members and support them in decision making during this difficult moment. In this frame, the psychologist is responsible for establishing clear criteria, that are shared with all health care professionals, to determine whether and how to intervene[52]. The psychological needs of family members to consider in the development of these interventions are the following: The need to be informed and updated about the medical condition of their loved one, the need to be emotionally supported by receiving reassurance and listening, the need to maintain a connection with the patient, even at a distance, and the need to receive support during the grieving process in case of death of their loved one[53]. In all these situations, it is important not to view as pathological any emotional reactions of family members but to consider them as being normal in the context of the difficult moment they are experiencing[52].

Most interventions aimed at family members used digital tools to reduce the possibility of transmitting COVID-19. Phone and video calls were the preferred tools for addressing relatives' psychological needs[54,55]. However, in case of a high psychopathological risk, family members were allowed to access the ICU. For instance, in-person visits accompanied by the psychologist were encouraged to preserve the relationship between the patient and his/her relatives. Personal protective equipment was used to protect all those involved[53].

Interventions aiming at addressing the psychological implications of COVID-19: Interventions with health workers

During the pandemic, intensive care workers, exposed to a high workload and high risk of infection, reported states of severe anxiety, insomnia, irritability, anxiety, and fear[56]. For this reason, ICU

healthcare professionals also seemed to be at serious risk of developing a burnout syndrome. The main factors associated with this risk include weak communication among staff members as well as organisational difficulties[57].

This highlighted the need to develop interventions aimed at ensuring ICU health care professionals' well-being and preventing emotional distress. These interventions must be designed on the basis of certain primary needs, *i.e.*, the need to feel safe, the need to belong to a unit group with clear, well-defined, and shared goals, the need to be listened to and, finally, the need to emotionally decompress [53]. The literature has confirmed the need for psychologists and psychological interventions in ICUs even during the pandemic; in fact, the applicability of psychological knowledge and skills to staff well-being before and during the pandemic were shown for example to promote teamwork and group cohesion and also to lead defusing activities[53]. Indeed, group defusing can allow for reframing the meaning of a traumatic event by reducing its emotional impact[58]. Defusing is the process of helping a disaster victim through the use of brief conversation and may help survivors in shifting from a survival mode to focusing on practical steps to reach stability again and to better understand the thoughts and feelings linked to their experience of the disaster[59]. Defusing involves professionals in three stages with different functions. Introduction is the general presentation of the intervention to clarify and engage participants. Exploration is the moment in which traumatic experiences related to working in ICU emerge or are extracted, through the recollection of particular thoughts and emotions. Information aims to normalise stress reactions by providing continuous support, reassurance, and coping strategies to address emotional distress[60]. As the pandemic is still persisting or returning under new forms, rapid, pandemic-specific assessment tools may be needed to allow better evaluation of patients' stress in the ICU[61].

It may also be useful to set up a room for the ICU healthcare professionals to allow them to offload tensions by promoting physical and psychological decompression[53]. Relaxation techniques showed efficacy in managing stress, preventing burnout, and increasing work motivation, in particular autogenic training[62]. Relaxation techniques during COVID-19 confirmed their effectiveness as procedures apt to improve quality of life, work motivation, burnout and stress perceptions within the emergency department team[63].

Psychological interventions in this field should be considered as preventive and proactive health interventions, rather than as treatments for psychopathological problems, helping individuals to effectively express their own resources. Emergency psychology has offered appropriate techniques to achieve this goal[64]. Summarising, COVID-19 pandemic has highlighted the importance of frontline workers' mental health and the need to support the presence of psychologists in ICUs; in this way, healthcare workers could experience more relief from the many responsibilities that hamper the effectiveness of their work[45].

Humanised technology during COVID-19 pandemic: Digital communication

During COVID-19 pandemic in ICUs, patients' possibilities to see their relatives were reduced[65]. In this context, digital communication proved to be a very effective tool for facilitating communication despite visitation restrictions[66]. Digital interactions can bring significant benefits in terms of emotional support and communication of information to family members, and also in terms of patient recovery and increased ICU staff moral[22].

Recent studies have mainly explored the impact of digital interventions on family members: COVID-19 pandemic has reduced the possibility to see the patient and directly interfacing with the medical teams to receive clinical updates. In general, allowing family members to use video calls to see their loved ones has proven to be a good way to alleviate the discomfort of physical distance[54]. Other studies show that family members report mixed feelings about video calls with the patient. For example, they wanted the opportunity to see the patient but reported that the images of their loved ones lying down were upsetting. This fact underlines the importance of assessing each individual family for burden and preferences[67].

Regarding communication between family members and the medical team, phone calls were used as a tool to communicate quick information[54]. Video calls, instead, were preferred to align doctors and family members' perspectives on the patient's condition. Doctors' doubts about their capacity to transmit empathy at a distance were denied by family members' opinions, who reported a sense of closeness when using a telephone or a video, despite the distance[66]. An Italian team developed ten statements and two checklists to enable medical teams to communicate effectively with family members, that could be also used as guidelines[68].

It is appropriate at this point to talk about the barriers limiting the use of digital tools in intensive care. In fact, family members do not always have the necessary skills to access the set video platforms or they not even possess a suitable technological device. Problems with the Wi-Fi connection and, in some cases, lack of time and of specific training in the staff add to the above-mentioned barriers[22].

Humanised technology during COVID-19 pandemic: VR interventions

Several ICUs during the COVID-19 pandemic used VR interventions to deal with patients' psychological symptoms such as anxiety, stress, PTSD, and depression[69]. VR bring the user into a "realistic, immersive multi-sensory environment" through computer-generated visuals[70] and this digital tool

proved to be effective in reducing anxiety and pain, by distracting the user and providing a relaxing experience[71]. In the presence of full-blown PTSD, VR can subsequently be used as 'exposure therapy'; it can promote deep involvement and activation of the user's traumatic memory of fearful stimuli[72], such as those experienced in an ICU[73]. For this reason, VR exposure therapy turned out to be also one of the most popular game-based digital interventions for the treatment of depression caused by fear [74], although in PTSD patients, it did not reduce the anxiety and did not differentiate from other standard treatments[75].

The use of VR as a therapy for the psychological sequelae of COVID-19 patients has some important advantages. First, it could be helpful for reconstructing the phases the patient experienced during the ICU hospitalisation, so to adjust to unpleasant memories, as proposed in a protocol[76]. Second, it can be used remotely to respect social distance needs. Third, it allows to manage more patients at the same time. However, VR implementation should overcome some barriers. These mainly concern the organization of VR interventions at home and remote support. For this purpose, it is necessary to design a toolkit that is safe, comfortable, and easily accessible[70].

Other possible applications of VR during COVID-19 pandemic in ICU include its use to rapidly upskill healthcare professionals and to reduce perceived interindividual stress[56], but also to improve communication of information about ICU treatment and ICU environment to patients' relatives (ICU-VR-F)[77].

Current and future perspectives

The present review identified 65 studies targeting COVID-19 in ICUs and the ensuing psychological problems, of which 43 focused on the role of the psychologist in increasing team cohesion, reducing distress of patients, relatives, and staff and preventing or reducing burnout in the latter, and highlighting that during the COVID-19 pandemic the psychologist is playing an increasingly important role within the ICU.

Special psychological needs emerged for the patient and his/her relatives, and also for healthcare professionals. Frequently psychologists acted promptly through interventions aimed at providing psychological support to all involved and facilitating communicative exchanges, despite the restrictions imposed. In this way, the medical team members were relieved of much workload and were free to focus mainly on the medical aspects of the cases inside the ICU[74].

As the coordinated interventions of the medical team and the psychologist has proven to be very effective in patient care and in promoting patient well-being, it is desirable that the presence of the psychologist becomes a structural feature of ICUs and other hospital areas that deal with emergencies. Based on the literature, digital tools were much used in ICUs during the COVID-19 pandemic to promote communication between patients, family members, and healthcare professionals[56,77]. The addition of new learning-based approaches, such as deep learning or machine learning[78] may help people overcoming this difficult moment by implementing psychological techniques[79]. Since the risk of contagion is still high, they can still be used - when in-person visitation is not strictly necessary - to make communication easier.

VR is a particular technological tool, which is useful in treating psychological sequelae of ICU inpatients. It is mostly used during the COVID-19 pandemic and can significantly improve the mental health of previously hospitalized patients. For their numerous benefits, digital tools, including VR, should be commonly used in ICUs. For this to be possible, however, it is necessary to overcome the previously outlined limitations and barriers.

Limitations

We did not include in our review other databases that could have accrued our results. The obtain results used diverse methodologies, leading to heterogeneity which did not allow us to perform sound statistical analyses such as meta-analyses or meta-regressions. We did not include specific distinctions regarding the target audience (geriatric patients, neonatal ICUs, or patients with disabilities), so we collected all studies independently from methodology. As a result, we cannot make generalizations regarding the efficacy or effectiveness of the mentioned interventions. Some of these interventions could be modified or adapted according to patients' needs.

CONCLUSION

In this review, we analysed the role of the psychologist in the ICU during the COVID-19 pandemic, focusing on the interventions with patients, family members, and healthcare professionals. We chose a narrative review of the literature because currently there is dearth of studies focusing on the psychologist's work in ICUs during the public health emergency represented by COVID-19. This fact, and the fact that the methodologies of the studies we were able to gather are heterogeneous, make the field not meta-analysable. Since the COVID-19 pandemic is not still over, we need further studies to support the standpoint that psychological support in the ICU is fundamental.

ARTICLE HIGHLIGHTS

Research background

Coronavirus disease 2019 (COVID-19) upset intensive care unit (ICU) function, increasing risk for psychological distress during and after hospitalisation. This paved the way for psychological interventions to support patients in ICUs.

Research motivation

To alleviate the increased workload and burden of ICU staff through psychological interventions.

Research objectives

We carried out a systematic review of the psychological issues raised in ICUs during the COVID-19 pandemic which concerned patients, their relatives, and the ICU staff (physicians, nurses, and auxiliary staff) as well as of the possible psychological treatments that could improve psychological measures.

Research methods

Search of PubMed and ClinicalTrials.gov databases, establishing inclusion/exclusion criteria and deciding eligibility through Delphi rounds among involved researchers.

Research results

We found 65 eligible articles, which summarised. Results point to increased perceived stress and psychological distress in staff, patients and their relatives. Some psychological interventions hold promise.

Research conclusions

Psychological programmes to improve psychological measures in ICU patients, relatives, and staff may enhance ICU functional efficiency.

Research perspectives

The role of interventions using digital tools and virtual reality may pave the way to a better work climate within ICUs, with psychologists gaining a liaison role within the staff.

ABOUT COVER

Editorial Board Member of *World Journal of Psychiatry*, Wei Wang, BMed, DSc, Chief Doctor, Full Professor, Department of Psychology, Norwegian University of Science and Technology, Trondheim 7491, Norway. wew@ntnu.no

AIMS AND SCOPE

The primary aim of *World Journal of Psychiatry* (*WJP*, *World J Psychiatry*) is to provide scholars and readers from various fields of psychiatry with a platform to publish high-quality basic and clinical research articles and communicate their research findings online.

WJP mainly publishes articles reporting research results and findings obtained in the field of psychiatry and covering a wide range of topics including adolescent psychiatry, biological psychiatry, child psychiatry, community psychiatry, ethnopsychology, psychoanalysis, psychosomatic medicine, *etc*.

INDEXING/ABSTRACTING

The *WJP* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Current Contents/Clinical Medicine, Journal Citation Reports/Science Edition, PubMed, PubMed Central, Reference Citation Analysis, China National Knowledge Infrastructure, China Science and Technology Journal Database, and Superstar Journals Database. Abstract

In the beginning of the 1900s, the prevalence of catatonia in inpatient samples was reported to be between 19.5% and 50%. From the mid-1900s, most clinicians thought that catatonia was disappearing. Advances in medical sciences, particularly in the field of neurology, may have reduced the incidence of neurological diseases that present with catatonic features or mitigated their severity. More active pharmacological and psychosocial treatment methods may have either eliminated or moderated catatonic phenomena. Moreover, the relatively narrow descriptive features in modern classifications compared with classical texts and ascribing catatonic signs and symptoms to antipsychotic-induced motor symptoms may have contributed to an apparent decline in the incidence of catatonia. The application of catatonia rating scales introduced in the 1990s revealed significantly more symptoms than routine clinical interviews, and within a few years, the notion of the disappearance of catatonia gave way to its unexpected resurgence. Several systematic investigations have found that, on average, 10% of acute psychotic patients present with catatonic features. In this editorial, the changes in the incidence of catatonia and the possible underlying causes are reviewed.

Key Words: Catatonia; Historical overview; Frequency of catatonia; Diagnostic and Statistical Manual of Mental Disorders-5; Wernicke–Kleist-Leonhard school; Bush-Francis Catatonia Rating Scale

Core Tip: Although the prevalence of catatonia was reported to be between 19.5% and 50% in the early 1900s, most clinicians thought that catatonia was disappearing by mid-century, However, more recent systematic investigations have found that catatonia continues to be a common clinical disorder with an average prevalence of 10%. The apparent historical changes in the prevalence of catatonia reflects shifts in the socio-cultural context of psychiatry, the type of service, diagnostic criteria, research methods, and advances in treatment and clinical practice. We propose the establishment of an international society and journal dedicated to the study of catatonia to facilitate understanding and research.

INTRODUCTION

During most of the last century, in line with the prevailing Kraepelinian tradition, catatonia essentially was used to refer to catatonic schizophrenia, although a careful reading of Kraepelin's textbook shows a more sophisticated view of catatonia[1-4]. In the two authoritative classical textbooks, the prevalence of catatonia in inpatient samples is reported to be between 19.5%[1] and 50%[5], whereas it was 35.4% according to the Wernicke–Kleist–Leonhard school[6]. However, from the mid-1900s, there was a growing consensus among clinicians that catatonia was becoming nearly extinct, as Mahendra[7] famously asked, "Where have all the catatonics gone?". Such clinical impressions were supported by a few, although not all[8,9], epidemiological studies that attempted the nearly impossible task of determining the changes in the real prevalence of catatonia across several years or decades against the background of shifts in the socio-cultural context of psychiatry, the type of service (inpatient, outpatient, and community), diagnostic criteria, research methods, and advances in treatment and clinical practice in general.

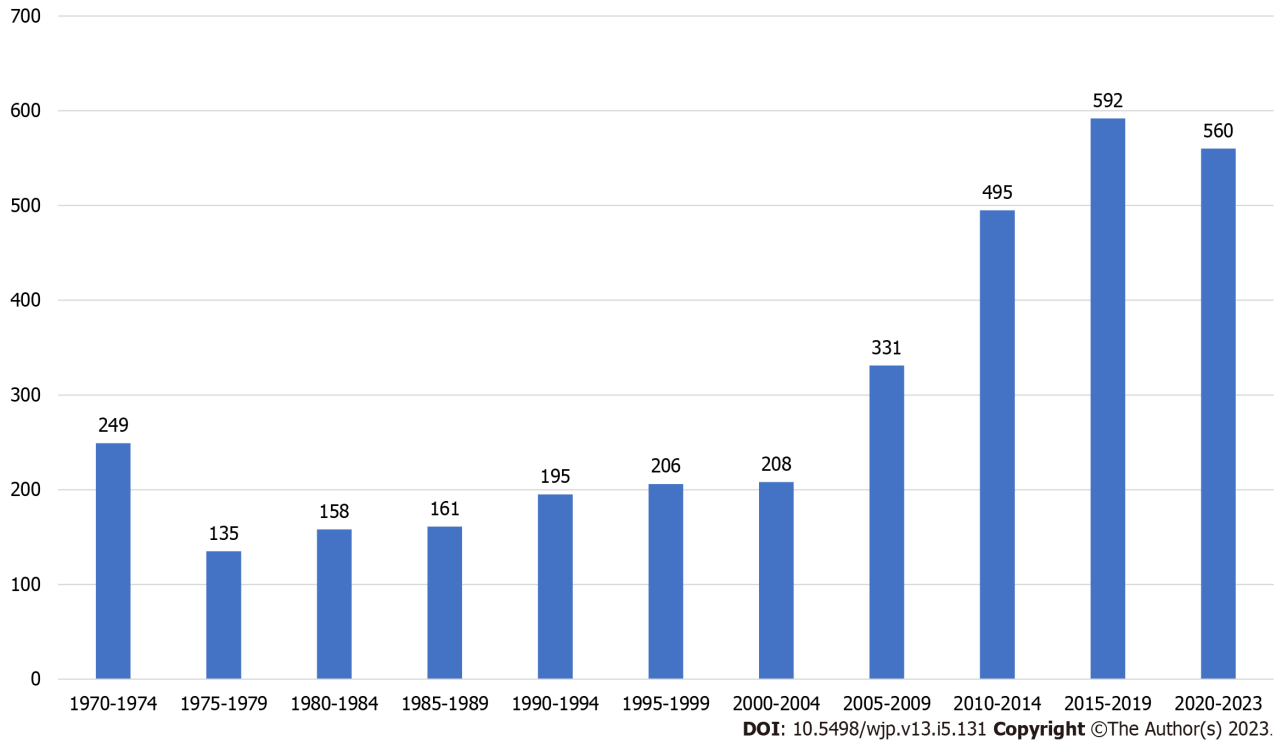
DISCUSSION

Relatively comparable, albeit not necessarily reliable, rough estimates of the changes in the frequency of catatonia can be made by focusing on single sites when comparing two time periods. For example, between 1850 and 1950, the rate of first admissions for catatonia decreased from 6% to 0.5% in the Bethlem royal hospital, a leading hospital and academic center in London, United Kingdom[10]. Another example from Finland showed a decline in the frequency of admissions for catatonic schizophrenia from 40.1% to 11% over just 20 years from 1933–1935 to 1953-1955[11]. In two Polish hospitals, where catatonia was diagnosed very conservatively, the frequency of catatonic schizophrenia diagnoses decreased 190-fold from 1924–1929 to 1994–1999 and 36-fold from 1958–1963 to 1994–1999[12]. From 1964 to 1984, catatonic schizophrenia nearly disappeared entirely in a university hospital in Santiago, Chile[13]. In a Belgian academic center, based on a chart review of 19309 admissions, the diagnosis of catatonic schizophrenia decreased from 7.8% to 1.3% in the two consecutive decades of 1980–1989 and 1990–2000[14].

Several plausible reasons have been proposed for the decline in the rate of catatonia observed in the second part of the last century. Advances in medical sciences, particularly in the field of neurology, may have reduced the incidence of neurological diseases that present with catatonic features or mitigated their severity[7]. More active pharmacological and psychosocial treatment methods may have either eliminated or moderated catatonic phenomena. Moreover, the relatively narrow descriptive features in modern classifications compared with classical texts and ascribing catatonic signs and symptoms to antipsychotic-induced motor symptoms may have contributed to the reduced incidence of catatonia[15, 16]. The application of catatonia rating scales introduced in the 1990s[17] revealed significantly more symptoms than routine clinical interview, suggesting that insufficient diagnostic practices were responsible for the under-recognition of catatonia[14].

From the 1990s, the situation changed, and within a few years, the notion of the disappearance of catatonia gave way to its unexpected resurgence[18,19] (Figure 1). Several systematic investigations have found that, on average, 10% of acute psychotic patients present with catatonic features[20], with a wide range of frequencies from 1% in Nigeria[21], 3.7% in Mexico[22] to 38% in Greece[23], 50% in Belgium[24] and 68% in the United States[25]. The corresponding figures reached 20% for depression [26], 31% for mania[27], and almost 100% for the chronically hospitalized psychotic population[28]. Awareness has also broadened to encompass catatonia occurring in the context of general medical conditions[16,18]. Since the 1990s, interest in the epidemiological[16], clinical[29,30] and neurobiological [31,32] aspects of catatonia has continued unabated, stimulated by its semi-independent place in the Diagnostic and Statistical Manual of Mental Disorders, fifth edition[33,34] and in addition to secondary catatonia occurring in the context a wide range of psychiatric and medical conditions also appeared as an independent diagnostic category in the International Classification of Diseases, 11th revision[35].

The apparent disappearance of catatonia from psychiatric practice and research for decades and its recent re-discovery raises serious questions. The intriguing fact is that a well-known and easily observable motor phenomena, which has been reported in such a high proportion in acute psychiatric admissions over the past two decades, was declared to be essentially extinct for approximately four decades in the second part of the last century. The logical argument is that, if catatonia had temporarily become extinct, there must have been a very significant environmental and/or neurobiological change responsible for this, which went unnoticed for a while and then stopped. However, there has been no suggestion that such panoramic environmental or biological changes affecting motor symptoms in psychiatric patients have occurred. However, if catatonia did not actually disappear, which is the likely scenario, the question remains how mainstream psychiatry missed an important aspect of mental disorders for decades. A possible answer to this puzzling question may provide important information about the nature of catatonia and psychiatric diagnostic practice. However, this is a complex issue and reaching a firm conclusion is unlikely as the available studies on catatonia are fraught with major methodological flaws that make it difficult to make comparisons between studies across time[16].



We posit that catatonia may have been modified in its manifestations and may have lessened in intensity and frequency due to advances in treatment of schizophrenia and mood disorders, but never disappeared entirely[15]. Rather, it was not given adequate attention by clinicians, particularly in the internationally dominant Anglo-American psychiatry with pockets of exceptions in Europe, such as at the Wernicke–Kleist-Leonhard school of psychiatry[6,36]. There are also indications that catatonia never disappeared in developing countries[37], but has occurred at a similar or even higher frequency and severity to those in Western settings[38] albeit possibly with a different symptom profile[39]. Over the past three decades, several Indian studies examined the phenomenology[40,41] and the frequency of catatonia in acute inpatient admissions that ranged from 4.8%[40] to 10.3%[41], 16.3%[42] and 37.2%[43].

In the following section, we outline some of the factors that support our view that the disappearance of catatonia was apparent, but not real. From a broader perspective, the temporary disappearance of catatonia in psychiatric research and practice during the middle decades of the 20th century is the logical consequence of the development of psychiatry in the last century.

In the second part of the 20th century, the whole fabric of psychiatric practice moved away from traditional stand-alone institutions that existed at the fringes of society to a more community and office-based model focused on outpatient therapy. From the 1920s, psychodynamic psychiatry, based on psychoanalysis and its versions, had an increasingly large impact on mainstream psychiatry, mainly in the United States and to a lesser degree in other Western countries, although isolated examples of biologically-oriented descriptive psychiatry, such as the Wernicke–Kleist–Leonhard school or French neuropsychiatry[44] never ceased to exist in continental Europe. As psychodynamic psychiatry focuses on the inner psychic life of the patients and not the observation of patients' manifest behavior or motor symptoms, catatonia lost its significance in English-language psychiatry, and its signs and symptoms were glossed over in diagnostic practice.

Diagnostic practices have also undergone profound changes from the 1960s with the introduction of objective rating scales[45] and then operationalized diagnostic criteria in the 1970s[46]. The original psychopathological descriptions, including those for catatonia, were made by psychiatrists who had the opportunity to observe their patients every day in different situations over several weeks, months, or years. Many of these psychiatrists actually lived in the institutions and had fewer commitments outside of their clinical work than their modern counterparts. The democratization and decentralization of psychiatric practice, coupled with the widespread introduction of simplified cross-sectional diagnosis, as in the Diagnostic and Statistical Manual of Mental Disorders third edition[47], greatly altered the relationship between patients and psychiatrists and the diagnostic process.

In the developed world, this situation emerged starting in the 1960s with the arrival of de-institutionalization; the establishment of short-term acute psychiatric wards in general hospitals; community outpatient psychiatry evolving to brief 15-min "med checks"; and the collaborative role of allied mental health professionals providing psychiatric services, just to mention a few important factors. As a result, psychiatrists began spending less and less time in direct contact with their patients in the modern era, which may have reduced the likelihood of detecting catatonic symptoms. For instance, restructuring a regional psychiatric service in the United Kingdom resulted in psychiatrists having access to "less than 20% of the total case-load"[48].

Figure 1 Published articles on catatonia based on PubMed broken down by 5 years.

Another aspect of contemporary psychiatric practice that may have hindered the easy detection of catatonia is exemplified by a landmark study conducted at the Institute of Psychiatry in London, one of the leading academic psychiatric centers in the world that have provided the scientific foundation to sanction diagnostic practices in the modern era[49]. In a series of diagnostic exercises, 28 psychiatrists with at least 4 years of clinical experience were asked to diagnose patients during the same 5-min diagnostic interviews based on either a video of the patients during the interview, a soundtrack recording of the interview, or only written transcripts. Surprisingly, the diagnostic accuracy measured against the final hospital discharge diagnoses was essentially identical in these three different diagnostic situations. Kendell came to the important conclusion that observing the patients' behavior did not improve diagnostic accuracy, indicating that behavioral or motor symptoms had no, or negligible, currency in the diagnostic process although this academic center stressed the importance of behavioral symptoms and careful observations. Kendell also found that diagnostic accuracy did not increase after 4 years spent in psychiatric practice, thereby questioning the value of accumulated experience and the power of observation developed during this experience in making a diagnosis. Furthermore, based on the diagnostic accuracy of 70% reached after 5 min in each rating situation, the author suggested significantly shortening the standard 1-hour diagnostic interview. The implications of these findings on the under-recognition of catatonia are obvious.

It is well known from classical textbooks that the frequency and intensity of catatonic episodes fluctuate over time[1,5,6] and that they may not manifest at the time of cross-sectional assessment, which is how modern catatonia rating scales are conducted, resulting in a potential failure to detect the whole scope of catatonic symptomatology, particularly in chronically ill patients. For example, the Bush–Francis Catatonia Rating Scale (BFCRS)[17], the most widely used rating instrument, requires only 5–10 min to complete, although raters are encouraged to consult their medical notes covering the previous 24-h period, albeit only for the items of "withdrawal" and "autonomic abnormality." The BFCRS has been shown to be adequate for assessing acute catatonic episodes[17], but it may not be entirely sufficient for persistent or periodic catatonia in patients with chronic illness[50], as previously suggested[51]. A study comparing the number and severity of catatonic signs and symptoms covered by the BFCRS, rated by skilled clinicians, with the "gold standard" of extended, unobtrusive observations by an experienced clinician found that the latter method yielded significantly higher ratings[52]. Signs and symptoms that were most frequently missed by cross-sectional assessment, but captured by longitudinal clinical observations were mannerisms, stereotypy, grimacing, perseveration, and apparently purposeless impulsivity[52].

Following the widespread introduction of antipsychotic drugs in psychiatric practice in the mid-1950s, it took about a decade to recognize the full spectrum and significance of drug-induced motor symptoms and syndromes referred to as extrapyramidal side effects (EPS). The importance of EPS in psychiatry may have overshadowed catatonic and other illness-related motor symptoms in clinical practice. Catatonic signs and symptoms may have been obscured by and ascribed to drug-induced EPS

[15]. EPS-like motor symptoms have been consistently reported in drug-naïve patients since the 1990s, raising the possibility that, in many instances, catatonia may have been indeed misdiagnosed as EPS [53]. Even if this were not the case, the recognition of motor symptoms in drug-naïve patients helped refocus attention to catatonia.

CONCLUSION

We believe that the growing number of publications on catatonia and the number of clinicians and researchers displaying a keen interest in this subject have reached the level that warrants the establishment of an international society and a journal dedicated to the study of catatonia, to bring together interested parties, promote and coordinate research, and disseminate relevant knowledge to the broader mental health community. This may be one the avenues to further facilitate a greater understanding of catatonia, thereby improving the lives of patients with catatonia.

Abstract

Current ICD-11 descriptions for attention deficit hyperactivity disorder (ADHD) were recently published online, in the same year as the DSM-5-TR (text revised edition) was released. In this commentary, we compare and contrast the DSM-5/DSM-5-TR and ICD-11 diagnostic criteria, summarize important differences, and underscore their clinical and research implications. Overall, three major differences emerge: (1) The number of diagnostic criteria for inattention (IA), hyperactivity (HY) and impulsivity (IM) symptoms (*i.e.*, DSM-5-TR has nine IA and nine HY/IM symptoms, whereas ICD-11 has eleven IA and eleven HY/IM symptoms); (2) the clarity and standardization of diagnostic thresholds (*i.e.*, the diagnostic thresholds for symptom count in IA and HY/IM domains are explicitly specified in DSM-5-TR, whereas in ICD-11 they are not); and (3) the partitioning of HY and IM symptoms into sub-dimensions (*i.e.*, difference in partitioning HY and IM symptom domains relates to the differences between the current and previous editions of DSM and ICD, and this has important research implications). Currently, no ICD-11 based ADHD rating scales exist and while this absence represents an obstacle for respective research and clinical practice, it also presents opportunities for research development. This article highlights these challenges, possible remedies and novel research opportunities.

Key Words: Attention deficit hyperactivity disorder; ICD-11; DSM-5-TR; Clinical implication; Diagnostic threshold; Taxonomy; Research

Core Tip: Three major differences between DSM-5-TR and ICD-11 are: (1) The number of diagnostic criteria for inattention, hyperactivity (HY) and impulsivity (IM) symptoms; (2) the clarity and standardization of diagnostic thresholds; and (3) the partitioning of HY and IM symptoms into sub-dimensions between previous and current editions of DSM and ICD. Currently, no ICD-11 based attention deficit hyperactivity disorder (ADHD) rating scales exist. The absence of research evidence to inform and reconcile these differences represents opportunities for research. Emerging research findings suggest that 'impulsivity' is likely the key latent factor underlying different expressions of ADHD symptoms; and the current criteria merging HY/IM could limit such explorations.

INTRODUCTION

ICD-11 descriptions for attention deficit hyperactivity disorder (ADHD) were recently published online [1]. In addition, the DSM-5-TR[2] was published in print along with a more extended digital e-edition version. While there is greater alignment between ICD-11 and DSM-5-TR, there are nevertheless differences (albeit subtle in parts), which entail important implications for research and clinical application. This commentary paper critically distils and articulates these differences (particularly diagnostic symptoms and symptom threshold for diagnosis). As no revisions were made to the diagnostic criteria of ADHD in DSM-5-TR, the remainder of this commentary refers to DSM-5-TR instead of 'DSM-5' or 'DSM-5 and DSM-5-TR', unless otherwise specified. A more severe variant of ADHD is called hyperkinetic disorder (HKD) in ICD-10[3]. The symptom compositions for HKD in ICD-10 are comparable with the 'combined presentation' of ADHD in DSM-5-TR, but not the 'predominantly inattentive' or 'predominantly hyperactive-impulsive' presentations. The ICD-11 revision of ADHD is now more aligned with DSM-5-TR, by including less severe presentations/types other than HKD.

With reference to DSM and ICD comparisons, we first summarize the major differences between DSM-5/DSM-5-TR and ICD-11 diagnostic criteria. The implications of these differences for clinical practice and research are then discussed. To place our discussion in context, we present first a summary of DSM-5-TR and ICD-11 and compare them. By undertaking this commentary we seek to facilitate a deeper understanding and appreciation of these different, but related, classification systems, and how they contribute to better research and clinical practice.

Summary of DSM-5-TR and ICD-11

Table 1 provides a summary of DSM-5-TR and ICD-11 diagnostic criteria for ADHD in relation to their descriptions, onset, presentation patterns, and symptom criteria, with regards to settings, duration and impairment. As can be seen in Table 1, while there is much alignment between ICD-11 and DSM-5-TR, important differences exist, especially in terms of symptom composition and criteria. We will focus on these in the next section.

MAJOR DIFFERENCES BETWEEN DSM-5-TR AND ICD-11

There are at least four major differences between DSM-5-TR and ICD-11 and their previous editions that are noteworthy of consideration.

Difference in splitting one inattentive symptom criterion

First, in contrast to DSM-5-TR which lists nine inattention (IA) symptoms, ICD-11 has 11 IA symptoms. The specific DSM-5-TR IA symptom for "Often fails to give close attention to details or makes careless mistakes in schoolwork, at work, or with other activities" is split into two separate IA symptoms in ICD-11: "Lacking attention to detail", and "Making careless mistakes in school or work assignments". This gives rise to the first extra symptom.

Additional IA and hyperactivity/IMP symptoms in ICD-11

In addition, the specific DSM-5-TR IA symptom "Is often forgetful in daily activities" is also partitioned into two separate similar IA symptoms in ICD-11: "Is forgetful in daily activities" and "Has difficulty remembering to complete upcoming daily tasks or activities". This gives rise to the second extra

Table 1 Comparison of DSM-5-TR and ICD-11 diagnostic criteria for attention-deficit/hyperactivity disorder

	DSM-5-TR	ICD-11
Name	ADHD	ADHD
Onset	Some symptoms present before 12 yr	Some symptoms present before 12 yr
Symptoms	9 IA symptoms	11 or 9 IA symptoms
	9 HY/IM symptoms	11 or 10 HY/IM symptoms
Presentation types/symptom criteria for children	(1) ADHD combined: At least 6 IA and 6 HY/IM symptoms; (2) ADHD predominantly inattentive: At least 6 IA symptoms; and (3) ADHD predominantly hyperactive/impulsive: At least 6 HY/IM symptoms	(1) ADHD combined: IA and HY/IM symptoms present with neither predominating; (2) ADHD predominantly inattentive: IA symptoms predominating; and (3) ADHD predominantly hyperactive/impulsive: HY/IM symptoms predominating
Presentation types/symptom criteria for persons aged ≥ 17	(1) ADHD combined: At least 5 IA and 5 HY/IM symptoms; (2) ADHD predominantly inattentive: at least 5 IA symptoms; and (3) ADHD predominantly hyperactive/impulsive: At least 5 HY/IM symptoms	
Settings	Present in at least 2 settings	Multiple settings–but symptoms may vary according to the structure and demands of the setting
Duration	≥ 6 mo	≥ 6 mo
Impairment	Social, academic, or occupational functioning	Social, academic, or occupational functioning–IA symptoms less evident in stimulating and rewarding activities and HY/IM during free-play

ADHD: Attention deficit hyperactivity disorder; IA: Inattention; HY: Hyperactivity; IM: Impulsivity.

symptom. A new IA symptom for ICD-11, not present in DSM-5-TR, is "Frequently appears to be daydreaming or to have mind elsewhere". This is the third extra symptom. However, this symptom could be regarded as being more in line with the "sluggish cognitive tempo (SCT)" symptom when considered in light of the SCT literature[4]. In addition, the specific DSM-5-TR IA symptom "Often has trouble holding attention on tasks or play activities" is not present in ICD-11.

With reference to hyperactivity (HY)/impulsivity (IM) symptoms, ICD-11 lists 10. Two of these relate to overactive behavior: "Has difficulty sitting still without fidgeting" and "Feelings of physical restlessness, a sense of discomfort with being quiet or sitting still". ICD-11 specifies that the former be applied to younger children, and the latter be applied to adolescents and adults (*i.e.*, age 17 years or older). These can be regarded as developmental variants of the same symptom. For this reason, there are in reality 10 HY/IM symptoms in ICD-11. The symptom of "is often 'on the go', acting as if 'driven by a motor….' experienced by others as being restless…" in DSM-5-TR is absent in ICD-11; however, this could potentially be comparable to 'feelings of physical restlessness' in ICD-11. A new HY/IM symptom in ICD-11, which is absent in DSM-5-TR, is "A tendency to act in response to immediate stimuli without deliberation or consideration of risks and consequences (*e.g.*, engaging in behaviors with potential for physical injury; impulsive decisions; reckless driving)". This symptom captures the classical description of dispositional trait IM. In contrast, in DSM-5-TR, IM is solely represented by three directly observable behavioral symptoms (*i.e.*, 'blurt out', 'can't wait' and 'interrupt'), as an absence of deliberation or risk consideration that cannot be directly observed, but often only inferred or disclosed by the actor upon retrospective reflection.

In summary, DSM-5-TR has nine IA and nine HY/IM symptoms, whereas ICD-11 has 11 IA and 11 HY/IM symptoms (but 10 if 'fidgeting' in children and 'mental restlessness' in adults are combined as one).

Differences in partitioning of HY and IM symptom sub-dimensions

The third difference relates to previous and current editions of DSM and ICD. Specifically, whether HY and IM symptoms should be considered as separate dimensions by contrasting DSM-IV-TR[5] with DSM-5-TR, and by contrasting ICD-10 with ICD-11. Currently, in DSM-5-TR, HY and IM symptoms are considered to represent a single dimension regarding threshold for diagnosis. This means an adult will meet diagnostic threshold of the HY/IM domain regardless of whether they have HY or IM symptoms. The HY/IM threshold can be met by two different adults: One with five HY symptoms and another with mixed two HY symptoms and 3 IM symptoms. Although ICD-11 also groups HY and IM as a single dimension, diagnostic thresholds are not specified for either children or adults.

In the previous DSM-IV-TR edition, symptoms were listed separately under HY and IM subheadings. Likewise, ICD-10 contemporaneous with DSM-IV-TR also considered them separately, but with 'talkativeness' listed within the IM grouping. By applying the ICD-10 framework, it can be postulated that out of the 10 ICD-11 HY/IM symptoms, five symptoms are HY ('motor activity', 'leaving seat', 'running

about', 'difficulty setting still'/'physical restlessness', and 'difficulty in not engaging in activity quietly'), while the other five symptoms ('talkativeness', 'blurt out', 'can't wait', 'interrupt', and 'immediate response without considering consequences') are IM symptoms. Recent empirical findings from factor analytic studies provide support that HY and IM symptoms should be grouped separately, and that 'talkativeness' should be grouped with IM rather than HY in line with ICD-10 configuration[6,7].

Differences in clarity and standardization of diagnostic thresholds

Fourth, the diagnostic thresholds for symptom count in IA and HY/IM domains are explicitly specified in DSM-5-TR (*i.e.*, six for each domain for children and five for each domain for adolescents/adults aged 17 or above), whereas in ICD-11 they are not.

Noting that ADHD symptoms may vary with developmental age and ADHD severity, ICD-11 states that "several symptoms" from the IA and HY/IM clusters need to be present. This approach is however consistent with the general approach used by ICD-11[8], in order to avoid arbitrary cutoffs related to symptom counts and duration; and as such, terms such as "several days", "several weeks", and "several symptoms" are used in ICD-11.

The approach used by ICD-11 is considered to be more in line with how clinicians actually make diagnoses, allowing more flexibility in exercising clinical judgment and avoiding algorithmic requirements (regarded by some as 'pseudo-precision'), such as a prescribed threshold of symptom counts. This flexibility is an innovative feature in ICD-11, and is more consistent with the dimensional classification[8]. However guidelines on how to establish thresholds are not provided in ICD-11. Therefore, when using ICD-11, the onus is placed on individual clinicians to apply their own judgement in determining clinical thresholds. The potential problems with this approach include diagnostic difficulty (especially for less experienced clinicians) and the increased heterogeneity of ADHD above and beyond that yielded by the DSM-5-TR defined ADHD diagnostic criteria.

IMPLICATIONS OF THE DIFFERENCES BETWEEN DSM-5/DSM-5-TR AND ICD-11 FOR RESEARCH AND CLINICAL PRACTICE

With reference to ADHD diagnostic criteria, the differences related to the number of criteria, the thresholds for ADHD diagnosis, and whether the HY and IM symptom groups are merged or grouped separately have a number of implications for clinical practice and research.

First, in relation to clinical practice, as mentioned previously, the thresholds for the different symptom domains are unspecified in ICD-11, thereby increasing the likelihood of greater diagnostic heterogeneity. Greater standardization generally improves diagnostic reliability, but this prescribed algorithmic approach is not adopted by ICD-11 per se; in contrast, ICD-11 prefers the dimensional approach. In this respect, we suggest that until clearer guidance from ICD-11 and its future revision is forthcoming, researchers using ICD-11 should be cognizant of providing very detailed descriptions of the samples (including symptom count) examined in their studies. Moreover, it is anticipated that ICD-11 will in due course release its Clinical Descriptions and Diagnostic Guidelines (CDDG). These will likely provide more operationalized diagnostic guidance for clinicians and researchers, and with more than a decade of work invested in their development[8], be 'designed to assist mental health clinicians in making a confident diagnosis'. We therefore highly recommend readers to access and study in detail the ICD-11 CDDG for more information, when it becomes available.

Secondly, for DSM-5/DSM-5-TR, questions have been raised about whether the proposed/implied two-factors (*i.e.*, IA and HY/IM dimensions) is the optimum structural model. This is because many studies that have compared different latent structural models of ADHD have reported less support for the two-factor model than for three-factor models (especially IA, HY and IM factors aligned to ICD-10 [3]. Relatedly, recent studies[7,9] have provided empirical support for the S-1 bifactor model to account for the latent factor structure of ADHD. That is, ADHD is likely a disorder predominantly driven by latent IM substrates[7] in line with the 'trait impulsivity hypothesis'[10]. In this S-1 bifactor model, 'impulsivity' is best represented by four ICD-10 IM items ('talkativeness', 'blurt out', 'can't wait' and 'interrupts') in line with the ICD-10 configuration, rather than the DSM-5-TR three IM items ('blurt out', 'can't wait' and 'interrupts'). A consistent finding in these studies is that the HY factor is poorly defined (insignificant and/or negative loadings) and lacks reliability (omega coefficient levels below 0.50). Therefore HY is observable in individuals with ADHD, the relevance of HY for ADHD at the latent trait levels is questionable.

These considerations have important research implications that can potentially be compromised by the current ICD-11 and DSM-5-TR definitions. At present we lack knowledge about the psychometric properties of ICD-11 ADHD symptoms, and therefore need to use caution when using ICD-11 for clinical practice relating to ADHD. Indeed, for this reason, some in clinical practice may question the present clinical utility of ICD-11, until greater clarity emerges.

Thirdly, the differences indicate that existing measures, such as DSM-5 based ADHD ratings scales, may not be appropriate for ICD-11 defined ADHD assessment, and that there is a need to develop new ADHD rating scales based on ICD-11. The absence of ICD-11 based rating scales for ADHD can be

considered an important obstacle for research and clinical practice using ICD-11. However, as a temporary solution, researchers could utilize the listed criteria as defined by ICD-11. Notwithstanding this, the absence of a validated ICD-11 defined rating scale, or a measurement instrument or semi-structured diagnostic tool to capture the full range of ICD-11 symptom criteria, provides opportunities for researchers to construct appropriate measures with empirically derived reliability and validity. This is important as the identification of the underlying structure will be determined not only by the clinical elements, but also by the scope of the tools that are used in its recognition. The absence of thresholds for the IA and HY/IM symptom groups in ICD-11 means that for clinicians who still wish to use ICD-11 for clinical diagnosis of ADHD, the onus is placed upon them to use their own cut-off scores to establish clinical caseness. This approach is likely to reduce inter-rater and test-retest reliability, thereby increasing the heterogeneity of ADHD beyond what we currently observe when DSM-5 ADHD diagnostic criteria are applied. Additionally, such a scenario would limit the comparability of findings across studies in which the diagnostic caseness is based on ICD-11. It is also conceivable that the failures of DSM-5-TR and ICD-11 in classifying and partitioning HY/IM symptoms into respective HY and IM subdimensions will dissuade researchers from further exploring the three-factor structure of ADHD (*i.e.* IA, HY and IM three subdimensions), or the S-1 bifactor modelling in which different patterns of partitioning HY and IM symptoms are evaluated[7].

Another issue relevant to research and clinical practice here is biomarkers. The World Federation of Societies of Biological Psychiatry and the World Federation of ADHD previously concluded that there is still no reliable biomarker for ADHD[11]. Nevertheless potential promising candidates should be further explored[12,13]. When the roles of different biological markers become established, they may play a role in improving diagnostic precision and reducing heterogeneity, and may contribute towards differentiating the validity and utility of DSM-5-TR and ICD-11 with respect to their differences as identified in this review.

CONCLUSION

In this commentary, we have articulated the differences in diagnostic criteria of ADHD between DSM-5-TR and ICD-11 and the implications of these differences for clinical practice and research. The major differences were noted in symptom composition and diagnostic thresholds for the IA and HY/IM domains. The clinical and research implications of these include: (1) The current lack of rating scales and measurement tools to capture the full spectrum of ICD-11 symptom items; and (2) the lack of standardized diagnostic threshold for the IA and HY/IM symptom domains in ICD-11, with ensuing problems for validity, reliability and increased heterogeneity. Moreover, the lack of distinction between HY and IM symptoms run contrary to recent empirical findings and limit future opportunities to explore the three-factor or S-1 bifactor modelling of IA, IM and HY as key components in the latent structure of ADHD. In closing, this commentary seeks to provide clinicians and researchers with a succinct summary of the issues, as well as important insights, regarding the clinical and research implications of the recent changes in DSM-5-TR and/or ICD-11.

Abstract

Resilience to psychological stress is defined as adaption to challenging life experiences and not the absence of adverse life events. Determinants of resilience include personality traits, genetic/epigenetic modifications of genes involved in the stress response, cognitive and behavioral flexibility, secure attachment with a caregiver, social and community support systems, nutrition and exercise, and alignment of circadian rhythm to the natural light/dark cycle. Therefore, resilience is a dynamic and flexible process that continually evolves by the intersection of different domains in human's life; biological, social, and psychological. The objective of this minireview is to summarize the existing knowledge about the multitude factors and molecular alterations that result from resilience to stress response. Given the multiple contributing factors in building resilience, we set out a goal to identify which factors were most supportive of a causal role by the current literature. We focused on resilience-related molecular alterations resulting from mind-body homeostasis in connection with psychosocial and environmental factors. We conclude that there is no one causal factor that differentiates a resilient person from a vulnerable one. Instead, building resilience requires an intricate network of positive experiences and a healthy lifestyle that contribute to a balanced mind-body connection. Therefore, a holistic approach must be adopted in future research on stress response to address the multiple elements that promote resilience and prevent illnesses and psychopathology related to stress allostatic load.

Key Words: Resilience; Stress; Allostatic load; Epigenetics; Circadian rhythm; Attachment; Oxytocin; Diet; Microbiome; Exercise

Core Tip: There are multiple reviews in the literature that address different factors contributing to resilience, an adaptation to stress. To our knowledge, none of these reviews takes into consideration the complexity of the system that leads to allostasis or allostatic load, an indicator of physiologic "wear and tear" resulting from repeated exposure to stress and inability to cope. The purpose of this review is to shed light on the complexity of the system and discuss the molecular mechanisms that may contribute to resilience. Lastly, we conclude by emphasizing the need for a comprehensive approach to reduce stress allostatic load.

INTRODUCTION

According to the American Psychological Association (APA), "resilience is the process and outcome of successfully adapting to difficult or challenging life experiences, especially through mental, emotional, and behavioral flexibility and adjustment to external and internal demands". Adaptation to adversities depends on several factors: Individual's engagement and view of the world, the availability of social and communal resources, and the use of specific coping strategies (APA, 2022, https://www.apa.org/topics/resilience). It is worth noting that resilience and coping are inter-related but have different constructs with respect to their impact on behavioral changes[1]. While coping manages stressful events by using cognitive and behavioral strategies[2], resilience refers to the adaptive capacity to recover from traumatic or stressful situations[3].

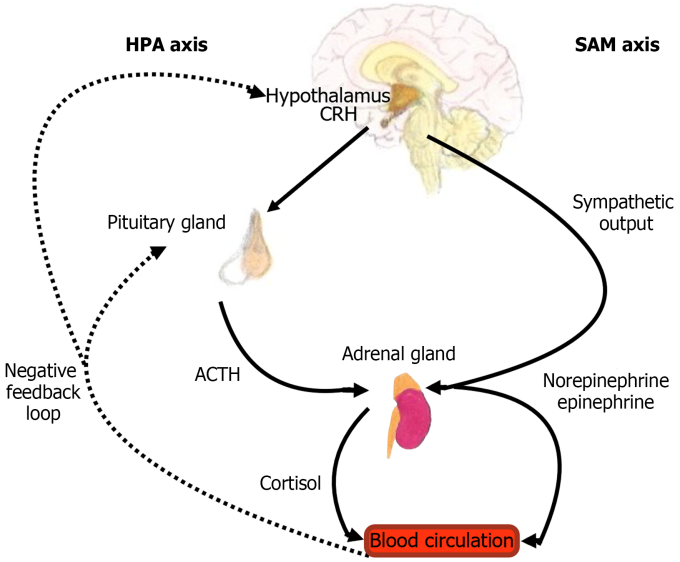
Research in humans over the last two decades has demonstrated that resilience and use of adaptive coping skills in the face of adversity in both children and adults are the main factors that protect from developing mental and physical illnesses. While personal characteristics such as personality traits of persistence and determination, and cognitive flexibility are key elements, perceived parental care, adolescent peer relationships, adult romantic relationships, community support systems, dietary lifestyle, exercise, and circadian rhythm are all implicated in building resilience[4-11]. Resilience is an active adaptive process that helps mitigate negative social, psychological, and biological consequences of extreme stress[12]. The adaptive behavioral manifestations of resilient people are described as enhanced internal locus of control, self-efficacy, happiness, life satisfaction, the ability to derive a sense of life meaning, ability to foster social and communal interactions, and problem-solving skills[13,14].

Fostering resilience early in life may be an effective preventative measure prior to the development of trauma[15]. It is estimated that 60% of men and 50% of women would experience at least one potentially traumatic event in their lifetime, however only 8% of women and 4% in men develop post-traumatic stress disorder (PTSD) (National Center of PTSD, 2022, https://www.ptsd.va.gov/). The development of resilience is an ongoing dynamic process throughout the lifespan in both children and adults, even in those who have suffered from adverse early life experiences, to successfully adapt to or overcome traumatic stress-related illnesses[16,17]. Indeed, resilience can aid in developing positive changes in the aftermath of traumatic events, such as gaining the capacity to relate to others, personal strength, spirituality, and life appreciation[18]. Resilience is implicated in changes in brain regions involved with the social networks that promote empathy, social connectedness, and modulation of central responses to stress[19].

The objective of this review is to summarize the existing knowledge about the multitude factors and molecular alterations that result from resilience to stress response. Our aim is to create awareness for future research studies on allostatic load and stress response about the intricate network contributing to resilience. The methodology we used is Literature Review performed through PubMed, PsycINFO and Scopus databases for peer-reviewed English-language articles published prior to December 2022 using the following keywords: Chronic stress, allostatic load, trauma, biomarkers, circadian rhythm, resilience, neurobiology, genetic, epigenetic, attachment, oxytocin, gut microbiome, diet, mindfulness, exercise, and psychotherapy. We will first describe the existing knowledge about the biologic aspects of the stress response and implications of chronic stress. Then we will present the different factors that contribute to resilience and associated molecular changes.

STRESS RESPONSE AND HYPOTHALAMIC-PITUITARY-ADRENAL ACTIVATION

The neurohormonal mechanism of stress response



The stress response involves a neurohormonal mechanism activated by the cross talk of the hypothalamic-pituitary-adrenal (HPA)-axis and the sympathetic-adrenal-medullary (SAM)-axis that results in widespread hormonal, neurochemical, and physiological alterations. The SAM axis activates the peripheral sympathetic nervous system to release epinephrine and norepinephrine[20,21]. HPA axis activation leads to a cascade of events whereby corticotropin releasing hormone released from the hypothalamus stimulates the release of adrenocorticotropic (ACTH) from the pituitary gland, which in turn results in production of glucocorticoids (GCs) from the adrenal cortex. GCs, also known as cortisol in mammals and corticosterone in rodents, regulate cellular function by interacting with steroid receptors that modulate the neural circuitry and neuroendocrine systems involved in behavioral responses to stress[21]. These receptors, glucocorticoid receptors (GR) and mineralocorticoid receptors (MR), are expressed throughout the brain, mostly in the prefrontal cortex (PFC), hippocampus, amygdala, and other limbic and midbrain structures[17,22]. Under conditions of threat, HPA activation leads to increased release of GCs to promote acute survival by mobilizing stored energy, hence contributing to a state of increased arousal and vigilance. The stress response is then terminated by a negative feedback loop that attenuates the HPA-axis at the level of GR, causing GCs levels to return to normal (Figure 1)[23]. In contrast to GR, MR modulates basal and stress-induced HPA-axis activity to appraise stress and fear-related memories. Enhanced expression and function of MR may improve resilience to traumatic stress and reduces the risk for psychiatric disorders[21]. Studies have shown that MR dampen glucocorticoid receptor sensitivity to stress *via* regulation of FK506-binding protein 5 (FKBP5), a potent negative regulator of glucocorticoid signaling that plays an important role in fine-tuning the MR:GR balance in the hippocampus[24].

When the HPA axis is activated, dehydroepiandrosterone (DHEA) is also released by the adrenal glands along with GCs. DHEA is an important mediator of the HPA axis since it facilitates the N-methyl-D-aspartate receptor function, antagonizes g-Aminobutyric Acid A receptors, and facilitates metabolism of cortisol to the inactive metabolite cortisone. DHEA-Sulfate (DHEA-S), a more potent form than DHEA, plays a neuroprotective role by inhibiting GC effects at the level of the GR as well as supporting neurogenesis[25-28]. Cortisol/DHEA-S ratio represents a balance between the catabolic effects of cortisol and the anabolic, regenerative function of DHEA-S[27,29]. In fact, a higher DHEA-S to cortisol ratio predicted stress resilience in male military personnel, lowering symptoms of PTSD and showing greater improvement over time[30]. On the other hand, a lower resting DHEA/cortisol ratio has been associated with childhood trauma[26].

Circadian control of the HPA axis

Multiple studies have demonstrated the close connection between the circadian rhythm and stress systems to maintain allostasis. The homeostasis of the HPA axis, which produces the primary mediators in adaptation to stress, is closely regulated by the circadian rhythm output[31]. The nearly 24-h periodic peripheral rhythms are controlled by the master circadian pacemaker located in the hypothalamic suprachiasmatic nucleus (SCN). The SCN generates a daily rhythm of transcription and translation feedback loop that align with the 24-h external light-dark environment[32]. The central clock in the SCN orchestrates peripheral clocks at the cellular level to synchronize physiological and behavioral rhythms and regulates the activity of various humoral and neuronal allostatic mediators, among which GCs that show a robust time-of-day dependence[33-35]. These robust circadian dynamics of the allostatic mediators enable the host to flexibly respond and adapt to various physiological stressors[36,37]. In this current modern society and lifestyle that humans live in, where light at night is widespread due to adoption of electrical light, we developed a deranged temporal adaptation that our physiological systems have not evolved to cope with. The chronic disruption of circadian rhythms predisposes to physiologic and behavioral changes that can lead to maladaptive allostatic mechanisms and compromising resilience[32,36].

Animal studies have shown that disruption of the circadian rhythm by misalignment to the natural light/dark cycle in mice results in neurobehavioral changes resulting in decreased complexity of neurons in the prefrontal cortex, the brain center involved in executive and emotional control, and reduction in cognitive flexibility[38]. Even short-term circadian misalignment has been shown to disrupt memory consolidation in response to fear-conditioning that could compromise resilience[39]. The bidirectional communication between the central clock and HPA axis is also evident by circadian disruption in response to early life stress that contributes to metabolic derangement occurring later in life[40]. Hence, re-alignment of circadian rhythms by following the natural light/dark cycle can enhance allostatic adaptive resilience and can be especially beneficial for individuals with psychiatric disorders who struggle with sleep disturbances[41-43]. Interestingly, timing of Trauma Exposure therapy to specific trauma-associated cues can have a different outcome in the process of healing. One study found that exposure to trauma cues is more efficacious when administered during the morning time compared to the evening[44,45].

Chronic stress and allostatic load

As presented above, exposure to stress triggers several biological mechanisms in the body that release stress hormones as primary mediators in order to adapt to short term or acute stress. Maintaining stability through change is a phenomenon known as allostasis[46,47]. Allostasis is considered a beneficial adaptive mechanism that promotes host survival through the appropriate activation of energetic resources[48]. However, repeated exposure to stress, also known as chronic stress, can result in prolonged activation of the HPA and SAM axes, which may lead to activation of secondary inflammatory and metabolic mediators, and ultimately lead to deleterious effect on metabolic, immune, and cardiovascular functions as well as brain and behavior (Figure 2)[49-52]. The cumulative effects of chronic stress reduce the ability of the host to flexibly cope with subsequent stressful situations, which lead the system to shift from allostasis to allostatic load or physiological "wear and tear"[53-56].

Impact of chronic stress on brain and gene expression

While it is beyond the scope of this minireview to discuss all the structural, biological and genetic modifications in response to chronic or developmental stress, we will briefly discuss few structural changes and gene variants involved in the stress response, which may result in either negative or positive associations to resilience. Animal studies have shown structural changes in different brain regions whereby chronic stress increases dendritic spine number or branching in the amygdala and nucleus accumbens, reduces dendritic arborization and glutamatergic dendritic spine density of pyramidal neurons in PFC and hippocampus, and decreases hippocampus neurogenesis[57].

The impact of the environment and specifically early life stress profoundly alters key genes involved in stress response *via* epigenetic modification. Many of these genes can be modified through epigenetic alterations and variation in microRNAs (miRNA), short non-coding RNAs detected in body fluids, in response to environmental influences[58,59]. Little is known about the role of miRNA in psychiatric disorders and resilience. One animal study showed that the systemic knockdown of miRNA-144-3p reduced the depression-like phenotype in stress-susceptible mice[60]. Another study demonstrated that knockdown of miRNA-144 and miRNA-33 in the hippocampus increased the proportion of resilient female animals[61]. Studies also showed that low maternal care is associated with epigenetic modification by increased methylation of the gene encoding GR (*NR3C1*), leading to decreased GR expression in the hippocampus[62,63]. Another important player in regulating the stress response is the *FKBP5* gene. This gene modulates intracellular glucocorticoid signaling and homeostatic regulation of the stress response[64]. Studies have shown that epigenetic modifications induced by early life stress or single nucleotide polymorphisms (SNPs) in human *FKBP5* gene result in differential induction of the FKBP5 protein upon glucocorticoid stimulation, thereby adding to the variability of stress perception and response, and increasing the risk of developing stress-related psychiatric disorders[65,66].

FACTORS CONTRIBUTING TO BUILDING RESILIENCE

Role of psychosocial interventions: Brain and epigenetic alterations

While early-life stress can induce permanent changes in behavioral and physiological responses to stress through epigenetic modification, DNA methylation is potentially reversible through intervention. Using blood samples from human, methylation levels of specific regions within *FKBP5* and brain derived neurotrophic factor (*BDNF*) were changed in response to psychotherapy and were associated with recovery and improvement[67,68]. For example, Exposure-based Cognitive Behavioral Therapy results in a decrease in *FKBP5* methylation and leads to a positive treatment response[69]. Furthermore, maternal stroking and tactile stimulation can normalize DNA methylation in the leukocytes of infants who had been exposed to high levels of pre- and postnatal maternal depression[70]. Mindfulness practice is well known to improve cognitive and social functioning, and reduce symptoms of depression and anxiety[71,72]. The mechanisms whereby mindfulness regulates the stress response is through activation of brain regions involved in interoception, self-awareness, emotion regulation, and threat detection[73-75]. Mindfulness practice has been shown to alter different immune and endocrine pathways, as well as epigenetic methylation of the *FKBP5* gene in adults with PTSD[76-78].

These findings are in line with animal studies demonstrating that intervention by enrichment can reverse the epigenetic, plasticity, and behavioral deficits in rats exposed to early life stress[79]. Indeed, our group has recently published a new treatment approach, Cue Centered Therapy (CCT) for complex developmental trauma in children and adolescents. CCT emphasizes resiliency and positive adaptation factors by using the life timeline as a core component for both positive and negative events in youth's life. CCT has shown effectiveness in improving functioning and reducing child and parent post-traumatic stress. Treatment outcome research of CCT have demonstrated PTSD symptom improvement as measured by cortical activation patterns using functional near-infrared spectroscopy, a non-invasive neuroimaging technique[80,81].

Role of oxytocin and attachment

Another important molecular determinant of resilience is oxytocin (OXT), which is closely tied to attachment. Humans are considered social mammals that develop various forms of social attachments and bonds from infancy throughout life[82,83]. The influence of secure attachment to a caregiver modulates physiology and behavior and is essential for a healthy psychological development and well-being. Attachment is a psychological/behavioral construct for infant's self-regulation that is promoted and facilitated by caregiver's ongoing emotional availability. Infants internalize their interactions with their caregiver and build internal working models that represent their attachment figures in relation to themselves[82]. Attachment styles during early life predict moderate stability of attachment over the years but can be susceptible to change by significant relationship experiences[84]. The different attachment styles are believed to have a profound shaping of an individual's emotional and psychosocial functioning as well as resilience or predisposition to psychopathology[85-87].

It is established that sudden separation of children from their parents, interpreted as abandonment, threatens the attachment bond and results in profound sense of shame and complex emotions especially in the absence of adequate support[88,89]. In addition to the impact of separation on secure attachment, transgenerational maternal experiences with unresolved attachment to their own caregivers can influence the quality of bonding of those mothers to their children. Children of mothers who exhibit higher distress and disruptive behavior exhibited a significantly higher cortisol compared to ones with no disruptive behavior[90]. These differences in cortisol levels and behavior may be related to gene polymorphism of the OXT and OXT receptor (OXT-R) in children from mothers with negative maternal experiences. These genes moderate the stress response of children, and polymorphisms can be associated with the disorganized behavior independent of maternal experiences[91].

The OXT system activated through social interaction is thought to have an important implication in building resilience by playing an important role in the regulation of affective and social behaviors as well as modulating stress response[92-94]. OXT is a neuropeptide produced by hypothalamic paraventricular, supraoptic, and accessory nuclei, and is released to the posterior pituitary gland and ultimately to the peripheral blood circulation[95,96]. In addition to OXT's role in parturition and lactation[97], the neuropeptide plays a key role in promotion of postnatal sensitive maternal caregiving to optimize infant's social and emotional development[98-100]. Higher levels of OXT have been linked with increased attention to social cues[101] while lower levels have been seen in maltreated children [102]. A positive association between OXT level and interpersonal bonding and affiliation, as well as stress modulation in interpersonal situations is well established. In animal models, OXT facilitates mating-induced pair bonds *via* mesolimbic dopamine system, however, variation in striatal OXT-R density predicts resilience and susceptibility to neonatal social neglect[103,104]. Growing evidence from animal and human studies showed that OXT signaling early in life by parental nurturing can buffer against physical and emotional stressors and help establish the neural networks needed during adult life to form social bonds[105-110].

Maternal care during early life, which overlaps with behaviors involving OXT in mother and infant through embedded hidden regulators, maintains the stress hyporesponsive period and direct HPA maturation during heightened plasticity[62]. It has been established that early life stress in human and non-human primates is associated with changes in cerebrospinal fluid OXT level and social behavior, as well as the ability of parental presence to attenuate stress response to a novel environment[111-113]. Animal studies have shown that OXT controls the secretion of ACTH under stress condition and enhance the long-term HPA axis response to stress in adult rats, which may act as a feedback regulator to enhance recovery from stress-related symptoms[114-116].

