ABOUT COVER

Editorial Board Member of *World Journal of Stem Cells*, Yu-Chen Hu, Professor, Department of Chemical Engineering, National Tsing Hua University, 101, Sec. 2, Kuang Fu Rd., Hsinchu 30013, Taiwan

AIM AND SCOPE

World Journal of Stem Cells (*World J Stem Cells*, *WJSC*, online ISSN 1948-0210, DOI: 10.4252), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJSC covers topics concerning all aspects of stem cells: embryonic, neural, hematopoietic, mesenchymal, tissue-specific, and cancer stem cells; the stem cell niche, stem cell genomics and proteomics, and stem cell techniques and their application in clinical trials.

We encourage authors to submit their manuscripts to *WJSC*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

INDEXING/ ABSTRACTING

World Journal of Stem Cells is now indexed in PubMed Central, PubMed, Digital Object Identifier, and Directory of Open Access Journals.

Abstract

Alternative splicing (AS) is an essential mechanism in post-transcriptional regulation and leads to protein diversity. It has been shown that AS is prevalent in metazoan genomes, and the splicing pattern is dynamically regulated in different tissues and cell types, including embryonic stem cells. These observations suggest that AS may play critical roles in stem cell biology. Since embryonic stem cells and induced pluripotent stem cells have the ability to give rise to all

types of cells and tissues, they hold the promise of future cell-based therapy. Many efforts have been devoted to understanding the mechanisms underlying stem cell self-renewal and differentiation. However, most of the studies focused on the expression of a core set of transcription factors and regulatory RNAs. The role of AS in stem cell differentiation was not clear. Recent advances in high-throughput technologies have allowed the profiling of dynamic splicing patterns and cis-motifs that are responsible for AS at a genome-wide scale, and provided novel insights in a number of studies. In this review, we discuss some recent findings involving AS and stem cells. An emerging picture from these findings is that AS is integrated in the transcriptional and post-transcriptional networks and together they control pluripotency maintenance and differentiation of stem cells.

Key words: Alternative splicing; Stem cell; Pluripotency; Differentiation; Splicing factor

Core tip: Alternative splicing (AS) produces multiple transcript isoforms from a single gene, and the regulation of cell-type-specific splicing pattern is crucial for the properties and functions of cells, including pluripotent stem cells. A better understanding of the role of AS in stem cell pluripotency maintenance and differentiation will offer potential new approaches for enhancing the production of induced pluripotent stem cells and/or better control of cell differentiation for research or therapeutic purposes. In this brief review, we provide a timely update of recent studies related to stem cell regulation and splicing in a genome-wide scale.

Figure 1 Major alternative splicing events in the metazoan transcriptome. Major types of alternative splicing events are shown. Brown boxes indicate constitutive exons, while boxes in other colors indicate alternative spliced exons.

INTRODUCTION

The splicing of messenger RNA precursors, namely the precise removal of introns and the joining of exons, is a crucial yet highly dynamic and flexible process in the synthesis of mature eukaryotic mRNAs. Alternative splicing (AS), the inclusion of different exons in mature mRNA by selecting different splice sites in pre-mRNA, can result in different transcript isoforms from a single gene, and give rise to a much larger number of proteins compared to the number of genes encoded in metazoan genomes^[1-3]. AS regulation plays an important role in almost every aspect of eukaryotic biological processes, including cell growth, death, pluripotency maintenance, differentiation, development, circadian rhythms, response to external changes, and disease^[4,5]. Recent advances in high-throughput RNA sequencing technology revealed that a greater number of multi-exon genes can produce alternatively spliced transcripts than previously thought^[6,7]. In humans, more than 90% of genes were estimated to undergo AS in different tissues and/or cell types. Compared with other RNA processing mechanisms such as alternative transcription initiation, RNA editing and alternative poly(A) site selection, AS is the most prominent in generating mRNA complexity. In addition, AS events can introduce premature termination codons in mature mRNAs, triggering mRNA degradation by the process of nonsense-mediated mRNA decay (NMD)^[8,9]. AS events can also cause mRNA untranslated region (UTR) variation, which affects mRNA translation efficiency, stability and localization^[10-12].

Splicing of pre-mRNA involves the formation of active splicing complexes on pre-mRNAs *via* a stepwise assembly process. The basal splicing machinery (spliceosome) is comprised of five small nuclear ribonucleoprotein particles

(snRNP), such as U1, U2, U4/U6 and U5 in the case of the major spliceosome, and U11, U12, U4atac/U6atac and U5 in the case of the minor spliceosome. AS is primarily regulated by approximately 200 RNA-binding proteins (splicing factors) together with a basal spliceosome through direct recognition of short sequence motifs near exon/intron boundaries^[13]. Depending on the pattern of exon inclusion/skipping, AS events can be categorized into at least six major types, including cassette exon skipping, mutually exclusive exons, alternative 5' splice site selection, alternative 3' splice site selection, alternative retained intron, and tandem cassette (Figure 1). There are more complex patterns but they are much fewer in number than these major types, therefore most analyses of AS events focus on these six types, particularly cassette exon skipping which represents the majority of AS events.

The knowledge of the crosstalk between splicing and other layers of gene regulatory network is fundamentally important for understanding biological processes such as cell differentiation, development, and pluripotency maintenance. In this review, we will highlight recent progress related to these themes, with an emphasis on studies involving both AS and stem cell research, to provide timely insight into AS regulation and its important roles in the determination of cell fate. The general principles of splicing regulation have been covered in detail in a number of excellent reviews, and readers who are interested in the mechanisms of splicing regulation can refer to these^[9-11,14-21].

GENOME-WIDE METHODS APPLIED IN AS RESEARCH

Our understanding and knowledge about AS has increased rapidly during last decade, thanks to the advancement

Figure 2 Methods for profiling alternative splicing events. The diagram depicts methods used for profiling AS events. The cassette exon AS event is used as an illustration for simplicity. "E1" and "E2" are constitutively spliced exons, and "A" is an alternative exon. Probes designed for specific regions are noted with a "Pr-" prefix. A: Splicing sensitive microarray for AS profiling. Adopted from^[2]. B: RNA sequencing for AS profiling. Percent spliced-in value (PSI) #E1A, #E1E2, #AE2 are the number of reads mapped to the spliced junctions. AS: Alternative splicing.

of several high-throughput technologies. To better understand AS regulation, it is necessary to be familiar with the basic principles of these technologies. Here, we summarized some of the technologies that were applied to study AS in a genome-wide scale.

The first genome-scale AS study was carried out using microarray platform. Traditional microarrays have been designed to measure the total level of expression of a gene, without discrimination of its different isoforms^[22-24]. To probe AS events, several splicing-sensitive microarray platforms have been developed^[3,25,26]. Although there are variations between them, these splicing-sensitive microarrays all utilize short oligonucleotide probes designed to cross exon-exon junctions. cDNA samples were derived from mRNA and hybridized to the probes (Figure 2A). The signal intensity of these junction probes can then be used to infer exon inclusion ratios by sophisticated algorithms^[27-37]. These microarrays have been applied in a number of studies to generate genome-scale profiling of AS, and provided quantitative measurements of AS at different time points of development, across tissues, and upon perturbation of interesting splicing factors^[28,31,32,34,35,37]. From these pioneering studies, genome-level regulatory mechanisms of AS have been better understood, and have largely transformed our

view about AS in every aspect including their evolution, dynamic regulation, and their organization in global transcription networks^[2,19].

Recently, RNA sequencing technology has been evolving rapidly, and has become the method of choice for genome-wide AS analysis. In RNA sequencing methodology, cDNA fragments derived from poly(A) selected RNA population are sequenced from the ends and generate a large number of short sequence tags (reads). These reads can then be mapped (aligned) back to the reference transcriptome and splice-mapped reads can reveal the exon-exon junctions (Figure 2B)^[38,39].

Compared with microarrays, RNA sequencing (RNA-Seq) does not rely on probes pre-designed across exon-exon junctions based on prior knowledge about the transcriptome under study, thus novel exons and splice junctions can be detected in an unbiased manner. RNA sequencing also has other advantages such as no cross-hybridization issues, higher sensitivity and broader dynamic range^[40-46]. As the technology keeps improving and costs continue to decline, longer read length and more extensive sequencing coverage can lead to more accurate AS detection at a reasonable price.

High-throughput reverse transcription-polymerase chain reaction (RT-PCR) has also been developed and used

for monitoring AS changes^[47-49]. Although the number of AS events monitored is limited by prior knowledge from the reference AS database, in theory, it has the advantage of avoiding bias towards the highly expressed genes, and can quantify AS of medium- and extremely low-expressed genes^[50]. There is also a very good correlation between percent spliced-in (PSI, the percent of transcripts that include a specific AS exon; Figure 2) values obtained with RNA-Seq data and the PCR-based method for events in which RNA-Seq data had enough coverage to produce confident PSI estimates, suggesting that the PCR-based method is consistent with RNA-Seq and these two methods can complement each other^[48,51].

Methods for directly mapping RNA-binding protein (RBP) and the mRNA interaction transcriptome-wide *in vivo* have also been developed, complementing AS event profiling to decipher the regulatory network of splicing by RBP. To identify binding targets, a specific RBP together with its associated RBP complex is immunoprecipitated from cell lysate, and bound RNA transcripts are then purified and subjected to high-throughput sequencing^[52-54]. After mapping the reads back to the reference genome sequence, potential binding locations of RBPs can then be inferred by computer algorithms. RBP complexes can be immunoprecipitated under native condition; however, this can increase the risk of losing low-affinity yet specific *in vivo* binding or of obtaining artificial binding following cell extraction^[55]. A cross-linking step is usually performed to circumvent these problems. Several methods have been developed in this area. The CLIP-Seq (cross-linking immunoprecipitation and high-throughput sequencing, or HITS-CLIP) method uses UV light to crosslink proteins with RNAs^[56]. In PAR-CLIP (photoactivatable-ribonucleoside-enhanced crosslinking immunoprecipitation), photoreactive ribonucleotide analogs are used to treat cells and are incorporated into RNAs before UV treatment^[57]. And individual-nucleotide resolution cross-linking and immunoprecipitation (iCLIP) employs a self-circularization strategy to achieve individual-nucleotide resolution^[58]. RBP mapping combined with AS profiling can be used for constructing “RNA maps” which correlate binding site positions with splicing regulatory differences upon perturbation of specific splicing factors.

ALTERNATIVE SPLICING IN STEM CELLS

Advanced technologies have recently been adopted to profile AS in stem cells. Extensive AS patterns were observed in stem cells and their contribution to pluripotency maintenance and differentiation has been noted.

Pervasive splicing in embryonic stem cells

Embryonic stem cells (ESCs) are pluripotent cells which can self-renew and has the ability to differentiate into all three germ layers^[59,60]. As ESCs can generate most if not all of the cell types of a human body, they serve as an excellent model for studying early embryonic development. ESC is also a valuable source for producing differentiated

cells for potential cell therapeutic purposes^[61,62]. Thus, intensive efforts have been devoted to stem cell gene expression profiling, and genes associated with pluripotency were discovered^[63,64]. However, only recent advances in next generation sequencing technology made it possible to profile the AS pattern of a given cell/tissue in a global scale. A number of genome-wide studies showed specific transcriptome changes during the differentiation of ESCs into different lineages^[65-70].

In 2005, Pritsker *et al.*^[65] started using expressed sequence tag collections derived from stem cells to identify splice variants in ESCs and hematopoietic stem cells, and this was one of the first AS analyses in stem cells on a genome-wide scale. AS was detected in > 1000 genes. Although the technology is outdated nowadays, it showed that AS generates a large diversity in the stem cell molecular repertoire.

Further studies using advanced technologies confirmed the pervasive AS in ESC. A study by Wu *et al.*^[66] adopted three types of RNA sequencing technologies and profiled the transcriptome changes during the differentiation of human ESCs (hESCs) into the neural lineage. The authors combined Illumina single and paired-end reads (sequence reads from both ends of cDNA fragments; 35 bp reads) and longer Roche 454 FLX and titanium sequencing reads (250-450 bp reads) to discern transcript structure and analyze transcriptome complexity. Transcriptome profiles of cells in the ESC stage, N1 (early neural initiation) stage, N2 (neural progenitor) stage, and N3 (early glial-like) stage were reconstructed from mapped sequencing reads. Utilizing the unique spliced junction reads detected from each gene across all four stages, the authors then calculated a “junction complexity index” and found that splicing isoform diversity is highest in undifferentiated hESCs and decreases upon differentiation, a phenomenon they named “isoform specialization”. Observations like this can only be achieved with a genome-scale study, demonstrating the power and potential of RNA sequencing in AS research. In 2010, Revil *et al.*^[71] applied splicing-sensitive exon microarray technology to profile alternative isoform expression in embryonic day 8.5, 9.5 and 11.5 embryos and placenta. Although the profiling was not performed using pure ESCs, their results revealed frequent AS during embryonic developmental stages. Intriguingly, a number of RBPs, including putative splicing factors, are differentially expressed and spliced across developmental stages, suggesting these RBPs may be involved in regulating tissue and temporal variations in isoform expression.

During reprogramming, the AS profile of induced pluripotent stem cells is reversed to an ESC-like state

It is well known that when somatic cells are reprogrammed to pluripotent stem cells (PSCs), the transcription of most genes reverted to an ESC-like state. An interesting question is whether this is also true for AS?

Several recent studies answered this question by profiling both induced PSC (iPSC) and ESC AS patterns in a

genome-wide scale. Ohta *et al.*^[72] combined RNA-seq and high-throughput absolute qRT-PCR to analyze splicing pattern changes during the reprogramming process. The somatic cell splicing profiles reverted to a pluripotent-like state during reprogramming. In addition, to determine whether alterations in splicing patterns are specific for PSCs, the authors identified 27 genes which undergo alterations during the reprogramming process, and profiled the splicing pattern of these genes across multiple tissues by qRT-PCR. Interestingly, the splicing patterns in iPSCs were most similar in the testes compared with other tissues, suggesting an intriguing hypothesis that PSCs regulate AS using the same mechanism as the testes does. Other work also showed that the splicing pattern is similar in iPSCs and ESCs^[48,51]. These observations raised the possibility that manipulating specific splicing regulators can potentially fine tune the reprogramming process.

ALTERNATIVE SPLICING INFLUENCES PLURIPOTENCY

In addition to investigating AS patterns during ESC differentiation, efforts have also been made to determine the functional impact of AS in ESCs^[65]. In the study of Pritsker *et al.*^[65], splicing complexity in ESCs was observed, and they also found that AS can modify multiple components of signaling pathways which are important for stem cell function. The distribution of splice variants across different classes of genes indicated that tissue-specific genes have a higher tendency to undergo AS than ubiquitously expressed genes. Comparisons between all orthologous genes which undergo AS in human and mouse transcriptomes showed that the patterns of AS are only weakly conserved, supporting that AS patterns evolve fast^[73,74]. Because multiple genes in stem cells undergo AS and these genes are enriched in regulatory proteins, stem cell molecular networks are highly dependent on AS.

Salomonis *et al.*^[67] investigated the roles of AS and alternative promoter selection in differentiating mouse ESCs using the Affymetrix exon-exon junction microarray. Among approximately 7500 genes and 40000 putative exon-exon junctions represented in the microarray, the authors identified 170 unique alternative exons (AEs) corresponding to 144 genes. It was predicted that 67% of these AEs altered the protein sequence and domain composition. Pathway analysis of these genes showed enrichment in genes associated with Wnt and transforming growth factor-beta receptor signaling pathways, the actin cytoskeleton, lipid transport, muscle contraction, mRNA metabolism, and embryonic development. Most of these 170 AEs were conserved between mouse and human, suggesting their functional importance. In order to examine the functional impact of AS, two genes, *SERCA2* and *Tcf3* that showed large differences in the expression level of alternative isoforms, were selected for examination. *SERCA2* is a Ca^{2+} pump that hydrolyzes ATP during the translocation of calcium from the cytosol to sarco/endoplasmic reticulum^[75]. PCR confirmed that one of its isoform (SERCA2b), with

an additional 44 amino acids and a longer 3'UTR region, was expressed in both ESCs and embryoid bodies (EBs), whereas another isoform with a shorter alternative 3'UTR (SERCA2a) was mainly expressed in EBs. Interestingly, the 3'UTR of SERCA2b was predicted to be targeted by many microRNAs (miR-200b, miR-214, *etc.*) but not SERCA2a in both mice and humans. This is consistent with the observation that SERCA2b mRNA is more degraded than SERCA2a in an experiment *in vitro*^[76], indicating 3'UTR of SERCA2b can inhibit protein expression. Using a library of miRNA mimics, the authors further confirmed that miR-200b and miR-214 among other miRNAs were indeed targeting SERCA2b. Bioinformatics analysis showed that miR-214 and miR-200b binding sites were enriched for inhibitor genes of cardiac differentiation, indicating they play functional roles in cardiac development by repressing cardiac inhibitor gene expression. In addition, previous studies showed that miR-200b and SERCA2a are both highly induced upon cardiac differentiation^[75,77,78]. Taken together, this study suggests that *SERCA2* can avoid direct repression by miRNAs through selectively expressing one of its isoforms (SERCA2a) which has no miRNA target sites in differentiated ESCs. This observation implies the ability of AS to regulate protein expression, without affecting gene or miRNA transcription. The other gene studied is *Tcf3* (TCF7L1 in humans), a Wnt signaling transcription factor and a repressor of ESC self-renewal. *Tcf3* inhibits ESC self-renewal through repression of Nanog and Oct4 transcription^[79,80]. The authors identified a longer isoform of *Tcf3* [Tcf3(l)] which is enriched in ESCs but downregulated upon differentiation. Tcf3(l) includes a 42-bp cassette exon which encodes an additional 14 amino acids overlapping with the Groucho binding domain^[81,82]. This domain is necessary for *Tcf3* to repress Nanog expression^[79]. Tcf3(l) is upregulated in ESCs compared with EBs, while a shorter isoform of *Tcf3*, Tcf3(s), is expressed at a constant level. Selective knockdown of Tcf3(l) in ESCs revealed several distinct targets of transcriptional repression compared with Tcf3(s). For example, knocking down any *Tcf3* isoform increased Nanog expression whereas Oct4 was upregulated only during knockdown of Tcf3(l). Knockdown of one or both *Tcf3* isoforms can lead to delayed differentiation in ESCs. Interestingly, Tcf3(l) knockdown and Tcf3(s) knockdown inhibit distinct differentiation pathways, raising the intriguing hypothesis that isoform-specific regulation of *Tcf3* targets affects distinct lineage commitment decisions. In short, these examples demonstrate that specific AS events can modulate transcriptional networks involved in pluripotency maintenance *vs* differentiation.

ALTERNATIVE SPLICING IS INTEGRATED IN THE CORE REGULATORY CIRCUIT OF ESCs

During the last decade, a core set of transcription factors (TFs), including OCT4 (POU5F1), NANOG and SOX2

among others which control the pluripotency of ESCs, has been uncovered^[83]. Together with specific microRNAs and long non-coding RNAs, these TFs control the expression of gene cohorts required for establishment and maintenance of ESC pluripotency^[84-86].

The AS of the core TFs can directly influence pluripotency control. One classic example is the pluripotency gene *OCT4*. The *OCT4* gene was identified to encode three isoforms which were named *OCT4A*, *OCT4B* and *OCT4B1*^[87]. Two isoforms, *OCT4A* and *OCT4B*, were shown to encode different binding domains which resulted in different target genes. While *OCT4A* can regulate genes that are responsible for stemness^[83,88], *OCT4B* does not have the ability to maintain ESC self-renewal and it regulates genes that are responsive to cell stress.

Not only can the AS of core TFs affect pluripotency control, but the AS of several other genes is also linked to stem cell self-renewal and lineage specification^[89-93]. Genes that have ESC-specific isoforms are particularly intriguing. A study conducted by Gabut *et al.*^[94] used microarray profiling to compare patterns of AS in undifferentiated and differentiated hESCs, and identified an evolutionarily conserved ESC-specific AS event of the gene *FOXP1* (Forkhead box transcription factor 1). Experimental validation showed that inclusion of *FOXP1* exon 18b is specific to self-renewing, pluripotent hESCs, thus this transcript isoform was named “*FOXP1-ES*”. The inclusion of exon 18b within *FOXP1-ES* changes the DNA-binding specificity of *FOXP1*, and allows *FOXP1-ES* to regulate distinct programs of gene expression in hESCs. Knockdown of *FOXP1-ES* results in a significant decrease in the expression of the pluripotency genes *OCT4*, *NANOG*, *NR5A2*, *GDF3*, and *TDGF1*, and an increase in the expression of differentiation-associated genes, including *GAS1*, *HESX1*, *SFRP4*. Chromatin immunoprecipitation followed by high-throughput sequencing (ChIP-Seq) was performed to identify genes that are directly regulated by *FOXP1-ES* and *FOXP1* in hESCs. The *FOXP1-ES* binding target genes significantly overlap with the set of genes that are dependent on *FOXP1-ES* expression in hESCs and a set of genes that are regulated by *OCT4* in hESCs. Overexpression of *FOXP1-ES* in mESC also promotes mESC self-renewal and pluripotency. Collectively, this study provided evidence that an AS switch regulating the *FOXP1-ES* isoform is integrated into the core circuit of the transcriptional regulatory network required for ESC pluripotency and iPSC reprogramming.

SPLICING FACTORS INVOLVED IN THE MAINTENANCE OF PLURIPOTENCY

Compared with transcription factors, little is known about splicing factors that may contribute to stem-cell self-renew and lineage specification. Technology advancement allows the identification of functional RNA cis-elements related to AS and splicing factors in stem cells recently.

In 2007, Yeo *et al.*^[68] studied the AS events in hESCs and neural progenitors using exon array analysis combined with sophisticated algorithms to identify exons undergoing AS. The analysis showed that RBFOX binding motif GCAUG was enriched proximal to a set of exons that are alternatively spliced in hESCs, suggesting that RBFOX splicing factors may play a critical role in hESCs. Following this study, the same group constructed an RNA map for RBP RBFOX2 to identify functional RNA elements in the human genome in hESCs^[91]. RBFOX2 is expressed abundantly in hESC cell lines, whereas RBFOX1 is not. Using CLIP-seq technology, thousands of RBFOX2 RNA targets were uncovered, representing approximately 7% of human genes in hESCs. Many RBFOX2 targets are themselves splicing factors, suggesting that RBFOX2 might act as an upstream regulator of many splicing factors. Interestingly, RBFOX2 pre-mRNA is also the target of itself, supporting the autoregulation of RBFOX2. It is possible that AS of RBFOX2 pre-mRNA may result in distinct proteins that can target different pre-mRNAs. RBFOX2 depletion in hESCs led to rapid cell death, indicating that RBFOX2 is important in maintaining hESC viability. However, RBFOX2 depletion in neural progenitor cells or primary human fetal neural stem cells did not cause cell death, suggesting that RBFOX2 has a different set of targets in different cell types.

Several recent studies have also used CLIP-seq to map binding sites of specific splicing factors. Combined with AS profiling, these studies revealed several splicing factors that are potentially associated with pluripotency maintenance. The work of Han *et al.*^[51] demonstrated a systematic strategy to study the function of specific splicing factors. They combined RNA-seq, CLIP-seq datasets, and “splicing code” analysis (a computational method which predicts cis-elements that promote or repress specific splicing events) to identify splicing regulators that are differentially expressed between stem cells and differentiated cells and control cell-specific AS. In particular, MBNL1 and MBNL2 were found to have the lowest relative expression levels in stem cells (ESCs and iPSCs) compared with differentiated cells in both humans and mice, suggesting that these proteins performed their function by repressing ESC-specific AS events. The authors tested the hypothesis using the *FOXP1* transcription factor. As mentioned previously, isoform *FOXP1-ES* contains an ESC-specific exon which allows *FOXP1* to bind and activate genes (*OCT4* and *NANOG*, *etc.*) required for pluripotency. Supporting this hypothesis, the experiments showed that the *FOXP1-ES*-specific exon was retained in differentiated cells in which MBNL1 and MBNL2 were knocked down, whereas, over-expression of MBNL1 and MBNL2 in ESCs promoted differentiated cell-like splicing patterns. Furthermore, MBNL knockdown enhanced the efficiency of reprogramming from fibroblasts into iPSCs by about 2-fold. Taken together, the study revealed that MBNL protein expression plays a functional role in differentiation

by promoting FOXP1-ES specific exon skipping, and their knockdown can facilitate reprogramming of somatic cell into iPSCs.

Another study by Venables *et al.*^[48] found that splicing factors MBNL1 and RBFOX2 cooperate to control pluripotency in stem cells. The authors adopted high-throughput RT-PCR technology to monitor splicing changes of more than 3000 AS events annotated in the RefSeq database during the induction of fibroblasts into iPSCs, and their subsequent re-differentiation. Comparing the AS profiles in fibroblasts and iPSCs, and fibroblasts re-differentiated from iPSCs, the authors observed that AS changes are reversible during these processes. Their finding uncovered a program of concerted AS changes involved in late mesoderm differentiation. The authors selected 47 AS regions (in different genes) whose splicing profiles showed an equivalent near-perfect anti-correlation in reversible stem cell induction and re-differentiation, and used these AS regions to investigate splicing mechanisms involved in stemness and maintenance of pluripotency. To identify the splicing factors involved in pluripotency and reprogramming, the authors knocked down 81 potential splicing factors in various cell lines and monitored these 47 AS regions using RT-PCR. The differences in PSI values (between iPSCs and original fibroblasts used for inducing pluripotent cells) of these 47 AS events were then compared with the differences in PSI values before and after 81 splicing factors were knocked down individually during reprogramming of fibroblasts into iPSCs. They found that MBNL1 knockdown correlated most strongly with the splicing profile change in the induction of pluripotency. Splicing factor RBFOX2 knockdown showed the second highest correlation with the induction of pluripotency. By knocking down both MBNL1 and RBFOX2 in fibroblasts, a significant correlation between splicing changes and the induction of pluripotency was observed, and the correlation was even higher than knocking down MBNL1 and RBFOX2 individually, suggesting that MBNL1 and RBFOX2 cooperate to establish the splicing program involved in stem cell differentiation.

Ohta *et al.*^[72] used siRNA screening in PSCs to identify RBPs involved in the reprogramming process by enhancing stem cell specific AS. After a screen of 92 RBPs, 9 RBP-coding genes that had a major effect on the splicing patterns were examined to assess the impact on somatic cell reprogramming using shRNA knockdown. The downregulation of U2af1 and Srsf3 was found to suppress both the efficiency of alkaline phosphatase-positive colony formation and ESC marker gene expression.

AS can also affect RNA stability through NMD. Most recently, Jangi *et al.*^[95] performed a genome-wide analysis of RBFOX2 activity in mESCs by mapping RBFOX2 binding sites to transcriptome changes after loss of RBFOX2. Using iCLIP and RNA-seq technologies, the authors identified more than 200 AS-NMD (AS-coupled nonsense mediated decay) splicing events that were mediated by RBFOX2 in mESCs. These events showed

minimal splicing changes but appreciable changes in gene expression upon RBFOX2 knockdown due to the degradation of the NMD-inducing isoform. About 70 of these AS-NMD events were within genes encoding RBPs. Many of these RBPs were also autoregulated. A large fraction of bound but apparently unregulated events likely generated the NMD isoforms. This led to the hypothesis that RBFOX2 can control the gene expression level by regulating AS-NMD. The authors further demonstrated that RBFOX2 determines a threshold for the ratio of NMD to non-NMD isoforms for several of these RBPs. These findings uncovered an unexpectedly broad multilayered regulatory network controlled by RBFOX2, and established a model for how autoregulatory splicing networks are tuned.

CONCLUSION

Induced PSCs hold the promise of future cell-based therapy. A thorough understanding of the mechanisms underlying stem cell pluripotency and differentiation is critical for harnessing the cell reprogramming process. In this review, we have summarized recent progress in the field of AS and its role in stem cell pluripotency maintenance and differentiation. It was found that AS is pervasive in stem cells, and reprogramming reverts the splicing pattern to an ESC-like state. AS has a fundamental impact on stem cell differentiation by regulating different isoforms of the core pluripotency transcription factors. AS of genes other than the core factors is also linked to stem cell self-renewal and lineage specification. Additionally, splicing factors can regulate pluripotency by affecting stem cell-specific AS. In summary, these findings present a picture in which AS is integrated in the transcriptional and post-transcriptional networks, and the crosstalk between AS and other layers of the gene regulatory network have a fundamental effect on stem cell pluripotency maintenance and differentiation. These findings can lead to novel approaches for improving iPSC development and a better control of cell differentiation.

Abstract

Outcomes following peripheral nerve injury remain frustratingly poor. The reasons for this are multifactorial, although maintaining a growth permissive environment in the distal nerve stump following repair is arguably the most important. The optimal environment for axonal regeneration relies on the synthesis and release of many biochemical mediators that are temporally and spatially regulated with a high level of incompletely understood complexity. The Schwann cell (SC) has emerged as a key player in this process. Prolonged periods of distal

nerve stump denervation, characteristic of large gaps and proximal injuries, have been associated with a reduction in SC number and ability to support regenerating axons. Cell based therapy offers a potential therapy for the improvement of outcomes following peripheral nerve reconstruction. Stem cells have the potential to increase the number of SCs and prolong their ability to support regeneration. They may also have the ability to rescue and replenish populations of chromatolytic and apoptotic neurons following axotomy. Finally, they can be used in non-physiologic ways to preserve injured tissues such as denervated muscle while neuronal ingrowth has not yet occurred. Aside from stem cell type, careful consideration must be given to differentiation status, how stem cells are supported following transplantation and how they will be delivered to the site of injury. It is the aim of this article to review current opinions on the strategies of stem cell based therapy for the augmentation of peripheral nerve regeneration.

Key words: Peripheral nerve; Augmentation; Regeneration; Stem cells

Core tip: Outcomes following peripheral nerve injury remain poor. Stem cells may increase Schwann cell numbers and longevity, prolonging their ability to support regeneration. At the level of the cell body, they may have the ability to rescue populations of neurons destined for apoptosis. They may also be used in non-physiologic ways in order to protect muscle targets from the detrimental effects of denervation. Aside from stem cell type, consideration must be given to differentiation status, scaffolding support and the mechanism of delivery. This article reviews current opinion on the strategies of stem cell-based therapy for the augmentation of peripheral nerve regeneration.

INTRODUCTION

Peripheral nerve injury, repair and challenges to recovery

Following nerve transection, the cell bodies of axons swell in anticipation of the increased metabolic demand of regeneration. Some nerve cells, particularly in response to proximal sectioning of axons, will then go on to apoptosis, lowering the number of regenerating neurons permanently. The Schwann cells (SCs), the principal glial cells of the peripheral nervous system and orchestrators of regeneration, switch from a myelinating to a phagocytic phenotype and, through chemotactic signaling, recruit circulating macrophages into the zone of injury. This heralds the beginning of Wallerian degeneration and serves to clear the distal stump of axonal and myelin debris in preparation for the reception of the regenerating growth cone. Through complex and incompletely understood cell signaling, arborized daughter axons extending from the proximal stump are attracted to columns of SCs known as the Bands of Büngner. These scaffolds nurture and guide regenerating axons towards their distal basal lamina tubes. Once SCs and the regenerating axon have been reunited, a growth promoting symbiosis is established. Any interruption in this process results in chronic SC senescence, down-regulation, a loss of axonal support and compromised recovery.

The gold standard method of nerve repair involves re-approximation using suture. Even with meticulous tissue handling and accurate, tensionless re-orientation of fascicular anatomy, outcomes are limited by suture inflammation, intra- and extra neural scar tissue, escape of axons and neurotrophic factors into the surrounding tissues, axonal mis-direction and the extremely slow rates of regeneration. These limitations are amplified following proximal limb injuries and in nerve gap reconstructions when axons must traverse two coaptation sites bridged by nerve grafts.

Autologous nerve grafts represent the gold standard bridging material for nerve gaps but these are limited by the morbidity of harvesting an “expendable” nerve. In addition, following severe trauma involving multi-limb amputation, demand for autologous material may exceed supply. In these situations, alternatives such as conduits or acellular nerve allograft (ANA) must be considered. The efficacy of hollow conduits is limited to short distances due to the lack of cellular components and extracellular matrix (ECM) to aid axonal guidance. Despite increasingly elaborate designs, these fail to replicate the efficacy of autogenous nerve. The use of ANA provides the most accurate representation of ECM, however, these grafts lack SCs and must be

repopulated with endogenous SCs migrating from adjacent nerve. As a result, outcomes following the use of these grafts for large gaps have typically been poor in comparison to autografts, though better than conduits. Improving the performance of conduits and allografts by adding stem cells, ECM components and growth factors is an area of intensive research, one that may have enormous clinical implications.

The overarching goal of any stem cell based approach to peripheral nerve injury is to establish a more favorable environment for regenerating axons and perhaps more importantly, maintain this support for an extended period of time. Repopulation of the depleted motor or sensory neuron pools with stem cells would potentially provide higher numbers of neurons for regeneration, which could aid regeneration in an additive fashion to the creation of a favorable environment. Preventing SC senescence and down-regulation during prolonged recovery periods, such as occurs in proximal injuries and long nerve gaps, and expediting the re-innervation of distal targets should translate to improvements in recovery. Finally, stem cell transplantation into denervated muscle may provide a means of preventing the expected sequelae of denervation, preventing atrophy and leaving the tissue more receptive to reinnervation over longer periods. It is the aim of this article to discuss how stem cell-based strategies have attempted to overcome these problems and how they may provide solutions in the future.

AUGMENTING NERVE REGENERATION USING STEM CELLS

The ideal stem cell for clinical application, including peripheral nerve repair, must be easily accessible, rapidly expandable in culture, capable of *in vivo* survival and integration into host tissue and must be amenable to stable transfection and expression of exogenous genes^[1]. If the process of nerve regeneration is deconstructed into a sequence of individual events, a strategy for optimizing outcome can be formulated. Emphasis has been placed on the importance of stem cell type, differentiation, cell scaffold and method of cell delivery^[2]. The influence on regeneration of each of these components has been thoroughly investigated. An overview of each of these, in addition to proposed mechanisms of action behind the therapeutic effect, will now be provided. Table 1 supplements the section on stem cell type, summarizing outcomes following the application of different stem cells in animal models.