OXT seems to play an important role in fear modulation where it strengthens fear memory to predictable or cued fear while attenuating fear memory to unpredictable, diffuse threats (contextual fear and non-cued fear)[117-122]. Thus, OXT fosters adaptive defensive behaviors and accurate fear discrimination of relevant and imminent threats, yet reducing sustained fear responses to distant threats[123]. Animal studies have shown that administration of OXT by intracerebroventricular injection or intranasally facilitated cued fear extinction and reduced chronic stress-induced deficits in fear extinction in male rats, respectively. In contrast, administration of OXT-R antagonist impaired fear extinction in male rats[124,125]. These studies emphasized the role of OXT in reducing sustained fear responses and anxiety-like behaviors while strengthening fear responses to relevant and predictable threats. Nuclei of the central amygdala are the main output that connect to the brainstem to eventually mediate the fear response, including freezing behavior. OXT-R transmission in the amygdala switches from passive freezing to active escape behaviors in confrontation with an imminent, but escapable threat[126-128]. OXT also mediates affiliate and prosocial behaviors. OXT-R signaling facilitates social transmission of fear between familiar conspecifics, which might serve as warning system of impeding threat[129,130].

SNPs of the OXT-R gene, rs53576, has been shown to be associated with individual differences in social and emotional abilities, predisposition to psychopathology, and environmental adversity in the prediction of anxiety and depression[131-138]. Human brain-imaging studies in repeated childhood trauma and emotional neglect have demonstrated structural and functional variations in the amygdala, hypothalamus and cingulate gyrus in response to OXT-R gene polymorphism leading to variations in social and behavioral outcomes[139]. Furthermore, epigenetic alterations to specific OXT-R gene polymorphisms can attenuate resting parasympathetic tone and increasing central amygdala grey volume, thereby altering traumatic stress reactivity[140].

Role of diet, gut microbiome, and exercise

There is an extensive connection between the mind and body in which the wellbeing of one influences the other. A major element of this mind-body connection is the brain-gut axis. Indeed, there is an association between early life adversities and changes in the brain-gut axis that may occur *via* pathways related to glutamatergic excitotoxicity and oxidative stress, predisposing to negative mood and stress [141].

Maternal diet and resilience: The quality of dietary interventions during a critical period of neural development predicts the function of the brain-gut axis and plays a key role in building resilience to stress. Earlier studies showed that maternal nutrition during pregnancy plays a fundamental role in

intrauterine developmental programming and predicts child's resilience to stress and vulnerability to psychiatric disorders, such as anxiety and depression. Maternal malnutrition during fetal development has a detrimental long-term impact on the physical, cognitive, and emotional development[142,143]. A deficit in maternal dietary protein during pregnancy alters the brain neurochemistry and behavior by reducing 5-hydroxytryptamine 1A receptor and the responsiveness to stress during adult life[144]. It has been shown that branched-chain amino acids such as leucine, isoleucine or valine are essential nutrients that promote resilience *via* activation of hippocampal BDNF signaling[145]. An unbalanced diet during pregnancy is linked to heightened HPA axis responses to stress and higher cortisol levels as well as epigenetic changes in genes controlling glucocorticoid action in adult offspring[146-148].

Microbiome and gut-brain axis: The gut microbiota plays a major role in shaping how the body responds to stress. Animal studies have shown that Germ-free mice with absent microbiota have significant variations in their stress response caused by abnormal development of the HPA axis that was reversed by inoculation of Bifidobacteria infantis[149]. Exposure to early life adversity is correlated with changes in microbial diversity of the gut where taxonomic abundances predicted PFC activity[150].

The microbiome-derived short-chain fatty acids (SCFA) are the most studied metabolites because they ameliorate the gut-brain axis and stress-induced cortisol release in humans and rodents[151]. The composition of diet is essential because it can impact gut-brain pathways involved in stress response. A healthy diet rich in fibers, phytochemicals, or live bacteria can increase microbial diversity and enhances production of SCFA and other bioactive compounds[152,153]. Western diet, lacking in dietary fibers, is associated with suboptimal gut microbiota composition and a low-grade systemic inflammation that can predispose to mental illness, gastrointestinal and metabolic disorders, and obesity[154,155]. In addition to diet, exercise has been shown to increase SCFA availability, thereby influencing microbiome composition[156]. Gut microbes also play a major role in synthesizing key neuroactive molecules such as serotonin, gamma-aminobutyric acid, and catecholamines like norepinephrine and dopamine. For example, *Lactobacillus* can stimulate the conversion of dietary tryptophan into 5-hydroxytryptamine by enterochromaffin cells, which then interacts with the autonomic nervous system and conveys the signal to other brain structures, such as the hypothalamus, nucleus accumbens, and ventral tegmental area [157-159].

Microbiome-targeted therapies known as "psychobiotics" that include administration of live organisms, fecal microbial transplants, and dietary interventions to reshape the microbiome composition and function have beneficial effects on brain and behavior[152,160,161]. Administration of the probiotic organisms *Bifidobacterium* and *Lactobacillus* is known to confer resilience in social defeat model and has been tested in clinical depression[161,162]. Additionally, probiotics supplementation results in higher DHEA-to-corticosterone fecal metabolite ratios and reduces microglia immunoreactivity in the basolateral amygdala in rodent models, thereby mitigating the pervasive effects of early life stress on anxiety and depressive behavior as well as HPA axis activity[163].

Modulating the microbiota–gut–brain-axis through diet is also a promising approach to prevent and treat mental health disorders. Consumption of a Mediterranean diet resulted in a significant improvement in depressive symptoms after 12 weeks of dietary intervention compared to control group among patients with major depressive disorder[164,165]. Studies have also shown that adherence to Mediterranean diet, consumption of fruits and vegetable-based dietary pattern and dietary polyphenols were positively associated with psychological resilience[166]. Polyphenols are stress-modifying phytochemicals composed of hydroxylated phenyl moieties and are abundant in fruits, vegetables, tea, caffeine, curcumin, herbs, citrus peel, and grape seeds. They have anti-inflammatory actions, which may be involved in fighting psychosocial stress. Therefore, polyphenols are considered adaptogens (stress response modifiers that have beneficial effects to protect from chronic diseases) because of their ability to adapt to and survive external stressors[167-171]. Polyphenols are also considered 'prebiotics' because of their ability to enhance the growth of specific beneficial bacteria that produce bioactive phenolic acids, which promotes cognitive resilience to depression and anxiety[172-175].

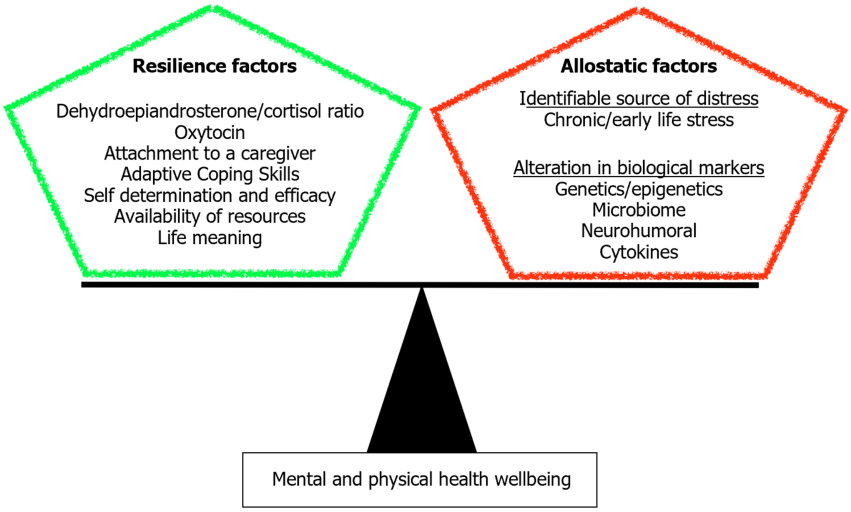
Exercise and resilience: Exercise is well known for its benefit in enhancing resilience and longevity. Physical activity through exercise activates endocrine, paracrine, and autocrine pathways through the release of exerkines (signaling particles that have a potential role in improving health in response to exercise), cytokines, nucleic acids, lipids, and metabolites from multiple organs[176]. Exercise is well known to improve brain function, most notably the effect on learning and memory. Indeed, aerobic exercise increases hippocampal volume and improves memory, increases plasma levels of BDNF, and delays the onset of neuro-degenerative conditions in older adults human studies[177-179]. These findings are in line with animal studies on rodents where chronic exercise resulted in upregulation of BDNF in the hippocampus, leading to hippocampal neurogenesis, neural plasticity, and improved cognition and mood[180]. A possible mechanism of the upregulation of BDNF in hippocampus is through the release of irisin from myokines, which plays an important role in hippocampal neurogenesis, increased neurotrophin levels, and enhanced mood and cognition[181]. Another benefit of exercise is the release of adiponectin from adipocyte that seems to have neuroprotective effects by crossing the blood–brain barrier and resulting in increased neurogenesis and reduced depression-like behaviors[182]. Kynurenic acid, another molecule of interest produced in muscles in response to chronic

aerobic exercise, has been shown to protect the brain from stress-induced depression[183]. Vigorous exercise is also associated with lower emotional distress, depression, and anxiety[184,185].

Studies have linked the adaptative changes in opioid systems to regular exercise, which reduces noradrenergic-induced stress responses. Regular exercise activates the endogenous opioid in the peripheral and central nervous system and is implicated in mood improvement[186,187]. The stress-reducing effect of exercise in response to both physical and psychological challenge is reversed by administration of naloxone, an opioid antagonist[188,189].

DISCUSSION

We have addressed in this minireview the biological basis of resilience as an outcome of structural and molecular alterations resulting from various determinants. Understanding the molecular aspect of resilience can provide insight for therapeutic discoveries and interventions to promote resilience in face of adverse life events. Here we showed that building resilience requires an intricate network of positive experiences and healthy lifestyle that contribute to a balanced mind-body connection (Figure 3). Indeed, positive childhood experiences such as interpersonal social and emotional support can mitigate the impact of adverse childhood experiences, thereby reducing the risk for adult onset depression and poor mental health[190].



Clinical and preclinical investigations showed that resilience is implicated in molecular alterations and changes in brain regions involved with the social networks that promote empathy, social connectedness, and modulation of central responses to stress. DNA methylation in response to early life stress is potentially reversible through intervention. Resilience promoted by psychotherapy and mindfulness practices reverses the epigenetic modification of *FKBP5* and *BDNF* genes caused by stress response and alters cortical activation to improve PTSD symptoms[76-78,80,81]. Investigations also showed that DHEA-S, OXT and enhanced expression of MR can be used as important predictors of resilience[21,24,30]. OXT, a neuropeptide tied to attachment, plays a key role in promotion of postnatal sensitive maternal caregiving to optimize infant's social and emotional development and establish the neural networks needed during adult life to form social bonds[105-110]. OXT is also a feedback regulator of the HPA axis that enhance recovery from stress-related symptoms[114].

Recent studies also showed the association between early life adversities and circadian rhythm disruption as well as changes in brain-gut axis that may occur *via* pathways related to glutamatergic excitotoxicity and oxidative stress, predisposing to metabolic derangement, negative mood and stress [37,141]. Re-alignment of circadian rhythms to the natural light/dark cycle is an important health behavior that enhances resilience and adaptation to various stressors[41-43]. Additionally, a healthy brain-gut axis plays an important role in building resilience where gut microbial diversity, healthy diet and exercise can ameliorate the gut-brain axis and stress-induced cortisol release in humans and rodents. Administration of probiotics confer resilience in social defeat model and results in higher DHEA-to-corticosterone fecal metabolite[161,162], thereby mitigating the pervasive effects of early life stress on anxiety and depressive behavior as well as HPA axis activity[163].

Despite the advances in studying resilience and the multitude of contributing factors, there are still gaps in literature about genetic determinants that differentiate resilient individuals from vulnerable ones. Here we reviewed that epigenetic modification of *FKBP5* and *BDNF* genes in response to stress can be reversed by interventions to reduce stress[67,68]. Our group is currently conducting a large-scale study to determine what other genes are implicated in resilience in response to CCT psychotherapy. The advances in miRNA research can also be a powerful tool that can serve as a therapeutic target to improve resilience.

CONCLUSION

This minireview emphasized the dynamic process of resilience and showed that it continually evolves by the intersection of different domains in human's life; nature, nurture, environment, and microbiome. Despite the large number of research studies on resilience to stress, none have established one causal factor that differentiates a resilient person from a vulnerable one. This minireview demonstrated that a holistic approach, both clinically and for research purposes, must be adopted to address the multiple elements that promote resilience and prevent physical illnesses and psychopathology. Our future direction is to further understand the role of epigenetic gene silencing in chronic stress in order to identify potential resilience genes that can be reactivated by psychotherapy and the other resilience-promoting interventions mentioned above.

Abstract

Problematic social media use (PSMU) is a behavioral addiction, a specific form of problematic Internet use associated with the uncontrolled use of social networks. It is typical mostly for modern adolescents and young adults, which are the first generations fully grown up in the era of total digitalization of society. The modern biopsychosocial model of the formation of behavioral addictions, postulating the impact of a large number of biological, psychological, and social factors on addictive behavior formation, may be quite applicable to PSMU. In this narrative review, we discussed neurobiological risk factors for Internet addiction with a focus on current evidence on the association between PSMU and structural/functional characteristics of the brain and autonomic nervous system, neurochemical correlations, and genetic features. A review of the literature shows that the vast majority of the mentioned neurobiological studies were focused on computer games addiction and generalized Internet addiction (without taking into account the consumed content). Even though a certain number of neuroimaging studies have been conducted for PSMU, there is practically no research on neuropeptide and genetic associations for PSMU to date. This fact points to the extremely high relevance of such studies.

Key Words: Internet addiction; Problematic social media use; Addictive behavior physiopathology; Neurobiology; Genetics

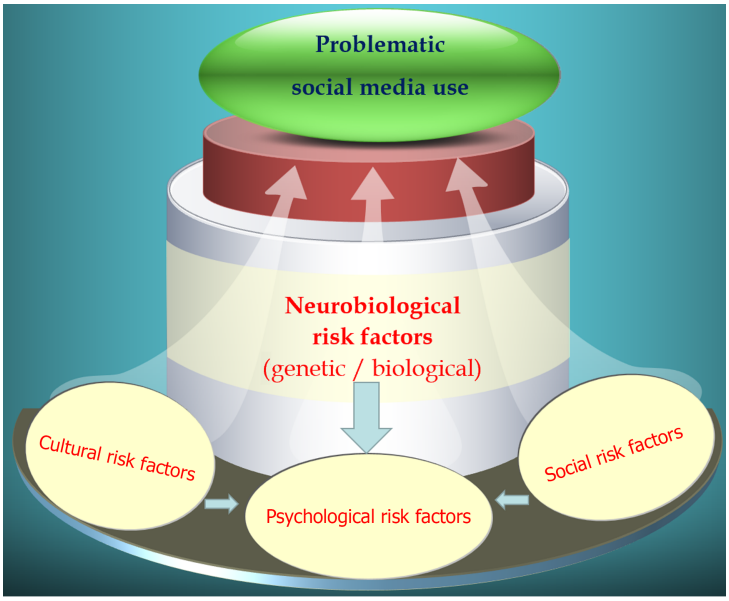
INTRODUCTION

The last few decades have been characterised by the complete digitalization of society and the ubiquitous penetration of Internet technologies into our daily lives[1,2]. The advantages associated with the widespread introduction of Internet technologies into people's daily lives are undeniable (for example, quick access to a large amount of information and various services, rapid dissemination of news on a global scale, the introduction of Internet technologies related to health, *etc*.). However, a certain number of Internet users, mainly adolescents and young adults, experience the phenomenon of Internet addiction or "problematic/compulsive use of the Internet" which is associated with several psychosocial problems[2,3]. The global concern about the impact of problematic Internet use (PIU) from the public and social health points of view became especially acute during the coronavirus disease (COVID) pandemic when each person had to use the Internet more often, and initially, predisposed individuals were losing control, showed more and more signs of pathological addictive behavior when diving into the network[4]. In particular, this trend has affected the most technologically advanced segments of society – the first generations who grew up surrounded by the Internet and gadgets – adolescents and young adults[5]. The situation can be significantly aggravated by the neurophysiological consequences of the pandemic, predisposing to the development of depression and anxiety, which are important risk factors of problematic social media use (PSMU)[6].

The modern "component bio-psychosocial model" of behavioral addiction formation postulates an individual combination of genetic/biological, psychological, social, and cultural factors leading, in the case of PSMU, to overuse of social media and negative consequences (Figure 1).

In this narrative review, we shall discuss neurobiological risk factors for Internet addiction with a focus on current evidence on the association between PSMU and structural/functional characteristics of the brain and autonomic nervous system, neurochemical correlations, and genetic features.



To find relevant publications, a search was conducted in PubMed, Scopus, Web of Science, and Reference Citation Analysis (https://www.referencecitationanalysis.com) for English-language sources using the following keywords and MeSH terms: "Internet addiction", "problematic social media use", "pathological social network use", "social media", "social networking", "specific Internet addiction", "video game addiction", "gaming disorder", "neurobiology", "behavior, addictive/physiopathology", "brain/physiopathology", "sympathetic nervous system", "parasympathetic nervous system", "neural pathways/physiopathology", "neurotransmitters", "biochemical correlates", "twin study", "genetics", "gene frequency", "genetic predisposition to disease", "polymorphism, single nucleotide".

TERMINOLOGY

The phenomenon of Internet addiction[7,8] was first described in the mid-1990s. There is currently no accepted formal definition of addictive online behaviour. Specialized literature offers such interchangeable terms as "problematic interactive media use"[9], "problematic Internet use", "pathological Internet use", "compulsive Internet use", and, finally, "Internet addiction". The European Network for Problematic Usage of the Internet (European research group) recommended in a recent review (2022) to use the term "problematic Internet use", as the most appropriate at this moment[4].

All of the above are umbrella terms, *i.e.*, reflect generalized (without reference to specific content and technology) PIU. Among the specific types of Internet activity, the following can be considered potentially addictive: Problematic video game use, PSMU, problematic Internet pornography use, Internet gambling, and web surfing addiction[10,11].

Only one of these five addictive behavior types, namely the problematic use of video games, is currently officially considered a mental disorder (Internet gaming disorder, diagnostic and statistical manual of mental disorders, fifth edition, American Psychiatric Association, 2013; gaming disorder, international classification of diseases-11, 2019). Recently, other specific forms of PIU have also been singled out: Online gambling disorder (it also includes intensive betting on online exchanges), online

Figure 1 Component bio-psychosocial model of problematic social media use.

buying-shopping disorder, Internet streaming disorder, cyberchondria, cyberbullying, and digital hoarding[4].

PSMU is a behavioral addiction, a specific form of PIU associated with the uncontrolled use of social networks. It is typical mostly for modern adolescents and young adults, which are the first generations fully grown up in the era of total digitalization of society. There are currently no universally recognized and official criteria for the diagnosis of PSMU. The European Network for Problematic Usage of the Internet (European research group) suggests the following definition[4]: PSMU is a persistent state of control loss when using social networks, manifested by: Violation of control over interaction with social websites (for example, in terms of time, frequency, and duration of use); predominance of time spent on social networks over other life interests and activities; negative consequences, *i.e.*, the use of social networks leads to significant distress or deterioration in personal, family, social, educational, professional activities, or other important areas of functioning; continued or increased use of social networks, despite the negative consequences (for example, poor school performance, negative impact on health, social isolation, interpersonal conflicts, neglect of duties); duration, *i.e.*, the use of social networks can be continuous or episodic and repetitive but manifests itself over a long period (at least 12 mo).

Although the criteria for the diagnosis of PSMU are not formally established, the existing validation methods using questionnaires are based on the interpolation of classical symptoms for chemical and non-chemical types of addictive behavior[12]. Currently, there is a consensus on diagnostic criteria that clearly distinguish the pathological component of addiction from the normal daily use of the Internet by adolescents: The clinical diagnosis of PSMU, as well as generalized Internet addiction, should include six obvious signs[11,13,14]: Salience and mood modification, such as behavioral, cognitive, and emotional preoccupation: The growing importance of a social network for an adolescent in his or her system of interests and values; the use of a social network leads to a positive change in the emotional state; Compulsivity and loss of control: An obsessive desire to use the social network, impulsivity, loss of time control, excessive use of the social network (especially while reducing the allocated time for other activities); Tolerance: The need to spend more and more time communicating on a social network, including to alleviate episodes of dysphoria; Withdrawal/abstinence symptoms: Mood changes in the absence of access to a social network (depression, anxiety, aggressiveness); Conflict, impaired role performance: Loss of previous interests and entertainment, loss of educational, cultural, sports, and other opportunities as a result of excessive use of social networks; disputes and lies regarding the use of the social network; continued use of social networks, despite the negative consequences. Relapse: Rapid return to the use of the network after abstinence, unsuccessful independent attempts to control the use of the social network.

However, PSMU must be distinguished from intensive adaptive use of social networks. Adaptive intensive use of social networks itself does not have obvious negative consequences, has little effect on the parameters of well-being, and in many individual cases can play a positive role in the development of an adolescent by increasing a "social capital"[15-17].

PREVALENCE

The latest summarized data show that the average prevalence of PSMU among adolescents in 29 European countries is 7.4%[18]. The recent systematic review by Cheng *et al*[19] showed a high ethnic and geographic heterogeneity of PSMU prevalence within 5%–26%. The highest levels of PSMU prevalence are registered in collectivist societies in Asia and Africa[19]. Recent cross-national analysis of the psychometric characteristics from the social media disorder scale (SMDS) questionnaire among adolescents from 44 countries has shown high levels of validity and reliability (comparative fit index and Tucker–Lewis index = 0.963 and 0.951, root mean square error of approximation = 0.057)[20]. SMDS is recommended by the research group European Network for Problematic Usage of the Internet as preferred, since it evaluates primarily the psychopathological aspects of addiction, while the recently criticized Bergen social media addiction scale questionnaire does not clearly distinguish between simple excessive or prolonged use of social networks from pathological one, with signs of addiction[4]. The prevalence figures obtained by the authors of the SMDS were 7.3%-11.6% for the Dutch adolescent cohort[21]. Other studies using the SMDS have found similar results: 9.9%-10.0% in a Dutch sample in a longitudinal study[22], 9.4% in a representative sample of 3408 Finnish adolescents[23], and 8.0% in a large sample of Russian adolescents (n = 4514)[24].

PSYCHIATRIC AND SOMATIC COMORBIDITY

A large number of foreign studies have convincingly shown the pronounced comorbidity of Internet addiction with a wide range of psychopathological conditions. Depressive disorder and attention deficit hyperactivity disorder have the strongest association with Internet addiction, while anxiety disorder, obsessive-compulsive disorder; social phobia, and suicidal behavior also have a smaller but significant association[25-28]. A recent meta-analysis by Shannon *et al*[12] has shown that PSMU, as a specific form of Internet addiction, also reveals a moderate, but statistically significant, association with depression, anxiety, and stress[12]. Another recent meta-analysis demonstrated a significant but weak negative association of PSMU with life satisfaction and self-esteem (as parameters of well-being) and a moderate positive association with depression and loneliness (as indicators of distress)[29].

At present, not much is known about the association of Internet addiction with psychosomatic diseases, although such a connection is highly likely, given the presence of common pathogenesis factors (anxiety-depressive and obsessive-compulsive disorders). The study by Wei *et al*[30] based on an Internet survey demonstrated the association of Internet addiction with chronic pain syndromes, which the authors link with psychosomatic diseases and muscle overstrain. The study conducted by Cerutti *et al*[31] did not reveal a statistically significant association between Internet addiction and tension headache/migraine, although, in general, somatic symptoms were more often reported in the Internet addiction group[31]. In addition, it was discovered that PIU among adolescents was associated with chronic conditions, back pain, overweight, musculoskeletal pain, and also with sleep disorders[32,33]. According to a recent systematic review, a wide range of somatic health problems are associated with smartphone addiction among adults[34]. A general decrease in immune functions was observed in Internet-addictive individuals, which the authors link with a common risk factor, *i.e.*, stress, which can affect the activity of the sympathoadrenal axis and increase cortisol production[35]. It is characteristic that the high activity in the sympathetic part of the autonomic nervous system was detected when analyzing the heart rate of adolescents with Internet addiction[36,37]. A decrease in the quality of life, including the parameters of somatic health, was demonstrated in a systematic review by Masaeli and Billieux[38]. A pronounced connection between Internet addiction with the general level of somatization was revealed among young adults[39].

PATHOGENESIS OF INTERNET ADDICTION FROM A NEUROBIOLOGY POINT OF VIEW

To date, several etiopathogenetic models of the formation of Internet-dependent behavior among adolescents and young adults have been proposed[40]. Some researchers suggest the presence of mainly neurobiological risk factors linked with the lack of maturity in certain parts of the adolescent brain, which is manifested by insufficient effectiveness of volitional control, high impulsivity, and an overly activated brain reward circuitry[41,42]. However, the most recognized by researchers at present is the "component biopsychosocial model", which assumes a combination of psychosocial problems and neurobiological risk factors[40,43-45].

Middle and late stages of adolescence in brain development are characterized by different time frames of the formation of the limbic system and prefrontal cortex lobes[46]. The prolonged development of the prefrontal cortex in comparison with the limbic system during adolescence leads to weakened inhibition from cortex lobes concerning underlying subcortical structures and increased impulsivity, which contributes to a high risk of addictive behavior[47].

To date, a large number of studies have been devoted to the pathogenesis of Internet addiction using various neuroimaging techniques, including magnetic resonance imaging, positron and single photon emission computed emission tomography. These techniques have revealed a number of structural brain changes associated with Internet addiction[48-50]: Dcreased grey matter density in several areas, including prefrontal and orbitofrontal cortical layers and an additional motor area[51]; abnormal functional activity of brain regions associated with reward dependence[41]; activation of sensorimotor synchrony with a concomitant decrease in audiovisual synchrony[52]; activation of brain regions associated with compulsive craving and impulsivity; increased glucose metabolism in brain regions associated with impulsivity, reward dependence and the urge to repeat sensations[53]; increased dopamine secretion with a concomitant decrease in dopamine receptor availability in the striatum[54]. Meta-analysis of 40 neurophysiological studies of PIU has shown that, regardless of the content, Internet-dependent behavior is characterized by a significant violation of inhibitory control, stop-signal task, decision-making, and working memory[55]. The meta-analysis by Zhang *et al*[56] has revealed the presence of a common pattern in a brain structural change related to chemical and behavioral addictions: Changes in prefrontal and insula areas associated with increased impulsivity[56]. Several meta-analyses and reviews have been published recently: Structural and functional brain alterations for a specific form of PIU – computer games addiction[57-59]. The features of electroencephalography in Internet addiction were analyzed in a recent review by Sharifat and Suppiah[60]. Distinctive characteristics of functional electroencephalography were revealed among patients with computer game addiction[61].

It should be noted that most of the above-mentioned studies have been conducted for cases of computer games addiction or generalized (undifferentiated by the content consumed) Internet addiction. The recently proposed for various types of behavioral addictions updated interaction of person-affect-cognition-execution (I-PACE) model theoretically substantiates the neurobiological mechanism of addictive behavior, which consists in an imbalance between structures of frontostriatal circuits (limbic/reward-oriented brain circuits and prefrontal control)[62]. The model has been intensively studied for gambling and gaming disorders, but not for PSMU. Despite this, a line of structural and functional neuroimaging findings concerning the I-PACE model for PSMU was published to date[63-68]. Neuroimaging studies for PSMU were analyzed by Wegmann *et al*[69]; a conclusion was made about the significant association of PSMU with reward processing and reinforcement learning. A recent study by Sadeghi *et al*[70] has revealed that email addiction positively correlates with depression and gray matter volume of the left rostrolateral prefrontal cortex closely involved in cognitive processes[70].

There is some evidence of autonomic nervous system dysfunction involvement in the pathogenesis of Internet addiction, in particular, by the imbalance of the sympathetic and parasympathetic divisions[71, 72]. A general decrease in immune functions was revealed among Internet-addictive individuals. The authors link this fact with a common risk factor, *i.e.* stress, which can affect the activity of the sympathoadrenal axis and increase cortisol production[35]. The role of chronic stress in the formation of PSMU has been shown by several studies[12,73,74]. It is characteristic that the high activity of the autonomic nervous system's sympathetic part was observed when analyzing the heart rate of adolescents with Internet addiction[36,37]. Data on the level of cortisol for Internet addiction are contradictory[75-77]; additional research is required, in particular, concerning the long-term cortisol content, which can be a good marker of chronic stress and mental problems[78].

Several neurotransmitters and neurotrophic factors may be involved in the neurobiological mechanisms of Internet addiction formation[79-81]. Neurochemical pathways include metabolic disorders of dopamine, serotonin, opioids, and some other neurotransmitters that affect reward processing, executive functioning, salience attribution, and habit formation, as well as in the case of substance-use disorders[82]. The participation of these neurotransmitters is partially confirmed by the effectiveness of some pharmacological agents controlling the corresponding neurochemical pathways [83,84]. Exercise-based interventions also may be efficient for Internet addiction (including PSMU)[85], by regulating the autonomic nervous system, the morphology of some parts in the central nervous system, and the exchange of neurotrophic factors and neurotransmitters, in particular dopamine[72].

Oxytocin, which is called the hormone of trust, social connection, and emotional attachment, is promising for the PSMU study. It plays an extremely important role in establishing emotional social contacts, including those using social networks[80,86]. Bonassi *et al*[87] showed that a low level of parental care was associated with low activity on Instagram for carriers of the A-allele in the polymorphic region rs2254298 for the oxytocin receptor gene[87]. The same group of researchers identified a greater number of followers among carriers of the A/A genotype in the region rs53576 for the oxytocin receptor gene in comparison with carriers of the G-allele[88].

A significant number of studies show a pathophysiological relationship between the functioning of the oxytocinergic system and the formation of various forms of addictive behavior[89]. The effectiveness of exogenous oxytocin in the treatment of various addiction types has been shown both in experimental animal studies[90] and in a whole series of clinical studies[89]. It is assumed that the relief of physical symptoms and an increase in emotional tone during withdrawal, reduction of anxiety, increased susceptibility to verbal interventions, facilitating the restoration of social contacts, and, finally, the physiological reduction of established tolerance are the main mechanisms of oxytocin therapeutic

impact for chemical addictions. The hypothesis of oxytocin's antistress effect as a possible protective factor seems convincing since psychological stress is an important etiological cause of the development of pathological addictions[91].

The following are promising neurotransmitters and neurotrophic factors in addition to oxytocin, whose role in the pathogenesis of addictive Internet behavior in adolescents is also highly probable, but still insufficiently studied:

Melanocortin (α-Melanocyte-stimulating hormone). An important role of melanocortin in the development of pathological addiction is suggested by recent studies by Orellana *et al*[92]. There was a tendency to increase melatonin levels in the presence of computer games addiction[93];

Neurotensin. It is actively involved in the modulation of dopamine signalling and the formation of pathological addictions, attempts have been made to treat some addictions with synthetic neurotensin [94];

Orexin. It is supposed to be involved in the formation of sleep disorders and addictive behavior[95]. Choi *et al*[93] demonstrated an increase of orexin in the plasma of adolescents with Internet gaming disorder a while ago[93];

Substance P (neurokinin A). Impairment in the production of substance P is thought to be associated with the development of various pathological addictions; active attempts are currently being made to treat addiction by modulating the activity of neurokinin receptors[96,97];

Brain-derived neurotrophic factor (BDNF). This is a neurotrophic factor that plays a role in the development of addiction[98,99]. Data on the association of BDNF expression with Internet-addictive behavior are contradictory. Some authors found elevated plasma levels among addicts, the others did not confirm such an association[72,81]. A recent study by Choi *et al*[93], which has been mentioned above, found no direct link between addiction and BDNF levels, although it revealed a negative correlation with the time spent playing a computer game[93].

Glial cell line-derived neurotrophic factor (GDNF). It is a neurotrophic factor that plays an important role in supporting the function of dopaminergic neurons. A decrease in the level of GDNF in plasma was detected among Internet gaming addicts; besides, the expression of BDNF was negatively correlated with the severity of computer games addiction[100].

It is important to note that the vast majority of studies on neuropeptides and neurotrophic factors have been conducted for computer game addiction, as in the case of neuroimaging and neurophysiological research methods.

GENETICS OF INTERNET ADDICTION

Unlike other types of addictive behavior (for example, substance abuse or gambling), a very small number of studies have been devoted to the search for genetic predictors of Internet addiction. In the first twin study (2014) the authors managed to prove the presence of an innate component based on the results of a survey of 825 adolescents from the Chinese population. The component was estimated at 58%–66%[101]. Similar results were obtained a little later in the study of Turkish (19%–86%, 2014[102]) Dutch (48%, 2016[103]), Australian (41%, 2016[104]), and German (21%–44%, 2017[105]) twin cohorts. Positive genetic correlations (20%–40%, 2012) were also discovered in the study of various mobile phone use patterns by twins[106]. Although these data are limited by the volume of samples and various ethnic and geographic conditions, there is likely a tendency for a greater contribution of genetic factors in males.

Thus, the presence of a genetic component in Internet addiction formation has been convincingly shown by twin studies by the example of different populations, but no specific genes involved in the mechanisms of such heritability have been identified. Small pilot studies, however, verified polymorphic regions of nine candidate genes, the following are among those:

r1800497 [dopamine D2 receptor gene (*DRD2*), Taq1 A1 allele] and rs4680 [methionine variant of dopamine degradation enzyme catecholamine-o-methyltransferase gene (*COMT*)] – the first of such studies (2006–2007) conducted among adolescents in South Korea and showed an association between minor alleles connected with low dopamine production (rs4680) and a low number of dopamine receptors in the prefrontal cortex (rs1800497) with the presence of pathological Internet gaming disorder [107]. At the same time, *DRD2* A2 allele (high-activity) homozygotes and A1 allele (low-activity) carriers demonstrated no significant differences concerning Internet addiction; neither differences were revealed when comparing *COMT* high-activity (H) variant homozygotes and low-activity (L) variant carriers [108]. Later, the association of the C allele carrier rs1800497 (*DRD2* gene) with computer games addiction was confirmed for young adults[109]. Another study did not prove such a fact[110]. It is known that the *DRD2* gene is in linkage disequilibrium with the *ANKK1* gene, which plays a significant role in the formation of chemical addictions[111]. Therefore, by now, it is not possible to accurately establish the association of Internet addiction with the reception of dopamine at the DRD2 level[45]. The association of the homozygous variant Val/Val (GG) rs4680 (Val158Met, *COMT* gene) with addiction to computer games was further confirmed by the study by Yen *et al*[112] in 2022; In addition, a recent study by Kim *et al*[113] showed that the presence of interpersonal stress for *DRD2* rs6277 T allele and

rs1800497 Taq1 A1 allele showed higher scale values of computer games addiction[113].

rs6277 (promoter of the *DRD2* gene, *141C Ins/Del* polymorphism) – although a direct association between rs6277 polymorphism and Internet addiction has not been established, the *-141C* polymorphism may play a role in the pathogenesis of addiction as a mediator of temperament characteristics[110]; the dopamine D4 receptor gene (*DRD4* gene, VNTR polymorphism in exon 3) – as it was shown, the carriers of *DRD4* 4R/4R variants are more predisposed to the formation of generalized Internet addiction[108]. More recent studies have not shown an association with Internet-addictive behavior[114,115];

rs25531 (serotonin transporter gene (*SS-5HTTLPR*), short allelic variants) – the research by Lee *et al*[116] demonstrated that short allelic variants of the serotonin transporter gene might be associated with Internet addiction. Similar data were later obtained by Sun *et al*[108] but for men only[108]. As a large number of studies have shown, these genetic variants are also linked to a predisposition to depression, which is the most frequently detected comorbid condition among Internet-addictive individuals. Recent studies revealed that a link between depression and autistic personality traits with generalized Internet addiction could be modulated by such polymorphism (*5-HTTLPR*/rs25531), as well as ethnic and geographic factors[115,117].

rs1044396 [nicotinic acetylcholine receptor subunit alpha 4 gene (*CHRNA4*)] – study by Montag *et al*[118] revealed an association between Internet addiction and the rs1044396 CC genotype, which can also be associated with nicotine addiction and attention disorders. Later, Jeong *et al*[119] conducted a pilot study of the target exome, involving 30 adults with addiction to computer games and 30 healthy individuals, which included a study of 72 candidate genes. This study showed a statistically convincing association with one site only – rs1044396. No such association was found in another study[114];

rs2229910 [neurotrophic tyrosine kinase receptor type 3 gene (*NTRK3*)]– Kim *et al*[120] have conducted in turn a pilot study of the target exome involving 30 adults with addiction to computer games and 30 healthy individuals, which included a study of 83 polymorphic sites. Their study also revealed a statistically convincing association with one site only – rs2229910, presumably also associated with anxiety-panic, depressive disorders, obsessive-compulsive disorder, and psychologically determined eating disorders;

rs28364027 [Corticotropin Releasing Hormone Receptor 1 gene (*CRHR1*)] – a study involving Korean adolescent boys revealed that carriers of the AA genotype and the A allele were more predisposed to online computer games addiction[114]. It was previously determined that corticotropin-releasing hormone was involved in the mechanisms of negative effects realization when weaning from the addiction factor[121] and was associated with the risk of alcohol dependence for adolescents, especially when combined with stressful effects[122-124];

rs1137070 [monoamine oxidase-A gene (*MAOA*), EcoRV polymorphism] – the association of this polymorphism with an addiction to computer games with a mediator effect of hostility was evaluated for young adults. Participants with the TT rs1137070 genotype had a higher odds ratio of 2.52 (1.37-4.64) for gambling addiction compared with carriers of the C allele[125];

rs2268498 [oxytocin receptor gene (*OXTR*)] – it has been shown that male carriers of the TT genotype (but not female) have lower levels of generalized Internet addiction compared to C allele carriers[126];

rs6265 (*BDNF* gene) – Russian researchers discovered in 2019–2020 that genetic polymorphism of *BDNF* rs6265 (Val66Met), as well as the abovementioned *DRD4* exon 3 VNTR and *NTRK3* rs2229910, are were with the risk of generalized Internet addiction for young adults[127].

The latest (2022) review by Werling and Grünblatt[128] and the data presented in this article demonstrate that all currently known studies of genetic associations have been conducted for computer games addiction or (less often) for generalized Internet addiction. As far as is known, not a single study of genetic associations concerning PSMU has been published.

DISCUSSION

Neurobiology and genetics research on Internet-addictive behavior conducted over the last 10–15 years has allowed accumulating the necessary amount of knowledge to make certain intermediate conclusions, summarized recently in a significant number of meta-analyses and reviews. A large number of neuroimaging and neurophysiological studies have shown that Internet addiction is characterized by certain structural and functional features of the brain, accompanied by a significant violation of inhibitory control (increased impulsivity as a common factor in various forms of addictive behavior), stop-signal task, decision-making, and working memory. It has been discovered that, like other types of chemical and behavioral addictions, Internet addiction is characterized by an impairment of the metabolism of dopamine, serotonin, opioids, and some other neurotransmitters, which affects reward processing, executive functioning, salience attribution, and habit formation. A small number of pilot projects partially confirm the genetic basis of Internet addiction pathogenesis, previously demonstrated by twin studies.

An important aspect and trend in modern research on Internet-addictive behavior is an attempt to avoid the study of generalized, undifferentiated Internet addiction in favor of analyzing its specific

forms, such as computer games addiction and PSMU[24,129,130]. At the same time, the vast majority of the mentioned neurobiological studies were focused on computer games addiction (*e.g.* 85% of patients for functional magnetic resonance imaging[131]) and generalized Internet addiction (without taking into account the consumed content). Even though a certain number of neuroimaging studies have been conducted for PSMU[66,67,69], there is practically no research on neuropeptide and genetic associations for PSMU to date. Attempts to use neuroimaging to look for common neurobiological mechanisms between PSMU and other addictions have so far produced conflicting results, at least in relation to the prefrontal cortex[66,67,132-134].

Although studies of generalized Internet addiction – especially for women – can be partially extrapolated to PSMU (taking into account common gender and psychosocial characteristics for some populations[24]), it is extremely important to study the directly verified PSMU, which differs significantly from computer games addiction. Further research is needed to better identify commonalities and differences in the neurobiology of different types of addictive online behavior in the context of the content consumed, the devices and technologies used, and the stability of symptoms across age. The study of neuropeptides directly involved in social bonding: Oxytocin and vasopressin, as well as orexin, melatonin, and neurotrophic factors (BDNF and GDNF), looks promising for PSMU neuromolecular associations.

Genetic studies conducted on small samples, conflicting and still quite scarce, should also be expanded to specific forms of Internet addiction, such as PSMU and smartphone addiction. Replication studies with a large number of participants are urgently needed, as well as genome-wide association and polygenic risk score estimate projects.

CONCLUSION

In this narrative review, we discussed neurobiological risk factors for Internet addiction with a focus on current evidence on the association between PSMU and structural/functional characteristics of the brain and autonomic nervous system, neurochemical correlations, and genetic features. A review of the literature shows that the vast majority of the mentioned neurobiological studies were focused on computer games addiction and generalized Internet addiction (without taking into account the consumed content). Even though a certain number of neuroimaging studies have been conducted for PSMU, there is practically no research on neuropeptide and genetic associations for PSMU to date. This fact points to the extremely high relevance of such studies.

Abstract

Deep brain stimulation (DBS) is a medical treatment that aims to obtain therapeutic effects by applying chronic electrical impulses in specific brain structures and neurological circuits. Over the years, DBS has been studied for the treatment of many psychiatric disorders. Scientific research on the use of DBS in people with autism has focused this interest mainly on treatment-resistant obsessive-compulsive disorder, drug-resistant epilepsy, self-injurious behaviors (SIB), and aggressive behaviors toward the self. Autism spectrum disorder (ASD) includes a group of developmental disabilities characterized by patterns of delay and deviance in the development of social, communicative, and cognitive skills and the presence of repetitive and stereotyped behaviors as well as restricted interests. People with autism often have numerous medical and psychiatric comorbidities that worsen the quality of life of patients and their caregivers. Obsessive-compulsive symptoms can be found in up to 81.3% of people with autism. They are often severe, refractory to treatment, and particularly difficult to treat. SIB has a high prevalence in severely retarded individuals and is often associated with autism. Drug treatment of both autism and SIB presents a therapeutic challenge. To describe the current state of the art regarding the efficacy of DBS in people with ASD, a literature search was conducted for relevant studies using the PubMed database. Thirteen studies have been considered in this paper. Up to date, DBS has been used for the stimulation of the nucleus accumbens, globus pallidus internus, anterior limb of the internal capsule, ventral anterior limb of the internal capsule, basolateral amygdala, ventral capsule and ventral striatum, medial forebrain bundle, and posterior hypothalamus. In the total sample of 16 patients, 4 were adolescents, and 12 were adults. All patients had symptoms resistant to multiple drug therapy. Many patients taken into consideration by the studies showed clinical improvements as evidenced by the scores of the psychopathological scales used. In some cases, clinical improvements have varied over time, which may require further investigation. Among the new therapeutic perspectives, DBS could be a valid option. However, further, and more in-depth research is needed in this field.

INTRODUCTION

Deep brain stimulation (DBS) is a medical treatment that aims at obtaining therapeutic effects of certain neurological and psychiatric disorders by applying chronic electrical impulses in specific brain structures and neurological circuits[1]. The modern beginning of DBS can be traced back to the work of Benabid, Pollak, and colleagues at the Joseph Fourier University in Grenoble in the 1980s[2], based on several decades of clinical work and biophysical discoveries[3]. The clinical success of DBS has opened the door to other neurostimulation therapies such as transcranial magnetic stimulation and has motivated an intense analysis of the neural circuits affected by neurological disorders such as Parkinson's disease[4]. The first use of DBS for a psychiatric indication was published by Nuttin *et al*[5] in 1999. Over the years, DBS has been studied for the treatment of obsessive-compulsive disorder (OCD)[6], tardive dyskinesia (TD)[7], treatment-resistant depression[8-10], Tourette's syndrome[11], treatment-refractory anorexia nervosa[12].

Autism spectrum disorder (ASD) includes a group of developmental disabilities characterized by patterns of delay and deviance in the development of social, communicative, cognitive skills and the presence of repetitive and stereotyped behaviors as well as restricted interests[13]. In addition to core symptoms, people with ASD often have numerous medical and psychiatric comorbidities that worsen the quality of life of patients and their caregivers[14]. Obsessive-compulsive symptoms can be found in up to 81.3% of people with ASD. They are often severe, refractory to treatment, may be clinically confused with core symptoms of ASD, and are particularly difficult to treat[15,16].

Self-injurious behavior (SIB) has been defined as "behavior which produces physical injury to the individual's own body"[17]. SIB has a high prevalence in severely retarded individuals and is often associated with autism. Indeed, up to 42% of people with autism may exhibit repetitive SIBs[18]. Additionally, over 75% of children with SIB will have these behaviors persist into adulthood sometimes resulting in serious harm and even death[19-21].

In approximately two-thirds of cases, SIB is maintained by social variables[22], while in approximately one-quarter of cases, SIB occurs independently of social consequences [automatic reinforcement subtype, automatically maintained SIB (ASIB)][23]. ASIB is considered the most challenging subtype to treat, because the events that cause and maintain it are not known. Currently, ASIB is classified into three subtypes[24,25]. Subtype 1 ASIB is characterized by higher rates of SIB in conditions with minimal external stimulation. Subtype 2 ASIB is characterized by high or variable rates of SIB across high and low stimulation conditions. Subtype 3 ASIB is characterized by the presence of self-restraint[26].

Drug treatment of both autism and SIB presents a therapeutic challenge. Some drugs such as risperidone, aripiprazole, and fluoxetine have shown positive efficacy evidence for treating irritability in people with ASD but not for specifically reducing self-harm[27-30]. Currently, the most successful therapeutic strategies for SIBs are based on applied behavioral analysis techniques[31,32] combined

with pharmacological treatments with neuroleptics, mood stabilizers, sedatives, but some patients remain refractory[33].

The present work aims to describe the current state of the art regarding the efficacy of DBS in people with ASD.

A literature search was conducted for relevant studies using PubMed database. In drafting this paper, the authors decided to consider the published articles, classifying them according to the brain regions stimulated by DBS and not according to the pathologies treated.

There are clinical studies on animal models in the literature, but in this article, we will only consider human clinical studies, as we are more interested in the usefulness and efficacy of DBS in clinical practice.

Scientific research on the use of DBS in people with autism has focused this interest mainly on treatment-resistant OCD, drug-resistant epilepsy (DRE), SIBs, and aggressive behaviors toward self. Four studies in the literature have used DBS to treat OCD and other comorbidities in people with ASD [34-37] (see Table 1). Five studies investigated the efficacy of DBS in the treatment of SIB in people with autism[38-42]. A protocol for the application of DBS in children and young adults has recently been published, but the results are not yet available[43]. Furthermore, Heiden *et al*[44] published a retrospective study of the use of DBS in ten patients, including two patients with autism, but the results were not extrapolated for the different pathologies. This makes it impossible to consider the efficacy of DBS in the autistic patients included in the study. Torres *et al*[45] also published a study on the use of DBS for aggression in 7 patients, 5 of whom had autism. The results were not divided for a single patient not allowing to identify of the efficacy of DBS for autistic patients. Recently Benedetti-Isaac *et al* [46] published a follow-up study on the use of DBS in 5 pediatric autistic patients with aggressive behaviors resistant to drug therapy, but the results were not divided by single patient.

In the total sample of 16 patients, 4 were adolescents (all males), and 12 were adults (5 males and 7 females). All patients had symptoms resistant to multiple drug therapy. Generally, treatment resistance consists of three core components: Correct psychiatric diagnosis, adequate treatment, and symptoms not responding adequately despite treatment[47].

USE OF DBS IN PEOPLE WITH AUTISM

In patients with autism, the literature published so far has used DBS for the stimulation of the nucleus accumbens (NAc), Globus Pallidus internus (GPi), anterior limb of internal capsule (ALIC), ventral ALIC (vALIC), basolateral amygdala, ventral capsule and ventral striatum, medial forebrain bundle (MFB), posterior hypothalamus (PHyp).

Three studies[33,34,39] have applied DBS to the NAc of people with autism and numerous comorbidities. Past literature has shown that the NAc may be a key structure for the control of OCD symptoms[48,49], in modulating aggression[50], and in improving the response to social stimuli in ASD [51].

Segar *et al*[34] showed the efficacy of DBS in a 24-year-old female patient with Kleefstra Syndrome with comorbidities of ASD, OCD, and Tourette-like symptoms. The clinical improvements mainly concerned the patient's compulsive behaviors, coprolalia, language, and social interaction, with marked improvement in the global assessment of functioning scores.

In 2019, Doshi *et al*[35] reported a 42-year-old woman with autism who underwent bilateral NAc DBS for control of severe OCD and aggression (violent outbursts against others and hitting and injuring others and herself) refractory to pharmacological treatments. In the days following the surgery, the patient had shown a marked difference in her behavior and eye contact, and appropriate laughter. Clinical improvements were consistent with improvements in administered psychopathology scale scores [Yale-Brown obsessive-compulsive scale (Y-BOCS), Hamilton depression scale, Hamilton anxiety scale, and social communication questionnaire].

Park *et al*[40] observed remarkable clinical improvements in a 14-year-old boy with ASD and SIB treated with bilateral NAc DBS. The clinical improvements (assessed with the Y-BOCS, clinical global impression scale, attention deficit hyperactive disorder rating scale, and social responsiveness scale), were accompanied by functional and structural changes in the brain after DBS, demonstrated using fluorodeoxyglucose positron emission tomography/computed tomography imaging. Furthermore, at the 2-year post-operative evaluation, the boy showed improved language comprehension and expression skills, and improved eye contact.

Two studies[38,41] have applied GPi DBS to people with autism to improve movement impairments. Stocco *et al*[39] applied GPi DBS to two people with ASD, severe stereotypies, and SIB (one patient simultaneously received DBS in GPi and the Anterior limb of the internal capsule). Only the patient who received GPi DBS had maintained clinical improvements over time, even reducing drug therapy. As suggested by the authors, GPi DBS may provide relief for severe pharmacologically unresponsive stereotypies in some patients. Indeed, the characteristics of the ideal patient to be subjected to DBS should be better explored.

Table 1 Summary of deep brain stimulation studies for autism spectrum disorder

Ref.	Patients' age/sex	Diagnosis and comorbidities	Indications for DBS	DBS targets	Pre-BDS scores	Post-BDS scores	Main outcomes
Segar *et al*[34]	24, F	KS, OCD, ASD, epilepsy	Biting hands, picking skin	NAc	GAF 20	GAF 50-60	Clinical improvements mainly for compulsive behaviors, coprolalia, language and social interaction
Doshi *et al*[35]	42, F	OCD, ASD, epilepsy	OCD, aggression	NAc	Y-BOCS 19, HAMD 20, HAS 30, SCQ 26	Y-BOCS 5, HAMD 15, HAS 18, SCQ 16	Marked improvements in OCD symptoms, aggressive behavior, eye contact and appropriate laughter
Park *et al*[40]	13, M	ASD, Develop-mental Delay	Self-mutilation, face-hitting	NAc	CGI-S 6; ABC 106; CY-BOCS 22; K-ARS 54; SRS 101	CGI-S 4; ABC 40; CY- BOCS 7; K-ARS 36; SRS 98	Decreased in SIB and improvement in verbal communication
Stocco *et al* [39]	19, F	ASD, ID, monosomy 2q and trisomy 20p	Self-picking, Severe stereotypes	GPi	JHMRS 46	JHMRS 4	Marked improvement in the SIB and dystonia
	17, M	ASD, ID, anxiety	Punching of arms and legs, biting, Severe stereotypes	GPi and ALIC	JHMRS 67	JHMRS 19	Substantial initial improvement in SIB, but the benefit disappeared after 6 mo and was not regained
Kakko *et al* [42]	19, M	ASD, ID, epilepsy, TD	Aggression, self-mutilation, lacerations	GPi	NR	NR	TD symptoms were markedly improved. The anxiety, behavioral symptoms had ceased
Sturm *et al*[38]	13, M	Kanner's Autism, ID, infantile cerebral palsy	Self-aggression	Basolateral amygdala	Parental score of 6	Parental score of 2	Decreased in SIB and core symptoms of the autism spectrum in the emotional, social, and cognitive domains
Davis *et al*[36]	44, M	OCD, ASD, MDD, tics, epilepsy	OCD, aggression	Ventral capsule/ventral striatum	Y-BOCS, MADRS, YGTSS	Y-BOCS, MADRS and YGTSS scores decreased by 68%, 66%, and 75% respectively	The clinical improvements were maintained, albeit with fluctuations, after 3 yr. No effect on core symptoms of ASD
Graat *et al*[37]	39, F	OCD, ASD, Depressive episodes	OCD	vALIC	Y-BOCS 33, HAMD 27	Y-BOCS 12, HAMD 7	50% reduction of OCD symptoms following DBS, especially obsessions
	54, F	OCD, ASD	OCD	vALIC, then MFB	Y-BOCS 38, HAMD 30	Y-BOCS 18, HAMD 4	Initially did not benefit from DBS. Thereafter OCD symptoms improved and decreased by more than 50%
	32, M	OCD, ASD, ADHD	OCD, aggressive intrusions	vALIC	Y-BOCS 31, HAMD 18	Y-BOCS 23, HAMD 12	Partial responder probably due to several transient side effects of DBS
	31, F	OCD, ASD, DD, OCPD, AN	OCD	vALIC	Y-BOCS 34, HAMD 30	Y-BOCS 32, HAMD 27	Only some subjective improvements
	51, M	OCD, ASD	OCD	MFB	Y-BOCS 34, HAMD 5	Y-BOCS 0, HAMD 2	Obsessive-compulsive symptoms disappeared entirely. Improved confidence and less social

							shyness
	30, F	OCD, ASD, PDD, GAD, UPD	OCD,	MFB	Y-BOCS 34, HAMD 23	Y-BOCS 22, HAMD 22	35% reduction of OCD symptoms following DBS
Benedetti-Isaac *et al*[41]	27, M	ASD, TBI, epilepsy	Aggressive behavior towards self	PHyp	OAS 9	OAS 1	Improvements in seizures, in aggressive behavior, in quality of life, in daily living skills
	16, M	ASD, epilepsy, Developmental Delay	Self-aggression	PHyp	OAS 8	OAS 1	Aggressive behavior controlled for a month. After 2 mo it reappeared as before surgery

ABC: Antecedent, behavior, consequence; ADHD: Attention deficit hyperactive disorder; ALIC: Anterior limb of internal capsule; AN: Anorexia nervosa; ASD: Autism spectrum disorder; CGI-S: Clinical global impressions-severity; CY-BOCS: Children's Yale-Brown obsessive-compulsive scale; DBS: Deep brain stimulation; DD: Depressive disorder; F: Female; GAD: Generalized anxiety disorder; GAF: Global assessment of functioning; GPi: Globus Pallidus internus; HAMD: Hamilton depression scale; HAS: Hamilton anxiety scale; ID: Intellectual disability; JHMRS: Johns Hopkins motor stereotypy rating scale; K-ARS: Korea attention deficit hyperactive disorder rating scale; KS: Kleefstra syndrome; M: Male; MADRS: Montgomery-Asberg depression rating scale; MDD: Major depressive disorder; MFB: Medial forebrain bundle; NAc: Nucleus accumbens; NR: Not reported; OAS: Overt aggression scale; OCD: Obsessive-compulsive disorder; OCPD: Obsessive-compulsive personality disorder; PDD: Persistent depressive disorder; PHyp: Posterior hypothalamus; SCQ: Social communication questionnaire; SRS: Social responsiveness scale; TBI: Traumatic brain injury; TD: Tardive dyskinesia; UPD: Unspecified personality disorder; vALIC: Ventral anterior limb of the internal capsule; Y-BOCS: Yale-Brown obsessive-compulsive scale; YGTSS: Yale global tic severity scale.

Tardive dyskinesia (TD) is probably the most severe form of extrapyramidal symptoms (EPS) secondary to antipsychotic drugs, manifesting usually after months or years of therapy with involuntary choreiform movements and dystonia, frequently affecting the face and tongue[52]. While there are drug treatments for TD, it is often chronic and irreversible. Furthermore, patients with intellectual disabilities (ID) are more susceptible to EPS[53]. Past literature has shown encouraging evidence of DBS in the treatment of dystonic cerebral palsy in children[54]. GPi DBS in a young adult diagnosed with ASD and ID markedly improved TD symptoms[42]. The anxiety, restlessness, behavioral symptoms, and self-destructive behavior have ceased. Furthermore, the patient's skills, especially communication skills, have returned to the level before the presentation of aggressive seizures.

In 2013 Sturm *et al*[38] treated a 13-year-old boy with ASD and SIB with DBS in the amygdaloid complex and supra-amygdaloid projection system. The implantation of the electrodes in the two areas had been made necessary to testify that possible mechanical irritations, micro-lesions or inflammations in the projections of the amygdala were not effective in controlling the symptoms. Only stimulation of the basolateral nucleus of the amygdala proved effective in improving self-harm and core symptoms of ASD in the emotional, social, communicative, and cognitive domains in a 24-mo follow-up.

Davis *et al*[36] subjected a 44-year-old man with treatment-resistant OCD, major depressive disorder, ASD, and tics to DBS. DBS targets were represented by the ventral capsule and ventral striatum. After 3 years, the clinical improvements obtained within 6 mo of the surgery were maintained, albeit with fluctuations. Indeed, the scores on the Y-BOCS and the Montgomery-Asberg depression rating scale indicated that his symptoms were in the mild range, while the scores on the Yale global tic severity scale were much improved. On the other hand, as expected by the authors, full resolution of symptoms was never achieved and the patient continued to experience the clinical features of ASD.

In 2022, Graat *et al*[37] published the results of six patients with refractory OCD comorbid with ASD who underwent DBS of the vALIC or MFB. The efficacy of DBS on obsessive-compulsive and depressive symptoms was tested with the Y-BOCS and the Hamilton depression rating scale, respectively. Considering Y-BOCS scores, four patients were responders (> 35% decrease Y-BOCS), one patient was a partial responder (25%–35% decrease Y-BOCS) probably due to transient side effects of DBS, and one patient was a non-responder (< 25% decrease Y- BOCS), even though she had subjective symptom improvements.

After considering previously published studies[55,56] on the evidence of surgical treatment of the PHyp in aggressive drug-resistant behaviors, Benedetti-Isaac *et al*[41] published the results of PHyp DBS in 5 patients with DRE associated with intractable aggressive behavior. Only two patients among those recruited were also affected by ASD. A 27-year-old man with ID associated with severe autism, reported improvement in quality of life, better access to special education, and improvements in daily living activities. On the other hand, the aggressive behavior of a 16-year-old boy with ID and severe autism, was partially controlled for a month, but after 2 mo it reappeared as before surgery despite stimulation.

Only one study[37] reported adverse effects of DBS. One patient showed severe transient side effects: an infection of the DBS system that required removal of the system and, at a later stage, a suicide attempt (overdosed of quetiapine). Suicidality resolved without changing stimulation settings. Other

transient adverse effects were represented by restlessness, hypomania, tics, impulsivity, agitation, forgetfulness, cramp/joint pain, headache, memory complaints, agitation, hallucinations, and delusions.

CONCLUSION

The multiple comorbidities associated with ASD and the drug resistance in some patients lead to a decrease in the quality of life of patients and their family members or caregivers. To date, DBS has been used in people with autism solely to treat comorbid conditions. Despite encouraging results for the treatment of drug-resistant diseases, positive effects on core symptoms of ASD have only occasionally been reported. Finding new and innovative treatments is a fundamental aspect for those who take care of people with autism and comorbid conditions resistant to conventional treatments. Among the new therapeutic perspectives, as highlighted by the studies presented in this article, DBS could be a valid option to improve the management of disabling pathologies comorbid with autism and consequently the quality of life. However, further, and more in-depth research is needed in this field.

Abstract

With the Food and Drug Administration designation in 2017 of 3,4-methylenedioxymethamphetamine (MDMA) as a breakthrough therapy in post-traumatic stress disorder and psilocybin in treatment-resistant depression, psychedelic drugs have continued to garner the attention of researchers and clinicians for their promise of unmatched, rapid improvement in a multitude of psychiatric conditions. Classic psychedelic drugs including psilocybin, lysergic acid diethylamide, and ayahuasca, as well as non-classic drugs such as MDMA and ketamine, are currently being investigated for a potential therapeutic role in trauma, depressive disorders, and other psychopathologies. However, psilocybin and MDMA each have a functional profile well-suited for integration with psychotherapy. The present review focuses on psilocybin and MDMA in psychedelic-assisted therapy (PAT), as these studies compose most of the literature pool. In this review, we discuss the current and future uses of psychedelic drugs, with an emphasis on the role of MDMA and psilocybin in PAT in the setting of trauma and related comorbidities on the efficacy of psychedelic drugs across multiple psychiatric disorders. The article concludes with thoughts for future research, such as incorporating wearables and standardization of symptom scales, therapy styles, and assessment of adverse drug reactions.

Key Words: Psychedelics; Trauma; Depression; Methylenedioxymethamphetamine; Ecstasy; Psilocybin

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Psychedelic-assisted therapy with psilocybin or 3,4-methylenedioxymethamphetamine (MDMA) is strongly supportive across psychiatric conditions, especially trauma and related comorbidities, as demonstrated through a pattern of rapid and sustained symptom relief. Both treatments seem to have benefits beyond the Food and Drug Administration breakthrough designations of treatment-resistant depression for psilocybin and post-traumatic stress disorder for MDMA.

INTRODUCTION

The psychedelic renaissance of modern psychiatry can trace its resurgence to 2017-2018, when the Food and Drug Administration (FDA) designated breakthrough therapy status to psilocybin in treatment-resistant depression and 3,4-methylenedioxymethamphetamine (MDMA) in post-traumatic stress disorder (PTSD). Psychedelics can be broadly categorized as classic psychedelics that act as agonists at the 5-HT_{2A} receptor [*i.e.*, psilocybin, lysergic acid diethylamide (LSD), ayahuasca/dimethyltryptamine], empathogens that increase serotonin levels (*i.e.*, MDMA), antagonists at N-methyl-D-aspartate receptors (*i.e.*, ketamine), and atypical hallucinogens with effects across neurotransmitter systems[1,2]. Psychedelic-assisted psychotherapy (PAT) involving MDMA or psilocybin composes most of the literature pool, though studies involving other psychopathologies and compounds have also been investigated to a lesser extent. The predominance of both psilocybin and MDMA in the literature may be attributed to the properties that make each an ideal adjunct to psychotherapy.

Psilocybin and its active metabolite psilocin are derived from psychoactive mushroom species originally used in ceremonial settings to facilitate spiritual experiences in Central and South America, later introduced to Western culture in the 1950s[1,3]. As a classic psychedelic, psilocybin is a 5-HT_{2A} receptor agonist that was found to produce rapid yet enduring improvement in treatment-resistant depression and major depressive disorder (MDD)[4-6]. More recently, psilocybin was compared to escitalopram in a double-blind trial. Both treatments were found to have similar efficacy in depression, which will be discussed in more detail in the present article[7].