Mechanism of action

Stem cells have the potential to replace lost neurons or increase the number of glial support cells. Replacing lost neurons has been widely demonstrated *in vitro* and has great potential in the CNS. Although not yet demonstrated in the dorsal root ganglia or ventral horn of the spinal cord, stem cells have the potential to rescue and replenish axotomized neurons as well as to manipulate the

Table 1 Summary of current evidence assessing the efficacy of different types of stem cell on peripheral nerve regeneration

Stem cell source	Author	Experimental model	Stem cell Diff.	Scaffold	Delivery system	Outcome
Embryonic	Cui <i>et al</i> ^[71]	Rat sciatic transection (10 mm gap)	D	Culture medium	Epineurium natural conduit	Cell survival and differentiation into SCs after 3-mo; superior regeneration of myelinated axons in comparison to culture media alone
	Lee <i>et al</i> ^[75]	Mouse sciatic transection (2 mm gap)	U	Matrigel	Direct injection of microspheres	ESC-derived MSC sphere-treated nerves recovered significantly greater CMAP, SFI and histological parameters than ESC-MSC single cell suspension
	Kubo <i>et al</i> ^[77]	Mouse tibial	D	PBS	Direct injection into gastrocnemius muscles following nerve transection and repair	Co-culture identified formation of new NMJs; muscle transplanted with stem cells experienced less atrophy 7 and 21-d post injury; cells transplanted after 2-wk were unable to provide any protective effect; motor recovery following repair superior in those muscles receiving stem cells
	Craff <i>et al</i> ^[76]	Rat sciatic + gastrocnemius muscle	D	PBS	Direct injection into gastrocnemius muscles following nerve transection	Muscles injected with stem cells retained muscle weight preservation and myocyte cross sectional area in comparison to control muscle after 7-d post injury. New NMJs observed. Benefits lost after 21 d
Neural	Fu <i>et al</i> ^[15]	Rat sciatic transection (15 mm gap; gene transfection)	U (gene therapy)	Culture medium (cells seeded directly onto conduit wall)	Poly(D,L-Lactide) conduit	Enhanced expression of BDNF and GDNF in transfected cells; conduits with transfected cells led to larger myelinated axons and improved functional and electrophysiological outcome
	Zhang <i>et al</i> ^[62]	Rabbit facial nerve transection (5 mm gap)	U	Collagen medium	HA-collagen composite conduit	Conduits with NSCs and NT-3 experienced superior outcomes in comparison to NSC alone; results equivalent to normal nerves after 12-wk
	Murakami <i>et al</i> ^[86]	Rat sciatic transection (15 mm gap)	U	Collagen gel	Silicone conduit	NSCs differentiated into astrocytes, oligodendrocytes and schwann cell-like cells; dNCs implanted into 15 mm defects; Improved axon number, diameter and myelination compared with controls; labeled cells present after 10-wk; expressed markers of SC phenotype
	Guo <i>et al</i> ^[87]	Rabbit facial nerve transection (10 mm gap)	U	Collagen sponge	Chitosan conduit	Electrophysiological and histological outcomes and immunohistochemistry superior in chitosan conduits seeded with NSCs and NGF in comparison to conduit+NGF alone. Results comparable to standard autograft
	Liard <i>et al</i> ^[88]	Pig nervus cruralis transection (30 mm gap)	U	Neurosphere in culture medium	Autologous vein graft	Grafts containing NSCs recovered superior EMG recording and immunohistochemistry profiles in comparison to empty conduits; NSCs identifiable after 240 d follow-up.
	Johnson <i>et al</i> ^[89]	Rat sciatic crush, transection, (10 mm gap)	U (C17.2)	Culture medium	Direct injection	12/45 rodents developed neuroblastomas
	Zhao <i>et al</i> ^[160]	Rat sciatic transection (15 mm gap)	U	Fibrin glue	ANA	Survival of BMSCs within fibrin glue; growth factor secretion preserved (NGF, BDNF); equivalent results when cells injected directly into nerve compared with around nerve
Bone marrow	Hu <i>et al</i> ^[165]	Monkey median transection (50 mm gap)	U	Culture medium	Chitosan conduit with longitudinally aligned PGLA fibers	Functional and electrophysiological recovery and FG retrograde tracing after 1-year with BMSC-laden conduits equivalent to autograft and superior to empty conduits
	Dezawa <i>et al</i> ^[19]	Rat sciatic transection (15 mm gap)	U + D	Matrigel	Matrigel graft	Successful differentiation into SC phenotype; Axon number and elongation superior with dBMSCs
	Jia <i>et al</i> ^[32]	Rat sciatic transection (10 mm gap)	U	Gelatin	Acellular xenograft	Neurotrophic factor expression elevated in BMSC xenografts; regeneration and functional recovery significantly better than empty xenografts and equivalent to autograft
	Mohammadi <i>et al</i> ^[34]	Rat sciatic transection (10 mm gap)	U	Culture medium	Vein graft	Veins filled with uBMSCs had significantly improved functional, histological and immunohistochemical outcomes compared with veins filled with PBS
	Nijhuis <i>et al</i> ^[36]	Rat sciatic transection (15 mm gap)	U	Culture medium	Vein graft +/- muscle	BMSC identifiable after 6 and 12-wk follow-up; vein graft + muscle + BMSCs outperformed vein graft+muscle but inferior to autograft
	Salomone <i>et al</i> ^[39]	Rat facial nerve transection (3 mm gap)	U + D	Matrigel	Silicone conduit	Histological outcomes superior in conduits containing uBMSCs and dBMSCs compared to empty and matrigel containing conduits; functional outcomes superior using uBMSCs

	Wang <i>et al</i> ^[41]	Rat sciatic transection (15 mm gap)	U	Culture medium	Direct injection into ANA	BMSC produced NGF and BDNF; CSPGs reduced in grafts treated with ChABC Allograft containing BMSCs and ChABC resulted in superior functional, electrophysiological and histological outcome compared with BMSC alone
Adipose	di Summa <i>et al</i> ^[28]	Rat sciatic transection (10 mm gap)	D	Culture medium	Fibrin glue conduit	Reduced muscle atrophy in autograft, dADSC and dBMSC groups in comparison to empty conduits; dADSCs recovered greatest axon and fiber diameter, evoked potentials and regeneration of motoneurons; results comparable to autograft
	Tomita <i>et al</i> ^[21]	Rat common peroneal nerve transection (no gap)	D	Culture medium	Direct injection into distal nerve	dADSCs survived for at least 10 wk <i>in vivo</i> ; dADSCs associated with axons and participated in re-myelination; dADSCs resulted in regeneration superior to cultured SCs
	Zhang <i>et al</i> ^[31]	Rat sciatic transection (10 mm gap)	D	Collagen gel	Xenogeneic acellular graft	dADSCs formed columns resembling bands of Büngner and expressed NGF, BDNF and GDNF; axon regeneration, retrograde labeling and electrophysiology were similar between dADSCs and SC supplemented grafts, superior to empty grafts but inferior to standard autograft
	Mohammadi <i>et al</i> ^[33]	Rat sciatic transection (10 mm gap)	U	Culture medium	Vein graft	No difference in functional, morphometric or immunohistochemistry between ADSCs and BMSCs
	Erba <i>et al</i> ^[45]	Rat sciatic transection (10 mm gap)	U	Fibrin	PHB conduit	Lack of sufficient quantities of viable cells 14-d after transplantation; conclusion that regenerative effect due to initial growth factor boost or paracrine effect on resident cells
	Sun <i>et al</i> ^[51]	Rat facial transection (8 mm gap)	D	Matrigel	Decellularized allogeneic artery	dADSCs persisted at repair site and integrated with regenerated tissue; conduits containing dADSCs achieved results comparable to those of SC-containing conduits and superior to matrigel-containing conduits alone; results inferior to autograft
Fetal	Pan <i>et al</i> ^[106]	Rat sciatic crush	U	Fibrin glue	Direct injection at site	High expression of BDNF, CNTF, NGF and NT-3 found in AFMSCs; motor function, CMAP and conduction velocity improved in those nerves augmented with AFMSCs; high levels of S-100 and GFAP and reduced fibrosis found at repair site
	Pan <i>et al</i> ^[111]	Rat sciatic crush	U	Fibrin glue	Direct injection at site	HBO therapy reduced production of inflammatory cytokines and macrophage chemokines following crush injury; when administered with AFMSCs, HBO reduced apoptosis of AFMSCs in comparison to AFMSCs alone; myelination and motor recovery superior in HBO + AFMSC group
	Pan <i>et al</i> ^[110]	Rat sciatic crush	U	Fibrin glue	Direct injection at site	Anti-apoptotic, anti-inflammatory agent G-CSF, when administered with AFMSCs, reduced crush-induced inflammation, and apoptosis in comparison to AFMSCs alone; myelination and motor function superior with AFMSCs + G-CSF in comparison to AFMSCs alone
	Matsuse <i>et al</i> ^[109]	Rat sciatic nerve transection (8 mm gap)	U + D	Matrigel	“Transpermeable” tube	Differentiated UC-MSCs regenerated greater number of myelinated axons and thicker nerve fibers compared with undifferentiated UC-MSCs; number of labeled cells greater in dUC-MSC nerves; results comparable to SC group
	Cheng <i>et al</i> ^[113]	Rat sciatic crush	U	Matrigel	Direct injection at site	AFMSCs successfully transfected; high expression of GDNF detected for 4 wk before subsiding; GDNF-modified AFMSCs recovered greatest SFI, conduction velocity, CMAP and muscle weight in comparison to AFMSCs alone
	Gärtner <i>et al</i> ^[108]	Rat sciatic crush	D	Culture medium	Cells seeded onto PLC wrap	Wraps seeded with UC-MSCs resulted in superior increased myelin thickness, motor and sensory function in comparison to unseeded wraps
Skin	McKenzie <i>et al</i> ^[120]	Mouse sciatic crush	D/ U	Culture medium	Direct injection at site	SKPs successfully induced into SKP-SCs; SKP and SKP-SCs associated with and myelinated axons
	Marchesi <i>et al</i> ^[123]	Rat sciatic transection (16 mm gap)	D	PBS	(1) Synthetic co-polymer L-lactide and trimethylene carbonate; and (2) collagen conduit	SFI and CMAPs were significantly better in conduits filled with SDSCs; number of regenerated myelinated axons significantly greater in SDSC conduits; no significant difference in neurotrophic factor expression
	Walsh <i>et al</i> ^[124]	Rat sciatic transection (12 mm gap)	D	Culture medium	Direct injection into acellular freeze-thawed nerve graft	SKP-SCs maintained differentiation up to 8-wk; outcomes significantly improved in comparison to cell free grafts and comparable to cultured SCs; neurotrophic factor release greater in SKP-SCs
	Walsh <i>et al</i> ^[121]	Rat CP/tibial (Immediate <i>vs</i> chronic repair; no gap)	D	Culture medium	Direct injection into distal nerve	Muscle weight and CMAPs superior in SKP-SC group in comparison to media injected controls; significantly higher counts of axon regeneration in SKP-SC group equivalent to immediate suture group
	Walsh <i>et al</i> ^[22]	Rat sciatic transection [acute <i>vs</i> chronic <i>vs</i> ANA (12 mm gap)]	U/ D	Culture medium	Direct injection into nerve ends and ANA	SKP-SCs maintained <i>in vivo</i> viability and differentiation better than uSKP; viability poorest in normal nerve, best in acutely injured nerve; SKP-SCs remain differentiated over time and myelinate axons; neuregulin able to prevent apoptosis following transplantation
	Khuong <i>et al</i> ^[122]	Rat sciatic and tibial (12 mm gap)	D	Culture medium	Direct injection into ANA	SKP-SCs containing allografts resulted in superior functional and histological outcomes in both acute and delayed injury models compared with SCs and media controls

Hair follicle	Amoh <i>et al</i> ^[135]	Mouse sciatic and tibial transection (no gap)	U	Culture medium	Direct injection at site	HFSC transplanted nerves recovered significantly greater function compared with untreated nerves; GFP-labeled cells differentiated into GFAP positive schwann cells and were involved with myelination
	Amoh <i>et al</i> ^[133]	Mouse sciatic crush	U	Culture medium	Direct injection at site	HFSCs transplanted around crushed nerve differentiated into SC-like cells and participated in myelination; gastrocnemius muscle contraction significantly greater compared with untreated crushed nerves
	Amoh <i>et al</i> ^[134]	Mouse sciatic transection (2 mm gap)	U	Culture medium	Direct injection at site	HFSCs differentiated into GFAP expressing SCs and were able to myelinate axons; gastrocnemius muscle contraction significantly greater compared with untreated nerves
	Lin <i>et al</i> ^[136]	Rat sciatic transection (40 mm gap)	D	PBS	Direct injection into acellular xenograft	Differentiation into neurons and SCs maintained for 52-wk; number of regenerated axons, myelin thickness and ratio of myelinated axons to total nerve count significantly higher in dHFSCs compared with acellular grafts; conduction velocity slower in dHFSC nerves
Induced pluripotent stem cell	Ikeda <i>et al</i> ^[146]	Mouse sciatic nerve (5 mm gap)	D	Microsphere seeded into conduit	Mixed PLA/PCL conduit +/- iPSC microspheres +/- bFGF	Regeneration was accelerated by combination of iPSCs + bFGF within conduits in comparison to iPSCs and bFGF alone; outcomes remained inferior to autograft controls; empty conduits performed least well
	Uemura <i>et al</i> ^[148]	Mouse sciatic nerve (5 mm gap)	D	Microsphere seeded into conduit	Mixed PLA/PCL conduit +/- iPSC microspheres	Motor and sensory recovery was superior in iPSC group at 4, 8 and 12 wk in comparison to empty conduits. Axonal regeneration superior in iPSC group. Conduit structurally stable after 12 wk
	Wang <i>et al</i> ^[149]	Rat sciatic nerve (12 mm gap)	D	Matrigel	PLCL/PPG/sodium acetate copolymer electrospun nanofiber conduit	Conduits filled with either (1) matrigel; (2) matrigel + NCSCs differentiated from ESCs; and (3) matrigel + NCSCs differentiated from iPSCs; NCSC differentiated into SCs and integrated into myelin sheaths; electrophysiology and histology showed equivalent regeneration in all NCSC containing conduits; no teratoma formation observed after 1-yr

microenvironment of the neurons during regeneration. In the peripheral nervous system, emphasis has been placed mostly on increasing SC number and activity. This approach is driven by the pragmatic difficulties associated with autologous SC culture. Achieving sufficient autologous SC numbers requires explantation of healthy nerve, extended periods of purification and expansion and consequently, delays to repair. Prolonged axotomy and denervation only exacerbate central cell body apoptosis and loss of SC-mediated axonal support in the distal nerve^[3,4]. As a result, the use of cultured SCs is considered impractical.

Exogenous stem cells differentiated into SC-like phenotype may integrate into Bands of Büngner and aid axonal guidance and re-myelination. Transplanted cells enhance growth factor secretion and ECM production. These factors may be released directly or, through cell-to-cell contact and paracrine signaling, can stimulate endogenous SCs to upregulate secretory activity^[5]. Increased recruitment of circulating macrophages into the area can potentiate this effect^[6].

ECM proteins such as collagen I, collagen IV, fibronectin

and laminin, and neurite guidance proteins such as netrin and ninjurin-2 have pro-regenerative effects^[7,8]. Other ECM components such as chondroitin sulphate proteoglycan are potent inhibitors of axonal regeneration and the degradation of this protein by liberated matrix metalloproteinase-2 has been shown to support regeneration^[9,10].

The production of nerve growth factor (NGF), brain derived neurotrophic factor (BDNF), glial cell line-derived neurotrophic factor (GDNF), ciliary neurotrophic factor and neurotrophin-3 (NT-3) by endogenous SCs and transplanted stem cells has been described^[5,7,8,11-17]. Angiogenic factors such as vascular endothelial growth factor, basic fibroblast growth factor (bFGF), hepatocyte growth factor and angiopoietin-1 may also be released^[12]. Hypoxia has been found to potentiate the angiogenic and neurogenic influence of some stem cells, leading to improved blood vessel and nerve fiber formation^[7]. This has led some investigators to attempt pre-conditioning and differentiation in hypoxic environments^[7]. The expression of leukemia inhibitory factor and insulin-like growth factor has also been detected^[8]. These factors are thought to improve neuronal survival, promote corticospinal tract growth,

increase astrogliosis and potentiate the inflammatory response^[8,18]. The observed immunomodulatory effects of stem cells are believed to be due to the secretion of factors such as granulocyte and macrophage colony stimulating factor (G-CSF, M-CSF), interleukin-6, 7, 8, and 11 (IL-6, IL-7, IL-8, IL-11) and TNF- α ^[8]. Suppression of the host immune response may help reduce the detrimental impact of inflammation and fibrosis following nerve repair and is obviously desirable in the context of allotransplantation of cells. The relative contribution of each of these mechanisms and therefore the levels of ECM protein and growth factor production may vary not only with stem cell type but also with the differentiation status of transplanted cells.

Differentiation

Stem cells can be transplanted in their undifferentiated state or can undergo a period of *in vitro* differentiation into SC-like cells. This is commonly achieved with exposure to β -mercaptoethanol, all-trans retinoic acid, fetal bovine serum, forskolin, recombinant human bFGF, recombinant human platelet derived growth factor-AA, and recombinant human heregulin β -1^[19,20]. The purported benefits of differentiation include superior *in vivo* viability and an enhancement of neurotrophic factor secretion and myelinating ability^[14,21,22]. Many investigators have shown the beneficial effects on regeneration of these cells^[19-21,23-31]. Some claim that transplanting undifferentiated cells risks *in vivo* differentiation along unwanted, non-neuronal lines in response to other dominant cells in the area.

Interestingly, however, the positive effects of undifferentiated cells have also been widely reported^[5,7,13,32-51]. These investigators claim that *in vitro* differentiation incurs an unnecessary delay, limiting clinical applicability. In one study, the process of differentiation actually reduced the secretion of neurotrophic factors^[52]. Others have reported difficulties with maintaining *in vivo* neuronal differentiation, claiming that once *in vitro* differentiation cues are removed, cells tend to revert back to their original phenotype^[53]. Evidence suggests that undifferentiated cells may undergo *in vivo* differentiation in response to local stimuli^[20,40,54-56], although others have been unable to show this^[45,49,57]. A small number of direct comparisons have been performed and have shown either a small advantage for differentiated cells^[20,23], a small advantage for undifferentiated cells^[39] or no significant difference^[45,48].

Stem cell source

Embryonic stem cells: Thomson *et al.*^[58] described the isolation of pluripotent cell lines from human blastocysts in 1998. Since this discovery, stem cells have been harvested from a variety of different fetal and adult tissues (Figure 1). Embryonic stem cells (ESCs) can form derivatives of all three embryonic germ layers and can provide an unlimited source of cells with superior differentiation potential and long-term proliferation capacity in comparison to mesenchymal stem cells (MSCs)^[59]. Unlike adult sources, these cells are homogenous, are not susceptible to the

detrimental impact of age and disease and can be harvested without physical discomfort^[60]. However, differentiation down specialized neural cell lines is challenging and established protocols only exist for a limited number of lines^[61,62]. Additional disadvantages include immunogenicity, tumorigenicity and potential ethical controversy due to the fact that cells are harvested during the blastocyst stage of development and consequently result in the destruction of embryos.

ESCs have been shown to migrate and differentiate into neurons, and glial cells of the central and peripheral nervous system and have the capacity for *in vivo* myelination^[61,63-70]. Studies reporting the successful application of these cells to peripheral nerve repair are limited, perhaps reflecting the lack of facile clinical translatability^[71]. In recognition of the limitations, investigators have derived mesenchymal precursors from ESC^[59,72-74]. Augmentation of peripheral nerve regeneration following the transplantation of spheres of human MSCs derived from ESCs has been reported^[75]. Our group has shown in small animal models of sciatic and tibial nerve transection that ESCs transplanted directly into muscle can preserve short-term muscle mass and myocyte cross-sectional area following injury and repair^[76,77].

Nerve stem cells: Nerve stem cells (NSCs) naturally differentiate into neurons and glial cells. However, the process of neurogenesis almost exclusively occurs during embryogenesis and continues in the adult in response to injury only within very limited locations of the CNS^[78]. NSCs were first isolated from adult murine brain in the early 1990s^[79,80]. This was followed by similar discoveries in humans and non-human primates^[81,82]. The subventricular zone and the subgranular zone in the brain represent the primary sites of NSC differentiation in adult mammals (Figure 1). Most recently, populations of NSCs and neurogenesis have been discovered in adjacent areas of the adult human striatum^[83]. Neural crest stem cells have been isolated from fetal rat sciatic nerve but the existence of such cells in peripheral nerves of the adult human is unknown^[84,85].

Many have reported positive results following NSC implantation into peripheral nerve injury^[15,62,86-88]. Heine *et al.*^[9] showed that the beneficial effects of NSC transplantation are not confined to acute peripheral nerve injury. Transplantation of NSCs into chronically denervated nerve had a beneficial effect on morphological and electrophysiological recovery in comparison to controls. Immortalized murine C17.2 NSCs have become commercially available and are commonly used for *in vivo* animal studies. However, experience with C17.2 NSCs in the PNS has not been uniformly positive. Following the implantation of these cells into rat models of crush, transection and graft, high rates of neuroblastoma formation have been encountered^[89]. In addition to these concerns, pragmatic difficulties associated with cell harvest have limited their use.

MSCs: MSCs are multipotent stromal cells that originate from the bone marrow and a variety of non-marrow

Figure 1 Different stem cell sources. Embryonic stem cells are obtained from the inner cell mass of the blastocyst and therefore require destruction of the embryo. Nerve stem cells are harvested from the subventricular layer of the lateral ventricle and the subgranular layer of the hippocampus. Bone marrow derived stem cells are harvested from the marrow cavity of long bones. Adipose derived stem cells are derived from subcutaneous fat and are abundantly available following commonly performed procedures such as liposuction. Skin derived precursors are harvested from the dermis and represent a related population of cells harvested from hair follicles. Fetal tissue provides populations of cells from amniotic membrane, amniotic fluid, umbilical cord blood, umbilical cord tissue and Wharton's jelly. Dental pulp stem cells can be harvested from deciduous teeth.

sources such as adipose tissue, fetal tissue, skin, hair follicle and dental pulp (Figure 1). Although the potency of these cells was originally considered to be limited to tissues of mesodermal origin, differentiation into non-mesodermal lineage is now generally accepted. It is precisely this characteristic that endows MSCs with the ability to support neuroregeneration. An overview of the main sub-types of MSC and the evidence behind their application to peripheral nerve regeneration will now be discussed.

Bone marrow derived stem cells: In contrast to embryonic and NSCs, bone marrow derived stem cells (BMSCs) are readily accessible and have no potential ethical concerns. Under appropriate conditions BMSCs can differentiate into non-mesodermal lineages such as neurons, astrocytes and SC-like cells^[90]. Many studies have shown that the addition of BMSCs to conduits and acellular grafts results in superior outcomes when compared with empty or cell deplete channels^[24,36-38,40,41]. Although some have failed to show that BMSCs can match outcomes achieved with cultured SCs^[20], the majority of reports show that performance is at least equivalent^[27,43,91]. There is a dearth of studies showing superiority over gold standard autograft although some report equivalent outcomes^[42,44]. Evidence suggests that these outcomes may be dose dependent^[92].

Although BMSCs are more clinically applicable than ESCs, NSCs and cultured SCs, stem cell fraction is low and in comparison with other sources, BMSCs generally have inferior proliferation capacity and differentiation potential. In addition, harvest is invasive and painful. This has driven the pursuit of less invasive MSC sources such as fetal tissue, skin, hair follicle and adipose tissue.

Adipose derived stem cells: Adipose tissue is abundant, easily harvested and is a frequent waste product of commonly performed procedures such as liposuction. It has a superior stem cell fraction in comparison to bone marrow and adipose derived stem cells (ADSCs) have superior proliferation and differentiation potential in comparison to BMSCs^[93,94]. Unlike BMSCs, donor age and site of harvest does not seem to significantly influence the therapeutic effect of ADSCs^[50].

Multiple neuronal and SC markers have been expressed from differentiated ADSCs^[7,30,95-97]. The expression of myelin protein zero, peripheral myelin protein-22 and myelin basic protein also suggest the retention of myelinating capability^[98]. Although some reports have found no difference in outcome between ADSC-filled conduits and cell deplete products^[49], the vast majority of studies show an augmented effect^[13,28,29,31,99]. Several studies have shown that

ADSCs are at least as effective as autologous SCs^[21,45,51]. As with BMSCs, a small number of investigators have reported equivalent outcomes in comparison to autograft^[13,28,29] with even fewer reporting superior outcomes^[48]. Studies directly comparing the performance of ADSCs to BMSCs have found no significant differences between the two^[33,45]. Low morbidity of harvest, wide availability and superior stem cell characteristics have helped establish ADSCs as the preferred option for pre-clinical studies.

Fetal derived stem cells: Fetal tissues represent the most primitive source of MSCs. These tissues are ordinarily discarded following birth and are therefore in abundant supply. Tissue age rarely exceeds 42-wk and therefore, in comparison to other adult sources, cells have accumulated less genetic damage due to age, environment and disease^[100]. Stem cells can be harvested from amniotic membrane, amniotic fluid, umbilical cord cells, umbilical cord blood and Wharton's jelly. These cells are readily expandable in culture and possess the ability to differentiate into neural phenotype^[101,102].

Wharton's jelly derived mesenchymal stem cells can differentiate into functional SC-like cells, produce neurotrophic factors such as NGF, BDNF and NT-3 and stimulate neurite growth *in vitro*^[103]. Amniotic fluid derived stem cells (AFDSCs) express characteristics of both mesenchymal and NSCs^[104], can differentiate into neural tissue^[105] and, following transplantation into rat sciatic nerve gap models, have been shown to promote peripheral nerve regeneration^[106,107]. Umbilical cord-derived mesenchymal stem cells have also been shown to improve outcomes following crush and transection injuries in rodent models^[108,109].

Survival of AFDSCs following transplantation can be limited and as a result, efforts have been made to improve *in vivo* survivability. Inhibition of inflammatory mediators can attenuate the apoptotic cascade^[110-112]. Cells can be genetically modified in order to over-express therapeutic genes. GDNF-modified human AFMSCs have been shown to improve viability, regeneration and motor outcomes in rodent models^[113]. Stromal cell-derived factor-1 α (SDF-1 α) is chemotactic towards MSCs and is expressed in several tissues in the rat, including injured nerve. By timing intravenous administration of AFDSCs with peak expression of SDF-1 α , this novel approach has been shown to improve AFDSC numbers at the repair site and nerve regeneration^[114].

Fetal tissue represents a promising alternative source of stem cells. However the use of autologous cells following injury is currently impractical. The use of allogeneic cells and their associated immunoreactivity are obstacles that are not encountered with other adult sources such as adipose tissue. Widespread banking of fetal products following birth offers a solution to this problem.

Skin derived precursors: Skin derived precursors (SKPs) reside in the dermis and are an accessible source of adult multipotent cells that are easily expandable in culture. SKPs

exhibit a remarkable similarity to embryonic neural crest cells, a migratory population of multipotent cells that gives rise to a diverse array of cell types such as melanocytes, craniofacial cartilage, bone and connective tissue, smooth muscle of vasculature, endocrine cells, and neurons and glial cells of the autonomic and peripheral nervous system^[115]. Neuregulin is known to promote proliferation and differentiation of SCs from embryonic neural crest precursors^[115-117] and is also believed to be mediate SC proliferation during Wallerian degeneration^[118]. When cultured with neuregulin-1 β , rodent and human SKPs express markers consistent with functioning SCs^[115-120]. Exogenous neureglins and heregulin-1 β may also improve *in vivo* viability by reducing apoptosis^[22].

Both undifferentiated and differentiated SKPs (SKP-SCs) have been shown to have positive effects on regeneration. In rodent models, SKP-SCs have been shown to maintain differentiation and viability, myelinate axons, and exhibit superior outcomes following de-myelination and crush injury^[117,120], acute and chronic transection injury^[22,120-122] and following implantation into ANAs^[122-124].

Hair follicle stem cells: Hair follicles are dynamic dermal appendages and are abundant and readily accessible sources of pluripotent stem cells. The hair follicle is derived from the neural crest and harbors NCSC-like cells^[125]. Hair follicle stem cells (HFSCs) were discovered following the detection of nestin, a marker for neural progenitor cells, in the cells of the hair follicle bulge in mice^[126] and humans^[127]. They are readily expanded in culture, although, as with SKPs, clinical applicability may be limited by prolonged periods of cell expansion. HFSCs are positive for ESC transcription factors Nanog, Oct4 and nestin, and have the ability to differentiate into adipocytes, smooth muscle cells, melanocytes, neurons and glial cells^[116,128,129]. Differentiation into epithelial and vascular cells emphasizes the important role HFSCs have in vascularizing the skin and dermis^[130-132].

A small number of studies have reported the use of undifferentiated HFSCs in murine models of sciatic and tibial nerve crush and transection injuries^[133-135]. HFSCs were found to differentiate into glial fibrillary acidic protein positive SC-like cells and participated in myelination. Functional outcomes were significantly improved in those nerves receiving HFSCs. The efficacy of differentiated HFSCs seeded into acellular xenografts has also been investigated^[136]. Cells were able to maintain differentiation long term and the number of regenerated axons and myelination in cell-supplemented xenografts was higher than cell-free xenografts.

Dental pulp stem cells: Dental pulp is neural crest-derived tissue that can be harvested from exfoliated deciduous teeth and arguably represents the most convenient source of multipotent stem cells. As with fetal tissue, widespread application of autologous cells would require harvest and storage of teeth at an early age. Although experience is limited with this newly described population of cells,

evidence shows that these cells may have a role in supporting peripheral nerve regeneration. In avian embryonic models, dental pulp stem cells (DPSCs) have been shown to chemo-attract trigeminal ganglion axons^[137]. DPSCs have also been shown to successfully differentiate into SCs *in vitro* and were able to support DRG neurite outgrowth^[138]. When implanted into a collagen gel matrix, DPSCs were able to form aligned columns and had the ability to guide and myelinate neurites^[138]. Rat DPSCs have also been shown to provide axonal support following hemisection of the spinal cord^[139,140].

Induced pluripotent stem cells: In 2006, Takahashi *et al*^[141] described the derivation of induced pluripotency in somatic mouse cells following ectopic co-expression of transcription factors^[141]. This ability to reprogram cells questioned the stability of cellular identity and injected new optimism into the quest to develop a patient specific pluripotent stem cell that could circumvent the limitations of ESCs. Although multiple similarities between ESCs and induced pluripotent stem cells (iPSCs) exist, subtle differences have also been detected^[142]. Currently it is believed that these cells are neither identical nor distinct populations and instead represent cells with overlapping identity. These differences do not abrogate their potential. Since their discovery, iPSCs have furthered the understanding of many disease mechanisms and have advanced *in vitro* drug screening and the assessment of therapeutic efficacy following pharmaceutical and cell-based interventions^[142].

In addition to differentiation into various somatic cell lines, established protocols now exist for the *in vitro* differentiation of iPSCs along neural lineages^[143,144]. Although evidence suggests that differentiation occurs with reduced efficiency and increased variability^[145], iPSCs have been shown to have a pro-regenerative effect in small animal models of central and peripheral nervous system injury^[146-149].

These cells possess several advantages over embryonic sources such as the avoidance of ethical and immunosuppressive issues. However, concerns surrounding these cells exist. Retained epigenetic “memory” from their somatic cells of origin, coupled with chromosomal aberrations resulting from re-programming, can render these cells even more tumorigenic than ESCs^[150].

The preferred option: Adipose derived stem cells represent the most practical source of cells for transplantation. In light of easier harvest, superior stem cell fraction, differentiation potential and proliferation capacity, they have supplanted bone marrow derived cells. Other alternatives such as fetal, hair follicle and tooth pulp have great potential but are currently limited by the lack of autogenous supply and the requirements for cell expansion. Whether these cells are best differentiated prior to transplantation is a contentious issue although the use of undifferentiated cells obviates the requirement for *in vitro* differentiation. The beneficial effect of these cells on regeneration has been widely reported

and, until clear evidence emerges that differentiation is superior, the use of undifferentiated cells is the most pragmatic and clinically translatable option. Optimizing the effect of the preferred option is heavily reliant on appropriate delivery and support.

Cell scaffolds and methods of delivery

Cell scaffolds aim to maintain cell viability, support proliferation and permit intercellular communication and growth factor elution. N-methacrylate glycol chitosan, alginate, hyaluronic acid, polyethylene glycol, fibrin and Matrigel have all been shown to successfully fulfill these requirements^[151-157]. In addition to their supportive role, scaffolds also help prevent unwanted cell dissipation from the site of injury and, when used in combination with nerve conduits, have emerged as useful adjuncts for improving the delivery of cells.

In cases where nerves are repaired primarily or when autograft or allograft nerve is going to be used, stem cells can be delivered by a variety of different methods (Figure 2). Cells suspended in culture medium can be microinjected into nerve ends or grafts (Figure 2A)^[28,29,32,40,158-160]. Although this delivers cells directly to the site of injury, the process of micro-injection can be traumatic to the delicate intra-neural architecture and can result in unpredictable cell distribution. Evidence suggests that intra-neural injection may be unnecessary. Cells suspended in fibrin matrix that were injected around repair sites maintained neurotrophic factor secretion and cell migration and resulted in outcomes that were not significantly different in comparison to injected nerves (Figure 2B)^[160].

Cells can be injected within the lumen of a conduit (Figure 2C) or can be seeded onto conduit matrix (Figure 2D). Natural conduits including vein and artery grafts are rich in ECM proteins such as collagen and laminin and provide a useful substrate for cell adhesion, though only at the periphery of the constructs^[33,34 37,161-163]. Vessels can remain empty or can be pre-filled with tissue such as muscle to support axonal guidance^[36]. Commercially available natural conduits are usually composed of ECM components such as collagen^[38] and fibrin^[28]. Synthetic materials include polyglycolic acid^[57], Poly(lactic-co-glycolic) acid^[164], silicone tube^[39,43], polyhydroxybutyrate^[20], polytetrafluoroethylene^[24] silk fibroin^[42] and chitosan^[91,165]. The degradation profile of conduits must be carefully considered when used with cell therapy. Natural conduits tend to degrade in a predictable, non-toxic fashion, though the rate of degradation may not be sufficiently slow in some cases to allow for adequate regeneration time. Some synthetic polymers can acidify the microenvironment during degradation and can have a detrimental impact on cellular activity^[166].

In recognition of the importance of basal lamina and other ECM framework for axonal guidance, conduits with internal structure have become more popular than hollow, single lumen tubes. These structures may be organized arrangements of multiple fibers^[23,164,165] or less orderly structures such as collagen sponge^[24]. However,

Figure 2 Methods of stem cell delivery. A: Direct injection into nerve ends or bridging nerve graft; B: Injection of cells suspended in matrix around nerve rather into the substance of the nerve; C: Nerve gap model using a conduit as the bridging method. Conduit lumen can be injected and filled with cells suspended in scaffold; D: Nerve gap model using conduit as bridging method. Conduit has been cultured and seeded with stem cells. Lumen of conduit may also be filled with cells. Hollow conduits may have internal framework added. This framework may also be seeded with cells; E: Systemic injection of cells. Stem cells have been shown to home to the site of injury; F: Cells may also be injected into neuromuscular junctions of peripheral muscles.

in the absence of cells, attempts to replicate the structural complexity of the nerve have led to disappointing results.

Recent evidence exists that systemic administration of stem cells following peripheral nerve injury can be efficacious (Figure 2E)^[5,114]. With further refinement, it may become possible to sustain regenerative support through regular systemic dosing. There is also evidence that stem cells may be efficacious when administered at the level of neuromuscular junction (NMJ) (Figure 2F) or when distributed within denervated muscle^[76,77,167].

Future

Nerve regeneration and re-innervation is a protracted and dynamic process. Any attempts to improve the speed and integrity of this process must be equally enduring and migratory. Local delivery of biochemical mediators to the site of repair is a common approach, though this provides only finite support that is unable to follow the advancing growth cone, not to mention recapitulate the elegant temporal coordination of myriad different factors. Development of systemic administration and cell homing to bring these cells to the advancing neural growth cone and the regenerating axons may help sustain regenerative support.

A fusion of cell based therapy and optogenetics may also hold promise by restoring motor function in those that have lost central control. Murine embryonic stem cell derived motor neurons have been induced to express the light-sensitive ion channel channelrhodopsin-2. When engrafted into mouse sciatic nerve, not only did axons re-

innervate hind limb muscles, but function was restored in a controllable manner through optical stimulation and did not require connection to the central nervous system^[168].

CONCLUSION

Despite *in vitro* and pre-clinical success, the application of stem cells to peripheral nerve repair has yet to make an impact in the clinical arena. Translation is currently limited by justified concerns regarding genetic manipulation, cell instability and the risks of tumorigenesis. However, perhaps the most pertinent issue is that despite great effort to manipulate the regenerative process, the use of stem cells simply has not led to outcomes that significantly and consistently surpass those achieved with conventional techniques. Augmentation of peripheral nerve repair with stem cells must consider stem cell type, differentiation, cell scaffold and method of delivery in order to offer effective new therapies. These factors, in addition to animal and injury models, vary widely in the current literature, making it very difficult to draw definitive conclusions as to which combination is most efficacious.

The ideal strategy would involve administration of stem cells immediately, or as soon as possible, following injury and for this to be sustained throughout the period of regeneration and recovery. This may require a shift away from the development of methods of local delivery and a re-focus on developing cells that can be administered systemically and that have the ability to specifically target and support not only the migrating growth cone, but also

centrally located cell bodies and peripherally located NMJs.

Abstract

The origins of the complex process of intratumoral heterogeneity have been highly debated and different cellular mechanisms have been hypothesized to account for the diversity within a tumor. The clonal evolution and cancer stem cell (CSC) models have been proposed as drivers of this heterogeneity. However, the concept of cancer stem cell plasticity and bidirectional conversion between stem and non-stem cells has added additional complexity to these highly studied paradigms and may help explain the tumor heterogeneity observed in solid tumors. The process of cancer stem cell plasticity in which cancer cells harbor the dynamic ability of shifting from a non-CSC state to a CSC state and vice versa may be modulated by specific microenvironmental signals and cellular interactions arising in the tumor niche. In addition to promoting CSC

plasticity, these interactions may contribute to the cellular transformation of tumor cells and affect response to chemotherapeutic and radiation treatments by providing CSCs protection from these agents. Herein, we review the literature in support of this dynamic CSC state, discuss the effectors of plasticity, and examine their role in the development and treatment of cancer.

MODELS OF TUMOR CELL HETEROGENEITY

The concept of tumor heterogeneity has evolved in the last few decades into a complex picture of phenotypic,

functional, and genetic heterogeneity not only within tumors but also between primary cancers and metastases. Adding to this multifaceted heterogeneity are the continuously changing extracellular influences that can modulate tumor development and progression including, but not limited to, inflammatory stimuli, microenvironmental signals, and immune cell interactions.

Recent technological advances have permitted in depth and rapid analysis of individual cancer genomes at the single-nucleotide level. These advances have shed light on intratumoral heterogeneity both within tumor biopsies and between spatially separated biopsies of the same tumor^[1,2]. Sequential tumor sampling and analysis has also revealed that intratumoral heterogeneity temporally evolves during the course of disease^[3]. This observed heterogeneity may present major challenges in the development of biomarkers, therapeutics, and personalized-medicine approaches.

CLONAL EVOLUTION, CANCER STEM CELLS, AND MOVEMENT TO A UNIFIED MODEL

The origins of intratumoral heterogeneity have been highly debated and different cellular mechanisms have been hypothesized to account for the diversity within a tumor. The clonal evolution theory, first introduced by Peter Nowell in a landmark article published almost four decades ago, proposed cancer to be an evolutionary process where most neoplasms arise from a single cell of origin, and tumor progression results from a stepwise acquisition of mutations within the original clone allowing sequential selection of more aggressive subclones. He hypothesized that cells in the dominant subclone populations would possess similar tumorigenic potential^[4]. The second theoretically opposing hypothesis is the cancer stem cell (CSC) paradigm. Unlike clonal evolution, where subclones possess tumorigenic potential, the CSC hypothesis postulates that only small subpopulations of the tumor, the CSCs, are capable of self-renewal and the have potential to give rise to a tumor-the rest of the tumor consists of phenotypically diverse cells with limited proliferation and tumorigenic potential. The benchmark work that helped to establish the CSC theory in solid tumors also showed that no clear morphological distinction was apparent between tumorigenic and nontumorigenic breast cancer cells, with the two populations displaying equal cell kinetics-yet the tumors appeared to be hierarchically organized when tested functionally. The group identified the CD44+/CD24- cells as putative CSCs. When these isolated cells were injected into immunodeficient mice, tumors arose in 89% of cases-and only as few as 100 CD44+/CD24- were needed to recapitulate the tumor^[5]. Further studies by other groups consistently verified that the frequencies of tumorigenic cells were low, variable, and were able to recapitulate some of the heterogeneity of the original tumors^[6].

Proving that cancers strictly follow either the clonal

evolution or CSC model is limited by experimental methodologies. The elucidation of a CSC model has been dependent on xenograft limiting dilution assays and tumor-specific CSC markers to isolate the tumor initiating cells. This assumes that the resulting increased tumorigenicity lies with an intrinsic trait of CSCs but does not rule out the that these cells are just somehow better suited to growth within an immunocompromised mouse that bears little resemblance to the normal human environment. It also relies heavily on the use of surface markers that may not adequately delineate the CSCs from non-CSCs. However, elegant lineage tracing experiments have clearly demonstrated that CSCs are a tumorigenic reservoir, capable of surviving chemotherapy, and drive relapse in mouse models of cancer^[7-9]. Even with these experiments, direct evidence that unmanipulated human solid tumors harbor cells with self-renewing properties that fuel sustained tumor expansion is lacking. Further, the CSC model alone cannot account for functional heterogeneity in all tumors. Despite these complexities, recent studies illustrate that a stem cell-like gene expression signature is related to relapse in glioblastoma (GBM) and is predictive of patient outcome in human leukemia, breast cancer, GBM, ovarian cancer-lending support to the clinical relevance of cancer stem cells^[10-13]. Furthermore, ample evidence exists that the prevalence of cells with a CSC phenotype can predict response and that these cells persist even after chemotherapy or radiotherapy. Despite experimental, analytical, and theoretical caveats for both the clonal evolution and CSC models, clinical studies in leukemia have shown that in a cancer distinctly driven by stem cells, such as in chronic myelogenous leukemia, clonal evolution is observed when tyrosine-kinase inhibitors are administered^[14,15]. This initially successful therapy can result in the emergence of subclones that harbor mutations in the *BCR-ABL* fusion gene, the target of imatinib, giving rise to a tumor-resistant phenotype^[15,16]. Moreover, it has also been demonstrated that CSCs harbor the *BCR-ABL* fusion gene but remain insensitive to imatinib. Instead, these CSCs revert to a normal dependence on cytokines for survival and proliferation^[17]. These cells could therefore be the ones that survive the initial therapy and sustain further mutations giving rise to a fitter clone.

These observations highlight fact that the progression of tumor heterogeneity is a wildly complex process and support the possibility that clonal evolution and the CSC model are not mutually exclusive. A single tumor may comprise several cancer stem cell clones that have a common ancestor (the cell that sustained the first oncogenic mutation) yet are genetically distinct. These cancer stem subclones with self-renewal capabilities would persist over time and accumulate epigenetic and genetic changes required for cancer initiation and progression. Each different CSC subclone would give rise to intermediate progenitors as well as more differentiated, non tumorigenic cancer cells. The intermediate transit-amplifying cells would lack self-renewal capabilities, but could continue to accumulate genetic changes and

Figure 1 Schematic of unified model of clonal evolution and cancer stem cells. The proposed unified model depends on dynamic hierarchical organization and clonal mutations for tumor heterogeneity. In this depiction, the originating CSC that sustained the first oncogenic mutation gives rise to subclones with self-renewal capabilities that accumulate epigenetic and genetic changes over time. Each different CSC subclone gives rise to intermediate transit-amplifying progenitors that lack self-renewal capabilities. A subset of these progenitors (shown in green) follows a model of tumor cell plasticity and bidirectional conversion between non-CSC to CSC states. This phenotypic change is modulated by microenvironmental stimuli which confer CSC self-renewal capacities to the differentiated cell. CSC: Cancer stem cell.

possibly a mutation conferring self-renewal capabilities to the cell. Alternatively, these cells could follow a model of tumor cell plasticity in which microenvironmental stimuli could co-opt self-renewal mechanisms and acquire CSC characteristics—a process that is inherently transitory and would also allow the conversion from cancer stem cell to non-self-renewing progenitor (Figure 1).

The concept of cancer stem cell plasticity and bidirectional conversion between stem and non-stem cells has added additional complexity to the CSC and clonal evolution models and may help explain the tumor heterogeneity observed in solid tumors. Recent studies provide evidence that a select group of cancer cells can readily switch between non-tumorigenic and tumorigenic cell states in response to appropriate stimuli and that this conversion may be modulated by endogenous transcription factors^[18–20]. This suggests that both CSCs and non-CSCs are highly adaptable populations capable of transient evolution and plasticity. This review will focus on the evidence for this transient state and discuss how these observations impact our understanding of the evolution of cancer and its treatment.

EPITHELIAL-TO-MESENCHYMAL TRANSITION AND CANCER STEM CELLS

Epithelial-to-mesenchymal transition (EMT) is a process integral to early embryogenesis and development where epithelial cells transdifferentiate into motile mesenchymal cells^[21]. During the process of conversion into mesenchymal cells, epithelial cells lose their cellular junctions and apico-basal polarity, reorganize their cytoskeleton, and reprogram their signaling patterns and gene expression to gain the ability to migrate, increase motility, and invade adjacent tissue^[22,23]. During embryogenesis, EMT allows epithelial cells to travel through the embryo and participate in the formation of internal organs. The processes underlying EMT can also be reactivated for wound healing and cancer progression^[24,25]. The mechanism of EMT is transient

in nature and allows transformed mesenchymal cells the capability to reacquire their epithelial phenotype upon arriving at their organ or tissue of destination where they proliferate and differentiate into organs, a process termed mesenchymal to epithelial transition (MET)^[22,23]. The ability of epithelial cells to transform into mesenchymal cells and back into epithelial cells illustrates the inherent plasticity of the epithelial phenotype. These EMT and MET programs are coordinated by pleiotropic EMT transcription factors (TFs) and a multitude of extracellular signals^[26,27]. Three families of transcriptional regulators that are essential during EMT events have been identified as core EMT regulators: The zinc finger E-box binding homeobox members *ZEB1* and *ZEB2*^[28], the SNAIL zinc finger family^[29], and the TWIST family of basic helix-loop-helix transcription factors^[30].

Recent studies have elucidated molecular links between EMT/MET-TFs and self-renewal, one of the defining traits of cancer stem cells, suggesting that EMT processes play a role in the development of the CSC state. Several groups have demonstrated that EMT activation can induce CSC generation^[18,19]. Using a mammary tumor progression model, Morel and others showed that EMT induction can drive mammary epithelial cells to acquire stem and tumorigenic characteristics of CSCs following the activation of the Ras-mitogen-activated protein kinase pathway^[18]. In a correlative study, Mani *et al.*^[19] illustrated that cells that have undergone an EMT behave similarly to stem cells isolated from normal or neoplastic cell populations. The group induced EMT in nontumorigenic, immortalized human mammary epithelial cells (HMLEs) by ectopic expression of either the TWIST or SNAIL transcription factors (capable of inducing MET in epithelial cells). They found that most of the HMLEs that underwent MET acquired a CD44^{high}/CD24^{low} antigenic phenotype representative of mammary CSCs and that their mammosphere-forming ability was increased by 30-fold. Additionally, they demonstrated that CD44^{high} stem-like cells are more mesenchymal than their CD44^{low} counterparts^[19].

More recently, a study using a model of basal breast carcinoma elucidated a new role of EMT transcription factors in regulating CSC plasticity during tumor progression. Chaffer and group showed that neoplastic non stem cells (CD44^{low}) can readily convert to a stem-like state (CD44^{high}) and that this transition is mediated by *ZEB1*, a well-characterized EMT-TF. Further, they demonstrated that TGFβ, a recognized EMT-inducing stimulus can efficiently promote non-CSC-to-CSC conversion in their basal cell model^[20]. Taken together, these studies highlight the role of EMT regulators TWIST1, SNAIL2, and *ZEB1* in regulating CSCs in some tumor models. Importantly, complementary studies by these groups indicate that EMT transcription factors and extracellular signals cannot universally induce a CSC phenotype in all models, highlighting the heterogeneity of tumor progression and its microenvironment.

A DYNAMIC CSC STATE

Cancer stem cells are characterized as having an intrinsically determined state of unrestricted proliferative potential that permit self-renewal and give rise to progenitors with limited proliferative potential^[31]. Recent studies have proposed the concept of cancer stem cell plasticity in which these two states may not be definitive but instead have a transitional capability of shifting from a non-CSC state to a CSC state and vice versa^[20,32-36]. In experimental models of melanoma, tumorigenic cells display considerable plasticity transiently acquiring stemness properties depending on the tumor context. An early study revealed that both CD133+ and CD133- melanoma cells have the ability to form tumors, suggesting that CD133 is reversibly expressed by tumorigenic melanoma cells rather than identifying cells at a static level in a hierarchy^[37]. This group further characterized 22 markers and found that none of them robustly distinguished tumorigenic from non tumorigenic cells; instead, they observed phenotypically distinct melanoma cells having the capacity to form tumors that recapitulated the parent tumor^[33]. A complementary study further corroborates the plasticity of melanoma cells. The group showed that JARID1B histone demethylase is a regulator of tumorigenicity in melanoma cell lines and that JARID1B negative cells can become positive and acquire self-renewal potential. They proposed the hypothesis that the tumorigenicity of a single tumor-initiating cell is reversible and that some stem-like cells from solid tumors may not actually be static, but rather have a transient nature and acquire stem-cell-like properties depending on the tumor context^[34]. These results are compatible with the concept that tumorigenic potential might reflect a reversible state in cancer.

There is additional evidence supporting the model of dynamic stemness in breast cancer studies^[20,32,35]. Gupta and group developed and validated a theoretical quantitative Markov model of phenotypic transitions that predicts evolution toward equilibrium in cancer cell populations. Their model predicts that cancer cells could

interconvert between different states in a manner that maintains equilibrium in the proportions of cellular states; more specifically, it predicts that cancer stem-like cells can arise from non-stem-like cells. To test this prediction, they evaluated the ability of stem-like, basal, and luminal cells of seeding tumors. They demonstrated that the luminal and basal fractions could indeed generate functional stem-like cells *in vivo* supporting their hypothesis that convergence toward equilibrium cell-state proportions could be occurring due to cell-state interconversion within tumors^[35]. Additional work by the Weinberg group proposes that not all cancers adhere to a unidirectional model of cancer stem cell hierarchy. They identified subpopulations of non-cancer stem cells that could readily switch from a non-CSC to a CSC state. They found that the non-CSC population could give rise to aggressive CSCs^[32]. Further, they found that this plasticity is enabled by the transcription factor *ZEB1* (a well-characterized EMT transcription factor) and that microenvironmental stimuli could enhance the rate of non-CSC to CSC conversion. Importantly, they note that this plasticity and stimulus-mediated conversion is readily observed in basal-type cells, but not in luminal-type cells^[20]. Together, these studies suggest that certain cancer types may be following a bi-directional CSC model; however, they are not without limitations. The experiments described above rely on cell sorting to isolate and characterize cells, yet definitive surface markers are lacking for CSCs and their progenitors in undisturbed human tumors. Additionally, the results are obtained using artificial experimental systems, however delineation of functional plasticity will require minimally manipulated human cells or clinically relevant models of human disease. Further, if CSCs are present in a dynamic equilibrium, their respective isolation will be confounded by this fluctuating phenotype.

Two recent investigations in glioblastoma and colon cancer further validate the model of dynamic stemness and elucidate potential reprogramming factors responsible for the plastic phenotype^[36,38]. Suva and colleagues identified a set of core neurodevelopmental transcription factors (*POU3F2*, *SOX2*, *SALL2*, and *OLIG2*) that are essential for GBM propagation. They introduced each transcription factor individually into differentiated glioblastoma cells (DGCs) and monitored enhanced sphere formation ability. Next, they coinfecting DGCs with different combinations of TFs in a stepwise fashion and observed that the combined induction of *POU3F2* + *SOX2* + *SALL2* + *OLIG2* yielded cells capable of tumor initiation in 100% of animals. They showed that this set of TFs coordinately bind and activate CSC-specific regulatory elements and are sufficient to fully reprogram differentiated GBM cells to “induced” stem-like cells, recapitulating the epigenetic landscape and phenotype of native CSCs^[39]. Similarly, a study in colorectal cancer introduced a set of defined factors (*OCT3/4*, *SOX2* and *KLF4*) into human colon cancer cells and observed an enhancement in CSC properties such as sphere formation capability, marker gene expression, chemoresistance, and tumorigenicity. The tumors derived from these induced

CSCs had immunohistological similarities to human colon cancer tissue and their phenotypes were reproducible in serial transplantation experiments^[38].

Tumor suppressors have also been shown to play a role in CSC maintenance and plasticity. A study using an *in vivo* model of breast cancer showed knockdown of the *PTEN* tumor suppressor in normal mammary epithelial cells enriched for the stem/progenitor compartment leading to the generation of premalignant lesions^[40]. In cell lines, overexpression of *Mir-7*, a micro-RNA with tumor suppressor-like characteristics, decreased the population of breast cancer stem cells and partially reversed EMT by directly targeting the oncogene *SETDB1*^[41]. In prostate, *in vitro* analyses showed that *PTEN* and *TP53* play a role in regulating self-renewal and differentiation of prostate stem/progenitor cells^[42]. Further, using clonal epithelial cell lines the researchers showed that prostate epithelial *PTEN/TP53* loss led to transformation of multipotential progenitors, EMT, and increased plasticity of tumor cells^[43].

TUMOR MICROENVIRONMENT AND CSC PLASTICITY

The tumor niche or microenvironment is a complex network of cells, signaling molecules, soluble factors, and the extracellular matrix that plays a crucial role in tumor development, metastasis, and response to therapy^[44]. During embryonic development, niche factors affect stem cell gene expression and regulate cellular differentiation for fetal development. After birth, stem cells continue to be highly regulated for tissue homeostasis and during response to injury by the surrounding microenvironment^[45]. A tumor is comprised of neoplastic cancer cells together with microenvironmental factors that include hematopoietic cells, stroma, inflammatory cells, vasculature, and the extracellular matrix (a network of polysaccharides and proteins secreted by cells that serves as a structural tissue element and influences development and physiology)^[46,47]. Each of these cellular and non-cellular factors contributes to the transformation of tumor cells and may also affect response to chemotherapeutic and radiation treatments by providing protection from these agents^[46]. Similarly, cancer stem cell function and plasticity may be induced by specific microenvironmental signals and cellular interactions arising in the tumor niche^[48].

As discussed in the EMT section above, stromal cells secrete signaling factors that are received by epithelial cells and generate a signaling cascade that can orchestrate an epithelial to mesenchymal transition. A correlative interplay is observed between neoplastic cancer cells, CSCs, and the stroma in pancreas, breast, and colon cancer models. In the pancreas, stellate cells (myofibroblast-like cells found in the stromal compartment) remain activated after chemotherapy and radiation and impart a protective effect on cancer cells^[49-51]. Stellate cells have been shown to enhance spheroid-forming ability of CSCs through

induced expression of CSC-related genes and to promote the cancer stem cell phenotype through paracrine Nodal/Activin signaling at the tumor-stromal interface^[52,53]. Additionally, pancreatic stellate cells isolated from patients and co-cultured with pancreatic cancer cells enhanced cancer cell migration, and increased mesenchymal gene expression suggestive of an EMT phenotype^[54]. Parallel studies in breast and colon cancer revealed that CSC plasticity can be regulated by cytokine networks and growth factors^[55,56]. Vermeulen and group showed that hepatocyte growth factor can activate β -catenin-dependent transcription, CSC clonogenicity, and restore the CSC phenotype in more differentiated tumor cells both *in vitro* and *in vivo*^[56].

The interaction between immune cells and cancer cells has been shown to promote tumor development and progression and results in tumor immune evasion^[57]. In colorectal cancer, analysis of the type, density, and location of tumor-infiltrating immune cells within patient tumor samples revealed that this immunological data was a better predictor of patient survival than current histopathology methodologies used for staging that disease type^[58]. Some tumor cells escape immune system detection by decreasing the expression of specific antigen-presenting proteins on their cell surface, allowing them to evade cytotoxic T lymphocytes. Tumor cells can also secrete factors that inhibit effector T cell activity and promote the production of regulatory T cells that suppress immune responses^[57,59]. Similarly, stem-like cells in melanoma have been shown to preferentially inhibit T-cell activation and to support induction of regulatory T cells in order to evade immune system recognition^[60]. In GBM, CSCs suppress T cell response by producing immunosuppressive cytokines- they inhibit T cells through the *STAT3* pathway, and induce T cell apoptosis mediated by inhibitory molecules^[61,62]. A recent study has elucidated a novel role for how the immune system affects CSCs through paracrine signaling in colorectal cancer. This study revealed that CD4+ T cells secreted interleukin (IL)-22 which acted on cancer cells through *STAT3* and induced the core stem cell genes *NANOG*, *SOX2*, and *POU5F1*, resulting in increased cancer stemness and tumorigenic potential^[63].

The reciprocal communication and interplay between cancer stem cells and the immune niche can also induce CSC plasticity. This bidirectional phenotypic change may be driven by pro-inflammatory mediators such as tumor necrosis factor (TNF) and IL-6 that are secreted by various immune cells in the tumor microenvironment. Examples of cytokine-driven tumor cell plasticity have been demonstrated in melanoma, breast, and lung cancer where TNF and IL-6 can affect the differentiation state of tumor cells by the upregulation of mesenchymal genes- resembling an EMT-type switch. Similar changes have been observed in a study using an experimental model of colon cancer where elevated inflammatory nuclear factor kappa B signaling enhanced Wnt activation and induced dedifferentiation of non-stem cells that acquire tumor-initiating capacity. In an important complementary

study, a group at the Mayo Clinic observed that CD8+ T cells promoted EMT in an intact *in vivo* model of breast cancer. These transformed cells had characteristics of cancer stem cells that included potent tumorigenicity, the ability to reestablish an epithelial tumor, and enhanced resistance to drugs and radiation^[64]. In support of the hypothesis that cancer stem cell plasticity is driven by pro-inflammatory mediators induced by therapy regimens, gene expression signatures and histological studies in patients revealed an increase in mesenchymal markers in chemotherapy-resistant tumors^[65-67]. Taken together, these results suggest that immune cells and their related cytokines and growth factors can directly modulate and enhance the CSC phenotype. However, the niche effect likely will differ for different tumor subtypes with CSCs displaying diverse levels of dependency on these extrinsic microenvironmental interactions.

These experimental observations underscore the role of the tumor microenvironment, including immune cells, the stromal compartment, growth factors, and cytokines in phenotypic plasticity of tumor cells and CSCs and highlight potential novel targets to exploit therapeutic synergies to target multiple factors in the tumor niche.

CSC TARGETED THERAPIES

The data reviewed herein describe the hierarchical, molecular, extracellular, and plastic complexities of cancer and highlight the need for more comprehensive therapeutic strategies that address and target the multiple stages and branches of a single tumor. The renewed interest and deeper understanding of the CSC field have led to new ideas about therapeutic strategies including CSC signaling pathway inhibitors, immune mediated therapies targeting CSCs, and combination treatments targeting the microenvironment. However, CSC plasticity induced by microenvironmental and immune-related signals may limit the effect of CSC treatments. Therapies targeting CSCs would only be temporarily effective in eliminating this population since new CSCs may arise from non-CSCs left untargeted. Therefore, targeting each subpopulation or subclone within the tumor will be the most effective way of achieving a successful clinical response.

Data from high-throughput screening studies revealed that EMT programs rely on classic embryonal signaling pathways such as Notch, Wnt, Shh, and TGFβ^[68]. As reviewed, EMT processes play a role in the development of the CSC state and may be an attractive therapeutic target for inhibiting CSC plasticity. Because aberrant signaling in these pathways has been recognized to cause tumorigenesis in a broad variety of tissues, significant investment has been made by the industry to develop inhibitors towards them^[48]. It is possible that these agents already in development could be used to induce differentiation of CSCs in combination with drugs that would target the newly-differentiated cells. A number of experimental agents are being evaluated in the clinic for their ability to inhibit Wnt signaling that could be studied for this purpose^[69-72]. Novartis is currently testing

a Wnt-specific acetyltransferase inhibitor, LGK974, in a phase I study on malignancies dependent on Wnt ligands^[70]. Interestingly, their pre-clinical studies showed that cell lines with loss-of-function mutations in the Notch signaling pathway responded well to this inhibitor, suggesting an underlying mechanism of action for increased sensitivity to LGK974 in the Notch1 mutant carcinomas and highlighting the potential to target a subset of patients^[73]. One caveat of these therapies is the fact that the pathways they target are not exclusive to CSCs but are shared with normal stem cells. Identifying a threshold of killing activity of normal cells will be necessary to prevent deleterious effects. Additionally, it is unlikely that a single pathway will be operative in all of the CSCs in a given tumor; therefore, concurrent use of drugs that can affect multiple pathways that are essential to CSCs and EMT-mediated plasticity are likely to be obligatory to achieve effective therapies.

It is well-accepted that tumors deregulate certain immune-checkpoint pathways as a major mechanism of evasion and immune-mediated therapies (IMT) have been developed that utilize the immune system to target cancer cells. Cancer cells that undergo EMT develop a mesenchymal phenotype yet retain some epithelial characteristics^[64]. A recent study demonstrated that mesenchymal cells overexpress genes for immune inhibitory molecules including programmed cell death protein 1 (PD1)/PD-L1 and cytotoxic T lymphocyte-associated antigen-4 (CTLA-4)^[74]. It is also possible that mesenchymal cells resulting from EMT during bidirectional CSC conversion also express these molecules and that IMTs may have the potential to target this subgroup of dynamic cells. The two immune-checkpoint receptors that have been most actively studied in the context of clinical cancer immunotherapy are CTLA-4 and PD1. Both are inhibitory receptors and regulate immune responses at different levels and through different mechanisms^[75]. In 2010, a crucial Phase III trial using an anti-CTLA4 antibody, ipilimumab, demonstrated statistical survival benefit in patients with melanoma^[76]. This was the first immune-mediated therapy to demonstrate survival benefit in patients with advanced melanoma in a randomized trial. Other drug companies have accelerated preclinical studies to advance their immune-mediated therapies to the clinic^[77-79]. The observations that mesenchymal cells in non-small-cell lung cancer are associated with distinct immune phenotypes with increased expression of inhibitory molecules provide a potential mechanism for EMT-associated immunosuppression utilizing the therapies that are currently being tested in the clinic. Therefore, the IMTs described above may have the potential to target newly transformed CSCs as well as cancer cells that have not undergone a transformation thereby simultaneously eliminating both subpopulations leading to a more complete therapeutic response.

Cancer stem cells are characterized by immune suppressive activity and a low immunogenicity that enhance their ability to survive. CSCs need to evade immune reactions mounted by the host and adapt to the dynamic microenvironment altered by radiation and chemotherapy^[80]. Phenotypic

analysis in GBM, colorectal cancer, and melanoma revealed a potential impairment of antigen presenting function by CSCs helping to shield them from T-cells^[81]. Additionally, CSCs enhance immunosuppression by down-regulation of major histocompatibility complex MHC- I and - II (a milieu of proteins that regulate cell-mediated adaptive response) and through the release of immunosuppressive cytokines such as IL-10 and TGF β ^[60,61,81,82]. These cytokines can also affect the differentiation state of tumor cells by upregulating EMT genes. Therefore, Identifying targets that will inhibit and reverse the CSC escape from immunosurveillance may also elucidate targets for CSC plasticity and could prove necessary to successfully eliminate tumors.

PERSPECTIVE AND FUTURE DIRECTIONS

Additional understanding of the role of tumor cell dynamics will continue to inform our therapeutic strategies. Answers to important questions remain to be determined in the characterization of patient tumors and advances in technologies like single cell analysis are likely needed to identify a resolution. Perhaps the most important questions that remain with respect to therapeutic targeting are (1) whether plasticity causing non-CSCs to develop the tumorigenic properties ascribed to a CSC truly exists in human patient tumors and, even more importantly; (2) whether this interconversion results in a CSC clone that is different from the original clone and requires a different therapeutic approach. Additionally, (3) whether the extent of heterogeneity found within CSCs results in the need for independent therapies targeting of multiple CSC clones. Despite these questions, an overwhelming body of literature points to a need to develop therapeutics specifically targeted to CSCs as they are clearly implicated in disease relapse.

Continued research is needed to identify CSC-specific targets and to understand the effects of the stem cell niche on plasticity, survival, and tumorigenicity in order to develop novel therapeutic regimens. Identification of additional immuno-modulating therapies that can inhibit or reverse the ability of CSCs and their dynamic subclones to escape from immunosurveillance will contribute to the comprehensive cancer therapy approach that is likely necessary to achieve successful eradication of a tumor. Further, in order to achieve more complete therapeutic responses it will be necessary to pursue treatments against CSCs in each of their dynamic states or to first halt the interconversion between non-CSC to CSC and then eliminate each subpopulation therapeutically, and ultimately to combine these specialized CSC therapies with strategies that target the bulk population.

Abstract

Stem cells are capable of long-term self-renewal and differentiation into specialised cell types, making them an ideal candidate for a cell source for regenerative medicine. The control of stem cell fate has become a major area of interest in the field of regenerative medicine and therapeutic intervention. Conventional methods of chemically inducing stem cells into specific lineages

is being challenged by the advances in biomaterial technology, with evidence highlighting that material properties are capable of driving stem cell fate. Materials are being designed to mimic the clues stem cells receive in their *in vivo* stem cell niche including topographical and chemical instructions. Nanotopographical clues that mimic the extracellular matrix (ECM) *in vivo* have shown to regulate stem cell differentiation. The delivery of ECM components on biomaterials in the form of short peptides sequences has also proved successful in directing stem cell lineage. Growth factors responsible for controlling stem cell fate *in vivo* have also been delivered *via* biomaterials to provide clues to determine stem cell differentiation. An alternative approach to guide stem cells fate is to provide genetic clues including delivering DNA plasmids and small interfering RNAs *via* scaffolds. This review, aims to provide an overview of the topographical, chemical and molecular clues that biomaterials can provide to guide stem cell fate. The promising features and challenges of such approaches will be highlighted, to provide directions for future advancements in this exciting area of stem cell translation for regenerative medicine.

Core tip: Stem cells receive instructions from their niche environment, which guide their survival and phenotype. Stem cells receive physical and biochemical clues from their extracellular matrix where they reside *in vivo*. This paper will discuss the utilization of biomaterial surface topography and elasticity and delivery of chemical and genetic clues *via* scaffold materials to mimic the extracellular matrix to guide stem cell fate. The understanding of the parameters that guide stem cell differentiation is of great interest for the tissue-engineering field.

INTRODUCTION

Stem cells have the ability to differentiate into several tissue types and have captured a great interest for regenerative medicine due to their ability to regenerate and repair injured tissues^[1]. Stem cells are broadly classified into embryonic stem cells (ESCs) and adult stem cells (ASCs). ESCs are pluripotent stem cells capable of regenerating into cells types from all three germ layers (ectoderm, mesoderm and endoderm), being themselves derived from the inner cell mass of blastocysts^[2]. ESCs have a long term self-renewal capacity, ability to expanded for extended culture time and multi-lineage differentiation potential making them a very attractive tissue-engineering cell resource for regenerative medicine^[2]. However, efficient and safe isolation and differentiation protocols are required for their optimal clinical translation^[3]. In addition, ESCs have shown to differentiate into tumour cells, limiting their translation to clinical trials^[4]. The second type of stem cells that have attracted extensive research interest is ASCs. These cells are multi-potent cells derived from adult somatic tissues with the potential to differentiate into many specific cell types^[5]. Mesenchymal stem cells (MSCs) are the commonest type of ASCs investigated for tissue-engineered applications, which are found to be isolated from several tissue sources such as the bone marrow and adipose tissue^[6-8]. Controlling both the proliferative and differentiation abilities of stem cells has been the focus of utilizing stem cells for a therapeutic platform^[9]. In their *in vitro* environment stem cell fate is determined by a reservoir of biochemical and biophysical clues^[6]. The instructions stem cells receive from their stem cell niche will control their stem-ness, multi-potency and determine their phenotype of differentiation^[6].

Stem cells have the ability to differentiate spontaneously *in vitro* but this is uncontrolled and inefficient for tissue-engineering applications^[10]. Therefore, over the last decade it has become important to understand how to control stem cell fate effectively for regenerative medicine^[10]. A common approach to determine stem cell fate *in vitro* is by adding medium growth components including chemokines and hormones, to differentiate stem cells into a particular lineage^[7-9]. Chemical patterning has shown to be very successful in the differentiation of ASCs down osteogenic, chondrogenic and adipogenic lineages^[7-9]. Whilst understanding chemical clues of stem cell fate is important, with the advances in knowledge that stem cells are highly sensitive to their topography, stiffness and molecular environment, it may only be part of the strategy for controlling stem cell fate for regenerative medicine^[10]. The extracellular matrix (ECM) in the *in vitro* stem cell niche is arranged into complex topographic features,

which stem cells have shown to be sensitive to and provide clues to guide their phenotype^[11]. This evidence has prompted materials to be manufactured with surface topographical clues, which has shown to greatly influence cell behavior altering cell morphology, adhesion, motility proliferation and gene regulation^[12]. The *in vitro* mechanical clues from the ECM (stress, shear and strain) have also shown to play a part in the precise control of stem cell fate^[13]. With this knowledge material substrate stiffness is now taken into consideration to guide stem cell fate^[14]. As biochemical clues provide important instructions to stem cells *in vitro* growth factors have been immobilised onto material surfaces to guide stem cell behaviour^[15,16]. Further understanding of these environmental instructions on stem cell differentiation is emerging, with the hope to be able to better control stem cell fate for tissue-engineering purposes.

This unique review, aims to provide an update on the three main biomaterial parameters that are being explored to govern stem cell fate, with a focus on stem cell differentiation. The parameters discussed in this review will be the effect of topographical, chemical and genetic clues on guiding stem cell differentiation. In this review, both ASCs and ESCs will be considered to provide an overview of the different parameters that are being investigated to determine stem cell differentiation. The emphasis of discussion will be placed on the techniques used to govern stem cell fate rather than exploring their effect on different stem cell types. This review aims to highlight the successful strategies to control stem cells fate for regenerative medicine applications.

EFFECT OF STEM CELL FATE AND SURFACE TOPOGRAPHICAL CLUES

In their natural niche environment, cells are interacting with various nanotopographically sized clues^[17]. Cells will encounter different topographies sized clues *in vivo* from macro- (bone and ligament) to micro- (other cells) and nanotopography (proteins and ligands), all of which will influence cell behavior and consequently cell fate^[17]. The most important is the basement membrane, a vital structure of the ECM, which provides tissue support and organization^[17]. The basement membrane contains pores, ridges and fibers, which are all in the nanometer range^[17].

The use of topographically patterned surfaces for culturing cells has a very important advantage over chemical induction of stem cells, the disregard to using chemicals in the body yet still tailor stem cell for particular clinical applications. There is now growing evidence that topographical clues alone can produce the same effect as chemical induction^[18]. Extensive research has been attempted to understand the interaction of cells with their substrate topography using *in vitro* studies^[18]. With the advancement in micro and nanofabrication techniques, numerous studies have been able to be carried out to understand the effect of nanotopography on a wide range of materials. Patterning techniques such as soft lithography, photolithography, electrospinning, layer-by-

Figure 1 The effect of nanotopographies on stem cell shape and its consequential effect on the differentiation of stem cells. **A:** Brightfield images of human mesenchymal stem cells (hMSCs) plated onto small (1024 μm^2) or large (10000 μm^2) fibronectin islands after 1 wk in growth or mixed media. Note hMSCs plated on large islands showed differentiation for osteogenic differentiation and those on small islands showed differentiation for adipogenic differentiation. Lipids stain red; alkaline phosphatase stains blue. Scale bar = 50 μm ; **B:** Percentage differentiation of hMSCs plated onto 1024, 2025, or 10000 μm^2 islands after 1 wk of culture in mixed media. Taken with permission from McBeath R, Pirone DM, Nelson CM, Bhadriraju K, Chen CS. Cell shape, cytoskeletal tension and RhoA regulate stem cell lineage commitment. *Dev Cell* 2004; **6**: 483-495.

layer microfluidic patterning, three-dimensional (3D) printing, ion milling and reactive ion etching have all made it possible to create scaffolds materials with precise controlled geometry, texture, porosity and rigidity^[19-23]. Different types of surface topographies have been generated and investigated for their effect on stem cell differentiation including the topographical scale (micro or nano), type (ridges, pillar, pit or groove) and distribution (random or regular distributed features).

Stem cells have shown to rely on spatial information for differentiation, as this controls their cell shape and size, elongation and positioning of the focal adhesion (FA) formation and lastly cell-cell interactions^[24]. The effect of surface topography on cell shape and size, which will later determine stem cell fate has been explained by many researchers^[25-27]. For example, MSCs cultured

on large 10000 μm^2 islands allow spreading and permit differentiation down the osteoblastic lineage but MSCs on small 1024 μm^2 islands remain rounded and as a consequence differentiated into adipocytes (Figure 1)^[25]. Similarly MSCs cultured on small 30 nm nanotubes showed no obvious differentiation whereas 70-100 nm nanotubes showed cytoskeletal stress and osteoblastic lineage differentiation^[28]. Overall, it has been assumed that geometric changes causes an increase in actomyosin contractility leading to osteogenesis due to the activation of RhoA and its effector ROCK kinase^[28]. The surface topography also has significant effects on the alignment of the nuclei. The nuclear shape will be distorted during cell extension on material surfaces as the nucleus is mechanically integrated to the rest of the cell through filaments^[29]. Nuclear elongation has shown to influence osteoblastic stem cell differentiation^[29]. Geometric clues will also alter the cell-cell interactions. This is very clear with the example of directing differentiation of ESCs. Aggregation is an important step for the differentiation of ESCs. This was demonstrated by the enhancement of ESCs differentiation into cell aggregates called embryoid bodies (EBs), which recapitulate early stages of embryonic development. By creating microfabricated cell-repellent poly(ethylene glycol) (PEG) wells, EBs cell aggregates could be formed with controlled sizes and shaped defined by the geometry of the microwells^[30].