Psilocybin further enhances its synergism with psychotherapy by evoking a sense of unity, ego-dissolution, and awe through "mystical" experiences[8-10]. As described by Vaid *et al*[11] (2022), PAT may enable the processing of emotional experiences that were previously inaccessible due to trauma blocks. This promotes reconnection with the self and "foundational identity deficit repair," a re-stabilization of the core ideas that together represent the conscious identity, self-esteem, and other aspects of the self[11]. As will be described later in this article, patients in recent studies report significant reductions in symptom rating scales, with benefits partly attributed to this mystical component-experiences of oneness or ego-dissolution, connection to self-essence, and a broadened perspective beyond self-imposed limits on thought processes and rigid mental frameworks that may once have been adaptive responses to life events[12,13].

MDMA was initially developed by Merck & Co. for hemostasis in 1912, and its psychoactive effects were not published until 1978. After becoming popularized as recreational drug "ecstasy" in the 1980s [1,14,15], the Drug Enforcement Agency cited concerns of abuse potential and neurotoxicity and assigned schedule I status to MDMA in 1985. MDMA is part of a class of psychedelics, termed empathogens or enactogens, that increase empathy and social connection. Its effects are primarily mediated by serotonergic activity, including serotonin/norepinephrine transporter reuptake inhibition and partial agonism of serotonin receptors (5-HT_{2A}, 5-HT_{1A}, 5-HT_{2C})[1]. By far, MDMA studies formed most of the research elicited by the PubMed search terms. The reasons for the clear bias in the literature and its consequences are varied and discussed in the future directions section. Nevertheless, the research has yielded promising results across psychopathologies, though most research aligns with its FDA designation for PTSD. A recent double-blind, phase 3 clinical trial found that 67% of participants receiving MDMA-assisted psychotherapy no longer met PTSD criteria after 2 mo[16]. These improvements are attributed to several downstream changes in cognition that further complement psychotherapy.

MDMA has been previously shown to decrease amygdala response when patients are presented with angry faces, as well as increase ventral striatum response when viewing happy faces, further supporting that MDMA reduces threat response, enhances reward, and facilitates positive social interactions[1,17,18]. MDMA has the reputation of generating feelings of closeness, connection, and emotional empathy, although similar features also exist in classic psychedelics[19,20]. However, MDMA uniquely offers augmentation of the therapeutic alliance, easefully lowering barriers and enabling the patient to process traumatic memories without feeling overwhelmed[1,21].

MDMA, psilocybin, and other psychedelics appear to induce a temporary period of increased neuroplasticity with associated changes in psychological flexibility[21,22]. Psilocybin studies have demonstrated increased neurogenesis, spinogenesis, and synaptogenesis that facilitate the reconditioning of fear memory and the reversal of stress-induced changes to the prefrontal cortex[23-25]. The plasticity counters the deficits in fear memory extinction seen in PTSD, alleviating distress from the cycle of avoidance and flashbacks associated with persistent traumatic memories[26-28]. Kéri *et al*[29] suggest that psychedelic-induced serotonin-glutamate interactions affect memory pathways responsible for memory destabilization and reconsolidation[29]. The neuroplastic and fear memory changes enrich the benefits drawn from combination with psychotherapy.

The present focus is on psychedelics involved in PAT, namely MDMA and psilocybin as these studies compose much of the literature pool. A literature review was conducted through PubMed database search of ((psilocybin) OR (MDMA)) AND (trauma). The search was also performed on Reference Citation Analysis (https://www.referencecitationanalysis.com/). The aim is to summarize the literature on psychedelic drugs, with an emphasis on the role of MDMA and psilocybin in PAT in the setting of trauma and related depressive disorders, from 2020 to 2022, bridging the gap from Reiff *et al*'s review encompassing articles from 2007 to 2019 on the efficacy of psychedelic drugs across multiple psychiatric disorders[1]. The article concludes with thoughts for future research, such as incorporating wearables and standardization of symptom scales, therapy styles, and assessment of adverse drug reactions.

PSILOCYBIN

With its FDA designation for treatment-resistant depression, it follows to begin the discussion of psilocybin with updates in depression, a common comorbidity in trauma-related conditions. Carhart-Harris *et al*[7] published a clinical trial comparing psilocybin *vs* escitalopram in 59 patients with MDD [7]. The psylocibin group (n = 30) received 25 mg of psilocybin at the start and a second dose at 3 wk, all while receiving 6 wk of daily placebo. The escitalopram group (n = 29) received 1 mg of psilocybin at the start and a second dose of 1 mg at 3 wk, with daily oral escitalopram 10 mg throughout the 6-wk study. The primary outcome measure was changes from baselines scores (range 0 to 27) on the quick inventory of depressive symptomatology (QIDS-SR-16), with a response defined as reduction in score of at least 50% and remission defined as a score of 5 or less.

A response occurred in 70% of the psilocybin group and 48% of the escitalopram group, while remission occurred in 57% of the psilocybin group and 28% of the escitalopram group. Although these differences do not reach significance, it is notable that both psilocybin and escitalopram appear, at a minimum, to have equivalent impacts. The lack of control group prevents the comparison of each treatment to a baseline population, but it is promising that the efficacy is similar between psilocybin and escitalopram. The authors report that while the initial trial design included a placebo group, this became too practically complex and expensive. Other limitations of the study include the duration, as escitalopram may require more time to display its full efficacy. Additionally, the patients in the trial were not from varying socioeconomic or ethnic backgrounds, limiting external validity. The study also included many secondary outcomes, including scores on other symptom scales, but these were not considered useful as the data were unadjusted for multiple comparisons.

Further analysis of the study was conducted by Murphy *et al*[30] regarding the influence of therapeutic alliance. It was found that increased strength of therapeutic alliance led to greater emotional breakthrough and mystical experiences across two PAT sessions[30]. Interestingly, the average symptom severity scores at baseline were in the range for moderate depression[7], highlighting an additional application for psilocybin beyond treatment-resistant depression.

In a patient population with moderate to severe MDD, Davis *et al*[31] performed an 8-wk intervention consisting of two psilocybin dosing sessions less than two weeks apart with supportive psychotherapy. Exclusion criteria illustrate the reduced the severity of depression within the sample population: Selected patients were screened to avoid current antidepressant use, past diagnosis with a psychotic disorder, serious suicide attempts, or prior psychiatric hospitalization. However, enrolled patients required a score of at least 17 on the GRID-Hamilton depression rating scale (GRID-HAMD), the scale used to evaluate outcomes in this study at weeks 1 and 4 post-treatment with psilocybin. A total of 27 patients were selected and randomized into an immediate-treatment group (weeks 1-4, n = 14) and delayed-treatment group (weeks 5-8, n = 12), which served as a waiting list control condition that later received PAT as well. At baseline, the mean GRID-HAMD score was 22.8 with SD 3.9. Patients receiving immediate treatment showed significant reductions at weeks 1 and 4, with mean scores returning at 8.0

(SD 7.1) during week 1 and 8.5 (SD 5.7) at week 4. Overall, 17 patients demonstrated reductions in GRID-HAMD scores of at least 50%, 14 patients went into remission, and 3 patients dropped out before completing the intervention. Although preliminary, the effect sizes seen with psilocybin in this trial are several times larger than that seen in psychotherapy or antidepressant monotherapy[31-33].

The efficacy of psilocybin seen in depression studies likely offers benefits in a trauma-centered approach, due to the widespread comorbidity of trauma with depressive disorders. The role of psilocybin continues to expand outside its FDA designation for treatment-resistant depression. Khan *et al*[34] reported on an open-label study that provided psilocybin-assisted therapy in traumatized AIDS survivors. The authors noted reductions in PTSD symptoms, attachment anxiety, and demoralization. The intent underlying psychedelic use appears to be important. One survey demonstrated that therapeutic intent behind past psychedelic use in patients with history of child maltreatment showed significant reductions in complex trauma symptoms and internalized shame[35]. This further suggests that psilocybin's benefits extend beyond depression and into trauma-related pathologies. Though outside the scope of the present article, psilocybin is being explored across several domains including substance use disorders, neurodegenerative diseases such as Alzheimer's disease[36].

Adverse reactions

In the psilocybin and escitalopram study, the escitalopram group had a higher prevalence of anxiety, dry mouth, sexual dysfunction, and reduced emotional responsiveness. Due to these side effects, four patients self-discontinued the medication and one patient modified regimen to half a daily dose. No patients in the psilocybin group requested dose adjustment or discontinuation[7]. In the trial by Davis *et al*[31], participants reported mild-to-moderate headache, as well as difficult emotions during in-session time only. No serious adverse events were reported or observed[31].

MDMA

In 2021, Mitchell *et al*[16] reported data from a double-blind, phase 3 clinical trial found that 67% of participants receiving MDMA-assisted psychotherapy ceased to meet PTSD criteria after 2 mo[16]. The MDMA-treated group (n = 46) showed significant decreases on clinician-administered PTSD Scale for DSM-5 (CAPS-V) compared to inactive placebo with therapy (n = 44). Participants attended three experimental sessions, spaced four weeks apart. The first session started with 80 mg MDMA and the option for a supplemental half-dose of 40 mg, 1.5-2.5 h later. For the next two sessions, the initial dose was increased to 120 mg with supplemental half-dose of 60 mg. No tolerability issues led to participants being withheld the supplemental doses.

MDMA-assisted therapy led to increases in posttraumatic growth, encompassing increased positivity towards self-perception, relationships, or philosophy of life[37]. Scores from 60 participants, pooled from three phase 2 clinical studies meeting PTSD criteria, were assigned to treatment with 75-125 mg MDMA (n = 45) or active control (0-40 mg MDMA, n = 15). The MDMA group had significantly improved scores on the posttraumatic growth inventory and greater reduction in PTSD symptom severity at 12 mo, and 67% of participants no longer met criteria for PTSD. MDMA may promote adaptive stress responses in PTSD that lead to the downstream benefits seen in recent research, such as reduced ratings of PTSD symptom severity by clinicians[38,39].

MDMA has also been studied in the setting of couples therapy, in which one partner has a current diagnosis of PTSD. One study included 6 romantic dyads, in which both partners received MDMA followed by couples' cognitive behavioral therapy. This led to improved happiness and significant reductions across PTSD symptoms, as unanimously rated by patient, partner, and clinician[40]. Further analysis of this study found enduring improvements in post-traumatic growth, social intimacy, and relational support at 6-mo follow up[41].

These benefits extend to common comorbidities seen in PTSD such as depression[42], substance use [43] and sleep disorders[44], with improvements in Pittsburgh sleep quality index scores that remained significant at one-year follow up. MDMA also shows promise in various other psychopathologies including eating disorders[45] and end of life anxiety associated with life-threatening illness[46], in which patients reported increased ability to cope as they faced illness and existential fears, as well as overall improved quality of life. See Table 1 for a summary of relevant articles discussed in the above psilocybin and MDMA sections.

Adverse reactions

Mitchell *et al*[16] concluded that MDMA was safe and well-tolerated and note that the treatment did not induce abuse potential, suicidality, or QT prolongation[16]. Other studies show that risk factors for developing hyperthermia may include adolescent age and increased alcohol consumption[47-49]. Hyperthermia and rhabdomyolysis are likely context-dependent, occurring at lower frequency when used with therapeutic intent rather than recreational use in the setting of other risk factors[47,50]. Likewise, the "come downs" previously associated following MDMA use may be due to research confounds related to environment and drug sourcing, as clinically administered MDMA has noticeably

lacked this side effect[51]. Other reports in the literature include hepatotoxicity that improved with vitamin E[52], and a case of spinal cord injury suspected to be due to the serotonin surge induced by MDMA, as the vasoconstrictive properties of serotonin may have induced ischemia[53].

FUTURE DIRECTIONS

Dual therapy

As the evidence for each treatment builds independently, the future may include the integration of both treatments in sequence. In this scenario, MDMA would likely be used first as it has a larger influence on building therapeutic alliance. The augmented therapeutic alliance would allow for a potentially improved psilocybin experience upon switching at next session, aligning with previously discussed research that strong therapeutic alliances are associated with greater mystical experiences and emotional breakthroughs. Treatment with MDMA has been associated with persistent depressive symptoms, and the antidepressant effects of psilocybin may alleviate this following administration[42]. In a model described by Oehen and Gasser[54], MDMA tended to be used in the first phase to build the therapeutic alliance and increase the patient's openness to change, leading to enhanced resilience and lowered stress levels. Once further changes were noticed, such as improved self-regulation, less negative self-perception, and increased tolerance to trauma exposure, LSD was introduced to assist psychotherapy. The deepening of the therapeutic process led to improvement per clinical judgment, without adverse events.

Standardization

Although variation in research methodology is needed to enrich the literature pool, standardization in several aspects may allow for more informed comparisons between treatment modalities. Symptom rating scales for depression (*i.e*, QIDS-SR, GRID-HAMD) and PTSD (*i.e*, CAPS-IV, CAPS-V) varied, with some studies using subjective reports of PTSD diagnostic criteria. Similarly, the therapy modalities that accompanied psychedelic administration were diverse, including uniquely developed forms of therapy as in the accept-connect-embody manualized therapy developed in a psilocybin trial[7,30], supportive therapy[31], and couples' cognitive behavioral therapy[40]. The future may look more like the manualized MDMA-assisted therapy provided through public benefit corporation Multidisciplinary Association for Psychedelic Studies (MAPS). MAPS also has an ethics code, a vital addition to future

protocols as patients are placed in a state of increased suggestibility and affective instability during and after the treatment[55]. This critical period requires a trauma-informed approach to care, with support for transgender and gender diverse patients[56]. Lastly, the method of eliciting adverse drug reactions may benefit from standardization. Studies varied in terms of asking open-ended questions, prompting for specific symptoms, and documenting clinical observations. It is comforting that current studies have not shown any serious adverse events, and future studies may benefit by drawing upon a standardized set of common symptoms.

Wearables

Wearable technology has previously demonstrated efficacy as a bridge between patients and providers in mental health, such as in MDD, dementia, schizophrenia[57-59]. Wearables are likewise being used in non-psychiatric contexts, including medical monitoring in oncology and gastroenterology[60,61]. It follows that wearables may have clinical utility in monitoring patient symptoms during and after PAT. Daily functioning, including wearable-derived sleep and activity data, is incorporated in a protocol examining the effects of microdosed psychedelics and may be a useful metric to track long term changes following psychedelic treatment[62].

CONCLUSION

The literature on PAT using psilocybin or MDMA is strongly supportive across psychiatric conditions, especially trauma and related comorbidities. Both treatments seem to have benefits beyond the FDA breakthrough designations of treatment-resistant depression for psilocybin and PTSD for MDMA. As adjuncts to psychotherapy, psilocybin and MDMA show a pattern of rapid and sustained symptom relief. Future studies may consider the advantages of a standardized approach to symptom rating scales, therapy styles, and assessment of adverse drug reactions. Wearables may also offer additional metrics to examine the long-term trends in activity and sleep. As clinical trials continue to show positive results, providers and patients become closer to seeing the effects translate to the clinic and the community.

Abstract

BACKGROUND

The teaching mode of fitness exercise prescriptions for college students in physical education conforms to the scientific principles and rules of fitness, which can adapt to the characteristics of students' individual physiological functions and stimulate their interest in learning.

AIM

To analyze the effect of prescribed exercise teaching on the sports quality and mental health of college students.

METHODS

The participants of the study were 240 students in our class of 2021, of which 142 were men and 98 were women. The 240 students were randomly divided into an experimental group using the exercise prescription teaching model and a control group using the conventional teaching model. The experimental and control groups were divided into four classes of 30 students each. The teaching activities of the two teaching mode groups were strictly controlled, and the same tests were used before and after the experiment to test the subjects' exercise quality (including standing long jump, 50 m race, 800 m race, sit-ups, sit-and-reach), physical form (including height, weight, Ketorolai index), cardiopulmonary function (including heart rate, blood pressure, spirometry, 12-min running distance, maximum oxygen intake) and mental health (SCL-90, including somatization, obsessive-compulsive, interpersonal, depression, anxiety, hostility, phobia, paranoia, psychotic symptoms) to understand the effects of the exercise prescription teaching mode on students' physical and mental health status.

RESULTS

There were differences in the exercise scores of standing long jump, 50 m, 800 m/1000 m running, sit-ups, and sit-and-reach in the experimental group after the experiment compared with those before the experiment, and the above indices of

the experimental group were different from those of the control group after the experiment ($P < 0.05$). There were differences in body weight and Ketorolai index in the experimental group after the experiment compared to those before the experiment, and the indices of the experimental group were also different from those of the control group after the experiment ($P < 0.05$). After the experiment, there were differences in spirometry, 12-min running distance, and maximum oxygen intake in the experimental group compared to those before the experiment, and the indices of the experimental group were also different from those of the control group after the experiment ($P < 0.05$). After the experiment, the indicators of somatization, interpersonal sensitivity, depression, anxiety, and hostility in the experimental group were different from those in the pre-experimental group, and the indexes of the experimental group were also different from those of the control group after the experiment ($P < 0.05$).

CONCLUSION

Exercise prescription teaching can mobilize college students' consciousness, enthusiasm, and initiative; expand personalities; enhance physical fitness and improve their mental health more than the conventional fitness exercise prescription teaching method.

Key Words: Exercise prescription teaching; College students; Exercise quality; Mental health status

Core Tip: In order to better create a positive and optimistic outlook on life for college students and increase their interest in physical exercise, it is necessary to apply the physical health prescription course in the process of school physical education teaching. By using sports prescription teaching, teachers develop targeted teaching contents and methods in the teaching class according to the physical quality and health status of students, combine the teaching materials with students' self-learning, self-exercise, self-control, self-regulation and self-evaluation, give full play to students' main role, mobilize students' subjective initiative, realize the transformation from exam-oriented education to quality education, and promote students' all-round development. In view of the continuous decline in the physical and mental health of college students, based on the perspective of special teaching of physical education in colleges and universities, this study starts with the diagnosis of students' physique, provides students with personalized sports prescription teaching experiments with the main purpose of promoting physique, and provides scientific basis for improving students' current physical and mental health, guiding students to conduct scientific and reasonable physical exercise, and improving the effectiveness of school physical education.

INTRODUCTION

Higher general education institutions are the cradles of training qualified personnel of comprehensive quality[1]. College students, as practitioners of China's social, economic development and socialist core values, play the role of the backbone in the future development of society. Ensuring the mental health of college students is increasingly becoming a real problem in the development of China[2,3]. In recent years, problems concerning the physical and mental health of college students have also become the focus of attention, and the results of a large number of surveys and studies[4-6] have shown that the physical conditions, psychological and mental health problems of contemporary college students are more prominent than previously. Therefore, there is an urgent need to find practical and effective measures to strengthen the mental health education and physical exercise of college students, and to strive to improve the physical and mental health of college students.

To create a more positive and optimistic outlook on the lives of college students, as well as to increase their interest in physical exercise, it is necessary to apply physical health prescription courses in the process of physical education in schools[7]. In the traditional process of teaching physical education in institutions, the lack of attention given to exercise health by teachers and students has left many college students facing health problems. Exercise prescription teaching is a highly targeted teaching content and method developed by teachers according to students' physical fitness and health status. It combines teaching according to the material with students' self-learning, self-practice, self-control, self-regulation,

and self-assessment, which can realize the transition from examination-based education to quality education and promote students' overall development by providing full attention to the main role of students and mobilizing their subjective initiative[8-10]. Currently, colleges and universities are making unremitting efforts to continuously "enhance students' physical fitness" and implement "lifelong sports." The physical education mode of self-management and self-development for college students by developing different exercise and fitness prescriptions is beneficial to the physical and mental development of college students.

In response to the trend of continuous decline in the physical and mental health of college students, based on the perspective of college physical education special teaching, this study conducted physical fitness tests on students before the experiment, analyzed the students' various test results, corresponding indices, and provided students with personalized exercise prescription teaching experiments with the main purpose of promoting physical fitness for students' deficiencies in endurance, speed, and strength. It is expected to provide a scientific basis for improving students' current physical and mental health, guide students toward scientific and reasonable fitness, and improve the effectiveness of school physical education.

MATERIALS AND METHODS

Study population

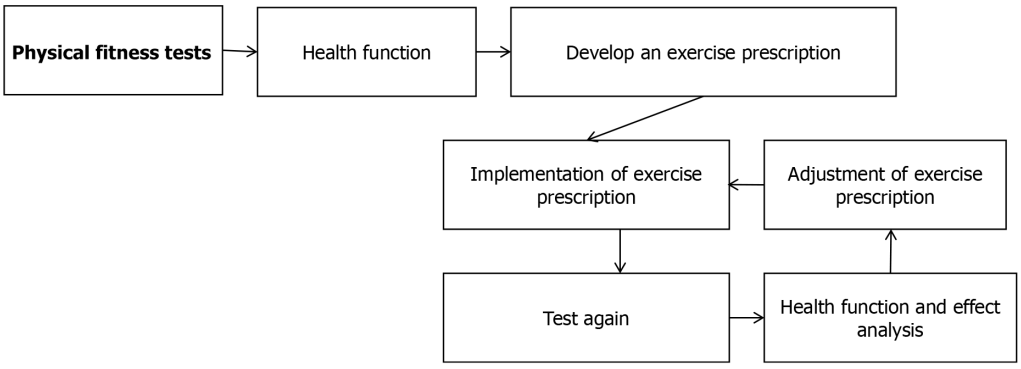
In this study, 240 students from our school class of 2021 were randomly selected (142 men and 98 women), and all participants had no contraindications to sports after taking their medical history and physical examination. The 240 students were randomly divided into an experimental group using the exercise prescription teaching model and a control group using the conventional teaching model. In the experimental group, there were four classes of 30 students each with a total of 120 students, including 69 men and 51 women, aged 18-21 years, with a mean of (19.21 ± 0.61) years. In the control group, there were four classes of 30 students each with a total of 120 students, including 73 men and 47 women, aged 18-20 with a mean of (19.16 ± 0.39) years. The differences in baseline information such as sex, age, height, and weight between the two groups of students were not statistically significant ($P > 0.05$) and were comparable. The study was approved by our ethics committee and all participants signed an informed consent form.

Literature method

We reviewed many articles and textbooks related to exercise prescription teaching as well as teaching curriculum reform and collected the results of domestic and international research on exercise prescription in recent years through Internet searches and other methods for an in-depth understanding of the current state of research and cutting-edge development. Simultaneously, relevant literature was organized and analyzed to provide more informative theoretical data and case support for the study.

Questionnaire method

Questionnaire content: A questionnaire was developed for the implementation of exercise prescription teaching, and the students were divided into experimental and control groups; the results were analyzed and compared in depth. The survey effectively reflected students' opinions on physical education classes, which laid the foundation for the future development of exercise prescription teaching. The survey reflected students' exercise attitudes, learning habits, interests, and other aspects. This way, a scientific exercise prescription curriculum could be effectively developed.



Distribution and recovery of questionnaires: Students in the experimental and control groups participated in a questionnaire survey (Table 1).

Experimental content

Exercise prescription teaching is a highly targeted teaching method developed by the teacher according to the physical fitness and health status of students in the teaching class. It was a method in which the teacher combined the teaching of students according to their abilities with self-learning, self-practice, self-control, self-regulation, and self-assessment. By providing full attention to the main role of students and mobilizing their initiative to achieve the transition from examination-based to quality education, we promoted the overall development of students. The experimental group and the control group were both taught by the same physical education teacher. The experimental group used "exercise prescription" as the basic teaching procedure, the implementation process was cyclic and repetitive (Figure 1). A physical fitness test was conducted to evaluate the exercise ability of students and will be used as the basic basis for exercise prescription control. Teachers analyzed the students' physical fitness according to comprehensive scoring levels in the National Student Physical Fitness Standards and assessed their health functions. Corresponding to the weaknesses of the students in the experimental group, relevant exercise prescriptions (development of speed quality exercise prescription, development of muscle strength exercise prescription, development of endurance exercise prescription, improvement

of physical function exercise prescription, *etc.*) were designed to develop appropriate exercise content, exercise load, intensity, frequency, and duration; each exercise prescription determines the upper and lower limits of effective physical exercise for the students[11,12]. The experimental group participated in one physical education class (two class periods) and two extracurricular physical activities every week and exercised according to the formulated exercise prescription. Teachers conducted physical fitness tests every four weeks and adjusted the exercise program according to the actual situation of students to ensure the scientific nature of students' physical exercise. The control group was taught according to the normal physical education syllabus (including formation and assembly, teachers and students greeting each other, teacher briefly introducing the teaching content and requirements, yoga to warm up, and starting exercise), with one physical education class (two class periods) per week and two extracurricular physical activities conducted by the students themselves.

Teaching plan

The exercise prescription intervention lasted for 16 wk, as shown in Table 2.

Observation index

Motor quality: The test items included the standing long jump, 50-meter run, 800-meter run, sit-up, and sit-and-reach. The tests were conducted and scored on a standard athletic field using standard sports equipment. The test content and test methods were tested in accordance with the requirements of the "Student Physical Fitness Standards (pilot program)" published by the People's Education Publishing House. Measurements were taken before and after the experiment, and specific values were recorded.

Body shape: Included height, weight, and Ketorai index. The equipment used for height and weight measurement was the XTC series of student body mass measurement instruments sold by Dandong Tiankang Sporting Goods Co. Measurements were taken before and after the experiment, and specific values were recorded.

Cardiopulmonary function: Heart rate was measured directly by an electronic meter using the manual pulse measurement method; blood pressure was measured using a mercury sphygmomanometer; spirometry was measured using a Tiankang XTC series student physical measurement spirometer, and a total of three measurements were taken at 15 s interval each time, and the maximum value was taken as spirometry. Maximal oxygen uptake: Extrapolation was done by 12 min running distance performance, and a 12 min running distance was measured on the track of a 400 m standard athletic field. After measuring the 12-min running distance, the maximum oxygen uptake per kilogram of body weight was determined using an extrapolation table developed by the Japan Sports Science Center. Measurements were taken before and after the experiment, and specific values were recorded.

Mental health: A name-based questionnaire was used to assess the mental health status of students using the SCL-90, a self-assessment scale for mental health and psychiatric conditions in China. The scale has 90 items, and the severity level is classified according to the weight of each item (Table 3). This scale consists of 10 main factors: somatization, obsessive-compulsiveness, interpersonal sensitivity, depression, anxiety, hostility, fear, paranoia, psychoticism, and others. The high-weighting factor also

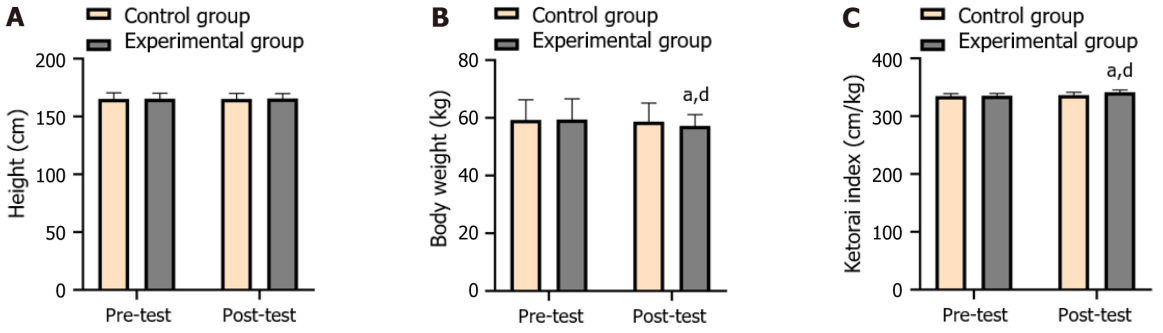
Table 3 Classification of SCL-90 severity levels

Serial number	Grade	Symptom
1	No	Self-perceived absence of symptoms
2	Mild	Conscious presence of the symptom, but no real effect on the subject
3	Moderate	Conscious presence of the symptom, with some effect on the subject
4	Fairly severe	The symptom is often perceived and has a significant impact on the subject
5	Severe	The frequency and intensity of symptoms are very severe

laterally reflects the presence of mental health problems. Measurements were taken before and after the experiment, and specific values were recorded.



Statistical analysis

The relevant data obtained from the survey and test before and after the experiment were analyzed using SPSS 20.0, and a *t*-test was conducted to verify whether there were differences between the experimental and control groups. Therefore, the experimental results were quantified and the objectivity and feasibility of the study were ensured.

RESULTS

Comparison of exercise quality between the two groups before and after the experiment

The differences between the two groups in the pre-experimental exercise test scores for standing long jump, 50 m, 800 m/1000 m running, sit-ups, and sit-and-reach were not significant ($P > 0.05$). After the experiment, there were differences in the exercise scores of standing long jump, 50 m, 800 m/1000 m running, sit-ups, and sit-and-reach in the experimental group compared with those before the experiment, and the indices of the experimental group were also different from those of the control group after the experiment ($P < 0.05$) (Figure 2).

Comparison of body morphology between the two groups before and after the experiment

The differences in height, weight, and Ketolai index before the experiment were not significant between the two groups ($P > 0.05$). There were differences in body weight and Ketolai index in the experimental group after the experiment compared with the pre-experimental group. The above indices of the experimental group were also different from those of the control group after the experiment ($P < 0.05$), and there were no significant differences in height between the two groups before and after the experiment ($P > 0.05$) (Figure 3).

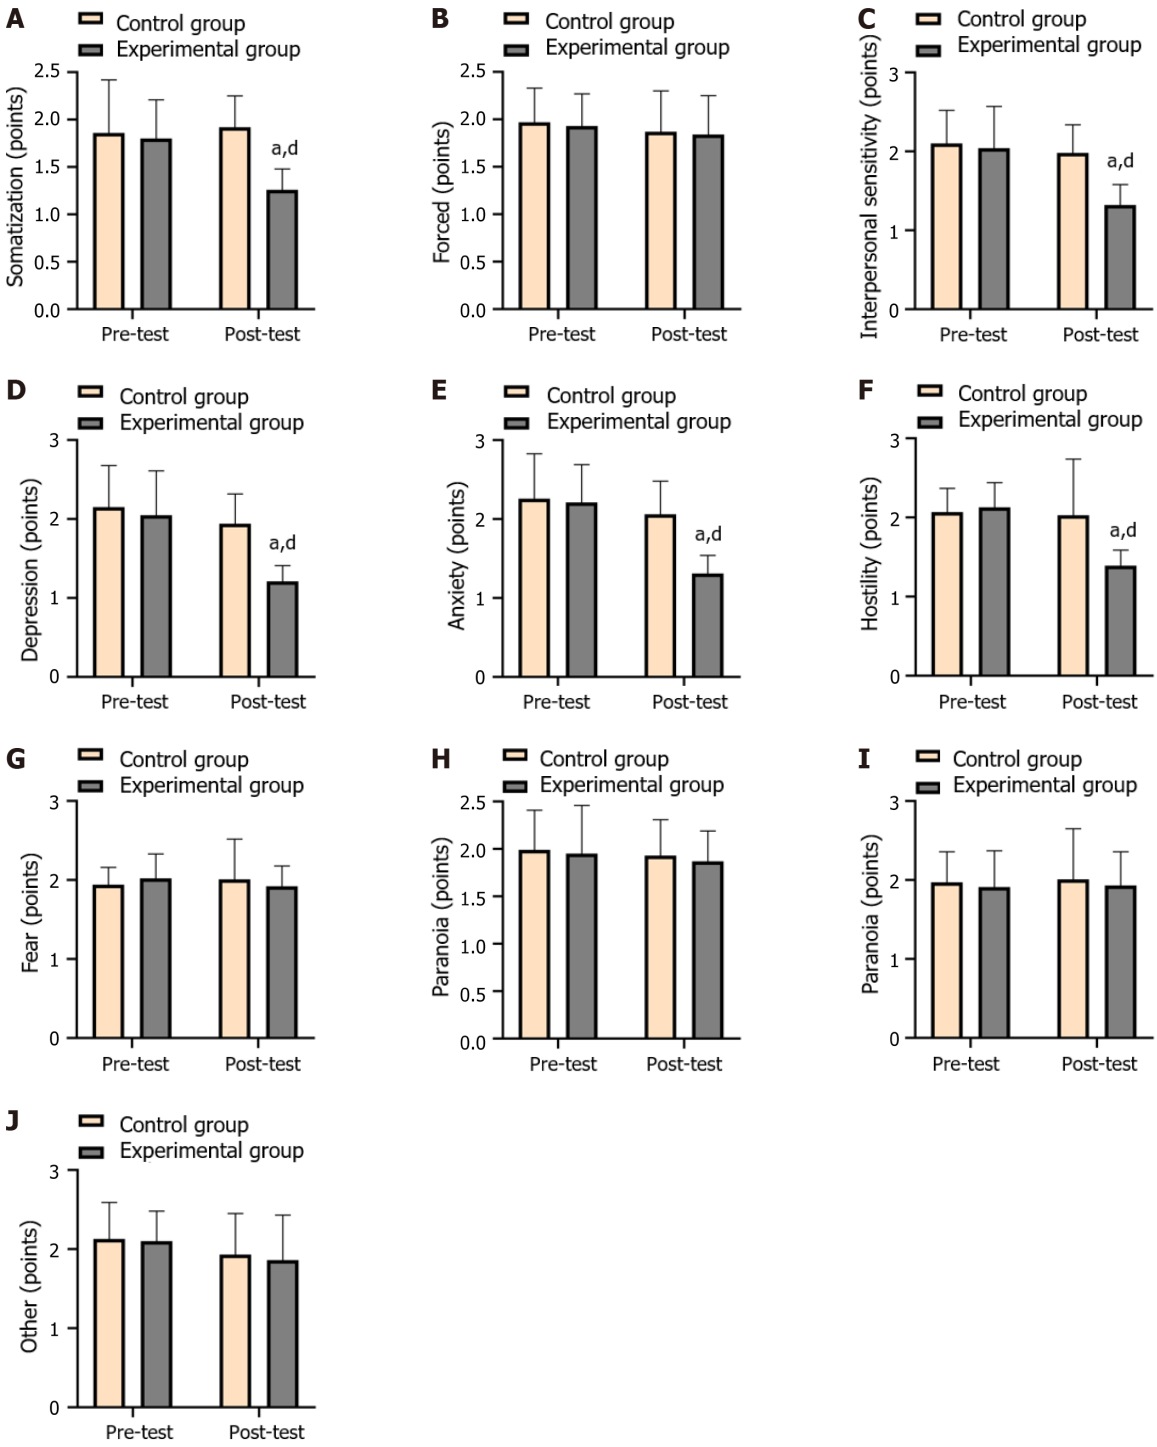
Figure 4 Comparison of cardiopulmonary function between the two groups before and after the experiment. A: Heart rate (beats/min); B: Systolic blood pressure (mm/Hg); C: Diastolic blood pressure (mm/Hg); D: Spirometry (mL); E: 12-min running distance (m); F: Maximum oxygen intake (mL/kg/min). [a]*P* < 0.05 *vs* the same group before teaching. [d]*P* < 0.05 *vs* the control group after teaching. SBP: Systolic blood pressure; DBP: Diastolic blood pressure.

Comparison of cardiopulmonary function between the two groups before and after the experiment



The differences between the two groups in heart rate, systolic blood pressure (SBP), diastolic blood pressure (DBP), spirometry, 12-min running distance, and maximum oxygen intake before the experiment were not significant ($P > 0.05$). There were differences in the post-experimental spirometry, 12-min running distance, and maximum oxygen uptake in the experimental group compared with those before the experiment; the above indices of the experimental group were also different from those of the control group after the experiment ($P < 0.05$), and there were no significant changes in heart rate, SBP, and DBP levels before and after the experiment in both groups ($P > 0.05$) (Figure 4).

Comparison of the mental health status of the two groups before and after the experiment

Differences in the indicators of somatization, obsessive-compulsive symptoms, interpersonal sensitivity, depression, anxiety, hostility, and paranoia were not significant between the two groups before the experiment ($P > 0.05$). Post-experimental somatization, interpersonal sensitivity, depression, anxiety, hostility, and other indicators in the experimental group differed from the pre-experimental comparison. These indices of the experimental group were also different from those of the control group after the experiment ($P < 0.05$). The post-experimental compulsion, fear, paranoia, psychoticism, and other index scores of the experimental group did not differ significantly from the pre-experimental scores, nor did they differ significantly from those of the control group ($P > 0.05$). No significant changes were seen in the index scores of the control group before and after the experiment ($P > 0.05$) (Figure 5).

DISCUSSION

In recent years, problems regarding the physical and mental health of college students have become a focus of attention, and the results of a large number of surveys and studies have shown that the physical conditions, psychological and mental problems of contemporary college students are very prominent [13,14]. The exercise prescription teaching mode interrupted the teaching material system of teaching competitive sports technology and established a fitness-centered fitness teaching system that realized the consistency of teaching purpose, content, and form and made the enhancement of physical fitness come into practice[15-17]. This study explored interventions for college students' mental health through sports and the use of exercise prescriptions to find new ways to improve college students' mental health.

Effect of exercise prescription teaching on students' motor quality

As can be seen from Figure 2, the results of motor quality tests after the experiment for students in the experimental group showed significant changes in motor ability such as a 50 m run, 800 m/1000 m run, standing long jump, sit up, and sit-and-reach show significant changes, indicating that the students' speed, endurance, spring, and upper body strength have been greatly improved. The reason for this may be that the exercise prescription instruction is well arranged and has a good effect on improving all aspects of students' abilities The above suggests that college students should pay attention to strength training, especially the strength training of lower limbs and shoulder belt muscles[18,19].

Effect of exercise prescription teaching on students' body morphology

After the exercise prescription teaching mode exercise, body morphological indices such as height, weight, and Ketorai index before and after the experiment in the control group were not significantly different, whereas there was little change in height before and after the experiment in the experimental group, which was related to the basic stability of bone development in college students. The weight and Ketorolai index of the experimental group differed significantly after the experiment compared with those before the experiment, which may be related to an increase in physical exercise and energy consumption. Slight weight loss is a good adaptation to exercise, and a more significant weight loss may be related to the physical condition of the subject and the content of the exercise received; however, these are all normal conditions[20].

Effect of exercise prescription teaching on students' cardiorespiratory function

From the changes of cardiopulmonary function assessment indexes before and after the experiment. There was no significant difference between the cardiopulmonary function indexes of the experimental group and the control group before the experiment. After the experiment, the vital capacity, 12-min running distance, maximum oxygen intake, step index, and other indices of the experimental group were different from those before the experiment and from those of the control group. The changes in the indexes of students' cardiorespiratory fitness indicate the enhancement of physical fitness and the improvement of exercise capacity, and that the physical exercise of the exercise prescription teaching model has greatly improved students' physical quality and mastery of athletic skills[21,22].

Effect of exercise prescription teaching on students' mental health status

The average score of the SCL-90 scale in the experimental group showed that after 16 wk of exercise prescription teaching, the scores of all factors in the experimental group were decreased, and the scores of interpersonal relationship, anxiety, and depression factors were significantly decreased, and there were very significant differences when compared with those before the experiment. This shows that the implementation of a fitness exercise prescription affected the psychological health of the experimenter. The university stage is a period of gradual maturation of students' psychological processes and complex psychological changes. In a good classroom atmosphere, students experience the pleasure of living with teachers and other students through the medium of cognition and emotion. The elimination of negative emotions caused by the social environment through exercise can have good short- and long-term benefits on the psychological quality of students[23,24].

CONCLUSION

Students can master practical methods to strengthen their bodies and be better prepared for "lifelong sports" activities. Through this study, we found that the application of an exercise prescription teaching model in tertiary institutions has some limitations, such as venues, instruments, equipment, resulting in the limited tests and exercises that can be completed. Therefore, it is impossible to develop comprehensive, effective, and targeted exercise prescriptions. In a follow-up study, we may consider combining social professional outreach training with college sports to provide the necessary conditions for a comprehensive design of exercise prescription training.

ARTICLE HIGHLIGHTS

Research background

The teaching mode of fitness exercise prescriptions for college students in physical education conforms to the scientific principles and rules of fitness, which can adapt to the characteristics of students' individual physiological functions and stimulate their interest in learning.

Research motivation

The physical, psychological, and mental health problems of contemporary college students are more prominent than ever. Therefore, there is an urgent need to find practical and effective measures to strengthen mental health education and physical exercise for college students, and strive to improve their physical and mental health. In order to have a more positive and optimistic view of the lives of college students and increase their interest in physical exercise, it is necessary to apply physical fitness prescription courses in school physical education teaching. In the traditional physical education teaching process in colleges and universities, teachers and students pay insufficient attention to sports health, resulting in many college students facing health problems.

Research objectives

Currently, the main research is to assess the physical fitness and mental health of college students, and this field will continue in the future.

Research methods

Total 240 students were randomly divided into an experimental group and a control group. The experimental group used exercise prescription teaching mode, while the control group used traditional teaching mode. The experimental group and the control group were divided into four classes with 30 students in each class. Strictly control the teaching activities of the two teaching mode groups, and use the same tests before and after the experiment to test the exercise quality, body shape of the subjects, Cardiopulmonary function and mental health to understand the impact of sports management teaching models on students' physical and mental health.

Research results

In response to the trend of continuous decline in the physical and mental health of college students, based on the perspective of college physical education special teaching, this study conducted physical fitness tests on students before the experiment, analyzed the students' various test results, corresponding indices, and provided students with personalized exercise prescription teaching experiments with the main purpose of promoting physical fitness for students' deficiencies in endurance, speed, and strength. It is expected to provide a scientific basis for improving students' current physical and mental health, guide students toward scientific and reasonable fitness, and improve the effectiveness of school physical education.

Research conclusions

Sports prescription teaching can mobilize college students' consciousness, enthusiasm, and initiative, and improve their mental health level.

Research perspectives

Through this study, we found that the application of an exercise prescription teaching model in tertiary institutions has some limitations, such as venues, instruments, equipment, resulting in the limited tests and exercises that can be completed. Therefore, it is impossible to develop comprehensive, effective, and targeted exercise prescriptions. In a follow-up study, we may consider combining social professional outreach training with college sports to provide the necessary conditions for a comprehensive design of exercise prescription training.

Abstract

BACKGROUND

Functional near-infrared spectroscopy (fNIRS) is commonly used to study human brain function by measuring the hemodynamic signals originating from cortical activation and provides a new noninvasive detection method for identifying dementia.

AIM

To investigate the fNIRS imaging technique and its clinical application in differential diagnosis of subtype dementias including frontotemporal lobe dementia, Lewy body dementia, Parkinson's disease dementia (PDD) and Alzheimer's disease (AD).

METHODS

Four patients with different types of dementia were examined with fNIRS during two tasks and a resting state. We adopted the verbal fluency task, working memory task and resting state task. Each patient was compared on the same task. We conducted and analyzed the fNIRS data using a general linear model and Pearson's correlation analysis.

RESULTS

Compared with other types of dementias, fNIRS showed the left frontotemporal and prefrontal lobes to be poorly activated during the verbal fluency task in frontotemporal dementia. In Lewy body dementia, severe asymmetry of prefrontal lobes appeared during both verbal fluency and working memory tasks, and the patient had low functional connectivity during a resting state. In PDD, the patient's prefrontal cortex showed lower excitability than the temporal lobe during the verbal fluency task, while the prefrontal cortex showed higher

excitability during the working memory task. The patient with AD showed poor prefrontal and temporal activation during the working memory task, and more activation of frontopolar instead of the dorsolateral prefrontal cortex.

CONCLUSION
Different hemodynamic characteristics of four types of dementia (as seen by fNIRS imaging) provides evidence that fNIRS can serve as a potential tool for the diagnosis between dementia subtypes.

Key Words: Functional near-infrared spectroscopy; Frontotemporal lobe dementia; Lewy body dementia; Parkinson's disease dementia; Alzheimer's disease

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Four types of dementia showed different patterns of activation when examined by functional near-infrared spectroscopy (fNIRS) during two tasks and a resting state. The patient with frontotemporal dementia showed the lowest activation during the verbal fluency task and the patient with Alzheimer's disease showed the lowest activation during the working memory task. During the resting state, functional connectivity was poor in the patients with Lewy bodies dementia and Parkinson's disease dementia. fNIRS imaging in dementia patients may be able to differentiate between types of dementia, and may be useful in diagnosis for these patients.

INTRODUCTION

Dementia is a disease commonly studied in psychiatry and neurology. Clinical diagnosis is based on symptoms and is supplemented by neuropsychological scales and laboratory examinations. Brain imaging technology is an important tool for exploring brain diseases, and has undergone a period of rapid development in the past 20 years. To improve the accuracy of diagnosis between types of dementia, different technologies have been developed, including computed tomography (CT), positron emission tomography (PET) and magnetic resonance imaging (MRI) to examine brain structure, electroencephalography (EEG) to examine electrical physiology[1]. In addition to functional MRI (fMRI), EEG, and event-related potentials, functional near-infrared spectroscopy (fNIRS) to examine functional connectivity between regions has become an important supplement to existing functional imaging technologies[2,3].

fNIRS imaging evaluates human brain activity by measuring the oxygen level in the prefrontal and temporal cortices[4]. While participants perform different tasks, the fNIRS system provides continuous and real-time oxygen change display of oxy-hemoglobin (oxy-Hb) and deoxygenated hemoglobin values[5]. In aspects of specificity and temporal resolution, fNIRS assessment of cognitive function eliminates many shortcomings of fMRI[6]. While PET and MRI studies have generated insights into the pathological changes in brain oxygenation and activity associated with mild cognitive impairment (MCI) and dementia, these methods have some limitations involving the injection of radioactive compounds and motion artifacts[7].

fNIRS imaging systems possess high temporal and spatial resolutions, which are critical to withstand interference (both electromagnetic and from head motion). The temporal resolutions of fNIRS (11 Hz in this study) and EEG are in the order of seconds and milliseconds, respectively. The spatial resolution of fNIRS (3 cm in this study) was higher than that of EEG[8,9]. Because EEG recording is a surface potential change of skull, the accuracy of spatial localization is not high. fNIRS probe acquires the cortical activity directly and has a centimeter level of resolution[10]. fNIRS is used to monitor hemodynamic changes evoked by neural activity by taking advantage of the fact that biological tissues are relatively transparent to near-infrared light 700-1000 nm[11]. Recent studies on fNIRS detection of dementia focused on MCI and Alzheimer's disease (AD)[12,13]. It was shown that resting-state fNIRS recordings from prefrontal regions can provide a potential methodology for detecting MCI and its progression[14]. The sensitivity and specificity increase as the cognitive impairment worsens[15].

Amnestic MCI is more predictive of AD than nonamnestic MCI, and nonamnestic MCI is more predictive of other types of dementia including Lewy bodies dementia (LBD) and frontotemporal dementia (FTD)[16,17]. To measure cortical activation in patients with behavioral variant of the FTD (bvFTD), fNIRS was used while performing the verbal fluency task[18]. The flexible of fNIRS makes the possibility of measurement of the neurology of gait in cognitive dysfunction or dementia during dual-task gait assessment[19]. Similar studies focused on old people with risk of dementia, such as those with subjective memory complaints, were reported to be examined by fNIRS indual-task gait[20].

The use of optical techniques, specifically fNIRS, to study brain hemodynamics and to assess prefrontal cortex's activity of older adults for detection of certain types of seizures and cortical spreading deactivation in cognitive tasks is also important. fNIRS can be useful to investigate the altered prefrontal mechanisms of neurological and neuropsychiatric diseases and discover neuroimaging biomarkers for different neurodegenerative disorders[21-24]. The reliability of fNIRS in estimating global cerebral function was supported by previous studies[25]. fNIRS measurements are reproducible and can be reliable used in single subjects for neuroscientific research and clinical applications[26]. It could be a critical tool to investigate frontal lobe oxygenation in patients with different types of dementia and age-related decline of neurovascular coupling responses[27,29].

In this study, using fNIRS, we examined brain functional patterns in patients with four types of dementia: FTD, LBD, Parkinson's disease dementia (PDD), and AD. Because of neurovascular coupling, different types of dementia may cause different hemodynamic alterations. Here, we report four subjects in which fNIRS was used to examine the brain function of patients with dementia (during two tasks and a resting state).

MATERIALS AND METHODS

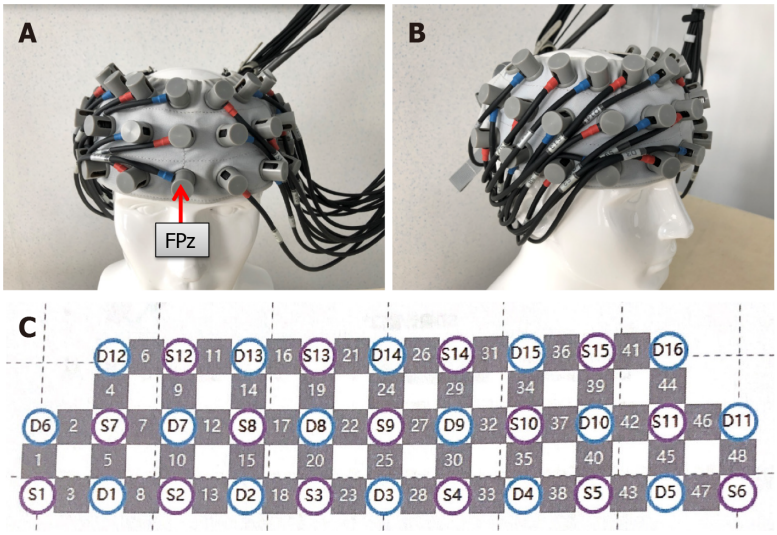
fNIRS data acquisition

Patients with FTD, LBD, PDD, and AD signed an informed consent form and underwent routine fNIRS examinations at a brain function testing center in the hospital. A multi-channel continuous-wave fNIRS imaging system (Nirscan, Danyang Huichuang Medical Equipment Co. Ltd, China) was employed to measure signals from the frontal and bilateral temporal cortices as described in our previous study[8]. This light-emitting diode-based fNIRS system contained 24 light sources and 24 detectors. The distance between detectors was 3 cm, as shown in Figure 1. The center detector of the middle probe set row was placed at FPz, according to the 10/20 international system. The sampling rate was 11 Hz and the wavelengths used were 780, 808, and 850 nm.

Verbal fluency task

The verbal fluency task consisted of three steps: (1) Participants repeatedly counted from 1 to 5 for 30 s to obtain the baseline value of cognitive performance; (2) during the task period, participants were instructed to generate as many words as possible, they continuously named different words beginning with a specific letters for 20 s (trials for three letters totaled 60 s); and (3) participants repeated step 1 for 70 s to return to baseline. The task took less than three minutes total. Other matters needing attention were described in previous studies on verbal fluency task of fNIRS[30-33].

Memory task



The memory task contained two components on a tablet computer: A working memory search task and a non-working memory search task. In the working memory search task, three graphic icons appeared. Participants were instructed to remember the colors, shapes, and order in which they appeared; subsequently, they were asked to identify the icons in the summary diagram. In the non-working memory search task, participants only needed to select the icons when prompted. The two sets of tasks were alternated and repeated four times. Working memory performance was used to reflect the cognitive function in many studies[34-36].

Resting state

The resting-state signal was recorded continuously for at least 10 min, during which participants were required to sit still and close their eyes without falling asleep. Functional connectivity was calculated on a scale from 0 to 1, where 0.3 represents an average level of functional connection strength (Supplementary Figure 1).

fNIRS experiment

The participants were guided to the experimental room, and seated on a wooden stool with a wooden table. During the experimental preparation phase, the participants were asked to wear an electrode cap. The experimenter repeatedly adjusted the electrode cap to maximize the signal channel gain. When the experiments begin, participants performed the task by listening to the instruction (verbal fluency task) or using an ipad (working memory task), as our previous work[8].

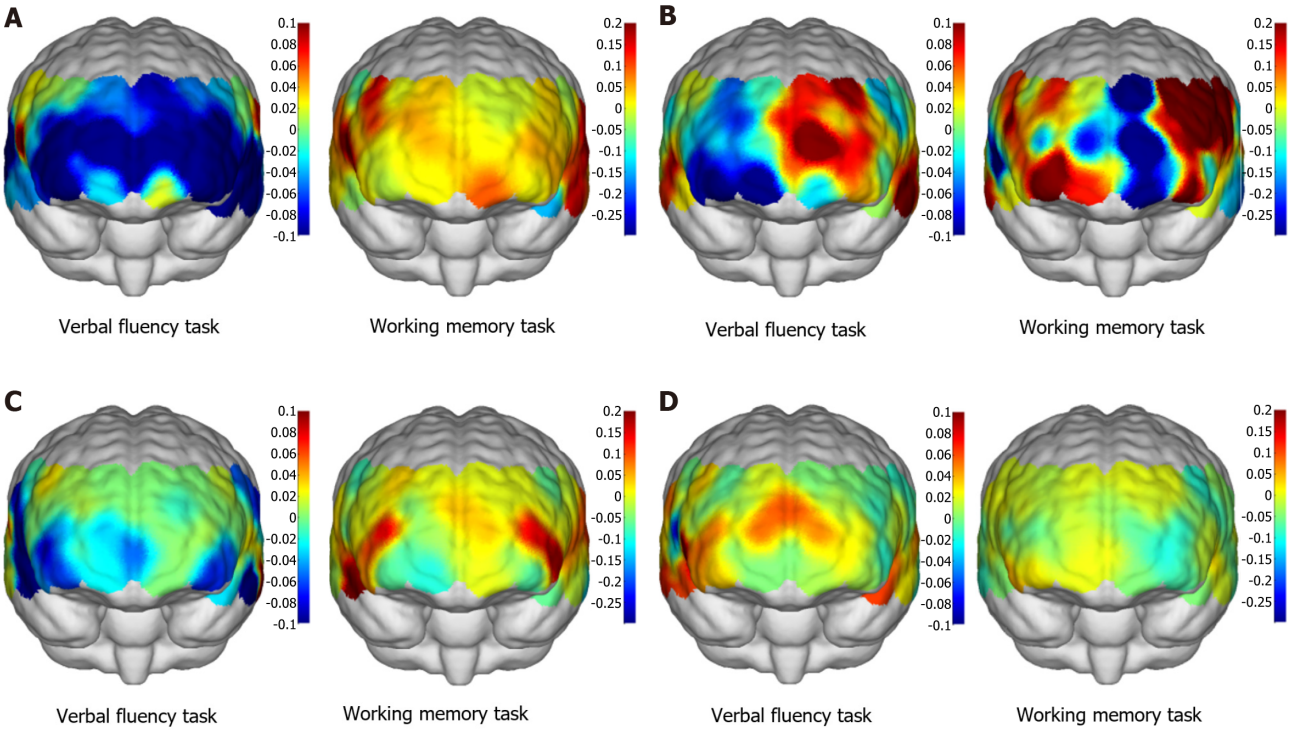
Figure 1 Diagrammatic sketch of localization of the functional near-infrared spectroscopy probe set over left and right frontotemporal cortex. A: Anterior view; B: Lateral view; C: Probe arrangement. Blue circle: Detectors; Purple circle: Light source.

Data analysis

The NirSpark software package (Danyang Huichuang Medical Equipment Co. Ltd, China) was used to analyze the fNIRS data, as previously described[37-39]. Physiological noises (including respiration, cardiac activity, and low-frequency signal drift) were corrected by a band-pass filter with cutoff frequencies of 0.01-0.20 Hz. The cubic spline interpolation method was adopted to eliminate motion artifacts. The modified Beer-Labert law was used to convert the optical density into changes in oxy-Hb and deoxy-Hb concentrations. A general linear model was used to calculate brain activation strength. Functional connectivity was calculated by conducting Pearson's correlation analysis between the time series of every pair of measurement channels.



RESULTS

Subject 1 FTD

Clinical manifestation: A 57-year-old man was diagnosed with FTD. Two years prior, the patient began to show impaired judgment without warning and was defrauded of 700000 yuan. He reported insomnia, anxiety, and depression. His mental state continued to deteriorate, and he was initially diagnosed with "recurrent depressive disorder". He also exhibited memory problems such as being unable to recall whether he had eaten or not, and he was often unable to complete tasks assigned to him by his family. For the past 2 years, the patient had been treated with systematic antidepressants (such as sertraline, doxetine, mirtazapine) and modified electroconvulsive therapy. His depression partially eased, but his memory problems persisted. One month previously, the patient again showed nervousness and fidgeting. The patient also experienced hallucinations, slow walking, and involuntary limb shaking. He had been admitted to the neurology department, who had ruled out Parkinson's disease before he was admitted to our department for further treatment.

Examinations: The patient's psychiatric examination at admission showed clear consciousness, accurate orientation, lack of cooperation, less autonomous language, decreased language expression ability, poor vocabulary, stereotypes and imitation speech, stable mood, no obvious manifestations of emotional depression, and partial decline in memory intelligence. Physical examination revealed that the patient's right lower limb twitches could be relieved after massage. A brain MRI showed cystic foci in the left medial temporal lobe and senile brain changes. His Mini-Mental State Examination (MMSE) score was 22/30. Considering to his education level of high school, the severity of dementia was moderate. The patient was diagnosed as FTD accompanied by mild depression.

fNIRS results: In Figure 2A, fNIRS showed global lower activation in frontotemporal lobe when the patient performed the verbal fluency task. This was consisted with his clinical manifestation of poor verbal function. During the working memory task, the patient's prefrontal lobe activation was lower than that of the temporal lobe, and the frontal lobe activation was also low. Frontalpolar and temporopolar area showed most activation than other regions. The overall pattern was different from other three subtypes of dementia. During a resting state, the average strength functional connection of

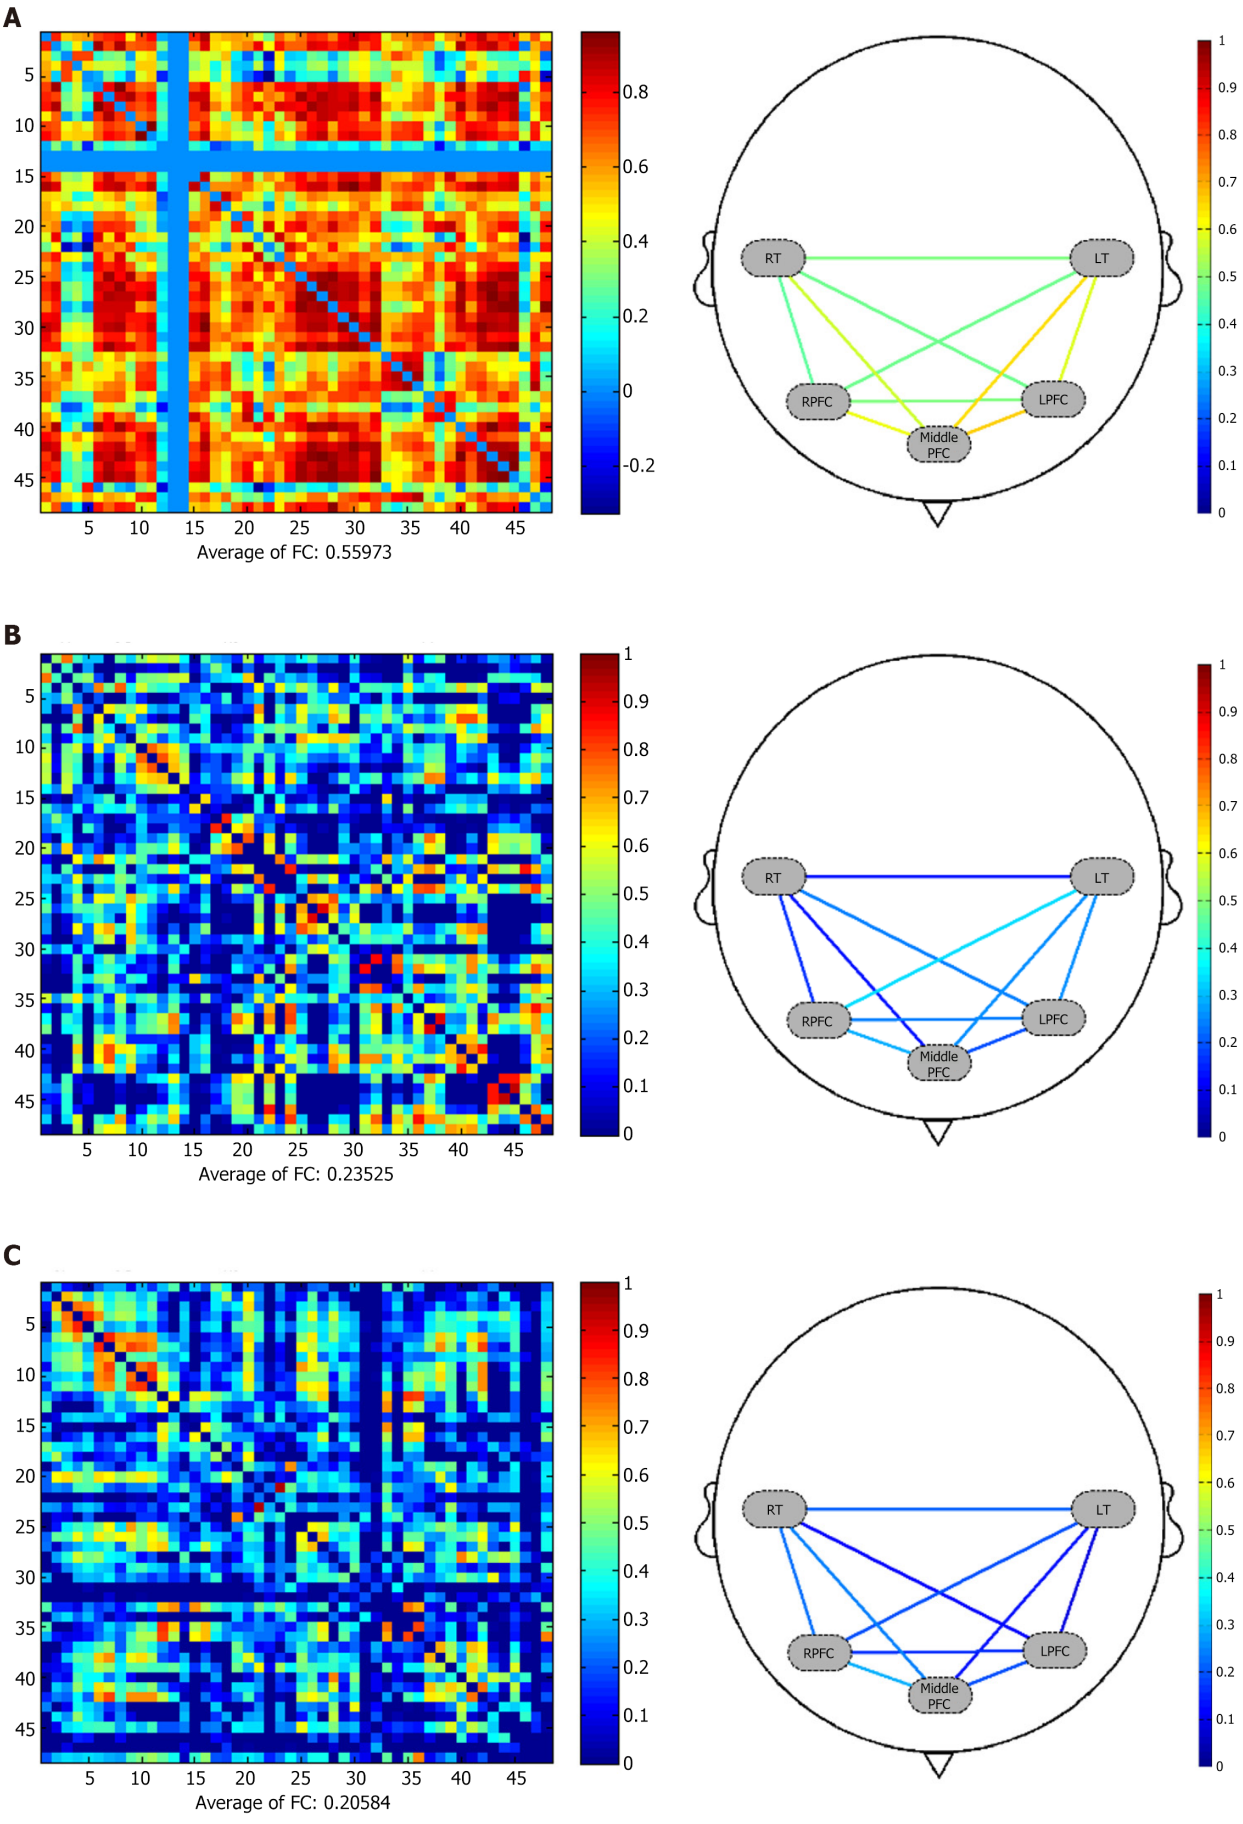
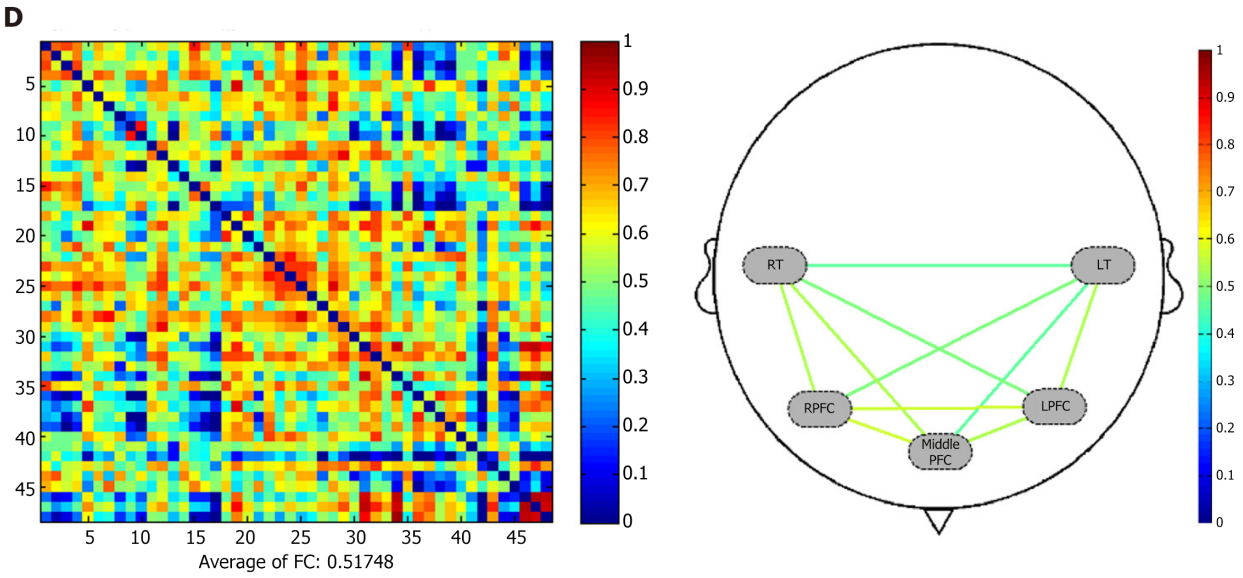
Figure 2 Comparison of functional near-infrared spectroscopy patterns and task performances during the verbal fluency task (left) and the working memory task (right) between four types of dementia patients. A: Frontotemporal lobe dementia; B: Lewy body dementia; C: Parkinson's disease dementia; D; Alzheimer's disease. Red indicates higher activation, while blue indicates lower activation.

all channels was considered high at 0.559 as shown in Figure 3A.