A seminal paper showed that the order of the nanotopography is also important in controlling stem cell fate. Dalby *et al*^[31] compared the osteogenesis of osteoprogenitor cells and human mesenchymal stem cells (hMSCs) on polymethylmethacrylate substrate with ordered square and hexagonal pattern, disordered square and random nanopits using electron beam lithography (EBL) (Figure 2). Osteogenesis was the highest on the disordered square array without the presence of any induction medium and the lowest on the surfaces with high symmetry^[31]. Quantitative Polymerase Chain Reaction and microarray data showed an increase in expression of genes responsible for osteogenic differentiation, which was of a comparable level to those cells on a flat planar surface in osteogenic medium^[31]. Stein *et al*^[32] followed up this work, by illustrating that skeletal stem cells cultured on these surfaces had a normal differentiation profile according to the osteogenic differentiation model explained by Stein and Lian. The authors provided further evidence that differentiation of skeletal stem cells cultured on nanotopographical surfaces, provided an equal and effective technique of differentiation of stem cells compared to chemical induction^[33]. Zouani *et al*^[34] similarly showed that hMSCs cultured on polyethylene terephthalate substrates with nano-depths of varying degrees, had higher osteogenic differentiation on the 100 nm patterns compared to the 10 nm patterns. The organization of the hMSCs on the 100 nm was believed to induce FA contacts, generating stress in the actin filaments. Actin tension was found to be important in the osteogenic differentiation of the cells as the osteoblastic phenotype was inhibited by cytochalasin D^[34].

Figure 2 The effect of nanopits on the differentiation of stem cells. The top row showed the nanotopographies produced using electron beam lithography. All have 120 nm diameter pits (100 nm deep, absolute or average 300 nm centre-centre spacing) with square (B, G), displaced square 20 (± 20 nm from true centre), (C, H), displaced square 50 (± 50 nm from true centre) (D, I) and random placements (E, J). There is lack of positive staining for osteocalcin (OCN) and osteopontin (OPN) on control nanotopographies (A, F) but good positive staining for expression for OPN and OCN for cells grown on displaced square 50 nanotopographies (D, I). Actin = red, OPN/OCN = green. Taken with permission from Dalby MJ, Gadegaard N, Tare R, Andar A, Riehle MO, Herzyk P, Wilkinson CD, Oreffo RO. The control of human mesenchymal cell differentiation using nanoscale symmetry and disorder. *Nat Mater* 2007; 6: 997-1003.

Nanogrooves have found to be particularly useful for controlling cellular morphology, orientation and direct cell migration in a mechanism called “contact guidance”, proposed by Harrison in 1911^[35]. Harrison illustrated that ESCs cultured on a spider followed the pattern of the fibers of the web^[35]. It has emerged that phenotypic changes can occur using nanoscale grooves to direct stem cell differentiation towards the neuronal lineage^[36,37]. For example, bone marrow derived stem cells were cultured on micro and nanoscale ridges and found to undergo neurogenesis without the presence of chemical induction medium. In this study, hydrogenated amorphous carbon groove topographies with width/spacing ridges ranging from 80/40 μm , 40/30 μm and 30/20 μm and depths of 24 nm were used^[37].

Grating like surfaces have also shown to be a clue for ESC differentiation. Smith *et al.*^[38] demonstrated that mouse ESC differentiation was induced on poly-L-lactide (PLLA) matrices with a grating morphology, a fibrous nano-architecture with diameters of 50-500 nm. ESCs were cultured on PLLA nanofibrous scaffolds and compared to elastin-coated tissue-culture polystyrene and PLLA films and demonstrated an increase in osteogenic markers on the nanofibrous matrix than the other substrates^[38]. Grating like surfaces have also demonstrated to induce the differentiation of ASCs^[39]. Human MSCs have shown to differentiate into the neuronal lineage on polydimethylsiloxane (PDMS) with and without retinoic acid induction with nanogratings of 350 nm width^[39].

Vertically standing nanotubes illustrate another topographical control of stem cell fate^[11]. The diameter size of vertically aligned titanium dioxide (TiO_2) nanotubes formed by anodization has showed to be crucially vital to determine stem cell response^[11]. For example, 15 nm TiO_2

nanotubes allowed integrin clustering and cell spreading but this was suppressed when grown on 100 nm TiO_2 nanotubes^[11]. This morphological effect resulted in less differentiation of the MSCs into smooth muscles and endothelial cells on the 10 nm compared to the 15 nm tubes in chemical induction medium^[11].

Stem cells will respond to the mechanical properties of the material, which they are adhering and growing^[40]. A influential paper by Engler *et al.*^[40] showed that hMSCs on polyacrylamide hydrogels of varying stiffness, coated with collagen I were capable of differentiation without any inducing medium (Figure 3). Soft gels mimicked the rigidity of brain tissue (0.1-1.0 kPa), enabled the hMSCs to undergo neurogenic differentiation, stiffer gels which resembled muscle tissue provided clues for myogenic differentiation and very stiff gels which resembled bone tissue enabled osteogenic commitment (25-40 kPa). Zouani *et al.*^[41] similarly found that culturing hMSCs on poly(acrylamide-co-acrylic acid) surfaces and then varying the stiffness of the gels depending on the % of cross-linker bis-acrylamide could cause myogenic (13-17 kPa) or osteogenic differentiation (45-49 kPa). Other researchers have also reported that stiffness of the cell culture substrate is important for stem cell differentiation in 2D-culture^[42-44]. The mechanism by which the elasticity of ECM on culture substrates induces specific stem cell differentiation is still under debate. However, it is thought that the elasticity of the ECM induces changes in the FA protein activity and remodeling. Furthermore, as the growth and elongation of the FA will change according to the substrate stiffness, which means the elasticity regulates the FA assembly^[45,46]. Integrins have been suggested to be the starting point for cells to sense the mechanical stimuli of the biomaterial to which they are adhered^[45,46].

Table 1 Examples of studies, which have demonstrated surface topographies can direct stem cell differentiation

Modification to the FA complexes can cause a cascade of signaling pathways and allow differentiation of stem cells^[45,46].

Elasticity of scaffolds has also shown to cause specific lineage differentiation modifications to stem cells in 3D-culture. For example, Banerjee *et al.*^[47] showed that the proliferation and differentiation of rat neural stem cells encapsulated in 3D-alginate hydrogels showed enhanced expression of neuronal marker β -tubulin II in the softer hydrogels, which resembled brain tissue than the stiffer hydrogels. Murphy *et al.*^[48] found that cross-linked collagen-glycosaminoglycan scaffolds with three varying stiffness of 0.5, 1 and 1.5 kPa showed difference in their chondrogenic differentiation capacity. The scaffolds with the lowest stiffness showed an upregulation of sox expression and MSCs on the stiffest scaffolds showed differentiation down the osteogenic lineage^[48]. This study highlighted that MSC fate in 3D-culture can be controlled even in the absence of differentiation supplements^[48]. Table 1 provides the summary of the key research studies highlighting the effect of nanotopographies on directing stem cell fate^[49-56].

EFFECT OF STEM CELL FATE AND CHEMICAL CLUES

As previously highlighted, stem cells in their niche environment interact with their ECM. The stem cells will recognise and attach to specific amino acid sequences *via* integrins, which are surface receptors composed of heterodimers of α - and β -subunits^[57,58]. Cells will receive chemical signals from the

ECM that will initiate signaling cascades, which will determine critical cell functions including proliferation, differentiation, migration and apoptosis^[57,58]. Therefore, an important goal of regenerative medicine is to mimic the critical chemical clues of the ECM to control cell function and direct cell fate (see Table 2)^[15,16,59-79].

Growth factors are one key chemical clue that is provided by the ECM, which regulates a key number of cellular functions including adhesion, proliferation and differentiation^[80]. Kuhl *et al.*^[80] were the first to illustrate that providing growth factors in their matrix-bound mode to regulate cell response rather than providing it in a soluble mode allowed effective cell behavior control. They demonstrated that mouse epidermal growth factor covalently tethered to a glass substrate *via* star poly (ethylene oxide) could induce DNA synthesis^[80]. Whole proteins are usually denatured or degraded during the biomaterial modification step and as a consequence short peptide sequences are often implemented to control cell response, which provides increased specificity, stability and the capability for high concentrations^[81]. The specific peptide sequence arginine-glycine-aspartic acid (RGD) sequence present in ECM proteins [*i.e.*, fibronectin (FN)] has been extensively attached to several natural and synthetic biomaterials and found to regulate MSC behaviour^[81]. Surfaces functionalised with RGD ligands has demonstrated to increase the osteogenic and chondrogenic lineage compared to unmodified surfaces^[82-85]. Other peptide sequences have also shown to influence stem cell differentiation for example, Martino *et al.*^[86] investigated the effect of fibronectin's central binding

Table 2 Example of studies, which have demonstrated that the use of different chemical inducers can direct stem cell differentiation

Immobilised chemical inductor	Scaffold type	Functional group	Differentiation outcome	Ref

domains (FN III9-10) variants with varying specificities to integrin $\alpha 5 \beta 1$ on stem cell differentiation on fibrin matrices. The data illustrated that MSC underwent osteogenic differentiation on the modified surfaces. The spatial density of RGD peptide has also illustrated to influence stem cells differentiation^[85]. Frith *et al*^[84] showed that as the lateral spacing of RGD peptide increased, the ability of the MSCs to spread was reduced and that their morphology changed from well-spread cells with normal fibroblastic morphology and defined stress-fibres, to less-spread cells with numerous cell protrusions and few stress fibres. Using qRT-PCR to determine gene expression levels and a quantitative alkaline phosphatase assay, they showed that MSC osteogenesis was reduced on surfaces with increased lateral spacing while adipogenic differentiation was increased^[84].

Peptide sequences that resemble several growth factors and chemokines have also been immobilised onto

substrates to induce specific stem cell differentiation. Bone morphogenic proteins have shown to play an important role in stem cell activity and control of differentiation of stem cell *in vitro* for osteoblastic differentiation and bone formation^[87]. RGD and RKIPKASSVPTLSAISMLYL peptide sequence, which mimicked BMP-2 was grafted onto the poly(acrylamide-co-acrylic acid) surfaces of different stiffness through carbodiimide chemistry^[41]. The study illustrated that hMSCs showed commitment to the osteoblastic lineage in the presence of the BMP-2. Interestingly, the osteogenic differentiation did not occur on the softer scaffolds, highlighting the important interaction of biochemical and mechanical stimuli to guide stem cell fate^[41]. Several other chemical inducers have also been investigated to control stem cell fate, including collagen type I (COL-1), bone sialoprotein (BSP) and osteopontin (OSP)^[88-92]. The $\alpha 2 \beta 1$ integrin is highly

Figure 3 Effect of substrate stiffness on the differentiation of stem cells. A: The neuronal cytoskeletal marker $\beta 3$ tubulin is expressed in branches (arrows) of initially naive mesenchymal stem cells (MSCs) (> 75%) and only on the soft, neurogenic matrices. The muscle transcription factor MyoD1 is upregulated and nuclear localised (arrow) on myogenic matrices and osteoblast transcription factor CBF- α 1 (arrow) is expressed only on stiff, osteogenic gels. Scale bar is 5 μ m; B: The microarray profiles of MSCs cultured on 11 or 34 kPa matrices. The expression was normalised first to actin and then to expression of committed C2C12 myoblasts and hFOB osteoblasts; C: The highest fluorescent intensity of differentiation markers was observed at the substrate elasticity of the elastic modulus typical of each tissue type. expressed on osteoblasts and a major adhesion receptor for COL-1, playing an important role in the activation of FAs kinase and pathways for osteoblastic differentiation^[88]. BSP is another important molecule involved in the bone mineralization process by inducing hydroxyapatite

nucleation^[89]. OSP is a glycosylated phosphoprotein highly expressed in bone and shown to be responsible for the formation and remodelling of bone^[90]. COL-1 and OSP peptides have demonstrated to promote osteogenesis of stem cells when immobilised onto scaffolds materials^[91,92].

Applying growth factors to scaffold materials has shown not only to induce osteogenesis of stem cells but demonstrated beneficial effects on several differentiation pathways. NSCs cultured on agarose scaffold immobilised with RGD and platelet derived growth factor AA (PDGF-AA) showed differentiation into oligodendrocytes, being confirmed at a protein and gene level^[75]. Nerve growth factor (NGF) immobilised onto nanofibrous polycaprolactone- polyethylene glycol (PCL/PCL-PEG) scaffolds also induced the neural differentiation of MSCs^[76]. Vascular endothelial growth factor (VEGF) has also demonstrated to induce differentiation of mouse ESCs and human MSCs into endothelial cells^[77-79].

The modification of materials with specific chemical functional groups is a common strategy to induce specific stem cell behaviour^[93]. Surface chemistries have shown to sufficiently induce differentiation of MSCs alone^[94]. Benoit *et al*^[60] has provided and modelled the effect of unique chemical environments on the differentiation of stem cells (Figure 4). In this study, PEG hydrogels were functionalised with carboxylic groups to mimic the glycoaminoglycans in cartilage, phosphate groups for their role in bone mineralization and tert-butyl to mimic the lipid rich environment in adipose tissue^[60]. After functionalisation, the gels were able to direct the differentiation of the stem cells down the chondrogenic, osteogenic and adipogenic pathways as hypothesised^[60].

Self assembled monolayers (SAMs) have been an effective tool for reviewing the effect of specific surface chemistries for stem cell differentiation^[93]. SAMs are highly organised substrates that are adsorbed onto a solid surface^[94]. Phillips *et al*^[95] illustrated using SAMs functionalised with four different functional groups, methyl (-CH₃), hydroxyl (-OH), carboxyl (-COOH) and amino (-NH₂), effected the adsorption of fibronectin onto the surfaces, which consequently allowed the osteogenic differentiation of hMSCs. The study illustrated that -NH₂ allowed the highest level of osteogenic differentiation in osteoconductive medium, with up regulation of Runt-related transcription factor 2 (Runx2), BSP and osteocalcin (OCN) expression and alizarin red staining^[95]. Similarly, Curran *et al*^[66] investigated methyl (-CH₃), hydroxyl (OH), carboxyl (-COOH), amino (-NH₂) and thiols (-SH) and also observed that hMSCs cultured on -NH₂ surfaces showed a higher capability for osteogenic differentiation than other cell lineages or to remain in an undifferentiated state. Valamehr *et al*^[96] have also used the SAM technique to create different surface hydrophobicities and found the increase in surface hydrophilicities could increase hESC proliferation and differentiation. With the emergence of plasma surface modification over the last ten years, which alters the surface chemistry with different chemical functional groups, controlling stem cell fate using chemical is likely to receive extensive research^[64].

DELIVERY OF GENETIC CLUES FOR STEM CELLS

The last technique is to provide genetic clues to direct

stem cell fate decisions. Traditionally the expression of specific genes has been forced in the stem cells by using viral and non-viral delivery systems. Viral transfection are highly efficient but their size limits restricts its transfection efficiency^[97]. Adenoviruses have been illustrated to have higher transfection efficiency but their poor *in vivo* responses including early failures has led to a decrease in use^[97]. Several studies have shown to use viral gene therapy to induce the differentiation of stem cells. Chuang *et al*^[98] found that BMP-2 transduced using the baculovirus into human BMMSCs successfully induced differentiation into osteoblasts after two weeks when seeded onto alginate scaffolds in nude mice. Li *et al*^[99] similarly investigated the effect of BMP-7 adenovirus on the mandibular damage in a rabbit model. The addition of BMP-7 induced early bone regeneration compared to scaffold hydroxyapatite/ polyamide (nHA/PA) only and scaffold with non-transduced BMMSCs^[99]. Adenoviruses with Runx2 and fibroblast growth factor-2 have also shown to effectively enhance the osteogenic differentiation of stem cells^[100,101]. Despite viral strategies promising effect on stem cell fate, non viral techniques have been employed to overcome the limitations of viral strategies including transposons (mobile DNA elements), plasmids (circular, self-replicable double-stranded DNA), short-interfering RNA molecules (siRNAs), cell-penetrating peptides, or bacterial artificial chromosomes (DNA constructs) to deliver a transgene^[102].

An exciting area of research is non-viral gene delivery *via* biomaterials to direct stem cell function. The gene delivery could be in the form of DNA plasmids or siRNAs. This would allow localised and sustained delivery of the genetic siRNA clues to the stem cells to direct their fate more precisely^[102-105]. Furthermore, by delivering genetic clues *via* a scaffold they are protected from biodegradation^[102-104]. Delivering the gene *via* scaffolds also allows the potential of prolonged delivery of the genetic material^[102-105].

DNA plasmids can be incorporated into the scaffold *via* encapsulation or surface mobilisation^[106]. Few studies have highlighted the delivery of DNA plasmids *via* scaffold to control stem cell fate^[104-107]. Im *et al*^[106] showed successful chondrogenic differentiation of adipose derived stem cells (ADSCs) by the plasmid DNA (pDNA) containing SOX trio (SOX-5, -6, and -9) genes into poly(lactic-co-glycolic acid) PLGA scaffolds after 21 d. Furthermore, after implanting the ADSCs seeded scaffold *in vivo* gross and histological findings confirmed cartilage regeneration^[106]. Furthermore, porous chitosan/ collagen scaffold prepared using freeze drying process and loaded with the plasmid vector encoding human bone morphogenetic protein-7 (BMP-7) gene, enabled human dental pulp stem cells to undergo odontoblastic differentiation confirmed by PCR studies^[107].

An emerging tool for controlling stem cell fate and biology is the use of RNA interference (RNAi) by which delicate control of gene expression is created^[102-105]. The focus of RNAi has already been utilised extensively in treating genetic disease or cancerous cells by combining it with chemical conjugates^[102-105]. However, recently there has been a shift in focus of using the RNAi to stem

Figure 4 Effect of surface chemical functional groups on the differentiation of stem cells. Encapsulation of human mesenchymal stem cells (hMSCs) in phosphate and t-butyl functionalised polyethylene glycol hydrogels affected the CBFA1 and PPARG expression. A: CBFA1, PPARG, and β -actin expression of hMSCs encapsulated in control, t-butyl, and phosphate-functionalised PEG hydrogels was performed. Immunoblots were quantified with ImageJ software and CBFA1 (B) and PPARG (C) expression levels over the 21-d culture period were normalised to β -actin expression; D: Differentiation was confirmed using Masson's trichrome stains collagen blue (left column) and Oil Red stains intracellular lipid deposits red (third column). (bar = 100 μ m). Taken with permission from Benoit DS, Schwartz MP, Durney AR, Anseth KS. Small functional groups for controlled differentiation of hydrogel-encapsulated human mesenchymal stem cells. *Nat Mater* 2008; 7: 816-823.

cell differentiation and regenerative medicine. In 2003, Hribal *et al*^[108] was the first to induce the pluripotent P19 teratocarcinoma cells by using small interfering RNAs (siRNA) targeting the pan-Foxo genes, without the induction agent dimethyl sulfoxide (DMSO). RNAi works by silencing any gene of interested by eradication of

the target mRNAs by the introduction of siRNAs^[102-105]. Several areas of research have endeavoured to use siRNA to induce specific differentiation of stem cells. Studies examining the effect of siRNA have shown to influence stem cell fate in the presence and in the absence of chemical induction medium^[109-112]. One of the main

limitations of using siRNA in controlling stem cell fate is the low transfection efficacy of stem cells. It has been demonstrated that stem cells are not very sensitive to the common transfection agents, which cause transfection using “proton-sponge” effect, which causes disruptions the nucleic acid complexes in the endosomes^[109]. Some specific transfection reagents are being designed for stem cell transfection including Oligofectamine™ and siPORT™, which may begin to increase the use of siRNA for controlling stem cell fate^[109-111]. Alternatively nanoparticle-based delivery of siRNA is already well developed for therapeutic purposes in tumour cells but have yet to be tested extensively on stem cells. Nanoparticle based delivery hold promise for stem cell transfection due to their less disruption on genetic modification compared to viral mediated transduction^[112]. Few studies are now emerging to investigate this area of research^[112]. Poly-ethylenimine (PEI) modified poly(lactic-co-glycolic acid) (PLGA) nanoparticles were used to deliver SOX5, SOX6, and SOX9 into human MSCs to enhance chondrogenesis. The delivery of the genes was capable of inducing chondrogenic differentiation of stem cells^[112].

An exciting area of research is scaffold based siRNA transfer. Over the last few years, few studies have now utilised siRNA to guide stem cell fate^[113]. PCL scaffolds functionalised with TransIT-TKO/siRNA nanoparticles enabled the successful gene silencing of tribbles homolog 2 and BCL2L2 causing an increase in expression of adipogenic and osteogenic differentiation respectively^[113]. The group further implanted the scaffold *in vivo* and demonstrated the capability of stem cells to commit to different differentiation pathways in specific locations within the same implant, by placing different siRNAs in distinct locations^[113]. Nguyen *et al.*^[114] recently highlighted that siRNA delivered *via* a hydrogel was able to ensure the osteogenic differentiation of stem cells. Low *et al.*^[115] showed that RE-1-silencing transcription factor (REST) siRNAs could successfully enhance the neuronal commitment of mouse neural stem cells. As there are many benefits of using scaffold for gene delivery to control stem cells, it is likely that extensive research will be carried out to exploit the RNA-functionalised scaffolds in the future. Furthermore, the added benefit of priming the scaffold with topographical and chemical inductors as discussed earlier means gene delivery *via* scaffolds shows exciting advantages, which deserves further research interest.

FUTURE PERSPECTIVES

Nanotopographical clues have shown to provide important clues for stem cells and surface patterning has presented to be an important tool to control specific stem cell responses. Using nanotopographies of biomaterials to guide stem cell fate holds great promise, as surface modifications are not affected by degradation over time unlike chemical medium components. Furthermore, nanotopographies could be varied on a single biomaterial to induce different stem cell responses by inducing

gradients on the surfaces, creating further scope for therapeutic applications. One of the main challenges in using nanotopographical clues in the medical field is the application of the required tightly controlled nanofeatures for large scale production that have been shown to control stem cell fate. Newer technologies such as colloidal lithography could provide the solutions for the large-scale production but further work is required.

The immobilisation of growth factors and chemical groups to biomaterials has proved to be successful in guiding stem cell differentiation. However, despite growth factors immobilisation proving to be better than the delivery of soluble factors in the stem cell's culture medium to control stem cell fate, there are difficulties that must be overcome for successful clinical translation. A greater control of the bioactivity, orientation and spacing, of the growth factor must be found to yield the desired control of stem cell differentiation. Another important question is the response of the stem cells to the growth factors and functional groups in the long term due to the continuous activation of the cells. Greater control of the inductive chemical clues needs to be found to ensure the desired response is specific for the intended purpose. Similarly, the response of the other cells *in vivo* to the chemical clues provided may cause unwanted effects, which warrants further investigation.

Despite the emerging studies of gene delivery *via* scaffolds to stem cells to control stem cell fate currently it is very difficult to translate these results to human clinical practice. Further work, is required to find optimal transfection and safe gene transfer to fully appreciate the impact of molecular control of stem cells for tissue engineering and regenerative medicine. Extensive safety reports will need to be undertaken to fully appreciate the effectiveness of gene therapy for future regenerative medical applications.

Many studies have investigated the effect of different environmental parameters on stem cell behaviour; however few studies have taken into account more than one environmental clue to control stem cell fate. In the future, as technology advances allow microarrays to test the effect of more than one environmental parameter on stem cell behaviour, greater knowledge will be obtained. For biomaterial design it will be important to understand the biophysical and biochemical properties that are optimal to guide stem cell response.

CONCLUSION

There is accumulating evidence to demonstrate that stem cell fate could be regulated by surface topography and chemical and molecular clues delivered using biomaterials. It is clear that this field of research is still emerging but there is great promise that stem cell fate could be controlled by creating advanced biomaterials, which are responsive to their environment for intended applications.

have been used with varying successes to augment the natural regenerative processes which occur following nerve injury. Stem cell therapy in peripheral nerve injury may be an important future intervention to improve the best attainable clinical results. In particular adipose derived stem cells (ADSCs) are multipotent mesenchymal stem cells similar to bone marrow derived stem cells, which are thought to have neurotrophic properties and the ability to differentiate into multiple lineages. They are ubiquitous within adipose tissue; they can form many structures resembling the mature adult peripheral nervous system. Following early *in vitro* work; multiple small and large animal *in vivo* models have been used in conjunction with conduits, autografts and allografts to successfully bridge the peripheral nerve gap. Some of the ADSC related neuroprotective and regenerative properties have been elucidated however much work remains before a model can be used successfully in human peripheral nerve injury (PNI). This review aims to provide a detailed overview of progress made in the use of ADSC in PNI, with discussion on the role of a tissue engineered approach for PNI repair.

Core tip: Adipose derived stem cell differentiation is an area of important active research at present. Since adipose tissue is ubiquitous throughout the body it is an ideal source of cells for regeneration of damaged body parts. In the peripheral nervous system there are currently significant limitations in the methods of treatment and subsequent rehabilitation. Adipose stem cells can express proteins which are similar to schwann cells and are termed schwann like cells. In this review we provide an update on the current methods used in peripheral nerve reconstruction using adipose stem cells.

Abstract

Unlike central nervous system neurons; those in the peripheral nervous system have the potential for full regeneration after injury. Following injury, recovery is controlled by schwann cells which replicate and modulate the subsequent immune response. The level of nerve recovery is strongly linked to the severity of the initial injury despite the significant advancements in imaging and surgical techniques. Multiple experimental models

INTRODUCTION

Background

The peripheral nervous system (PNS) consists of 3 principle cell types: axonal, glial and supporting stromal tissue^[1] arranged in long efferent (motor) and afferent (sensory) fibres relaying information to the CNS. Peripheral nerve injury (PNI) is common occurring in 2.8%-5% of poly trauma patients^[2,3] and may lead to long term functional deficiencies.

Traction related injuries are the most common pathophysiology seen during PNI^[4]. The natural elasticity of the endoneurium and perineurium of the nerve permits stretching to occur within the planes of the collagen fibres. If a sufficient traction force is applied to the nerve a route avulsion may lead to disruption of anatomy and complete loss of function. The perineurium has much greater elastic strength than the endoneurium^[4]. Therefore, elasticity is maintained within the nerve undergoing a stretching injury until the perineurium is devitalised. Peripheral nerve lacerations related to by penetrating trauma from knives and glass account for up to 7% of all brachial plexus lesions^[5]. These injuries are usually partial injuries where a segment of the injured nerve remains in continuity. When a clean laceration occurs this is usually amenable to a primary repair^[6]. Another common cause of peripheral nerve injuries is direct compression onto the nerve^[4]. This pressure on the nerve results in both mechanical compression and ischaemia. Initial microvascular damage to the nerve is usually reversible if the injurious mechanism is discontinued within 8 h of initial injury. Early investigation of these nerves showed most of the early damage was occurring in the periphery of the nerve as opposed to the central segment were the greatest ischaemia occurred^[4]. When these compressed tissues were viewed under electron microscopy the typical morphological features seen included: dislocations of the nodes of ranvier, as well as paranodal penetration and and subsequent invagination^[7]. Figure 1 shows the common pathophysiological response to the damaging compression forces associated with nerve crush injuries.

Other less common causes of PNI can be attributed to thermal, electrocution, radiation, percussion and vibration injuries^[3,8]. Irrespective of the cause of injury "the functional outcome of PNI depends on the severity of the injury"^[9].

Classification of PNI

The severity of PNI was initially classified by Seddon and subsequently reclassified by Sunderland^[10,11] as shown in Figure 2. Neurapraxia is the least severe form of nerve injury in the Seddon classification equating to grade I in

Figure 1 Changes occurring in a peripheral nerve following compression injuries adopted and modified from Ref^[9].

Sunderland. Although the overall anatomy of the nerve remains the same, areas of segmental demyelination lead to reductions in the frequency of transmitted electrical signals^[12]. Recovery from the primary injury is highly variable but most motor neuron lesions should resolve within 3 mo^[13]. Axonotmesis and neurotmesis lie along a continuum and again are subcategorised by Sunderland. Sunderland grade II is equivalent to axonotmesis with an intact endoneurium, grade III occurs where the endoneurium is compromised but the perineurium remains and grade IV is where only the epineurium remains as demonstrated in Table 1. Sunderland grade V or neurotmesis is associated with a complete transection of the peripheral nerve. Neurotmesis is an indication for surgical exploration to perform: debridement to healthy tissue, tensionless nerve approximation, accurate fascicle alignment and atraumatic mechanical coaptation of the nerve ends^[6]. The simplest nerve repair involves the approximation of the outermost layer of nerve tissue the epineurium. When 90% of the axonal tissue is lost, the remaining tissue heals by regeneration which is highly dependent upon the schwann cell (SC)^[12].

Wallerian degeneration

Wallerian degeneration is a process that results following nerve injury, where the axon separated from the neuron's cell body degenerates distal to the injury. Wallerian degeneration occurs in a proximo-distal direction in the distal nerve stump associated with loss of integrity of the granular structures of the axonal cytoskeleton^[14]. The cytoskeletal changes occurring were described in terms of a "cell body reaction"^[15]. Multiple cellular changes occur within the injured nerve tissue including chromatolytic changes in neuronal cell body, eccentric positioning and change in nerve function to a nerve capable of growth and sprouting^[9]. There is an influx of extracellular ions which cause macrophage influx and eventually apoptosis of the axon^[1]. During the wallerian degeneration process SCs replicate whilst altering their morphology to produce mRNA to produce substances such as p75, nerve

Figure 2 Sunderland classification of nerve injury adapted from Deumens *et al*^[9], 2010.

growth factor and monocyte chemoattractant protein-1^[16]. Reciprocal changes occur within the proximal nerve stump as SCs try to bridge the gap between the two nerve endings. Distal to proximal degeneration occurs within the proximal nerve ending. The degree of nerve tissue loss is dependent on the proximity of the nerve to the cell body in the spinal cord^[1]. It has been shown that the survival rate of motor neurones close to the cell body following spinal nerve avulsion in the context of brachial plexus injuries is 10%-20%^[17]. Lesions distal to the cell body cause axon death to occur up to the nearest node of ranvier in comparison to proximal lesions which may lead to apoptosis of the whole axon.

ADIPOSE DERIVED STEM CELL AND PERIPHERAL NERVE REPAIR

A key part of current peripheral nerve reconstruction involves the harbouring of SCs from autologous nerves. However, this technique is limited by the associated morbidity of sacrificing viable neurological tissue as well as the slow growth of SCs *in vitro*^[18]. Adipose derived stem cells (ADSC) still remain a therapeutic option since they are multipotent and thus have an inherent ability to differentiate into mature adipocytes, chondrocytes, osteoblasts and muscle cells (Figure 3). Similar to the neural stem cell they are able to differentiate into specialised neurospheres under

the action of growth factors^[19-21]. This is combined with the benefit of being “easily obtained, rapidly expanded, showing low immunogenicity and can be differentiated into SCs *in vitro*”^[22], thus making them potentially ideal for future peripheral nerve regenerative processes. The exact mechanism of how ADSCs interact with the regenerating nervous system is not known and theories are discussed in this review.

ADSC characterisation and harvesting

ADSC reside around pericytes structures within the mesodermally derived adipose tissue and are active during the first 50 d of the porcine embryo development and the 2nd trimester in humans^[23]. They are multipotent cells, which are able to differentiate into multiple tissues of mesodermal origin including bone or skeletal muscle endodermal and ectodermal tissues such as neurone like tissue^[20,24]. The ADSC express similar proteins and differentiating capabilities as cord and bone marrow mesenchymal stem cells (BMMSCs)^[25,26]. They are the best characterised multipotent stem cell population^[20] and form the basis of many of the early studies investigating the role of mesenchymal stem cells in nerve regeneration^[27,28]. However, the ADSC have the advantages of minimally invasive harvesting and high cellular yield of between $0.25-0.375 \times 10^6$ cells per millilitre of liquid fat^[29]. Since the early work of Rodbell *et al*^[30] on adipocyte extraction; type I collagenase extraction has been a popular

Table 1 Summary of seddon and sunderland classifications following peripheral nerve injury adapted from^[98]

Sunderland	Seddon	Injury	Neurosensory impairment	Recovery potential
I	Neuropraxia	Intrafascicular oedema, conduction block	Neuritis, paraesthesia	Ful (1-7 d)
		Segmental demyelination	Neuritis, paraesthesia	Full (1-2 mo)
II	Axonotmesis	Axons severed, endoneurial tube intact	Paraesthesia, episodic dysesthesia	Full (2-4 mo)
III		Endoneurial tube torn	Paraesthesia	Slow, Incomplete (12 mo)
IV		Only epineurium intact	Hypoaesthesia, dysaesthesia neuroma	Neuroma

method of adipocyte isolation. Following the discovery of ADSCs by Zuk's team in 2001^[31], multiple techniques of ADSC isolation have been described^[32]. The collagenase ADSC technique of isolation involves the gradual separation of the adipose tissue layers followed by numerous washes with PBS removing the contaminating RBCs, and incubation with type I A collagenase solution^[33]. The infranatant is removed, followed by centrifugation to form the stromal vascular fraction (SVF) pellet. The SVF is acquired which contains the ADSCs which will be used for cell culturing and experimentation. The final processing of the SVF before culture is the repeated washing with PBS to remove the final adherent RBCs and adipocytes. Alternative, more economical methods of ADSC isolation including the use of trypsin and red blood cell lysis buffer solution have been described as an alternative to type I collagenase usage. Despite the relative expense and large number of steps required of the collagenase isolation method, it has remained the most popular method of ADSC isolation and results in up to 5 × more ADSCs available for experimental use^[19,31-33].

The vast majority of studies in the literature for ADSC culture, involve the use of fetal bovine serum (FBS) as a standard ADSC culture condition^[34]. FBS has multiple functions in tissue culture including a source of: growth factors, protein transport, fatty acid lipids as well as protease inhibitors^[35]. Due to the approximately 1000 different

chemicals within FBS, a serum free alternative has been difficult to manufacture with similar cellular efficacy to FBS. Serum free alternatives to FBS are limited in their availability and usefulness in the culturing of these and other types of MSCs^[35]. Xenogenic and serum free growth factor media better comply with the good manufacturing practice (GMP) which is essential for any cell therapies which are to be considered in trials of animals or humans. Xenogenic and serum free alternatives have shown much promise thus far and the treated mesenchymal stem cells (MSCs) retain similar morphology, genetic expression, differentiation and proliferative capacities as those treated with xenogenic serum culture media^[34,36]. Xenogenic serum free alternatives include human serum in the form of allogenic and autologous serum, allogeneic umbilical cord blood serum as well as human platelet derivatives^[35].

Neurological differentiation of the ADSC

Early studies by Woodbury and colleagues provided evidence for the ability of MSCs to transdifferentiate into a neural phenotype^[28]. They used human and rat BMMSCs under the stimulation of 1 mmol/L β-mercaptoethanol (BME). Following stimulation, these cells expressed neuron specific enolase (NSE); they were morphologically transformed so that they developed contracted cell bodies and terminal bulbs appearing similar to mature neurons.

Table 2 Table of various neuron markers their distributions and function adapted from^[99]

Marker	Distribution	Protein function
GFAP	Mature cells of glial origin	Specifically found in astroglial cells
MAP 2	Mature marker of neurones	Thought to be involved in microtubule assembly during neurogenesis
Nestin	Developing nervous system, myogenic, endothelial and hepatic cells	Intermediate filament protein expressed in multiple tissues
NF-70	Most PNS neurones	Structural protein supporting large axons and synapses
NSE	Early neuronal marker	Three variants: α , β , γ with only the γ isoenzyme expressed in neuronal tissue
S100	Cytoplasm of SCs, astrocytes and astrogliosis	Non-specific cell marker involved in multiple cell processes including cell cycle progression and differentiation
Synaptophysin	Brain synaptic vesicles	Directs vesicle associated membrane protein-2 to intracellular compartments
TAU	Axons	β Neuronal microtubule associated protein stabilising microtubules and link to signalling pathways to cytoskeleton
β III-tubulin	Central and peripheral nervous system axons	β tubulins heterodimerize to form microtubules involved in axon guidance

GFAP: Glial fibrillary acid protein; MAP2: Microtubule associated protein-2; NSE: Neuron specific enolase; PNS: Peripheral nervous system; SCs: Schwann cells.

Figure 4 Morphological differences in stimulated vs unstimulated adipose derived stem cell. A: Unstimulated adipose derived stem cells (ADSCs) grown under normal conditions with fibroblast like morphology; B and C: Induced ADSC with a neuronal like phenotype reproduced from Cardozo *et al*^[40] 2012. hASCs: Human adipose-derived stem cells.

Since ADSC share many characteristics with BMMSCs and have easier harvesting, many groups pursued ADSCs for the same reason^[37,38]. Other groups followed on from this early work using a similar neurogenesis protocol to Woodbury, whilst Ashijan *et al* substituted BME for insulin, indomethacin and isobutylmethylxanthine (IBMX)^[37,38]. Despite the modifications of previous work, their differentiated cells lacked the mature markers of neural development and were not tested for their ability to respond following electrophysiological stimulation^[26]. Further concern was raised by other early reviewers Safford's team addressed both of these inherent problems in their modified protocols of Zuk and Woodbury^[39]. They used the combinations of butylated hydroxyanisole/KCL/valproic acid/forskolin/hydrocortisone/insulin. They also successfully demonstrated the expression of mature SC markers such as: glial fibrillary acid protein (GFAP), microtubule associated protein-2 (MAP2), β -III tubulin; the presence of voltage-gated calcium channels and the ability to upregulate the glutamate receptor. A summary of neural markers and tissue they originate from is shown in Table 2.

Following the varying successes of early models to induce MSCs to a neural lineage some authors believe both genetic and immunocytochemical staining are necessary to confirm this transdifferentiation^[26]. Cardozo

et al^[40] recently showed the cell morphological, genetic and immunocytochemical changes associated with the previous methods of chemical differentiation of ADSCs. A comparison between differentiated and undifferentiated ADSCs over a 14 d period was performed by real time polymerase chain reaction (RT-PCR) showed a reduction in the levels of GFAP and nestin in the differentiated cells whilst there was an increase in β -III-tubulin, NSE, TAU, MAP2 synaptophysin^[40]. Figure 4 shows the classic morphological changes seen in ADSCs undergoing chemical differentiation under the action of BME.

Alternative methods of inducing chemical differentiation to a neural lineage involves the addition of growth factors such as platelet derived growth factor (PDGF), basic fibroblast growth factor (bFGF) along with BME to ADSCs which again results in the changes in cellular morphology and expression of SC markers such as S100, GFAP, p75 and β -III tubulin^[41,42]. Using these protocols the differentiated ADSCs promoted significantly greater neurite outgrowth from the NG108-15 motor neurones than uncultured ADSCs suggesting a local stimulatory effect between the stem cell and the neuron. Further modifications of techniques have shown the potential of IBMX alone to differentiate ADSC into cells expressing ectodermal markers such as neurofilament 70 and cyclic nucleotide phosphodiesterase

Figure 5 Appearance of neurospheres (A) Phase contrast image of free floating neurospheres; B: Fluorescence staining of nestin (Green) and nuclear stain (Blue) of neurosphere adapted from Radtke *et al.*^[43], 2009.

Table 3 Comparison the different methods of chemical differentiation of adipose derived stem cells

Nerve differentiation chemicals	Histochemical markers positive	Ref.
B27/bFGF/EGF	MAP2, β -III tubulin, S-100, GFAP, Nestin,	[19,21,42-45,47]
IBMX/dexamethasone/insulin/indomethacin	S100, GFAP	[94]
β -mercaptoethanol/butylated hydroxyanisole/retinoic acid/EGF/bFGF	GFAP, Nestin, β -III tubulin, NSE, TAU, MAP2 and Synaptophysin	[40]
β -mercaptoethanol/retinoic acid/PDGF/bFGF/forskolin/GGF-2	GFAP, S100	[41,58,59,95]

GFAP: Glial fibrillary acid protein; MAP2: Microtubule associated protein-2; bFGF: Basic fibroblast growth factor; NSE: Neuron specific enolase; EGF: Epidermal growth factor; IBMX: Isobutylmethylxanthine; PDGF: Platelet derived growth factor; GGF-2 glial growth factor-2.

(CNPase); which are associated with oligodendrocytes from the CNS as well as SCs.

Alternatively, similar immunocytochemical markers are seen when ADSCs are cultured exclusively with bFGF and epidermal growth factor (EGF) to form neurospheres. Figure 5 demonstrates the morphological appearances of neurospheres staining positive for nestin as well as the non-specific nuclear stains. Neurospheres were originally found to develop from neural stem cells. However, these confluent groups of differentiated cells can be obtained from ADSCs and express the SC markers such as S100, P75 and GFAP^[43]. A recent study compared the differentiation protocols of BME *vs* bFGF and EGF together^[28,44,45]. The neurospheres produced from the latter protocol had higher cell viability and improved expression of neural markers when tested at weeks 1 and 3^[45]. The higher cell viability of ADSCs in the absence of BME suggests an increased toxicity in the cells exposed to BME. This observation has been suggested in the literature previously using BMSCs^[27] and similar findings are reported by authors using dimethyl sulfoxide (DMSO) as the principle differentiation chemical^[46]. Razavi *et al.*^[47] 2013 demonstrated greater neuron generation relative to glial cells when ADSCs were co-cultured with neurotrophic factor secreting ADSCs compared to control neurogenic and conditioned media. They showed the expression of MAP2 to be two times greater than GFAP in the control group. Neurotrophic ADSC containing media contained much higher levels of both brain derived neurotrophic factor (BDNF) and nerve growth factor (NGF)^[48].

Neuronal markers of differentiation

As shown in Table 3, there are a variety of markers which are expressed during the various neurological differentiation

protocols of ADSCs within the literature. The molecular code model of ADSC differentiation has been mentioned elsewhere in the literature thus far^[40]. In this model each marker is representative of neural tissues at different stages of neural differentiation and maturity. Each different neurological differentiation protocol results in the expression of a range of different cell surface proteins or markers. The markers expressed are dependent on various factors including cell passage, culturing media, as well as the differing types of induction media^[49]. When the process of neurogenesis is compared *in vitro* ADSC differentiation model, the gradual changes in cell surface markers have been documented previous studies depending on the maturity of the tissue and are found to be time dependent^[40,50].

THERAPEUTIC STRATEGIES AND EXPERIMENTAL MODELS FOR PNI REPAIR USING NERVE CONDUITS AND ADSCS

As discussed earlier, multiple *in vitro* studies have shown the transformation in the morphology of ADSCs under a range of stimuli to form tissues similar to neural tissue. Multiple animal studies have been described using ADSC to treat a range of canine and murine specific neurological conditions^[51,52]. To bridge the gap in the damaged peripheral nerves some authors used conduits combined with ADSCs whilst others used ADSC therapy with nerve allografts. Since axons only grow a short distance beyond their own reparative matrix and an intact endoneurium is associated with better outcomes, there has been a strong research focus on bridging the gap *via* conduits as well as

reconstruction of the extracellular matrix^[1,53].

Nerve conduits

Nerve conduits are used in peripheral nerve gaps of up to 3 cm in length^[54]. Natural conduits include the autogenous vein nerve conduits (AVNCs), allografts and autogenous nerve harvesting^[14]. A variety of synthetic conduits are also available for nerve repair, including Polyglycolic Acid (PGA), Poly-carprolactone (PCL), Collagen, Polyvinyl alcohol which have passed FDA testing and thus permitted for use in humans^[55].

The rat sciatic nerve model remains a classic clinical model for investigating the effects of cells on peripheral nerve regeneration. PCL conduits have been tested over a 6mm gap model to compare the nerve regenerative effects of autografts as well as PCL conduits containing ADSCs with and without nerve guides and a negative control of an unrepaired nerve^[56]. At 3 wk the cells containing the guides and ADSCs were associated with a significant improvement in the sciatic nerve index (SNI) compared to other groups ($P = 0.010$). However, this effect only lasted for 5-6 wk before the sciatic nerve function became similar to the other groups. The re-harvested sciatic nerves which were observed after cellular implantation of ADSCs were also thicker than those with the conduit alone. This suggests a possible interaction between the implanted ADSC and the conduit material, thus aiding the regeneration of the peripheral nerve. Similar results were found by other authors who used sciatic nerve defects of 13 mm^[57]. In their study there were several experimental groups, which included rats receiving allografts from similar breeds as a positive control. The other experimental groups included rats receiving silastic conduits containing either differentiated or undifferentiated ADSCs; these both of these groups also either had or didn't have exchange of ADSC media on days 14 and 28. The groups of rats, which received allografts as well as those receiving the silastic conduit containing differentiated ADSCs and media exchange, had the highest Sciatic Functional Index (SFI) when measured at 3 and 4 mo. In this paper the authors also reviewed another motor function and found that the extensor postural thrust was highest in the allograft group as well as the differentiation and undifferentiated ADSCs within silastic conduits with media exchange. The findings from this study suggest a role for ADSC in peripheral nerve recovery and also stress the importance of maintaining the stem cell *via* supplementation with fresh nutrients. Despite the multifaceted improvements in motor function, the presence of ADSCs leads to a slower improvement than compared to sensory function. Similar to a previously mentioned^[56] study, the ADSCs did not differentiate into SCs within the injury model.

When fibrin conduits have been used for 10 mm rat sciatic nerve models; it was associated with decreased growth associated protein (GAP-43) expression in the dorsal root ganglion relative to the spinal cord and could account for the difference in sensory and motor nerve

regeneration seen in previous studies^[58]. These findings may suggest ADSCs are better at regenerating motor neurones specifically^[56]. Fibrin conduits have also been used in rat 10 mm sciatic nerve model and compared to SCs alone, ADSCs and BMMSCs^[42] (Figure 6). SCs were able to regenerate over significantly greater distances than ADSCs and BMMSCs. However, there was no statistical significant difference between the ADSC and BMMSC. Poly-3-hydroxybutyrate conduits have also been used within a fibrin matrix conjugated with PDGF, bFGF and glial growth factor-2 for 10 mm sciatic nerve gap models^[59]. The variables in this study included ADSCs with and without growth factors. Axonal regeneration was significantly improved in all of the models which contained ADSCs with P values < 0.05 . The addition of these growth factors didn't result in a significant improvement in nerve regeneration. In this study ADSCs survived for a short period, which may be explained by immune consumption or an inability to form a niche in the requisite environment^[18].

Alternatively, microporous conduits over a 15 mm nerve gap have been used to compare the effects of ADSCs, ADSCs co-cultured with SCs, SCs alone or dental pulp stem cell co-cultured with SCs^[60]. ADSC and SC co-culture was associated with better motor recovery and nerve conduction velocity. ADSC and SC co-culture resulted in 50% increase of NGF release which is thought to be an important factor in SC development^[61]. Table 4 provides a summary of the animal studies using ADSCs in peripheral nerve recovery.

Cell based therapy and xenogeneic acellular nerve matrices

Adipose cell transplantation without the use of a conduit is an option for reconstructing peripheral nerves. The cells may be administered systemically *via* intravenous, subcuticular or intramuscular routes as used for traditional drug therapy. When ADSCs have been introduced intravenously, they spread throughout the body and locate to damage tissue. In the context of traumatic brain injury, these cells spread *via* the reticuloendothelial system directly into the diseased brain tissue^[62]. In this study, the observed benefits of human ADSC injection were largely dependent on the recipient rat's age. In the older rats, fewer cells transited through the spleen. This subsequently led to differences in cell distribution within injured parts of the rat's brains. In other studies when ADSCs were administered *via* the intravenous route they were also shown to improve neuropathic pain in rats which had the ill effects of chronic pain simulated^[63].

In other studies when ADSCs were administered *via* the subcutaneous route, the cells were found to stay within the area of infiltration and did not translocate to distal sites such as the spleen or brain^[64]. For up to 1 year the transplanted cells were found to slowly migrate from the upper to lower subcutaneous adipose layers. Many of the cells were found to differentiate into adipocytes following injection. Therefore, this route of administration is unlikely to be the adequate to allow a sufficient yield of stem cells to engraft within the

Table 4 Animal studies modelling adipose derived stem cells and conduits for peripheral regeneration

Animal models	Details	Measured outcomes	Ref.
Rat	Polycaprolactone conduit for 6 mm nerve gap	SNI, nerve thickness	[56]
Rat	Fibrin conduit 10 mm nerve gap	Axon regeneration	[42]
Rat	Polyhydroxybutyrate conduit 10 mm nerve gap	Axon regeneration	[59]
Mouse	Nerve crush model and local administration ADSC ± matrigel	Axon regeneration	[48]
Rat	Decellularised vascular conduit v autogenous nerve and vascular conduits containing ADSC	Axon regeneration, nerve conduction velocity	[90]
Rat	Silastic conduit for 13 mm nerve gap	SNI, EPT, sensory nerve function	[57]
Rat	Silicon conduit ± collagen or ADSCs	Axon regeneration, nerve conduction velocity	[100]
Rat	Nerve crush model with systemic injection of ADSC	Axon regeneration, motor recovery	[68]
Rat	Genipin-Gelatin-Tricalcium phosphate conduit 10 mm nerve gap	SNI	[92]
Rat	ADSC injected into repaired chronic denervated nerve	Axon regeneration, PFI	[89]
Rat	Microporous conduit for 15 mm nerve gap	Motor recovery	[60]
Rat	Fibrin conduit for 10 mm nerve gap	Motor recovery, GAP-43 expression in dorsal root ganglion	[58]
Dog	Polytetrafluoroethylene tube and alginate hydrogel 17 mm nerve gap	Axon regeneration	[51]

injured neural tissue.

Conduits are currently not used in humans for nerve gaps greater than 3 cm nor are they used on large nerves^[65]. Combinations of bridging acellular nerve matrices and rate ADSCs have been used in 15 mm sciatic nerve gaps in rats^[66]. Similar to conduits studies motor response and nerve conduction velocities are regularly measured. The implanted ADSCs and nerve graft were associated with improved walking track analysis, nerve conduction and increased number of myelinated fibres within the grafted tissue. When human ADSCs were injected into an acellular nerve graft as therapeutic cells, similar improvements in rat motor peripheral nerve function were obtained^[67].

In a sciatic crush nerve model, infiltration of ADSCs was associated with significant improvements in SFI score and axonal regeneration which was marked by increased GAP-43 expression in the recovering nerves^[68]. The allogenic ADSCs also reduced the immune response to the nerve injury and were able to migrate through the reticuloendothelial system to home to the zone of injury. Using ADSC therapy the authors were able to maintain the levels of glial cell line derived neurotrophic factor (GDNF) which has been proven to be important in increasing the number of myelinated axons in previous sciatic nerve injury models^[69]. The effects of transforming growth

factor beta-1 (TGFβ-1) on the survival of ADSCs injected into xenogeneic acellular nerve matrices (XANM) has been reviewed in multiple animals^[52]. In a 50 mm nerve defect, the combination of XANM-ADSC-TGFβ-1 led to significantly greater areas of axonal regeneration compared to XANM-ADSC or XANM- TGFβ-1; but the level was similar to that seen when an autograft was implanted. Significantly greater proportions of cells from the XANM-ADSC-TGFβ-1 compared to the XANM-ADSC survived over a 28 d time period (0.46 ± 0.16) *vs* (0.2 ± 0.13). TGFβ-1 lead to increased expression of genes for collagen I, collagen III and Laminin which are key structures in developing neurones^[2,70]. TGFβ-1 also led to a 7x increase in the release of vascular endothelial growth factor (VEGF) which was thought to be neuroprotective. When the ranges of growth factors secreted by ADSCs was tested, IGF-1 was found to be the most important in the prevention of caspase 3 and akt mediated apoptosis in rat cerebellar granule neurone^[71]. The theoretical interactions between ADSCs and the regenerating nerves are shown in Figure 7.

Electrical stimulation techniques

Electrical stimulation has been shown experimentally to improve neurite outgrowth particularly towards the negatively charged cathode electrode and axonal

Figure 7 Potential interaction of adipose derived stem cells and the effects on peripheral nerve regeneration. ADSCs: Adipose derived stem cells.

regeneration^[72,73]. Electrical stimulation of ADSCs has been used in a number of studies for various potential clinical applications^[74-78]. BMMSC have been shown to respond in different ways to various form of electrical stimulation including capacitive coupling (CC), pulsed electromagnetic field, degenerate wave (DW) as well as the direct current (DC)^[79]. When these transformed cells were tested in assays those which had CC and DW stimulation showed greater invasive propensity to invade a collagen type I matrix *vs* DC treated cells which showed the greatest galvanotaxis effects. These differences in the behaviour of these cells could be used in an engineered approach for regenerating nerves. Adipose stem cells have also been shown to have improved galvanotaxis following DC stimulation were they preferentially migrate to the cathode electrode; assemble perpendicular to the applied electric field, disassemble gap junctions and modify the expression of multiple genes^[74,75]. The ability of adipose stem cells to respond to electrical stimulus is explained by findings of multiple ion channels found within this heterogeneous group of cells^[80]. The galvanotaxis effect has been found to be dose dependent and involves a number of cellular pathways including is mediated through MAPK, PI3K and its downstream target Akt as well as ROCK pathway and transient increases of intracellular calcium^[74]. More recently electrical stimulation of mesenchymal stem cells (MSC) has been combined with surfaces which have high conductivity to improve the cues for necessary to obtain neural differentiation^[81]. A range of different conductivities of Polyaniline (PANI) was combined with standardised electrical stimulation of MSCs. The higher conducting polymers of PANI were associated with greater expression of neural phenotypes Nestin and β -III-tubulin confirmed by RTPCR and

immunocytochemistry. These cells also underwent morphological changes to appear as neuron like cells although their functionality was not confirmed. On the surface of highest conductivity the cellular processes extended further than those surfaces which were less conductive.

DISCUSSION

ADSC based therapy remains an area of strong scientific research; they have been shown to improve the neurological recovery in murine nervous system ischaemic models^[71,82]. ADSCs can differentiate into a range of supporting structures such as Schwann like cells which carry many of the markers of mature PNS cells using chemical or neurosphere differentiation^[37,38,83]. These cells also have a morphological phenotype similar to mature SCs. Scepticism exists within the literature as to the functionality and safety of these differentiated cells with many believing the *in vitro* morphological and cytological changes to be secondary to the toxicity of the chemical differentiating protocols^[27]. The regeneration of diseased tissue occurs through the 3 processes of cell engraftment and differentiation, release of neurotrophic factors and immunosuppression^[84]. The cell engraftment is necessary for the ADSCs to form a cell niche, whilst differentiation is required for these cells to transdifferentiate from mesodermal to ectodermal lineages. Cell engraftment occurs following administration of these cells into a host environment. The ADSCs release a range of neurotrophic factors such as EGF, TGF β -1, VEGF, bFGF, HGF, IGF-I, and BDNF secreted at different phases of tissue regeneration which is also thought to aid the healing of the damaged peripheral nerve^[48,84-86]. In particular TGF β -1/3

Figure 8 Interactions of topography, biochemical and electrical cues in engineering nerve tissues taken from^[72].

are found in high concentrations amongst undifferentiated ADSC may have future immunomodulatory roles which are greater than that of BMMSC^[87,88]. The combination of greater immunomodulatory effects and easier harvesting further justifies the greater emphasis of ADSC as opposed to BMMSCs. The question of whether ADSC can regenerate PNS neurons remains contentious. In smaller murine sciatic nerve models, ADSC neurotrophism has been shown to benefit both motor and sensory functions^[57,60]. The sensory recovery appears to be faster than that of motor recovery^[57]. The reason for this is currently unknown. Despite the numerous improvements in motor and sensory indices discussed in multiple studies following ADSC placement; there is yet to be a unified opinion regarding the precise mechanism of ADSC engraftment and differentiation at the nerve injury site^[56,57,89,90]. This uncertainty is confounded by a lack of convincing evidence of ADSC transformation to neural tissue at the repair site^[56,57]. It could be the improvements in the neurological recovery of injured animals was secondary to ADSCs providing a surge of growth factors which stimulate the remaining SCs still active within the nerve^[60]. The authors believe the improvements in the multiple facets of neuron recovery in murine models may be related to their ability to stimulate the remaining surviving SCs through angiogenesis and the release of the numerous growth factors mentioned previously^[52,91]. This would therefore suggest that ADSCs were partially able to regenerate a damaged neuron by stimulating the remaining functional cells within the neuron.

The murine model for nerve defects ranging from 1-2 cm in size remains the standard model for investigating ADSCs and nerve regeneration^[42,57-60,92]. Studies have since been scaled up to a canine model to observe ADSC roles in larger animals more comparable to human sized defects^[51,52]. Similar results were found to murine models where the ADSCs regenerated nerves to higher functionality in terms of faster nerve conduction velocities than those without ADSC application. Future research should be translated to larger animals in the longer term since multiple murine models have been trialled with variable successes. ADSCs may be placed *in vivo* in pre-differentiated or in undifferentiated states. Studies have shown the cells have neurotrophic effects in both states; however differentiated cells retain their regenerative capacity for longer^[57]. Future challenges will involve the supplementation of ADSCs to enable them to maintain their regenerative properties for the time required *in vivo*.

Conduits remain an option for nerve reconstruction but are limited to defects less than 3 cm in size^[93]. The conduits which have been used are a combination of natural and synthetic materials produced by a range of manufacturing processes. As discussed by Marquadt and Sakiyama Elber 2013 the ideal conduit would contain a combination of biochemical, topographical and electric cues to help determine the fate of the regenerative cells within the construct^[72] (Figure 8). The combination of all 3 of these factors would possibly yield an improvement on the results seen with the current conduit engineering techniques. Concern exists with the stability of cells

treated with high concentrations of glial growth factors. There are many studies in the literature where ADSCs are given large doses of glial growth factors and are forced to become either neurone or schwann like cells^[40-42,58,59,94,95]. The long term stability of these cells is largely unknown which may limit their clinical translatability into a peripheral nerve lesion human model. Alternative and potentially safer techniques using combinations of electrical stimulation and highly conductive topographical materials with MSCs have been used to obtain neural lineage absence of augmenting glial growth factors^[81]. This growth factor negative technique of producing neural like cells may be useful and a safer option whilst becoming a platform regenerative medical technology using ADSC for peripheral nerve regeneration. These transformed cells could be co-cultured with SCs taken at the time of surgery and these schwann cells used to maintain the neural phenotype of these cells over a long time period.

Cell therapy with Xenogenic Acellular Nerve Matrices (XANMs) is a viable option where the natural extracellular matrix of the PNS is replaced. When injected systemically ADSCs had a homing response to the injured neurological tissues and passed through multiple cell systems to get to their target organs^[68]. Porcine ANM have been used in rat models and were found to be well tolerated by the rat immune system despite the infiltration and interactions with host cell fibroblasts^[70]. Therefore, it appears that if ANM are sufficiently decellularised and/or immunosuppressant therapy is used ADSC and XANM may be a therapeutic alternative to autografts alone. ANM may be suitable for long nerve gaps where a like for like tissue is required. This could potentially be supplemented with ADSC which could help regenerate the nerve as well as provide immunosuppressive cues to limit the amount of immunosuppressant required to prevent rejection of the xenogenic material.

CONCLUSION

Peripheral nerve injury recovery remains a problem despite advances in the surgical and medical management of this debilitating illness. There are multiple studies using ADSCs in a variety of animal models to aid the recovery. At present the role of the ADSC in PN injury is still being investigated and the optimum timings and methods of insertion of ADSC has yet to be determined. For translation into humans; ADSC therapy will need to build upon the knowledge already acquired from *in vitro* and *in vivo* small animal studies. The preliminary results so far suggest a future role in peripheral nerve regeneration, but future research is need towards further optimisation and safety. The literature is saturated with the use of growth factors and other inducing chemicals such as BME and future studies should use less toxic methods of differentiating the stem cells. Electrical stimulus could provide a useful alternative method of reducing the number and concentrations of growth factors required to obtaining a neural lineage from the ADSCs.

The authors also feel greater focus should be given to surface modifications of nanomaterials to aid stem cell differentiation. Modifications of surface chemistry and nanotopography can be further adapted to support the expression of neural proteins within ADSCs. Material surface modifications along with electrical stimulation and essential glial growth factors could provide the stimulus required to obtain the neural lineages shown in previous studies, whilst reducing the risks of long term malignant transformation. The transplanted cells also need to be observed into larger animals than murine, as well as monitored for longer periods of time. This long term active surveillance would help to determine the malignant transformation potential of the ADSCs exposed to supraphysiologic levels of growth factors.

including analgesia and physiotherapy often fails and surgical treatment, such as spinal fusion, is required. Stem cells offer an exciting possible regenerative approach to IVD disease. Preclinical research has demonstrated promising biochemical, histological and radiological results in restoring degenerate IVDs. Cell tracking provides an opportunity to develop an in-depth understanding of stem cell survival, differentiation and migration, enabling optimization of stem cell treatment. Magnetic Resonance Imaging (MRI) is a non-invasive, non-ionizing imaging modality with high spatial resolution, ideally suited for stem cell tracking. Furthermore, novel MRI sequences have the potential to quantitatively assess IVD disease, providing an improved method to review response to biological treatment. Superparamagnetic iron oxide nanoparticles have been extensively researched for the purpose of cell tracking. These particles are biocompatible, non-toxic and act as excellent MRI contrast agents. This review will explore recent advances and issues in stem cell tracking and molecular imaging in relation to the IVD.

Key words: Intervertebral disc; Stem cells; Cell tracking; Magnetic resonance imaging; Intervertebral disc degeneration

Core tip: Mesenchymal stem cell (MSC) transplantation shows exciting promise for the future regenerative approach to intervertebral disc (IVD) disease. Extensive preclinical research has demonstrated benefits from MSC treatment in disc degeneration. Cell tracking, with iron oxide nanoparticles and MRI, provides an opportunity to develop an in-depth understanding of stem cell survival, differentiation and migration, enabling optimization of stem cell treatment. This review summarizes the current literature relating to MSC tracking in the IVD, which is limited to short term monitoring. Medium to long-term cell tracking is required to accelerate translation of MSC treatment in the IVD to clinical practice.

Abstract

Low back pain is a common clinical problem, which leads to significant social, economic and public health costs. Intervertebral disc (IVD) degeneration is accepted as a common cause of low back pain. Initially, this is characterized by a loss of proteoglycans from the nucleus pulposus resulting in loss of tissue hydration and hydrostatic pressure. Conservative management,

Mesenchymal stem cell tracking in the intervertebral disc. *World J Stem Cells* 2015; 7(1): 65-74 Available from: URL: <http://www.wjgnet.com/1948-0210/full/v7/i1/65.htm> DOI: <http://dx.doi.org/10.4252/wjsc.v7.i1.65>

INTRODUCTION

Low back pain is the leading cause of disability in the developed world^[1]. Lifetime prevalence is 75%-80%^[2], with the annual cost in the United States alone estimated to be as high as \$500 billion^[3]. Low back pain is strongly linked to disc degeneration, with a two-fold increase in chronic lower back pain in patients with radiological evidence of degeneration^[4,5].

Current treatments, including analgesia, physiotherapy and spinal fusion only address symptoms, not the underlying disease. Regenerative strategies, such as stem cell therapy, provide an exciting future in the treatment of intervertebral disc (IVD) disease. Tracking and long term monitoring of these cells is essential to develop an understanding of their survival, migration, proliferation and differentiation *in vivo*, which will enable optimization of this promising therapy. Magnetic resonance imaging (MRI) combined with contrast agents is the modality of choice for cell tracking. This review will summarize recent advances in stem cell tracking, current problems and their application to the treatment of IVD disease.

PATHOLOGY OF BACK PAIN

The intervertebral disc is composed of 3 main regions: the tough annulus fibrosis (AF), peripherally, the amorphous nucleus pulposus (NP), centrally, and cartilaginous endplates which bind the disc to the adjacent superior and inferior vertebral bodies^[6]. With ageing and degeneration, significant cellular and matrix changes occur within the IVD. An early hallmark of disc degeneration is the loss of proteoglycans (PG), and associated water molecules, from the NP and AF, accompanied by structural changes to the lamellae of the AF^[7-11]. With the loss of the water binding PGs from the disc, its functional capacity as a hydroelastic cushion is diminished, leading to additional mechanical stresses acting on the fibrocartilaginous AF. With time, these events can result in the presence of concentric and radiating tears in the lamellae of the AF that may eventually extend into the NP^[7,8,11-13]. In addition, there is emerging evidence that damage to the cartilaginous endplate plays a role in the pathophysiology of degenerative disc disease, up-regulating matrix degrading enzymes and inflammatory cytokines in the NP^[14]. Structural deficiencies in the NP are considered to provoke neovascularisation and growth of nerve fibers, normally confined to the periphery of the AF, to the deeper regions of the disc^[13,15]. The establishment of these extended nerve fibers has been cited as a major cause of chronic lower back pain in degenerate discs^[15-17].

CURRENT TREATMENT OF BACK PAIN

Current strategies to treat low back pain fail to regenerate

the intervertebral disc or even reverse the degenerative process. Analgesics, non-steroidal anti-inflammatory drugs, physical therapies and other multimodal palliative modalities represent the mainstay of conservative therapy for low back pain^[18-20]. There is no evidence, however, that any of these therapies provide long-term benefit by improving the underlying pathobiology of disc degeneration. In fact, recent research has demonstrated simple analgesia does not improve recovery time from acute low back pain^[21]. When non-operative treatments fail, surgical interventions such as spinal fusion or total disc arthroplasty are commonly undertaken. These interventions aim to remove the pain generator, however, many patients remain with chronic pain and disability. Furthermore, spinal fusion has biomechanical consequences, which accelerates degeneration at adjacent levels^[22-24].

REGENERATIVE STRATEGIES FOR THE INTERVERTEBRAL DISC

Recent research suggests novel biological therapies can provide restorative treatment of disc degeneration. Cell types investigated include NP cells^[25-29], chondrocytes^[30-33] and mesenchymal stem cells (MSC)^[29,30,34-43]. MSCs, initially isolated from bone marrow, can also be derived from a range of tissues, including adipose and synovial^[44,45]. In addition, MSCs are reported to be non-immunogenic and, in contrast to embryonic stem cells, cannot undergo malignant transformation^[46,47]. Moreover, MSCs have the capacity for self-renewal, enabling maintenance of an undifferentiated phenotype in multiple subcultures^[48]. However, in the appropriate environment, MSCs are capable of differentiating into multiple cell types including chondrocytes, osteocytes, tenocytes and adipose cells^[44,45].

There are numerous preclinical studies investigating the use of MSCs in rat, rabbit, goat and porcine models^[29,30,34-43]. MSC implantation in the rabbit model has resulted in an increase in PG content, partial restoration of disc height and disc hydration^[42,43]. In the ovine model, intra-discal MSCs treatment has been shown to restore disc extracellular matrix, increase disc height and reduce radiological and histological grading scores 6 mo following injection^[49,50]. How stem cells produce these effects remains unclear from current preclinical studies.

Early clinical research has been promising. Yoshikawa *et al*^[51] reported two cases of autologous MSC implantation in markedly degenerate intervertebral discs. Symptomatic and radiological improvement was demonstrated without significant adverse effects^[51]. A larger series of 10 patients treated with autologous MSCs demonstrated improvement in pain, disability and disc hydration^[52]. Prior to translation to clinical practice, greater understanding of the mechanism of action of these cells is required.

NEED FOR CELL TRACKING

Longitudinal tracking of MSCs is necessary to ensure survival, evaluate distribution and assess if cells migrate to affected pathological sites in the IVD. Previous methods,

Figure 1 9.4 Tesla magnetic resonance imaging-Gradient Echo 2* weighted image of ovine lumbar intervertebral disc (normal control). Image obtained from our group 2014/02/18, not previously published.

based on histological analysis provide a snapshot view of the cells at a set time point. This is useful at the end of a scientific study but these methods cannot be translated to the clinical setting. Cellular labeling provides a non-invasive technique to assess the cells *in vivo* at any given time point. Thus, it can assess cell viability, track cell migration patterns and provide some information on efficacy. It may provide an understanding on mechanism of action, for example, potentially being able to determine whether cells differentiate into chondrocytic cells or act to modulate the resident native cell population through paracrine actions. In addition, cell tracking is required to ensure MSCs retention, as leakage of transplanted cells outside the disc has been reported to induce osteophyte formation^[53].

CURRENT IMAGING TECHNIQUES

In vivo, non-invasive techniques are required for cell tracking in the research and clinical setting. Multiple imaging modalities have been utilized, including MRI^[54-58], positron emission tomography (PET)^[59-62], single photon emission computed tomography^[63], bioluminescence imaging^[64,65], fluorescence imaging^[66-72] and computed tomography (CT)^[73]. MRI has been accepted as the best modality given its high spatial resolution (< 100 microns), prolonged effective imaging window, lack of ionizing radiation and ability to provide detailed anatomical information^[74,75]. There are now very high resolution MRI machines available such as 9.4 Tesla which provides high quality images (Figure 1).

CELL LABELING FOR MRI

The ideal contrast agent would be highly sensitive, biocompatible, non-toxic, easily taken up by the targeted cells and provide clear contrast between the labeled cells and surrounding tissue. Due to their superior sensitivity and excellent biocompatibility, iron oxide nanoparticles are the preferred contrast agent for cell labeling^[76]. Superparamagnetic iron oxide nanoparticles (SPIONs) consist of an iron oxide core, usually magnetite (Fe_3O_4) or

maghemite ($\gamma\text{Fe}_2\text{O}_3$) and a biocompatible coating. Coating substrates include dextran, carboxydextran, polyethylene glycol (PEG), polystyrene and silica^[77]. Iron oxide nanoparticles can be subdivided into standard SPION, 60 to 150 nm in size, and ultrasmall superparamagnetic iron oxide nanoparticles (USPION) which measure 10 to 20 nm^[78,79]. The type of coating, size and method of synthesis affect the SPIONs biocompatibility and magnetic properties^[80].

MRI generates images by utilizing the differences in proton density and the local magnetic environment of hydrogen atoms^[75]. There are two MR relaxation time constants, T1 and T2. Commonly used contrast agents, paramagnetic gadolinium analogues, alter longitudinal (T1) relaxation time of hydrogen protons and appear hyperintense. The abovementioned, superparamagnetic nanoparticles, affect the transverse (T2) relaxation time of hydrogen protons and appear hypointense. Due to their size, USPION demonstrate additional T1 effects^[75]. Iron oxide nanoparticles can be detected at micromolar concentrations and offer sufficient sensitivity to be identified on T2* weighted imaging^[81].

MR cell labeling requires the transfer of particles from extracellular to intracellular. The simplest method is spontaneous uptake of particles by phagocytic cells such as macrophages. While enhanced with an appropriate biocompatible coating, iron oxide nanoparticles are not efficiently taken up by stem cells^[82,83]. However, labeling can be facilitated by incubation with cationic transfection agents, including poly-L-lysine and protamine sulfate^[82,84-86]. If extended incubation time is not appropriate, other rapid techniques, magnetoelectroporation or magnetosonoporation, can be employed^[87,88].

A number of contrast agents have been approved for clinical use in medical imaging. Previously, the most commonly used iron oxide nanoparticle for cell labeling was Feridex[®], which contains an iron oxide core and dextran coating^[77]. Dextran coated SPIONs have been shown to be biocompatible and biodegradable *via* iron metabolism through Kupffer cells, located in the liver^[89]. Another widely used SPION, Resovist[®], has a carboxydextran coating^[90,91]. Both these products have been discontinued from production by the pharmaceutical companies^[77,92]. Other commercial products continue to be utilized, such as SiMAG[®], an SPIO with an unmodified silica surface. For example, Markides *et al*^[93] labeled MSCs with SiMAG[®] in a rheumatoid arthritis mouse model.

Extensive research has been devoted to designing novel iron oxide nanoparticles for the purpose of stem cell labeling^[92]. van Buul *et al*^[94] demonstrated ferumoxides (Endorem[®]) complexed with protamine sulfate are superior to ferucarbotran particles for cell labeling. Subsequently, this group demonstrated safety and efficacy of the ferumoxide-protamine sulfate complex for MSC labeling in articular cartilage repair^[95]. USPION have also been investigated recently. Coated with dextran and PEG and combined with protamine sulfate, USPIONs have been cultured with human Adipose Derived Stem Cells (hADSCs) within a three dimensional scaffold^[96]. *In vitro*, no effect on cell viability or osteogenic differentiation was seen from cell

labeling. The USPIOs were effectively internalized by the hADSC and demonstrated T2* signal change. Hypointense regions, representing labeled cells, were seen *in vivo* 28 d following implantation^[96]. Further research is required to optimize SPIONs for cell tracking.

ISSUES WITH CELL LABELING

Transfection agents are potentially toxic and, furthermore, there is capacity for iron oxide nanoparticles *in vivo* to cause toxicity to other organs, including liver and spleen^[97,98]. Small polyhedral SPIONs with a silica coating have shown efficient MSC labeling without the need for a transfection agent and may offer a solution^[99].