Subject 2 LBD



Clinical manifestation: A 74-year-old man was diagnosed with LBD. He had been experiencing progressive memory loss for three years, as well as symptoms such as hand shaking and bradykinesia; the neurology department considered him to have Parkinson's disease. Over three years, the patient's memory waxed and waned, while symptoms such as slow walking persisted. The patient occasionally experienced hallucinations such as seeing vivid images of dead people. In the last six months, his memory problem had significantly worsened; sometimes, he could not recall a family member's name. His speech was not very fluent, and he had difficulty communicating with others. His sleep was poor. His ability to perform daily living had significantly declined and he needed someone to take care of him.



Examinations: The patient was admitted to our hospital for further treatment, and his psychiatric examination at admission showed clear consciousness, loss of sense of smell, unsteady gait, varying degrees of limb tremor, and increased muscle tone. He had slow thinking, aphasia, impaired memory, impaired common sense, reduced calculation ability, and visual hallucinations. A brain MRI showed localized atrophy in the temporal, frontal and parietal lobes. His MMSE score was 6/30. The degree of dementia was severe. The patient was diagnosed as primary neurodegenerative disease LBD.

fNIRS results: The fNIRS showed severe asymmetry in both hemispheres during both the verbal fluency and working memory tasks, particularly that the left frontal lobe showed more activation than the right lobe as shown in Figure 2B. In Figure 3B, the patient had low functional connection strength of 0.235 during a resting state.

Subject 3 PDD

Clinical manifestation: A 79-year-old man was diagnosed with PDD. Two years prior, the patient began to develop symptoms such as hand tremor and slow gait, and was subsequently diagnosed with "Parkinson's disease" by the neurology department. He was given symptomatic treatment of dopamine (0.0625 g tid) and pramipexole (0.25 mg bid) in oral form since then, and symptoms such as hand tremors and slow gait improved. About six months ago, his family reported development of memory problems. The patient forgot things immediately after being told, and forgot where he put things. His ability to perform daily tasks slowly declined, sometimes requiring family members to help him dress.

Figure 3 Resting state functional connections were calculated by conducting Pearson's correlation analysis between the time series of every pair of measurement channels. A: Frontotemporal lobe dementia; B: Lewy body dementia; C: Parkinson's disease dementia; D: Alzheimer's disease. Red indicates higher activation, while blue indicates lower activation.

Two months prior, the patient's mental state worsened due to sleep disorders and frequent nightmares. On occasion, he wakes in the middle of the night and begin to choke his wife. The patient was admitted for further treatment, and reported a family history of AD (in his sister).

Examinations: Upon mental examination, the patient's consciousness was clear. His recent memory decline was evidenced by his report of no memory of events after he went to bed. He gave simple answers to questions and demonstrated limited vocabulary and emotional instability, particularly irritability. His risk-taking behavior had increased, particularly in dangerous movements that may lead to falls or rejecting advice from others. CT showed multiple ischemic foci in both the frontal and parietal lobes and periventricular white matter. His MMSE score was 13/30. The degree of dementia was severe. The patient was diagnosed as typical PDD accompanied by sleep disorders.

fNIRS results: fNIRS showed that the patient's prefrontal cortex had lower excitability than the temporal lobe during the verbal fluency task, while the patient's prefrontal cortex had higher excitability during the working memory task. As shown in Figure 2C, the dorsolateral prefrontal cortex (DLPFC) was activated strongly (symmetrical pattern; in red color region) during the working memory task. During a resting state in Figure 3C, the average strength functional connection of all channels was 0.206, lower than the normal level.

Subject 4 AD

Clinical manifestation: A 73-year-old woman was diagnosed with dementia secondary to AD. About one year prior, the patient began to experience short-term memory loss, such as forgetting what she had said and done and failing to find the objects she had just placed. The ability to perform daily tasks declined slowly, requiring partial assistance from family members. The patient had a history of recurrent depressive disorder for approximately 10 years and long-term antidepressant treatment was moderately effective.

Examinations: The mental examination on admission found memory decline, computing power decline, orientation impairment, comprehension and expression ability decline, language vocabulary reduction, and emotional stability. A brain MRI showed reduced hippocampal volume and internal olfactory cortex volume bilaterally (MTA-score > 2). Her MMSE score was 14/30. The degree of dementia was moderate to severe due to her education level of 1 year. The patient was diagnosed as typical AD accompanied with mild depression.

fNIRS results: fNIRS revealed poor prefrontal and temporal activation during the working memory task (Figure 2D). The patient had high functional connection strength of 0.518 during a resting state (Figure 3D). The contrast of the two demented subjects (PDD *vs* AD) was characterized by a nearly symmetrical pattern in both task contrasts: prefrontal lobe was more activated in verbal fluency task in the AD than in PDD, while the frontotemporal lobe was more activated in working memory task in the PDD than in AD (Figure 2C and D). Regarding to the working memory task, the activation of brain in

AD was the weakest of four dementias.

DISCUSSION

The results of this study indicate that cortical activation measured with fNIRS while performing a verbal fluency and working memory task differs in patients suffering from four types of neurodegenerative dementia including FTD, LBD, PDD, and AD. Furthermore, this activation differs between the four types of neurodegenerative dementia, a result shown for the first time using fNIRS in antidiastole of dementia subtypes.

Patients with FTD show low function or atrophy of the frontotemporal lobe that may be accompanied by low levels of oxy-Hb low function of the frontotemporal lobe[40]. Although patients with FTD and those with psychiatric disorders behave similarly, differences can exist in hypoperfusion and hypometabolism of the frontotemporal lobe regions[41]. A reduction in cortical activation during verbal fluency task performance in FTD patient compared to other three dementias has been shown in this study. FTD disorders include behavioral variant FTD (bvFTD), nonfluent/agrammatic variant primary progressive aphasia (nfvPPA), and semantic variant PPA (svPPA)[42]. PPA patients showed differential linguistic features of verbal fluency from bvFTD[43]. In this FTD case, the patient showed the poor verbal function. The fNIRS pattern showed low activation during the verbal fluency task. He had been treated with antidepressants. Currently, antidepressants are routinely used in the treatment of dementia to supplement serotonin availability[44]. There was no effect on vasculature at the relevant therapeutic dose for this patient, so it is unlikely that this affected blood flow in this patient. Furthermore, depressive pseudo dementia can also manifest as cognitive decline, but the brain functions, as well as neurovascular coupling, are not as poor in these patients compared to patients with dementia[45]. Thus, fNIRS can distinguish between depressive pseudo-dementia and dementia.

The AD pattern is weaker and more similar to the healthy pattern, whereas the bvFTD pattern is qualitatively different, namely more frontopolar and without frontoparietal compensation activation [18]. Our results showed the AD patient have lower and slower activation in the bilateral PFC and left parietal cortex during working memory maintenance. This was consisted with previous study on moderate to severe AD[2]. aMCI patients, as early stage AD, were reported a larger reduction in frontal deoxy-Hb during the memory task[46].

Regarding to the functional connection reflected by fNIRS, connections between different brain regions, as well as synergies between them, work together to provide comprehensive cognitive functions. As shown in Figure 3, the total scores of MMSE of patient with PDD and AD were similar in our study, but the functional connection strength is much different. The MMSE scale included six cognitive domains of orientation, immediately recall, attention, delayed recall, language and executive, and visual function[47]. Although the total MMSE scores of PDD and AD patients are close, they have different sub-scores in different cognitive domains, which reflect different brain area functions. In this aspect, the functional connectivity reflected by fNIRS can distinguish these differences, and enhanced the diagnostic accuracy as an auxiliary method.

The blood supply to the brain can reflect local changes in functional activity. In dementia patients, brain activity demonstrates a gradual increase in oxygenated hemoglobin and decrease in deoxygenated hemoglobin[48]. The working mode is believed to require networks across the entire brain; that is, no complex function is performed by a single brain area[6]. Imaging of the resting-state networks can also reveal information, such as the correlations between neural activities and the efficiency of transmission [49]. This is especially significant for patients with a low degree of cooperation[50]. Regarding to prefrontal cortex, primarily DLPFC, activation has a positive correlation with working memory load and performance until the working memory load exceeds the capacity[51].

fNIRS technology is widely used in the detection of neuropsychiatric disorders and brain functions individuals abusing different types of drugs[52-54]. Changes to oxy-Hb concentration of the bilateral prefrontal cortex in a schizophrenia group were reported to be significantly lower than those in a healthy group[55]. fNIRS has also been used to accurately distinguish patients with major depression from those with bipolar disorder or schizophrenia who have depressive symptoms[56]. When fNIRS technology was utilized to explore functional connectivity and network changes in patients with attention-deficit/hyperactivity disorder (ADHD), the development pattern of brain networks in children with ADHD was different from that of healthy children[57]. fNIRS also has applications in the field of sleep research to study brain activation during dreaming[49,57].

Limitations and future directions: one limitation is that a single patient for each group may introduce individual differences, including sex, age, and education. A larger sample size would help to eliminate the impact of such individual differences. Our results show that further study is needed to examine the diagnostic utility of fNIRS in dementia. Although our fNIRS recording technique was a multichannel flexible tool to detect the brain function in patients with different type of dementia, it focused on the frontal and temporal lobe of the brain, not the global brain region. This can be improved by using whole brain detection of fNIRS in the future.

CONCLUSION

Although subtypes of dementia may have similar clinical symptoms, they have different objective indicators; some that are observable during a resting state and some that are observable during the task state. Since fNIRS can detect changes in both states, it may be a useful tool for differential diagnosis. This study visualized four different types of dementia (FTD, LBD, PDD, and AD) using fNIRS, and found differences of brain activation during the task condition and functional connectivity during the resting state for all four types. The patient with FTD showed the lowest activation during the verbal fluency task and the patient with AD showed the lowest activation during the working memory task. During the resting state, functional connectivity was poor in the patients with LBD and PDD. These differences could be used as biomarkers to distinguish the different subtypes of dementia. In the future, as a non-invasive tool, multichannel fNIRS technology can provide high spatial and temporal resolution signals to continuously assess regional cerebral oxygenation. The sensitivity of fNIRS increased its use as a wide-spread clinical tool for the robust assessment of brain function.

ARTICLE HIGHLIGHTS

Research background

In addition to functional magnetic resonance imaging, electroencephalography, and event-related potentials, functional near-infrared spectroscopy (fNIRS) to examine functional connectivity between regions has become an important supplement to existing functional imaging technologies.

Research motivation

fNIRS technology will be widely used in the detection of neuropsychiatric disorders.

Research objectives

fNIRS could be a potential tool for the diagnosis between dementia subtypes.

Research methods

We tested four types of dementia by using fNIRS in the verbal fluency task, working memory task and resting state task.

Research results

fNIRS examinations were adopted to test the fNIRS paramters. The results shown that different types of dementia have different fNIRS patterns.

Research conclusions

fNIRS can be used as a potential method to diagnose dementia and cognitive decline.

Research perspectives

We want to study whether the fNIRS can be a potential tool for the diagnosis between dementia subtypes.

Abstract

BACKGROUND

In China, the identification rate and treatment rate of mental disorders are low, and there are few surveys on the prevalence of mental disorders among college students using diagnostic tools such as Mini-International Neuropsychiatric Interview (MINI), so the prevalence and treatment of mental disorders among college students are unclear.

AIM

To estimate prevalence of mental disorders among medical students in Hebei

Province, and provide guidance for improving their mental health.

METHODS

This was a cross-sectional study based on an Internet-based survey. Three levels of medical students in Hebei Province were randomly selected (by cluster sampling) for screening. Using the information network assessment system, the subjects scanned the 2D code with their mobile phones, clicked to sign the informed consent, and answered a scale. A self-designed general status questionnaire was used to collect information about age, gender, ethnicity, grade, and origin of students. The MINI 5.0. was used to investigate mental disorders. Data analysis was performed with SPSS software. Statistically significant findings were determined using a two-tailed *P* value of 0.05.

RESULTS

A total of 7117 subjects completed the survey between October 11 and November 7, 2021. The estimated prevalence of any mental disorders within 12 mo was 7.4%. Mood disorders were the most common category (4.3%), followed by anxiety disorders (3.9%); 15.0% had been to psychological counseling, while only 5.7% had been to a psychiatric consultation, and only 10% had received drug therapy in the past 12 mo.

CONCLUSION

Although the estimated prevalence of mental disorders in medical students is lower than in the general population, the rate of adequate treatment is low. We determined that improving the mental health of medical students is an urgent matter.

Key Words: Medical students; Estimated prevalence survey; Mental disorders; Mood disorders; Treatment rate

Core Tip: College students' mental health is important to national mental health. In most previous studies of medical students, there have been few investigations using Mini-International Neuropsychiatric Interview (MINI) as a diagnostic tool to assess the prevalence of mental disorders. In this study, MINI 5.0 was used to investigate the prevalence of mental disorders among medical students in Hebei province, representing the largest series of mental disorders among medical students in China ever reported. Based on these data, the prevalence and treatment of mental disorders among medical students in Hebei were introduced.

INTRODUCTION

From a sociological perspective, college students have a variety of social roles: they continue to seek knowledge, while developing social and interpersonal skills, and face more complex roles in society, personal relationships, and employment. With a growing number of college students in China, there is an increasing pressure in terms of learning, interpersonal relationships, and career decisions. Psychological health of college students has gradually become a focus of attention. In 2021, the General Office of the Ministry of Education issued a "Notice to Strengthen the Management of Students' Mental Health," which required the construction of a psychological counseling service platform. That year, the report "Exploring the Characteristic Service Plan for Prevention and Treatment of Depression" was issued by the General Office of the National Health Commission of China. This requires that depression screening should be included in students' physical examination.

Compared to the general population, college students have the ability to assess their own mental health, and most will turn to the psychological counseling center at their school when they suspect that they have psychological problems[1]. The prevalence of depression and anxiety among college students

has increased compared with before the coronavirus disease 2019 (COVID-19) pandemic. According to a survey by Hong Kong researchers, the fraction of students with moderate to higher levels of depression was significant (40.0%), including general anxiety (50.7%)[2]. Kavvadas *et al*[3] found that depression and anxiety in college students increased in the past 2 years. Hossain *et al*[4] conducted a 15-mo longitudinal study of 1140 college students. They found that, with time, there was a 22.5% and 27.1% increase in depression and anxiety, respectively. Mental disorders have increased each year, suggesting the importance of regular assessment of mental health issues.

Despite many studies on students' mental health, most had shortcomings, such as small sample size or lack of complete and structured diagnostic interviews. Huang *et al*[5] conducted a nationwide survey on the prevalence of mental disorders, without inclusion of college students. There has been no large sample study on the mental health of medical students in Hebei Province. This study screened the prevalence of mental disorders among medical students and analyzed the psychosocial risk factors. This will provide some direction for college student mental health services in the future.

MATERIALS AND METHODS

Study design and sampling

This was a cross-sectional study based on the Internet. We screened medical undergraduates at a university in Hebei Province from October to November 2021, which was a relatively stable period for the COVID-19 pandemic in Shijiazhuang, and randomly selected three levels of students by cluster sampling. Freshmen (grade 1), sophomores (grade 2), and juniors (grade 3) were concentrated at school, and we selected two of the above three grades for random evaluation. Most students in the senior and fifth grades had completed internships and were scattered among several hospitals, and their grades were randomly selected for evaluation.

Assessment tools

The screening tool for this study was an information network evaluation system developed by Saitron Information Co. Ltd. (Cangzhou, Hebei, China). Subjects scanned the QR code and clicked to sign the informed consent. For screening information so stay confidential, subjects logged into the system with a virtual student number and their initials. A one-to-one correspondence between the virtual student number and the actual student number was kept by the instructor. Subjects could check screening results on their mobile phones, and physicians interpreted screening results on site. This allowed subjects to know their mental health status at any time.

A self-designed status questionnaire was used to collect the subjects' basic information: age, gender, nationality, grade, and region were included. The Mini-International Neuropsychiatric Interview (MINI) was translated into Chinese by Sheehan *et al*[6]. MINI is a structured interview that assesses 16 categories of mental disorders. Research shows that it has good reliability, validity, and high consistency among different studies. The version used in this study was MINI 5.0.

Quality control

The screening staff comprised physicians and medical students from the Mental Health Center of Hebei Medical University. Before participating in the survey, screening personnel were trained with standardized guidelines, developed to ensure consistency of survey results. Some students were randomly selected for pretesting before formal screening. We summarized and revised ambiguities, using PowerPoint to explain subjects' biases, and to reduce biased screening.

Statistical analysis

Quantitative data were expressed as mean ± SD, and qualitative data were described by numbers and percentages. Comparison between groups with theoretical frequency $T \geq 5$ was tested by Pearson's χ^2 test; comparison between groups with theoretical frequency < 5 but ≥ 1 was tested by continuity correction χ^2 test; and comparison between groups with theoretical frequency < 1 was tested by Fisher's exact test. All data were analyzed using SPSS version 26.0 (SPSS, Chicago, IL, United States). The statistical significance of our findings was assessed with a two-tailed P value of 0.05.

Ethical approval

This study was approved by the Ethics Committee of the First Hospital of Hebei Medical University (approval No: 20210354).

RESULTS

A total of 7555 undergraduates from three grades were selected for MINI assessment; 218 refused to participate in the screening and 7337 were screened. A total of 163 students with incomplete data and 57

with inaccurate data caused by careless attitudes in answering questions were excluded. Finally, 7117 students were included in the statistical analysis. The average age was 19.9 ± 2.06 years, with 36.7% males and 63.3% females. There were 3471 sophomores, 2974 juniors and 672 seniors (Table 1).

Among medical students in Hebei Province, 7.4% suffered from at least one mental disorder in the past 12 mo, 15.0% had psychological counseling, 5.7% went to a psychiatric hospital, and only 10% received drug treatment. Mood disorders were the most common category, followed by anxiety disorders. Lifetime estimated prevalence of each subcategory of mood disorders ranged from 0.5% to 4.9%, with the 12-mo estimated prevalence ranging from 0.2% to 3.5%. Major depressive disorder (MDD) was the most prevalent mood disorder (lifetime estimated prevalence 4.9% with 12-mo estimated prevalence of 3.5%), followed by bipolar disorder (0.5% and 0.4%) and dysthymia (12-mo estimated prevalence of 0.2%). Obsessive–compulsive disorder (OCD) was the most common anxiety disorder (12-mo estimated prevalence of 2.1%), followed by generalized anxiety disorder (1.7%) and social phobia (1.4%). The estimated prevalence of other anxiety disorders was < 1%, with the lowest estimated prevalence being agoraphobia without panic disorder (0.1%). The 12-mo estimated prevalence of substance disorders ranged from < 0.1% to 0.4%, with alcohol abuse the most prevalent (0.4%) and substance abuse the lowest (< 0.1%). The estimated prevalence of any alcohol disorder was higher than that of any drug disorders (0.6% *vs* < 0.1%). Lifetime estimated prevalence of any type of schizophrenia was 0.2% and 30-d estimated prevalence was 0.1%. The 12-mo estimated prevalence of any eating disorder or antisocial personality disorder was < 0.1 (Table 2).

Among mood disorders, the estimated prevalence of MDD was 4.3% in males, and was higher than 3.1% in females. The estimated prevalence of bipolar disorder was 0.6% in males and 0.2% in females, with a significant difference. Among anxiety disorders, the estimated prevalence of OCD was 2.8% in males and 1.6% in females. For individual substance disorders, the estimated prevalence of alcohol abuse and dependence was higher in males than in females (0.5% *vs* 0.1% for alcohol dependence, 0.7% *vs* 0.2% for alcohol abuse). There was no significant gender difference for other diseases, except MDD (Table 3).

The estimated prevalence of MDD was 3.8% in sophomores, 2.9% in juniors, and 4.9% in seniors. There were significant differences between junior and senior college students. There was no significant difference in the estimated prevalence of some diseases among medical students from different areas of origin. Regarding the experiences of left-behind children, results showed that the estimated prevalence of individual substance disorders had different etiologies. The estimated prevalence of alcohol dependence in left-behind children was higher than in children without being left-behind (1.0% *vs* 0.2%). There were also significant differences in drug dependence and eating disorders, but the estimated prevalence of these diseases was < 0.1%.

For treatment, the rate of medical students who were in psychological counseling varied between 14.4% and 36.4%, whereas 36.4% of students with dysthymia had counseling, and 35.3% of medical students with psychotic symptoms had counseling. Moreover, 25% of patients with agoraphobia without history of panic disorder, 20% with panic disorder, 18.4% with compulsive disorders, and 16.4% with MDD had counseling. The proportion of students who visited a psychiatric hospital varied between 3.9% and 33.3%; of which 23.5% were for psychotic disorders, 20.0% for post-traumatic stress disorder (PTSD), 18.2% for MDD, 13.2% for bipolar disorder, and 8.8% for OCD. The rate of treatment in 12 mo varied between 9.1% and 33.3%, with 26.7% for PTSD, 33.3% for substance dependence, 15.8% for bipolar disorder, and 9.6% for MDD (Table 4).

DISCUSSION

The rapid development of the Chinese economy, along with a change in the learning and employment environment, may have caused an increase in pressure on college students. Medical students are a special group – as compared to college students, as they have more academic pressure, take a longer time to obtain a degree, and have less diversity, which can lead to pressure and increased mental disease. As such, it is critical to investigate such disorders among medical students.

It was also found that 7.4% of medical students in Hebei had suffered from one mental disorder over the past 12 mo, but only a few sought help with a healthcare professional, and fewer received adequate medication within 12 mo – contrary to previous results. The World Health Organization-World Mental Health International Undergraduate Program conducted an Internet-based self-assessment questionnaire among freshmen at 19 universities in eight countries. It included screening for the 12-mo prevalence of six common Diagnostic and Statistical Manual of Mental Disorders-IV psychiatric disorders (MDD, mania/hypomania, generalized anxiety disorder, panic disorder, alcohol use disorder, and substance use disorder). It was shown that 31% of students had at least one of these disorders within 12 mo, with 16.4% receiving psychiatric treatment[7]. Compared to this study, Winkler *et al*[8] found that the 12-mo prevalence was higher, possibly related to the survey population, the survey time, or the assessment tools. Previous studies found that depression and other diseases were more common in freshmen than for those in other grades. This study did not include freshmen, so prevalence could more easily be reduced[9].

Unlike the findings of many western scholars, the estimated prevalence of drug abuse and eating disorders in this study was low[10,11]. This may have something to do with the differences between Chinese and western cultures. In terms of drug abuse, China has strict supervision on addictive drugs, so students have less exposure to addictive drugs. Moreover, medical students have some understanding of pharmacology and are more aware of the harm of drug abuse[12-14]. In terms of eating disorders, most medical students focus on finishing school and pay less attention to habitus index, so fewer of them lose weight through excessive dieting, which may explain the lower incidence of anorexia[15]. Medical students understand nutritional metabolism and the importance of regular diet, which may also explain the low prevalence of eating disorders[16].

The proportion of students seeking treatment was lower in this study compared to others. It mirrors national conditions in China: patients tend to have an insufficient appreciation of diseases associated with stigma, resulting in lower diagnosis and treatment rates[17,18]. In the future, it will be necessary to increase publicity about mental diseases and increase their understanding, so that individuals can objectively evaluate diagnosis and treatment rate. In previous studies, the 12-mo rate in the Chinese population was 9.3%, which was higher than in this study. This may be because the population was aged 18-24 years and did not include any other age groups. In addition, Yueqin *et al*[5] found that those aged 50-64 years had the highest prevalence of mental health problems. However, medical subjects with psychiatric symptoms, substance abuse, and other diseases that affect social function was consistently lower than for social personnel, with an overall prevalence slightly lower as well.

It is well-known that increasing targeted treatment for mental disorders (*e.g.*, anxiety disorders, affective disorders, and alcohol and drug abuse) is a recognized issue in academic circles. In this study, 58 (16.4%) of the 354 patients with depression had psychological counseling, 17 (4.8%) visited psychiatric hospitals, and 34 (9.6%) received adequate medication. Lu *et al*[19] examined the prevalence and treatment of depression in China in 2021 and found that of 1007 participants with a 12-mo history of depression, only 84 (weighted 9.5%) had received treatment at any facility: 38 (3.6%) were in specialized mental health groups, 20 (1.5%) in general medicine, two (0.3%) in public services, and 21 (2.7%) in complementary/alternative medicine. Only 12 (0.5%) of 1007 patients with depression received adequate treatment. In the medical student population, treatment was higher than in the general population. This may be attributed to how the school attends to students' mental health, with sufficient awareness of the disease. Premedical students better understand depression and take the initiative for both diagnosis and treatment. Yet, compared to other physical diseases, these measures are still low.

The 12-mo estimated rate of depression, OCD, and other mental diseases was higher in males than females, similar to the research of Li *et al*[20]. This could be a function of adolescent males being more likely to show symptoms of the MINI diagnosis, such that prevalence would gradually decrease with age. While comparing different grades, we found the detection rate of depression in seniors to be higher than in juniors, confirming results of previous research. It may be that the pressure of graduation, plus postgraduate entrance examinations, in tandem with COVID-19, may have led to increased depression

Table 2 Lifetime and 12-mo prevalence of mental disorders in medical students (*n* = 7117)

	Lifetime prevalence		12-mo prevalence	
	Frequency	Prevalence, % (95%CI)	Frequency	Prevalence, % (95%CI)
Mood disorders				
Any mood disorders	95	1.3 (1.08-1.63)	307	4.3 (3.86-4.81)

Personality disorder				
Antisocial personality disorder	2	< 0.1 (0.01-0.12)		

in the population and in undergraduate students as well[21].

We found that the estimated prevalence of alcohol dependence and abuse was higher in males than in females. This is consistent with previous research. It may be that males make friends more quickly when drinking at parties, and drinking with a greater preference for alcohol[22-24]. We also found that the estimated prevalence of alcohol dependence among those who were left-behind was higher than among people who did not have that experience. Left-behind children deal with emotional neglect and are more likely to engage in behaviors such as smoking and drinking, and then develop alcohol dependence [25].

The 12-mo estimated prevalence of mental disorders, according to MINI (7.4%), is low, considering that the recognition and acceptance of mental disorders among medical students is higher than among other undergraduates. College students are the future of any nation, with a responsibility to promote social development, so that more attention is given to mental health; this also coincides with implementing effective intervention measures.

Table 3 12-mo prevalence of mental disorders by gender in medical students (*n* = 7117)

	Male		Female		*P* value
	Frequency	Prevalence, % (95%CI)	Frequency	Prevalence, % (95%CI)

[a]$P < 0.05$ (male *vs* female).
[b]$P < 0.01$ (male *vs* female).

Our study had some limitations. First, subjects were medical students, excluding other college students, and there was also some selection bias in overall estimation of college students. Second, this study was cross-sectional, so that there may have been recall bias that affected the lifetime prevalence of mental disorders.

CONCLUSION

Our study provided supplemental data on mental health disorders in the medical students, not investigated by Huang *et al*[5]. College students' mental health is important to national mental health. The purpose of this study was to establish mental health records for students, and psychiatrists were involved in the whole screening process. Our mental health department has opened a convenient channel for students diagnosed with mental diseases by MINI 5.0. Students can voluntarily go to the hospital for treatment, and psychiatrists will give more comprehensive examination and evaluation at any time. We will thus expand our research in exploring the prevalence of mental disorders in other college students, followed by more information on mental health care for Chinese students in general.

ARTICLE HIGHLIGHTS

Research background

In China, the identification rate and treatment rate of mental disorders are low, and there are few surveys on the prevalence of mental disorders among college students using diagnostic tools such as Mini-International Neuropsychiatric Interview (MINI), so the prevalence and treatment of mental disorders among college students are unclear.

Research motivation

To clarify the prevalence and treatment of mental disorders in college students, and to provide protection for their mental health.

Research objectives

This study firstly conducted diagnostic assessment for medical students to understand the estimated prevalence and treatment of medical students, so as to provide protection for the mental health of medical students.

Research methods

MINI 5.0 was used in this study to evaluate medical students in Hebei and collect their treatment information, which can provide a more accurate understanding of the prevalence and treatment rate of

mental disorders.

Research results

Among medical students in Hebei Province, 7.4% suffered from at least one mental disorder in the past 12 mo, 15.0% had psychological counseling, 5.7% went to a psychiatric hospital, and only 10% received drug treatment.

Research conclusions

The results of screening for prevalence using MINI have high confidence. The estimated prevalence rate of mental disorders among medical students in Hebei is lower than that of the general population, but the treatment rate is also lower. In the future, it is necessary to increase the awareness of medical students to mental diseases and improve the treatment rate, so as to ensure their mental health.

Research perspectives

In the future, the scope of screening should be gradually expanded to more than one university, so as to comprehensively understand the prevalence of mental disorders among college students, and contribute to the development of mental health field.

Abstract

BACKGROUND

In patients with post-stroke depression (PSD) in diabetes, the situation may be more complex, requiring simultaneous treatment of blood glucose, depressive symptoms, and neurological dysfunction. Hyperbaric oxygen (HBO) therapy can improve tissue oxygen content and improve the situation of ischemia and hypoxia, thus playing a role in protecting brain cells and restoring the function of brain cells. However, there are few studies on HBO therapy for patients with PSD. This study explores the clinical efficacy of such therapy for stroke complicated with depression and diabetes mellitus, and to provide reference and basis for clinical treatment and development through the application of relevant rating scales and laboratory test indicators.

AIM

To evaluate the clinical effects of HBO therapy on patients with diabetes with PSD.

METHODS

A total of 190 diabetic patients with PSD were randomly divided into observation and control groups (95 patients per group). The control group received escitalopram oxalate 10mg once a day for eight weeks. In addition, the observation group was also given HBO therapy, once a day, five times a week, for eight weeks. The Montgomery Depression Rating Scale (MADRS), National Institutes of Health Stroke Scale (NIHSS), hypersensitive C-reactive protein, tumor necrosis factor (TNF)-α, and fasting glucose levels were compared.

RESULTS

There were no significant differences in age, sex, or depression course between the groups (P > 0.05). After HBO treatment, MADRS scores in both groups decreased significantly (14.3 ± 5.2), and were significantly lower in the control group (18.1 ± 3.5). After HBO treatment, NIHSS scores in both groups decreased significantly, and scores in the observation group (12.2 ± 4.0) decreased more than in the control group (16.1 ± 3.4), the difference was statistically significant (P < 0.001). The levels of hypersensitive C-reactive protein and TNF-α in both groups were significantly decreased, and the observation group was significantly lower than the control group (P < 0.001). Fasting blood glucose levels in both groups decreased significantly, and those in the observation group decreased more (8.02 ± 1.10) than in the control group (9.26 ± 1.04), with statistical significance (t = -7.994, P < 0.001).

CONCLUSION

HBO therapy can significantly improve depressive symptoms and neurological dysfunction in patients with PSD, and reduce the levels of hypersensitive C-reactive protein, TNF-α and fasting blood glucose.

Core Tip: Post stroke depression is one of the common complications of stroke patients. It affects stroke patients in the acute phase and also occurs in the rehabilitation phase, with an incidence rate of about 33%. However, many patients with post-stroke depression may still not be diagnosed and treated. It is currently believed that biological and psychological factors are involved in the occurrence and development of post-stroke depression. Risk factors of post-stroke depression include gender, psychiatric history, size and location of stroke, poor social support and degree of physical injury. Post-stroke depression may not only affect the emotional state and quality of life of patients, but also hinder the recovery of neurological function, and even increase the mortality of patients. Studies have shown that changes in ischemic hypoxia and brain cell damage are common mechanisms of stroke and post-stroke depression, so improving ischemic hypoxia may be an effective treatment. Diabetes is a chronic disease characterized by elevated blood sugar and other metabolic disorders. diabetes is associated with an increased risk of stroke and post-stroke depression.

INTRODUCTION

Post-stroke depression (PSD) is a common complication in stroke patients, which can affect those in the acute stage and also occur in the convalescence stage, with an incidence of approximately 33%. However, many patients with PSD may remain undiagnosed and untreated[1]. Biological and psychological factors are currently believed to be involved in the occurrence and development of PSD[2]. Risk factors include gender, history of mental illness, size and location of stroke, poor social support, degree of physical impairment, and so on[3]. PSD may not only affect patients' emotional state and quality of life, but also hinder the recovery of neurological function and even increase patient mortality[4]. Studies have suggested that changes in ischemic hypoxia and brain cell damage are the common mechanisms of stroke and PSD, so improving ischemic hypoxia may be an effective treatment[5]. Diabetes is a chronic disease characterized by elevated blood glucose and other metabolic disorders, and is associated with increased risk of stroke and PSD[6]. Therefore, in patients with PSD in diabetes, the situation may be more complex, requiring simultaneous treatment of blood glucose, depressive symptoms, and neurological dysfunction. Hyperbaric oxygen (HBO) therapy can improve tissue oxygen content and improve the situation of ischemia and hypoxia, thus playing a role in protecting brain cells and restoring the function of brain cells[7]. However, there are few studies on HBO therapy for patients with PSD. This study explores the clinical efficacy of such therapy for stroke complicated with depression and diabetes mellitus, and to provide reference and basis for clinical treatment and development through the application of relevant rating scales and laboratory test indicators.

MATERIALS AND METHODS

Patients

From June 2018 to June 2021, a total of 190 diabetic patients with PSD diagnosed and treated in the General Hospital of Chinese PLA were recruited, all of whom met the diagnostic criteria of PSD. Inclusion criteria: (1) Patients aged ≥ 18 years in line with PSD[8]; (2) The vital signs were stable, and the clinical laboratory indicators related to stroke were basically normal; (3) No serious complications or comorbidities, normal consciousness, and cognition; and (4) Diabetes was diagnosed before stroke and in line with the diagnostic criteria of the American Diabetes Association in 2018[9]. Exclusion criteria: (1) Complicated with serious dysfunction of heart, liver, kidney, and other organs; (2) Complicated with malignant tumor and coagulation diseases; and (3) Failure to cooperate with treatment or adherence. The study protocol was approved by the Ethics Committee of the General Hospital of Chinese PLA, and all patients or their families were informed and signed the consent. Among the 190 patients, there were 52 males and 43 females in the control group, with an average age of 63.7 ± 9.3 years, 49.2 ± 14.5 d of depression and 5.9 ± 3.4 years of diabetes. There were 55 males and 40 females in the observation group, with an average age of 62.9 ± 6.1 years, 50.1 ± 12.6 d of depression and 5.6 ± 3.6 years of diabetes. Data on the patients' age, sex, smoking history, past disease history, and disease course were collected. The patients' height and weight were measured, and their body mass index (BMI) was calculated. Their blood pressure was measured in the resting state.

Patient grouping and treatment methods

The patients were divided into observation and control groups using the random number table method, with 95 patients in each group. Patients in both groups were given nutritional cerebrovascular application (including mecobalamin 0.5 mg), once a day, three times a week, intramuscular or intravenous injection, which can be increased or decreased according to age and symptoms, anti-platelet (thromboxane A2 inhibitor aspirin, 75-100 mg/time, Once a day), hypoglycemic [exenatide's initial dose is 5 μg twice a day, and can be increased to 10 μg twice a day after 1 mo of treatment according to the patient's clinical response; injections should be given within 60 min before breakfast and dinner (or before 2 main meals per day; Approximately 6 h or longer)] and other conventional treatments. The control group received oral escitalopram oxalate, 10 mg, once a day (Sichuan Kelun Pharmaceutical Co., Ltd.) for eight weeks., In addition to the oral drug regimen of the control group, the observation group received HBO therapy, once a day, five times a week, for eight weeks.

The HBO treatment was as follows: An HBO chamber (OxyHealth Europe, Vitaeris 320™) was pressurized for 20 min to reach 0.25 mpa. The patient then put on a mask and breathed pure oxygen for 40 min, breathing cabin air at 10-min intervals. Finally, patients decompressed for 30 min to normal pressure, and then left the cabin. Treatment was once a day, 10 times for a course of treatment, each course of intermittent 7-10 d, for a total of two months of observation.

Observation indicators

The following observation indexes were used to evaluate the efficacy before and after treatment: (1) Depression evaluation: The Montgomery Depression Rating Scale (MADRS) scale was used to evaluate patients' depression. The scale is divided into 10 items, with each item being rated from 1 to 6. On a scale of 0 to 60, the higher the score, the more severe the depression; (2) Neurological function evaluation: The National Institutes of Health Stroke Scale (NIHSS) scale was used to evaluate patients' neurological function. The scale includes 14 items, scored from 0 to 42. The higher the score, the more severe the neurological impairment; and (3) Measurement of hypersensitive C-reactive protein and tumor necrosis factor (TNF)-α: 10 mL of fasting venous blood was taken before and after treatment, and the upper serum was centrifuged after standing. Levels of the aforementioned were determined by enzyme-linked immunosorbent assay as per the manufacturer's instructions.

Statistical analysis

Enumeration data were expressed as frequencies (percentage) and the χ^2 test was used to assess differences between the two groups. mean ± SD was used to represent measurement data, and the difference between the two groups was assessed *via* *t*-test. The differences of MADRS score, NIHSS score, hypersensitive C-reactive protein, TNF-α and fasting blood glucose levels between the two groups before and after treatment were determined by *t*-test. $P < 0.05$ was considered statistically significant (bilateral), and IBM SPSS 21.0 was used for statistical analysis of the data.

RESULTS

General patient information

This study included 190 patients with diabetes and PSD. Patients in the observation group were aged 64.4 ± 9.4 years, and male patients accounted for 57.9% (55/95). The course of depression was 50.8 ± 15.3

d, and the course of diabetes was 6.2 ± 3.6 years. The proportion of patients with hypertension, coronary heart disease and hyperlipidemia was 54.7% (52/95), 38.9% (37/95) and 66.3% (63/95), respectively. BMI of patients in the observation group was 25.8 ± 3.8 kg/m^2, and systolic blood pressure was 139.2 ± 13.3 mmHg. In the observation group, 57 patients (60%) had ischemic stroke and 38 (40%) had hemorrhagic stroke. In the control group, the patients were aged 63.0 ± 9.2 years, 51.6% (49/95) male, the course of depression was 47.5 ± 13.4 d, and the course of diabetes was 5.7 ± 3.2 years. In the control group, 48.4% (46/95) had a history of hypertension, 33.7% (32/95) had a history of coronary heart disease, 54.7% (52/95) had a history of hyperlipidemia. The BMI of the control group was 26.2 ± 4.1 kg/m^2, and the systolic blood pressure was 137.6 ± 12.3 mmHg. In the observation group, 48 patients (50.5%) had an ischemic stroke and 47 (49.5%) had a hemorrhagic stroke. There were no significant differences in these characteristics between the two groups ($P > 0.05$, Table 1).

Depressive state and neurological function scores

Before treatment, the MADRS score of observation group (33.7 ± 5.0) was not statistically significant compared with the control group (33.0 ± 4.0, $P > 0.05$). After HBO treatment, the MADRS scores in both groups decreased significantly; that of the observation group (14.3 ± 5.2) was significantly lower than that of the control group (18.1 ± 3.5), and the difference was statistically significant ($P < 0.001$). Before treatment, the NIHSS score of the observation group (21.9 ± 4.1) was compared with the control group (21.0 ± 3.9), and there was no statistical significance ($P > 0.05$). After HBO treatment, NIHSS scores in both groups decreased significantly; scores in the observation group (12.2 ± 4.0) decreased more than those in the control group (16.1 ± 3.4), the difference being statistically significant ($P < 0.001$) (Table 2).

Levels of hypersensitive C-reactive protein and TNF-α

Before treatment, there was no statistical significance in the level of hypersensitive C-reactive protein in the observation group (7.71 ± 1.73) compared with the control group (7.43 ± 1.53, $P > 0.05$). After HBO treatment, the level in both groups decreased significantly, and the level in the observation group (2.87 ± 1.49) was significantly lower than that in the control group (4.52 ± 1.42); the difference was statistically significant ($P < 0.001$). Before treatment, there was no significant difference in TNF-α between the observation group (57.2 ± 13.6) and control group (58.6 ± 11.9, $P > 0.05$). After HBO treatment, TNF-α in both groups decreased significantly, and decreased more in the observation group (26.7 ± 12.5) than in the control group (33.9 ± 11.1), with statistical significance ($P < 0.001$) (Table 3).

Fasting blood glucose level

Before treatment, there was no significant difference in fasting blood glucose level between the observation group (10.96 ± 0.91) and control group (11.16 ± 0.93). After HBO treatment, the level decreased significantly in both groups, and that in the observation group decreased more than that in the control group (9.26 ± 1.04); the difference was statistically significant ($t = -7.994$, $P < 0.001$, Table 4).

DISCUSSION

We found that HBO therapy improved depressive symptoms and neurological dysfunction in patients with PSD, and reduced levels of hypersensitive C-reactive protein and TNF -α compared with the control group. It is worth noting that patients with diabetes and PSD who underwent HBO therapy had lower fasting glucose levels.

Stroke is an acute cerebrovascular disease with high disability and mortality rates, and PSD is a common complication that may affect nearly one-third of patients[10-12]. Importantly, PSD not only affects the patient's psychosis but may also affect the treatment effect and recovery of neurological dysfunction in patients with stroke, and even increase the incidence of recurrent stroke and all-cause mortality[13,14]. Diabetes, a chronic disease mainly characterized by elevated blood glucose, may increase the risk of stroke and PSD[15,16]. Additionally, PSD combined with diabetes may increase the risk of recurrent stroke, aggravate depressive symptoms, and even increase patient mortality[17]. Therefore, diabetes is a major cause of stroke. With the development of diabetes, patients are prone to metabolic abnormalities, cholesterol will be further increased, and thrombosis will be formed, finally leading to ischemic stroke[18]. Timely control of blood glucose is an important prevention of stroke.

Currently, escitalopram is the main first-line drug for the treatment of PSD, and the use of this drug can improve patients' emotional symptoms, but studies have demonstrated that some patients with PSD still have depressive symptoms after using escitalopram, with poor efficacy[19]. Treatment includes changing the antidepressant, adding another antidepressant, or augmenting the treatment by adding another drug, such as an atypical antipsychotic or lithium. Non-pharmacological forms of augmentation of depression treatment have also been proven to be effective, including cognitive-behavioral psychotherapy, psychoeducation, aerobic exercise, neuromodulatory treatment through vagus nerve stimulation, electroconvulsive therapy (ECT), transcranial direct current stimulation (TDCS), repetitive transcranial magnetic stimulation (rTMS) or deep brain stimulation and light therapy; however, non-pharmacological forms of biological treatment used in the treatment of treatment-resistant depression

Table 1 Clinical characteristics of patients in two groups, *n* (%)

Clinical characteristics	Observation group	Control group	t/χ^2	*P* value
Patients	95	95	-	-
Age (yr)	64.4 ± 9.4	63.0 ± 9.2	1.052	0.294

also do not show substantial efficacy. Despite the improvement achieved during electroshocks, ECT has no lasting effect, and despite continued pharmacotherapy, relapses are observed in a large (37%) proportion of patients[20]. TDCS has been used with a moderate effect on depression, similar to rTMS, which also has moderate and short-term efficacy in improving mood and cognitive function in people with depression[21]. Light therapy has proven to be ineffective in enhancing the effects of antidepressants in both seasonal and recurrent depression[22]. Currently, HBO therapy is known to be an effective and safe method for treating PSD, which has been the subject of numerous studies. This study found that HBO therapy can improve depressive symptoms and neurological dysfunction in patients with PSD, specifically improving the blood supply to the lesion and facilitate the blood supply to the focal point of the stroke. Under the action of HBO, the phenomenon of counter-stealing blood will appear in the tissue, which is conducive to the blood supply to the ischemic lesion. Increase vertebrobasilar artery blood flow: Under HBO, the vertebrobasilar artery system is the only blood vessel that

Table 4 Fasting blood glucose levels of the two groups

Group	Patients	Before treatment	After treatment	*t* value	*P* value
Observation group	95	10.96 ± 0.91	8.02 ± 1.10	20.177	< 0.001
Control group	95	11.16 ± 0.93	9.26 ± 1.04	13.256	< 0.001
t value	-	-1.475	-7.994	-	-
P value	-	0.142	< 0.001	-	-

does not contract but dilates, thus increasing the blood supply and oxygen supply to the brain stem and reticular structure, which is conducive to the improvement of the patient's wakefulness and mood. HBO therapy was found to improve depressive symptoms and neurological dysfunction in patients with PSD. Similar to this study, a meta-analysis established that HBO treatment reduced NIHSS scores (mean difference = 2.77 points, 95%CI from 3.57 to 1.98 points, $P < 0.001$) and improved Hamilton Depression Scale scores (mean difference = 4.33 points, 95%CI from 4.82 to 3.84 points, $P < 0.001$)[7].

Ischemic anoxic injury may be a common initiating factor of stroke and PSD, and inflammatory processes may also be involved in the occurrence and development of depression. It has been suggested that patients with PSD had higher levels of TNF-α compared with non-depressed patients (25.65 ± 9.24 *vs* 17.29 ± 4.27, $P < 0.001$)[23]. In this study, diabetic PSD patients in the observation group had lower levels of hypersensitive C-reactive protein and TNF-α compared with the control group. This suggests that inflammatory factors can be used as biomarkers of PSD in patients with diabetes and may be effective early treatment targets[24]. Interestingly, the present study found that patients with PSD and diabetes who underwent HBO therapy had lower fasting glucose levels. Previous studies have suggested that HBO therapy can promote insulin secretion in patients with diabetes and enhance glucose uptake by brain cells[25].

This study has some limitations. Owing to the small sample size, fewer variables were collected, and the observation time was short. Large randomized controlled clinical trials are required to validate the role of HBO therapy in patients with diabetes and PSD.

CONCLUSION

In conclusion, HBO therapy can significantly improve depressive symptoms and neurological dysfunction in patients with PSD, and reduce the levels of hypersensitive C-reactive protein, TNF-α and fasting blood glucose, which is worthy of clinical promotion.

ARTICLE HIGHLIGHTS

Research background

This study explores the clinical efficacy of such therapy for stroke complicated with depression and diabetes mellitus, and to provide reference and basis for clinical treatment and development through the application of relevant rating scales and laboratory test indicators.

Research motivation

Changes in ischemic hypoxia and brain cell damage are common mechanisms of stroke and post-stroke depression, so improving ischemic hypoxia may be an effective treatment. Diabetes is a chronic disease characterized by elevated blood sugar and other metabolic disorders. diabetes is associated with an increased risk of stroke and post-stroke depression.

Research objectives

This study explores the clinical efficacy of such therapy for stroke complicated with depression and diabetes mellitus, and to provide reference and basis for clinical treatment and development through the application of relevant rating scales and laboratory test indicators.

Research methods

Patients in both groups were given nutritional cerebrovascular application, once a day, three times a week, intramuscular or intravenous injection, which can be increased or decreased according to age and symptoms, anti-platelet, hypoglycemic and other conventional treatments. The control group received oral escitalopram oxalate, 10 mg, once a day for eight weeks., In addition to the oral drug regimen of the control group, the observation group received hyperbaric oxygen (HBO) therapy, once a day, five times

a week, for eight weeks. The HBO treatment was as follows: an HBO chamber was pressurized for 20 min to reach 0.25 mpa. The patient then put on a mask and breathed pure oxygen for 40 min, breathing cabin air at 10-min intervals. Finally, patients decompressed for 30 min to normal pressure, and then left the cabin. Treatment was once a day, 10 times for a course of treatment, each course of intermittent 7-10 d, for a total of two months of observation.

Research results

There were no significant differences in age, sex, or depression course between the groups. After HBO treatment, Montgomery Depression Rating Scale scores in both groups decreased significantly, and were significantly lower in the control group. After HBO treatment, National Institutes of Health Stroke Scale scores in both groups decreased significantly, and scores in the observation group decreased more than in the control group, the difference was statistically significant. The levels of hypersensitive C-reactive protein and tumor necrosis factor (TNF)-α in both groups were significantly decreased, and the observation group was significantly lower than the control group. Fasting blood glucose levels in both groups decreased significantly, and those in the observation group decreased more than in the control group, with statistical significance.

Research conclusions

HBO therapy can significantly improve depressive symptoms and neurological dysfunction in patients with post-stroke depression, and reduce the levels of hypersensitive C-reactive protein, TNF-α and fasting blood glucose.

Research perspectives

The future research direction is mainly to study the influence of depression in diabetes patients.

Abstract

BACKGROUND

Developing methods to monitor exercise load and evaluate body fatigue and muscle injury over time in hiking training remains a key problem to be solved. A widely used psycho-physical tool to assess the subjective perception of effort during exercise is Borg's rating of perceived exertion (BRPE) scale. Data on the relationships and validity of the BRPE compared to objectively assessed metabolic criteria are still lacking, especially urinary organic acid concentrations.

AIM

To verify whether the BRPE scale could be used in the prescription of outdoor hiking with weight-bearing and reveal the relationship between the BRPE scale and urinary physiological measures.

METHODS

Eighty-nine healthy men (average age: 22 years) were enrolled in a 40 km (6 h) hiking training exercise with a 20 kg load. After training, the BRPE scale (6-20) was completed. All participants were divided into three groups according to the rating of the BRPE scale. Urine samples were collected before and after training. Urinary myoglobin levels were measured immediately using the fluorescent immunoassay method. The remaining urine was subpacked and frozen for the subsequent detection of urinary organic acids using gas chromatography and mass spectrometry.

RESULTS

The contents of organic acids and myoglobin in urine were significantly increased after participants hiked 40 km (6 h) with a 20 kg load. Only orthogonal partial

least-squares discrimination analysis performed well in separating the group with a BRPE score of 6-12 from the group with a BRPE score of 13-20. Significant differences in the urine levels of several organic acids were observed between the two groups, and the heatmap also presented different metabolic profiles based on BRPE. According to the standard of a variable importance in the projection > 1, fold change > 1.5 and $P < 0.05$, 19 different metabolites of urinary organic acids were screened and enriched in pathways mainly including the citrate cycle (tricarboxylic acid cycle) and alanine, aspartate and glucose metabolism.

CONCLUSION

The BRPE scale identified significantly different urinary organic acid profiles between the higher and lower BRPE value groups, and, thus, could be used to monitor body fatigue in individuals participating in long-distance outdoor hiking with weight bearing.

Key Words: Borg's rating of perceived exertion; Urine; Organic acid metabolism; Exercise intensity; Myoglobin; Hiking

Core Tip: Developing methods to monitor exercise load and evaluate body fatigue over time in endurance training is a key problem to be solved. Borg's rating of perceived exertion (BRPE) scale has been widely used as a psycho-physical tool to assess the subjective perception of effort during exercise. In this study, we aimed to verify whether the BRPE scale could be used in the prescription of outdoor hiking with weight-bearing and reveal the relationship between the BRPE scale and urinary physiological measures, particularly urinary organic acid concentrations. Underlying mechanisms related to body fatigue and metabolic disorders were also analyzed in this study.

INTRODUCTION

Long-distance weight-bearing hiking in the field is an important part of physical training, that helps improve cardiopulmonary endurance and muscle endurance. Many countries use this type of exercise as an essential component of endurance training for soldiers[1,2]. In this process, an excessive exercise load may lead to fatigue accumulation, which imposes risks of physical and mental stress[3]. It represents an inconspicuous and gradual process. If overtraining continues, more severe injury in soft tissue or skeletal muscle will occur[4,5]. Therefore, developing methods to monitor exercise load and evaluate muscle injury and body fatigue over time remains a key problem to be solved.

Exercise tests have been conducted for more than 60 years[6]. Many indices, such as lactate, creatine kinase, and myoglobin, which are based on blood biochemical tests, have been applied during exercise monitoring[7,8]. However, these invasive tests with complex methodologies and high costs are difficult to implement in the field. Noninvasive tools and indices are needed to assess the intensity of physical activity during outdoor hiking exercise interventions.

A widely used psycho-physical tool to assess the subjective perception of effort during exercise is Borg's rating of perceived exertion (BRPE) scale[9-11]. It assesses the mental load of exercise with the subjective level of physical exertion. First, the subjective level of physical exertion is divided into scores ranging from 6-20[9]. Later, other rating methods, such as methods with 10 levels and 100 levels, also appeared[12,13]. A BRPE value of 10 times was used to estimate the heart rate of the trainer. The American College of Sports Medicine has suggested that the BRPE value may be considered to add precision to heart rate when monitoring exercise intensity and even replace it once the relationship between the heart rate and BRPE value is known for an individual[14]. With the advantages of simplicity, economy and strong operability, the BRPE scale facilitates the collection of training load data efficiently and conveniently. Many studies have revealed that the BRPE value is useful both in the prescription of alternated-intensity training exercises and continuous tests in a laboratory[15-17], underlining the strong relationships between the BRPE value and the indices of physiological strains. Nevertheless, only a few studies have been performed within a more ecologically valid environment.

Previous studies examining hiking have reported that the BRPE scale is significantly higher as load mass increases[18]. However, data revealing the relationships and validity of the BRPE value compared to objectively assessed metabolic criteria, especially urine organic acid concentrations, are still lacking.

In the present study, we examined the relationship between the BRPE scale and physiological measures (urinary organic acid metabolite and myoglobin levels) of exercise intensity after 40 km outdoor hiking with weight-bearing of approximately 20 kg. The aim of this study was to verify whether the BRPE score collected after hiking could be used to prescribe these training exercises.

MATERIALS AND METHODS

Participants

This study included 89 healthy young men (average age: 22 years, range from 18 to 24 years). Individuals with basic diseases, such as heart and lung disease, anemia, bone injury, and hypertension, and those who were taking drugs were excluded. Individuals with fever or musculoskeletal or soft tissue injury in the 7 d before hiking were also excluded. All participants signed the informed consent form. This study was reviewed and approved by the Ethics Committee of Chinese PLA General Hospital (S2021-019-01).

Hiking walking settings

All participants experienced a hiking training exercise of 40 km with 20 kg carriages in plain areas. The whole training exercise lasted from 8:00 to 14:00. Two short 10-min breaks were allotted to supply water and a longer 30-min break was provided at 11:00 am for the prescribed lunch.

At the end of training, everyone truthfully completed the BRPE scale (Table 1), and urine samples were collected before and after training. The level of myoglobin in urine was measured immediately, and the remaining urine was separated and frozen at -80 °C for organic acid measurements.

Detection of the urine myoglobin concentration

According to the instructions of the myoglobin assay kit (fluorescence immunochromatography) (Beijing Danda Biotechnology Co., Ltd. Beijing, China), the level of myoglobin in urine was determined using a fluorescence immunoassay analyzer (Beijing Danda Biotechnology Co., Ltd. Beijing, China). First, information from the calibration card was input into the analyzer, and the standard curve of the urine sample type was selected. Then, the test card was removed, and 80 μL of the urine sample was added into the sampling hole of the test card. After 15 min, the test strip was placed into the dry fluorescent immunoassay analyzer to read the data. The chemical signal was measured and analyzed to quantitatively obtain the myoglobin concentration in the tested sample.

Detection of urine organic acids

Sample prehandling: One hundred microliters of urine was mixed with 30 μL of urease and incubated at 37 °C for 30 min. Next, 100 μL of the internal standard (margaric acid, 100 ppm) and 1 mL of absolute ethanol were added and the mixture was centrifuged at 13000 rpm for 5 min at 4 °C. The supernatant was extracted, and after adding 2% hydroxylamine hydrochloride, it was added to the supernatant, it was incubated at 60 °C for 10 min. After cooling at room temperature, the supernatant was transferred to a glass bottle and dried with nitrogen. Finally, 100 μL of BSTFA + TMCS (99:1) were added and incubated at 80 °C for 30 min, and gas chromatography and mass spectrometry (GC/MS, TSQ 8000 EVO, Thermo Scientific, United States) was used for the organic acid analysis.

GC/MS parameters: The chromatography column was a DB-5 column (30 m × 0.25 mm × 0.25 μm) purchased from Agilent Technologies Inc. The injection temperature and transfer line temperature were set to 250 °C and 290 °C, respectively. The injection volume was 1 μL, the split mode was selected with a ratio of 1:20, and the flow rate of high purity helium was 1 mL/min. The initial oven temperature was set to 100 °C and maintained for 4 min; then it was heated at a rate of 4 °C/min to 280 °C and maintained for 7 min.

GC/MS acquisition: Standard solutions (Zhejiang Biosan Biochemical Technologies Co., Ltd., China) of organic acids were prepared using the procedures described above and analyzed with a scan range of 50-550 m/z using Xcalibur software (ver. 2.1, Thermo Scientific, United States). The characteristic retention time and fragment ions of each organic acid were determined, and an organic acid database was established. Next, the instrument acquisition method was established by performing timed acquisition with the scan type of single iron monitoring (SIM). Timed acquired SIM data were analyzed using Trance Founder software (ver. 3.0, Thermo Scientific, United States). The GC/MS data of urine samples were qualitatively compared with the spectrometry database, and the final results were reported as the ratio of the peak area of the detected compound to the peak area of the internal standard.

Table 1 The Borg's rating of perceived exertion scale (6-20)

Score	Perceived exertion
6	No exertion at all
7	Extremely light
8	
9	Very light
10	
11	Light
12	
13	Somewhat hard
14	
15	Hard
16	
17	Very hard
18	
19	Extremely hard
20	Maximal exertion

Statistical analysis

Data are presented as the means ± SD for normally distributed data or medians + interquartile ranges for nonnormally distributed data. For statistical comparisons, independent sample *t* tests or Mann-Whitney *U* tests (nonnormally distributed data) were performed using SPSS 25.0 and GraphPad Prism 8.0 software. SIMCA14.1.0 software was used for principal component analysis (PCA) and orthogonal partial least-squares discrimination analysis (OPLS-DA). Heatmaps and radar charts were processed on the Xiantao website (http://www.xiantao.love). The pathway analysis was performed using MetaboAnalyst 5.0 (https: //www.metaboanalyst.ca/).

RESULTS

Changes in organic acid and myoglobin levels before and after exercise

The volcano map of the results for organic acid metabolism before and after exercise is shown in Figure 1. Log2 (fold change) was set as the abscissa and -Log10 (*P* value) was set as the ordinate. The results showed that the levels of oxalic acid, pyruvic acid, 3-OH-butyric acid, 2-OH-isovaleric acid, 2-methyl-3-OH-butyric acid, benzoic acid, maleic acid, glyceric acid, fumaric acid, 3-methylglutaric acid, 3-methylglutaconic acid, glutaconic acid, decanoic acid, malic acid, adipic acid, creatinine, 2-OH-glutaric acid, pimelic acid, 2-ketoglutaric acid, phenylpyruvic acid, aconitic acid, vanillic acid, homovanillic acid, azelaic acid, citric acid, sebacic acid and palmitic acid were significantly increased after exercise. The myoglobin level was also increased after exercise ($P = 0.0133$).