T2 signal change is due to the overall effect of magnetic nanoparticles rather than total number of cells^[100]. Typically, a few hundred cells are required for detection with conventional MRI sequences^[77]. Stem cells are known to proliferate following transplantation, leading to dilution of the iron oxide label and loss of MR signal over time^[77]. If cells divide asymmetrically, with one daughter cell receiving the majority of nanoparticles, rapid dilution of signal can occur to an undetectable level^[101]. Labeled cells could also become undetectable if they migrate in small rather than large groups. Sensitivity may be improved with post acquisition software analysis or a higher magnetic field strength.

A number of endogenous substances produce negative (or hypointense) MR signal, such as blood products containing haemosiderin or methaemoglobin. This leads to challenges differentiating blood product from labeled cells in an injured IVD. Novel MRI methodology has been adopted to help differentiate the labeled cells from endogenous substances, such as Inversion-Recovery With ON-Resonant Water Suppression, which delineates SPION labeled cells as positive contrast^[102]. Further novel sequences are being developed to provide an exciting possibility to enhance non-invasive cell tracking.

Iron oxide nanoparticles fail to differentiate between live and dead cells. SPION signal has been demonstrated in the CNS long after cell death^[103]. Multimodal imaging may be required to ensure cellular function, such as combining MRI with PET imaging. A study investigating iron oxide labeled stem cells in hemi-Parkinsonian rats used this multi modal technique. MRI visualized stem cells in the striatum and PET confirmed cellular viability^[104].

CELL LABELING IN THE INTERVERTEBRAL DISC

To date, there is limited published research tracking MSCs in the IVD and this is summarized in Table 1. Saldanha *et al.*^[105] demonstrated feasibility by imaging MSCs labeled with SPION (Feridex®) *in vitro* to quantitatively characterize signal intensity loss using T1, T2 and T2* relaxation parameters. T2* weighted gradient echo (GRE) images demonstrated the most significant loss of signal intensity from labeled cells. Conversely, SPION labeled cells were indistinguishable

from unlabeled cells on T1 weighted imaging^[105]. This group also demonstrated SPION labeled cells, loaded in a fibrin gel and injected *via* fluoroscopic guidance, could be identified *ex vivo* within the IVD of excised rat tails^[105]. Further research by Prologo *et al.*^[62] imaged MSCs labeled with a radioactive marker (iodine-124 2'fluoro-2'-deoxy-1β-D-arabinofuranosyl-5-iodouracil) using CT and PET. Four female pigs had approximately 100000 labeled MSCs injected under fluoroscopic guidance to the NP of discs which had degeneration induced 10 d prior. CT and PET were performed immediately following and three days after cell delivery. One animal was inaccurately injected. Results from the other three demonstrated accurate delivery and maintenance of labeled cells at three days^[62]. While demonstrating useful preclinical results, using radioactive cell labeling in conjunction with CT and PET requires a significant amount of ionizing radiation, a consideration if used in clinical practice.

Recently, Barczewska *et al.*^[106] developed a technique for real time non-invasive monitoring of minimally invasive MSC delivery. IVD degeneration was induced in porcine discs of 3 animals *via* a fluoroscopic guided IVD vaporization procedure. Subsequently, the animals were placed in a 3T MRI scanner and 3×10^6 SPIO labeled MSCs were injected into the IVD through a plastic catheter in two divided injections. T2 weighted imaging was performed prior to, and following, each injection. Results demonstrated a statistically significant difference in signal intensity between both SPIO labeled MSCs compared with unlabeled MSCs and SPIO compared with control discs^[106].

Although limited, current research has demonstrated MRI is a suitable modality for detecting SPION labeled MSCs in the IVD. Current data, utilizing both MRI and CT/PET, provides only short term tracking of labeled cells, demonstrating adequate initial placement of transplanted cells. Further research is required to monitor long-term retention of MSCs in the IVD. Moreover, longitudinal tracking of injected cells is required to improve understanding of the therapeutic mechanism of action of MSCs in IVD disease.

ADDITIONAL BENEFITS OF MRI IN CELL TRACKING

In addition to monitoring labeled MSCs, MRI has the potential to non-invasively measure response to biological therapies in IVD disease. Several techniques have been developed to classify disc degeneration by MR image criteria^[107-110]. All are based on conventional T2 weighted sagittal imaging characteristics, which correspond to later morphological changes in IVD degeneration. The Pfirrmann classification system is the most widely used in the literature, utilizing an algorithm to generate five morphological grades^[107]. Research has demonstrated acceptable intra and inter-observer variability for grading systems^[107,109]. Ultimately, however, each is based on qualitative assessment and prone to inter-observer

Table 1 Review of stem cell tracking in the intervertebral disc in animal models reported in the literature

Ref.	Animal model	Cell type	Label	Imaging	Results
Saldanha <i>et al.</i> ^[105] , 2008	Rat tail (<i>ex vivo</i>)	Human MSCs (Loaded in fibrin gel-Tisseel)	FE-Pro (Feridex and Proatmine Sulphate)	3T MRI	No significant effect of labeling on MSC viability Hypointensity (signal loss) seen in discs injected with labeled cell
Prologo <i>et al.</i> ^[62] , 2012	Porcine <i>n</i> = 4	Human MSCs	Iodine-124 2'-fluoro-2'-deoxy-1b-D-arabinofuranosyl-5-iodouracil	PET/CT	Inaccurate delivery in 1 animal Three animals showed persistence and containment of labeled cells 3 d following injection
Barczewska <i>et al.</i> ^[106] , 2013	Porcine <i>n</i> = 1 (<i>ex vivo</i>) <i>n</i> = 3 (<i>in vivo</i>)	Porcine MSCs	Molday ION USPION	3T MRI	<i>Ex vivo</i> -Injected labeled cells clearly visualized <i>In vivo</i> -hypointense regions identified immediately following injection of labeled cells. Histopathology performed 2 wk later confirmed the presence of MSCs in the disc

MSC: Mesenchymal stem cell; MRI: Magnetic resonance imaging; USPION: Ultrasmall superparamagnetic iron oxide nanoparticle; PET/CT: Positron emission tomography/computed tomography.

variability. In addition, conventional MRI sequences lack sufficient sensitivity to identify early disc biochemical changes^[111].

Novel MRI sequences have the potential to quantitatively assess early IVD degeneration. T1 ρ MRI uses long duration, low power radiofrequency, or spin-lock (SL) pulses, applied on-resonance to lock magnetization in the transverse plane. Spin-locked magnetization relaxes with the time constant T1 ρ , spin lattice relaxation in the rotating frame^[112,113]. Post acquisition computer software analysis can be utilized to generate a quantitative T1 ρ measurement for a region of interest, such as the NP. T1 ρ has been shown to be sensitive to PG content in articular cartilage and the IVD^[114,115]. Furthermore, Borthakur *et al.*^[112] demonstrated T1 ρ values in IVDs correlate with low back pain. Another quantitative method recently developed is the NP voxel count, which has been shown *in vivo* to quantitatively assess disc degeneration. This assesses nuclear size and hydration with T2-relaxation time measurements^[116]. These imaging techniques have the potential to non-invasively, quantitatively, monitor response to biological treatments, as well as diagnose early IVD degeneration.

SUMMARY AND EXPERT OPINION

MSC transplantation shows exciting promise for the future regenerative approach to IVD disease. Cell labeling techniques are integral to ongoing research, to ensure accurate delivery and long-term retention of cells. Current research is limited to only short term monitoring. A greater understanding of the mechanism of action is required, with longitudinal tracking of implanted MSCs. Further research is required to discover if cells remain *in situ* long term, if they remain viable and if they track to sites of pathology in the IVD. MRI, with SPIONs as contrast agents, provides an excellent imaging modality for cell tracking. Some issues remain, such as dilution of signal through cell division or migration and differentiating labeled cells from intrinsic negative signal. These may be addressed with stronger magnetic fields, post-processing analysis and novel MRI techniques. Furthermore, novel MRI sequences can non-invasively quantify early biochemical changes in disc

degeneration. In conjunction with conventional MRI, this provides a mechanism for measuring response to biological therapy, in both the research and clinical setting. Ongoing effective research will facilitate the translation of MSC treatment for IVD disease to clinical practice.

eNSC mobilization non-invasively in the live brain remain scarce, but considerable progress has been made in this field in recent years. This review summarizes and discusses the current imaging modalities suitable to monitor eNSCs in individual experimental animals over time, including optical imaging, magnetic resonance tomography and-spectroscopy, as well as positron emission tomography (PET). Special emphasis is put on the potential of each imaging method for a possible clinical translation, and on the specificity of the signal obtained. PET-imaging with the radiotracer 3'-deoxy-3'-[¹⁸F]fluoro-L-thymidine in particular constitutes a modality with excellent potential for clinical translation but low specificity; however, concomitant imaging of neuroinflammation is feasible and increases its specificity. The non-invasive imaging strategies presented here allow for the exploitation of novel treatment strategies based upon the regenerative potential of eNSCs, and will help to facilitate a translation into the clinical setting.

Key words: Neural stem cells; Positron emission tomography; Magnetic resonance imaging; 3'-deoxy-3'-[¹⁸F]fluoro-L-thymidine; [¹¹C]PK11195

Abstract

The discovery of endogenous neural stem cells (eNSCs) in the adult mammalian brain with their ability to self-renew and differentiate into functional neurons, astrocytes and oligodendrocytes has raised the hope for novel therapies of neurological diseases. Experimentally, those eNSCs can be mobilized *in vivo*, enhancing regeneration and accelerating functional recovery after, *e.g.*, focal cerebral ischemia, thus constituting a most promising approach in stem cell research. In order to translate those current experimental approaches into a clinical setting in the future, non-invasive imaging methods are required to monitor eNSC activation in a longitudinal and intra-individual manner. As yet, imaging protocols to assess

Core tip: Endogenous neural stem cells (eNSCs) in the adult mammalian brain can be mobilized by, *e.g.*, pharmacological methods to facilitate regeneration and enhance functional recovery in neurological disease. In order to translate experimental approaches into the clinical setting, non-invasive imaging of eNSCs is required to monitor their fate *in vivo*. This review summarizes current imaging modalities suitable to monitor eNSCs in individual experimental animals over time, including optical imaging, magnetic resonance tomography and-spectroscopy, as well as Positron-Emission-Tomography, placing emphasis on the specificity of the signal obtained, as well as on their potential for clinical translation.

NEURAL STEM CELLS IN THE ADULT MAMMALIAN BRAIN

The discovery of neural stem cells (NSCs) in the adult brain and their ability to self-renew and differentiate into tissue-appropriate, functional cell types has raised intense scientific interest and the hope for radical new therapies of neurological diseases. Altman *et al*^[1] first detected the ability of the adult mammalian brain to generate new neurons, and their work was followed up by Kaplan *et al*^[2]. Using radioactive thymidine to label all dividing cells and histological examination of postmortem brains, they found labeled neurons. This proved that new neurons in the adult brain can be generated following cell division. After those pioneer studies focusing on neurogenesis, later studies aimed to detect the immature precursor cells capable of differentiating into all three cell fates of the central nervous system (CNS): neurons, astrocytes and oligodendrocytes. Several biomarkers have been suggested to identify those undifferentiated stem cells in the brain, the first one being the intermediate filament nestin (neuroepithelial stem cell intermediate filament^[3]). Subsequently, NSCs were characterized in the developing and in the postnatal/adult mammalian brain^[4-11]. More biomarkers were consecutively identified including *Sax2*, *Shh* pathway components, PDGF, EGFR, GFAP, Hes3, Hes5, Musashi, and CD133^[5,12-22]. However, since no single marker has yet been identified to unambiguously distinguish NSCs from somatic cells, co-stainings are usually required to comprehensively characterize them. It is now well accepted that endogenous NSCs (eNSCs) persist in the adult mammalian brain in at least two distinct regions, the subventricular zone, lining the lateral ventricles, and the dentate gyrus of the hippocampus^[23,24].

Insults to the CNS such as cerebral ischemia or neurodegenerative disease result in a mobilization of eNSCs and their migration towards the compromised areas^[25-29], constituting a physiological regenerative response of the brain. However, in most cases the intrinsic regenerative response of eNSCs is obviously not sufficient to lead to functional recovery. Experimentally, it has been shown that eNSCs can be mobilized pharmacologically for therapeutic purposes. Early studies showed that activating the tyrosine kinase receptors for fibroblast growth factor 2 and epithelial growth factor on eNSCs by introducing those growth factors into the lateral cerebral ventricle of experimental animals stimulates the proliferation of eNSCs *in vivo*^[30,31]. Ligands for these receptors also show benefit in animal models of cerebral ischemia, where growth factor-induced eNSC mobilization is associated with enhanced functional recovery from motor deficits^[32,33]. Recently,

several other drugs have been identified to mobilize eNSCs in the naïve and in the injured rodent brain, including Notch-ligands^[13], angiopoietin 2^[14], the neural cell adhesion molecule mimetic peptide FG Loop^[34], and aromatic-turmerone^[35]. Enhancing this (physiological) mobilization of eNSCs by pharmacological intervention leads to an improvement of neurological function after, *e.g.*, cerebral ischemia^[13,32,33]. To convey these regenerative effects, it seems that the differentiation of eNSCs into mature neurons that functionally integrate into the damaged circuitry-previously thought to be required for regeneration-only plays a minor role^[36]. Rather, eNSCs secrete trophic factors supporting neuroprotection such as glial-derived neurotrophic factor, vascular endothelial growth factor, or *Shh*^[13,37]. Other regenerative processes induced by NSCs include remyelination, angiogenesis, remodeling, and immunomodulation^[38,39]. Since treatments based on the transplantation of stem cells harbor several disadvantages including poor long-term cell survival, a lack of integration into the host circuitry, immune reactions against the transplants, and limited availability of appropriate cells^[40], mobilizing the endogenous neural stem cell niche for therapeutic purposes constitutes a most promising approach in stem cell research.

IMAGING ENDOGENOUS NEURAL STEM CELLS *IN VIVO*

Developing strategies to mobilize the endogenous NSC niche *in vivo*, with the aim to later translate them into clinical applications, creates the need for *in vivo* imaging technology to monitor those interventions. Imaging techniques should be non-invasive, so they can be applied repetitively in the same individual in a longitudinal fashion, and thus track quantity and localization of endogenous NSC over any period of time. While considerable progress has been made in recent years to track transplanted, pre-labeled cells^[41-47], the detection of endogenous NSCs in the living brain remains elusive. Current approaches to image eNSCs *in vivo* include (1) the use of transgenic animals whose eNSCs exhibit certain imaging properties; (2) labeling eNSCs *in vivo* by injecting a labeling substance into the brain; or (3) imaging some intrinsic and putative unique property of eNSCs with a tailored imaging assay.

Transgenic animals expressing a fluorescent or bioluminescent protein under the control of a stem cell-characteristic promoter such as nestin or doublecortin render their eNSCs detectable by optical imaging techniques^[48-52]. Under ideal conditions, optical imaging can specifically detect clusters of about 10³ cells *in vivo*, but its sensitivity is limited by the relatively poor spatial resolution with shallow tissue penetration^[53]. Moreover, the need for transgenic mice limits the potential applications of optical imaging and prohibits its translation into a clinical setting.

In the attempt to (specifically) label eNSCs *in vivo*, various methods have been suggested. Labels can be micro-injected directly into (or close to) the neurogenic

Figure 1 Monitoring the migration of endogenous neural stem cell labeled with iron oxide particles in the rat brain *in vivo*, using magnetic resonance imaging. Migrating cells were imaged 1 d (A), 3 d (B), and 8 d (C) after labeling, migrating from the subventricular zone (left in the sagittal images) to the olfactory bulb (on the right). White circles surround migrating cells. Granot *et al.*^[54], with permission. MRI: Magnetic resonance imaging.

niches, or they can be coupled to a vector in order to specifically target certain cells. Direct injection of a paramagnetic label such as small particles of iron oxide allows for cell detection using magnetic resonance imaging (MRI) with excellent spatial resolution on the single cell level (Figure 1)^[54-59]. However, this type of labeling is neither specific for a certain cell type, nor does it reflect cell viability, as only the particles themselves are visualized^[53]. Moreover, directly injecting iron oxide in *e.g.*, the lateral ventricles of the brain results in image distortion in the region of injection, allowing only for the detection of cells migrating away from the injection site^[54,57,58]. A more specific *in vivo* labeling approach is achieved by attaching an imaging label to a retro- or lentiviral vector, thus targeting proliferating cells in particular. This has been shown to be effective for optical imaging techniques after introduction of firefly luciferase^[60,61] or channelrhodopsin-2^[62]. Alternatively, ferritin can be introduced into proliferating (stem) cells using viral vectors, rendering them detectable for MR-imaging^[63,64]. Recent progress in this field has also been made by the development of a monoclonal antibody binding to neural precursor cells, coupled to magnetic glyconanoparticles allowing for their detection by MRI^[65]. While these approaches are quite promising to track eNSCs in individual experimental animals, a major disadvantage of those *in vivo* labeling approaches is the lack of applicability in human beings due to the invasiveness of the labeling procedure.

Truly non-invasive imaging techniques, utilizing methods that could be translated from the bench to the bedside, are rare. Manganas and colleagues investigated the spectrum of electromagnetic energy from established neurogenic niches using proton magnetic resonance spectroscopy (1H-MRS). They observed a prominent peak in the spectrum at the frequency of 1.28 parts per million (ppm) in the hippocampus of the adult mammalian brain *in vivo*, which was not observed in other regions of the brain^[66]. Later studies investigating this phenomenon have shown that it is not specific to eNSCs or neurogenesis, but closely related to apoptosis and quiescence^[67,68]. Since apoptosis is a major selection

process during neurogenesis, 1H-MRS may be used as an indirect method to detect neurogenesis within the known neurogenic niches and under physiological conditions. Disorders of the CNS associated with increased apoptosis of neural- or other non-neural cells, however, cannot be studied with this approach. Besides, MRS offers quite a low spatial resolution, failing to notice small clusters of cells and leading to the low sensitivity of this method.

We took advantage of the proliferative activity of eNSCs to develop an imaging assay using positron emission tomography (PET). Extensive studies in neurooncology have established the radiotracer 3'-deoxy-3'-[¹⁸F]fluoro-L-thymidine ([¹⁸F]FLT) to label proliferating cells in the adult rodent and human brain, allowing for non-invasive imaging of tumor cell proliferation with PET^[69-72]. [¹⁸F]FLT is a thymidine analogue that is incorporated into the DNA of dividing cells-similar to bromodeoxyuridine (BrdU) well established for their immunohistochemical detection- where it is irreversibly trapped, its positron-emitting properties allowing for its non-invasive detection^[73]. No evidence of toxicity or other complications have been reported following intravenous injection of [¹⁸F]FLT^[74]. [¹⁸F]FLT-PET detects ceasing glioma cell proliferation as soon as 3 d after initiation of an anti-proliferative treatment, as we have previously shown in mice and humans^[69,72]. Besides tumor cells, proliferating NSCs incorporate [¹⁸F]FLT both *in vitro* as well as *in vivo* after its systemic (intravenous) injection into adult rats^[75]. Thus, [¹⁸F]FLT labels proliferating eNSCs in the neurogenic niches of the healthy rodent brain with high sensitivity (Figure 2A), corresponding to BrdU-accumulation (Figure 2B). Moreover, [¹⁸F]FLT-PET quantifies eNSC mobilization mediated by pharmacological stimulation (Figure 2C). The resulting PET-signal can be quantified to reflect the extent of eNSC mobilization^[75]. Using a high-resolution PET-scanner and optimizing image reconstruction, the detection level can be as low as 10^4 cells. However, the PET-signal is not specific to endogenous NSC, since other proliferating cells are labeled as well. To increase specificity of this imaging assay, multi-modal imaging protocols can be applied as detailed below.

Figure 2 [^{18}F]FLT labels proliferating endogenous neural stem cell in the neurogenic niches of the healthy rodent brain. A, A': eNSC proliferation in the subventricular zone of adult rats as assessed by [^{18}F]FLT-PET; B: The signal corresponds to BrdU-positive cells in the region; C: Activation of eNSC by pharmacological stimulation with fibroblast growth factor 2, delta-like 4, and insulin is visualized with [^{18}F]FLT-PET. eNSC: Endogenous neural stem cell; [^{18}F]FLT-PET: 3'-deoxy-3'-[^{18}F]fluoro-L-thymidine-positron emission tomography; i.c.v.: Intracerebroventricular application. STEM CELL-MEDIATED REGENERATION AFTER FOCAL CEREBRAL ISCHEMIA

Stroke is the third leading cause of death and the leading cause of adult disability in the Western world^[76]. Since rescue of affected neurons can only be achieved by re-perfusion within a very narrow time window, treatment is mainly confined to the amelioration of neurological deficits and the prevention of further events. Especially in the subacute and chronic phase, *i.e.* days to months after stroke, therapeutic options are limited to physiotherapy, ergotherapy and logopedia to rehabilitate impaired neurological functions. However, from the pathophysiological point of view, evolution of ischemic damage is not limited to the minutes after vessel occlusion. After the disruption of blood flow below a threshold has led to rapid necrotic cell death within a localized region, the surrounding tissue that has been spared in this initial phase consecutively also undergoes relevant, but less rapid changes which aim at encapsulating the necrotic tissue, clearing of debris, and facilitating regeneration. These processes - often referred to as neuroinflammation - involve the rapid activation of glial cells (microglia, astrocytes) as well as recruitment of hematogenous cells (granulocytes, T-cells, monocytes/macrophages) from the blood stream^[77-82].

While neuroinflammation on the one hand contributes to the evolution of secondary damage to the surrounding

tissue by the excessive production of reactive oxygen species and pro-inflammatory cytokines secreted by the immune cells, it also has beneficial effects on the prevention of secondary tissue damage^[83]. Besides the containment of necrotic tissue, another most relevant beneficial aspect of stroke-induced neuroinflammation is the induction of a strong regenerative response, leading to a robust expansion of eNSCs^[84]. Quality, extent and timing of neuroinflammatory processes determine whether manipulating that particular response after stroke will be deleterious or therapeutically beneficial. The activation of resident microglia can under some circumstances be neurotoxic^[85], under others neuroprotective^[86], depending on the specific activating conditions^[87]. Interestingly, differentially activated microglia also have opposing effects on NSC^[88]. eNSC are attracted to the site of the lesion by various inflammation-associated cytokines such as stromal cell-derived factor-1^[89-91], tumor necrosis factor- α , and interferon- γ ^[84,92]. This mobilization of eNSCs has been shown for various ischemia models in experimental animals, including transient global ischemia^[28], transient focal ischemia^[26,36], or permanent focal ischemia^[93]. However, without any further pharmacological mobilization, the vast majority of newly generated neuroblasts in ischemic stroke models die by the time they have reached the peri-infarct area^[36]. Moreover, neurogenesis after stroke seems to play even less a role in humans than it does in rodent models^[94]. Those recent findings highlight the

Figure 3 Conclusive differentiation between cell proliferation from endogenous neural stem cell and immune cells. After transient focal ischemia (lesion outlined in white), A: Neuroinflammatory processes are visualized with [^{11}C]PK11195-PET, depicting inflammation in the infarct core as well as in the ischemic border zone; B: [^{18}F]FLT-PET data acquired in the same imaging session without moving the animals in the scanner demonstrates additional cell proliferation in the subventricular zone (white arrow), originating from endogenous neural stem cells. Adapted from Rueger *et al*^[97], with permission. [^{18}F]FLT-PET: 3'-deoxy-3'-[^{18}F]fluoro-L-thymidine-positron emission tomography.

importance of developing novel therapeutic approaches to additionally mobilize and invigorate eNSCs after stroke, either by pharmacological^[34,35] or by non-pharmacological treatments^[95].

In order to advance those experimental therapeutic approaches into the clinical setting, non-invasive imaging assays have to be established that reliably monitor eNSC activation in the rodent and human brain under the pathophysiological condition of stroke. In this context, the post-ischemic neuroinflammatory processes introduced above resemble a major impediment, since immune cells proliferate in the ischemic brain just as eNSCs do, and [^{18}F]FLT-PET does not differentiate between stem cell- and immune cell-derived proliferation. An elegant way to circumvent this problem consists of an imaging assay specific to (neuro-)inflammatory cells that does not visualize eNSCs. The radiotracer [^{11}C]PK11195 fulfils this requirement by selectively binding to the translocator protein-18 kDa expressed on inflammatory cells, specifically visualizing post-ischemic cellular neuroinflammatory processes^[96]. Since [^{11}C]PK11195 is radiolabeled with the isotope 11-C with a half-life of ~20 min, sequential PET-imaging with [^{18}F]FLT is possible by waiting for ~5 half-lives or 100 min between scans. During this time, the animal remains anesthetized within the PET-scanner, avoiding any movement, and enabling an exact co-registration of the imaging data^[97]. This co-registered imaging data on [^{11}C]PK11195- and [^{18}F]FLT-accumulation allows for a conclusive differentiation between cell proliferation from eNSCs and immune cells (Figure 3).

Therefore, PET is a promising tool to image eNSCs in a non-invasive fashion in neurological disorders that can be translated from bench to bedside. However, to further advance the imaging technology in this direction, complementary verification of imaging parameters

with immunohistochemical analyses are still needed, and the actual translation of such strategies to a clinical environment has yet a long way to go. However, the non-invasive imaging strategies presented here will help to facilitate translation into the clinical setting, and allow for the exploitation of novel treatment strategies based upon the regenerative potential of eNSCs.

and hematologic tumors, so the idea of CSCs has been proposed for MM, even if MM CSCs have not been defined yet. The existence of myeloma CSCs with clonotypic B and clonotypic non B cells was postulated by many groups. This review aims to focus on these distinct clonotypic subpopulations and on their ability to develop and sustain MM. The bone marrow microenvironment provides to MM CSCs self-renewal, survival and drug resistance thanks to the presence of normal and cancer stem cell niches. The niches and CSCs interact each other through adhesion molecules and the interplay between ligands and receptors activate stemness signaling (Hedgehog, Wnt and Notch pathways). MM CSCs are also supposed to be responsible for drug resistance that happens in three steps from the initial cancer cell homing microenvironment-mediated to development of microenvironment-independent drug resistance. In this review, we will underline all these aspects of MM CSCs.

Core tip: Multiple myeloma is a still incurable malignancy. Several study about multiple myeloma cancer stem cells showed their ability of self-renewal, survival and drug resistance. Besides, these cells are able to initiate and develop tumor when transferred into mice recipients. So understanding multiple myeloma cancer stem cells mechanisms become important to design new efficient targeting strategies for multiple myeloma. The aim of this review is to elucidate the state of art about multiple myeloma cancer stem cells and their critical role in maintenance of disease.

Abstract

Multiple myeloma (MM) is a hematologic malignancy of monoclonal plasma cells which remains incurable despite recent advances in therapies. The presence of cancer stem cells (CSCs) has been demonstrated in many solid

Saltarella I, Lamanuzzi A, Reale A, Vacca A, Ria R. Identify multiple myeloma stem cells: Utopia? *World J Stem Cells* 2015; 7(1): 84-95 Available from: URL: <http://www.wjnet.com/1948-0210/full/v7/i1/84.htm> DOI: <http://dx.doi.org/10.4252/wjsc.v7.i1.84>

MULTIPLE MYELOMA

Multiple myeloma (MM) is the second most common hematologic malignancy after non-Hodgkin lymphoma. It is characterized by uncontrolled proliferation of malignant plasma cells (PCs) that infiltrate in the bone marrow (BM), although small numbers of MM cells can be encountered in the peripheral blood circulation.

The first effect of MM is on the bone, but the blood and the kidneys are also involved. In bone marrow, malignant PCs induce damages in two ways: (1) proliferating cells form clusters disrupting the physiological structure of bone and causing osteolytic lesions; and (2) MM cells secrete not only cytokines and growth factors (GFs) that promote tumor progression and survival aging on MM cells themselves and on BM stromal cells (BMSCs) but also PCs secrete high amounts of monoclonal paraprotein (M protein) an abnormal immunoglobulins (Igs). Tumor cells interfere with hematopoiesis inducing a reduction in the number of white blood cells, condition known as leukopenia and increase the risk of infection. Moreover the decrease in red blood cells results in anemia, and low platelets level (thrombocytopenia) reduces normal blood clotting. Finally, the Bence Jones proteinuria, free light chain κ and, more important, λ , induces interstitial nephropathy and kidney failure because of their precipitation in distal tubules and collecting ducts^[1].

MM is usually preceded by a pre-malignant stage termed monoclonal gammopathy of undetermined clinical significance (MGUS) which progresses to overt MM at a rate of 0.5% to 3% per year^[2].

MGUS is characterized by a low number of PCs in BM and it isn't related to organ damages. MGUS has an increasing prevalence with age, affecting early 6% of over 60 years, but no treatment is indicated in these patients. Many studies evidence that patients with MGUS have a risk approximately 1% per year to develop to myeloma or to other related diseases^[3].

Another stage is represented by smouldering multiple myeloma (SMM). In these patients, the tumour burden is higher than in MGUS; they have a higher risk of progression to symptomatic myeloma and they require therapy. The current care for SMM patients is the monitoring disease and in case of progression, the treatments are recommended^[4].

MM it's still incurable despite the implementation of novel therapies and the great part of patients relapse even if initially they response to therapy. This is due to the presence of clonogenic cells inducing the so-called undetectable minimal residual disease (MRD)^[5].

BONE MARROW MICROENVIRONMENT AND THEIR PRECURSOR CELLS

MM progression is strongly supported by bone marrow microenvironment. A complex and mutual interactions between PCs and BMSCs support tumor cells growth, migration, survival, differentiation, drug resistance and angiogenesis^[6,7].

MM microenvironment is composed by extracellular matrix (ECM) proteins such as laminin, vitronectin, fibronectin, collagen, and by a large number of different stromal cells: fibroblasts, osteoblasts/osteoclasts, endothelial cells (ECs) and endothelial progenitor cells (EPCs), cells of immune system, hematopoietic and mesenchymal stem cells (HSCs and MSCs). During cancer progression, tumor cells are able to modify the surrounding stroma to build a promoting microenvironment from whose take advantages. The interplay between PCs and BMSCs is mediated by several cytokines, receptors and adhesion molecules^[8].

Plasma cells

The majority of PCs is identified in the bone marrow and a critical role in B cells development is played by stromal cells. Indeed they get in touch and secrete cytokines and growth factors needed to B cells maturation. The early stages of B cells proliferation depend on the interplay of PCs with stromal cells through vascular cell adhesion molecule-1 (VCAM-1) and thanks to growth factors such as interleukin-7 (IL-7), stem cell factor (SCF) and CXC chemokine ligand 12 (CXCL12)^[9].

During the development of B cells, within BM, the B cell precursors became independent from interaction with microenvironment and from cytokines secreted by stromal cells, and in the final stage, immature B cells, located near to the central sinus, lose expression of CXC chemokine receptor-4 (CXCR4), CXCL12 receptor, and they are released from marrow. Therefore, entering in the central sinus, immature B cells migrate to the spleen, where they complete their development becoming naïve mature B cell. Then, they may pick up antigen within the tissue, alternatively, B cells may return to bloodstream and they continue to look for antigen activating themselves. The activation of B cells induces the differentiation into memory B cells, PCs or plasmablasts that will move to the BM.

First, plasmablasts and PCs to stromal cell and derived factors (*e.g.*, IL-6), for their survival, besides chemokines appear responsible for plasmablast entry into BM as well as PCs retention. PCs express CXCR4 on their surface and migrate towards CXCL12, produced by stromal cells and sinusoidal ECs in the BM, showing that PCs express membrane antigen required for their localization in the BM.

The most specific PCs surface marker is Syndecan-1 (CD138), that has been shown to bind fibronectin, collagen and basic fibroblast growth factor (b-FGF); PCs express the adhesion molecules CD44 and very late antigen-4 (VLA-4) the presence of several interplays between PCs and stroma.

Myeloma PCs express on their surface antigens such as $\alpha_v\beta_3$, VLA-4, LFA-1 MPC-1, CD54, CD56 which allow interaction with BMSCs and stimulate the production of IL-6, RANK ligand (RANKL), insulin-like growth factor, tumor necrosis factor alpha (TNF α), vascular endothelial growth factor (VEGF), stromal cell-derived factor (SDF-1) promoting their proliferation^[10-12].

During maturation, PCs acquire specific lineage antigens and lose early markers, thus, BM PCs exhibit CD138, the survival factor Bcl-2, adhesion molecules such as VLA-4 and the chemokine receptor CXCR4, while they lose the B cell phenotype [CD19, CD20, CD22, human leukocyte antigen-DR (HLA-DR), Pax-5] and the death receptor CD95^[13].

Cancer associated fibroblasts

Fibroblasts represent the main component of BM stroma. Several fibroblasts, activated by cytokines and growth factors circulating in the microenvironment such as FGF and transforming growth factor-beta (TGF- β), are called cancer associated fibroblasts (CAFs). Markers identifying CAFs are alpha smooth muscle actin (alpha SMA), fibroblast activation protein, fibroblast-specific protein-1, Thy-1, desmin, and S100A4 protein^[14]. CAFs are able to promote cancer cell growth and to increase the invasiveness of cancer and stromal cells through cell-cell interactions, the production of pro-invasive cytokines, chemokines and inflammatory factors. This interplay between PCs and CAFs may serve as direction for cancer migration, breaking of the adjacent ECM and basement membrane, which represents the first step for cancer cells escape into the blood system^[15,16]. Furthermore, CAFs act also in immune responses producing pro-inflammatory cytokines and chemokines which attract immune cells such as macrophages, neutrophils, and lymphocytes to cancer region^[17].

Tumor-associated macrophages

Macrophages moved towards cancer bulk attracted by chemotactic factors and here they differentiate into tumor-associated macrophages (TAMs) favoring tumor progression^[18]. Macrophages allow tumor cells to escape immune-surveillance creating a particular microenvironment characterized by chronic inflammation and immune tolerance allowing cancer to escape immune-surveillance^[19]. Besides TAMs release a number of factors such as VEGF, hepatocyte growth factor (HGF), matrix metalloproteinase-2 (MMP-2), IL-8 which influence ECs behavior. Our group showed that BM macrophages in patients with active MM contribute to build neovessels through vasculogenic mimicry^[20,21]. TAMs preserve their own CD14 and CD68 lineage markers, indicating that they do not trans-differentiate into ECs, but only adapt themselves functionally, phenotypically and morphologically to ECs, under VEGF and FGF-2 stimulation produced by PCs^[22]; moreover macrophages secrete themselves VEGF and FGF-2, inducing BM angiogenesis^[8]. Finally, BM monocytes and macrophages from patients with MM are able to form capillary-like structures through vasculogenesis *in vitro* and contribute to vasculogenic mimicry *in vivo*^[23].

Osteoblasts and osteoclasts

In patients with MM the physiological balance between bone resorption and bone formation is often altered as results of a dysregulation of osteoclast and osteoblast activity, resulting in the formation of osteolytic lesions,

accompanied by bone pain^[24]. Many factors are involved in osteoclast activation, including macrophage inflammatory protein-1 α (MIP-1 α), IL-3, and IL-6 and receptor activator of NF- κ B ligand (RANKL)^[25]. RANK is a transmembrane receptor expressed by osteoclast cells; the interaction of PCs with BMSCs induce an increase of RANK ligand (RANKL) expression which binds its receptor expressed by osteoclast precursor cells, promoting their differentiation by NF- κ B and Jun-N-terminal kinase pathways^[26]. A great contribution to bone destruction is also due to the inhibition of osteoclast apoptosis by RANKL and to the suppression of osteoblast activity. Besides osteoblasts are important in this mechanisms cause they are able to supports MM cells growth and survival thanks to the secretion of IL-6^[27,28].

Endothelial cells and angiogenesis

Tumor ECs are more different from that of healthy vessels. They have an higher proliferation rate, in according to the enhanced angiogenesis that typically contributes to tumor progression. MM ECs highly express antigens such as VEGFR-2 and Tie/Tek, FVIII-RA, CD31 and VE-cadherin and their activity depends on growth factors circulating in BM microenvironment. They have an unusual shape and they are very permeable thanks to the presence of fenestrae, vesicles and a discontinuous basement membrane and they participate to the formation of new vessels with tumor cells capable to form mimic vessels. Angiogenesis plays a critical role in tumor progression important for tumor growth, invasion and metastasis not only in solid malignances but also in haematological malignances, such as MM. Angiogenesis is a multistep process which occurs in the switch from the avascular to the vascular phase in MGUS patients and leads to the transition to MM. Our group demonstrated an increase of angiogenesis in BM biopsies from patients with active MM compared with MGUS patients which suggest the passage from an avascular phase in MGUS or SMM to a vascular phase in active MM. The angiogenic switch is accompanied by mutations in PCs which acquire an angiogenic phenotype secreting growth factors (VEGF, FGF, HGF and others), and stimulating chemotaxis and proliferation of stromal cells^[21].