Differentiation in the BRPE scale groups based on urinary organic acids

Figure 2 shows the PCA and OPLS-DA scores of the BRPE scale and urine organic acid levels. An unsupervised PCA was performed as the statistical analysis to evaluate the difference in organic acid metabolites among the groups with scores of 6-12, 13-16 and 17-20. PCA results showed no significant separation among the three groups. The supervised OPLS-DA model was subsequently used for analysis, and the results showed a clear separation between the groups with scores of 6-12 and 13-16 (Figure 3A) and between the groups with scores of 6-12 and 17-20 (Figure 3B). The model parameters of Q_2Y and R_2Y for those two group separations were 0.315 and 0.452 and 0.299 and 0.527, respectively. Although the groups with scores of 12-15 and 16-20 could not be separated (Figure 3C), the model parameters of Q_2Y and R_2Y were 0.0777 and 0.312, respectively.

Since the distinction between the groups with scores of 13-16 and 17-20 was not obvious, groups with scores of 13-16 and 17-20 were combined into one group (score of 13-20) for analysis. The OPLS-DA results showed that the two groups were separated (Figure 3D), and the model parameters of Q_2Y and R_2Y were 0.236 and 0.368, respectively. The statistical results also showed significant differences in the levels of most of the organic acid indicators between the two groups (Table 2).

Comparison of metabolic profiles in urinary metabolites between the low and high BRPE score groups

The heatmap cluster analysis (Figure 4) revealed the metabolic profiles of organic acids between the groups with scores of 6-12 (low BRPE score group) and 13-20 (high BRPE score group). The redder color represents a higher content. The urine contents of organic acids in the group with a score of 6-12 were generally low.

According to a fold change > 1.5, variable importance in the projection > 1 and $P < 0.05$ for organic acids, the differentially abundant compounds between the groups with scores of 6-12 and 13-20 were screened, and 19 differentially abundant compounds were identified (Table 3). A radar chart of these metabolites was then constructed based on the abundance of organic acids (Figure 5). Compared with the group with a score of 6-12, the organic acid levels in the group with a score of 13-20 were significantly increased. Because of the high order of magnitude for creatinine, which was significantly different from the other organic acids, the creatinine index was removed, and a radar chart without creatinine was constructed, as shown in Figure 5B. Figure 6 shows the metabolic pathways of the differentially abundant metabolites, and the results revealed significant differences in the metabolic pathways of the citrate cycle [tricarboxylic acid (TCA) cycle] and alanine, aspartate and glucose metabolism.

Correlation analysis between the BRPE score and myoglobin level

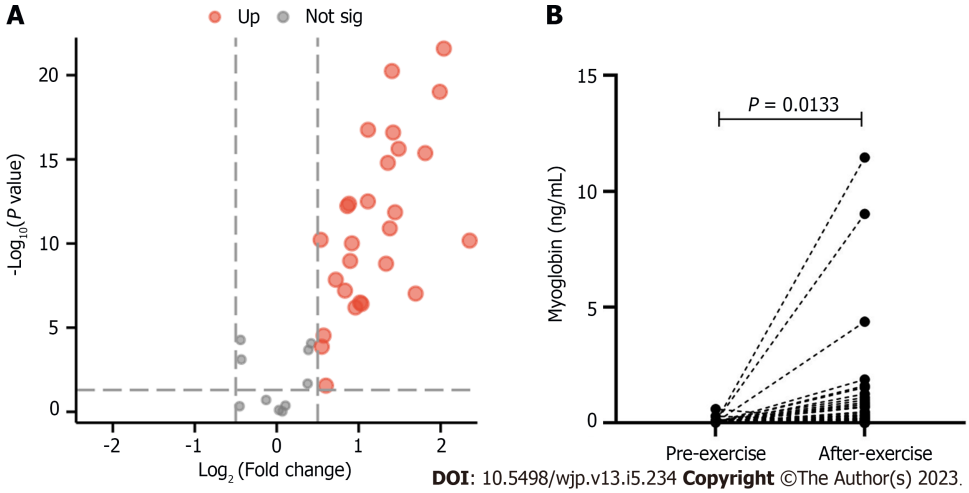
The statistical results for the myoglobin levels among the groups with BRPE scores of 6-12 and 13-20 are shown in Figure 7A. No significant differences were observed between the groups with scores of 6-12 and 13-20. The results of Spearman's analysis of the Borg scale showed no significant correlation between the Borg scale and myoglobin level (Figure 7B).

DISCUSSION

In this study, 89 healthy young men were enrolled in a 40 km (6 h) outdoor hiking training exercise. We compared urine organic acid and myoglobin levels before and after hiking and analyzed the underlying correlation between the BRPE score and urine organic acid levels.

The results showed that the levels of most of the organic acid metabolites increased after hiking. Organic acids are a class of carboxylic acids produced from amino acids, fats and carbohydrates in the metabolic process of the body, which directly participate in many biochemical reactions involved in life activities. They are also related to the metabolic activities and mutual transformation of sugar, fat and protein. Previous studies have shown an increased level of glycolysis products, such as TCA cycle intermediates, nucleotide products and branched-chain amino acids, which are usually related to energy metabolism, during endurance training[19-21].

Urine myoglobin levels were also detected before and after exercise. Myoglobin exists in cardiac muscle and skeletal muscle cells and has a close relationship with exercise-related fatigue and sports injury[22,23]. When exercise causes skeletal muscle injury, the content of myoglobin in blood or urine may consequently increase. Our results showed that urinary myoglobin levels increased after exercise but were within the normal range, indicating that exercise-related fatigue may have occurred after exercise, but we could not clearly determine what extent of fatigue occurred.



The BRPE scale is a simple method to quantify the degree of self-perceived exertion of the human body, particularly in fatigue evaluations[24,25]. We collected the BRPE scores of the trainees after exercise and divided them into groups with scores of 6-12, 13-16 and 17-20 according to self-perceived exertion measured using the BRPE scale. Only the supervised OPLS-DA model performed well in separating trends between groups. We observed that the 6-12 score group was significantly separated from the 13-16 and 17-20 score groups. However, the latter two groups were not separated because no obvious differences in metabolism were detected between the two groups. Therefore, we combined those two groups into a 13-20 score group. This result indicates that organic acid metabolism changed when "somewhat hard" was reported as a psychological perception of exercise. The heatmap of the BRPE score and organic acid metabolites directly showed that the contents of organic acids increased in the higher BRPE score group (13-20). These findings support the results of our study that individuals with higher BRPE values experienced more metabolic changes related to body fatigue. There is a need to individualize the recovery or training strategies in the same excises. Our study is the first to compare metabolomic responses controlled by the BRPE in hiking training. Our data indicate that for individuals undergoing the same training, the BRPE score may discriminate those with different stress ranges at a biochemistry level. This result is also consistent with previous research that the BRPE could show the relevance of individual recovery treatments and the sensitivity and predictability of metabolomics to prevent biochemical and physiological disturbances[26].

Then, we screened differentially abundant metabolites according to the multivariate and univariate statistical significance criteria. Nineteen differentially abundant metabolites identified between the groups with scores of 6-12 and 13-20 are shown in Table 3 and Figure 5. A subsequent pathway enrichment analysis showed that the TCA cycle and alanine, aspartate and glutamate metabolism were the main distinctive metabolomic characteristics in the 13-20 score group. The TCA cycle is the process

supplying energy through aerobic metabolism in the body[27]. Aerobic metabolism has a long oxygen supply capacity and is an important pathway of energy metabolism[28]. Exercise-related fatigue after long and intense exercise is related to metabolic changes in TCA cycle[29]. High intensity training significantly increased the content of intermediates in the TCA cycle, Tsai *et al*[30] reported that succinic acid and fumaric acid were significantly elevated after exhaustion. In this study, we also observed higher levels of intermediate products of the TCA cycle in the higher BRPE scale group, which is consistent with previous studies mentioned above, suggesting fatigue occurrence in higher BRPE scale individuals. Interactions between the amino acid pool and the TCA cycle are suggested to play a central

role in the energy metabolism of the exercising muscle[31]. These results were consistent with the current "wear out doctrine" and "blockage doctrine" for the mechanism of training-induced fatigue; namely, the consumption of a large amount of energy substances and accumulation of metabolites during physical exercise/training leads to a decrease in the functional capacity of tissues, muscles, and organs, ultimately resulting in fatigue[1].

In addition, there was no significant difference between groups with scores of 6-12 and 13-20, and no correlation between myoglobin levels and BPRE scores. This result explains why serious muscle injury does not occur in the body even if a participant feels very tired psychologically during the 40 km exercise. However, at this time, organic acid metabolism has changed significantly and precedes the occurrence of muscle injury.

There are still some limitations in this research. First, the number of people in the group with a score of 6-12 was slightly small, which may have affected the data to a certain degree. Second, the population in this study only included men, and the difference between men and women was not assessed. Third, there was an absence of more direct assessment indicators, such as heart rate, blood biomarkers and others, which might be correlated with metabolic data. Combining all of these data might further help to confirm the ability of higher and lower BRPE values to differentiate metabolic profiles.

CONCLUSION

In conclusion, our results showed that after long-distance hiking with weight bearing, individuals with high BRPE values have a significant higher disturbance in organic acid metabolism. The differentially abundant metabolites are concentrated in the energy metabolism pathway. The BRPE value is not correlated with urine myoglobin levels but was shown to be able to discriminate individuals with exercise-related fatigue as a convenient predictor.

ARTICLE HIGHLIGHTS

Research background

The Borg's rating of perceived exertion (BRPE) scale was widely used to access subjective perception of effort during exercise, but the relationship between BRPE scale and urinary organic acids metabolism has not been studied.

Research motivation
Our article mainly explored the relationship of urinary organic acids metabolism and the BRPE scale during exercise and reflected the psychological perception degree of effort from an objective physiological perspective.

Research objectives
In this work, we aimed to evaluate whether the BRPE scale could be used in the prescription of outdoor hiking with weight-bearing based on urinary organic acids metabolism, which provides an objective physiological data support for the application of BRPE scale in outdoor hiking training.

Research methods
Eighty-nine healthy men participated in this project and underwent 40 km (6 h) training with 20 kg carriages. After the training, they truthfully filled in the BRPE scale and urinary organic acids were detected. We used multidimensional statistical analysis including principal component (PCA) analysis and orthogonal partial least-squares discrimination (OPLS-DA) analysis and heat map analysis to explore the differences in metabolic profiles of organic acids with different BRPE scale. At last, differential metabolites were screened and pathway analysis was performed.

Research results
There were significant statistical differences in urinary organic acids before and after exercise. According to the BRPE scale, individuals were divided into groups of 6-12 scale (easy), 13-16 scale (somewhat hard) and 17-20 scale (very hard). PCA results showed no separation trend among the three groups. Further analysis with OPLS-DA showed that, group of 6-12 scale and 13-16 scale, 6-12 scale and 17-20 scale could be separated obviously, and group of 13-16 scale and 17-20 scale could not be separated, so group of 13-16 scale and 17-20 scale were combined into group 13-20 scale. OPLS-DA results showed that group 6-12 scale and 13-20 scale could be separated. Heat map results also showed significant metabolic differences between group of 6-12 scale and 13-20 scale. According to the standard of a variable importance in the projection > 1, fold change > 1.5 and $P < 0.05$, 19 different metabolites were screened, which mainly in citrate cycle (tricarboxylic acid cycle) and alanine, aspartate and glucose metabolism.

Research conclusions
Our results showed that the BRPE scale could be used to monitor body fatigue in long-distance outdoor hiking with weight bearing.

Research perspectives
We provide an objective method to evaluate body fatigue in outdoor-hiking exercise.

Abstract

BACKGROUND

Several genetic testing techniques have been recommended as a first-tier diagnostic tool in clinical practice for diagnosing autism spectrum disorder (ASD). However, the actual usage rate varies dramatically. This is due to various reasons, including knowledge and attitudes of caregivers, patients, and health providers toward genetic testing. Several studies have therefore been conducted worldwide to investigate the knowledge, experiences, and attitudes toward genetic testing among caregivers of children with ASD, adolescent and adult ASD patients, and health providers who provide medical services for them. However, no systematic review has been done.

AIM

To systematically review research on knowledge, experiences, and attitudes towards genetic testing among caregivers of children with ASD, adolescent and adult ASD patients, and health providers.

METHODS

We followed the Preferred Reporting Items for Systematic Reviews and Meta-analyses guidelines and searched the literature in three English language databases (PubMed, Web of Science, and PsychInfo) and two Chinese databases

(CNKI and Wanfang). Searched literature was screened independently by two reviewers and discussed when inconsistency existed. Information on characteristics of the study, characteristics of participants, and main findings regarding knowledge, experience, and attitudes of caregivers of children with ASD, adolescent and adult ASD patients, and health providers concerning ASD genetic testing were extracted from included papers into a charting form for analysis.

RESULTS

We included 30 studies published between 2012 and 2022 and conducted in 9 countries. Most of the studies (n = 29) investigated caregivers of children with ASD, one study also included adolescent and adult patients, and two covered health providers. Most (51.0%-100%) of the caregivers/patients knew there was a genetic cause for ASD and 17.0% to 78.1% were aware of ASD genetic testing. However, they lacked full understanding of genetic testing. They acquired relevant and necessary information from physicians, the internet, ASD organizations, and other caregivers. Between 9.1% to 72.7% of caregivers in different studies were referred for genetic testing, and between 17.4% to 61.7% actually obtained genetic testing. Most caregivers agreed there are potential benefits following genetic testing, including benefits for children, families, and others. However, two studies compared perceived pre-test and post-test benefits with conflicting findings. Caregivers concerns included high costs, unhelpful results, negative influences (*e.g.*, causing family conflicts, causing stress/risk/pain to children *etc.*) prevented some caregivers from using genetic testing. Nevertheless, 46.7% to 95.0% caregivers without previous genetic testing experience intended to obtain it in the future, and 50.5% to 59.6% of parents previously obtaining genetic testing would recommend it to other parents. In a single study of child and adolescent psychiatrists, 54.9% of respondents had ordered ASD genetic testing for their patients in the prior 12 mo, which was associated with greater knowledge of genetic testing.

CONCLUSION

Most caregivers are willing to learn about and use genetic testing. However, the review showed their current knowledge is limited and usage rates varied widely in different studies.

Key Words: Autism spectrum disorder; Genetic testing; caregivers; Child and adolescent psychiatrists; Knowledge; Experience; Attitudes

Core Tip: More action should be taken to improve the knowledge level about genetic testing among caregivers of patients with autism spectrum disorder (ASD). Health education from health providers such as physicians and psychiatrists appear the most effective method. Improving the knowledge level of ASD genetic testing among health providers is necessary for better utilization of genetic testing in ASD practice. Caregivers of patients with ASD and patients themselves generally hold a positive attitude toward genetic testing. More comprehensive knowledge is needed to avoid potential misunderstandings.

INTRODUCTION

Autism spectrum disorder (ASD) is a group of severe neurodevelopmental disorders currently with limited treatment effectiveness[1]. The prevalence of ASD is around 1% but has been steadily increasing over the past two decades[2]. Diagnosis of ASD lacks objective biomarkers and primarily relies on subjective parameters such as clinical observation and evaluation of individuals' behavioral and developmental characteristics[3]. However, most patients are too young to express their feelings, clinical symptoms are complex and heterogeneous, not easily detected by parents and many patients do not receive timely diagnosis and treatment. This can lead to severe social dysfunction and heavy economic burden to families and society[4-6]. Although the specific etiology of ASD is unknown, it is widely accepted that both genetic and environmental factors contribute to the pathogenesis of ASD. The estimated heritability of ASD ranges from 64% to 91%[7], and there are a large number of studies to

elucidate the genetic mechanism of this disorder. Thousands of ASD risk genes carrying different kinds of mutations have been reported, such as rare *de novo* mutations, single nucleotide polymorphisms (SNPs), and copy number variations (CNVs)[8-10]. There are several comprehensive databases that aim to summarize all ASD risk genes and SFARI Gene (gene.sfari.org)[11] is one of the most well-recognized. SFARI Gene features a ranking system that gives users an estimate of the strength of the evidence in favor of each gene. For example, there are 232 genes with high confidence, which means these genes have been clearly implicated in ASD. As a result, several genetic testing techniques have been applied as an auxiliary examination tool when diagnosing ASD.

In clinical practice, genetic testing, such as Karyotype analysis, fluorescence in-situ genomic hybridization (FISH), fragile X testing, chromosome microarray analysis (CMA), and next-generation sequencing have all been utilized for ASD patients. Karyotype analysis was first used in the 1970s to identify extremely large CNVs[12] and FISH has been performed to identify submicroscopic CNVs since the 1990s[13]. In 2005, the American College of Medical Genetics and Genomics (ACMG) recommended karyotype analysis and FISH as standard testing for children with developmental delay or mental retardation, which included ASD[13-15]. For ASD with specific genetic causation, genetic testing could be utilized as the first-tier diagnostic tool. For example, 30%-50% fragile X syndrome caused by > 200 repeats of the CGG motif in FMR1 was shown to manifest as ASD[16]. In 2007, the American Academy of Pediatrics recommended Fragile X testing to be performed when ASD was diagnosed[17-19]. Given that ASD is polygenic, screening mutations genome-wide is necessary. CMA that could detect CNVs and SNPs across the genome has been increasingly used in the clinical practice of ASD[20]. The latest next-generation sequencing with higher resolution, including Whole Exome Sequencing (WES) and Whole Genome Sequencing could be used to detect single nucleotide variants, indels and other variants in patients[21]. CMA and WES have been recommended as the first-tier clinical diagnostic test for individuals with developmental disabilities, including ASD by the ACMG in 2010 and 2013, respectively [12,22]. So far, the clinical diagnostic yield of CMA and WES for ASD was 9.3 to 24.1%[23], and 8.4% to 15.4%[24,25] respectively.

There are many potential benefits of genetic testing for patients with ASD and their families, including promoting early diagnosis and intervention, identifying etiology, reducing medication compliance, providing scientific suggestions for parents' fertility planning, and reducing parents' guilt and anxiety[26,27]. However, the usage rate of genetic testing varies dramatically across countries and regions. As far as we know, the highest rate of receiving any type of genetic testing was reported in France in 2014 (61.7%)[28]. Much lower rates were reported in America in 2020 (17.4%) and Malaysia in 2022 (19.8%)[29,30]. Even within the same country in the same year (for example, America in 2018), rates ranged from 28.0% to 57.1%[31,32]. This could be due to several factors. First, genetic testing does not always identify pathogenic variants because the complex genetic architecture of ASD is still not fully understood[33,34]. Second, a positive finding from genetic testing is not always helpful in clinical management. Third, the test is costly for some families[31]. Furthermore, the usage rate of genetic testing is affected by awareness and attitudes of both caregivers and health providers who are involved in the diagnosis and care of children with ASD, especially child and adolescent psychiatrists (CAP)[31, 35]. In a previous study, 67.5% of parents reported that the main reason why they did not get genetic testing was they did not receive suggestions from physician[36].

To maximize the benefit of genetic testing in ASD clinical practice, it is very important to understand caregivers' and health providers' opinions towards genetic testing for ASD. To date, several studies have investigated knowledge, experiences, and attitudes toward genetic testing for ASD. In the present article, we systematically reviewed the literature published up to October 2022 to outline the current state of knowledge level, experiences, and attitudes toward ASD genetic testing among caregivers of children with ASD, adolescent and adult ASD patients, and health providers. In addition, to summarize factors related to the underutilization of genetic testing and provide a direction for future improvement.

MATERIALS AND METHODS

Literature search

We searched the literature in 3 English databases (PubMed, Web of Science, and PsychInfo) and 2 Chinese databases (CNKI and Wanfang). The search items were (caregivers* OR caretakers* OR parents * OR psychiatrist* OR specialists*) AND (autism spectrum disorder OR ASD* OR autism* OR autistic) AND (genetic testing OR genetic assessment OR genetic risk assessment) AND (knowledge* OR awareness* OR perception* OR attitudes* OR experiences* OR utilization* OR utility* OR interest*). The final search was done on October 7, 2022, and searched literature was exported to Endnote X9.

Inclusion and exclusion criteria

Peer-reviewed articles that met all the following criteria were included in our research: (1) The targeted disease was ASD; (2) participants were either caregivers of children with ASD, adolescent and/or adult ASD patients, or health providers who provided medical services for them; and (3) the article focused on evaluating the knowledge, experiences, or attitudes about ASD clinical genetic testing. Articles were

excluded if: (1) Participants other than the target population described above were included; (2) none of the three topics of interest was covered; (3) the study focused on prenatal genetic testing; (4) the article was not written in English or Chinese; (5) the study was a review; or (6) full-text was unavailable.

Selection of sources of evidence

We first screened the searched papers by reading titles and abstracts. Then, full texts of the remaining studies were read and those that met the eligibility criteria were included for further study. These two steps were carried out by two independent reviewers. When there was non-conformity, a discussion was organized, and a senior reviewer was invited if necessary. The whole process of selection was displayed in the PRISMA flowchart (Figure 1)[37].

Data charting process

Relevant information of included papers was extracted into a charting form, including: (1) Characteristics of the study (author affiliation, country, year of publication, time period(s) of the study, study setting, sample size, sampling method, survey methods, and tools); (2) characteristics of participants (age of child at diagnosis and at survey time, financial insurance of child, relationship with ASD patients, age, gender, marital status, educational level, annual income, current employment status, number of children, number of children with ASD, and family history of ASD); and (3) main findings of the study (knowledge, experience, and attitudes concerning ASD genetic testing). The details were displayed in supplementary materials. After reading all 30 included articles and discussing them, a coding instruction was summarized by two reviewers. The data were then extracted by one reviewer and checked by another reviewer.

RESULTS

Search results

The original search yielded 483 records. After removing duplications and screening abstracts, 78 remained for full-text screening, after which, 30 records were included. Reasons for exclusion were a. inclusion of subjects other than the target population, for example, caregivers of patients with developmental disorders other than ASD, such as intellectual disability, developmental disorder (n = 16), general population (n = 16); b. not covering any of the three topics of our interest (n = 5). The process of article selection is displayed in Figure 1.

Characteristics of studies

Among the final included 30 studies, 20 (66.7%) investigated knowledge, 17 (56.7%) investigated experience, and 22 (73.3%) investigated attitudes toward ASD genetic testing. They were published between 2012 and 2022, and conducted in 9 countries, with 19 (63.3%) in United States. More than half (n = 17, 56.7%) utilized convenience sampling. Other sampling methods included purposive sampling (n = 6, 20.0%), random sampling (n = 3, 10.0%), and snowballing sampling (n = 3, 10.0%). Investigating methods included online surveys (n = 16, 53.3%), face-to-face interviews (n = 9, 30.0%), and telephone calls (n = 7, 23.3%). The most frequently used instrument was a questionnaire with open-ended questions (n = 14, 46.7%). Some instruments included both close-ended and open-ended questions (n = 7, 23.3%), or only close-ended questionnaires (n = 7, 23.3%). More details can be found in Table 1. A standard questionnaire which was defined as a questionnaire with focused themes and standard evaluating methods and could be utilized by other researchers with a similar research purpose was used in two studies—Perceptions of ASD Genetic Testing Survey developed by Zhao *et al*[38] and The Centers for Autism and Related Disabilities developed by Cuccaro *et al*[39].

Characteristics of participants

The majority of the studies (n = 29, 96.7%) investigated parents of children with ASD, including 23 (75.9%) that only covered parents, 4 (13.8%) that also covered other caregivers[27-29,31], one also included health providers[32], and 1 (3.4%) that included adolescent and adult patients[40]. Only one study investigated CAP alone[41]. The sample size of the 30 included studies ranging from 20 to 1444. Of 19 studies that provided gender information, 60%[35] to 95%[42] of the participants were female. Of 13 studies that reported the mean age of parents, these ranged from 37.4[36] to 46.7[43]. Of 8 studies that reported the marital status of parents, 81.3%[44] to 92.3%[45] were married or living as married. Of 8 studies that investigated current employment status, 51%-71.1% of caregivers were employed. Of 16 studies that provided information about the educational level of caregivers, 21.0%-69.4% had a college or higher degree. The lowest educational level of parents was reported in 2 studies that only involved parents of children with ASD who had taken CMA testing[46,47].

Age information of children with ASD was provided in some studies, including 7 (24.1%) that reported mean current age ranging from 5.2 to 16.5 years old[26,43] and 5 (16.7%) that reported mean age at diagnosis ranging from 3.0[29] to 4.7[48] years old. Among 7 studies that reported the number of

children with ASD, most families (17.8%-93.7%) had only one child with ASD, while 5.9%-17.9% of families had two or more children diagnosed with ASD. Of 7 studies that addressed family history, 10.5%-34.6% of participants had a positive family history of ASD.

Knowledge, experiences, and attitudes

Specific questions related to the three topics of interest were (1) Knowledge: perceived cause(s) of ASD, knowledge about genetics and genetic testing, pathways to acquire such knowledge, and information needs prior to genetic testing; (2) Experience: experience of being referred to genetic testing and using genetic testing; and (3) Attitudes: why participants supported genetic testing and their concerns about genetic testing; for participants who have not done genetic testing, their intention to pursue genetic testing in the future; for participants who had done genetic testing, their satisfaction with ASD genetic testing and willingness to recommend genetic testing to others (Table 2).

Knowledge of genetics and ASD clinical genetic testing among parents and other caregivers: In total, there were 7 studies that surveyed the perceived cause(s) of ASD of the parents and other caregivers. These studies found that 51.0%-100% of the them thought ASD was partly or fully explained by genetic factors, and 11.9%-12.0% thought ASD was entirely explained by genetic factors. Parents who believed that their child's ASD was permanent tended to attribute ASD to genetic factors[16]. One study reported parents' understanding of genetics: parents stated that they were familiar with and knew the meaning of DNA (94%), genes (92%), chromosomes (86%), genetic testing (87%), and CMA (21%)[39].

In addition, there were 14 studies that investigated caregivers' knowledge of genetic testing for ASD. Of seven studies that asked them whether they were aware of ASD genetic testing before the study, 17.0% to 78.1% answered yes[29,49-54]. However, one study reported that 95% of the participants said

they did not know what genetic tests can test[26]. Furthermore, in one study of participants without genetic testing experience conducted in Sweden in 2020, only 16.2% of parents and 19.6% of autistic adolescents and adults believed that genetic testing for ASD was available[40]. There were three studies from the same team using the same seven-item questionnaire about knowledge of ASD genetic testing. In this questionnaire, wrong and correct answers were scored 0 and 1, with a total score ranging from 0 to 7. The three studies were all performed among parents with children with ASD from United States in 2019. The mean score for those studies were 2.4 ± 1.2 (n = 411), 2.5 ± 1.2 (n = 552), and 2.5 ± 1.2 (n = 443), respectively[18,24,26]. Caregivers' knowledge of ASD genetic testing was positively associated with their educational level, the number of children with ASD, and socioeconomic status, and negatively related to the severity of the child's ASD diagnosis[52,54,55]. Furthermore, caregivers who had visited a genetic service and who had received information from physicians rather than other sources also had a higher level of knowledge[55,56].

In 4 studies that reported the pathways through which the parents had acquired knowledge about ASD genetic testing, 18.3%-57.7% of the participants received related information from physicians[49,50,54,55]. Other main resources include the internet or mass media (23.9%-45.7%)[50,54,55], ASD organization or support groups (12.0%-42.9%)[50,54,55], and other parents of children with ASD (17.0%-36.4%)[50,54,55]. Two studies reported what information parents wanted to know to improve their knowledge about genetic testing. This information included: accuracy of genetic testing (38% and 88.4%), cost (60.0% and 85.9%), benefits of genetic testing (48.0% and 83.8%), testing procedure (29.0% and 77.8%), eligibility to undergo genetic testing (62.4%), potential harms caused by genetic testing (29.0% and 56.1%), previous use and experience among individuals affected by ASD (50.8%), and confidentiality issues (12.0% and 48.0%)[53,55].

Experiences of ASD clinical genetic testing: Parents and other caregivers: Three (10.0%) of the 30 studies only included parents of children with ASD who had undergone CMA testing, and one only included parents who had been offered any genetic testing for their child with ASD. Among the remaining studies, 6 reported that 9.1% to 72.7% of caregivers and 2.8% of autistic adolescents/adults [40] had been referred to genetic testing, and 13 (43.3%) studies reported rates of using any type of genetic testing ranging from 17.4% in United States[29] to 61.7% in France[28]. Regarding specific types of genetic testing, fragile X testing was most widely used by parents, with utilization rates ranging from 4.4% to 39.2%[36,39,49,56]. The utilization rates of CMA and karyotype tests were 7.4%-13.1%[49,56],

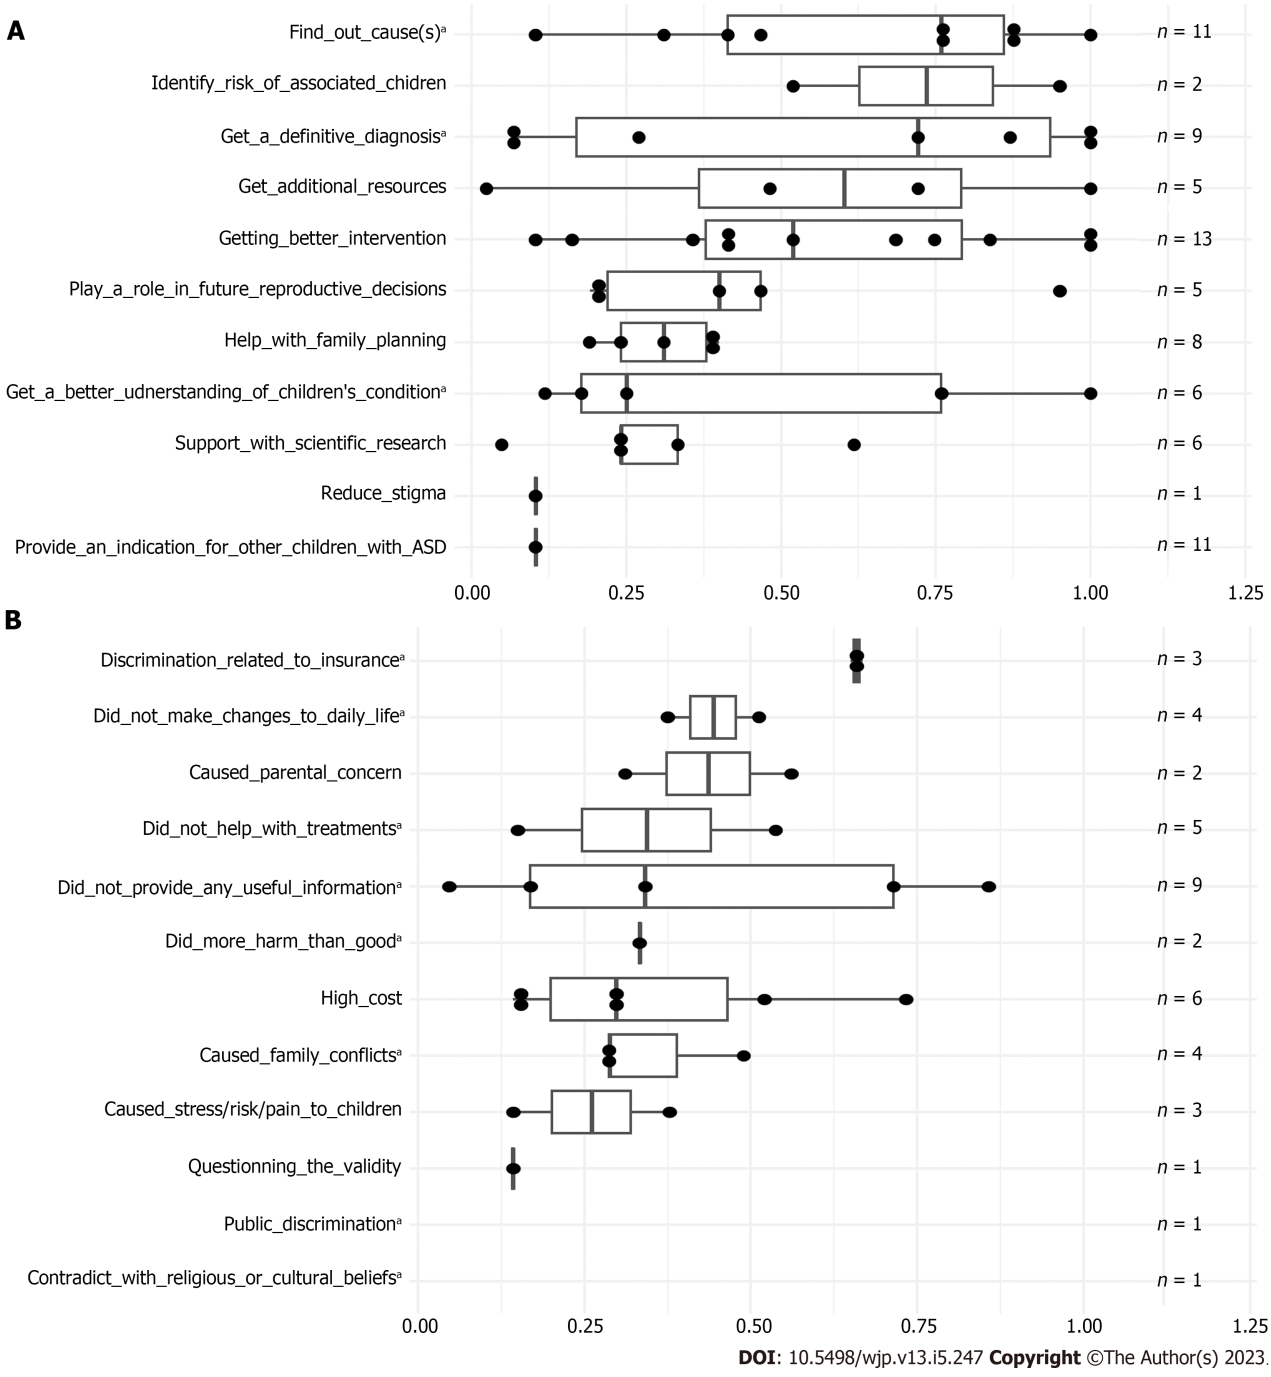
Figure 1 PRISMA flowchart.



and 0.7%-37.6%[36,49,56], respectively. Only one study in Jordan reported that the usage rate of WES was 3.3%[36]. The associated factors of caregivers' usage of genetic testing were reported in 4 studies. Those who had a higher awareness level of genetic testing[49], who received related information from healthcare providers rather than other sources[31,49], who had visited geneticists[31,56], and those with higher household income[36] were more likely to conduct genetic testing for their child.

Health providers: Only one study was of CAP and was performed in United States in 2021. It showed that 54.9% of respondents had ordered ASD genetic testing for their patients in the prior 12 mo. Psychiatrists who accepted a higher percentage of ASD cases, who had more knowledge about genetic testing and higher perceived utility of ASD genetic testing, and who were at a University medical center were more likely to request genetic testing for their patients with ASD; participants with more years of working experience tended not to order genetic testing for their patients with ASD[41].

Attitudes towards ASD clinical genetic testing: Parents and other caregivers: There were 15 surveys among caregivers which reported participants' reasons for supporting genetic testing. Reasons could be categorized into three groups: (1) Benefits for the child, including getting better intervention (n = 13), finding out the cause(s) of ASD (n = 11), getting a definitive diagnosis (n = 8), getting a better understanding of their condition (n = 6), and additional resources (n = 5); (2) Benefits for family and parents, including helping with family planning (n = 8), and future reproductive decisions (n = 5), identifying risk of associated children (n = 2), and reducing stigma (n = 1); and (3) Benefits for other people, including promoting scientific research (n = 6), and providing an indication for other children with ASD (n = 1) (Figure 2A).

Of caregivers who had taken their child for genetic testing, more than half held positive attitudes toward their experience of genetic testing, reporting that genetic testing had been helpful for their child and their family[29,46,49]. Getting additional resources (81.8%), getting a definitive diagnosis (81.8%), contributing to scientific knowledge (61.8%), identifying associated medical risks (25.0%), playing a role in future reproductive decisions (19.1%), helping with treatment planning (12.5%, 16.2%, 90.9%), gaining a better understanding of the child (10.3%), finding a cause of ASD (10.3%, 12.5%), and helping with family planning were reasons why they thought genetic testing was useful[29,31,46,49]. Two studies compared perceived benefits between caregivers, one who had taken their children for genetic testing and the other who never had. The first showed that the post-test group had more positive attitudes toward ASD genetic testing[31], the second reported less positive attitudes[27].

There were 15 studies that reported caregivers' concerns about genetic testing. They can be divided into four areas: (1) High cost (n = 6); (2) useless results: Would not provide any useful information (n = 9), would not help with treatments (n = 5), and would not make changes to daily life (n = 4); (3) negative influences: Would cause family conflicts (n = 4), would cause stress/risk/pain to children (n = 3), cause parental concern (n = 2), would do more harm than good (n = 2), and contradict their religious or cultural beliefs (n = 1); would cause discrimination when buying financial insurance (n = 3) and public

Figure 2 The support rates of potential benefits and concerns of autism spectrum disorder genetic testing. A. Potential benefits of autism spectrum disorder (ASD) genetic testing; B. Potential concerns about ASD genetic testing. Each dot represents a study and the total number of studies that report the corresponding benefit/concern is displayed on the right side of the figure. Benefits/concerns were sorted by the median of the reported support rate of the participants. [a]indicates that there are studies that only report a qualitative description.

discrimination (n = 1); and (4) other: The test had poor validity (n = 1) (Figure 2B). Four studies reported concerns of participants who had taken their child to genetic testing: lack of detailed information and did not help with further treatment and financial costs were the main reasons for dissatisfaction[26,40,44,49]. Parents' attitudes towards genetic testing were positively related to their perceived severity of ASD[57] and negatively related to their perceived barriers in conducting genetic testing[57], and parents' age and educational level[52].

There were 8 (26.7%) studies which reported that 46.7%[54] to 95%[56] of caregivers without previous genetic testing experience intended to pursue genetic testing in the future, and 2 studies showed that 50.5% and 59.6% parents who have purchased genetic testing services for their children would recommend genetic testing to other parents. It is reported that parents' willingness to pursue genetic testing for their children with ASD was positively associated with their attitudes towards genetic testing, their perception of other people's opinions, and their self-efficacy in pursuing genetic testing

[57].

Health provides: Only one survey among CAP reported why they order genetic testing for their patients. The main reason is to diagnose ASD and reported by 59.9% of those who had ordered a genetic testing in the prior 12 mo[41].

DISCUSSION

To the best of our knowledge, this is the first study that systematically reviewed caregivers', patients', and health providers' knowledge, experiences, and attitudes toward genetic testing for ASD. We searched the related literature without area and time limitations, extracted, and analyzed information from 30 studies. We found that most caregivers agreed that genetic mutations are causes of ASD and knew a little about ASD genetic testing but lacked a deeper understanding of the tests. Caregivers can obtain information about ASD genetic testing from several sources, including physicians, the internet, ASD organizations, and other caregivers of ASD patients. Most obtained information from non-professionals, although obtaining information from professionals contributes to better knowledge and more willingness to use ASD genetic testing. The usage rate of ASD genetic testing is generally low and varied dramatically among studies, even within the same country in the same year, as did the rate of being referred for ASD genetic testing by health providers. In addition, caregivers generally held positive attitudes toward genetic testing. More than half of the parents who had used genetic testing would recommend it to other parents and 46.7% to 95% of caregivers without previous genetic testing experience intended to pursue genetic testing in the future.

Although it is repeatedly reported that awareness level of genetic testing was closely associated with its usage rate and users' attitudes[41,49,56,58]. the awareness level of ASD genetic testing among both caregivers and health providers was not ideal. Most caregivers had heard a little about genetic testing, but few of them had a deep understanding. For example, less than 5% knew the diagnosis rate/yield of ASD genetic testing and the legitimate rights of children with ASD[57]. In contrast, over half of participants showed an interest in gaining more knowledge about genetic testing[55]. This indicates that caregivers generally have limited access to such knowledge. Given that a variety of methods to obtain relevant knowledge have been reported, the problem of the low knowledge levels among caregivers can easily be resolved if appropriate actions are taken.

Health providers, such as physicians and psychiatrists are key to improving the knowledge level of caregivers about ASD genetic testing because parents who acquire genetic information from them were more likely to agree to genetic testing[27,46]. However, most parents did not receive such knowledge from their health providers. For example, one study reported that only 35.3% of parents who were aware of genetic testing received information from their physicians[55]. In addition, another study, not included in our review, reported that more than half of caregivers had not received any additional information about ASD from their physicians following diagnosis, let alone knowledge about genetic testing[59]. This may be linked to lack of knowledge about screening and diagnosis of children with ASD among physicians[60]. A previous study reported that about half of pediatricians who had cared for children with ASD did not know the clinical guideline regarding genetic testing for children with ASD[61]. It is possible and of concern that physicians who know related guidelines may not comply with them. This could result in even lower usage rate of genetic testing[62]. Not receiving doctors' recommendations was also an important reason why ASD genetic testing usage rate was low[46]. Only 18% of physicians would recommend genetic testing to all children with ASD[61]. Physicians should be encouraged to learn more about genetic testing. They can also recommend genetic counseling to patients, which could help to increase parents' awareness level about genetic testing[30].

Although genetic testing is more widely approved and prices are decreasing, the usage rate has not recently increased. For example, in United States, the usage rate was 17.4% in a survey conducted in 2018, whilst four years earlier the rate was 57.1%[29,32]. The usage rate of 57.1% was reported in a survey in Washington[32]. As the capital of the United States, Washington is economically more developed than other regions in America, which contributes to a higher usage rate. The usage rate differed dramatically among different areas. The usage rate of any type of genetic testing was 19.8% in Malaysia in 2022, which was much lower than that in Spain in 2017 (51.0%) and in France in 2012 (61.7%)[28,30,56]. This might be caused by different level of economic development. Also, a study reported large difference in usage rate of genetic testing between America and France, with 27.8% in America and 61.7% in France[28]. The free access to care in France may be associated with higher compliance with genetic testing recommendations[28].

Although most caregivers agreed with the benefits of ASD genetic testing and expressed positive attitudes towards future testing, many concerns still exist which prevent them from seeking genetic testing. The most frequently reported concern was that they thought genetic testing would not provide any useful information for them and could not help with further treatment. This was also an important explanation for why they were unsatisfied with genetic testing[44]. Parents may hold high expectations, hoping test results bring a definitive diagnosis and etiology of ASD[44,49]. However, only 35% of ASD cases had genetic abnormalities, and about 80% of cases received negative results from CMA testing[25,

46]. Visiting genetic counselors should also be encouraged before and after testing to help caregivers make an informed decision, understand, and use testing results more wisely[63]. Besides, the high cost of genetic testing and lack of insurance were also important reasons why genetic testing was underutilized. A study in Jordan indicated that 72% of families reported overall costs of CMA and fragile X testing constituted over 30% of their annual income, and lack of testing resources and insurance coverage further increased the financial burden[36]. However, in the long term, genetic testing may promote an earlier diagnosis and improve the prognosis of children with ASD, consequently, saving future costs[25]. Governments are therefore encouraged to offer affordable genetic testing. For example, government-funded CMA tests are freely available for children diagnosed with ASD in Israel[25]. However, genetic testing results can cause negative emotions for parents and children. For example, some parents believed that they would be blamed or discriminated against if the ASD was verified as inherited from one of them[51], the testing procedure, especially blood draws, would make their child uncomfortable, and the stigma attached to mental illness would increase their level of stress[43,52]. Genetic counseling before and after testing is therefore necessary to minimize misunderstanding about genetic causes and psychological or marriage counseling may need to be considered to alleviate negative emotions.

There were some limitations in this systematic review. Firstly, published research was limited and mainly concentrated in United States and other developed countries. Understanding implementation of ASD genetic testing in low and middle-income countries could not be achieved from this review. Secondly, only two studies targeted health providers. Because it is one of the most effective ways to impart knowledge about genetic testing to caregivers, it is very important to understand both health providers' understanding and attitudes toward genetic testing. Furthermore, there was little uniformity in instruments used in studies lack uniformity making it difficult to synthesize and compare results.

Clinical implications

Firstly, more actions should be taken to improve the knowledge level of genetic testing among caregivers of patients with ASD. Health education through health providers, like physicians and psychiatrists, is the most effective way. Secondly, improving the knowledge of genetic testing among health providers is necessary for better utilization of genetic testing in ASD practice. Thirdly, caregivers of patients with ASD and patients themselves generally hold a positive attitude toward genetic testing. More comprehensive knowledge is needed to avoid potential misunderstandings.

CONCLUSION

The usage rate varied widely in different studies. It is mainly affected by the knowledge level of related parties. However, the review showed that although most caregivers are willing to learn about and use genetic testing, their current knowledge is limited.

ARTICLE HIGHLIGHTS

Research background

The popularity of genetic testing for patients with autism spectrum disorder (ASD) varies dramatically across countries. It is highly dependent on the knowledge, experiences, and attitudes toward genetic testing among caregivers of children with ASD, adolescent and adult ASD patients, and health providers. As a result, many related studies have been conducted worldwide but no systematic review has been done.

Research motivation

Getting a better knowledge of factors that are associated with the usage rate of genetic testing for patients with ASD has the potential to maximize the benefits of the test for patients.

Research objectives

To systematically review research on knowledge, experiences, and attitudes towards genetic testing among caregivers of children with ASD, adolescent and adult ASD patients, and health providers.

Research methods

We conducted a systematic review by searching the related literature without area and time limitations in both English language and Chinese language databases.

Research results

In 30 studies conducted in 9 countries,17.0% to 78.1% of caregivers/patients were aware of ASD genetic

testing. However, they lacked a full understanding of it. Between 9.1% and 72.7% of caregivers in different studies were referred for genetic testing, and between 17.4% and 61.7% actually obtained genetic testing. Among caregivers, 46.7% to 95.0% without previous genetic testing experience intended to obtain it in the future, and 50.5% to 59.6% of parents who previously obtained genetic testing would recommend it to other parents. In a single study of child and adolescent psychiatrists, 54.9% of respondents had ordered ASD genetic testing for their patients in the prior 12 mo.

Research conclusions

The usage rate varied widely in different studies. It is mainly affected by the knowledge level of related parties. However, the review showed that although most caregivers are willing to learn about and use genetic testing, their current knowledge is limited.

Research perspectives

Firstly, more actions should be taken to improve the knowledge level of genetic testing among caregivers of patients with ASD. Health education through health providers, like physicians and psychiatrists, is the most effective way. Secondly, improving the knowledge of genetic testing among health providers is necessary for better utilization of genetic testing in ASD practice. Thirdly, caregivers of patients with ASD and patients themselves generally hold a positive attitude toward genetic testing. More comprehensive knowledge is needed to avoid potential misunderstandings.

ABOUT COVER

Editorial Board Member of *World Journal of Psychiatry*, Lenin Pavón, PhD, Professor, Laboratory of Psychoimmunology, National Institute of Psychiatry, "Ramón de la Fuente", Mexico City 14070, Mexico.
lkuriaki@gmail.com

AIMS AND SCOPE

The primary aim of *World Journal of Psychiatry* (*WJP*, *World J Psychiatry*) is to provide scholars and readers from various fields of psychiatry with a platform to publish high-quality basic and clinical research articles and communicate their research findings online.

WJP mainly publishes articles reporting research results and findings obtained in the field of psychiatry and covering a wide range of topics including adolescent psychiatry, biological psychiatry, child psychiatry, community psychiatry, ethnopsychology, psychoanalysis, psychosomatic medicine, *etc*.

INDEXING/ABSTRACTING

The *WJP* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Current Contents/Clinical Medicine, Journal Citation Reports/Science Edition, PubMed, PubMed Central, Reference Citation Analysis, China National Knowledge Infrastructure, China Science and Technology Journal Database, and Superstar Journals Database. The 2022 Edition of Journal Citation Reports® cites the 2021 impact factor (IF) for *WJP* as 3.500; IF without journal self cites: 3.313; 5-year IF: 7.380; Journal Citation Indicator: 0.62; Ranking: 89 among 155 journals in psychiatry; and Quartile category: Q3.

Abstract

Available pharmacotherapies for autism spectrum disorders (ASD) are reviewed based on clinical and research experience, highlighting some older drugs with emerging evidence. Several medications show efficacy in ASD, though controlled studies in ASD are largely lacking. Only risperidone and aripiprazole have Federal Drug Administration approval in the United States. Methylphenidate (MPH) studies showed lower efficacy and tolerability for attention deficit hyperactivity disorder (ADHD) than in the typically developing (TD) population; atomoxetine demonstrated lower efficacy but comparable tolerability to TD outcomes. Guanfacine improved hyperactivity in ASD comparably to TD. Dextroamphetamine promises greater efficacy than MPH in ASD. ADHD medications reduce impulsive aggression in youth, and may also be key for this in adults. Controlled trials of the selective serotonin reuptake inhibitors citalopram and fluoxetine demonstrated poor tolerability and lack of efficacy for repetitive behaviors. Trials of antiseizure medications in ASD remain inconclusive, however clinical trials may be warranted in severely disabled individuals showing bizarre behaviors. No identified drugs treat ASD core symptoms; oxytocin lacked efficacy. Amitriptyline and loxapine however, show promise. Loxapine at 5-10 mg daily resembled an atypical antipsychotic in positron emission tomography studies, but may be weight-sparing. Amitriptyline at approximately 1 mg/kg/day used cautiously, shows efficacy for sleep, anxiety, impulsivity and ADHD, repetitive behaviors, and enuresis. Both drugs have promising neurotrophic properties.

Key Words: Autism; Pharmacotherapy; Dextroamphetamine; Loxapine; Amitriptyline; Minimally verbal; Neurotrophic

Core Tip: Most prescribing in autism spectrum disorders (ASD) is off-label; only risperidone and aripiprazole are Federal Drug Administration-approved in ASD, for irritability. Atypical antipsychotics are associated with metabolic side effects. Loxapine at 5-10 mg/day resembled an atypical antipsychotic in positron emission tomography studies; preliminary studies and clinical experience in ASD suggest efficacy and a promising metabolic profile. Controlled attention deficit hyperactivity disorder (ADHD) medication trials in ASD youth include methylphenidate, atomoxetine and guanfacine. The author recommends dextroamphetamine as an important treatment option for ADHD in ASD. Amitriptyline often improves impulsive aggression, self-injury, sleep, anxiety and enuresis. This article recommends additional older drug trials in ASD: Detroamphetamine, amitriptyline, loxapine, and lamotrigine for likely seizures.

INTRODUCTION

Autism spectrum disorder (ASD) is diagnosed using criteria of significant deficits in social communication and interaction, together with at least two types of restricted and repetitive interests and behaviors (RRBs)[1]. ASD develops prenatally and during early childhood. There is no longer an age cut-off for diagnosis, though it is often evident by age 1-3 years. The prevalence of ASD has risen globally since 2000. Two separate United States studies using the 2016 National Survey of Children's Health reported ASD prevalence of 1 in 40 children[2,3]. After decades there is still no definitive medication treatment for the core features of autism likely due to the heterogeneity of ASD, including various genetic causes. Recent studies with negative findings for core symptoms include oxytocin, bumetanide and selective serotonin reuptake inhibitors (SSRIs) fluoxetine and citalopram for RRBs[4]. A meta-analysis confirmed there are still no treatments with efficacy for RRBs[5].

In addition to core ASD disabilities, the majority of these individuals have other serious challenges affecting them. Approximately 30%-50% also have intellectual disability (ID)[6]. Those more severely affected for example by birth injuries may have hydrocephalus and cerebral palsy, along with varying degrees of motor paralysis. Although there is a tendency worldwide to diagnose ASD in high-functioning, milder cases, an estimated quarter of individuals with ASD have less than 20 words of expressive language and are thus minimally verbal[7]. Approximately 20%-40% of those with ASD also have epilepsy, with greater rates in the more severely affected[8], which includes minimally verbal individuals.

In addition, psychiatric illness occurs several times more commonly in those with ASD than in the general population[9,10]. Common presenting problems include hyperactivity, impulsive aggression, property destruction and self-injury, which are not Diagnostic and Statistical Manual-fifth edition-Text Revised (DSM-5-TR) diagnoses. A study of 1380 youth with ASD found that over two thirds (68%) manifested aggression towards a caregiver, and almost half (49%) showed aggression towards non-caregivers[11]. Psychiatrist training in the field of developmental disabilities is seriously lacking in most universities worldwide, and has marginally improved in the United States in the past 5 years[12,13]. Individuals with ASD and their caregivers have great difficulty identifying a provider in their geographical area who will treat them. The field still suffers from a serious lack of clinical trials to guide treatment of psychiatric comorbidity. Those providers who treat such patients must rely on the few ASD clinical trials published, experience gained by different medication trials, and extrapolation from studies in typically developing (TD) individuals.

An analysis of 33565 children with ASD, found that 35% received 2 or more psychotropic medications, while 15% received 3 or more[14]. Polypharmacy especially with antipsychotics is even greater in adults, when many non-psychiatric medications are also prescribed apart from psychotropic medications[15]. The lack of evidence base results inevitably in exposure of these individuals to repeated medication trials, an unnecessary burden of side effects, and attrition from care[16]. Individuals with ASD often have one or more comorbid DSM-5-TR diagnoses. Working DSM-5-TR diagnoses are important guides for selecting classes of medications. Diagnostic symptoms of DSM-5-TR diagnoses may be more difficult to recognize in those more severely affected, including the minimally verbal. The Diagnostic Manual of Intellectual Disabilities-2 (DM-ID2)[17] is a useful crosswalk for applying DSM-5 criteria to individuals with intellectual and developmental disorders and/or ASD. Clearly the verbal criteria for diagnoses are not used in the minimally verbal.

Only risperidone and aripiprazole are Federal Drug Administration (FDA)-approved in the United States for individuals with ASD and irritability. The few other drugs prospectively studied in

randomized controlled trials (RCTs) in ASD include methylphenidate (MPH), atomoxetine (ATX), guanfacine, the SSRIs fluoxetine and citalopram, and valproic acid[18]. Metformin, arbaclofen, lovastatin, trifinetide, 5-hydroxytryptamine7 (5-HT7) agonist ligands, flavonoids, and the dietary supplement sulfurophane amongst others, are still being studied[4]. More RCTs are urgently needed for individuals with ASD/ID. While studies continue to test possible treatments for the core symptoms of ASD, even experts frequently run out of options for the many comorbidities, after many medication trials including clozapine have failed. It may also turn out that no one drug will target and treat the core symptoms in ASD, given the vast heterogeneity of genetic and other causes.

Behavior analysis and psychosocial treatments play a key role in any overall management plan, since problems due to environmental factors or maladaptive learning will not respond to medication treatments. This article highlights several available older medications, with decades of community use in the general population, that show promise in ASD. Emerging evidence about them includes preliminary observed efficacy, neurotrophic effects and apparent tolerability in low dose.

ATTENTION DEFICIT HYPERACTIVITY DISORDER: EXISTING STUDIES AND EMERGING EVIDENCE ON OTHER OLD MEDICATIONS

Symptoms of attention deficit hyperactivity disorder (ADHD) include inattention, distractibility, hyperactivity and impulsivity. ADHD in ASD is often associated with dangerous behaviors including impulsive aggression and self-injury[19]. Prior to DSM-5, ADHD was not recognized as a separate diagnosis for individuals with ASD. Since it does not manifest in all individuals with ASD but does so in a large proportion, notably 28%-68%[20] it is now included as a separate diagnosis. ADHD is increasingly identified and treated in adults with ASD; a recent study found high rates of ADHD in 63 tertiary-referred adults with ASD screened for psychiatric comorbidity, notably 68% for lifetime prevalence of ADHD[9]. Additionally, ADHD is less likely to improve after adolescence in youth with ASD than in the general population with ADHD. In the community, inattentive-type ADHD is the most common subtype found in ASD/ID, however it is often untreated.

The hyperactive-impulsive subtype of ADHD has poorer outcomes in individuals with ASD, related to the more disruptive nature of hyperactivity as well as a greater likelihood of impulsive aggression, self-injury and property destruction[19]. Affect dysregulation, the inability to properly regulate and modulate emotions, was not included in DSM-5 as a diagnostic feature of ADHD, but is emphasized in DM-ID2 as an important feature in individuals with developmental disabilities including ASD. The authors of the DSM-5 ADHD criteria later published an article emphasizing affect dysregulation as an important part of ADHD[21]. ADHD-associated mood fluctuations present an important source of impairment especially in those with developmental disabilities and ADHD. Especially in adults with ASD, the ADHD diagnosis may be overlooked, resulting in a bipolar or borderline personality disorder misdiagnosis.

ADHD medications are important for improving learning, speech and language, and executive functions including inhibitory self- control. These medications improve affect dysregulation in ASD, which often manifests as impulsive aggression when the person is frustrated. Response inhibition of affective fluctuations such as laughing or crying is impaired in ADHD, related to executive function deficits. A meta-analysis of executive function in ASD found that broad executive function deficits remain stable and do not improve across development in such individuals[22]. Obsessive compulsive disorder (OCD) is very commonly associated as well in ASD, and could complicate treatment of ADHD with stimulants since the latter may increase anxiety in a dose-related manner[23]. On the other hand, non-stimulant ADHD medications may help reduce OCD and repetitive behaviors in ASD, although studies are still needed. Medications for ADHD can be divided into stimulant and non-stimulant drug categories.

When to try stimulants in ASD?

Stimulants are more likely to show efficacy and tolerability in higher-functioning individuals with ASD who have predominantly ADHD symptoms in contrast to cases with OCD symptoms, prominent repetitive behaviors or self-injury. In the latter group, non-stimulant medications may be a more tolerable choice. Young children with ASD often begin their first ADHD medication trials when their disruptive behavior interferes with education of themselves and others in the classroom. As with TD young children with ADHD, the first drug tried is usually the stimulant MPH, in divided doses three times a day, up to 1 mg/kg/day or less; individual responses vary.

Dextroamphetamine (DEX) immediate release (ir) merits study in ASD, according to the author's decades-long experience. DEX has double the potency and duration of action as MPH, notably 4 to 6 h. A meta-analysis comparing efficacy of stimulants in 23 controlled studies for ADHD found a modest advantage of amphetamines over MPH for treating ADHD in pediatric patients[24]. Divided doses given morning, lunch time, and a half-dose at 4 pm if needed, totaling approximately 0.5 mg/kg/day or less give good coverage, better than MPH. Overall, DEX ir produces less lunch-time appetite suppression, less anxiety and irritability than long-acting stimulants according to author experience.

Despite the current low level of evidence for DEX in ASD, clinical trials are warranted, and patient trials in the office may be beneficial.

However, MPH is the only stimulant studied so far in ASD, with findings of lower tolerability and lower efficacy than in TD youth. Large studies include a multisite study by the group Research Units on Pediatric Psychopharmacology (RUPP)[25], and a Cochrane database systematic review[26]. The RUPP study of 72 children with ASD, aged 5 to 13 years, found all low doses studied were superior to placebo for hyperactivity and impulsivity. Subjects were pre-selected for ability to tolerate a test dose of MPH for a week. Total doses, each given for a week, were 0.125 mg/kg, 0.25 mg/kg, and 0.5 mg/kg and were deliberately low in order to minimize side effects. However only 49% were responders, a rate much lower than the 75% response rate in TD children. Even the greatest effect size of 0.54 was significantly lower than that for ADHD response in TD children. Side effect rates were approximately double those found in TD children, and 18% exited the study early due to intolerable side effects. These included irritability, decreased appetite, and insomnia. Parent-rated lethargy, social withdrawal, and inappropriate speech increased significantly. There are also two small RCT studies and one multisite study of MPH for ADHD in ASD. Two small RCT studies of MPH for aggression in ASD found benefit over placebo on the Aberrant Behavior Checklist-Irritability (ABC-I) subscale[27-29]. Intolerable side effects were common in the latter study also, including mood changes, agitation and abnormal movements.

The Cochrane systematic review[26] of MPH in children and adolescents with ASD included 4 crossover studies, totaling 113 children ages 5 to 13 years; most (83%) were boys. There was a significant benefit on teacher-rated inattention but insufficient data to perform an impulsivity-outcome meta-analysis. Treatment duration for each dose of MPH was 1 wk. High-dose MPH significantly improved hyperactivity as rated by teachers in 4 studies, 73 subjects, ($P < 0.001$) low quality evidence, and parents in 2 studies, 71 subjects ($P = 0.02$), low quality evidence. Ratings were on the hyperactivity subscale of the ABC. MPH clinical usefulness is also limited by its short half-life of 2-4 h.

Of the long-acting stimulants in ASD, only one small study has been published. This small study of 24 children, mean age 8.8 years, found significant benefit of MPH-extended release in ASD[30]. However this was not a representative ASD sample, since the participants' mean IQ was 85.0 (SD = 16.8). MPH-ER may be useful and more tolerable for example in high-functioning individuals with ASD. Comparative studies of long-acting stimulants are lacking in ASD, including for irritability[31]. Long-acting stimulants were designed to take effect and wear off gradually, and to reduce side effects and rebound effects in the general population with ADHD. However, clinical observations suggest that in ASD, long-acting stimulants may have even greater side effects than immediate-release preparations, including worsened anxiety, appetite suppression, self-injury, lip-licking, nail-picking, trichotillomania, and compulsive behaviors, in a dose-dependent manner. The more severe the ASD, the more of a problem such side effects present, although studies are needed. Therefore, non-stimulant ADHD medications may be preferable in these individuals.

When to try non-stimulant ADHD medications in ASD?

As stated, non-stimulant ADHD medications are preferable to stimulants for individuals who have more severe ASD, and those who also have prominent OCD, RRBs and self-injury. These include ATX, alpha agonists and tricyclic antidepressants (TCAs). Clinical experience in ASD suggests that these medications can be added to low-dose stimulants that are partially helpful if the person is unable to tolerate stimulant dose increases due to side effects. Several clinical trials in TD individuals have found efficacy and tolerability of ATX in combination with stimulants, although such combinations are not FDA-approved[32]. A recent review compared responses between MPH, ATX and guanfacine in 9 controlled studies of 430 children with ASD[33]. MPH and ATX were superior to placebo for ADHD. Poorer response was found in more cognitively disabled individuals.

Atomoxetine (ATX)

ATX is a noradrenergic reuptake inhibitor shown to produce improvements in inhibitory control as part of executive functions. Importantly, acute ATX administration increased behavioral inhibition as measured by a stop-signal task in adult ADHD not accompanied by ASD[34] as well as in normal adults without either ADHD or ASD[35]. Author experience confirms that ATX may be a good choice for impulsive aggression in ASD including in adults and minimally verbal individuals, and for poor focus and disorganization in higher-functioning individuals. A randomized, multisite 10-wk double-blind placebo-controlled trial of ATX, with or without parent training, was performed for ADHD in 128 children aged 5 to 14 years with ASD. ATX showed greatest efficacy together with parent- training, but also the drug alone was superior to placebo[36]. Overall, tolerability was good, to a maximum dose of 1.8 mg/kg/day; mean dose was 1.4 mg/kg/day. Dosing was divided into twice-daily doses, to reduce side effects. The most common side effects were nausea, decreased appetite, early morning wakening and fatigue. Suicidal ideation and QTc changes were not found, in contrast to findings in children without ASD[37]. In addition, another acute RCT study of 97 youths with ASD treated with ATX, including open long-term follow-up, showed moderately improved ADHD symptoms and side effects similar to those found in studies of ATX in youth with ADHD but no ASD[38,39].

ATX trials are warranted in ADHD in adults with ASD, especially for impulsive aggression, based on author experience. The strategy is to "start low and go slow" while response is observed for, using divided doses of twice a day to improve tolerability and coverage. A recent retrospective study disputes the need for extra caution however and found similar responses to ADHD treatments in adults with ADHD and ASD to those found in a comparison group with ADHD but no ASD[40]. The therapeutic window may be narrower in minimally verbal and lower-functioning individuals with more severe degrees of ASD, according to clinical experience. Should behavioral worsening occur after an ATX dose increase, the beneficial response is usually recaptured by dose reduction.

Amitriptyline

Amitriptyline in low doses may be especially useful if used with caution, in comparison with other available non-stimulant medications, despite a lack of comparative studies. TCAs including amitriptyline are second only to stimulants in ADHD efficacy, although most evidence for their use in ADHD is from studies of the second generation TCA desipramine in youth without ASD. An advantage over stimulants according to this author's experience is that amitriptyline may benefit ADHD, anxiety, OCD, gastrointestinal pain, headaches, enuresis and insomnia[15]. Though currently there is a low level of published evidence, prospective studies are warranted, in the author's opinion. A retrospective chart review on amitriptyline[41] published by the author's group examined 50 tertiary-referred children and adolescents with ASD, ADHD and high rates of aggression and self-injury, who received low dose AMI (mean dose 1.3 ± 0.6 mg/kg/day) with mean trough blood level of 114.1 ± 50.5 ng/mL. Response occurred clinically in 60% of patients at the final visit, and in 82% of patients for at least 50% of follow-up visits. Importantly, 30% had failed ATX, and 40% had failed 3 or more other ADHD medication trials. Amtriptyline was used in combination with stimulants, most often low dose DEX ir, and also low dose risperidone or aripiprazole. In the low doses used amitriptyline did not cause complaints of constipation or urinary retention. Side effects included QTc increase on routine electrocardiogram, which did not halt treatment except in 3 cases with QTc > 440, behavioral activation and worsening of aggression. Prospective, randomized controlled studies of amitriptyline in ASD are warranted.

While a 2014 Cochrane review[42] of TCAs in TD youth showed no serious adverse events associated with taking TCAs, mild increases in pulse rates and diastolic blood pressure occurred. Of note is that the overdose risk with TCAs is lower in individuals with ASD since most individuals including adults with ASD do not self-administer their medications. TCAs should not be prescribed for use in chaotic households or those with a risk of overdose by a family member.

Alpha agonists

The class of alpha-agonist drugs is FDA-approved for ADHD in TD children but not in ASD. Since these drugs may benefit tics and Tourette disorder, they are usually a first-line treatment choice in such individuals. This drug class includes guanfacine, clonidine, long-acting guanfacine (Intuniv TM) and long-acting clonidine XR (Kapvay TM). An 8-wk multisite study of extended-release guanfacine in 62 children with ASD and ADHD, mean age 8.5 years, found a significant improvement in comparison with placebo. Modal guanfacine ER dose was 3 mg/day (range 1-4 mg/day)[43]. The most common side effects were fatigue, drowsiness and decreased appetite. For subjects on guanfacine, blood pressure dropped in the initial 4 wk, but returned almost to baseline by week 8. Pulse rate also dropped but remained lower than baseline at week 8. A small study of clonidine[44] examined response of 8 male children with autistic disorder in a double-blind, placebo-controlled crossover design for ADHD symptoms. While parent-rated Conner's questionnaire ADHD ratings improved significantly during clonidine treatment, teacher ratings were not significantly improved except for oppositional behavior. Side effects included drowsiness and decreased activity. Due to their short half-lives, the immediate-release preparations of clonidine and guanfacine should be dosed 3 times a day. Dosing is built up gradually while monitoring for dizziness, hypotension and bradycardia. Other side effects include weight gain, sedation and irritability.

Although alpha agonists improve attention, studies in otherwise TD youth with ADHD have shown their combination use with a stimulant medication produces greater attentional improvement than does either alone. Combination treatments of alpha agonists and stimulants are FDA-approved for ADHD in the non-ASD population, but not in ASD. Clinical experience suggests however that alpha agonists may be less helpful for ADHD symptoms in adults with ASD.

Thus in the author's opinion, DEX, ATX and amitriptyline may be useful additions to treatment options for ADHD comorbid with ASD, including in adults.

EXISTING ANTIPSYCHOTIC STUDIES, AND EMERGING EVIDENCE FOR OTHER ANTIPSYCHOTICS

Antipsychotics are used to treat psychosis as well as irritability in ASD, and are classified into two classes: Atypical/novel antipsychotics and typical/classical antipsychotics. ASD core symptoms

including odd, stereotyped talk on unusual restricted topics of interest are still often misdiagnosed as schizophrenia symptoms in everyday practice. Psychosis can also be confused with bizarre behavior related to subclinical seizures, in which case antiseizure medications may help. Psychotic disorders can be comorbid with ASD, including schizophrenia, delusional disorder, unspecified psychosis, or as a component of a major mood disorder such as bipolar disorder, major depressive disorder or schizoaffective disorder[45].

Typical antipsychotics

Typical antipsychotics block dopamine D2 receptors to alleviate psychosis or mania, but produce motor side effects including acute dystonias, extrapyramidal side effects (EPS), tardive dyskinesia and more rarely, neuroleptic malignant syndrome which can be fatal. Haloperidol was studied in early trials by Campbell and colleagues, in young children, but found to produce tardive withdrawal movements[46, 47] and further studies were halted. According to clinical experience, typical antipsychotics often have a lag time to onset of response in individuals with ASD, and increasing the dose early in treatment especially of high potency antipsychotics like haloperidol may result in extremely severe EPS and dysphagia after a while, especially more severely disabled individuals, with resulting joint contractures [16]. Low potency typical antipsychotics including chlorpromazine produce hypotension, slowing, cognitive dulling and weight gain in those with developmental disabilities as well as in the general population. Thioridazine produced QTc prolongation and is no longer marketed.

The medium-potency, typical antipsychotic loxapine blocks serotonin as well as dopamine, and in low doses resembles an atypical antipsychotic in positron emission tomography (PET) studies, but with less or no weight gain[48-50] which will be discussed in more detail below. Atypical antipsychotics were designed to overcome these motor side effects of typical antipsychotics by a different mechanism of action, notably by blocking serotonin as well as dopamine receptors, amongst others. However an unanticipated side effect of the atypical antipsychotics turned out to be weight gain, Type II diabetes and multiple other medical side effects[51], which are more severe in those with developmental disabilities. Atypical antipsychotics also produce possible motor side effects including neuroleptic malignant syndrome and tardive dyskinesia in the general population but also in ASD.

Atypical antipsychotics

Only two antipsychotics are FDA-approved in ASD, for children ages 6 years and older with irritability, notably risperidone and aripiprazole. The RUPP multisite 8-wk risperidone RCT study of 101 children and adolescents, mean age 8.8 years, found significant efficacy of risperidone *vs* placebo for irritability on the Clinical Global Impressions-Improvement subscale[52], and the ABC-I subscale[29] at a mean dose of 1.8 mg/day. Effect size was 1.2. Side effects included significant weight gain, appetite increase in 73%, fatigue in 59%, and drowsiness in 49%, as well as prolactin elevation. The greatest benefits reported by parents were for self-injury and aggression. Another larger multisite RCT study of risperidone and parent training in 124 children and adolescents ages 4 through 13 found that parent training could lessen the dose of risperidone needed[53]. Risperidone doses were a mean of 2.26 mg/day or 0.071 mg/ kg in the risperidone-only group, *vs* 1.98 mg/day or 0.066 mg/kg (P = 0.04, two-sided test) in the combination group of risperidone plus parent training.

Weight gain associated with risperidone treatment was marked, especially in some individuals in a double-blind crossover study performed by the author's group, of risperidone *vs* placebo for challenging behaviors in participants aged 6 to 65 with ID and ASD[54]. In a subset of 19 subjects over approximately a year, weight gain was as follows: Children (n = 5) ages 8 to 12 years gained 8.2 kg on average, adolescents (n = 6) aged 13 to 16 years gained 8.4 kg on average, and adults gained 5.4 kg on average[55]. Prolactin elevation is greater with risperidone than with other atypical antipsychotics. Breast development, galactorrhea and amenorrhea should be monitored[56]. It is important to monitor for weight gain and metabolic syndrome abnormalities, notably hypertension, glucose elevation, midline obesity, and triglyceride elevations. These are important predisposing factors for diabetes, stroke, myocardial infarction, and cognitive dysfunction and brain abnormalities[55]. In the author's experience, keeping risperidone doses low at or below 2 mg/day total, and splitting dosing to three times a day can help minimize weight gain. Importantly, clinical experience suggests that risperidone may be the most effective antipsychotic for self-injurious behavior.

A multisite RCT of aripiprazole in 218 children and adolescents with ASD, aged 6-17 years, mean age 9.3 years, found significant improvement in irritability in the aripiprazole *vs* the placebo group. Doses were 5, 10 or 15 mg/day in this 8-wk, parallel groups study. However, there was no protection against long-term relapse, the author agrees with this finding based on clinical practice, meaning that the efficacy may decrease over time, and increasing the dose may not recapture the initial good response. Side effects included sedation, the most common side effect leading to discontinuation, and significant weight gain[57]. Mean weight increases at week 8 were 0.3 kg for placebo, 1.3 kg for 5 mg/day, 1.3 kg for 10 mg/day and 1.5 kg for 15 mg/day groups, all $P < 0.05$ *vs* placebo. Importantly, aripiprazole in a low dose of 1 mg/day normalizes prolactin for example in an individual responding to risperidone who has elevated prolactin producing gynecomastia[58]. One small open pilot study compared olanzapine with haloperidol in children with autistic disorder[59] and one studied ziprasidone *vs* placebo[60] in ASD. Metformin for weight gain treatment with atypical antipsychotics was studied in a 16-wk, 4-center

multisite RCT of 60 children. Metformin was associated with reductions in future weight gain, notably body mass index (BMI) z-scores decreased significantly more from baseline to week 16 than in the placebo group (P = 0.003). However metformin did not alter lipid abnormalities, and gastrointestinal side effects identified included abdominal discomfort, abdominal pains and diarrhea[61] (in contrast to loxapine substitution discussed below).

Loxapine resembles an atypical antipsychotic at 5-10 mg/day

Loxapine shows promise clinically in adolescents and adults with ASD according to preliminary studies, and RCTs are warranted. This antipsychotic is a dibenzoxazepine tricyclic structure classified in the medium potency group of the typical antipsychotic class. Loxapine was designed in the 1980s to resemble clozapine but without the clozapine molecular component causing agranulocytosis. Loxapine has a history of extensive use in schizophrenia, usually at 40 to 80 mg/day (maximum dose of 200 mg/day) and may lack the marked weight gain and metabolic side effects of clozapine and other atypical antipsychotics[62]. A case report of a 10 year old female with autistic disorder who responded to loxapine 15 mg/day described its efficacy for treatment-resistant aggression and self-injurious behavior [63]. In low doses of 5 to 10 mg/day, loxapine resembles an atypical antipsychotic on PET brain studies, but lacks the weight gain and metabolic side effects[64,65]. A prospective 12-wk open trial of loxapine for irritability and aggression in 16 adolescents and adults with ASD[48], demonstrated that loxapine in low doses of 5 to 10 mg per day significantly improved irritability ratings on the ABC-I, with large pre- to post- treatment effect sizes on 4 subscales, d = 1.0-1.1. Fourteen of 16 subjects completed the study, all of whom had Clinical Global Impressions-Improvement scale ratings of Very Much Improved or Much Improved at week 12. Larger clinical trials are warranted.

A retrospective loxapine chart review, also by the author's group, of 15 outpatient adolescents and adults with ASD and irritability, illustrates the strategy of adding loxapine 5-10 mg/day, followed by extremely gradual taper of offending antipsychotics, which reversed weight gain, metabolic syndrome and insulin resistance including diabetes[49]. All those in the series had gained weight and manifested at least one other metabolic abnormality since starting on the baseline antipsychotic. Fourteen of the subjects were being treated with atypical antipsychotics and one received chlorpromazine, prior to addition of loxapine 5 to 10 mg daily, followed by behavioral improvement and then taper of the offending antipsychotic. Final loxapine dose in 12 subjects was 5 mg/day, and 10 mg/day in 2 subjects. At the time of chart review, all but one subject (93%) were Very Much Improved or Much Improved on CGI-I. Mean weight loss after an average of 17 mo (range 7 to 26 mo) on loxapine was -5.7 kg, with BMI reduction averaging -1.9. Mean reduction in triglycerides was -33.7 mg/dL (P = 0.03). Two subjects were tapered off metformin by their endocrinologists, and one person's insulin for Type II diabetes was discontinued. Weight loss did not differ in those already receiving metformin at the time of loxapine add-on (n = 4) though the numbers are small and the reader is therefore cautioned.

In a long-term outcomes chart review study, of 34 children, adolescents and adults with ASD, mean age 23.4 years (range 8 to 32 years), long-term low-dose loxapine at a mean dose of 8.9 mg/day (range 5 to 30 mg) was associated with lower rates of tardive dyskinesia and EPS than expected for a typical antipsychotic, mean treatment duration was 4.2 years[50]. Stahl[62] describes the addition of low doses of a classical antipsychotic to an atypical antipsychotic to "lead in" or "top up" the effect. Using loxapine add-on at 5-10 mg/day, the author has been able to minimize risperidone dose increases above 1.5-2 mg a day total of risperidone and this strategy appears weight-sparing.

Dysphagia and bowel obstruction associated with antipsychotics

A clinical word of caution is important regarding minimally verbal and neurologically impaired individuals treated with antipsychotics. Dysphagia is a common but often overlooked side effect of antipsychotics, predisposing to aspiration pneumonia and initiation of parenteral feeding after surgical insertion of gastrostomy tubes, which may then be life-long if the antipsychotic medications are not changed. Aspiration pneumonia is more common in those with severe developmental disabilities and minimally verbal individuals and those with cerebral palsy or quadriplegia treated with even moderate doses of antipsychotics, especially if the individual also receives concomitant cytochrome P450 2D6 (CYP2D6)-inhibiting SSRIs[66].

Substitution of the antipsychotic with other medications if needed, and gradual dose taper may allow swallowing improvement and normal eating reinstatement provided a repeat video swallow study is normal. A large study in non-psychiatric inpatients without ASD receiving antipsychotics mostly for delirium control found a significant association with aspiration pneumonia in comparison with a non-antipsychotic-exposed group[67]. The association magnitude was similar for typical and atypical antipsychotics. Also repeated ED and medical visits are commonly needed for ostomy revisions and infections. In clinical practice the problem is often magnified in individuals with spasticity by high dose anticholinergics such as baclofen or tizanidine. SSRIs that inhibit CYP2D6 may increase the effective dose of antispychotics and other medications such that small-appearing doses actually are effectively much larger. In addition, such prescribing practices often lead to severe constipation, paralytic ileus, bowel obstruction and resection in individuals with severe disabilities. The author avoids using loxapine in individuals with severe disabilities and uses low dose risperidone in divided doses instead, due to the elevated dysphagia and EPS risks.

SSRI STUDIES IN ASD; AND WHAT DRUGS MAY HELP RRBs?

SSRI studies have not demonstrated efficacy for RRBs

While SSRIs may initially appear to help anxiety, depression and compulsive behaviors they may later worsen problems significantly and produce behavioral activation, especially in higher doses, in a dose-related manner. A 12-wk RCT study of 149 youth aged 5 to 17 years with ASD treated with citalopram, dosed up to 20 mg daily (mean dose 16 mg/day) for RRBs in ASD, was negative[68]. Overall there was no change in repetitive behavior but also significant side effects occurred. These included impulsiveness, increased energy level, hyperactivity, decreased concentration, increased RRBs, insomnia, diarrhea and skin dryness and itching.

A 14-wk RCT study of 158 youth aged 5 to 17 years with ASD, treated with fluoxetine found no differences from placebo for RRBs as rated on the Child Yale-Brown Obsessive Compulsive Scale-Pervasive Developmental Disorders version[69]. Another fluoxetine RCT was also negative; Australian investigators randomized 146 youth aged 7.5 to 18 years with ASD to fluoxetine (20 mg/day if < 40 kg or 30 mg/day if ≥ 40 kg) or placebo. Any differences favoring fluoxetine were statistically nonsignificant after variables of gender, verbal abilities and baseline differences were controlled for. There was also no significant trend toward improvement on secondary outcome measures of RRBs, irritability, anxiety or global change[70]. An older, smaller RCT study of 39 youths aged 5-16 years found that a mean dose of 9.9 mg/day of fluoxetine was superior to placebo[71], however this has not been replicated. Some individual case studies and a case series suggested fluoxetine response however[72].

SSRIs are the most commonly prescribed drugs in ASD[4], although their use is not backed by study evidence. In the author's experience they may be helpful in high-functioning individuals with ASD for anxiety or depression. The Cochrane collaboration literature review of SSRIs in autism found no overall benefit in ASD, weighing positive and negative studies against each other[73]. In the author's experience, non-stimulant ADHD medications rather than SSRIs can help OCD and repetitive behaviors, including ATX and amitriptyline, this is anecdotal evidence but could be worth a try in the clinic. Many times the patient is presenting on an antipsychotic already. RRBs may relate also to ADHD symptoms, notably impulsivity, as part of a common cognitive impairment of executive function ("putting the breaks on") *i.e.* non-specific response inhibition[74]. These investigators found significant associations between repetitive speech and impulsive speech, between stereotyped behavior and overactivity, and between restricted preferences and impulsivity. This study further justifies the argument for studying non-stimulant ADHD medications for RRBs.

The TCA clomipramine reduced RRBs in one small study

Two TCAs typically targeting OCD, repetitive behaviors and hyperactivity, notably clomipramine and desipramine were compared with placebo in one double-blind study[75]. The investigators compared clomipramine to placebo in 12 subjects with autism using a crossover design, together with 12 different subjects completing a parallel trial of clomipramine *vs* desipramine. Clomipramine was superior to placebo and desipramine in reducing ratings on stereotypies, compulsive ritualized behaviors ($P < 0.05$) and anger, while desipramine was no different from placebo except in reducing hyperactivity. However in the author's experience substitution of amitriptyline for clomipramine in patients who present on clomipramine has produced greater global clinical improvements. This was an empirical observation made by the author's team in the 1990s that appears valid still today[41].

In a small cross-over study, 5 of 18 children (28%) treated with low dose fluvoxamine responded[76]. Fluvoxamine was found to benefit RRBs, maladaptive behavior, aggression and language in a small 12-wk RCT of 30 adults with autistic disorder[77]. Treatment studies of SSRIs or other classes of agents for depression and for suicidal behavior in ASD are lacking. For anxiety disorders in general in ASD, some smaller studies suggest the efficacy of citalopram, and some were positive for buspirone. One buspirone study in ASD found worsening of aggression and self-injury[78].

Maintenance benzodiazepines are avoided as a general principle in individuals with developmental disabilities, except for insomnia and as pre-sedation for blood tests and other procedures including dental work. Downsides include disinhibition effects, cognitive slowing and impairment, clumsiness, falls and injuries associated with benzodiazepine treatment.

HOW TO APPROACH ANTI-SEIZURE MEDICATIONS?

The therapeutic behavioral effects of anti-seizure medications in ASD for use other than seizures are inconclusive, according to available evidence. An RCT by the author's team of valproic acid for aggressive behavior in youth with ASD was negative, although some subjects appeared to benefit from it, likely related to the heterogeneity within ASD[79]. Another study found valproic acid to be beneficial for RRBs in ASD, however this finding has not been replicated. Worsening of behavior occurred in 4 of 13 cases[80]. Divalproex was effective for controlling irritability associated with fluoxetine treatment in ASD[81].

Clinical experience suggests a trial of anti-seizure medication such as valproic acid or lamotrigine (LTG) may be beneficial especially if seizures are known or suspected, and the presentation of behavior problems is bizarre or atypical. This pertains especially to minimally verbal individuals with severe ASD, who have very high rates of seizures, and those with a known history of traumatic brain injury.

For mood disorders

Apart from ADHD, bipolar disorder is another, much less common cause of impulsive aggression in ASD. A 25% lifetime prevalence for bipolar disorder *vs* 68% for ADHD was found in a tertiary-referred population of high-functioning adults with ASD[9]. Minimally verbal individuals may also present with bipolar-like illness however studies of this portion of the ASD spectrum are still needed. Although lithium may be helpful, anti-seizure medications are a first line of treatment for bipolar disorder in individuals with developmental disabilities.

Divalproex and carbamazepine

Mood-stabilizing anti-seizure medications including divalproex and carbamazepine are the first-line treatments for mania, mixed or rapid cycling bipolar disorder in the general population[82] as well as in individuals with developmental disabilities. Valproate/divalproex is FDA-approved for bipolar mania but not for acute bipolar depression in the general population. Divalproex can also be effective for acute mixed bipolar disorder[83]. Side effects include weight gain, polycystic ovarian syndrome, low blood platelets, alopecia, elevated liver enzymes and less often pancreatitis. In addition, divalproex can cause ASD if taken in early pregnancy[84]. Weight gain, hepatic enzymes and blood cell counts require monitoring.

Both divalproex and carbamazepine are available in extended-release formulations. Carbamazepine is weight-neutral but side effects may include nausea, vomiting, dizziness, drowsiness, dry mouth, constipation and unsteadiness. A rare but extremely serious potential side effect of carbamazepine is Stevens-Johnson syndrome, which may start as an influenza-like illness but progress to a blistering skin rash, skin peeling and death.

Lamotrigine (LTG)

LTG is the mood-stabilizing anti-seizure medication of choice for bipolar depression treatment as well as prophylaxis[85]. Apart from the vigilance needed for a serious skin rash again associated with Stevens-Johnson syndrome, and the need to start LTG slowly to try and prevent this, the longer-term profile of LTG is favorable in comparison with other anti-seizure medications. Another important use for consideration in psychiatry, according to author experience, is for suspected seizures including spells of eye-blinking, mouth movements or disorientation episodes accompanied by bizarre behavior presentations in ASD, as mentioned above.

Evidence for LTG is weaker for acute bipolar depression and rapid cycling bipolar disorder in the general population. LTG must be started extremely slowly by adding a low dose every 1 to 2 wk, and even more gradually if the individual is receiving divalproex (adding 25 mg every 2 wk), to avoid a potentially life-threatening skin rash that begins on the upper chest region. Skin rash signs include skin peeling, blistering, hives, itching and painful sores in the mouth or around the eyes. Other LTG side effects include blurred or double vision, poor motor coordination, headache, drowsiness, and difficulty thinking or speaking.

Gabapentin

Gabapentin is an add-on anti-seizure medication often prescribed off-label in psychiatry for various indications despite negative RCTs including for bipolar disorder. Rather than acting on gamma-amino butyric acid, gabapentin likely acts on calcium channels in the brain and spinal cord, and has few drug interactions since it is renally excreted. Gabapentin add-on to valproic acid and low dose antipsychotic was helpful in an open study by the author, in adults with developmental disabilities[86]. Gabapentin in divided doses 3 times a day, totaling 900 to 1800 mg a day were effective as add-on to valproic acid and low dose antipsychotic, and also in a subset replaced lithium and thus eliminated lithium side effects. Gabapentin side effects included dizziness and clumsiness; to prevent these it was started at 100 mg daily and increased slowly by only 100-200 mg per week, although prospective RCT studies are needed.

While lithium is still used in ASD, the side effects are often worse in those with developmental disabilities, and include polydipsia and polyuria (excessive thirst, drinking and enuresis) and tremor. Acute toxicity is a medical emergency requiring dialysis and intensive care units treatment, and is a greater risk in individuals with disabilities. Vomiting, diarrhea, failure to drink fluids for any reason, and certain medications including the angiotensin-converting enzyme inhibitor losartan predispose to toxicity[86].

Insomnia is very common in ASD and should not be interpreted as mania-related illness unless accompanied by other observable mania features. Another pitfall is that loud, rapid speech and outgoing personality may not be due to bipolar disorder but an enduring personality trait with a life-long history.

Anti-seizure medication-related behavioral side effects

Importantly, several anti-seizure medications while benefitting seizures may produce adverse behavioral effects. The latter may not have been considered by the neurologist if the seizures are adequately controlled. Therefore identification of such side effects by the psychiatrist is essential. Barbiturate-based anti-seizure medications including phenobarbital and phenytoin, and benzodiazepine-based medications, as well as vigabitrin often worsen behavior. Such medications may lead to an ADHD-like picture of affect dysregulation, hyperactivity, restlessness, impulsive aggression and self-injury[87]. Carbamazepine, oxcarbazepine, levetiracetam and topiramate may also worsen hyperactivity, mood or psychotic symptoms or other behavior problems. LTG and divalproex may be less likely to have behavioral side effects in adults with ASD according to clinical experience.

IN SUMMARY

Studies included followed a broad and thorough literature review of pharmacotherapy in ASD, in order to provide a clear overview of the topic as well as the author's expert opinion. For a summary of key points for pharmacotherapy in ASD (Table 1). Limitations of this opinion review include that aside from evidence-based guidelines, prescribing practices may be extremely variable, not only by country and region, but also by individual practitioners who may find other medications useful in ASD. The author has however attempted to provide a personal but balanced view overall. Regarding future drug treatments for core ASD symptoms it may not be possible for one drug to target and treat all of the many subtypes of ASD, given the many genetic and other causes. Of note is that while certain drugs such as ATX may not be available in all countries, amitriptyline is approved in many countries and is available in generic forms.

CLINICAL PEARLS GLEANED OVER MANY DECADES OF RESEARCH AND PRACTICE TREATING ALL AGES WITH DEVELOPMENTAL DISABILITIES

Environmental and emotional causes are more likely to respond to behavioral consultation: This can be key also in treatment resistance

It is important to emphasize that environmental and emotional causes of behavior problems will be more likely to respond to behavioral consultation and psychosocial interventions. Of late, there has been greater recognition of environmental contributors to psychiatric illness in the field in general. Abuse of all types is also more likely in vulnerable individuals such as those with developmental disabilities. Taking a detailed longitudinal history is essential, regarding likely environmental stressors such as family deaths or job losses, moves and staff changes leading to frustration and severe "protest" behavior problems including aggression, before making psychiatric diagnoses and trying medication treatments. Protest behaviors and use of aggression as communication are more likely especially if the individual has demonstrated consistently good functioning over one or more periods of time in their past. A developmental and childhood psychiatric history is also essential to understanding of presenting problems. Irritability can result from many non-psychiatric causes, including medical illness, lack of sleep, general frustration or unhappiness with a living situation. Treating just dimensional behavior problems, such as irritability or hyperactivity with single medications may be feasible for milder cases. As in other branches of medicine, if the diagnosis is wrong then the treatment will unlikely help.

Closer examination for ADHD and trying ADHD treatments pays off, including in females and adults with severe disabilities

This applies to ADHD wrongly diagnosed as bipolar disorder, since antipsychotics and mood stabilizers do not adequately treat ADHD-related impulsivity. This was a personal lesson the author learned early on in practice after specializing in treating this population. Females diagnosed with depression and recurrent suicidality may also respond to ADHD treatments, allowing for cautious taper off of antidepressants. Parents and caregivers often describe a person with ADHD person as "anxious" since they rarely sit still, and "moody" due to lack of affect regulation associated with easy crying or laughing spells.

DEX, ATX and amitriptyline are useful for ADHD comorbid with ASD

Impulsive aggression such as cussing, hitting, kicking, biting, pinching and running off may respond to one or more ADHD treatments if the ADHD history and diagnosis are elicited. Many adults already received treatment for ADHD as children but once transitioning services happens the ADHD diagnosis is overlooked. Although only studies in TD individuals are available as discussed above, a combination of low dose stimulant together with a non-stimulant ADHD medication such as ATX, amitriptyline or guanfacine may be needed. Low dose risperidone may also be used in combination with the ADHD

Table 1 Key points for pharmacotherapy in autism spectrum disorders

ADHD medications	Antipsychotic medications	Anti-seizure medications
Stimulants for high-functioning ASD: (1) Methylphenidate in young children; and (2) Dextroamphetamine immediate release in children, adolescents and adults is often useful	Risperidone: Especially useful for self-injurious behavior: Also useful in children for irritability and aggression in low, divided doses	Phenytoin and phenobarbital frequently worsen behavior. Replace with newer medications in consultation with neurologist
Non-stimulants for lower-functioning ASD: (1) Atomoxetine; (2) Amitriptyline; and (3) Guanfacine in low, divided doses if tics/Tourette disorder	Loxapine at 5-10 mg/day: Useful in adolescents and adults for irritability, aggression, or with risperidone as a weight-sparing strategy	Levotiracetam, carbamazepine, benzodiazepines, and others may also adversely affect behavior
For greater effect: Low-dose combination of stimulant and non-stimulant medications may be tried	Watch out for the following, especially with high-dose antipsychotics: Difficulty in swallowing or bowel obstructions in more severely disabled individuals	Gabapentin may be useful as an add-on to divalproex for bipolar disorder, instead of lithium

Selective serotonin reuptake inhibitors may reduce anxiety or depression in high-functioning individuals but are unlikely to alleviate repetitive/compulsive behaviors in autism spectrum disorders, and often cause activation and behavioral worsening. ASD: Autism spectrum disorders; ADHD: Attention deficit hyperactivity disorder.

treatments, although again only one study in the TD participants is available regarding this[88].

Two ADHD medications may be needed (stimulant and non-stimulant) possibly also together with low dose antipsychotic such as risperidone in moderate-to -severe cases with aggression. In the author's experience, ATX is frequently clinically useful for ADHD with impulsive aggression, including in more severely disabled individuals. The tolerable doses may be lower than in higher functioning individuals, although improvements may be regained if the dose is decreased again after behavioral worsening following a dose increase occurs. More studies are warranted. Amitriptyline in low doses can be extremely helpful for cases with insomnia, headaches, gastrointestinal issues, ADHD, impulsive aggression and OCD, used with caution and watching for drug interactions. Studies are warranted of amitriptyline for RRBs in ASD according to author experience.

Are RRBs part of the ADHD spectrum, and could they respond to ADHD treatments?

The study by Burbridge and coworkers[74] leading to the concept of RRBs as related to ADHD, in other words a type of motor impulsivity, may be key to guiding future studies for RRB etiology and treatments. One study found ATX was somewhat effective for RRBs in youth with ASD, which is promising[39]. No known treatment currently exists for core ASD features, likely due to the heterogeneity and many different genetic causes. Metformin, arbaclofen, lovastatin, trifinetide, 5-HT7 agonist ligands, flavonoids, cannabidiol, cannabis and the dietary supplement sulfurophane amongst others, are still being studied[4].

Risperidone remains useful in youth with severe irritability and may be helpful for self-injury; dose at ≤ 2 mg/day in divided doses

Dosing risperidone at or below 2 mg/day given in divided doses may mitigate weight gain and metabolic side effects, though individuals vary in this regard. Another author observation is that risperidone may be the most effective medication for self-injurious behaviors including self-biting, head- banging, self-hitting and others. Weight gain and metabolic side effects require monitoring.

Loxapine at 5-10 mg/day resembles an atypical antipsychotic but likely with emerging safety evidence of a more favorable metabolic profile

Loxapine is one of the main antipsychotics now used in practice by the author and several colleagues in other regions, for adolescents and adults with ASD, related to an empirical finding made over 2 decades ago and then the preliminary published studies discussed above. Addition of 5-10 mg/day of loxapine often produces significant clinical improvement in irritability and aggression, which if needed then allows very gradual taper of other antipsychotics which have caused excessive weight gain or produced too little response. While a common practice may be to follow schizophrenia guidelines and convert a treatment-resistant person to a depo antipsychotic, hoping for improved aggression control, adding loxapine, in the author's experience produces superior results overall. However loxapine is likely not suitable for more severely disabled individuals due to its potent dopamine blocking action that may cause dysphagia in them; low dose risperidone may be preferable in this setting. Olanzapine is another cause of dysphagia in those with more severe disabilities, according to clinical experience.

Gabapentin may be a useful add-on to divalproex and low dose antipsychotic if lithium is not a good choice for the individual patient

Published preliminary evidence on gabapentin add-on to valproate and low dose antipsychotic in ASD

may be useful when lithium is not tolerated due to side effects, or if lithium toxicity has already occurred once or more. Studies are needed.

SSRIs may be helpful in higher-functioning ASD for anxiety or depression, but not for RRBs

SSRIs remain the most widely prescribed drug class in ASD in the United States overall. Recent negative studies of citalopram and fluoxetine for RRBs in youth with ASD are helpful in this clarification. In many cases, high dose SSRIs worsen OCD and agitation, while gradual SSRI taper may lead to clinical improvements. Also, in cases involving SSRIs increasing the effective antipsychotic dose due to CYP2D6 inhibition, swallowing impairment and bowel motility problems may be reversed by gradual SSRI taper and medication revisions.

CONCLUSION

Existing studies in ASD are useful guides for clinical practice, but many more are still needed. Most prescribing in individuals with developmental disabilities is of clinical necessity off-label. Some older psychotropic medications with emerging evidence may extend and improve possible successful treatment options for clinicians serving individuals of all ages with ASD and severe behavior problems. Until controlled studies of these drugs become available, cautious clinical use starting with low doses and minding drug interactions may be justified. Another important focus should be alerts regarding possible ADHD with impulsive aggression, especially in females and in adults with ASD. The older medications worth trying include, but are clearly not limited to, DEX, ATX and amitriptyline for individuals with ADHD associated with impulsive aggression.

For irritability and psychotic comorbidity in adolescents and adults with ASD, preliminary published evidence and clinical experience point to loxapine in doses of 5-10 mg/day having atypical antipsychotic properties but likely with lower metabolic risk associated. For likely seizure activity associated with bizarre behaviors that is unable to be worked up *via* electroencephalogram due to lack of cooperation, LTG may be considered, especially in those with severe disabilities since they have higher rates of seizures. No medications have been identified and replicated so far to treat the core symptoms of autism, including RRBs. Drugs without demonstrated benefit for core symptoms include risperidone, oxytocin, bumetanide, buspirone, citalopram, fluoxetine, fluvoxamine and N-acetyl cysteine. While SSRIs are the most commonly prescribed drugs in ASD and may help individual patients, recent RCT studies did not show significant efficacy for RRBs in ASD, but rather a significant side effect burden including behavioral activation. Clinical trials of the older drugs discussed are warranted. All medications should be used in conjunction with other multimodal therapies including behavioral consultation, and selected for the individual patient.

REVIEW

Operational definitions and measurement of externalizing behavior problems: An integrative review including research models and clinical diagnostic systems

Lidia Torres-Rosado, Oscar M Lozano, Manuel Sanchez-Garcia, Fermín Fernández-Calderón, Carmen Diaz-Batanero

Specialty type: Psychiatry

Provenance and peer review: Invited article; Externally peer reviewed.

Peer-review model: Single blind

Peer-review report's scientific quality classification

Grade A (Excellent): 0
Grade B (Very good): B, B
Grade C (Good): 0
Grade D (Fair): 0
Grade E (Poor): 0

P-Reviewer: Chen IH, China; Nassar G, France

Received: December 27, 2022
Peer-review started: December 27, 2022
First decision: February 20, 2023
Revised: March 4, 2023
Accepted: April 20, 2023
Article in press: April 20, 2023

Abstract

Measurement of externalizing disorders such as antisocial disorders, attention-deficit/hyperactivity disorder or borderline disorder have relevant implications for the daily lives of people with these disorders. While the Diagnostic and Statistical Manual of Mental Disorders (DSM) and the International Classification of Diseases (ICD) have provided the diagnostic framework for decades, recent dimensional frameworks question the categorical approach of psychopathology, inherent in traditional nosotaxies. Tests and instruments develop under the DSM or ICD framework preferentially adopt this categorical approach, providing diagnostic labels. In contrast, dimensional measurement instruments provide an individualized profile for the domains that comprise the externalizing spectrum, but are less widely used in practice. Current paper aims to review the operational definitions of externalizing disorders defined under these different frameworks, revise the different measurement alternatives existing, and provide an integrative operational definition. First, an analysis of the operational definition of externalizing disorders among the DSM/ICD diagnostic systems and the recent Hierarchical Taxonomy of Psychopathology (HiTOP) model is carried out. Then, in order to analyze the coverage of operational definitions found, a description of measurement instruments among each conceptualization is provided. Three phases in the development of the ICD and DSM diagnosis systems can be observed with direct implications for measurement. ICD and DSM versions have progressively introduced systematicity, providing more detailed descriptions of diagnostic criteria and categories that ease the measurement instrument

development. However, it is questioned whether the DSM/ICD systems adequately modelize externalizing disorders, and therefore their measurement. More recent theoretical approaches, such as the HiTOP model seek to overcome some of the criticism raised towards the classification systems. Nevertheless, several issues concerning this model raise mesasurement challenges. A revision of the instruments underneath each approach shows incomplete coverage of externalizing disorders among the existing instruments. Efforts to bring nosotaxies together with other theoretical models of psychopathology and personality are still needed. The integrative operational definition of externalizing disorders provided may help to gather clinical practice and research.

Key Words: Externalizing disorders; Measurement; Diagnostic and Statistical Manual of Mental Disorders; International Classification of Diseases; Hierarchical Taxonomy of Psychopathology; Psychopathology

Core Tip: Diagnostic and Statistical Manual of Mental Disorders and the International Classification of Diseases have evolved as a clinical tool but with several limitations associated to the operational definition for measuring externalizing disorders. Approaches such a Hierarchical Taxonomy of Psychopathology improve the conceptualization giving a general framework for psychopathology, although providing a more complex solution for clinicians. Present review shows a lack of measurement instruments integrating new theoretical advances and clinical utility.

INTRODUCTION

The measurement of mental disorders, like any other construct, is a complex process. In addition, unlike other psychological constructs, the measurement of mental disorders can have important implications for the daily lives of people with these disorders and their relatives. Mental disorders in the externalizing spectrum [*e.g.*, antisocial disorders, attention-deficit/hyperactivity disorder (ADHD), borderline disorder] are characterized by problematic behaviors that involve the self and especially interpersonal functioning[1,2]. Thus, these disorders can impact the educational development of young people[3,4] work activity[5], and even cause problems with serious legal consequences[6,7]. Thus, the correct diagnosis of these disorders will not only allow for adequate therapeutic planning but may also affect the living conditions of those affected. In this regard, and as established by the Standards for Educational and Psychological Measurement[8], the development of appropriate measurement instruments for these disorders requires a careful process of design, application, and interpretation of their scores.

Various tests have been developed for measuring externalizing disorders and associated problem behaviors based on various operational definitions. In this respect, the Diagnostic and Statistical Manual of Mental Disorders (DSM) and the International Classification of Diseases (ICD) have been the main theoretical bases for the development of a wide variety of these measurement instruments[9,10]. However, these nosotaxies have been updated in successive editions of these manuals, leading to changes in the diagnostic criteria used to operationalize externalizing disorders. In addition, another set of tests widely used as diagnostic tools was developed outside these classifications[11,12]. One example is the Wender-Utah Scale (WURS), which uses the operational definition of ADHD based on the Wender-Utah criteria[13,14].

In parallel to the above, new theoretical approaches have emerged in recent years that address the conceptualization and classification of these disorders from a dimensional approach. Some of these models focus on personality disorders (PDs), including externalizing disorders, such as the Alternative Model of PDs (AMPD)[15] and the ICD-11 personality model[16]. Other models include PDs and other psychopathological disorders within the externalizing spectrum. These include the Hierarchical Taxonomy of Psychopathology (HiTOP) model[17] or the conceptualization of externalizing behaviors proposed in the Minnesota Multiphasic Personality Inventory (MMPI)[18]. The variety of theoretical approaches to externalizing disorders implies a multitude of operational definitions for these disorders.

Therefore, the tests used to measure them use different content. That is, each operational definition generates a test that is conceptually different from the rest, and it is necessary to reflect on the extent to which tests with different operational definitions are measuring the same mental disorders, thus allowing for a comparison of their results and applicability.

In the field of measurement, it is necessary to differentiate tests that measure externalizing disorders to obtain a diagnostic label from those aimed at obtaining a dimensional psychopathological profile. The former is most commonly theoretically based on the DSM or ICD and preferentially adopts a categorical approach. That is, they use scoring systems that allow differentiation between the presence or absence of a disorder [*e.g.*, Structured Clinical Interview for DSM (SCID)[19-21], Composite International Diagnostic Interview (CIDI)[22]] or in three or four categories according to the severity of the disorder [23,24]. Due to the parsimony and utility of categorical measures, these have been the most widely used in both research and clinical settings, being considered particularly suitable for decision-making in a multitude of contexts (*e.g.*, social, judicial, and clinical). In addition, for such instruments, it is desirable to estimate their reliability through test-retest procedures and to provide evidence of validity based on expert judgment, as well as on the sensitivity and specificity of the scores.

In contrast, dimensional measurement instruments provide an individualized profile for the domains that comprise the externalizing spectrum. Examples of these tests are the Adult Self Report (ASR)[25]; the MMPI-2[18] and the Personality Assessment Inventory (PAI)[26,27]. These profiles are determined by applying a set of items that assess facets, traits, or behaviors on dimensional scales and whose combination of scores provides the possible presence of one or other disorders. This scoring system has become more relevant in recent years due to the possibility of carrying out transdiagnostic interventions [28]. However, these dimensional instruments are less widely used in practice. This is due, on the one hand, to the difficulties in generating a diagnostic label from these instruments, while on the other hand, fewer instruments are available within these approaches, with the majority only used for assessing personality traits.

Given the issues associated with the operational definition and scoring systems of the tests, a review of the specialized literature advocates the benefit of using dimensional models, as they more adequately capture the nature of the disorders[29-31]. However, it should not be forgotten that, to date, clinical practice is strongly associated with using categorical diagnoses. In this sense, some authors propose the need to adopt a hybrid conception, according to which it is possible to use tests with dimensional scores but indicating cutoffs that allow for identifying the presence or absence of a disorder[32-34]. While this approach can be practical and useful, when applying such instruments we should not overlook the impact on measuring the disorder in terms of content validity. With this in mind, this paper aims to review the theoretical frameworks underpinning the operational definitions used in the design of tests that assess externalizing disorders along with the most frequently used tests and their various implications. Finally, a proposed operational definition for a test is presented that integrates different theoretical perspectives, with the aim of achieving conceptual equivalence.

OPERATIONAL DEFINITIONS FOR MEASURING EXTERNALIZING BEHAVIORS

The specialized literature review reveals the existence of multiple and diverse theoretical frameworks that have helped to develop tests to measure externalizing disorders or problem behaviors. The analysis of operational definitions allows us to differentiate between those that use the criteria specified in the DSM and ICD diagnostic classification systems and another set of tests that use operational definitions based on other psychopathological models. In addition, the analysis of these definitions allows a better contextualization of the utility and relevance of each measurement instrument. The main theoretical frameworks used, and their operational definitions are discussed below.

Operational definitions based on the DSM/ICD classification systems

The DSM/ICD classification systems have generated versions with varying degrees of modification in their diagnostic criteria. From the first versions of these nosotaxies in the 1950s to the current DSM-5 and ICD-11, it is possible to identify three main stages concerning the definition of mental disorders, which have affected the operational definitions of the tests developed: (1) A first stage in which disorders were conceptualized through brief clinical or phenomenological descriptions (DSM-I and DSM-II, and ICD-6 to ICD-9); (2) A second stage that involved a paradigm shift, such that disorders are operationalized through the presence of a given number of diagnostic criteria (DSM-III to DSM-IV-TR, and ICD-10); and (3) Finally, a third stage characterized by the incorporation of diagnostic criteria and traits to be assessed in dimensional terms, particularly in PDs.

In the first stage, an analysis of the first versions of the ICD-6[10] and DSM-I[9] nosotaxies has revealed that the categories included in these diagnostic systems did not include operational definitions *per se*. ICD-6 aimed to serve as a statistical classification system rather than a diagnostic system, incorporating only the different categories and associated numerical codes, while the DSM-I provided brief clinical descriptions characterizing each disorder. The assessment and measurement of the disorders were based on the judgment of the clinician or researcher who relied on the descriptions

provided by DSM-I. Concerning the disorders, ICD-6 included 26 diagnostic categories, grouped into three major groups: Psychosis, psychoneurotic disorders, and disorders of character, behavior, and intelligence. These categories were maintained in the ICD-7 version[35], except for corrected errors. The descriptions provided in the DSM-I were based on psychodynamic etiologies resulting from the prevailing American trend at that time. In this sense, the DSM-I defined disorders as "reactions", emphasizing that the subject's maladaptation to environmental stressors could be the cause of the mental disorder.

The ICD-8[36] and DSM-II[37] versions introduced changes to increase their systematicity. Specifically, ICD-8 provided a glossary of descriptions of the diagnostic categories, and, as in DSM-II and ICD-9[38], the descriptions are incorporated directly into the diagnostic categories. Including these descriptions favored the development of instruments for measuring disorders, providing the first operational definitions. In addition, it should be noted that among the two nosotaxies, some categories were unified, which led to a convergence in the measurement of disorders using both classification systems.

In summary, this first stage comprises the versions ICD-6 (1948), DSM-I (1952), ICD-7 (1955), ICD-8 (1967), DSM-II (1968), ICD-9 (1975), characterized by the absence of a definition based on operational criteria. However, each new version shows a tendency toward greater categorization and specificity. This was evidenced by an increased specificity of the recognized mental disorders collected in multiple subdivisions of the disorder categories (*e.g.*, eight new alcoholic brain syndromes were defined). Moreover, the definition of mental illness was broadened to include not only the more severe extremes of psychopathology but also milder symptoms that might be observed in the general population and not exclusively in the clinical population.

The fact that measurement was left completely open to interpretation by the clinician limited the use of early versions of the nosotaxies for systematically measuring mental disorders. Criticism soon emerged against the absence of criteria, the use of diagnostic labels without an identity of concepts, and poor reliability of clinical judgment due to interpretative ambiguity arising from the narrow definitions [39-41]. It is not surprising, therefore, that measurement instruments for mental disorders in this early stage were scarce in the literature. A bibliographic search in the Pubmed and PsycInfo databases with the keyword "assessment", confined to the years corresponding to these editions of the classification systems (between 1948, year of publication of ICD-6, and 1980, year of publication of DSM-III), reveals, firstly, the non-existence of diagnostic instruments based on the first versions of the DSM and the ICD. The existing instruments at this stage (*e.g.*, Assessment of Personality[42]) offer measures framed within psychopathological models far removed from these nosotaxies. In the words of Mayes and Horwitz[43], large-scale clinical research based on these versions of diagnostic systems was impossible since the lack of reliable diagnostic categories in the manuals prevented replication by researchers.

The beginning of the second stage of establishing definitions of disorders from nosotaxies was marked by the publication of DSM-III[19]. This version constituted a shift in the psychiatric paradigm of classification systems[44] and thus in the definition of disorders. Advances in psychometrics were applied to psychiatric assessment, leading to a tendency towards quantifying disorders through tests, rating scales, and checklists, which became a standard in mental health research and practice. In turn, the declining use of psychodynamic paradigms led to the abandonment of psychodynamic terms and etiologies, which were difficult to measure psychometrically[45-47].

To a large extent, the operational definitions proposed in this second stage aimed to achieve reliable and valid diagnoses from a metric perspective. To this end, expert consensus was used to define the diagnostic criteria[48], which were used to operationally define the tests. However, it should be noted that the delimitation of diagnostic criteria followed a descriptive approach as opposed to biological or psychological models. Therefore, this conceptualization has been described as atheoretical, its aim being to describe signs or symptoms without proposing explanations or etiological models[45,49]. Furthermore, it is worth noting the polythetic nature of the criteria included in the diagnostic systems of this second stage. That is, the operational definition encompassed criteria in which no particular one was necessary but instead required a combination of various criteria from a defined set. Consequently, the measurement of disorders derived from this scoring system made it possible for two people to obtain the same diagnosis despite being phenotypically different based on their diagnostic criteria.

Another noteworthy aspect from a psychometric perspective is that, at this stage, the diagnostic criteria refer to a level of impairment or dysfunction of individuals. That is, thresholds are implicitly set for deciding whether the presence of a symptom generates significant distress and impairment for individuals and their context[50]. However, an individual assessment of each clinician and researcher was used to determine the level of impairment, and therefore it was open to interpretation and subject to ambiguity depending on who made the diagnosis. In any case, the inclusion of this assessment showed the need to differentiate between normal and pathological[51]. Consequently, on the one hand, measures of functioning began to emerge that sought to operationalize and measure the term dysfunctionality to support a clinical judgment of the level of impairment (*i.e.*, Health-Sickness Rating Scale, Global Assessment Scale). On the other hand, these scales - which initially appeared independently of the classification systems - were subsequently adopted by them. Thus, from DSM-III-R[52] onwards, the Global Assessment of Functioning Scale[53,54] and the Global Activity Evaluation Scale were incorporated as a measure of functioning in axis V of DSM-IV[55]. In the case of the ICD, dysfunc-

tionality was measured through the incorporation of the World Health Organization Short Disability Assessment Schedule[56], included in axis II of the Multiaxial Adult Version of the ICD-10 version[57]. On the other hand, symptoms were identified that caused clinically significant distress to individuals. However, they did not have a syndromic entity *per se,* leading to the emergence of the category "not otherwise specified".

Finally, from a psychometric standpoint, it was also important to organize externalizing disorders into different sections. Thus, impulse control and substance use disorders were included in one group (Axis I), while PDs (narcissistic, histrionic, paranoid, borderline, and antisocial) were included in Axis II [52,58]. This separation of disorders has repercussions for the operational definition of the disorders, considering PDs as a different entity from other psychopathological disorders, thus using different terms to definition one or the other section. Axis I disorders were mainly defined based on symptoms or signs. In contrast, Axis II disorders were defined on the basis of traits, the latter being considered more stable psychopathological attributes. As a result of this approach, tests based on nosotaxies are also distinguished according to whether the items assess symptoms (psychopathology) or traits (personality).

While this conceptualization of externalizing disorders and behaviors has had many positive consequences for their measurement, it also has limitations in psychometric terms. The World Health Organization pointed out that the definitions proposed in the ICD-10 version did not provide sufficient information for a reliable implementation of the diagnoses in the clinical context[59]. Therefore, to improve diagnostic reliability, several guidelines were published providing definitions and instructions for establishing diagnoses (Clinical Descriptions and diagnostic guidelines[59] and Diagnostic Criteria for Research[60]). In addition, diagnostic interviews incorporated as items transcriptions of the diagnostic criteria for nosotaxies, including indications on the inclusion or exclusion of diagnoses.

Finally, it should be noted that despite attempts during this stage to unify criteria between the different nosotaxias emerging from the World Health Organization and American Psychological Association, some authors argue that only a very small proportion of these categories are similar[61]. Consequently, diagnostic tools derived from these classification systems may provide a clinical diagnosis with a similar label, albeit based on different operational definitions.

The third stage in the operational definitions of nosotaxias is found in the recent DSM-5[15] and ICD-11[16] versions. Here, the changes in the conceptualization of the disorders mark the beginning of a paradigm shift in the operational definitions of the disorders. On the one hand, both versions aim to improve the clinical utility of the diagnostic criteria and to ground existing etiological and neurobiological research in the definitions of disorders, thus providing a theoretical framework for their classification. Similarly, one of the main changes was to introduce emerging evidence in favor of dimensional models into the conceptualization of psychopathology. In this sense, changes have been made concerning substance use disorder that affect its operational definition, unifying the concepts of abuse and dependence. In addition, some diagnostic criteria have been eliminated, while new criteria have been incorporated. There has been a shift from a categorical to a dimensional diagnosis, where the addition of diagnostic criteria has repercussions for diagnosing the severity of dependence. Likewise, changes affecting the operational definition of ADHD have also been noted, primarily the need to present fewer symptoms to diagnose ADHD in adults.

However, the main changes observed in both nosotaxias are associated with PDs. Although the DSM-5 proposes a diagnostic approach that maintains the DSM-IV criteria to preserve continuity with clinical practice, it also includes in a final section (section III) an AMPD that defines two criteria for the identification of PD. Criterion A establishes the need to assess personality dysfunction, while criterion B assesses 25 facets and traits organized into five more general personality domains, providing the typology of that dysfunction. The assessment of the 25 facets allows delineating a dimensional psychopathological profile, and the identification of elevation in certain facets indicates the presence of a PD. In this section III, we shift from defining ten PDs to six, of which three could be framed within the externalizing dimension (namely, narcissistic, antisocial, and borderline, as well as a trait-specified PD in the manner of PD not otherwise specified). While section III of the DSM-5 specifies which facets would indicate the presence of a PD, it does not unequivocally state the pathology threshold for each of the facets assessed. The combined assessment of criterion A and criterion B establishes the presence of PD and profile typology, respectively.

ICD-11 also eliminates the categorical diagnoses of PD, incorporating a continuous measure based on the assessment of personality domains. Like the DSM-5's AMPD, ICD-11 PD is operationalized according to two measures: A measure of personality functioning (severity of personality dysfunction) and another measure characterized by five general traits or domains. The combination of these two measures establishes the presence of the disorder. From a metric perspective, the measure of personality functioning (criterion A: Level of personality functioning for DSM-5 and severity of personality dysfunction for ICD-11) aims at establishing a threshold to differentiate normality from psychopathology. According to DSM-5, criterion A is operationalized according to two broad dimensions: self (identity and self-direction) and interpersonal functioning (empathy and intimacy). ICD-11, on the other hand, incorporates a functioning criterion focusing on harm to others and occupational roles to establish the diagnosis of PD on a continuum of severity[16]. Including the functioning measure in both models is conceptually significant, implying that the presence of an extreme trait would not necessarily be

pathological if dysfunction is not identified.

Similarities are also found in the operational definition of traits/domains offered by the ICD and DSM dimensional personality models. Both models identify five major domains, of which they share four in common. While the AMPD defines the domains of negative affect, detachment, antagonism, disinhibition, and psychoticism, the ICD-11 defines the domains of negative affectivity, detachment, dissociality, dishinibition, and anankastia. However, there are also differences between the two systems. The AMPD operationalizes its dimensions into 25 facets and traits, the combination of which generates personality profiles defining the disorders. However, the ICD-11 considered that this information added unnecessary complexity to the classification[62], so the definition is operationalized at the level of dimensions but not facets. These differences have implications from a metric point of view. Thus, tests from the AMPD model offer a measure of the domains based on the 25 facets to define the disorders. In contrast, those tests that assess according to the ICD model offer only an interpretable measure of the domains. Consequently, the degree of operationalization for test design is greater when applying the DSM-5 AMPD model than the dimensional diagnostic model arising from the ICD-11.

Concerning these models, it should be noted that despite the distinction between the measurement of the level of functioning and the measurement of the traits/domains, the specialized literature has revealed the controversy generated by this distinction. On the one hand, some authors point to an overlap between these two criteria, assuming that assessing pathological traits and facets is an implicit measure of pathological functioning[63,64]. Indeed, psychometric studies based on factor analyses indicate that measures of criterion A and criterion B cluster into common factors when both measures are included in factor analysis[64,65]. On the other hand, this overlap is explained based on the high correlations between dysfunction and pathological traits. Along these lines, some authors argue that the four lower dimensions of criterion A (identity, self-direction, intimacy, and empathy) were conceptualized as indicators of the general dimension of dysfunction[66] and therefore, only one general measure could be used.

On the other hand, the empirical results show a distinction concerning how each criterion A subdimensions are grouped with certain criterion B domains. Specifically, measures of self-functioning are grouped with the negative affect and detachment domains, while measures of interpersonal functioning load on the same factors as measures from the disinhibition and antagonism[63,67,68] domains. Thus, the overlap could be a manifestation of how PTs are expressed and associated with a continuum of severity and how this severity could have a greater impact on an interpersonal or self domain[66,69].

Operational definition of externalizing behavior proposed by HiTOP

The delineation of diagnoses based on diagnostic systems has raised several criticisms[30,70]. Such criticisms include the possibility that the high comorbidity observed between some disorders could reflect, from a metric point of view, a lack of specificity in the diagnostic criteria. This lack of specificity could impact tests based on these classification systems. In addition, the low diagnostic reliability of various diagnostic categories has been highlighted along with the arbitrary nature of the thresholds established to determine a behavior or pathological trait[71,72]. These criticisms are coupled with neurobiological evidence showing that psychopathology is not distinct from normality[30,73,74].

Consequently, other models and taxonomies are emerging that address psychopathology in a cohesive manner, encompassing externalizing personality and behavioral disorders. Possibly one of the most widely supported theoretical models is the HiTOP[17]. This model has introduced several changes: (1) It proposes a hierarchical structure of psychopathology; (2) It adopts a dimensional definition of symptoms, facets, and disorders; and (3) It integrates personality and psychopathology into a single model. The implications of these changes concerning test design are discussed below.

First, the HiTOP[17] defines a general psychopathology framework through a hierarchical structure. Thus, the model specifies (at the lowest level) a set of symptoms and components (*e.g.*, hostility, inattention). These are grouped into syndromes and disorders at the middle level of the hierarchy (*e.g.*, substance use disorder, antisocial PD) and, in turn, are organized into higher structures or spectra (*e.g.*, externalizing spectrum, internalizing spectrum) - that encompass disorders with a common etiology. Finally, at the top level of the hierarchy, a general psychopathology factor (p-factor) is defined that groups the remaining spectra (internalizing, externalizing, and thought disorder)[17]. This hierarchical structure aims to reflect the possibility that different disorders may have common etiological factors[73,75-77]. Therefore, the definition of higher levels is intended to provide an explanatory framework for the co-occurrence of disorders by grouping those disorders with higher co-occurrence into a single factor.

This conceptual advantage poses, however, some challenges in relation to the development of instruments within this approach. On the one hand, the grouping of lower-level facets and symptoms into general factors through a bottom-up approach has been developed on the basis of existing structural evidence in the literature, such as that obtained regarding the AMPD. This evidence, however, is inconsistent[78,79] with certain facets being interstitial (located in more than one domain) and others located in the wrong domain (facets with factor loadings in domains not defined in the models). Moreover, these inconsistent findings have also been noted in other parts of the model[80,81] making it difficult to translate them into a unified operational definition. Moreover, it is also important

to note that the hierarchical structure of the HiTOP implicitly assumes that higher-level latent factors (*e.g.*, internalizing) are the cause of covariation between lower-level symptoms (*e.g.*, fatigue, anhedonia), but the model is unable to represent direct relationships between lower-order elements (*e.g.*, fatigue may lead directly to anhedonia)[82]. These relationships, for example, are better captured through newly emerging network models[83,84]. Finally, it is important to determine at which level of the hierarchy operationalization occurs so that assessment of different components of the same level shows equivalent specificity or generality[85].

The second element of HiTOP with implications for the measurement of disorders is related to the conceptualization of disorders as a continuum from normality to pathology and defines a set of dimensions at all levels of the hierarchy. This dimensionality at the lower levels allows us to account for the variability of patients within the same disorder[30,86] and simultaneously aims to solve the problem of arbitrariness in the pathological thresholds. From a measurement perspective, adopting a dimensional approach increases the reliability of the measure and is shown to be a better model for explaining and predicting the chronicity of disorders[82]. However, this element also poses some measurement challenges. On the one hand, such a model is intended to be applied in the clinical setting and thus should facilitate clinicians' decision-making regarding administration of treatments or determining the time of discharge. On the other hand, for these decision-making processes, there is still a need to establish cutoff points to assist clinicians. According to the authors of the model, while diagnosis is oriented toward profiling the severity of a patient's symptoms, these thresholds can be established according to empirical evidence[28]. Although these cutoff points have begun to be defined for some parts of the model[87] many other parts still lack such guidance. Another alternative for interpreting HiTOP-compliant measure scores is to use normative data that transforms a patient's score into standardized scores[28]. However, it should be noted that many studies have been conducted with community samples, thus excluding those scores that fall within the pathological range. When interpreting a patient's score, this could be problematic.

The third relevant aspect of HiTOP for the operational definition of disorders concerns the integration of available structural evidence on psychopathology and personality[28,86,88-90]. Thus, personality and conduct disorders would fall under the same explanatory framework, eliminating the differentiation between personality and psychopathology. However, this aspect could be problematic, considering the time frame used for assessing symptoms and signs[90]. While personality facets (*e.g.*, Callousness) are conceptualized as stable characteristics and traditionally include broad assessment timeframes, behaviors or symptoms are understood as evidence of a person's one-off state (*e.g.*, Substance use, assessed with a shorter timeframe). Grouping personality facets and behaviors in the same model is challenging when assessing different time frames. This is especially relevant as different spectrums of the HiTOP taxonomy would be operationally defined to a greater extent by symptoms, while for others this is traits or a combination of both[85].

Concerning the structure of the externalizing spectrum, the HiTOP model, in its original version[17] proposes a definition according to two separate dimensions: Antagonistic externalizing and disinhibited externalizing. While the former includes aggressive traits and behaviors (especially in interpersonal contexts), disinhibited externalizing groups together traits and behaviors that manifest difficulty in controlling impulses. The operationalization of the externalizing spectrum in these two dimensions is supported by the replication of this structure in several previous models, albeit with different descriptive labels[91-93]. In addition, after the publication of HiTOP, this structure has received support from factor analyses and meta-analyses[89,94]. Furthermore, according to the model, taken together, these two dimensions - externalizing antagonism and disinhibition - contribute toward explaining antisocial and aggressive behavior[90].

The authors proposing HiTOP have worked along two lines concerning measurement. On the one hand, they have provided a list of previously available instruments that offer a HiTOP-compatible measure[17,85]. Within the externalizing spectrum, the Externalizing Spectrum Inventory (ESI)[74] stands out among the recommended instruments, as this instrument provides the most comprehensive - although not complete - measure of the two dimensions of the externalizing spectrum. On the other hand, the Measures Development Workgroup of the HiTOP is currently developing instruments specifically designed according to the model. Unfortunately, no measure is yet available, although Mullins-Sweatt *et al*[90] reviewed the externalizing facets that serve as an operational definition for a proposed externalizing spectrum measurement instrument.