EPCs and BM vasculogenesis

Vasculogenesis was first described as a phenomenon occurring in early embryogenesis, and was believed to not occur in adult tissues. In 1997, Moschetta *et al*^[29] purified a population of circulating cells that showed characteristics typical of ECs as well as progenitor cells, and identified these cells as “endothelial progenitor cells” (EPCs). In humans, EPCs are identified by the expression of VEGFR-2, CD34, VE-cadherin, CXCR4, CD31, CD133, CD105, CD144, CD106, and CD117 (c-Kit). Mobilization of EPCs may occur in response to factors secreted by ischemic tissues and by inflammatory and tumor cells and it results in the generation of new vessels. When EPCs are recruited to tumor sites, they differentiate in mature ECs, sustain neovessel formation *via* paracrine secretion of

proangiogenic growth factors and they integrate into the nascent vessels which are a mosaic of ECs, EPCs, tumor cells and macrophages^[29].

Many studies indicate that BM-derived circulating EPCs can take part to tumor angiogenesis and to sustain tumor cells proliferation. A great amount of EPCs have been found in the BM of patients with active MM compared with treated MM, MGUS, or healthy people, highlighting the increased angiogenic activity in MM patients. Besides, Ria *et al.*^[30] showed for the first time that EPCs had phenotypic and functional characteristics of the mature endothelium. In the MM BM microenvironment, they postulated that PCs and inflammatory cells recruit EPCs into tumor site, they induce their differentiation into ECs and they contribute directly in the formation of new vessels thus contributing to tumor vasculature.

STEM CELLS IN MULTIPLE MYELOMA

The implication of B cells in the pathogenesis of MM has been investigated by many groups because normal and myeloma PCs arise from their differentiation. The rearrangement of immunoglobulin gene and their resulting antibody allows to understand the different relationships between different clones in B cell tumors. Sequencing of immunoglobulin genes of MM PCs has underlined the presence of somatic hypermutation without intraclonal variation suggesting that MM arises from a post germinal center B cell compartment^[31]. Already in many tumors it has been shown the existence of cancer stem cells (CSCs) or cancer-initiating cells^[32-34]. While CSCs markers differ from one to another, their peculiar characteristics are common, such as self-renewal, tumorigenesis and drug resistance. Therefore, these stemness abilities are useful for identifying the MM stem cells. The idea of CSCs model bases on the concept that cancers are similar to hematopoietic system with an asymmetric division where CSCs should maintain cancer cells population.

The possible existence of MM CSCs was first postulated by Drewinko *et al.*^[35] that demonstrated the presence of a small population of MM cells with the capability of self-renewal in experiments with MM cell lines and primary cell lines from patients with MM. Then, Hamburger *et al.*^[36] and Pilarski *et al.*^[37] showed, respectively *in vitro* and *in vivo*, the capacity for self-renewal of MM primary lines. Finally, the onset of relapse in some patients after treatment gives the idea that, maybe, MM CSCs really exist.

Many studies underline the presence of different subpopulations able to give rise to MM: clonotypic B cell, clonotypic non B cell and side population (SP) cell.

Clonotypic B cells

MM cells are more functionally and phenotypically heterogeneous population. Within the tumor it has been identified a mature normal cell population and a minor one which is able to form tumor after transplantation into susceptible recipients in contrast to the first one. Matsui *et al.*^[38] demonstrated that clonotypic B cells are

capable to give rise to monoclonal immunoglobulin-secreting PCs *in vitro*. In particular, CD19⁺ B cells, isolated from MM patients, showed the capacity to form a new tumor in xenograft models implying the existence of cells with self-renewal ability. Moreover they found that CD138⁺CD34⁺ cells were able to form colonies *in vitro*, like CD138⁺ PCs *in vivo*, which present the same intracellular immunoglobulin light-chain restriction as MM patients.

Normal B cells maintain long-term immunologic memory thanks to the ability for self-renewal as well as the clonotypic B cells of MM lead to belief that myeloma PCs may arise from this compartment. Indeed Matsui *et al.*^[39] studying the CD138⁺ clonogenic myeloma cells, found that only cells which co-express CD19 and CD27 cell membrane antigen, typical of memory B cells, were able to form colony *in vitro*. They also reported that CD19⁺CD27⁺CD138⁺ cells isolated by peripheral blood of MM patients engrafted NOD/SCID (Non-obese diabetic/severe combined immunodeficiency) mice and gave rise to mature CD138⁺ MM PCs secreting M protein. CD19⁺ B cells isolated by these engrafted mice were able to induce MM in other recipient mice, underlining their self-renewal potential. These results mark that MM-initiating cells with tumorigenic ability, localized in clonotypic post-germinal B center, may differentiate and build up again the bulk of MM cells. Moreover, Boucher *et al.*^[40] showed that CD34⁺CD19⁺ immature B cells and CD34⁺CD19⁺ mature B cells, but not CD34⁺CD19⁺ cells, harvested from MM patients form colonies, suggesting that undifferentiated clonotypic B cell may present MM-initiating ability.

More recently, Kirshner *et al.*^[41] evaluated a novel *in vitro* 3D stromal culture system to study typical properties of BM microenvironment, in which results that tumor growth derived from clonotypic B cells. Pilarski *et al.*^[37] demonstrated that cells from the peripheral blood of patients with late-stage of MM or from patients with minimal residual disease, or cells mobilized through G-CSF, engrafted NOD/SCID mice. Engrafted mice presented high levels of circulating M protein and bone lesions as in patients with myeloma; besides these tumor cells could be transplanted successfully into secondary recipients indicating self-renewal ability. Indeed, Chaidos *et al.*^[42] found that the amount of circulating clonotypic B cells correlates with disease progression.

Clonotypic B cells play an important role in MM disease because they are also detected in MM patients with complete remission, becoming potential source for MM-initiating cells which could relapse.

Clonotypic non B cells plasma cells

Although all the evidences that clonotypic B cells could be MM CSCs, many studies demonstrate the clonogenic potential of non-B cell plasma cell population in MM.

First experiments demonstrating clonogenic ability of non-B cells was realized by Yaccoby *et al.*^[43]. They successfully induced human MM disease by intraosseous transplantation of CD38⁺CD45⁺ human cells in SCID mice implanted with rabbit femurs (SCID-rab mice)

or with human fetal bone fragments in SCID-hu mice creating a humanized microenvironment^[44]. In these models, the rabbit or human implanted bone fragments promote MM growth within the bone with several clinical aspects of MM including lytic bone lesions, hypercalcemia and circulating M protein. While, in the same work, Yaccoby *et al.*^[43] demonstrated that CD38⁺CD45⁺ peripheral blood B cells weren't able to engraft into SCID-hu mice as well as CD19⁺ B cells did not allow the xenograft in SCID-rab mice. But PCs regained from SCID-hu models were successfully transferred to secondary and tertiary recipients to produce MM disease with the clinical symptoms. In contrast, plasma cell-depleted BM cells did not induce MM disease in these models.

Hosen *et al.*^[45] studied the clonogenic MM plasma cells in terms of CD138 negativity in SCID-rab mice. Phenotypic CD138⁺CD19⁺CD38⁺⁺ PCs isolated from MM patients were engrafted in SCID-rab mice developing MM disease; moreover CD138⁺ PCs from patients were also able to induce MM in mice, although more slowly than CD138⁺ cells.

Recent studies carried out by Kim *et al.*^[46] tested the clonogenic potential of plasma cells in relation with BM microenvironment using NOD/SCID/common cytokine receptor γ chain-deficient (NSG) and recombinase-activating gene 2/common cytokine receptor γ chain-deficient (RAG2-/-) mice. The results of this work underlined the ability of only differentiated CD138⁺CD38⁺ cells, risen from patients, to repopulate of B lineage cells in human bone-bearing mice but no engraftments were detected in human bone-free mice. Besides, serial transfer of the disease to secondary recipients were possible. In these models, completely differentiated MM PCs enriched MM-initiating cells contrary to B cells. All these data showed that MM PCs can induce MM *in vivo* even in the absence of CD19⁺ B cells.

Finally, Paino *et al.*^[47] evaluated the presence and function of CD20⁺ putative MM stem cells population in several MM cell lines. In the RPMI8226 cell line they found a small subpopulation of CD20^{dim+} that was not essential for CD17-SCID mice engraftment. Moreover, CD20^{dim+} cells didn't differentiate into CD20⁻ cells, even if CD20⁻ cells can differentiate into CD20^{dim+} cells, suggesting a sequential differentiation order. All these outcomes showed that CD20 isn't a marker related to MM CSCs.

SP population

Moreover, the SP phenotype is characteristic of stem cells in various normal tissues as described by Challen *et al.*^[48] SP cells show a strong ABC (ATP-binding cassette) transporter activity resulting in high ability to efflux dyes as Hoechst 33342, a substrate for the ABC transporter ABCG2, also known as breast cancer resistance protein 1. SP cells have characteristics of stem cells such as the ability of self-renewal, expression of stem cell-like genes and resistance to chemo- and radio-therapy.

Loh *et al.*^[49] detected SP cells in both MM cell lines

and primary MM cells. Also Jakubikova *et al.*^[50] studied SP fraction in the same lines too. Their research showed that SP population is mainly presented in both CD138⁺ and CD138^{low} without any correlation between the lack of CD138 expression and amount of this fraction. Indeed they demonstrated that SP is composed of cells highly proliferating and with tumorigenic ability. Besides, they also showed that SP cells were susceptible to lenalidomide treatment in a dose- and time-dependent manner, in contrast, other authors displayed that lenalidomide results ineffective against other possible MM CSCs subpopulations (clonotypic CD19⁺ cells)^[39].

Interestingly, IMiDs reduced SP cells rate in co-culture with BMSCs, invalidating interplay between CSCs and the BM microenvironment; even if they did not affect ABC transporter function^[51].

Bone marrow stem cells

Bone marrow is a source of different tissue-specific stem cells, in fact BM hosts Bone marrow hematopoietic stem cells (BM-HSCs) and Bone marrow mesenchymal stem cells (BM-MSCs). Probably in the BM a universal adult progenitor exists and its phenotype could be modified by the local environment. Stem cells may move from BM to another tissue through the blood circulation and can differentiate into various types of stromal cells^[52]. A large part of BMSCs is composed by HSCs, important for the homeostasis of blood system, giving rise to all blood cells (lymphocytes, erythrocytes, monocytes, granulocytes and platelets). The distribution of HSCs in the BM is well-organized: the majority of HSC are located within the endosteal region, while progenitors and mature cells are principally sited in the central marrow area in proximity to the central marrow vessels^[53,54]. Most HSC express the CD34 antigen, an integral membrane glycoprotein that functions as a regulator of hematopoietic cell adhesion to BMSCs^[55]. Antigens such as CD90, CD117, and CD133 are also expressed by HSCs^[56]; moreover they express CD90, CD117, and CD133^[56] but not CD38, CD45RA, CD71, HLA-DR, or any other lineage-specific antigen according to their immaturity^[57]. Following injury HSCs are mobilized from the BM niche and they start proliferating to supply new mature cells.

The BM mesenchymal stroma is essential for the normal functioning of HSCs, ensuring their renewal and differentiation, creating an ideal microenvironment and contributing to the formation of the HSC niche^[58]. The first evidence of MSCs was reported by Cohnheim on "mesenchymal precursor cells" defining those cells as fibroblastoid, adherent, and extravasated cells at sites of tissue injury. In the early 1990s, these cells began to be known as "mesenchymal stem cells", cause they exhibit multipotential differentiation and self-renewal capacity^[59]. MSCs isolated from the adult BM have the ability to differentiate into osteoblasts, adipocytes, chondrocytes *in vitro* and to heterotopic osseous tissue when transplanted *in vivo*. MSCs express a large variety of surface markers including CD29, CD44, CD49a-f, CD51,

CD73, CD105, CD106, CD166 and they don't express typical hematopoietic lineage receptors such as CD11b, CD14, CD45^[60]. Wallace *et al.*^[61] compared BM-MSCs from patients with myeloma at diagnosis and normal donors to further examine the role of the bone marrow stroma in myeloma. They established that BM-MSCs from myeloma showed the same expression of adhesion molecules and of integrin, such as VLA-2, VLA-4, VLA-5, β 1, L-selectin, and CD44 and were negative for VLA-2, β 2, and β 3; however they had a weaker expression of VCAM-1 and fibronectin compared with normal BMSCs. Adhesion and migration cell abilities depend on the expression of adhesion receptors and on the type and concentration of ECM proteins. BM-MSCs low expression of cellular fibronectin, may cause localization and retention of malignant PCs in the BM because PCs lines show to move on fibronectin. Besides BM-MSCs express an intracellular RHAMM, a receptor for hyaluronan-mediated motility which induces the migration of several kinds of cells such as smooth muscle cells, fibroblasts, neuronal cells, and leukocytes. RHAMM activation results in a transduction signal which leads to cellular mitosis. Finally this study showed an over-expression of cytokines and growth factors by BM-MSCs, including IL-6 critical for PCs proliferation, survival and resistance. The analysis of mesenchymal cells in myeloma underlines the importance of BMSCs in myeloma cell growth and progression.

STEM CELL NICHE

Stem cells are located in a specific microenvironment defined niche. The niche and stem cells interact each other through adhesion molecules that activate molecular signals able to ensure stemness. For the first time, the idea of a stem cell niche was suggested by R. Schofield in 1978 for the HSC in BM^[62]. Schofield called "stem cell niche" the cellular environment, retaining stem cells. Until the stem cell restrains in the niche, its differentiation is avoided and so they replicate indefinitely as stem cell. Many groups investigate several types of stem cells and respective niches.

Osteoblastic niche

In human, hematopoiesis occurs in BM, where microenvironment creates optimal conditions for the HSCs maintenance and differentiation. Quiescent HSCs have been recognized near to the endosteal surface of the BM, in the trabecular bone, forming a source of HSC that can induce hematopoiesis after tissue damage. Lo Celso *et al.*^[63] showed that after transplantation, HSCs were localized closest to the endosteum and that as differentiation progressed, they moved to different locations^[63]. There are many pathways and molecules involved in the maintenance of stemness and stem niche. HSCs and osteoblasts interact through adhesion molecules, as N-cadherin (N-cdh) that is considered the most important cell-cell adhesion molecule expressed by many cancer cells. Vandyke *et al.*^[64] showed that expression of N-cadherin in primary MM cell lines correlates with

poor prognosis; in fact it has been demonstrated that N-cdh regulates HSCs proliferation^[64]. Sadler *et al.*^[65] proved that, inhibiting N-cadherin through a neutralizing antibody, the interaction between MM cells and stroma is prevented and it is induced the proliferation of HSCs compartment. Thus, stem cells are quiescent (G_0 stage) and they are not going to enter into the cell cycle until they received stimulations. Arai *et al.*^[66] found that osteoblasts express angiopoietin-1 (Ang-1) that binds Tie2 (tyrosine kinase receptor) expressed by BM-HSCs. This bond induces the activation of β 1-integrin and N-cadherin contributing to the close interaction between osteoblasts and stem cells necessary to ensure the maintenance of the stem cell and self-renewal capability.

The niche size is regulated by bone morphogenetic protein (BMP) signaling through its binding to osteoblasts receptor type IA (BMPRIA)^[67]; besides the stimulation by PTH (parathyroid hormone)/PTHrP (parathyroid hormone-related peptide) receptors produces high levels of Jagged 1, a Notch ligand, which recruit more HSCs in the niche. A study highlight Osteopontin (Opn) as another important osteoblasts receptor; in fact in these work knock-out mice showed that transplanted HSCs were randomly distributed within BM, whereas HSCs should be usually located at the endosteal region. This data suggests that Opn is involved in the interplay between HSCs and osteoblastic niche and it decreases HSCs proliferation^[68]. Furthermore, c-Myc is another regulator of HSCs fate: c-Myc deficient mice have a higher amount of HSCs in BM and their differentiation was maintained by interactions mediated by adhesion molecules between HSC and the niche, such as N-cadherin and integrins. Contrary, overexpression of c-Myc induces HSCs differentiation^[69]. Also ECM and its components play an important role in osteoblastic niche. Glycosaminoglycan hyaluronic acid (HA), is the major component of the ECM and its receptor, CD44, is a pleiotropic transmembrane protein presented by several cell types, including the HSCs and progenitors. HA is important in supporting and regulating hematopoiesis.

Osteoblasts are sited in endosteal area where there is a high calcium concentration, so Adams *et al.*^[70] supposed that on HSCs a sensor for calcium exists and it contributes to their homing and localization in the BM. They demonstrated this in CaR-deficient mice, showing that even if they had a healthy amount of primitive HSCs in the circulation and in spleen, they had very few of these cells in the BM^[70].

Vascular niche

Recently, vascular niche, was found within the sinusoidal vessels in BM or spleen. The presence of a vascular niche is confirmed by HSCs migration to the vascular region of the BM after injury, restoring hematopoiesis. So the vascular niche encourages proliferation, differentiation and the release in the bloodstream of HSCs^[71]. HSCs were identified as CD150⁺CD244⁺CD48⁻ cells, and many of them were in sinusoidal endothelium^[72], near to cells that express high level of CXCL12^[73]. Vascular niche is

also important not only in maintain HSCs but also in the regulation of the various phases of hematopoietic processes within BM, such as mobilization, migration, and differentiation of HSCs. So the discover of the vascular niche make the attention on its crucial role in blood system and hematopoiesis.

Kopp *et al.*^[74] showed that the only translocation of megakaryocyte progenitors near vascular sinusoids of BM was able to induce megakaryocyte maturation and platelet production. This process depends on chemokines such as SDF-1 and bFGF that enhance expression of adhesion molecules, as VLA-4 on megakaryocytes and VCAM-1 on BMECs. Besides, the breakdown of VE-cadherin-mediated adhesion BMEC makes in vascular niche incapable to induce megakaryocyte differentiation and to release platelet in peripheral blood. This focuses on the importance of ECs structural integrity for HSCs differentiation and homing. BM-ECs of sinusoidal vessels represent a barrier between BM stroma and the peripheral blood circulation, suggesting that they are implied not only in hematopoiesis but also in stem cells mobilization and homing^[74].

The different functions of osteoblastic and vascular niches aren't yet known. A difference between the two niches is the oxygen level: vascular niche presents a higher oxygen level than osteoblastic niche. In this conditions, cells resume their cell cycle, undergoing mitosis^[75].

Furthermore, a new model of hematopoiesis is proposed: in osteoblastic niche, in hypoxic environment, the HSCs are in G₀ stage. Under stimulation of cytokine such as G-CSF, granulocyte-macrophage colony-stimulating factor (GM-CSF), IL-7, IL-3, IL-12, SCF, and flt-3 ligand and chemokines like IL-8, Mip-1 and SDF-1, HSCs could move to the vascular niche, undergoing differentiation and supplying cells of bloodstreams^[76]. When no longer HSCs needed, they could return from the vascular niche to the osteoblastic one, where they revert to the G₀ stage again. The movement of the HSCs between osteoblastic and vascular niches appears to be necessary for well-balanced hematopoiesis^[77].

Cancer stem cell niche

It has been proposed that as well normal stem cells niche exists, as CSCs niche could exist and interplay with the cancer niche may have a similar role in differentiation, proliferation and self-renewal capability of tumor cells. The interaction between the niche and CSCs prevents their differentiation in response to chemokines and growth factors as happens for HSCs in the osteoblastic niche. Increasing evidence proved that factors secreted by the cancer microenvironment regulate cancer cells. The niche is able to anchor stem cells in their appropriate microenvironment through adhesion molecules, such as cadherin and β -catenin. In addition, recent data support the role of the vascular niche in initiating metastasis; MMPs family molecules are involved in the process of cancer migration and also integrins have been reported to be associated with tumor cell homing and mobilization

in which SDF1 and CXCR4 play an essential roles. For metastatic process, tumor cells must reduce cell-cell contacts and migrate to distant sites. Thus, these molecules, involved in stem cells mobilization from the niche, represent possible targets to block tumorigenesis, cancer progression and metastasis^[78]. Evidences showed that factors derived from tumor stroma niche are able to regulate cancer cells and to direct their diffusion, in fact genetic studies have shown that stromal cells are altered in many tumors and supports cancer progression. Specialized microenvironments of BM-ECs are needed for the homing and engraftment of both normal HSCs and cancer cells^[79]. There are several possible hypothesis for CSCs niche: (1) CSCs may not require specific niche for survival and are able to survive in the healthy stem cell niche; (2) a distinct CSCs niche may be necessary for their activation and CSCs may dependent on this tumor-niche for expansion; or (3) an inhibitory niche for CSCs could exists which provides factors that induce differentiation or death; (4) CSCs may provide signals that activate an otherwise quiescent niche, thus signals from the CSCs could result in amplification of an activated niche that already exists; and (5) CSCs may be niche independent and they may have acquired the ability to provide themselves with the necessary factors for expansion and self-renewal^[80].

PATHWAYS IN MM STEM CELLS

Many signaling that preserve physiological stem cells, are also involved in CSCs maintaince and self-renew. Three pathways results most activated in cancer stem cells: Hedgehog (Hh), Wnt and Notch.

Hedgehog signaling plays a crucial role during embryonic development, and it regulates cell proliferation, migration and differentiation. Hh signal transduction involves three ligands *i.e.*, Sonic (SHh), Indian (IHh) and Desert (DHh) which bind the cell surface antigen Patched (PTCH). Hh pathway normally inhibits the Protein Smoothed SMO, a trans-membrane receptor with a high homology with coupled G protein. When ligands bind PTCH, SMO is de-repressed and regulates the activity of 3 GLI proteins which act as transcriptional regulators. In particular, GLI1 induces the expression of cell cycle regulator cyclin D1, inducing mitosis; GLI2 can act as positive or negative transcriptional regulator depending on post-transcriptional and translational modification; whereas GLI3 is a negative downstream effector of Hh and down-regulates genes transcription. Altered Hh signaling has been found in many human tumors. In myeloma, *PTCH*, *SMO* and *GLI1* were over-expressed in both human cell lines and primary MM PCs compared to normal PCs and B cells^[81].

Wnt pathway is an ancient and conserved signaling which regulates cell fate determination, migration and differentiation. In MM Wnt pathway is activated by the interplay of BM microenvironment. Wnt stimulation by bond with Frizzled (Fz) activates several intra-cellular pathways, including the canonical Wnt/ β -catenin way and the non-canonical Wnt/ Ca^{2+} one. Komiya *et al.*^[82]

showed that genetic modifications of Wnt signaling induce alterations in development and function of several organs, in particular, down-regulation of Wnt pathway supports proliferation of both MM cell lines and primary patient samples. Finally, the inhibition of Wnt pathway by small molecule inhibitor disrupts the maintenance of MM cells both *in vitro* and *in vivo*. This result encourages the development of Wnt-targeted inhibitors for MM therapy^[82,83].

Notch signaling is an evolutionary pathway highly conserved both in vertebrates and in invertebrates. Notch pathway is involved in various neoplastic processes such as tumor angiogenesis, EMT, metastasis.

Mammals express four Notch transmembrane receptors (Notch-1, -2, -3, -4) and five ligands named Jagged1, Jagged2, Delta-like 1 (DLL1), DLL3, DLL4 which mediate Notch activation (cell to cell) in trans and inhibition (on the same cell) in cis. Activation of Notch receptors consists in three proteolytic cleavage which result in the formation of "notch transcriptional complex" (NTC) inducing the expression of many genes related to differentiation and survival, including hairy/enhancer of split (HES), the family of helix-loop-helix transcription factors, cyclin D, c-Myc^[84]. In MM, Notch activation advances cell proliferation and MM progression. Agarwal *et al.*^[81] searched the presence of Notch on BM clonotypic B cells from MM patients and found great expression of Notch that underlines Notch signaling implication in MMSCs.

DRUG RESISTANCE

Drug resistance remains an important complication to the cure of most cancers. During therapies cancer bulk initially response, but, over time, cancer stem cells may become drug resistant, thus therapies fail to eradicate them. So CSCs have not only the classic capacities of self-renewal and proliferation, but also are more resistant to chemo- and radiotherapy^[85]. But, in MM patients, drug resistance mechanisms that could arise during treatments, not explain completely MRD onset, though the BM microenvironment present components that can induce drug resistance and could reduce drug activity such as cytokines, stromal cells and ECM compounds.

Drug resistance development consists of three phases: (1) Cancer cells homing to the protective microenvironment represented by BM; (2) Initial microenvironment-mediated drug resistance; and (3) Development of microenvironment-independent resistance and acquired drug resistance.

Cancer cells homing to the protective microenvironment represented by BM

Cytokines and chemokines are more important in hematopoietic cells homing within BM. The major axis is the CXCR4/SDF-1 one, that promotes myeloma cells migration and homing to BM *in vivo* and *in vitro*^[86]. SDF-1 or CXCL12 is constitutively expressed by BMSCs and it is the main source of chemokines in adult. It retain hematopoietic cells and progenitors for growth and differentiation and impounds mature B cells to BM.

CXCR4 (CD184) is a G-coupled cell surface receptor and can be expressed by normal and malignant cells. The bond CXCR4/SDF-1 mediates cell survival, adhesion and migration contributing to tumor progression in several cancers. Moreover VLA-4-mediated adhesion to ECM (in particular to fibronectin and collagen) enhances the drug resistance in MM^[87]. The inhibition of this pathway not only blocks tumor homing and engraftment, but also avoids cell adhesion-mediated drug resistance and cells retain in BM decreasing VLA-4 expression.

Initial microenvironment-mediated drug resistance

In this phase, tumor cells acquire a soluble factor- and/or cell adhesion-mediated drug resistance (CAM-DR) *i.e.*, *de novo* drug resistance. The BM collects GFs and cytokines necessary to maintain cellular homeostasis. Among these GFs, IL-6 is essential to MM. The binding to its receptor on target cells induces STAT3 signaling that inactivates Fas-mediated apoptosis by up-regulation of Bcl-Xl with anti-apoptotic effect. Besides Frassanito *et al.*^[88] supported that myeloma clones secreting IL-6 were more resistant to both spontaneous and drug-induced apoptosis than non-IL-6 secreting clones that were sensible. Furthermore Voorhees *et al.*^[89] showed that blockage of IL-6 signaling in MM cell lines increases their sensibility to bortezomib.

Interaction between tumor cells and BMSCs is more complex than adhesion of integrin to ECM compounds alone because it involves other pathways and signaling events activated by adhesion molecules. In drug resistance development, cell-cell and cell-ECM interacts are more important and integrin-mediated adhesion to ECM compounds and stromal cells induces pathways that regulate proliferation, migration, and survival of normal hematopoietic cells. But integrins are also important in the tumorigenesis and integrin expression patterns are altered in tumor cells.

The role of VLA-4 has been investigated by several groups in mediating *de novo* drug resistance in hematopoietic malignancies. In these cases, CAM-DR is leaded by the interaction of cancer cells to ECM components and/or BMSCs *via* integrin $\alpha 4\beta 1$. Damiano *et al.*^[90] demonstrated that drug resistant MM cells up-regulate some integrins as $\alpha 4$, $\beta 1$ and $\beta 7$ while, when drug-sensible myeloma cells are seeded on fibronectin, a reversible *de novo* drug resistance phenotype was observed.

Thus, CAM-DR is characterized by non-transcriptional mechanisms into drug resistant cells. Adhesion-mediated survival and drug resistance pathways induced by soluble factors contribute to MRD allowing the development of more complex drug resistance mechanisms caused by the selective pressure of chemotherapy. Also the study of *de novo* drug resistance mechanisms from CAM-DR explains how tumor microenvironment promotes drug resistance onset.

Development of microenvironment-independent resistance and acquired drug resistance

Into BM microenvironment, cancer cells can survive to chemotherapies activity, resulting in MRD. In particular,

under continuous pressure of chemo-treatments, tumor cells acquire intrinsic genetic and epigenetic changes that lead to drug resistance phenotype without extracellular stimuli as soluble factor- and/or cell adhesion-mediated drug resistance. Furthermore, acquired drug resistance is mediated by intrinsic changes at the transcriptional level while *de novo* drug resistance is mediated by post-transcriptional mechanisms^[90]. A possible solution to destroy MM CSCs is targeting self-renewal and drug resistance signals specifically activated in CSCs: Hedgehog (HH), Wnt, and Notch pathways^[91,92].

For example, Nefedova *et al.*^[93] showed Notch1 receptors expression on MM cell lines that stimulates their adhesion to BMSCs, which express the membrane Notch ligand Jagged. The binding induces up-regulation of p21^{Cip1/WAF1} that encourages growth inhibition and protection from drug-induced apoptosis.

Indeed, the existence of a drug resistant sub-clone, which may be composted by CSCs and may expand during therapy, may represent the reason of tumor treatments fail^[94]. Most important, Peacock *et al.*^[95] affirmed that overexpression of RAR α 2 provided MM CSCs (CD138⁺ MM cells) drug resistance by activation ABCC3 gene through stem cell related pathways Hh (hedgehog) and Wnt. In effect, MM CSCs express also some functional markers such as drug efflux pumps (ABCC3), ALDH1 and RAR α 2 which have been associated with clonogenic potential and resistance to chemotherapy contributing to drug resistance and relapse in MM patients^[96].

Moreover, MM CSCs also express a telomerase which has a fundamental role in controlling normal stem cell functions and cancer drug resistance. Inhibitors of telomerase activity block MM CSCs clonogenic potential *in vitro* and *in vivo*, triggering differentiation of CD138⁺ cells into CD138⁺ cells and decreasing the number of ALDH1⁺ cells^[96].

CONCLUSION

Taken all together, these above studies provide strong evidence for existence of well-defined stem/progenitor cells possessing the three prominent features common to CSCs in all cancers: self-renewal, proliferation and drug resistance^[97].

Because MM remains still incurable, the idea of the MM CSCs has been suggested to explain the ability of self-renewal, survival and drug resistance of some myeloma cells. To evaluate this hypothesis, several groups use clonotypic B and non B cells and SP cells and transfer them into mice models with opposite results due to the different ability of BM microenvironment to sustain their survival inducing MM. Interestingly, there are many resemblances between the HSCs and MM CSCs about extracellular and intracellular receptors and signalings which can be employed to improve targeted therapy. So stemness pathways such as Hedgehog, Wnt and Notch, constitutively activated by the interaction between MM CSCs and their niche could represent new potential targets for MM treatment. The comprehension of interactions between

MM CSCs and the BM microenvironment will enable us to establish the necessary reasons for MM CSCs maintenance and avoidance from therapies inducing drug resistance^[98].

However, despite the introduction of novel therapy against MM, it still remains incurable. This shows the necessity to further elucidate causes of MM onset and implement innovative strategies in order to improve patient outcomes and reduce the rate of relapse.

health conditions affecting more than one third of the adult population worldwide. Pain from various mechanisms and origins is currently underdiagnosed and undertreated. The complexity of molecular mechanisms correlating pain and the progression of musculoskeletal diseases is not yet fully understood. Molecular biomarkers for objective evaluation and treatment follow-up are needed as a step towards targeted treatment of pain as a symptom or as a disease. Stem cell therapy is already under investigation for the treatment of different types of musculoskeletal-related pain. Mesenchymal stem cell-based therapies are already being tested in various clinical trials that use musculoskeletal system-related pain as the primary or secondary endpoint. Genetically engineered stem cells, as well as induced pluripotent stem cells, offer promising novel perspectives for pain treatment. It is possible that a more focused approach and reassessment of therapeutic goals will contribute to the overall efficacy, as well as to the clinical acceptance of regenerative medicine therapies. This article briefly describes the principal types of musculoskeletal-related pain and reviews the stem cell-based therapies that have been specifically designed for its treatment.

Key words: Molecular biomarkers; Musculoskeletal pain; Stem cells

Abstract

Musculoskeletal-related pain is one of the most disabling

INTRODUCTION

The musculoskeletal (MSK) system is comprised of the bones, joints, tendons, ligaments and other connective tissues within the body of an organism to provide form, support, stability and movement. The structural and functional integrity of these distinctive parts is crucial for organ functioning, as well as for its integration with other systems. The functioning of the MSK system influences complex inter-system connectivity, including from interactions between physical activity and the environment to interpersonal relationships and social integration. The status of the MSK impacts metabolic activities and overall health in individuals of all ages, as well as functional independence and cognitive preservation in the elderly^[1].

MSK diseases are a group of various acute and chronic traumatic, degenerative, tumoral or congenital conditions affecting one or several components of the MSK system. More than 150 MSK diseases or symptoms have been identified, comprising the most frequent cause of physical disability in the developed world. The global burden of MSK disease is dramatically rising, mainly due to the ageing of the population and incidence of musculoskeletal trauma^[2]. Pain and loss of function are major symptoms associated with MSK disease (Figure 1), which impact quality of life and result in increasing health expenditures that are a major concern at individual, familial and societal levels.

Although current therapies only partially address MSK diseases, regenerative medicine (RM) provides the potential for efficient prevention, early detection, and treatment^[3]. The use of stem cell therapies and stem cell-based tissue engineering offer clinically relevant solutions for the treatment of bone and cartilage defects, osteoarthritis (OA), inflammatory arthritis and tendon injuries^[4]. Moreover, RM provides an opportunity to design therapies that are noninvasive, avoid the use of inert implants, and shorten rehabilitation time^[5]. Although the primary goal of RM is complete structural and functional restoration of MSK tissues and organs, it may not be a realistic one due to the heterogeneous nature of MSK diseases, which include a wide diversity of associated pathologies and co-morbidities. As an example, different stages of OA and the complex situations generated by associated metabolic conditions present as distinct clinical entities. Such cases can be regarded as different forms of the same disease, which should be considered when designing RM therapies rather than aiming for a “one-size-fits-all” solution.

A clearly defined therapeutic goal backed by realistic assessment of individual necessities could help increase clinical applicability of RM interventions. It is known that MSK-related pain ranges from merely a symptom to a disease that solicits specific therapeutic intervention, such as with neuropathic pain in advanced stages of OA, or in OA associated with diabetes mellitus, complex regional pain or entrapment syndromes. Pain treatment should be regarded as a distinct therapeutic goal for functional and

structural rehabilitation of the MSK system. This article briefly describes principal types of MSK-related pain and reviews stem cell-based therapies that are specifically designed for its treatment.

PRINCIPAL TYPES OF MSK-RELATED PAIN

Acute pain

Two of the most common causes of acute pain are MSK trauma or inflammation. Trauma can be isolated or encountered during the onset or flare-up of chronic conditions (such as inflammatory arthritis, OA, or tendonitis). The intensity and duration of acute pain varies, and usually correlates with the intensity and duration of the producing agent. Acute pain has been defined by the International Association for the Study of Pain as “the normal, predicted physiologic response to an adverse chemical, thermal, or mechanical stimulus[...]associated with surgery, trauma, or acute illness^[5].” However, in its severe forms, acute pain needs to be regarded as potentially life threatening^[6,7].

Acute pain is the result of tissue-specific nociceptor activation, sensitization and hyperalgesia. Nociceptors are the sensory receptors activated by injury that have different reactivity levels, and are tissue- and stimuli-dependent. Primary hyperalgesia from trauma or acute inflammation is produced by nociceptor sensitization. Secondary hyperalgesia refers to the increased responsiveness of central nervous system neurons to otherwise normal or subliminal peripheral afferent input, termed central sensitization, resulting in increased pain responses to stimuli that are outside the area of the initial injury^[8]. Acute pain is normally self-limited, and can resolve completely or transform into chronic pain and/or generate immediate or delayed complications ranging from circulation and infection to complex post-traumatic syndromes.

Chronic pain

Chronic pain in the MSK system can occur due to unresolved acute pain, or arise as a distinct phenomenon. Degenerative diseases, tumors of articular cartilage, tendon, ligament or intervertebral discs, typically produce chronic pain of progressive intensity that alternates between periods of spontaneous relief and activation. MSK-related chronic pain particularly impacts the quality of life of the individual and family, as it is commonly associated with loss of mobility, which is the primary impediment to living independently^[8]. Moreover, chronic pain is involved in functional decline, muscle weakness and increased propensity to fall in the elderly^[9]. Individuals of all ages experiencing severe disabling chronic pain report poorer self-rated health, mental well-being and social functioning, and have high levels of depression and work loss^[10].