INSTRUMENTS FOR MEASURING DISINHIBITED AND ANTAGONISTIC EXTERNALIZING DISORDERS

It has previously been shown that there are various ways of operationalizing the externalizing constructs associated with the problem behaviors that are central to this study, focusing on nosotaxias and HiTOP as the most valid classification systems. However, a specialized literature review shows that there are still more existing measurement instruments for externalizing problem behaviors. After reviewing these instruments, we would like to point out several aspects. First, many published tests and

scales do not clarify the underlying operational definitions. This inadequacy may be due to the authors' negligence or aspects associated with editorial policies. In either case, failure to specify operational definitions results in a lack of specificity regarding the measured constructs. Another aspect that the authors noted in their review was the inconsistent use between the application of the psychometric techniques and the evidence they intended to provide. For example, there is an indiscriminate use of the factor analysis technique (in its exploratory, confirmatory, or exploratory structural equation modeling variants) to determine the structure of an instrument without conceptually delimiting the underlying theoretical structure. Consequently, we have observed how authors eliminate items with factor loadings below a specific arbitrary threshold[95,96], correlate item errors to improve fit indexes[97-99], or establish cross-loading without reflecting on the impact on the test content validity[99]. Finally, we would like to warn that the availability of a large number of tests, as is currently observed, most likely results in atomization in the measurement of these constructs, which is counterproductive for making progress in acquiring knowledge of these mental disorders. Given this, efforts should focus on targeting fewer instruments that are rigorously developed and versatile in their applications.

The following is a brief description of various interviews and tests available in the specialized literature that allow the measurement of externalizing problem behaviors. The selected instruments listed respond to their impact concerning their use in scientific publications and their clinical interest. Moreover, considering the large amount of psychometric evidence available, the authors have chosen to describe only and exclusively those metric aspects most directly associated with their underlying operational definition.

Instruments with diagnostic targets developed from the DSM and ICD

Diagnostic interviews to assess different disorders: Instruments that make clinical diagnoses are usually based on the DSM and ICD nosotaxias. Therefore, these diagnostic classifications form the basis for the operational definitions of these tests. These instruments provide a categorical scoring system that determines the absence or presence of a disorder. They are usually structured or semi-structured interviews whose items largely reproduce the wording of the diagnostic criteria that appear in the above nosotaxias. These items are often accompanied by clarifications to assist clinicians in the scoring process.

For the most part, changes in the diagnostic criteria of the different versions of the ICD and DSM have been reflected in updated versions of these structured and semi-structured interviews through modifications to their items. Considering the diffusion in their administration, the main structured clinical interviews that measure mental disorders - and therefore include externalizing disorders associated with problem behaviors - are the SCID-5[20,21] the CIDI[22], the Mini International Neuropsychiatric Interview (MINI)[100], Psychiatric Research Interview for substance and mental disorders (PRISM)[101] and the Schedules for Clinical Assessment in Neuropsychiatry (SCAN)[102]. However, there are differences between these interviews. The SCID, PRISM, and MINI interviews use the DSM diagnostic criteria to diagnose disorders, while CIDI and SCAN allow diagnosis from both nosotaxias. Moreover, there are also differences in the level of structuring of the interviews. This is why the skill level of those administering the interviews is relevant for obtaining reliable and valid diagnoses - the less structured the interview, the greater the need for interviewers to be adequately trained.

The SCID is an interview that highlights the distinction between the assessment of psychopathological disorders and PDs, publishing separate versions for both disorders[19-21]: SCID-I for DSM-IV Axis I disorders and SCID-II for DSM-IV Axis II. The changes introduced in the DSM-5 have been transferred to this diagnostic interview, developing the SCID-5-CV for psychopathological disorders and the SCID-PD for PDs. Concerning the disorders of concern in the present work, the SCID-5-CV is administered to assess substance use disorder and ADHD. The SCID-5-PD is administered to measure histrionic, narcissistic, borderline, and antisocial PD.

The CIDI[22] is an interview developed by the World Health Organization which has subsequently been updated[103,104], giving rise to the different versions of this structured interview. From a metric perspective, the latest version of this interview provides an evaluation according to DSM-IV and ICD-10 criteria. However, its items are not a translation of the diagnostic criteria of the nosotaxias. Among its distinctive features, it should be noted that this interview includes questions on general health followed by those associated with the diagnosis. These questions are designed to provide a screening tool that reduces the administration time of the instrument and limit interviewee fatigue, thus improving the validity of the information obtained. It also includes scales on clinical severity and impairment to determine whether the symptoms experienced by respondents produce clinically relevant distress.

The MINI is a structured interview aimed at screening for the presence of disorders[100]. It primarily focuses on measuring internalizing disorders. Among the externalizing antagonistic and disinhibiting disorders, the MINI plus version includes the assessment of substance use disorder, ADHD, and antisocial PD. The latest version of the MINI adapted to DSM-5 (MINI-7.0.2) does not include the assessment of ADHD. For measuring the disorders, the items of this interview are worded very similarly to the DSM-5 diagnostic criteria and its scoring system also reproduces that indicated in the DSM-5 for each disorder. Due to the lack of in-depth exploration of the possible presence of mental disorders, the MINI is considered primarily a screening interview.

The PRISM is a semi-structured interview designed to improve the reliability and diagnostic validity of psychiatric disorders in patients with substance use disorder[101]. This is because these patients mimic numerous symptoms present in other mental disorders[105]. Therefore, providing an instrument to identify when mental disorders are primary and induced by substance use was considered relevant. From a psychometric perspective, therefore, this interview aims to provide high specificity in diagnosing the disorders assessed. However, due to the detailed exploration involved in this interview, its duration is long. For this reason, computerized versions have been developed to reduce administration time. There is currently a version of the PRISM adapted to the DSM-5[106].

Substance use disorder specific assessment instruments: The assessment of substance use disorders based on the diagnostic systems is mainly achieved through the diagnostic interviews mentioned above. In addition to these, other diagnostic interviews and scales specific to substance use disorder have been shown to be useful for diagnosis.

The Substance Dependence Severity Scale (SDSS)[107,108] is a semi-structured diagnostic interview specifically used for substance use, whose items allow a diagnostic assessment according to DSM-IV and ICD-10 criteria. A Spanish version evaluates substance use disorder according to DSM-5[109,110]. This instrument consists of 16 items that operationalize the 11 diagnostic criteria proposed in the DSM-5. The items of the SDSS can be sectioned into two parts: A screening section and another section that assesses the severity of the substance use disorder. One of the characteristics of this interview is that, although it is guided by diagnostic criteria, it conducts the assessment using a time frame of the previous month, as opposed to the last 12 months used by the classification systems. This time frame is motivated by the search for the sensitivity of the scores to detect changes in patients[107,108]. To be congruent with making the diagnosis according to DSM criteria and to make the scores sensitive to changes in patients, a scoring system has been designed which is compatible with the DSM diagnostic procedure, which, in addition, provides a continuous score.

Problems associated with substance use have also been assessed employing other instruments which, although based on the diagnostic criteria of nosotaxias, do not pursue a diagnostic purpose as such. One such instrument is the Severity Dependence Scale[11]. This brief 5-item self-administered scale provides a severity score for drug dependence and is designed to measure the psychological aspects of dependence experienced by drug users. To this end, its items focus on measuring compulsive drug use, the individual's worry and anxiety about their own drug use, and feelings of impaired control over their drug use. Thus, although its items are based on the diagnostic criteria for nosotaxias, not all diagnostic criteria are operationalized in this instrument. This scale has been studied by adapting it to different drugs, and studies have confirmed its psychometric properties in users of heroin, cocaine, and amphetamine[11] alcohol[111], marijuana[112,113] ketamine[114] and codeine[115]. The Short Alcohol Dependence Data Questionnaire[116] assesses the severity of alcohol use disorder through 15 self-administered items. These items focus on measuring drinking habits and the physical and mental effects of drinking. Another scale that allows an assessment of alcohol consumption is the Severity of Dependence Questionnaire (SADQ)[117]. The current form of the SADQ is a 20-item questionnaire that assesses physical signs of withdrawal, affective signs of withdrawal, craving, quantity, frequency of drinking, and the speed of recovery from withdrawal symptoms. The Alcohol Use Disorders Identification Test[118] is a specific screening test for detecting problematic alcohol use. Its items operationalize some of the diagnostic criteria for nosotaxies, and due to its simplicity, this instrument is widely used in clinical and research settings.

Specific ADHD assessment instruments: Most instruments that assess ADHD are based on the diagnostic criteria for nosotaxies. However, some differences between them are worth noting. The following describes the most commonly used instruments and their main characteristics under a psychometric approach.

The Adult ADHD Self Report Scale (ASRS)[119,120] is a screening scale that operationalizes the diagnostic criteria proposed in the DSM-IV through 18 items. It also offers three types of scores (inattention score, hyperactivity score, and total score) according to the clinical signs of ADHD. It is, therefore, a scale that largely reflects the diagnostic procedure based on nosotaxies. However, its items do not explore the presence of the disorder in depth, and it is thus considered more of a screening than a diagnostic instrument.

The Current Symptoms Scales[121] is an 18-item instrument that can be completed by an observer (CSS-OR) and/or self-administered (CSS-SR). The 18 items describe the DSM-IV diagnostic criteria included in the inattention and hyperactivity/impulsivity domains. In addition, this instrument differs from others in that it includes a scale to assess the intensity with which the symptoms interfere with the individual's functioning in various areas of their life (work, family life, or money management).

The Connors Adult ADHD Rating Scale (CAARS)[122] is available in different versions (large version: 66 items, short version: 26 items, and screening version: 30 items), with two main formats: One self-report and one observational (CAARS-SR and CAARS-OR, respectively). This scale uses items based on - but not exclusively guided by - diagnostic classifications. Thus, it offers more items to explore inattention, hyperactivity, impulsivity, or self-concept. In addition, an index of the probable presence of ADHD can be derived from its scores along with indicators of the inconsistency of responses.

The WURS[13,14] is a scale that retrospectively assesses ADHD symptoms in childhood. This scale has two versions (the original version with 61 items and the short version with 25 items). This scale generates scores for hyperactivity, attention deficit, and impulsivity, along with emotional lability and behavior problems. The contents of this scale are based on the Utah criteria. Thus, while the WURS does not assess the criteria for nosotaxies *per se*, its cutoff scores (36 and 46) have shown to be useful for diagnostic categorization.

Specific instruments for the assessment of personality domains: The shift towards the definition of disorders based on personality traits has led to the emergence of various instruments aligned with this theoretical premise. The present study will characterize psychometrically those instruments that assess the dimensions of the externalizing spectrum underpinning the disorders associated with behavior problems corresponding to the antagonism and disinhibition domains of the DSM-5 and aligned with the dissociality and disinhibition domains, respectively, of the ICD-11[123]. Furthermore, among the existing instruments, the present study will analyze those that are most widely used, such as the Personality Inventory for DSM-5-PID-5-[33] and the Personality Inventory for ICD-11 (PiCD)[124].

The PID-5[33,34] assesses 25 facets/traits proposed in the AMPD, including those for disinhibition and antagonism. The original version of this instrument includes 220 items. Subsequently, other reduced versions of 100 items (PID-5-SBF)[125] and 25 items[126] have been published. This latest version (PID-BF) only provides a score for the domains. This instrument has been adapted to numerous languages[127-133], with considerable psychometric evidence. Thus, the review conducted by Al-Dajani *et al*[134] showed, in terms of reliability, alpha values ranging between 0.72 and 0.96. Regarding test-retest reliability, values above 0.90 have been reported for all dimensions. In terms of validity evidence based on the relationship with other variables, it has been found that the structure of the PID-5 converges with the FFM model[135]. Correlations above 0.60 have been reported in the convergence between disinhibition and antagonism with their respective counterparts in the NEO-PI-R and NEO-PI-3[67,136-138]. Regarding the factor structure, most factor analyses show that the factor for externalizing divided into two sub-factors is congruent with the domains of externalizing and disinhibition. It should be noted that this instrument allows the identification of personality traits and facets, and some authors have subsequently analyzed the congruence of these profiles with the categorical diagnoses of nosotaxies[69,67,129,139].

The PiCD[124] has been developed to measure the dimensional personality model proposed by the ICD. The PiCD assesses the five domains proposed by ICD-11, including the three specific externalizing domains of dissociality, disinhibition, and anankastia traits. This instrument includes 60 items, so the five domains are assessed based on 12 items each. Psychometric studies of the PiCD have shown adequate internal consistency coefficients[124,139-143]. Concerning evidence of convergent validity, PiCD scores have shown significant relationships with their counterparts in other personality models [140-142,144]. In the case of the disinhibition and dissocial dimensions, high correlations have been found with their convergent scales but not with scores measuring anankastia[140]. Regarding the factor structure, some studies replicate the five proposed theoretical factors[62,124,145], while other authors point to an overlap between the disinhibition and anankastia factors[140,144]. Although PiCD proposes a primarily domain-based measure congruent with DSM-5, Bach *et al*[146] developed scoring algorithms for the ICD-11 facets based on the PID-5 dimensions, finding a good fit for the disinhibition, antagonism/dissocial, and anankastia dimensions. These results have subsequently been replicated in other studies[147,148].

Instruments for assessing the antagonism and disinhibition externalizing domains compatible with other psychopathological models

In addition to the instruments mentioned above, other tests and scales allow the assessment of the traits included in the externalizing antagonistic and disinhibition domains that do not adopt the DSM and ICD classifications as a basis for operational definition. The items of these instruments do not tend to reproduce the diagnostic criteria of nosotaxies. Rather, their items are organized for the measurement of traits and facets, usually on a severity scale, which is indicative of the presence of problem behaviors or disorders.

On the other hand, it should be noted that numerous instruments measure each of the antagonistic and disinhibited problem behaviors. However, in the present work, we will incorporate instruments that measure more than one of these problem behaviors or disorders. In this regard, it should be noted that, as Mullins-Sweatt *et al*[90] reported, an instrument is currently being developed to measure problem behaviors and disorders within the externalizing spectrum.

One of the instruments worthy of note is the Achenbach System of Empirically Based Assessment (ASEBA)[149]. This assessment system integrates instruments for measuring various behaviors, competencies, and interpersonal problems. Its objective is concerned with detecting problematic behaviors that can be the object of clinical intervention, although it distances itself from the use of diagnostic categories proposed in the nosotaxies. This assessment system can identify profiles concerning various behaviors, including those framed within the externalizing spectrum. Its scales include the ASR and the Adult Checklist[150,151], which report on adaptive and problematic behaviors, including drug use.

The MMPI was originally developed by Hathaway & McKinley[152,153], and the third version (MMPI-3)[154] has been recently published. In its three updates, this instrument retains the aim of providing assessors with a clinical profile that contributes to the characterization of individuals in a comprehensive manner. Therefore, its different versions include many scales that are organized to provide trait and behavioral scores while providing scores from high-order scales, including specific scores associated with the antagonism and disinhibition domains.

The PAI[26,27] is another instrument that assesses various personality traits and facets, including the disinhibition and antagonism domains. It is an instrument whose aim is not only to provide clinically relevant information for diagnosis but also useful information for planning the treatment of patients. In this sense, the authors selected those syndromes that, at the time of their development, had the greatest relevance in the nosology of psychopathology and usefulness in clinical practice. In turn, the operational definition of these syndromes was based on a review of the specialized literature to identify the most central components. Subsequent versions of the PAI have included new scales that currently measure a wide range of behaviors and traits that allow for establishing detailed profiles of the persons assessed.

Krueger *et al*[74] developed the ESI to test a comprehensive model of externalizing disorders. To this end, the authors reviewed the literature and focused on how certain disorders (*i.e.*, substance use disorders or antisocial behavior disorders) could have common etiological bases and, therefore, should be integrated into the same continuum. Under this premise, the authors developed the ESI to provide scores for personality and behavioral domains based not on phenotypic manifestations but on the underlying common structure of these domains. From here, to develop the items the authors adopted/modified items from existing measurement scales, and also designed items based on the DSM-IV-TR diagnostic criteria.

INTEGRATION PROPOSAL

For years, several authors have postulated the need for integrative models based on the classic DSM and ICD approaches combined with other empirical models that address the underlying bases of the different disorders[155,44]. This approach is, for example, followed by the AMPD or the ICD for PDs. While recognizing the value and interest of these efforts, it should not be overlooked that moving from a model with categories that determine the presence or absence of a disorder to one in which profiles are developed to identify traits and facets with normal/pathological functioning, implies a considerable leap. Consequently, many clinicians may be unable to determine which clinical and pharmacological interventions are most appropriate for their patients. Likewise, considering the nature of the disorders addressed in this paper, professionals in the judicial and educational fields (among others) must become familiar with these new approaches to make the right decisions. However, the existing empirical evidence[30,31,70] and the promising results obtained in clinical settings with transdiagnostic interventions[156,157] suggest the need to adopt these new models.

As our review has shown, while efforts have been made to bring nosotaxies together with other theoretical models of psychopathology and personality, these have not played a prominent role in practice. However, nowadays, with the major development of models such as HiTOP, we may be moving closer to achieving convergence between these approaches, and to this end, tests and scales may play a central role.

Our research group is currently developing an instrument to measure the variable 'Externalizing disorder in adulthood' with the aim of constructing a test to identify profiles along the Agreeableness-Antagonism and Conscientiousness-Disinhibition continuums. In addition, our objective is to develop items that constitute indicators that can be used to determine the presence (or absence) of externalizing disorders according to DSM-5. Thus, the framework underpinning the operational definition of the test will be the HiTOP model[17,90] and the DSM-5 diagnostic criteria[15] and in the latter case, integrating the proposals of the alternative personality model and the diagnostic criteria of section II.

Our proposal begins with the definition of 'Externalizing disorder in adulthood' as "a set of maladaptive and/or problematic behaviors and personality traits that manifest themselves through outwardly directed behaviors, which cause deterioration in social relationships and interfere with the normal functioning of the person who presents them and their environment". This construct, congruent with that stipulated in the HiTOP, presents a hierarchical structure that integrates two major dimensions: Antagonism and disinhibition, divided into facets and traits. The disorders to be integrated are antisocial, narcissistic, paranoid, borderline, histrionic, ADHD, and oppositional defiant disorder. Substance use disorder, intermittent explosive disorder, and conduct disorder are not included for several reasons: (1) Concerning substance use disorder, there is abundant specialized literature showing that although it falls within the antagonism and disinhibition domains, these always clearly form an independent factor[158,159]. This means that some of the existing scales[107-109] can currently be used for their without disrupting the assessment of these two domains; (2) Explosive-intermittent disorder is not included due to the difficulty in identifying clear diagnostic criteria. Specifically, the DSM-5 only offers a list of behaviors or problems that must be present, although it does not define any criteria to determine their presence/absence; and (3) Conduct disorder is not included due to the lack of

adaptation of the set of diagnostic criteria to the adult population.

The DSM-5 definitions of facets and traits and those proposed by Mullins-Sweatt *et al*[90] have been adopted to delineate the operational definition. However, as indicated, our proposal integrates facets and traits with the criteria specified in section II of the DSM-5. In this sense, the research team members have reviewed the specialized literature to reach the proposal shown in Table 1. This table shows, for example, that the diagnostic criteria for antisocial PD fall within the two dimensions of our model: Five of the seven criteria refer to facets of disinhibition, and two of them to antagonism. For example, criterion 6, "Consistent irresponsibility, manifested by repeated inability to maintain consistent work behavior or meet financial obligations" corresponds to "Irresponsibility". It is therefore proposed that in the final version of the test, within the items measuring this facet, there should be items whose content deals with this diagnostic criterion.

Establishing equivalence between facets/traits and diagnostic criteria provides a conceptually equivalent operational definition. Thus, the test resulting from this definition may be of interest to professionals in various fields. First, quantitative data can be obtained to locate people along different continuums of facets, dimensions, and the externalizing spectrum. From a research standpoint, it will be possible to verify the hierarchical structure of externalizing behavior problems in the adult population and to analyze, through statistical models, their relationships with other variables of interest. Second, regarding clinical application, professionals will be offered equivalence scores that will allow them to determine the presence/absence of a given diagnostic criterion and, taking into account the relevant diagnostic criteria, the existence (or not) of the corresponding PD. The operational definition provided in present manuscript is a preliminary approach that attempts to combine the theoretical advances, result of the most recent empirical research, with the clinical practice, based on the nosotaxies internationally used.

CONCLUSION

Present work highlights the importance of that measurement of externalizing spectrum disorders has for people's living conditions[3-7]. The development of measurement instruments for these disorders requires a careful process of design, application, and interpretation[8]. The bibliographic review undergone show that among the available instruments, there are those framed within categorical diagnostic systems (DSM and ICD); those arising from recent dimensional theoretical approaches (AMPD or HiTOP) and other instruments with operational definitions in specific theoretical frameworks. While categorical approaches provide useful tools to facilitate clinical decision-making, dimensional approaches have extensive empirical support as better capturing the nature of the disorders and allow greater understanding of psychopathological phenomena[28].

On one hand, our review note that the different operational definitions used in these tests under the different frameworks, hinder the comparison of the findings and applicability. Regarding the definitions based on diagnostic classification systems, these have undergone an evolution throughout the different editions with three phases. While the first editions constituted mere statistical classification systems, later versions incorporated descriptions of diagnostic categories[9,10], providing the first operational definitions of psychological disorders in general and externalizing disorders in particular.

The development of measuring instruments for these disorders did not, therefore, truly flourish until diagnostic criteria were included on these taxonomies[43] on a second phase. The inclusion of these criteria lead to a tendency towards quantifying disorders through tests, rating scales, and checklists. In addition, the criterion of dysfunction to consider the presence of a disorder were incorporated into these taxonomies[50], which led to the development of new measures for the assessment of impairment[53-57]. However, while systematization in assessment increased, many of the instruments developed from this perspective have been criticized for lacking an etiological theoretical framework[45,49]. Also, the differentiation between Axis I (substance use and impulse control disorders) and Axis II (PDs) on these classification systems[52,58], caused that tests based on nosotaxies either assess symptoms (psychopathology) or traits (personality).

The assessment of disorders based on these categorical classifications in this second phase, has been criticized in a number of ways[30,70]. Criticisms included the observation of high rates of comorbidity - due to the lack of specificity of diagnostic criteria - and the arbitrary nature of the thresholds between normal and pathological behavior[71,72]. On the third phase of evolution of diagnostic classifications, latest versions of DSM and ICD had begun a shift towards a dimensional operationalization of mental disorders. The AMPD model included in DSM-5 Section III[15] and the ICD-11[16] constitute two first proposals for a dimensional classification of PDs. Again, it can be noted that the measurement of functioning play a relevant role on these proposals for defining the threshold that differentiate normality from pathology. However, empirical evidence show mixed results regarding the overlap when measuring functioning and pathological traits[64-69].

In addition to the operational definition of externalizing disorders provided in the different taxonomies, our review analyzed another recent dimensional model: The HiTOP model[17]. This recent dimensional model had provided an extended classification system that address all types of psycho-

Table 1 Relationship between diagnostic criteria (Diagnostic and Statistical Manual of Mental Disorders-5) and externalizing facets-dimensions

Externalizing disorders in adulthood			Internalizing
DSM-5 disorders (diagnostic criteria)	**Disinhibition**	**Antagonism**	
Antisocial [Personality disorder, diagnostic criteria section II (3/7)]	Non-compliance with standards (criterion 1)	Deception/fraud (criterion 2)	
	Impulsivity (criterion 3)	(Lack of) empathy (criterion 7)	
	Aggression (physical) (criterion 4)		
	Risk-taking (criterion 5)		
	Irresponsibility (criterion 6)		
Narcissistic personality disorder [Diagnostic criteria (5/9)]		Grandiosity (criteria 1, 2, 3, 5, 8, and 9)	
		Attention seeking (criterion 4)	
		Exploitation (criterion 6)	
		(Lack of) empathy (criterion 7)	
Paranoid personality disorder [Diagnostic criteria (4/7)]		Mistrust (criteria 1-4, and 7)	
		Hostility (criteria 5 and 6)	
Borderline personality disorder [Diagnostic criteria (5/9)]			Separation anxiety (criterion 1)
			Affective lability (criteria 2 and 6)
			Altered self-perception (criterion 3)
	Risk-taking (criterion 4)		
			Suicide (criterion 5)
			Depression (criterion 7)
		Hostility (criterion 8)	
			Dissociation (criterion 9)
Histrionic personality disorder [Diagnostic criteria (5/8)]		Attention seeking (criteria 1, 2, 4, and 6)	
			Affective lability (criterion 3)
			Superficiality (criterion 5)
			Suggestibility (criterion 7)
			Altered social perception (criterion 8)
ADHD [Inattention (5/9)]	Inattention (criteria a-i)		
Hyperactivity and impulsivity (5/9)	Hyperactivity (criteria a-f)		
	Impulsivity (criteria g-i)		
Oppositional defiant disorder [Diagnostic criteria (4/8)]		Hostility (criteria 1-3 and 8)	
		Rebellion (criteria 4-7)	

DSM: Diagnostic and Statistical Manual of Mental Disorders.

pathology. Regarding externalizing disorders, it provides a coherent theoretical background for explaining comorbidity through the definition of general factors - Antagonistic externalizing and Disinhibited externalizing, grouped in the Externalizing spectrum - that group co-occurring symptoms. This hierarchical structure however, is not clearly supported by empirical evidence[78-81], appear to ignore the direct relations between the lower level elements[82-84], and provide challenges on the operational definition under the different levels of the model. The dimensional conceptualization increases the reliability of the measure, although requires to establish empirical based cutoff points to

assist clinicians[82]. Finally, considering HiTOP model gather personality and conduct disorders, measuring sign and traits under the same instrument can pose differences on the time frame of assessment.

On the other hand, the review of existing instruments for measuring externalizing disorders have shown a large amount of test, resulting in an atomization in the measurement. This implies that researchers and practicioners should carefully revise the operational definition and target of each instrument to ensure a good choice of measurement instrument for a specific purpose, although our review show that this information may be of difficult access or not clear. Among the structured interviews developed under the classification systems, it is worth mentioning the SCID-5[20,21], the MINI[95], and the PRISM[96] under the DSM framework and the CIDI[22], and the SCAN[97] allowing diagnosis under both DSM and CIE taxonomies. Less structured interviews such as the PRISM or the CIDI, require interviewers to be adequately trained. Regarding instrument for assessing specific disorders, our review suggests the ASRS[119,120], the Current Symptoms Scales[121], the CAARS[122] within the DSM criteria and the WURS[13,14] based on the Utah criteria are the most frequent measurement instruments. On personality, due to the emergence of dimensional personality models, it can be found measurement instruments within dimensional frameworks such as the PID-5[33,34], the NEO-PI-R, NEO-P-3[67,136-138] and PiCD[124]. Other dimensional instruments targeted to measure antagonism and disinhibition include the ASEBA[149], MMPI[152-154], the PAI[26,27] and the ESI[74].

Present review show that the different instruments identified are either designed under a diagnostic taxonomy framework which allow a categorization of the respondents or under theoretical framework derived from research that delineate dimensional profiles. As our review suggests, efforts to bring nosotaxies together with other theoretical models have not played a prominent role in practice. We provide a preliminary operational definition that attempts to combine both approaches.

Abstract

Psychiatrists require frequent contact with and treatment of patients with mental illnesses. Due to the influence of associative stigma, psychiatrists may also be targets of stigma. Occupational stigma warrants special consideration because it significantly affects psychiatrists' career advancement, well-being, and their patients' health. Given that there is no complete summary of this issue, this study reviewed the existing literature on psychiatrists' occupational stigma to clearly synthesize its concepts, measurement tools, and intervention strategies. Herein, we emphasize that psychiatrists' occupational stigma is a multifaceted concept that simultaneously encompasses physically, socially, and morally tainted aspects. Currently, standardized methods to specifically measure psychiatrists' occupational stigma are lacking. Interventions for psychiatrists' occupational stigma may consider the use of protest, contact, education, comprehensive and systematic methods, as well as the use of psychotherapeutic approaches. This review provides a theoretical basis for the development of relevant measurement tools and intervention practices. Overall, this review seeks to raise public awareness of psychiatrists' occupational stigma, thereby promoting psychiatric professionalism and reducing its stigma.

Key Words: Psychiatrists; Occupational stigma; Conceptualization; Measurement; Intervention; Associative stigma

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Psychiatrists' occupational stigma, an area that is little noticed, deserves more attention from the public and professionals considering its negative effects. This study aimed to elucidate its concept, explore the potential measurement tools, and focus on effective interventions by comprehensively reviewing related literature. It is expected to encourage more studies in this field.

INTRODUCTION

Stigma is a form of social classification. Occupational stigma results when people make derogatory, insulting, or negative comments about others practicing their occupation[1]. Occupational stigma is the negative labeling of a profession that the general public views as having dishonorable, humiliating, and shameful features, leading to negative consequences of social exclusion, status loss, demeaning, discrimination, and pessimistic rejection[2-4]. Although stigma arises from dirty work in common sense, any occupation can face various levels and types of stigma[3]. Physicians, a typically prestigious profession [5], also suffer from stigma that seriously jeopardizes health care career development[6,7]. Furthermore, psychiatrists may experience intense stigma due to the nature of their profession and the population they serve[8]. A study of trainee psychiatrists found that 75% of individuals heard denigrating or humiliating remarks about the psychiatric profession[9].

Occupational stigma exerts negative impact on psychiatrists' career advancement, well-being, and patients' health. More specifically, the stigma may cause burnout, job dissatisfaction, and low professional value[10-17], and can act as a strong predictor of health and well-being[18,19]. Numerous studies have demonstrated that occupational stigma contributes to practitioners' withdrawal behaviors and the propensity for resignation[14,20-22]. At present, the shortage of psychiatrists cannot meet the demands of mental health workforce development[23]. Alarmingly, a study suggested that just about half of psychiatry college graduates moved on to work in related disciplines[24]. It has shown that occupational stigma plays a major role in that kind of phenomenon[25-28]. In addition, as a consequence of stigma, medical students rarely consider psychiatry a future career option, with the perception of taking psychiatrists as having low professional prestige and respect[29-31]. The professional shortage in psychiatry has been existing considering the insufficient medical graduates attracted by psychiatry[32, 33].

Moreover, it is noteworthy that stigma can straightly influence the establishment of the well physician-patient relationship and the treatment process. Stigma is classified as either public stigma or self-stigma, in which patients' stigma toward psychiatrists falls under the former[34]. That public stigma can reduce patient compliance and help-seeking behavior, thereby impeding treatment[32,35]. For another, psychiatrists' self-stigma may result in an increase in defensive medical behavior[36], such as little communication with patients, unnecessary testing, excessive medication, refusal, or referral[37-39], leading to not only health-care costs rise and poor medical relationship but also the potential negative impact on patient health and treatment effect[40].

In conclusion, psychiatrists influenced by associative stigma are perceived as a heavily stigmatized profession. Despite numerous studies showing that occupational stigma exerts a significant negative impact on the development of psychiatry, there is little literature reviewing psychiatrists' occupational stigma. To that end, the purpose of this literature review is to provide a comprehensive overview of the concept, measurement, and intervention of psychiatrists' occupational stigma by reviewing the extant literature, with the prospect of providing a theoretical reference for future research.

LITERATURE SEARCH

The authors sequentially searched the PubMed, Web of Science, and Reference Citation Analysis (https://www.referencecitationanalysis.com/) databases for articles containing a cross combination of the following topical keywords: "Psychiatrist," "stigma," "occupational stigma," "stress," "negative affect," "career satisfaction," "dirty work," "healthcare workers," "associative stigma," "psychiatry," "mental health professionals," "self-stigma," "mental illness," "intervention," "measurement," and "anti-stigma." March 2023 was the deadline for the keyword search, which yielded an initial total of 21098 papers. Literature selection criteria, as decided between the professor and students, were as follows: First, include a study relevant to and representative of the topic; second, any such study should be published in English or French; third, exclude duplicates. After review 195 papers met the selection

criteria and 20903 papers were excluded.

CONCEPTUALIZATION OF PSYCHIATRISTS' OCCUPATIONAL STIGMA

Research on occupational stigma can be traced back to Hughes[2] and his exploration of dirty work[2]. Impressive findings have been attained in the following studies that explore occupational stigma across practically all professions[3,41,42]. In his research on dirty work, Hughes[2] classified occupational stigma into three categories: physically, socially, and morally tainted in the aspect of work content[2]. Based on this, Ashforth and Kreiner[43] provided a precise definition of the three different forms of stigma[43]. Particularly, the term "physically tainted" refers to jobs that involve direct contact with trash, death, or filth[44,45] such as cleaner and mortician, or directly working in dangerous and harmful environment[46,47] such as firefighter and miner. The term "socially tainted" describes jobs like prison guards and infectious disease doctors that require regular contact with stigmatized groups as part of their duties[48,49], as well as those like nannies and tour guides that include a servant-subordinate relationship[50,51]. The term "morally tainted" refers to occupations that are viewed as being sinful and unethical[52,53] such as doctor who perform abortions or sex worker, as well as occupations with leading and deceptive traits[54,55] such as anchors who lead viewers to spend money and poker players who deceive their opponents. It is critical to note that one type of stigma may predominate in a given occupation, or two or even three types of stigma may exist concurrently[3,43]. Stenger *et al*[56] extended the three-dimensional classification, arguing that occupational stigma is a negative stereotype formed by the public of certain occupations' work images, social relations, or ethics[56].

In a follow-up study, Kreiner *et al*[3] further proposed the concepts of "breadth" and "depth" of taint applied to work tasks undertaken[3]. Breadth refers to the centrality of stigma in occupational identity, and the frequency of stigma-related behaviors occurring. Depth refers to the degree to which a practitioner is directly exposed to dirt. Accordingly, occupational stigma was further divided into pervasive stigma, compartmentalized stigma, diluted stigma and idiosyncratic stigma. At the same time, Ashforth and Kreiner[42] took occupational reputation as an important dimension of occupational stigma division, and then divided occupational stigma into high/low reputation physically tainted, high/low reputation socially tainted, and high/low reputation morally tainted[42]. In a recent study, Zhang *et al* [57] analyzed the four-level stigma literature of individual, occupational, organizational, and industry, and divided the sources of stigma into six types (physical, tribal, moral, servile, emotional, associational), which extended the three-dimensional classification of occupational stigma. The sources of occupational stigma are considered to include these six types. At the same time, five characteristics of stigma (concealability, controllability, centrality, disruptiveness, malleability) are further proposed. Scholars believe that the types of stigma source and the characteristics of stigma under different social conditions will jointly influence the formation of stigma[57].

At present, different scholars do not consistently agree on the concept of occupational stigma. The above-mentioned concepts of stigma proposed by Hughes[2], Ashforth and Kreine[41] are most commonly used in related studies. To this end, this study also defines the concept of occupational stigma toward psychiatrists in the aspect of physical, social and moral, and explores the specific causes of occupational stigma.

People with mental illnesses are frequently labeled as "violent," "offensive," "dangerous," and "aggressive"[58]. Compared to doctors in other clinical departments, the public attempts to consider that psychiatrists are more likely to encounter with violence and operate in a riskier setting[59,60], which were confirmed in a survey of psychiatric healthcare professionals[61]. In a study based on a sample in China, it was found that 78% of psychiatrists reported having experienced verbal abuse, compared to more than 30% who had experienced physical abuse[62]. Similar findings about psychiatrists' susceptibility to being hurt in medical injury incidents were discovered in surveys conducted in Germany[63], Ghana[64], Turkey[65], and Kuwait[66]. Psychiatrists are considered physically tainted because of the hazardous work environment.

For psychiatrists, associative stigma serves as a major source of occupational stigma[67,68]. Due to their frequent interactions with and treatment of patients with mental illness, psychiatrists may experience associative stigma that their clients may attach to them[9,69]. Patients with mental illness are a highly stigmatized group[70,71]. Their image is portrayed as negative, dangerous, and dishonest, and their social value is severely diminished[72]. To a large extent, the formation and development of stigma toward mental illness result from both religion and culture[73]. People with mental illness were thought to be possessed by evil spirits in Christianity[74] and Islam[75]. Expulsions and floggings, the confinement of mentally ill persons in jails and insane asylums, or even burning as a form of torture were all common practices in medieval Europe including Switzerland, Germany, and France[72]. Moreover, the thought of saving face is strongly ingrained in Chinese Confucian culture[76]. Concealing or avoiding the information that a family member suffers from a mental illness is typically done to preserve the family's reputation[68]. Even today, many people who suffer from mental illness and their family members still refrain from disclosing their situations to others for fear of prejudice and rejection. This ubiquitous phenomenon exists in nations where collectivist principles are valued[77,78]. The low

use of mental health services is partly caused by the stigma around mental illness[79]. Being socially tainted is, therefore, the most typical trait of psychiatrists' occupational stigma.

The possibility of being morally tainted among psychiatrists should not be overlooked. In treating people with mental illness, coercive measures such as seclusion, restraint, and forced medication are widely used[80]. Although patients perceive coercion as harmful to the treatment, healthcare professionals take it as an effective method of caring for, protecting, and treating patients[81]. Coercive measures have been the subject of heated debate in medical ethics, as well as legal scrutiny. Then, alternative options are sought and implemented by psychiatrists actively[82]. On the one hand, psychiatrists frequently consider physical and chemical restraints necessary, but on the other hand, they also recognize their potential to undermine patient rights and negatively impact the therapeutic relationship [83]. Therefore, it is understandable that psychiatrists may experience criticism, moral condemnation, and perceived intense moral pressure due to the dangers that coercive tactics may cause[84]. Now, an increasing number of researchers are advocating for improvements in the clinical practice of mental health medicine in order to reduce the use of coercive tactics[85]. In addition, electroconvulsive therapy (ECT) is frequently utilized to treat a variety of psychiatric diseases, including depression[86] and schizophrenia[87], with positive effects. However, ECT has been stigmatized and used as "proof" of psychiatrists' violence and harm to patients due to the media and the antipsychiatry movement[88]. As a result, psychiatrists also experience being morally tainted.

As illustrated above, the psychiatrists' occupational stigma is a complex idea that calls for multidimensional interpretations. Psychiatrists are seen as simultaneously being physically tainted, socially tainted, and morally tainted considering the potentially dangerous work environment, their exposure to and treatment of highly stigmatized populations, and the use of controversial and aggressive treatment methods. Occupational stigma could result in detrimental consequences for psychiatrists including isolation, discrimination, and loss of status and then made itself an indispensable factor to impede the advancement of medical and health services in mental health.

THE MEASUREMENT OF PSYCHIATRISTS' OCCUPATIONAL STIGMA

To date, no occupational stigma scales have been developed for psychiatrists. In such a pertinent quantitative investigation, this can be accomplished by adapting other occupational stigma instruments (see Table 1). There are four different categories of scales that can be used to gauge public stigma toward psychiatrists. One type is that one dimension or more of the scale's items indicates occupational stigma. Richmond *et al*[89] created the psychometrically reliable Trust in Doctors in General (T-DiG) and Trust in the Health Care Team scales (THCT) to assess public trust in medical professionals and healthcare teams. Both the T-DiG and THCT include 29 items, which are from seven dimensions that refer to stigma-based discrimination, communication skills, system trust, loyalty, confidentiality, fairness, and general trust[89]. The stigma-based discrimination dimension contains three items that doctors or people who work in health care would unfairly treat patients with a history of mental illness, HIV, or drug abuse. Although T-DiG and THCT can reflect the public occupational stigma against physicians to some extent, the richness of occupational stigma is not accessible by measuring a single dimension of the scale. Meanwhile, occupational stigma, the complex concept, must be examined from multiple perspectives. The T-DiG and THCT contain only one item, physicians' unfair treatment of patients with a history of mental illness, and can only assess specific aspects of occupational stigma.

The second is to measure patients' occupational stigma against physicians. Fan *et al*[90] developed the Patient Toward Physician Occupational Stigma Scale (PPOSS), which consists of 19 items divided into three dimensions, namely stereotype, prejudice, and discrimination. The cognitive, affective, and behavioral components of occupational stigma are measured respectively[90]. Although the PPOSS was created specifically to assess physicians' occupational stigma, there are significant differences between physicians in different departments regarding the source, type, and extent of occupational stigma[49,52,91,92]. Psychiatric patients were not chosen as the study subjects during the development of the PPOSS, and items reflecting the psychiatrists' professional characteristics were lacking. As a result, more evidence is needed to determine whether the PPOSS is suitable for assessing patients' occupational stigma toward psychiatrists.

The third is to measure the public's social distance from physicians to examine their stigmatizing attitudes. A key element of psychological distance is social distance, which measures the degree of intimacy between various groups and between people within the same cohort[93]. The Social Distance Scale (SDS) has been utilized as a measurement tool in a study to examine public stigma and public behavioral inclinations toward physicians[94]. However, the SDS was originally designated not to measure occupational stigma but to measure the public distance perception between various nations, ethnic groupings, races, or groups[95]. The concepts of social isolation and occupational stigma are not interchangeable because they have obvious distinctions. Currently, the SDS is employed in research on occupational stigma less frequently, particularly when assessing public stigma toward physicians. Only a small number of studies used the scale[96].

Table 1 Measurement tool of psychiatrists' occupational stigma

Scale title	Target	Content	Item	Dimension
[89]THCT	Public	Measure public trust in medical professionals and health care team	29	7 dimensions: Stigma-based discrimination; communication skills; system trust; loyalty; confidentiality; fairness; general trust
[90]PPOSS	Patients	Measure the cognitive, affective, and behavioral components of occupational stigma	19	3 dimensions: Stereotype (6 items); prejudice (7 items); discrimination (6 items)
[94]SDS	Public	Measure stigmatizing public perceptions of and behavioral inclinations toward the physicians	8	Single dimension
[97]Public attitudes towards psychiatrists' questionnaire	Public	Measure the public's unfavorable views and impressions of psychiatrists' professionalism, mental health, occupational authority and ethical standards	8	Single dimension
[98]OSCS	Practitioners	Measure the stigma awareness of practitioners in the service industry	6	Single dimension
[100]E16-COVID19-S	Practitioners	Measure specific aspects of physician occupational stigma	16	3 dimensions: Personalized stigma (8 items); concerns of disclosure and public attitudes (5 items); negative experiences (3 items)
[101]PSCP	Physicians	Measure perception of COVID-19-induced stigma in healthcare workers	10	2 dimensions: Environmental stigmatization; the perception of personal stigmatization
[103]Self-designed stigma questionnaire	Physicians	Measure mental health stigma	12	Single dimension
[104]DAQ	Medical students	Measure stigmatization of physicians suffering from mental disorders	3	Single dimension
[105]SOSS-D	Doctors	Measure the stigma of occupational stress and burnout among physicians	11	3 dimensions: Perceived structural stigma (5 items); perceived individual stigma (3 items); perceived other related stigma (3 items)
[106]MHPSS	Mental Health Professionals	Measure occupational stress and burnout stigma in mental health professionals	13	4 dimensions: Perceived other stigma (3 items); perceived structural stigma (4 items); personal stigma (3 items);self-stigma (3 items)
[107]PIOSS	Physicians	Measure physicians' identification with negative labels, perceptions of devaluation and discrimination, as well as the denial and disapproval of their own profession	19	3 dimensions: Label identification (5 items); status loss (8 items); career denial (6 items)
[108]FSS	Forensic	Measure internalized occupational stigma	12	2 dimensions: Dangerousness/unpredictability (7 items); responsibility/blame (5 items)
[13]Mental health professionals' questionnaire	Mental health professionals	Measure the perceived associative stigma	4	Single dimension
[110]Measuring Psychiatrist occupational stigma scale (the scale a)	Psychiatrists	Measure perceived stigma in terms of the perception of societal stereotypes	16	Single dimension
[110]Measuring Psychiatrist occupational stigma scale (the scale b)	Psychiatrists	Measure self-stigma in terms of stereotype agreement	16	Single dimension
[110]Measuring Psychiatrist occupational stigma scale (the scale c)	Psychiatrists	Measure perceived stigma in terms of structural discrimination	5	Single dimension
[110]Measuring Psychiatrist occupational stigma scale (the scale d)	Psychiatrists	Measure discrimination experiences	13	Single dimension
[110]Measuring Psychiatrist occupational stigma scale (the scale e)	Psychiatrists	Measure stigma outcomes	5	Single dimension

COVID-19: Coronavirus disease 2019; DAQ: Discriminative attitude questionnaire; FSS: Forensic Stigma Scale; OSCS: Occupational Stigma Consciousness Scale; PIOSS: Physician Internalized Occupational Stigma Scale; PPOSS: Patient Toward Physician Occupational Stigma Scale; PSCP: Perception of Stigma due to COVID-19 in Physicians; SDS: Social Distance Scale; SOSS-D: Stigma of Occupational Stress Scale for Doctors; THCT: Trust in doctors in general and Trust in the health care team scales.

Fourth, a non-standard assessment method was used to examine the public's negative perceptions of psychiatrists. Ta *et al*[97] used a self-designed Public attitudes towards psychiatrists questionnaire with eight items to assess public perceptions of psychiatrists. The questionnaire mainly measured the public's negative attitude and views of psychiatrists' professionalism, mental health, occupational authority and ethical standards[97]. Nevertheless, it is hard to state the reliability and validity of the research results because the questionnaire's reliability and validity were not assessed.

The scales that can be used to measure the self-stigma of psychiatrists could be divided into four categories. The first is the scale used to gauge psychiatrists' sensitivity to stigma. The Occupational Stigma Consciousness Scale (OSCS) is the most frequently used tool in studies on physicians' occupational stigma. The OSCS comprises six one-dimensional items that assess practitioners' perceptions of public stigmatization of their work. However, the OSCS was originally developed based on call center service workers and was primarily used to assess the stigma awareness of practitioners in the service industry[98]. According to the needs of researchers' studies, they appropriately adapted the scale for use in quantitative studies of various occupational stigma in subsequent studies[99]. It should not be ignored that psychiatrists are part of a high-prestige profession that differs significantly from dirty work regarding stigma manifestations and negative consequences.

The second is the scale for measuring specific aspects of physician occupational stigma. Based on the severe acute respiratory syndrome stigma scale, Mostafa *et al*[100] developed the new coronavirus disease 2019 (COVID-19) Stigma Scale (E16-COVID19-S)[100]. Similar to this, Oktar *et al*[101] developed the Perception of Stigma due to COVID-19 in Physicians (PSCP) with 10 items, including two dimensions that are environmental stigma and individual stigma perception[101]. These two scales measure specific components of physicians' occupational stigma, but fail to reflect its full spectrum of connotations.

The stigmatization of occupational stress and burnout among physicians has been the research focus in this field. For instance, Riley *et al*[102] discovered that physicians experience high stigma in mental health, work stress and burnout, manifested as inability to admit vulnerability and insistence on working, even if unwell[102]. A study by Wijeratne *et al*[103] on physicians' mental health stigma found that they tend to conceal their mental health conditions from colleagues and are less likely to seek help because there is a belief that physicians suffering from depression or anxiety disorders are perceived as untrustworthy[103]. This study applied a self-designed 12-item stigma questionnaire as a survey tool, which was not strictly tested for reliability nor validity, but only reported internal consistency coefficient values. Zarzycki *et al*[104] adopted a self-designed Discriminative Attitude Questionnaire (DAQ) to examine medical students' stigmatization of physicians with mental disorders[104]. The DAQ includes only three non-standardized items and is only applicable for assessing stigma regarding mental disorders. Furthermore, Clough *et al*[105] developed the 11-item Stigma of Occupational Stress Scale for Doctors (SOSS-D). There are three dimensions extracted in the SOSS-D including perceived structural stigma, perceived individual stigma, and perceived other related stigma[105]. To measure occupational stress and burnout stigma in mental health professionals, Clough *et al*[106] created the Mental Health Professional Stigma Scale (MHPSS)[106]. There are 17 items total in the MHPSS, which are broken down into four dimensions: Perceived other stigma, perceived structural stigma, personal stigma, and self-stigma. Stigmatizing attitudes, stress and burnout among psychiatrists can pose serious threats to their professional development. However, scales for measuring the stigma of occupational stress and burnout specifically among psychiatrists are lacking and should be developed in future research.

The third part include scales for assessing physicians' internalized occupational stigma. Fan *et al*[107] created a 19-item Physician Internalized Occupational Stigma Scale (PIOSS) divided into three dimensions including label identification, status loss, and career denial. The PIOSS scale is primarily used to evaluate physicians' identification with negative labels, perceptions of devaluation and discrimination, and denial and disapproval of their profession[107]. Besides, Healey *et al*[108] developed the Forensic Stigma Scale (FSS) with 12 items falling into two dimensions that refer to danger/unpredictability and blame/responsibility[108]. Although PIOSS and FSS have strong validity and reliability, the study subject did not include psychiatrists.

Fourth, there is a non-standard tool for assessing the perception of stigma among psychiatrists. A self-designed mental health professional's questionnaire was used in the study by Verhaeghe *et al*[109] Four items comprise the questionnaire, which mainly measures the perceived associative stigma among psychiatrists and other mental health professionals. However, Cronbach's alpha coefficient for the questionnaire was just 0.51 since it had not undergone a rigorous reliability test[109].

Fifth, there is a scale specifically designed to measure the occupational stigma of psychiatrists. The World Psychiatric Association (WPA) has developed specific action plans to reduce the stigma toward psychiatry and psychiatrists. One of the essential tasks is to develop standardized questionnaires[110]. The basic version comprises five scales: (1) Perceived stigma in terms of the perception of societal stereotypes; (2) self-stigma in terms of stereotype agreement; (3) perceived stigma in terms of structural discrimination; (4) discrimination experiences; and (5) stigma outcomes. The scales (1) and (2) consist of 16 items measuring the professionals' competence, professional conduct, and personality, as well as the stigma of psychiatry as a medical specialty and its treatment methods. Scale (3) and scale (5), consisting of five items, assesses the social aspects of stigma and the negative consequences of stigma. Scale (4)

consists of 13 items, assessing experiences made in contact with doctors from other disciplines and experiences made in personal life. The scale developed by the WPA is a valid tool for assessing the internalization of occupational stigma among psychiatrists.

THE INTERVENTION OF PSYCHIATRISTS' OCCUPATIONAL STIGMA

The study of stigma intervention strategies has been the main research subject in the stigma field. To effectively intervene with various demographics and stigma, the approaches used can be cross-referenced[111,112]. In a systematic evaluation of stigma intervention strategies, which included research findings from various countries (low-, middle-, and high-income), stigmatized populations (such as those with AIDS, mental health disorders, and leprosy), intervention targets (such as medical personnel, family members, and community members), and intervention strategies (such as contact, education, and training), the analysis discovered some similarities in the strategies, measures, and intervention outcomes achieved when intervening with different types of stigma[113]. A review of stigma intervention strategies can serve as a theoretical foundation for psychiatrists' occupational stigma intervention practice. Stigma intervention strategies can be roughly classified into six categories.

First, the protest approach is a strategy for the stigmatized community to voice their opinions and express their disapproval through public declarations, media exposure, and stigma-related commercials to minimize stigma[114]. However, protest tactics risk escalating stigma, leading to public conflict and rebellion[115]. Therefore, they are used relatively infrequently. Furthermore, compared to more conventional rallies and demonstrations, the usage of social media platforms on the internet is growing. For instance, rebuttals to stigmatizing attitudes about mental illness are shared on Twitter during Mental Health Awareness Week, an annual effort in May[116]. Similarly, Depression Awareness Week is coordinated on Twitter with the primary objective of lowering the stigma attached to mental illness [117].

Second, educational strategies are applied to alter erroneous beliefs and reduce stigma by delivering accurate information to the intervention target[118]. A few commonly employed techniques are class lectures, anti-stigma training, special lectures, workshops, role plays, case studies, watching instructional videos, reading professional publications, and creating self-reflection reports (see Table 2). In the pertinent literature, more attention is paid to the stigmatization of medical professionals and the general public toward people with mental illnesses. In contrast, relatively few research studies have been conducted on psychiatrists' occupational stigma. Educational strategies effectively change healthcare professionals' attitudes toward patients with mental illnesses and increase contact willingness and frequency[119-122]. Besides that, it is conducive to reducing self-stigma in patients with mental illnesses through education[123]. Moreover, interventions can be implemented in stand-alone educational formats, such as workshops[124] and educational videos[125], or in a combination of formats to achieve more significant results. For example, in Education Not Discrimination[126] and Mental Health First Aid[127], a combination of presentations, videos, action plan ideas, case discussions, and role plays is used.

Third, the contact strategy aims to strengthen relationships with stigmatized people to alleviate adverse stereotypes. In stigma interventions, the contact strategy has been applied most frequently and has produced promising benefits[128]. It is possible to boost intergroup connections and minimize prejudice by increasing the frequency of public contact with stigmatized individuals, especially high-quality contact[129]. According to Corrigan *et al*[130], contact approaches are approximately three times more effective than educational strategies with more prominent and persistent impact[130]. Even short-term exposure has the potential to improve attitudes and understanding about stigma[131] and lower stigma levels[132]. The question of how to accomplish the desired intervention outcomes and guarantee the effectiveness of the contact method has always been the focus of scholars[131]. Corrigan *et al*[133] proposed that the most critical factors influencing the effectiveness of interventions are design, target, staff, message, evaluation and follow-up in five areas[133]. Specifically, the intervention can be delivered face-to-face, with a person with extensive life experience serving as a speaker, designing a program that matches the target audience's characteristics and delivering the intervention through storytelling. After the intervention's completion, evaluation and follow-up of the intervention effects are also required[134].

In terms of forms of intervention, direct and indirect contact are included[135].Direct contact as a promising anti-stigma strategy can improve communication and cooperation between patients with mental illnesses and other patients, as well as between patients and family members and the general public[136]. By increasing contact between health science students and people with mental illnesses in the Co-Production with Dialogue Program for Reducing Stigma, it is possible to significantly reduce public stigma and improve mutual understanding between patients and students[137]. Psychoeducational materials, face-to-face workshops, and interventions based on cognitive behavioral therapy were generally well received in the workplace-based multi-country intervention tackling depression, anxiety, and mental illness-related stigma study[138]. In the "Honest, Open, Proud" project, self-exposure and community-based participatory research were used to reduce self-stigma among individuals with

Table 2 Intervention of education

Strategy	Target	Content	Objective
[119]Education training	Family caregivers of patients with schizophrenia	Teaching related knowledge and skills (90 min/8 sessions)	Reduce stigma toward patients with schizophrenia
[120]Anti-stigma training	Care assistant workers	Financial assistance policy of care assistant workers + mental health knowledge (2 h) + stigma related to mental illness (1 h)	Reduce stigma toward patients with mental illness
[121]Anti-stigma training	Community mental health staff	Two parts: Knowledge introduction + stigma related to mental illness (1 d)	Increase mental health knowledge; Reduce stigma toward patients with mental illness and social distance
[122]Anti-stigma training	Probation officers	Six modules in PPT about overview of severe and persistent mental illnesses; information about key diagnoses and the medications; services associated with those diagnoses	Increase mental health knowledge; Reduce stigma toward mental illness and behavior tendency
[123]NECT	Persons with severe mental illness	20 sessions (1 h): (1) Introduction (1 wk); (2) Psychoeducation (3 wk); (3) Cognitive restructuring (8 wk); and (4) Narrative enhancement (8 wk)	Reduce stigma toward mental illness
[124]Educational workshop	High School Students	Classroom-based workshop: (1) Introduction: Mental illness and public stigma; (2) Education; and (3) Treatment of mental illness and available community resources (1 h)	Reduce stigma toward mental illness
[125]Educational videos	High school students and college students	Educational film (10 min): (1) BMM about mental illness; or (2) RCM advocated by experts	Reduce more stigma in BMM than RCM
[126]END	Medical students	Short lecture; testimonies about the experiences and stigma; role-plays	Increase mental health knowledge; Reduce stigma toward mental illness and behavior tendency
[127]Mental health first aid training	Pharmacy and non-pharmacy students	Identify, understand, and respond to signs of mental illnesses and substance use disorders (8 h); Methods: Videos, role play sessions, action plan creation, discussion, and other interactive activities	Reduce stigma toward mental illness

BMM: Biomedical messages; END: Education not discrimination project; NECT: Narrative enhancement cognitive therapy; PPT: Power point; RCM: Recommended messages.

mental illness[139].

The typical indirect contact method is video contact. Researchers prefer video contact because of its low cost, broad audience reach, reusability, low resource possession, and ease of dissemination[130]. Short video interventions are an essential and effective intervention in studies of depression stigma and help-seeking attitude stigma[140], mental health-related stigma[141], and mental illness stigma[142].

Fourth, comprehensive strategies combine two or all three of the protest, education, and contact strategies. Education and contact strategies are most frequently employed (see Table 3). For instance, Tan *et al*[143] discovered that increasing interaction (direct contact) and attending lectures (education) improved people's attitudes and levels of acceptance toward those who suffer from depression[143]. Furthermore, a three-stage intervention paradigm was subsequently developed by Ahuja *et al*[144]. Specifically, participants in the intervention were required to watch a dance drama to learn about common misconceptions and correct perceptions of mental illness. Then, individuals were asked to listen to an informational lecture and directly communicate with people suffering from mental illness. Hawke *et al*[145] used an indirect intervention strategy, showing the recorded stage play to healthcare providers, college students, people with bipolar disorder and their friends and family members, and the general public. The findings revealed that education and exposure *via* video approach similarly reduced the stigma of bipolar disorder among intervention subjects and had sound delayed effects[145].

Some studies have attempted to integrate anti-stigma education into school curricula. Ma *et al*[146], for example, designed a teaching component covering knowledge, experience, and action, as well as education strategies, direct contact, and indirect contact, to reduce the stigma of mental illness among medical students[146]. Case discussions and systematic curriculum instruction[147,148] can be used to achieve intervention goals[149]. Both educational and direct contact strategies, as well as educational and indirect contact strategies, have demonstrated practical intervention effects[150-168]. However, in a study of an adolescent population, educational strategies alone were superior to combined education and contact strategies in reducing mental illness stigma[165]. The researchers suggest that the young age of the intervention subjects may have contributed to this result and that contact strategies should be used with caution when intervening with adolescents. As a result, more evidence is needed to determine whether the combined strategy is superior to the single intervention strategy in various age groups.

Fifth, systematic intervention strategies emphasize the importance of considering the interplay of factors at different levels when intervening with stigma and integrating different types of intervention

Table 3 Intervention of comprehensive strategies

Strategy	Type	Content	Target	Objective
[143]Lecture	Education + direct contact	Video + personal experience + questions and answers (50 min)	Undergraduate	Increase knowledge of depression and help-seeking willingness
[144]Three-stage intervention paradigm	Education + direct contact + indirect contact	Dance-drama + lectures + direct contact (2 h)	Undergraduate	Increase understanding and tolerance toward patients with mental illness; Decrease negative review, negative labels and social distance toward patients with mental illness
[145]Filmed theatrical intervention based on a personal narrative	Education + indirect contact	Filmed version of a one-woman stage play performed by a recognized educator and speaker on the lived experience of mental illness and recovery (50-min)	Health-care service providers, university students in a health-care-related course, people with BD and their friends and family members and the general public	Decrease stigma toward people with BD among health-care service provider (significant/sustainable); others (more limited)
[146]Course	Education + direct contact + indirect contact	Lecture + watch videos/movie + in-class discussion + direct contact + roleplay + action project (18 wk)	Occupational therapy students	Decrease stigma toward mental illness and social distance
[147]Course	Education + direct contact + indirect contact	Teaching (42 h) + movie (3/4 h) + contact + presentations (2 h) + clinical correlations (6 h)	Medical students	Increase student confidence; Decrease stigma toward mental illness
[148]Course	Education + direct contact + indirect contact	Face-to-face (45 min) + video-based contact (40 min) + educational lecture (90-min)	Medical students	Decrease stigma toward mental illness
[149]Case discussion	Education + direct contact + indirect contact	Document patient strengths and treatment recommendations; Group presentation discussion (10 wk)	Primary care providers	Increase willingness to help and hope for recovery; Decrease negative stereotypes
[150]Course	Education + direct contact	Personal experience + questions and answers (69-90 min)	Pharmacy students	Decrease stigma toward mental illness
[151]Workshop	Education + direct contact	Workshop (4 d): Knowledge teaching + personal experience + questions and answers	Public Health Services administrators	Decrease stigma toward patients with mental illness

BD: Bipolar disorder.

strategies into a unified framework[162]. According to Heijnders and Van Der Meij[169], the effects obtained by employing a single level of intervention strategy or intervening with a single target group are frequently insufficient and necessitate the integration of multiple factors[169]. As a result, Cook *et al*[170] developed a three-level ecosystem model that divides stigma intervention strategies into individual, interpersonal, and structural levels, arguing that interventions at any level can affect the effectiveness of interventions at other levels[170]. Individual-level interventions concentrate on enhancing coping mechanisms used by stigmatized individuals or altering the attitudes and conduct of stigma abusers. By enhancing engagement and contact between the group of stigma abusers and the group being stigmatized, interpersonal interventions aim to reduce intergroup barriers and foster greater mutual understanding. Through the creation of pertinent laws and regulations to lessen prejudice and discrimination, intervention at the structural level is primarily seen from the perspective of the socio-political environment.

Additionally, Heijnders and Van Der Meij[169] suggested a five-level stigma intervention program (individual level, interpersonal level, social level, organizational and institutional level, and governmental level)[169]. In particular, professional counselling and therapy can be used at the individual level to help the stigmatized population cope with stigma; interventions at the interpersonal level concentrate on improving how the stigmatized population interacts with the elements of their environment in order to gain care and support; and interventions at the social level focus on changing public attitudes through education, advocacy, or contact strategies. At the organizational and institutional levels, specialized training or the development of internal systems can be adopted to reduce stigma in a group, organization, or institution; at the government level, interventions focus on the establishment of relevant laws and policies, as well as the use of coercive measures, to reduce stigmatized speech and behavior.

Sixth, increasing researchers have attempted to incorporate psychotherapeutic approaches and techniques into stigma interventions and have achieved promising results (see Table 4). Hong *et al*[171] used mindfulness training to intervene with self-stigma in depressed patients and got excellent and long-lasting results[171]. It was found by Clinton *et al*[172] that Positive Empathy Intervention (imagining positive contact with the stigmatized person and establishing a positive emotional connection) was superior to traditional contact methods in terms of stigma reduction[172]. Cognitive-behavioral Intervention and Wise Intervention have been shown to increase perceived social support and reduce self-stigma in individuals[173,174]. Furthermore, Visual Information Image Interventions [175] and Work Integration[176] assist individuals in gaining correct knowledge, changing perceptions, and enhancing social inclusion, thereby reducing stigma.

Art Therapy is currently widely applied in the work practice of mental health education in schools. When intervening with the stigma of mental illness in adolescents, art therapy methods such as film, drama, and role-playing can be adopted[177,178]. Picture storytelling or fiction writing can enable the individual's indirect contact with an AIDS patient[179]. The Petkari's study[180] discovered that watching a series of movies about mental illness (over 10 wk) accelerated college students' agency, compassion, and proximity toward patients[180]. Acceptance and Commitment Therapy (ACT), based on relational framework theory, has been dubbed the "Third Wave" of behavioral therapy[181]. In interventions for weight stigma[182], substance use disorder stigma[183], and homosexuality stigma [181], ACT has shown significant positive effects. Furthermore, Narrative Therapy[184], Written

Table 4 Other intervention strategies

Strategy	Objective
[171]Positive thinking training	Intervene with self-stigma in depressed patients
[172]Positive empathy intervention	Establish a positive emotional connection with stigmatized person to reduce stigma
[173]Cognitive-behavioral intervention	Reduce self-stigma associated with mental illness
[174]Wise intervention	Increase perceived social support; Reduce personal discrimination
[175]Visual information image intervention	Increase sense of support and engagement; Reduce stigma
[176]Work integration	Reduce perceived stigma of workers with serious mental illness
[177-180]Art therapy	Reduce mental illness stigma of adolescents
ACT	Reduce weight stigma[182], substance use disorder stigma[183], and homosexuality stigma[181]
[184]Narrative Therapy	Reduce the level of stigma for patients with permanent enterostomies
[185]Written expression-based emotional intervention	Reduce negative emotion
[186]Sand tray therapy	Improve the development of self-esteem in sexually abused adolescents
[187]CBGT	Reduce the level of stigma in the population of people living with HIV
[188]Intergenerational choir	Reduce the stigma of Alzheimer's patients and increasing positive attitudes
[189]FSM	Reduce stigma and promote mental health help-seeking behavior

ACT: Acceptance and commitment therapy; CBGT: Compassion-based group therapy; FSM: Fresh start mindset framing.

Expression-based Emotional Intervention[185], Sand Tray Therapy[186], Compassion-Based Group Therapy[187], Intergenerational Choir[188], and Fresh Start Mindset Framing[189] can be used as stigma interventions.

To summarize, in the intervention of psychiatrists' occupational stigma, protest, education, contact, integrated and systematic intervention strategies, and multiple approaches such as positive thinking training, cognitive behavioral therapy, ACT, and art therapy are available to be adopted. In order to achieve optimal results, the appropriate intervention method must be chosen based on the characteristics of the intervention target. It should be noted that while the above intervention strategies have been applied to various types of stigma interventions with positive results, more evidence is needed to support whether the strategies mentioned above are applicable to psychiatrists' occupational stigma interventions and how they can be implemented to achieve significant intervention effects.

DISCUSSION

In summary, previous studies have yielded results regarding the concept, measurement, and intervention of psychiatrists' occupational stigma. Nevertheless, there is room for improvement in this field. This review aimed to elaborate on the thinking and practices of related issues. Therefore, future research should consider improving on the four aspects outlined below.

First, clarify and refine the concept of psychiatrists' occupational stigma. Although various scholars have defined the concept of occupational stigma, related research has focused more on dirty work. Indeed, there is a paucity of research specifically on psychiatrists' occupational stigma. Based on Ashforth and Kreiner's research[43], this paper elaborates on the sources and dimensions of psychiatrists' occupational stigma, namely physically, socially, and morally. This theoretical framework allows for the development of relevant quantitative research and intervention studies. Although Ashforth and Kreiner's concept[43] of occupational stigma has gained widespread acceptance, it is not formally classified other than according to the work content of an occupation. As such, it does not reflect the cognitive, emotional or behavioral components of occupational stigma. In addition, the understanding of occupational stigma is not consistent across disciplines. Future research should combine theories from other disciplines (including individual cognitive models, social identity theory, self-verification perspectives, and other conceptual models) to further explore and extend the conceptual connotations of psychiatrists' occupational stigma. Furthermore, the theoretical framework of occupational stigma should be combined with statistical analysis to determine the multiple dimensions of psychiatrists' occupational stigma. This study provides such a theoretical basis for future measurement and intervention studies.

Second, develop specific tools to measure psychiatrists' occupational stigma. Lately, as public awareness of the harm of occupational stigma has increased, relevant measurement tools have been refined. However, some existing instruments are not sufficiently reliable nor valid, and tools specifically designed to assess psychiatrists' occupational stigma are lacking. As no consensus exists on the conceptual and operationalization scope of occupational stigma, there is inconsistency in developing relevant dimensional and measurement scales. Furthermore, most tools lack rigorous cross-cultural consistency. Future research should consider the following: (1) Define the dimensional scale and classification of psychiatrists' occupational stigma based on a multidisciplinary synthesis; (2) Develop special assessment tools for different stigma types (public stigma and self-stigma) and cohorts (psychiatrists, psychiatric students, mental illness patients, patients' families, and the public); (3) Expand the sample scope across different races, countries and age ranges to determine the impact of cross-cultural backgrounds and generational effects on the results; and (4) Based on traditional self-reporting questionnaires, adopt more indirect survey methods such as virtual reality technology, videos, or games allowing for measurement methods with higher ecological validity and aligned to life situations that yield a realistic and contextualized understanding.

Third, improve intervention strategies for psychiatrists' occupational stigma. Intervention strategies specifically applicable to psychiatrists' occupational stigma are currently lacking. Initially, when intervening for psychiatrists' occupational stigma, other types of stigma intervention strategies may be considered. However, undoubtedly these could lead to biases in the effectiveness of the intervention. Therefore, future studies should test whether existing intervention strategies are suitable for psychiatrists. Follow-up horizontal comparison and longitudinal studies can be conducted on the effects of the three common intervention strategies (protest, education, and contact), as well as integrated, systematic, or other strategies, seeking to find the most appropriate traditional intervention strategies and setting for psychiatrists. It is necessary to acknowledge that stigma may exacerbate or impede such processes as psychological[190,191] and behavioral responses[192,193] or social relationships, intensifying stress and burnout that could result in mental health disorders. Some studies have demonstrated that educational interventions which provide in-depth information about the negative effects of stigma on mental health professionals can be effective in decreasing stigma, especially for general healthcare professionals with little or no formal mental health training. Alternatively, future research should develop unique, simple, and effective intervention strategies tailored to the characteristics of psychiatrists. Combining intervention studies with experimental studies could identify simple and accessible ways to reduce occupational public stigma directed toward, and self-stigma experienced by, psychiatrists. Importantly also consider that the effects of a particular intervention may not be uniform among psychiatrists from different countries, cultural backgrounds, or years of practice. Thus, when formulating intervention strategies, full consideration should be given to differences in intervention targets.

Fourth, identify cross-cultural consistency or differences in psychiatrists' occupational stigma. Self-evidently, psychiatrists' occupational stigma can vary culturally. Future research should explore the consistency or differences in occupational stigma concepts, measurements, and interventions among psychiatrists in cross-cultural settings. For example, in Chinese culture, traditional ideas conveyed across millennia, such as Confucianism, Taoism, Buddhism, and folklore, have influenced Chinese thinking and behavior towards self-regulation; this combined with strong family values and a face-saving culture, deems mental illness as both a personal sin and a family shame[194]. Other regions may have different stigma levels toward mental illness[195], so cultural traditions may influence the inception of psychiatrists' occupational stigma. Is it possible that perceptions of psychiatrists' occupational stigma differ across cultures? Dose this influence the measurement and treatment of psychiatrists' occupational stigma? Such interrogations have yet to be confirmed through in-depth research.

LIMITATIONS

It should be acknowledged that there were certain deficiencies in the process of screening and synthesizing many studies in this literature review. First, the selection criterion, which only considered English and French literature, was limiting. Therefore, it is possible that relevant studies that satisfied other inclusion criteria were excluded. Thus, overall integrity is somewhat lacking. Second, the literature search was carried out by both professors and students. Irrelevant studies, duplicates, or those arising from incorrect search results were excluded. However, given the excessive literature search results, no secondary duplication test was undertaken. Therefore, it is impossible to determine whether excluded studies should have been included, indicating a lack of rigor. Finally, this review was based on the authors' analyses and synthesis of the literature; although the study seeks to remain objective, it contains some subjectivity.

CONCLUSION

By surveying the existing literature, this literature review has proposed a theoretical reference of the concept, measurement, and intervention methods for psychiatrists' occupational stigma. Psychiatrists' occupational stigma is a complex concept that should be interpreted in multiple dimensions. Psychiatrists are associated with three types of stigma (physical, social, and moral taint) because of the dangers of their work environment, their exposure to and treatment of high-stigma groups, or their use of controversial or aggressive treatments. Currently, there is no occupational stigma scale applicable specifically to psychiatrists. Relevant quantitative research could achieve this by adapting other occupational stigma scales. Table 1 summarizes eight possible categories of occupational stigma measurement tools for psychiatrists, including four types for public stigma and another four for self-stigma. Currently, there are few studies on occupational stigma interventions for psychiatrists. Therefore, a theoretical reference for identifying relevant intervention practices for psychiatrists' occupational stigma is required. This study has classified such stigma intervention strategies into six categories: Protest, education (Table 2), contact, comprehensive strategies (Table 3), systemic strategies, and means of incorporating psychotherapeutic approaches (Table 4).

Given that research on psychiatrists' occupational stigma has received insufficient attention and discussion in the academic community, this study provided a theoretical basis and support for future practical research. The theoretical significance of this review lies in that it refines the concept and structure of psychiatrists' occupational stigma, expands the general research field of occupational stigma, and encourages the mutual discussion of multi-disciplinary occupational stigma theories. This study further outlines relevant empirical research for the development of specialized measurement tools and creative implementations of effective interventions to reduce psychiatrists' occupational stigma, thereby promoting the healthy development of psychiatry and physician-patient relationships.

Abstract

The global burden of psychopathologies appears to be underestimated, since the global psychiatric disorder burden is exceeding other medical burdens. To be able to address this problem more effectively, we need to better understand the etiology of psychiatric disorders. One of the hallmarks of psychiatric disorders appears to be epigenetic dysregulation. While some epigenetic modifications (such as DNA methylation) are well known and studied, the roles of others have been investigated much less. DNA hydroxymethylation is a rarely studied epigenetic modification, which as well as being an intermediate stage in the DNA demethylation cycle is also an independent steady cell state involved in neurodevelopment and plasticity. In contrast to DNA methylation, DNA hydroxymethylation appears to be related to an increase in gene expression and subsequent protein expression. Although no particular gene or genetic locus can be at this point linked to changes in DNA hydroxymethylation in psychiatric disorders, the epigenetic marks present good potential for biomarker identification because the epigenetic landscape is a result of the interplay between genes and environment, which both influence the development of psychiatric disorders, and because hydoxymethylation changes are particularly enriched in the brain and in synapse-related genes.

Key Words: Mood disorders; Suicide; Schizophrenia; Bipolar disorder; Hydroxymethylation; 5-hydroxymethycytosine; Gene expression

Core Tip: DNA hydroxymethylation is one of the least investigated epigenetic mechanisms but based on currently available results it is abundant in the brain, thus potentially influencing the development of psychiatric disorders through modulation of gene expression. Currently no particular genetic locus or gene can be linked to hydroxymethylation in psychiatric disorders. However, the dynamics in gene expression of the ten-eleven translocation enzymes that catalyze hydroxymethylation have been demonstrated, and changes in hydroxymethylation levels when comparing healthy subjects with psychiatric disorders can be determined using genome-wide and candidate gene approaches.

INTRODUCTION

The global burden of psychiatric disorders

Psychiatric disorders comprise different types of mental disorder, including anxiety disorder, major depressive disorder (MDD), bipolar disorder (BP), post-traumatic stress disorder, schizophrenia (SZ), eating disorders, neurodevelopmental disorders, disruptive behavior, and dissocial disorders. All disorders have in common a clinically significant disturbance in an individual's cognition, emotional regulation, or behavior and are normally associated with distress or impairment in important areas of functioning. In 2019, there were 970 million people around the world living with a psychiatric disorder. More than half of those people struggle with anxiety disorder (301 million) or depression (280 million), both of which are also common in children and adolescents. BP was experienced by 40 million people, and SZ by approximately 24 million people[1]. Obsessive-compulsive disorder (OCD) affects 1%-3% of the worldwide population[2]. Suicide is strongly connected with psychiatric disorders (in particular, depression and BP). However, many suicides happen impulsively in moments of crisis, such as breakdown in the ability to deal with life stressors, such as financial or relationship problems, chronic pain, or illness. More than 700000 people die due to suicide and there are many more people attempting it[3]. 13% of the global population is living with a psychiatric disorder which has a substantial effect on all areas of life, such as school or work performance, relationships with family and friends, and the ability to participate in the community[4]. Besides social impact, there is also an economic burden that costs the global economy US$ 1 trillion each year[5].

Biomarkers and psychiatric disorders

A biomarker is a measurable indicator of some biological state or condition. Diagnostic biomarkers serve for narrowing down diagnoses specific to an individual patient[6]. In the field of psychiatry, diagnoses are made based on psychiatric examination using the Diagnostic and Statistical Manual or Mental Disorders or International Classification of Diseases[7,8]. As clinical presentations of the same psychiatric disorders are heterogeneous, identifying biomarkers is essential step to facilitate diagnosis through markers that allow stratification of groups within the syndrome, early detection of the disease, prescribing the right medications, and improving treatment outcome[6]. Several factors, including genetic, neurobiological, cultural, and life experiences and their interplay contribute to psychiatric disorders. Heritability plays one part in understanding pathogenesis. For example, for the development of SZ and BP there is an approximately 80% contribution of heritability, while this drops to only around 40% for depression and suicidality[9]. Scientists have tried to understand the association of genetic polymorphisms on bigger cohorts by way of genome-wide association studies (GWAS), but there still remain many unanswered questions. This indicates that environmental factors also need to be taken into account[10]. Epigenetic mechanisms such as DNA methylation and hydroxymethylation, histone tail modifications and non-coding RNAs, respond to environmental factors and cause changes in gene expression or translation without changing DNA sequence[9]. The final biological outcome results from the interplay between different epigenetic mechanisms. In recent years hydroxymethylation has received increasing attention in the "neuroepigenome"[10]. There is particular interest in hydroxymethylation because it is highly enriched in brain and synapse-related genes, and exhibits dynamic regulation during development[11].

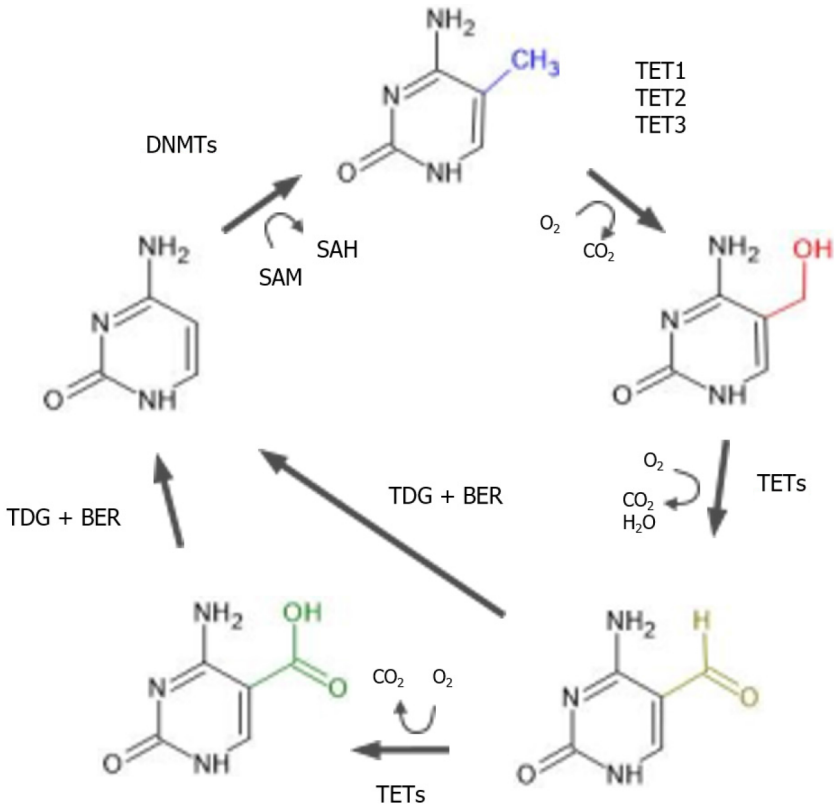
EPIGENETICS OF PSYCHIATRIC DISORDERS

DNA methylation

Mental disorders are influenced by many biological and external factors that can be linked together by epigenetics[9,12]. The term epigenetics describes innate (hereditary) or lifetime-acquired changes in gene expression that do not originate from differences in DNA sequence[13]. Epigenetics can thus help us understand the delicate interplay of environmental and genetic influences within the cell. One of the commonly studied mechanisms of epigenetic regulation is DNA methylation and the changes in its pattern. During the DNA methylation process a single methyl group is attached to the 5′ C site of the cytosine, making the cytosine either methylated or, when removed, unmethylated. DNA methylation can have a significant effect on the regulation of gene expression[14]. While DNA methylation is still the best researched and understood epigenetic modification, other types (such as noncoding RNAs) are getting more recognition[15,16].

DNA hydroxymethylation

DNA methylation was long thought of as a binary state; whether the switch was turned on (resulting in a methylated cytosine) or off (resulting in an unmethylated cytosine). However more recently it has been discovered that methylation can have stable intermediate stages, which can happen during the process of demethylation. Active demethylation is catalyzed by enzymes of the ten-eleven translocation (TET) family and the enzyme thymine-DNA glycosylase mediated base excision. TET family proteins (the enzymes TET1, TET2 and TET3) are 2-oxoglutarate and Fe(II)-dependent dioxygenases, which catalyze 5-methylcytosine (5mC) conversion to 5-hydroxymethycytosine (5hmC) (illustrated in Figure 1). DNA hydroxymethylation was first described in 1972 but it was only in 2009 that 5hmC was identified as an oxidation metabolite of DNA methylation[17,18]. 5hmCs are often localized in gene bodies and untranslated regions. Compared to methylation, levels of 5hmC are lower (roughly 10% of methylation levels), but a high abundance of 5hmC is observed in the central nervous system. Animal studies demonstrate that DNA hydroxymethylation appears to be important during neurodevelopment as levels of 5hmC in mice embryos increase in the absence of demethylation, making it a stable cell state. This is confirmed by many animal studies[19]. 5hmC can be recognized by specific binding proteins, and can be maintained through cell division[20]. While its exact role in adult brain is not known, it appears that DNA hydroxymethylation can affect neuroplasticity and neurotransmission. 5hmC as such serves a dual role, not only as an intermediate of active demethylation but also as an important mark of epigenetic regulation. As with DNA methylation, numerous environmental factors such as medication, stress and pollutants can affect levels of 5hmC[19].



Like DNA methylation, DNA hydroxymethylation also affects gene expression, but the manner and direction (upregulation or downregulation of gene expression) are not as well characterized as for DNA methylation. Nevertheless, research indicates that DNA hydroxymethylation of the gene body leads to increased gene expression. Enrichment of DNA hydroxymethylation is also often observed at 5′ splicing sites, enhancers and CpG island borders[21].

METHODS FOR DNA HYDROXYMETHYLATION DETECTION

Several methods are available for the analysis of DNA hydroxymethylation, following in the footsteps of DNA methylation methods. For DNA methylation, bisulfite conversion of DNA is the gold standard. During the conversion, unmethylated cytosines are deaminated, allowing methylated cytosines to be identified. However, the classical bisulfite conversion approach does not work for DNA hydroxymethylation because it is not possible to distinguish between methylated and hydroxymethylated cytosines[22]. Since the ratio of methylation to hydroxymethylation is approximately 9 to 1 in favor of methylation other approaches are needed to measure hydroxymethylation[23]. When the number of target genes is small, the candidate gene approach is most appropriate. When the number of target genes increases, a genome-wide approach is usually better in terms of finances, time, and information. Therefore, the selection of the appropriate method for DNA hydroxymethylation analysis should be based on the broader experimental design. Since genome-wide methods are more commonly used for 5hmC assessment, this section focuses only on such methods.

Genome-wide methods for detecting DNA hydroxymethylation

Genome-wide approaches are often better than candidate gene approaches when studying lesser-known epigenetic states such as hydroxymethylation. In addition, psychiatric disorders are complex behaviors that likely involve multiple genes. Currently, there are several methods. Some methods use restriction enzymes and glucosylation (the process by which β-glucosyltransferase specifically transfers a glucose unit to 5hmC, resulting in glucosylated 5hmC). One example is Aba-seq, which uses a restriction endonuclease AbaSI that selectively recognizes glucosylated 5hmC and cleaves DNA in its vicinity (within approximately 10 base pairs)[24]. Another example is Reduced Representation Hydroxymethylation Profiling, in which DNA is first digested with the enzyme MspI, which recognizes and

Figure 1 (De)methylation cycle of cytosine. Cytosines can be modified as a result of specific enzyme activity. DNA methyltransferases produce 5-methyl cytosine, which can be further oxidized to 5-hydroxymethyl cytosine by ten-eleven translocation enzymes. Further, two oxidative derivates, 5-formylcytosine and 5-carboxylcytosine, can also be generated and converted back to a cytosine form. BER: Base excision repair; DNMTs: DNA methyltransferases; SAH: S-adenosylhomocysteine; SAM: S-adenosyl methionine TET1: Ten-eleven translocation 1; TET2: Ten-eleven translocation 2; TET3: Ten-eleven translocation 3; TDG: Thymine-DNA-glycosylase.

cleaves the 5'-CCGG sequence. 5hmCs are later glucosylated, which prevents MspI from further cleavage, so that only fragments containing 5hmC are prevented from enzymatic digestion[25].

Tet-assisted bisulfite sequencing (TAB-seq) also takes advantage of glucosylation of 5hmC. After the glucosylation step, the DNA is oxidized using Tet proteins. The glucosylated 5hmC is retained, while 5mC converts to 5-carboxylcytosine (5caC). This oxidized DNA is then treated with bisulfite conversion and polymerase chain reaction (PCR) amplification, where unmethylated cytosines and 5mC (now 5caC) are converted to thymine, while glucosylated 5hmCs become cytosines. TAB-seq is more appropriate when only the 5hmC content is of interest[26].

A more complex method is a variant of bisulfite sequencing called oxidative bisulfite sequencing (oxBs-seq). In oxBs-seq, the sample of interest is divided into two parts; one part is subjected to bisulfite treatment, and after PCR amplification both 5hmC and 5mC are observed as cytosines. The second part of the sample is oxidized before bisulfite treatment, converting 5hmC to 5fC and after PCR amplification to thymine, with 5mC seen as cytosines. This parallel sequencing of the same sample allows accurate detection of 5hmC but increases the price because very high coverage is required[27].

Immuno-dot blot methods use antibodies that can recognize 5-hydroxymethylcytosine. A major advantage of these methods is their relative simplicity in terms of wet-lab work. They provide information on global DNA hydroxymethylation throughout the genome and provide a single numerical measure. The results do not provide detailed information on the state of hydroxymethylation in specific genomic regions, but can be used to provide a comprehensive overview of the state of hydroxymethylation in the genome[28]. A more complex immune approach uses the combination of hydroxymethylation-specific antibodies with next generation sequencing. In antibody-based methods such as hydroxymethylated DNA immunoprecipitation sequencing, DNA is cut into short fragments. Using antibodies against hydroxymethylation, only the hydroxymethylated DNA is isolated from the mixture of DNA fragments. A library is created from the purified DNA fragments and sequenced using next-generation sequencing[29]. Compared with oxBs-seq, this is a less costly option. It does not provide base pair resolution, but a resolution of a few hundred base pairs is usually sufficient for regional overview and gene identification[23,30].

Nanopore technologies is a third-generation (long-read) sequencing approach. Compared with the commonly used Illumina approach of "sequencing by synthesis", sequencing with Nanopore techno-

logies is based on small changes in current. During sequencing, DNA strands pass through protein nanopores about 1.8 nanometers in diameter embedded in a polymer membrane. As DNA strands enter the pore, the current changes according to the DNA bases that are inside the pore (about 6 DNA bases at a time). This also allows detection of epigenetic changes[31]. The advantage of this method is that it provides genome-wide information, while long reads (up to several Mb = 10^6 base pairs) allow detection of rare variants/deletions/insertions/repetitive regions as well as epigenetic DNA changes (both DNA methylation and hydroxymethylation), all in a single sample. This reduces the possibility of biological and technical errors. Although the price per sample is high (the total cost is nearly € 1000 per sample), it allows a much more detailed examination of a sample[32].

CURRENT OVERVIEW OF DNA HYDROXYMETHYLATION STUDIES AND PSYCHIATRIC DISORDERS

As mentioned above, psychiatric disorders are multifactorial disorders influenced by both genetic and epigenetic factors. As epigenetic mechanisms show a high degree of tissue specificity, the best biological source (tissue or organ) for studying psychiatric disorders is therefore the brain. Studies often focus on brain regions related to emotional and behavioral responses, and cognitive and executive control functions. These often-studied regions include the limbic system (hippocampus) and the prefrontal cortex (PFC) (Brodmann area 9 in the dorsolateral PFC)[33,34]. Since the brain is not accessible during life, other peripheral, more easily accessible tissues, such as blood, are often included in studies of psychiatric disorders as well. In the following paragraphs the available studies on DNA hydroxymethylation are summarized, with more technical data presented in Table 1.

DNA hydroxymethylation and suicidal behavior

In the field of suicidal behavior only two studies have been published that examined the pattern of DNA hydroxymethylation in suicide completers. Gross *et al*[35] examined DNA hydroxymethylation levels in PFC of male suicide completers with MDD. Compared to the control group, no global changes in DNA hydroxymethylation distribution were observed. They did however observe 550 differentially hydroxymethylated CpG sites in the genome. Lutz *et al*[36] included DNA hydroxymethylation analysis of opioid related genes in three brain regions (anterior cingulate cortex, thalamus and anterior insula). Suicide completers who experienced child abuse showed decreased level of DNA hydroxymethylation, while suicide completers with no history of child abuse did not. The decrease in DNA hydroxymethylation may therefore be a mark of child abuse.

DNA hydroxymethylation and SZ

SZ is a complex, multifactorial disease that causes psychosis. Psychotic symptoms include changes that affect personal and occupational life, *e.g.*, positive symptoms such as hallucinations, delusions, thought and movement disorder, and negative and cognitive symptoms[37]. SZ manifests in late adolescence or early adulthood. Due to psychotic symptoms, SZ is also accompanied by an elevated risk of suicide, which reduces life expectancy for people developing it[38].

Factors that contribute to the development of SZ are both genetic and environmental[39]. Large-scale GWAS has highlighted a large number of variants with small effects which are highly heterogeneous between individuals. The importance of environmental factors is studied through epigenetics. Genome-wide approach and specific candidate gene studies have shown differences in DNA methylation and histone modifications in schizophrenic patients. Associated genes are involved in axon and dendrite extension, oligodendrocyte differentiation, regulation of GABAergic transmission, metabolism of dopamine, and glutamate and serotonin receptors[40].

Candidate gene studies have shown hyper- and hypo-methylated genes in brain tissue in concordance with studies on peripheral tissue (whole blood, peripheral leukocytes, or saliva). However, the results of DNA methylation studies are not always similar between male and female patients. Moreover, many interesting results from DNA methylation studies have pushed interest toward DNA hydroxymethylation. Even though there are not as many studies investigating hydroxymethylation, and much more work needs to be done, some interesting results have been obtained[40].

The level of 5mC is increased in both male and female SZ patients, but 5hmC level in peripheral blood is increased in males and decreased in females compared to controls. Furthermore, 5mC globally increased with age in all participants (schizophrenic and controls), but there was no significant correlation with age for the 5hmC level[41]. An increased level of 5hmC was also reported in the promoter of the *GABRB2* gene in peripheral white blood cells of patients with SZ compared with controls. Furthermore, they found a correlation between promoter 5mC and 5hmC levels, with single nucleotide polymorphisms in patients with SZ. Heterozygous (C/A) genotypes of rs72815526 were correlated with increased 5hmC levels whereas heterozygous (C/T) genotypes of rs3811997 were correlated with decreased 5mC levels[42].

Table 1 Detailed data on DNA hydroxymethylation studies and psychiatric disorders

Ref.	Studied disorder	Subjects	Tissue	Method	Main results
Gross *et al* [35], 2017	Suicidal behavior/major depressive disorder	Subjects with major depressive disorder; *n* = 19 and psychiatrically healthy controls; *n* = 19	Prefrontal cortex	AbaSI sequencing	No differences in 5hmC density across the genome. Site-specific differential hydroxymethylation in the depressed brain
Lutz *et al* [36], 2018	Suicidal behavior	Suicide completers (severe child abuse history); *n* = 30, suicide completers (no child abuse history); *n* = 30 and control group; *n* = 34	Anterior insula	Targeted oxidative bisulfite sequencing	Childhood abuse in the past is associated with decreased hydroxymethylation of Kappa Intron 2
Jiang *et al* [41], 2017	Schizophrenia	Schizophrenic subjects; *n* = 264 and controls; *n* = 221	Peripheral blood	Dot blot-based measurement	5hmC levels increased in male SZ patients but decreased levels in female SZ patients
Zong *et al* [42], 2017	Schizophrenia	Schizophrenic subjects; *n* = 279 and controls; *n* = 256	Peripheral white blood cells	HpaII/MspI restriction-based EpiMark 5hmC/5mC Analysis Kit followed by qPCR	5hmC increased in the promoter of the *GABRB2* gene; correlation between heterozygous genotype rs72815526 (C/A) and 5hmC levels increased
Gavin *et al* [44], 2012	Schizophrenia and bipolar disorder	Schizophrenic subjects; *n* = 15, subjects with bipolar disorder; *n* = 11, and controls; *n* = 15	Parietal cortex (Brodmann area 39-40)	hMeDIP	5hmC increased at the promoter IXabcd of the *BDNF* gene
Dong *et al* [45], 2012	Schizophrenia and bipolar disorder	Schizophrenic subjects; *n* = 10, subjects with bipolar disorder; *n* = 9, and controls; *n* = 11	Inferior parietal lobule	Immuno-dot-blot analysis	5hmC increased at the *GAD67* gene at -537 to -415, and -145 to +21; 5hmC increased at the *BDNF* IXabcd gene at -60 to +50 not within *BDNF* exon IXd at +1185 to +1305
D'Addario *et al*[57], 2019	Obsessive compulsive disorder	Obsessive compulsive disorder; *n* = 35, and controls; *n* = 32	Peripheral blood mononuclear cells	Bisulfite conversion or oxidative bisulfite conversion, followed by pyrosequencing	*BDNF* hydroxymethlation decreased at promoter exon I; no changes in promoter exon IV and IX
Clark *et al* [60], 2022	Substance use disorder	Alcohol use disorder; *n* = 25, and controls; *n* = 25	Prefrontal cortex (Brodmann area 10)	Selective chemical labelling and enrichment of hmC (hMe-Seal)	*BAIAP2* hydroxymethylation increased

5hmC: 5-hydroxymethycytosine; SZ: Schizophrenia; 5mc: 5-methylcytosine; qPCR: Quantitative real-time polymerase chain reaction; BDNF: Brain-derived neurotrophic factor.

DNA hydroxymethylation and BP

BP is a chronic psychiatric disorder characterized by unusual shifts in mood, energy, activity levels, and concentration. Impulsive reckless behavior leads to an increased risk of suicide[43]. Since SZ and BP are both psychoses, some studies have been made on a combined group of people with SZ and BP[44,45].

A number of studies address DNA methylation in patients with BP but just two have investigated hydroxymethylation where patients with BP were included in the study alongside patients with SZ, forming a combined group of psychotic illnesses. In a study made on parietal cortical samples from psychotic patients (Brodmann area[39,40]), an increase in 5mC and 5hmC was observed at the promoter IXabcd of the brain-derived neurotrophic factor (*BDNF*) gene. This result was also associated with reduced transcription of the *BDNF* gene[44]. In another study on the inferior parietal lobule of psychotic patients increased expression of the *TET1* gene was detected. Consistent with the increase of expression the *TET1* gene, there was an increased level of 5hmC. Specifically, higher 5hmC levels were observed at the glutamate decarboxylase 67 gene at positions -537 to -415 and -145 to +21 in psychosis patients *vs* control. There was also an increase in 5hmC at the BDNF IXabcd gene at position -60 to +50 in psychosis patients *vs* control, but not within *BDNF* exon IXd at +1185 to +1305[45].

DNA hydroxymethylation and MDD

MDD is the psychiatric disorder that contributes the most to the global health burden, and is the primary cause of disability globally. The environmental factors that increase the risk of MDD the most are stress and exposure to adverse life events, meta-analyses and genome-wide studies have shown that genetic factors also contribute to its development, contributing about 40%[46].

The DNA methylation studies were summarized in a recent systematic review[47]. Out of 67 studies 61 were performed on blood samples and thus lacked information on the status of DNA methylation in the central nervous system. Among the already well-established genes, hypermethylation of BDNF and the serotonin transporter gene showed association with depression on general or MDD. Results of other genes showed mixed results[47].

Only two studies on hydroxymethylation in MDD have been reported so far the studies by Gross *et al* [35] and Lutz *et al*[36] mentioned previously. In both studies the brain tissue of subjects with MDD who died due to suicide was used, making it difficult to link the observed differences to MDD alone.

Although studies in human are lacking, three studies on mice strain C57BL/6 have been reported, all investigating the TET enzymes. Feng *et al*[48] applied chronic stress, and determined decreased levels of expression of *TET1* in the nucleus accumbens in stress-susceptible mice. In a *TET1* knockout genes related to the immune system were demonstrated to be the most highly dysregulated. Zhang *et al*[49] examined the *TET2* knockout animals, and identified some hydroxymethylated regions that overlapped with known depression-associated loci. They also showed abnormal translocation of TET2 protein from the cytosol to the nucleus in chronic stress induced mice. Cheng *et al*[50] showed that chronic restraint stress induced depression-like behavior in mice and reduced hydroxymethylation of the PFC. Knocking out *TET1* resulted in resistance to chronic restraint stress, while a knockout of *TET2* increased the susceptibility to chronic restraint stress[50]. The above results indicate that hydroxymethylation exhibits dynamic changes in response to stress-induced stimuli, resulting in changes of epigenetically regulated gene expression.

DNA hydroxymethylation and OCD

OCD is a psychiatric disorder characterized by obsessions and compulsions of various natures and degrees, and is in the majority of cases accompanied by at least one comorbid psychiatric disorder, most commonly MDD[51]. OCD is a heritable disorder with a polygenic background. Candidate gene and genome-wide studies suggest that the serotonergic, dopaminergic, and glutamatergic systems, and the interaction between them, contribute to the risk of the OCD[52]. Important contributing environmental factors are perinatal complications, childhood trauma, reproductive cycle events, and stressful life events[51].

Epigenetic studies of OCD have mostly investigated DNA methylation. Using the genome-wide approach, covering over 485000 CpG sites, genes previously associated with OCD were detected[53]. With the candidate gene approach the oxytocin receptor and serotonin transporter genes were interrogated. The results were mixed, showing both higher and lower level of methylation in OCD patients compared to controls[54-56].

In the context of the candidate gene approach *BDNF* methylation and hydroxymethylation have also been analyzed. Expression of *BDNF* in peripheral blood mononuclear cells demonstrated broad association with OCD, showing an increase in gene expression, as well as significant correlation of both lower methylation and higher hydroxymethylation at promoter exon I[57]. The results were replicated on saliva samples, showing lower levels of methylation in OCD compared to controls[2].

DNA hydroxymethylation and substance use disorder

Substance use disorder (SUD) is a mental disorder with a range of symptoms from moderate to severe. The most severe SUD is addiction. SUD affects a person's brain and behavior, which leads to the uncontrollable use of substances, such as drugs, alcohol, and medications[58]. It is common that people with SUD are also diagnosed with mental disorders and vice versa. Common mental disorders that co-occur with SUD are depression, BP, attention-deficit hyperactivity disorder, psychotic illness, borderline personality disorder, and antisocial personality disorder[59]. There are three suggestions for their joint occurrence. Firstly, common risk factors might contribute to SUD and other mental disorders; secondly, mental disorders can contribute to substance use and SUD; thirdly, substance use and SUD contribute to the development of other mental disorders[58]. It is estimated that there is a 40%-60% genetic contribution to vulnerability for developing SUD. For example, genetic vulnerability can be seen through changes in the degradation of the consumed, inhaled, or injected substance[59]. Moreover, there are also environmental factors that work through the epigenome[60].

There are several studies investigating 5hmC changes in the brains of people with SUD[61]. Clark *et al* [60] showed a difference in 5hmC of the BAIAP2 gene in the PFC from people with alcohol use disorder (AUD)[60]. One study showed differential expression of TET1 in the cerebellum of people with AUD, but no differences in 5hmC in the promoter of GABAergic genes[62]. More studies of SUD were made on model organisms, where they found 5hmC alteration after cocaine and methamphetamine administration in the nucleus accumbens[48,63,64], and a higher global 5hmC level was observed in nucles accumbens after ethanol administration[65].

CONCLUSION

In treatment of psychiatric disorders there is currently only a limited selection of validated biomarkers in use (*e.g.*, electrophysiological biomarkers, neuropsychological biomarkers, brain imaging biomarkers, blood biomarkers), while molecular-genetic markers particularly have not yet entered the routine practice. The selection of treatment is based on clinical interview. In many cases patients do not respond to the medication prescribed or their treatment is changed too quickly due to side effects, since the response to the same medication can be highly variable among patients. Thus, the screening of a

patient's genetic background could improve the selection of a suitable medicine(s) based on an individual's genetic background, taking into account pharmacokinetic and pharmacodynamics parameters. These specific differences in gene makeup have been tested in genes responsible for drug metabolism, however other genes also show changes that can significantly affect the development of disease. Shortly after the beginning of the millennium the human genome was sequenced, initiating exponential growth of genome-wide studies that continues until today. It has become evident that psychiatric disorders are polygenic, and that changes in gene sequences (*e.g.*, single nucleotide polymorhpisms, copy number variations) contribute small effects which result in the development of the disorder, also through genetic pleiotropy and epistasis. However, the results of these studies have been mixed, identifying different genes, so no particular genetic locus can be linked to a given psychiatric disorder and used as a biomarker. Since psychiatric disorders show a significant proportion of environmental risk factors, the study of epigenetics has become an important approach to linking genetics with environmental effects, and might therefore provide applicable biomarkers for diagnosis and treatment.

The majority of epigenetic studies have interrogated DNA methylation as the prime epigenetic mark, but again these have produced mixed results at the level of genome-wide analysis, while the candidate gene approach has confirmed the importance of genes involved in neurotransmission and neurotrophic growth factors. Since the development of psychiatric disorders stems from disrupted signaling in the brain DNA hydroxymethylation, which can affect neuroplasticity and neurotransmission, has become an interesting research field. To date not many studies are available, as this area develops, and joint studies on transcriptional regulation are carried out, we expect to be able to improve effects evoked by pharmacotherapy with beneficial effects on patients' health.

As is the case with genetic biomarkers, epigenetic biomarkers are not currently useful in a clinical setting, and many gaps remain in the understanding of their function. To advance our understanding of potential biomarkers, more studies simultaneously interrogating the status of the brain and peripheral tissue such as blood or even saliva are needed. Biomarkers showing good overlap between different tissue types could become key elements of validation studies on bigger, clinically well-defined cohorts, helping to discern the molecular mechanisms of psychiatric disorder development, diagnosis and treatment.

ACKNOWLEDGEMENTS

The authors would like to thank Dr. John Hancock for critical appraisal and scientific English editing of the manuscript.

FOOTNOTES

Author contributions: Kouter K, Šalamon Arčan I and Videtič Paska A organized and planned the manuscript; Šalamon Arčan I wrote Introduction, DNA hydroxymethylation and schizophrenia, bipolar disorder; Kouter K wrote Epigenetics of psychiatric disorders, Methods for DNA hydroxymethylation detection, DNA hydroxymethylation and suicidal behavior; Videtič Paska A wrote DNA hydroxymethylation and depression and obsessive-compulsive disorder, Conclusion; all authors reviewed and edited the manuscript; and all authors approved the final version of the manuscript.

Supported by Slovenian Research Agency, Young Researcher Grant to Šalamon Arčan I, No. P1-0390, J3-4533, Z3-2653.

Conflict-of-interest statement: All the authors report no relevant conflicts of interest for this article.

Abstract

There are various types of traumatic stimuli, such as catastrophic events like wars, natural calamities like earthquakes, and personal trauma from physical and psychological neglect or abuse and sexual abuse. Traumatic events can be divided into type I and type II trauma, and their impacts on individuals depend not only on the severity and duration of the traumas but also on individuals' self-evaluation of the traumatic events. Individual stress reactions to trauma include posttraumatic stress disorder (PTSD), complex PTSD and trauma-related depression. Trauma-related depression is a reactive depression with unclear pathology, and depression occurring due to trauma in the childhood has gained increasing attention, because it has persisted for a long time and does not respond to conventional antidepressants but shows good or partial response to psychotherapy, which is similar to the pattern observed for PTSD. Because trauma-related depression is associated with high risk of suicide and is chronic with a propensity to relapse, it is necessary to explore its pathogenesis and therapeutic strategy.

Key Words: Psychological trauma; Trauma-related depression; Reactive depression; Posttraumatic stress disorder; Antidepressant; Psychotherapy

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Exposure to psychological trauma may induce posttraumatic stress disorder (PTSD) and trauma-related depression. Major depression can be a progression secondary to PTSD. Both trauma-related depression and PTSD show good response to psychotherapy or prazosin, but a poor response to conventional antidepressants, suggesting that trauma-related depression should have different pathological mechanisms, like energy metabolism deficiency. It is necessary to explore the pathogenesis of and therapeutic strategy for PTSD and trauma-related depression.

INTRODUCTION

Psychological trauma is a stressful event that causes distress that exceeds an individual's ability to integrate the emotions and cognitions involved in the experience[1]. Its occurrence is unexpected and uncontrollable, often exceeding people's coping resources and making them feel powerless, helpless, and fearful. Besides natural disasters and wars, psychological trauma also encompasses various forms of physical and emotional abuse or neglect, sexual abuse, bullying, or household dysfunction experienced throughout one's entire lifespan[2].

Psychological trauma has attracted attention when the veterans returned from the Vietnam War. Although their lives have been restored, the scenarios on the battlefield always reappear and flash up in their brain every day accompanied by fragmentary memories, sleep disorders, nightmares, unstable moods, and anhedonia[3]. For the evaluation and intervention of the veterans' psychological crisis, posttraumatic stress disorder (PTSD) was first inserted in the third edition of Diagnostic and Statistical Manual of Mental Disorders in 1980[4].

Traumatic events increase not only the risk of PTSD but also depression. Trauma-related depression, which meets the criteria of major depressive disorder, can be caused directly or indirectly by psychological trauma. Previous studies showed that 61% of patients with first-episode depression and 51% with recurrent depression reported childhood or recent trauma, including adverse childhood experiences[5], recent life events[6], and occupational stressors[7]. While the pathological mechanism remains unclarified, trauma-related depression has attracted more attention because of its prolonged duration and resistance to conventional antidepressants. However, patients with trauma-related depression have a full or partial response to psychotherapy, like PTSD. Since trauma-related depression is at a high risk of suicide and is prone to relapse and be chronic, it is essential to explore the pathogenesis, therapeutic strategy, and causal relationships between psychological trauma, PTSD, and trauma-related depression. In this article, we will review the clinical characteristics of and relationship between PTSD and trauma-related depression, and their therapies.

TYPES AND CHARACTERICS OF TRAUMA

Terr[8] divided childhood trauma into type I and type II trauma (Table 1)[8,9] according to trauma characteristics. Type I trauma includes fully detailed memories, "omens", and misperceptions (such as a car accident) and has characteristics including: (1) The time of trauma formation is short or at one time; (2) trauma may occur in different stages of childhood and adulthood; (3) the duration of trauma is not long, usually within three months; and (4) some heal naturally, some benefit from treatment, and some transform into type II. Type I trauma may lead to acute stress disorder (ASD), PTSD, and adjustment disorders. Among these disorders, PTSD is the most harmful. The diagnostic requirements of PTSD include re-experiencing traumatic events, avoidance, increased sensitivity or alertness, and functional impairment.

Type II is complex trauma, including denial and numbing, self-hypnosis and dissociation, and rage, which repeatedly occurs in childhood and lasts for a long time, such as physical and emotional abuse and neglect. Its characteristics include a long time to form and a broad impact on an individual's body and mind. The trauma may occur in different stages of childhood development or adult life. In general, type II trauma presents complex and diverse symptoms and will not heal naturally. 25% to 30% of type II trauma may evolve from type I trauma[10]. Compared with type I, type II trauma has a more severe impact on individuals. It also significantly differs from type I trauma in terms of its symptoms, neuroimaging findings, treatments, and prognoses. Furthermore, it also often leads to complex PTSD (CPTSD)[11].

Table 1 Characteristics of Type I and Type II trauma

Characteristics	Type I	Type II
Resource	Disaster or accident	Abuse or violence or neglect
Onset	Acute onset	Acute or insidious onset in childhood
Duration	Sudden, transient	Repeated, long-lasting
Outcome	Be healed or develop to Type II	Be scarred or protracted
Manifestation	Re-experience, avoidance, alertness, *etc.* (take PTSD as an example)	PTSD symptoms, disorders in self-organization, disassociation
Mental disorders	Acute stress disorder, PTSD, adjustment disorder	CPTSD, adjustment disorder, Dissociative/conversive disorder

PTSD: Posttraumatic stress disorder; CPTSD: Complex posttraumatic stress disorder.

The term "complex PTSD" was proposed by Herman[11] to describe the repeated and long-term symptoms experienced by survivors of trauma, including changes in emotional regulation, consciousness, self-perception, and interpersonal relationships. This disorder can result from a single severe traumatic event or multiple chronic traumas that are difficult or impossible to escape, such as childhood abuse, domestic violence, torture, and imprisonment. The diagnosis of CPTSD in International Classification of Diseases 11th edition (ICD-11)[9] requires not only meeting the diagnostic criteria of PTSD but also evidence of disorders in self-organization, including affective dysregulation, negative self-concept, and disorders in relationships.

There is additional type of trauma called chronic unpredictable mild stress (CUMS), which has been used to model depressive symptoms in rodents[12]. Long-term (> 3 wk) exposure to a series of mild but unpredictable stressors can make animals depressive, which simulates a depressive state of human beings after encountering the stressors in the real world. However, there have been few clinical studies on CUMS thus far[13].

TRAUMA AND STRESS RESPONSE

The impact of trauma depends not only on the traumatic event itself but also on the individuals' perceptions, psychological defense mechanisms, and whether the support system is timely and sufficient. Although genetic heritability is one of the risk factors for the development of PTSD or major depressive disorder (MDD) in the population with traumas, a genetic factor may be less important as trauma exposure increases, that is, high levels of trauma are likely to lead to PTSD and MDD[14].

From the perspective of psychiatric phenomenology, traumatic events may lead to a series of nonspecific mental and behavioral symptoms of post-trauma reaction. The impact of trauma on an individual's mental state is mainly determined by the trauma's intensity, duration, and age. According to the theory of the classical response to stress[15], stress reaction can be roughly divided into alarm, resistance, and exhaustion stages[16]. In the alarm stage of post-trauma condition, a stress reaction may manifest a "fight or flight" response by activating the sympathetic nervous system to release catecholamine. If stress reaction is insufficient, ASD will occur. After the acute stage comes the resistance stage. This stage involves adjustment to the persistent trauma or the after-effects of traumatic events *via* the activation of the hypothalamus–pituitary–adrenal (HPA) axis and promotion of endogenous glucocorticoids function to maintain the internal environment. If the stress reaction is insufficient, the manifestations of PTSD will appear.

If the trauma is too intense or prolonged, Individuals will encounter the exhaustion stage by excessive mobilization of the sympathetic nervous system and HPA axis, and manifests maladjustment or trauma-related depression (reactive depression). Therefore, multiple traumatic events can have cumulative detrimental effects on mental health of the victims[17], manifesting depressive symptoms such as negative emotions, guilt, shame, self-blame, social withdrawal, or social isolation. They can also become irritable, aggressive, violent, and of self-injury or suicidal behaviors, or have persistent dissociative symptoms and acoustic and visual hallucinations similar to those that occur in psychosis[18, 19]. Individuals with post-trauma reactions are often diagnosed with depression or bipolar depression with or without psychotic symptoms or borderline personality disorder according to the ICD-11 or the Diagnostic and Statistical Manual of Mental Disorders 5th edition (DSM-5)[20].

PTSD AND TRAUMA-RELATED DEPRESSION

Relationship between PTSD and trauma-related depression

Studies have shown that collective trauma caused by earthquakes and plagues may lead to collective emotions accompanied by pro-social behaviors, thus reducing the adverse effects of traumatic events on individuals[21]. However, suffering from interpersonal trauma (individualized trauma) such as abuse, neglect, or sexual violence often brings negative consequences which are easily internalized, become chronic and gradually develop into "trauma mode" as Piaget referred to[22], which manifests as persistent depression, negative cognition, negative self-concept, and self-injury/suicide[23].

ASD usually occurs within minutes or hours after a severe traumatic event. The symptoms are transient, usually relieved within days or a week. Therefore, PTSD is the most common lasting and harmful stress response to trauma and it is dominated by negative emotions such as anxiety, fear, irritability, and depression. The onset of PTSD usually occurs one month or several years after traumatic events. PTSD and depression often occur comorbidly. As a result of a meta-analysis (k = 57 studies; n = 6670 participants), 52% of individuals with PTSD had comorbid MDD[23]. In addition, a number of overlapping symptoms were reported. Although it is sometimes challenging to differentiate, PTSD and MDD are two significantly different diseases.

Although the depressive symptoms present in PTSD can predict the occurrence and severity of depression, some scholars, such as Freedman *et al*[24] and Bleich *et al*[25] argue that there is no chronological progression from PTSD to MDD. However, many studies support the continuity between PTSD and MDD[26,27]. PTSD can lead to affective disorder[16], significantly increasing the risk for the first-onset of major depression[28].

The COVID-19 pandemic caused long-term psychological impacts on people, like insomnia, anxiety, depression, and burnout syndrome, which has raised public health concerns globally. Burnout is a state of physical or mental stress resulting from prolonged exposure to job stressors. Burnout prevalence differs in different specialties. Studies have shown that after a high workload or prolonged contact with patients, nearly one-third of healthcare workers met the clinical level of exhaustion and manifested anxiety, irritation, fatigue, depression, depersonalization, and PTSD[29,30]. A 1-year observational study showed that the prevalence of burnout and anxiety was similar at 3 mo (52% *vs* 51%) and 12 mo (23% *vs* 23%), while the prevalence of PTSD was higher than that of depression at both 3 mo (23% *vs* 11%) and 12 mo (11% *vs* 6%)[31].

The prevalence of depression and PTSD-like symptoms in adolescents increased significantly during the pandemic period of COVID-19[32,33]. During the COVID-19 pandemic, the comorbidity prevalence of PTSD and depression was about 50%[34]. However, a remote telephone interview revealed that the prevalence of PTSD and depression in patients who recovered from COVID-19 was 56.9% and 29.0%, respectively[35]. It indicates that PTSD symptoms are the main symptoms during or at the beginning of traumatic events.

In a survey of the elderly, the lifetime prevalence and 12-mo prevalence of sexual violence are 44% and 8%, respectively, while the lifetime prevalence of depression, anxiety, and PTSD are 27%, 26%, and 6%, respectively[36]. It indicates that the long-term effects of traumatic events on individuals are mainly depressive symptoms, and the patients might be diagnosed with major depressive disorder according to DSM-5 or ICD-10. Because this type of depression is associated with psychological trauma(s), it is often resistant to the treatment and much harmful.

Treatment and potential mechanism of PTSD and trauma-related depression

Trauma-related depression is caused by intense and persistent frustration or other psychological conflict factors. It may be considered reactive depression (stress-induced depression) and different from endogenous (biogenic) depression. Reactive depression and endogenous depression were proposed by the German psychiatrist Kurt Schneider in 1920[37] in trying to classify depression by its etiology. This classification enjoyed broad acceptance[38] up to the introduction of DSM-IV in 1994[39]. Since then, psychiatrists and scholars have returned to the principle of phenomenological description of mental disorders. For instance, if a patient has clinical manifestations that meet the descriptive criteria for depression, the patient will be uniformly diagnosed with depression without emphasizing its etiological classification, which makes the diagnosis and intervention much easier. The etiology of different depression types seemed less important, particularly since the discovery of tricyclic antidepressants and the establishment of a monoamine-based hypothesis[40].

However, since 1994 and even more since the COVID-19 pandemic, patients with reactive depression have increased markedly[41]. The poor efficiency of conventional antidepressants in reactive depression has again drawn attention to psychological trauma and "reactive depression", particularly depression with childhood trauma. Studies[42,43] have confirmed that depression related to trauma (especially childhood trauma) is very complex in clinical manifestations and many other aspects, such as neurobiological factors, treatment response and prognosis.

Childhood trauma or a recent traumatic event is an important precipitating and perpetuating factor of depression in adolescents and elderly patients[36,43]. Severe psychological trauma can also lead to PTSD or CPTSD with comorbid depression. For example, more than 50% of PTSD patients have

Table 2 Studies investigating the therapy on major depressive disorder patients with childhood trauma or recent trauma

Ref.	Study/review	Details	Tools	Results
Nemeroff *et al*[47], 2003	RCT	681 MDD patients with childhood trauma were assigned to nefazodone, CBASP, or combination	HRSD24	For those with childhood trauma, psychotherapy alone was superior to antidepressant monotherapy
Asarnow *et al*[52], 2009	RCT	334 youth failed in an adequate SSRI trial were randomized to 12 wk with an alternative SSRI, an alternative SSRI + CBT, venlafaxine, or venlafaxine + CBT	CDRS-R, CGI-I	The CBT or combined treatment was superior to medication alone
Nanni *et al*[50], 2012	meta-analysis	10 clinical trials of 3098 MDD subjects with childhood trauma were analyzed based on depression course: recurrence or persistence	CIDI, PSE, SCAN, MINI or HAMD	Childhood maltreatment was associated with lack of response to treatment and lack of remission (OR = 1.43, 95%CI: 1.11-1.83)
Williams *et al*[48], 2016	Cohort study	1008 MDD and 336 healthy controls were treated with escitalopram, sertraline or venlafaxine for 8 wk	QIDS_SR16, HRSD17	Below 7 yr of age predicted poorer outcomes, and 4-7 yr the poorest
Yrondi *et al*[51], 2019	Cohort study	In 291 TRD patients, 135 (52.7%) were available at 1-year follow-up	QIDS_SR, MADRS	Baseline CTQ scores had a significant influence on remission at 1 year [χ^2 (1) = 5.57; P < 0.05]
Christensen *et al*[6], 2020	Cohort study	61% of subjects (1113/1811) reported trauma history, and were treated with vortioxetine (5-20 mg/d) or placebo for 8 wk	MADRS, CGI-I	Subjects with trauma with placebo were more likely to relapse than with vortioxetine
Menke *et al*[55], 2021	Cohort study	150 in-patients of MDD were recruited in the 4-wk antidepressant trial, 68 with multiple childhood trauma (*i.e.* ≥ 3) and 59 with ≥ 3 severe recent life events	HRSD21	Severe recent life events were associated with a poor response to antidepressants (F = 7.456; df = 1; P = 0.008), These effects may not be observed with childhood trauma

RCT: Randomized controlled trial; MDD: Major depressive disorder; CBASP: Cognitive behavioral analysis system of psychotherapy; HRSD24: Hamilton rating scale for depression-24 items; SSRI: Selective serotonin reuptake inhibitor; CBT: Cognitive-behavioral therapy; CDRS-R: Children depression rating scale-revised; CGI-I: Clinical global impression–improvement; CIDI-C: Composite international diagnostic interview-core version; PSE: Present state examination; SCAN: Schedules for clinical assessment in neuropsychiatry; MINI: The MINI-international neuropsychiatric interview; HAMD: Hamilton depressive scale; OR: Odds ratio; 95%CI: 95% confidence interval; QIDS_SR16: The 16-item self-report versions of the quick inventory of depressive symptomatology; HRSD17: Hamilton rating scale for depression-17 items; TRD: Treatment-resistant depression; QIDS_SR: Self-report versions of the quick inventory of depressive symptomatology; MADRS: The Montgomery-Asberg depression rating scale; CTQ: The Childhood trauma questionnaire; HRSD21: Hamilton rating scale for depression-21 items.

comorbid depression[34]. Psychological trauma may affect the individual's response to antidepressants, clinical outcomes, and function. Regarding the treatment of PTSD, paroxetine, sertraline, fluoxetine, and venlafaxine are recommended, however, the efficiency of selective serotonin reuptake inhibitors (SSRIs) or serotonin and noradrenaline reuptake inhibitors in PTSD is comparably low (only about half as strong)[44]. Psychotherapy is the treatment of choice for PTSD, including cognitive behavior therapy (CBT), prolonged exposure, and eye movement desensitization and reprocessing (EMDR)[45].

The treatment of trauma-related depression, particularly in patients with childhood trauma, has been extensively studied (Table 2). Previous studies have shown that various childhood abuses is unfavorable to the treatment, and the poor response is significantly related to childhood abuse[46-48], particularly trauma that occurred before the age of 7 years. Even after 8 wk of therapy with antidepressants, there was no remission. Moreover, there was a high risk of recurrence[5,48]. Meanwhile, childhood trauma is also an important risk factor for suicidal ideation and the increased severity of refractory depression[49-51]. However, although patients with chronic depression after trauma have a comparatively good response to the psychotherapy with EMDR[47]. Asarnow *et al*[52] found that patients of refractory depression with a history of abuse have a significantly lower response to CBT than those without abuse. Shirk *et al*[53] believed that trauma-focused cognitive behavioral therapy (TF-CBT) could significantly improve depressive symptoms. A meta-analysis[54] showed that TF-CBT and EMDR are beneficial in alleviating the traumatic experience, depression, and anxiety of patients with PTSD. It was found that psychotherapy has better compliance than psychopharmacological therapy. Therefore, it is suggested that psychotherapy should be introduced in the early stage of the treatment of trauma-related depression[55].

Taken together, for the patients with trauma-related depression, the symptomatology is more complex; the suicide rate is higher[49]; the clinical condition is more prone to be chronic, and the response to antidepressant is poorer[5,42,47,48]. Therefore, it is speculated that trauma-related depression may have different biological mechanisms compared to other depressed patients[56,57].

Compared with classic depression, there are few studies on the underlying neurobiological mechanisms of trauma-related depression. It was previously thought that the occurrence of PTSD or chronic PTSD was related to noradrenergic dysfunction[58] or cytokines[57]. However, in recent years, we have learned by the CUMS model that energy metabolism disorder might play an important role[59-61].

Although the etiological mechanisms underlying PTSD or trauma-related depression are not known in detail, the efficacy of certain therapies may be indicative of existing pathomechanisms[62]. For example, in a case study, it was reported that low-dose prazosin led quickly to rapid improvement in depressive symptoms, including cognitive function in a therapy-resistant depressive patient with comorbid chronic PTSD[63]. The patient had previously received antidepressants that work *via* serotoninergic, noradrenergic, and dopaminergic mechanisms as well as several sessions of modified electroconvulsive therapy but did not benefit from these treatments, suggesting that prazosin may have acted by different pharmacological mechanisms from monoamine hypothesis[64]. This observation might turn out to be important in order to explore the pathogenesis of PTSD and trauma-related depression[65].

However, there is also a meta-analysis[50] has showed that, for adult depressive patients with childhood abuse, the effectiveness of antidepressant drugs alone, and psychotherapy alone, combined therapy is not satisfactory. In the same sense, some PTSD patients still have poor responses to psychotherapy. Therefore, we need to explore new treatment methods to improve the prognosis of PTSD patients with comorbid depression. For this purpose, it is necessary to expand our knowledge of the pathogenesis of trauma-related depression.

CONCLUSION

Exposure to psychological trauma may induce PTSD and trauma-related depression. Major depression can be a progression secondary to PTSD. Both trauma-related depression and PTSD show good response to psychotherapy or prazosin, but a poor response to conventional antidepressants, suggesting that trauma-related depression should have different pathological mechanisms, like energy metabolism deficiency. It is necessary to explore the pathogenesis of and therapeutic strategy for PTSD and trauma-related depression. Although we reviewed detailed features of trauma-related depression and PTSD, the relationship between them is ambiguous. In this article, one weakness is the limited discussion of the pathogenesis of trauma-related depression and PTSD, and the etiological roles in the pathogenesis.

Abstract

BACKGROUND

Insomnia is a disease where individuals cannot maintain a steady and stable sleep state or fail to fall asleep. Western medicine mainly uses sedatives and hypnotic drugs to treat insomnia, and long-term use is prone to drug resistance and other adverse reactions. Acupuncture has a good curative effect and unique advantages in the treatment of insomnia.

AIM

To explore the molecular mechanism of acupuncture at Back-Shu point for the treatment of insomnia.

METHODS

We first prepared a rat model of insomnia, and then carried out acupuncture for 7 consecutive days. After treatment, the sleep time and general behavior of the rats were determined. The Morris water maze test was used to assess the learning ability and spatial memory ability of the rats. The expression levels of inflammatory cytokines in serum and the hippocampus were detected by ELISA. qRT-PCR was used to detect the mRNA expression changes in the ERK/NF-κB signaling pathway. Western blot and immunohistochemistry were carried out to evaluate the protein expression levels of RAF-1, MEK-2, ERK1/2 and NF-κB.

RESULTS

Acupuncture can prolong sleep duration, and improve mental state, activity, diet

volume, learning ability and spatial memory. In addition, acupuncture increased the release of 1L-1β, 1L-6 and TNF-α in serum and the hippocampus and inhibited the mRNA and protein expression of the ERK/NF-κB signaling pathway.

CONCLUSION

These findings suggest that acupuncture at Back-Shu point can inhibit the ERK/NF-κB signaling pathway and treat insomnia by increasing the release of inflammatory cytokines in the hippocampus.

Key Words: ERK/NF-κB signaling pathway; Acupuncture; Insomnia; Inflammation; Acupuncture at Back-Shu point; Traditional Chinese medicine

Core Tip: In this study, insomnia was a condition that was unable to maintain a stable sleep state or to sleep. Western medicine mainly uses sedative and hypnotic drugs to treat insomnia, which easy to produce drug resistance and some adverse reactions. Acupuncture has excellent efficacy and unique advantages in the treatment of insomnia. This study aimed to investigate the molecular mechanism of Back-Shu acupuncture for insomnia.

INTRODUCTION

Insomnia is a common clinical disease. Sleeping difficulty and short sleep time are typical clinical symptoms of insomnia. Insomnia not only seriously affects patients' daily activities and work, but also leads to a reduction in their living standards. Some patients also have anxiety, depression, and other negative psychological emotions. Long-term sleep disorders can easily induce immunity and memory loss, increase the risk of cardiovascular and cerebrovascular diseases, and threaten the life and health of patients[1]. At present, sedatives, hypnotics, antidepressants, and other psychiatric drugs are mainly used to treat insomnia. However, high drug dependence and a high incidence of adverse reactions limit their clinical application[2]. Traditional Chinese medicine believes that insomnia is a type of restlessness caused by liver qi stagnation and spleen damage. Traditional Chinese medicine prescriptions and external treatment with traditional Chinese medicine have remarkable effects on this disease[3].