Chronic pain results from the persistent activation of nociceptors that produce increased release of neurotransmitters in the central neurons located in the dorsal horn of the spinal cord. At the same time, neuroinflammatory

Figure 1 Prevalence of musculoskeletal pain. A: Number of persons affected by musculoskeletal pain (millions); B: Global number of years lived with disability (YLD; millions); C: Causes of disability-adjusted life years (DALY). Data are as of 2010, updated from the Source Global Burden of Disease 2010 Study^[75]. OA: Osteoarthritis; MSK: Musculoskeletal.

peptides, such as substance P and calcitonin gene-related peptide, are released from the nerve endings at the site of injury and/or tissue inflammation and potentiate the inflammatory response^[11].

Neuropathic pain

Both mechanisms of peripheral and central sensitization have been involved in the appearance of a distinct form of chronic pain associated with MSK diseases, neuropathic pain. Neuropathic pain is the direct consequence of a lesion in the somatosensory nervous system^[12], involving tissue-specific nerve endings, medullary dorsal horn neurons, and the peripheral or central neurotransmitter balance. Neuropathic pain is a consequence of disproportionately enhanced intensity from painful stimuli (hyperalgesia) or of altered modality, such as hyperpathia or allodynia (pain produced by otherwise non painful stimulation). MSK-related neuropathic pain can also result from nerve entrapment, complex regional pain syndrome, joint pain associated with diabetes mellitus, and sensory nerve injury in advanced stages of OA^[13].

The assessment and discrimination of neuropathic pain remains difficult and subjective, as it is currently diagnosed from the description of pain characteristics (e.g., “burning”, “aching”, “lancinating”). However, new methods have been described that are designed to measure

peripheral and central pain in subjects with OA, which could allow for objective MSK pain evaluation in clinical settings in the near future. Quantitative sensory testing^[14] and assessment of pain threshold using algometers have been used to demonstrate pain sensitization in OA patients, which is likely due to the increased firing of peripheral nociceptors^[15]. In addition, brain neuroimaging tools, such as functional magnetic resonance imaging or fluorodeoxyglucose positron emission tomography, have been used to observe the activation of brain pain centers in hip and knee OA patients^[16,17].

Pain in the MSK system has distinct characteristics depending on the tissue of origin, such as the various modalities of tissue-specific pain receptor activation. For example, muscle-, tendon- or joint-specific pain receptor activation generates pain of different intensities, duration and therapeutic responsiveness. Improved knowledge about the molecular pathways involved in the generation of different tissue-specific types of pain is important for the design of targeted therapies^[18].

MOLECULAR MECHANISMS OF MSK PAIN

Inflammation plays an important role in the occurrence

of acute and chronic MSK pain. Persistent aberrant inflammation is related on a molecular level to MSK pain produced by peripheral or central sensitization. The proinflammatory cytokines interleukin (IL)-1, IL-2 and IL-6^[19] are associated with different intensities of MSK pain^[20]. Tumor necrosis factor (TNF)- α , a key molecule involved in inflammatory processes in various acute and chronic MSK diseases^[21], is also a pain mediator^[22] that maybe involved in the development of neuropathic pain of MSK origin^[23]. IL-17 has been demonstrated as involved in the development of neuropathic pain in rodent models^[24], and may contribute to neuropathic pain from rheumatoid arthritis as it is present in the synovial fluid of patients and IL-17 knockout mice do not develop collagen-induced arthritis^[25]. Proinflammatory cytokines are also released by microglia (the immune cells of the central nervous system) in response to trauma, infection, inflammation and ischemia, thereby contributing to the immune response as well as to alteration of neuronal function. Neuropathic pain has been shown to result from microglial activation *via* adenosine 5'-triphosphate receptors or persistent stimulation of p38 mitogen-activated protein kinase^[26].

OA pain can effectively be interrupted by local anesthetic treatment or after total joint replacement, suggesting that structures responsible for pain are in contact with the intra-articular milieu^[27]. Synovial tissue is one of the joint components that generate pain *via* several mechanisms. The extensive network of free nerve endings in synovial tissue could be implicated in both inflammatory and neuropathic pain. Increased synovial mononuclear infiltration and overexpression of inflammatory mediators, such as TNF- α and IL-1 β , are implicated in pain production during early stages of OA^[28]. During late stages of OA, the local nerve endings in fibrotic tissue^[29] or within lymphoid aggregates^[30], as well as the increased expression of neuromediators such as substance P and calcitonin gene-related peptide, could contribute to generation of neuropathic pain^[31]. Subchondral bone marrow and marrow cavities of osteophytes contain perivascular and free nerve fibers as well as nerve trunks that could be involved in generating neuropathic pain in advanced stages of OA^[32,33].

Indeed, OA progression has been shown to correlate with pain. A community-based population study found that pain was a predictor of structural and radiographic changes in hip OA; patients with hip pain were more likely to exhibit minimum joint space narrowing and undergo total replacement^[34]. In addition, a lesser degree of knee pain was weakly associated with loss of knee cartilage volume as assessed by quantitative magnetic resonance imaging, but not with Western Ontario and McMaster Osteoarthritis Index scores, joint space width, or levels of urinary biomarkers of cartilage degradation^[35]. However, pain intensity did not correlate with the severity of rotator cuff tear in terms of size, retraction, or superior humeral head migration^[36,37]. In our own experience, severe pain in patients with knee OA and diabetes mellitus is not correlated with radiologic and magnetic resonance

imaging findings (unpublished data) even in the absence of diabetic polyneuropathy or peripheral vascular disease, and advanced stage OA (Kellgren-Lawrence 3) can be detected by radiologic examination in some asymptomatic patients (Figure 2). These findings may be explained by individual differences in pain thresholds, psychological and emotional states, or the presence of comorbidities.

STEM CELLS FOR PAIN TREATMENT

Advancements in stem cell research may provide more effective on-pharmacologic treatment methods for various types of MSK-related pain. Such therapies could reduce or eliminate the need for repetitive drug administration and have longer-lasting effects, thus improving patient quality of life and reducing healthcare costs. To this end, several stem cell types are envisaged as having a potential for immediate clinical application: mesenchymal stem cells (MSCs), induced pluripotent stem cells (iPSCs), and genetically modified stem cells.

MSCs for the treatment of MSK diseases

MSCs or mesenchymal stromal cells are phenotypically heterogeneous populations of adult progenitors of mesodermal origin^[38]. Initially thought to reside only within bone marrow stroma^[39], MSC populations are found in a large variety of mesenchymal (fat^[40], muscle^[41], trabecular bone^[42]) or non-mesenchymal (dental pulp^[43], umbilical cord blood^[44]) tissues. MSCs of various origins have been shown to proliferate into clinically relevant amounts of cells and to differentiate into several specific mesenchymal lineages such as osteoblasts, chondrocytes, tenocytes, and adipose tissue. MSCs are currently being tested in several RM strategies of cell therapy and tissue engineering for the repair/regeneration of MSK tissues. Based on their capability of engraftment, *in vivo* differentiation and integration within the host, MSCs were initially sought for structural repair of damaged or diseased tissue^[45,46]. More recently, MSCs have been shown to exert cytokine-mediated paracrine effects contributing to tissue repair not only by direct participation, but also by means of recruiting local cells to induce repair^[47].

The immunomodulatory properties of MSCs contribute to the restoration of tissue homeostasis when used as a cell therapy^[38]. Moreover, MSCs are considered immune privileged as they express low major compatibility class I molecules but not class II, making them suitable as a source for allogeneic cells^[48]. However, recent reports describe the generation of antibodies against, and immune rejection of, allogeneic-infused MSCs. Although the clinical manifestations are benign, it is not known whether the immunogenicity influences their therapeutic effect^[49]. MSCs are known to modulate allogeneic immune responses by inhibiting maturation of dendritic cells and the proliferation and differentiation of B and T lymphocytes^[50]. MSCs act by decreasing inflammatory cytokines, such as IL-1 β and TNF- α , and by enhancing the amount of anti-inflammatory cytokines released by T cells^[51]. Autologous or allogeneic

Figure 2 Radiologic evidence of asymptomatic Kellgren–Lawrence grade 3 knee osteoarthritis. Bilateral knee anteroposterior (top) and profile (bottom) plain X-rays from a 57-year-old asymptomatic female patient taken during emergency care after a traffic injury.

MSCs have already been used in several clinical trials for the treatment of various MSK diseases, such as bone defects and non-unions, cartilage defects, osteoarthritis, and tendon suture augmentation^[52,53].

MSCs for the treatment of MSK pain

The immunomodulatory properties of MSCs together with their natural capability of homing to the site of injury and inflammation make them attractive for the treatment of post-traumatic or inflammatory pain, and they are currently being used in preclinical and clinical trials for the treatment of various types of MSK-related pain. Proinflammatory cytokines in the serum or synovial fluid has been associated with OA-related pain in animal models^[54], IL-6 and TNF- α in synovial fluid^[55], and TNF- α and IL-1 β in vastus lateralis muscle of late stage OA subjects correlate with the degree of experienced pain or muscle atrophy^[56]. It was suggested that the increased intensity of pain in those with degenerative disc disease compared to those with herniated discs is due to increased levels of TNF- α and IL-8 in the nucleus pulposus^[57].

The use of MSCs as an anti-inflammatory agent is considered an attractive and convenient method for pain relief. In a pilot study, low back pain and disability produced by degenerative disc disease was successfully treated by local MSC infusion, to a degree comparable with surgery

for spinal fusion^[58]. Encouraging interim results have emerged from an ongoing phase 2 trial testing injections of allogeneic MSCs into degenerated lumbar vertebral discs, indicating significant pain reduction and functional improvement when compared to patients treated with hyaluronic acid^[59]. Successful use of MSCs has been demonstrated for OA treatment in animal models^[60], and for prevention of post-traumatic arthritis^[61]. The alteration of intra-articular and serum cytokine levels reported by these studies may provide a basis for a method of pain treatment in both degenerating and traumatized joints.

A systematic review including eight completed studies and a total of 844 procedures of local autologous MSC delivery for the treatment of OA in human indicates that the procedure is safe, with no reported major adverse effects related to implanted cells^[62]. Pain assessed by visual analogue score and functional outcome in 50 knee OA patients were significantly improved by treatment with MSC concentrate (buffy coat) compared with arthroscopic debridement only^[63]. Functional improvement after 24 mo as measured by the American Orthopaedic Foot and Ankle Society's ankle-hindfoot scale was reported after surgical debridement of talar dome defects and local delivery of concentrated bone marrow nucleated cells supported by collagen powder or hyaluronic acid membrane as scaffolds^[64]. Core decompression and local delivery of

bone marrow auto grafts improved Harris Hip scores and significantly reduced the need for arthroplasty when the procedure was performed in patients before the collapse of the joint surface^[65]. Percutaneous delivery of culture-expanded autologous MSCs into OA knee joints resulted in improvement of visual analogue scores, physical therapy assessments, as well as increased cartilage volume^[66]. The same group conducted a safety study on 227 clinical cases receiving intra-articular delivery of cultured MSCs for the symptomatic treatment of various OA joints, and reported three cases of self-limiting cell-related complications as the only safety issues^[67]. No malignant transformations were detected during the two years of follow-up.

A large variability remains among reported methods for MSC isolation, purification and culture expansion. The development of MSC-based therapies requires concerted efforts for the establishment of optimized and standardized protocols for these methods, as well as for cryopreservation and storage of MSCs, which will significantly improve their clinical translation and provide new opportunities for cell-based pain treatment for MSK diseases^[68].

MSCs for the treatment of MSK-related neuropathic pain

Although neuropathic pain is a potentially disabling disease that dramatically decreases quality of life, the complexity of the involved molecular pathways makes it difficult to treat. Neuropathic pain from MSK conditions is often underdiagnosed and undertreated^[69], and when diagnosed, is treated with pharmacologic agents such as antidepressants, opioid analgesics and tramadol, which have a risk for addiction as well as of inducing other side-effects that can interfere with a normal, active life^[70].

Neuropathic pain has been associated with neuro-inflammation and IL-17 signaling in a mouse model of peripheral nerve injury^[24]. Inhibition of TNF- α -induced astrocyte and microglia activation can attenuate neuropathic pain, and IL-6 inhibition was shown to prevent vincristine-induced allodynia in rodents^[71]. In humans, increased biochemical markers of inflammation were found in patients with painful diabetic neuropathy^[72], and neuropathic pain correlates with joint inflammation in knee OA^[13]. In addition, increased levels of IL-1 β and IL-6 were found in cerebrospinal fluid of patients with complex regional pain syndrome^[73].

MSCs have been investigated as anti-inflammatory agents for the treatment of MSK-related neuropathic pain. In a mouse model of streptozotocin-induced diabetes, toll-like receptor 3-primed, immunosuppressive human MSCs^[74] attenuated neuropathic pain behaviors^[75]. Systemically delivered human MSCs also exhibit long-lasting improvement of neuropathic pain in a spared-nerve injury mouse model, observed as decreases in IL-1 β and IL-17, and increases in anti-inflammatory IL-10 and a marker of alternatively activated macrophages in the spinal cord^[76]. These increases in anti-inflammatory cytokines were detected for up to 90 d, demonstrating the lasting effect from a single injection of MSCs.

MSCs have also been examined as neuroprotective

agents in neuropathic treatment. Intravenous infusion of bone marrow mononucleated cells reversed neuropathic pain in rats produced by chronic constriction of the sciatic nerve, though the underlying mechanism of action could not be clarified^[77]. Bone marrow MSCs injected into lumbar dorsal root ganglia of mice with sciatic nerve injury migrated to ganglia on the ipsilateral side and prevented mechanical and thermal allodynia by attenuating injury-induced neuropeptide expression^[78]. In preclinical studies, MSCs were found to have a role in neuroprotection and axonal growth stimulation^[79]. There are several clinical trials underway assessing the safety and efficacy of allogeneic MSCs for the treatment of spinal cord injury^[80]. The potential for MSCs to reverse somatosensory system dysfunction in MSK-related neuropathic pain is still a matter of further investigation.

iPSCs for the treatment of MSK pain

The generation of iPSC populations from adult somatic cells by forced expression of several transcription factors represents a major scientific breakthrough and provides a new tool for RM. Patient-specific iPSCs could be used as autologous cell sources for any RM application by avoiding immune rejection and improving therapeutic specificity^[81]. iPSC technology is being developed for RM application, with the first clinical trial underway in Japan for the treatment of age-related macular degeneration^[82]. However, several important problems still need to be addressed, such as the method of delivery, the efficiency of reprogramming factors, and the genomic stability and epigenetic memory of reprogrammed cells. iPSCs will provide a major contribution to understanding molecular disturbances involved in the production of persistent, recurrent and MSK-related neuropathic pain through the generation of patient-specific disease models. Moreover, patient-specific iPSC-based models of complex neurosensory mechanisms that culminate in the generation of pain may enable the development of new drugs for patient and disease-targeted therapies.

Genetically modified stem cells

Stem cell-mediated gene therapy is regarded as a promising method of gene delivery that could provide long-term therapeutic impact^[83]. Due to their lifespan and homing capabilities, MSCs are appealing tools for sustained gene delivery in various therapeutic scenarios. MSCs can be engineered to express a variety of proteins both *in vivo* and *in vitro* for use in a variety of genetic or acquired diseases. The expression of these therapeutic genes could last the lifetime of the patient, thus dramatically improving quality of life and reducing healthcare costs. MSC-mediated gene therapy for chronic pain management is therefore an appealing avenue for research. *In vitro*, expression of the human preproenkephalin gene by MSCs increased the production of the opioid peptide, met-enkephalin, which could serve as a safe supply for the treatment of opioid-sensitive pain^[84]. Furthermore, hybrids produced by the fusion of opioid-producing chromaffin cells and

MSCs express a catecholamine-producing phenotype, which could be used to generate a clinically significant population of therapeutic cells^[85].

ESTABLISHING ENDPOINTS FOR THE TREATMENT OF MSKDISEASES

MSK-related pain is a widespread, potentially disabling condition for which effective treatments are lacking^[86]. MSK pain can evolve from a symptom to a difficult-to-treat condition. Mechanisms of central sensitization are known to contribute to the maintenance of a local inflammatory microenvironment that aggravates pain and affects regional structure and function. Its roles in the abolishment of biomechanical stimuli necessary for normal tissue maintenance and repair have not yet been fully evaluated. A correlation between muscular atrophy and/or sarcopenia and MSK degeneration has been demonstrated^[87], and MSK pain-related stiffness and muscular atrophy consistently decrease quality of life and interact with reparatory mechanisms. MSK system loss-of-function could be at least partially prevented if pain as a symptom or a disease could be more effectively treated. However, the molecular mechanisms implicated in pain-mediated MSK disease progression remain to be elucidated^[88]. The identification of reliable biomarkers for diagnostic and targeted therapy is a stringent clinical necessity in MSK pain treatment.

RM and the use of stem cells show promise for several chronic non-life-threatening yet disabling conditions such as MSK-related pain. Several ongoing clinical trials are testing various forms of autologous or allogeneic, freshly isolated or cultured MSCs for the treatment of OA^[89], tendon^[90] and intervertebral disc degeneration^[91]. It is therefore possible that therapeutic goals for MSK diseases can be re-established with the availability of more tangible results. Possible strategies such as elimination of local nociceptive stimuli, reversing the mechanism of central sensitization or somatosensory neuroprotection using paracrine effects from local, regional or systemic MSC delivery could prevail over the attempts of recomposing MSK structure.

The large majority of current clinical trials focusing on tissue repair/regeneration have pain reduction as secondary endpoint. From a clinical perspective, it is important to evaluate the long-term safety and efficacy of pain control in disabling MSK disorders. Not only will this allow for accelerated acceptance of such therapies among clinicians and patients, but it will also likely contribute to structural rehabilitation generated by intrinsic mechanisms that resume in the absence of pain. The discovery of pain-related biomarkers will offer a tool for quantitative evaluation of pain and its correlation with degree of structural impairment in various MSK conditions. Furthermore, validation of these biomarkers will provide important therapeutic targets as well as methods for disease evaluation and treatment follow-up.

Abstract

Despite the advances in the hematology field, blood transfusion-related iatrogenesis is still a major issue to be considered during such procedures due to blood antigenic incompatibility. This places pluripotent stem cells as a possible ally in the production of more suitable blood products. The present review article aims to provide a comprehensive summary of the state-of-the-art concerning the differentiation of both embryonic stem cells and induced pluripotent stem cells to hematopoietic cell lines. Here, we review the most recently published protocols to achieve the production of blood cells for future application in hemotherapy, cancer therapy and basic research.

Key words: Hematopoietic stem cells; Progenitor; Induced pluripotent stem cells; Reprogramming; Embryonic stem cells

Core tip: In the past few years, considerable advance has been made possible in the field of cellular therapy, both in its basic and clinically applied form. Stem cells may have important future applications in hematology, with the possibility of supplying the blood needed for transfusion with the use of blood products produced *in vitro*. Thus, in this paper, we summarize the recently established protocols for differentiating both embryonic and induced pluripotent stem cells into blood cells for possible future use for hemotherapy.

INTRODUCTION

Hemotherapy is considered to be the collection of techniques in which whole blood or its fractions are transfused into a patient in order to re-establish hemostasis and to treat certain conditions. It may be carried out using stocked whole blood or by using processed concentrates, red blood cells (RBCs), platelets or plasma, according to the needs of the patient. The blood transfusion, however, is closely related to causing iatrogenic events as a consequence of predictable or unpredictable reasons. Transfusion-related acute lung injury and hemolytic transfusion reaction (HTR) are the more commonly related conditions following blood transfusions which hinder the execution of this procedure with the life-threatening nature of these consequences^[1].

In order to minimize the inherent risks, blood transfusion requires immunological compatibility between the blood of the donor and recipient to avoid HTR and to ensure the therapeutic efficacy of the RBC concentrates. Identifying the blood group-related antigens in the surface of blood cells to be infused and the determination of hematological and immune status of the recipient serum are mandatory procedures before the blood transfusion. Many scientific works have made efforts towards the production of universal RBCs which may be transfused regardless of the antigenic phenotype of the recipient. These efforts tend to focus on management of cells by treating the AB antigens with polyethylene glycol or by erasing the AB epitopes by enzymatic digestion with glycosidase^[2,3]. However, these strategies have limited benefits and do not apply to silencing phenotypes other than the AB antigens or to impose the expression of a specific antigen in the cells.

The previously cited immunological compatibility between donor and receiver is due to the presence of membrane antigens on the donor cells that are bound to elicit an immune response in the receiver. More commonly discussed are the AB antigens that define the ABO group to which the individual belongs, so as to be used as guidance in blood transfusions, and are also aimed at when attempting to diminish eliciting an immune response of donor cells^[2,3]. However, transfusion-related iatrogenesis still happens despite using ABO compatible blood. Considerations about other possible antigens are necessary due to the occurrence of immune response that is not connected to the AB antigens. Thus, the phenotype of antigens of individuals may be classified into two clinically relevant groups, defined according to the frequency in which those antigens appear: public

antigens, the collection of antigens present in the great majority of the population; private antigens, those found in very few individuals^[4]. In order to prevent immune response, it is intuitively necessary to ensure compatibility of the greatest number of antigens possible. Matching donor and recipient bloods correctly would be highly unlikely due to the numerous phenotypes of blood cell antigens, rendering it necessary to perform immunological testing on the serum of the recipient in order to screen for the presence of antibodies against the most common antigens, namely public antigens. However, attainment of RBCs expressing a negative phenotype for a public antigen or a positive phenotype for a private antigen is difficult. Circumvention of this problem may only be done reliably by the installation of worldwide facilities for banking rare bloods^[4], which is logistically complicated and would add high costs to blood transfusions^[5].

It is necessary to consider the context of where the production of blood cells that induce no or less immune response is in order to achieve safety of the blood transfusion processes. The development of *in vitro* protocols capable of generating functional antigen-controlled cells is mandatory, as well as the compilation of those protocols. The use of stem cells characterizes an attempt to engineer blood cells which could serve the purpose of supplying the need of health systems for considerably voluminous amounts of safer blood products for transfusion, as well as for other applications in research that may culminate in future therapeutic protocols, including the production of cancer-targeted lymphocytes. Both embryonic stem cells (ESCs) and induced pluripotent stem cells (iPSCs) have been reported to be successfully differentiated *in vitro* to cells constituting blood products^[6-8].

DIFFERENTIATION OF ESCS TOWARDS BLOOD CELL PRODUCTION

ESCs may provide an inexhaustible and donorless source of cells for human hemotherapy, with the possibility of being indefinitely propagated in appropriate culture conditions. In addition to the proliferation competence of ESCs, these cells also display potentiality to differentiate into all tissues found in an individual, including hematopoietic differentiation. The possibility of manipulating the expression of antigen genes by homologous recombination is another feature that makes ESCs a suitable tool to generate blood cells of interest^[9]. Thus arises great interest in using human ESCs in order to supply the need for blood products. *In vitro* hematopoietic differentiation of ESCs has already been well documented along with the hematopoietic precursors involved, erythroid, myeloid, macrophage, megakaryocytic and lymphoid^[10-17]. Nevertheless, large-scale production of functioning blood cells is still in development. Substantial technological advances have been made in engineering mature hematopoietic tissue from murine ESCs; publications by Kitajima *et al.*^[18] (2003), Kennedy *et al.*^[19] (2003) and Fraser *et al.*^[20] (2003) display the practical aspects of murine cell differentiation^[18-21].

Here we have chosen to review the protocols being established in order to differentiate human ESCs into the various cell lineages of mature blood cells, including the differentiation to megakaryocytes through which platelets may be acquired, as well as to analyze the results obtained by the most recent advances.

Production of erythrocytes

The *in vitro* generation of RBCs is of particular interest as an alternative to classic transfusion in the sense that it could provide cells of a particular phenotype circumventing the problems related to immune response upon transfusion and, in addition, it would diminish the risk of infection by blood-borne pathogens^[22-24]. However, the viability of using the produced cells depends on their functionality and the capability of the method of producing enough quantity of blood product, factors still being developed by ongoing research.

Various protocols intended to achieve satisfactory erythrocytic differentiation of ESCs have been developed. As a consensus, the protocols rely on appropriate culture conditions and the use of cytokines that will be discussed later. Erythropoietin (Epo), responsible for activating anti-apoptotic pathways and stimulating hemoglobin synthesis, and stem cell factor (SCF) act mainly to promote proliferation of the erythroid progenitor cells and seem to be the two central factors in this differentiation^[25]; nevertheless, more recent research has been able to perform erythrocytic differentiation independently of Epo^[26], as detailed later.

The underlying regulatory molecular mechanism involved in the differentiation discussed in this topic requires alteration in expression of transcription factors of the GATA family. GATA1 is closely related to hematopoietic differentiation, including the erythroid lineages, and is mostly expressed during the final steps of the pathway by which RBCs are formed. GATA2, however, is responsible for maintaining the less differentiated status of the cells and proliferating^[27].

Production of erythrocytes via hemangioblasts:

Although extensively investigated, *in vitro* hematopoietic differentiated RBCs were not reported to successfully carry oxygen until the studies by Lu *et al.*^[28] in 2008, in which hemangioblasts were used as an intermediate for differentiation. Despite the success, the RBCs derived from *in vitro* differentiation still displayed structural differences concerning the globin chains expressed in the cells^[28].

Hemangioblasts are considered to be bipotential cells which differentiate into both hematopoietic cells and endothelial cells, placing them as an alternative for generating functional blood cells. Several research groups have already attempted to produce a significant amount of hemangioblasts which could be differentiated to erythrocytes as a final aim with clinical applications^[28-30]. However, the production of hemangioblasts is still considered to be insufficient due to its high costs and low

quantity of cells of interest produced.

In 2007, Lu *et al.*^[31] issued two publications in which a cheaper and significantly more efficient previously established protocol to produce hemangioblasts was detailed and tested. Also, the oxygen-carrying capability of the erythroid cells later produced was tested^[28,32]. The protocol established by Lu *et al.*^[31] is summarized in Tables 1 and 2.

Characterization of the cells produced after the steps in Table 1 displayed that the cells were nucleated and significantly larger than erythrocytes but showed an abundance of hemoglobin, whereas the cells obtained after the protocol in Table 2 were more similar to RBCs when morphologically compared as this protocol promoted enucleation of the cells.

The number of cells obtained with the delineated protocol was 800% higher than in previous studies^[31]. In addition, most of the cells produced expressed the RBC marker membrane proteins and did not express myelomonocytic or megakaryocytic antigens, 75% were CD 71 positive and 30% were CD 253a positive. Moreover, the erythroid cells successfully functioned as an oxygen carrier. Thus, the protocol employed by Lu *et al.*^[31] and summarized in Tables 1 and 2 is an advance in the attempts to produce RBCs.

Production of erythrocytes independently of erythropoietin:

More recently, Kim *et al.*^[26] proposed a method by which a substantially higher RBC production from ESC was possible without the use of Epo as a differentiation inducer^[26].

In this study, erythrocytic differentiation was achieved by transfecting the gene for the F36V-MPL protein with lentiviral vector which consists of the intracellular domain MPL and the drug binding extracellular domain F36V^[33]. The normal MPL protein is activated by thrombopoietin, while a small molecule, AP20187, may also activate the F36V-MPL protein, homodimerizing the MPL domain that activates erythropoiesis. MPL domain activation was found to up-regulate the expression of GATA1, commonly related to differentiation to erythroid cells. Additionally, the protein transduced in the cells does not suffer internalization as a negative feedback mechanism when the ligand binds to the external domain. These cited features show that the protocol used by the group has the capability of producing apparently superior results compared to previous studies^[26].

In the study by Kim *et al.*^[26], differentiation occurred satisfactorily and more efficiently. Globin chain expression and enucleation was higher than in previous studies using Epo, with the conclusion that the homodimerization of the transfected protein intracellular domain is more potent at promoting erythropoiesis than induction with Epo^[26]. Although it signifies a great step forward in the understanding of the underlying mechanisms of this differentiation, the use of lentiviral vectors poses a severe hindrance in its utilization for therapy due to the augmented possibility of malignant transformation of the

Table 1 Steps taken to obtain erythroid cells from human embryonic stem cells by the formation of hemangioblasts

Step-Days	Procedure
1-3.5 prior to step 2	EB formation is stimulated by plating hESCs on ultra-low attachment plates with serum-free medium supplemented with BMP-4, VEGF ₁₆₅ and basic FGF; 48 h later, half of the medium renewed and accreted with SCF, thrombopoietin and FLT3 ligand; EBs are formed and induced to differentiate to hemangioblasts
2-d 0 to 10	EBs formed are dissociated with trypsin and a single cell suspension is obtained; The cells are re-suspended in appropriate medium and further put in contact with BGM with added FGF and t-PTD-HoxB4 fusion protein, where they are expanded for 10 d; The hemangioblasts are expanded enough after this period of 10 d
3- d 11 to 20	Differentiation to erythroid cells may be achieved by culturing the hemangioblasts obtained in step 2 for 5 d with the addition of BGM supplemented with Epo to the medium used in step 2; The cells are then expanded for up to seven more days on Stemline II-based medium supplemented with SCF, Epo and methylcellulose
4-d 21	Erythroid cells obtained after step 3 were suspended in IMDM with 0.5% BSA in order to be collected by centrifugation The cells are washed with IMDM and BSA and normally plated so that non-erythroid cells adhere, allowing the non-adherent to be separated by collecting the medium and centrifugation

hESCs: Human embryonic stem cells; FGF: Fibroblast growth factor; BMP-4: Bone morphogenetic protein-4; SCF: Stem cell factor; BGM: Blast-colony growth media; Epo: Erythropoietin; IMDM: Iscove modified Dulbecco medium; BSA: Bovine serum albumin.

Table 2 Enucleation of Hemangioblasts. The technique here summarized starts by taking the hemangioblasts at the 7th day of step 2, clarified in Table 1

Step	Procedure
1	Hemangioblasts obtained on day 7 of the procedures described in Table 1 are filtered and plated with Stemline II medium supplemented with inositol, folic acid, monothioglycerol, transferrin, insulin, ferrous nitrate, ferrous sulphate and BSA, along with penicillin-streptomycin solution
2	For 7 d, the medium described in step 1 had hydrocortisone, SCF, interleukin-3 and Epo added; Cell density was kept at 10 ⁶ cells/mL
3	After the 7th day, SCF and interleukin-3 were no longer added to the medium
4	The cells were co-cultured with human mesenchymal stem cells or OP9 mouse stromal cells at different days between days 19 and 36; Medium was composed as described in Step 1 with the addition of Epo

SCF: Stem cell factor; Epo: Erythropoietin; BSA: Bovine serum albumin.

transfected cells.

Production of platelets

The genesis of platelets, both *in vivo* and *in vitro*, depends on the formation of the megakaryocytes as an intermediate. Megakaryocytes are polyploidy cells that underwent successive DNA replications without mitosis. Platelets are the result of the maturation of megakaryocytes in which they are fragmented^[34]. Efforts in understanding the dynamics of megakaryocytic differentiation as well as the final maturation to platelets are important in order to make advances in the *in vitro* production of this blood product that may be used for research about platelets and coagulation and eventually for thrombocytopenia treatment.

In 2002, Eto *et al*^[35] described the production of large quantities of megakaryocytes from murine ESCs. The ESCs were co-cultured with OP9 stromal cells and the differentiation was induced by thrombopoietin, IL-6 and IL-11 in order to obtain polyploid megakaryocytes and subsequently pro-platelets. The results were confirmed by the expression of α IIb β 3 and platelet glycoprotein Ib α as the cells obtained could successfully bind to fibrinogen by the α IIb β 3 integrin responding to platelet

agonists. No hematopoietic stem cell, erythrocyte and leucocyte markers were found to be expressed after differentiation^[35].

Years later, further research by Gaur *et al*^[36] managed the production of megakaryocytes starting with human ESCs, which also displayed properties of mature cells, responding to platelet agonists and binding to fibrinogen. Cell culture was also performed with OP9 cells and differentiation was induced by human thrombopoietin^[36].

Although Mks have been successfully produced by successful differentiation of both mouse^[35,37,38] and human ESCs^[12,39-42], a great part of the protocols employed required co-culture with stromal cells, imposing difficulties in determining the exact requirements for direct differentiation of ESC to megakaryocytes.

Production of mast cells

Mast cell differentiation using ESCs has been well documented by Kovarova *et al*^[43,44] since 2001. The process follows three steps: firstly, Ebs are formed after placing the ESCs in ultra-low attachment plates; secondly, the EBs are then transferred to Matrigel-treated plates where induction to differentiation starts by supplementation with SCF, IL-6, IL-3 and Fms-like tyrosine kinase 3 ligand (Flt-

3L) which yields non-adherent hematopoietic progenitors; and thirdly, the progenitors collected in the second step are further differentiated by adding fetal bovine serum (FBS), IL-6 and SCF^[43,44]. Although mast cells are not documented in the literature as prone to transfection, the *in vitro* differentiation of mast cells is relevant in the studies on inflammatory diseases^[44].

Production of macrophages: Mature macrophages can be classified into two groups, M1, which mainly mediate defence against pathogens and inflammatory response, and M2, more connected to wound healing and tissue remodelling. Fetal macrophages present with a M2-like phenotype that accounts for the scar-free wound healing in embryos. Thus, studies have been performed in order to study the properties of ESC-derived macrophages and their applications^[45]. Evidence was found that in spite of the M2 properties *in vivo* in embryos, the macrophages obtained from ESC differentiation do not promote better cutaneous tissue healing^[45]. In spite of these findings, the *in vitro* production of macrophages is still important for providing a cellular model for infections as these cells are the specific hosts for certain pathogens, namely, HIV-1, dengue virus, *Leishmania* and *Mycobacterium tuberculosis*^[46].

van Wilgenburg *et al.*^[46] provided the most recent detailed protocol for macrophage *in vitro* production, rendering the macrophage differentiation protocol more efficient and predictable^[47]. Two protocols were developed by the group: a “quick protocol”, in which EBs were formed by culturing the ESCs on a layer of mouse feeder cells before mechanical dissociation of the bodies that were then cultured on ultra-low attachment plates where differentiation was stimulated by IL-3 and macrophage colony-stimulating factor (M-CSF); and the “defined protocol”, where no feeder layer or serum was applied, EBs were formed by the spinning method^[48] and the medium used was the XTVIVO™ serum-free medium^[45].

Production of T lymphocytes

de Pooter *et al.*^[49] successfully differentiated mouse ESCs into T lymphocyte lineages following the culture conditions previously established by Nakano *et al.*^[50] where the stem cells were co-cultured with OP9 feeder cells and differentiation was induced by the flt-3 ligand and IL-7.

In vitro T-cell differentiation was reported to happen after ESCs were differentiated to hematopoietic stem cells (HSC), as described by Vodyanik *et al.*^[51]. When culturing the ESCs on a feeder layer of stromal cells and supplemented with Flt-3L, IL-7 and SCF, it was possible to attain a substantial number of hematopoietic progenitor cells (HPCs) which were later committed to the differentiated T lymphocytes^[52]. However, a detailed protocol to achieve efficient human T lymphocyte differentiation from ESCs has not yet been devised.

Production of B lymphocytes

In 2003, the production of functional B lymphocytes was described by Cho *et al.*^[53,54]. Flt-3L and IL-7 were

added to the medium on defined days; Flt-3L was added on the fifth day and IL-7 on the eighth day, when pre-B cells were obtained. Fully differentiated and functional B lymphocytes were produced after stimulation with lipopolysaccharide (LPS). The B cells produced expressed the markers that indicate commitment to this lineage, including IgM which had its expression enhanced by LPS stimulation^[54].

In the most recent publication on the subject, the induction of lymphopoietic differentiation of ESCs was found to yield two HPC phenotypes: CD34+CD45RA+CD7- and CD34+CD45RA+CD7+. CD7- had its potential turned more to the production of B cells but could differentiate into natural killer (NK) and T cells, while CD7+ was more likely to generate NK and T cells^[55].

Production of eosinophils

Hamaguchi-Tsuru *et al.*^[56] published a detailed protocol to differentiate eosinophils from murine ESCs and evidence of their functionality in 2004. The differentiation was achieved by cultivating the cells on OP9 stromal cells with stimulation of IL-5 and either IL-3 or granulocyte-macrophage colony stimulating factor (GM-CSF). Eotaxin was also employed in an attempt to differentiate the cells which was only achieved when combined with either IL-3 or IL-5. During the differentiation process, the level of expression of GATA1 transcription factor was found to increase the relationship between GATA1 and hematopoiesis, briefly explained earlier in this review. In addition, the expression of CCAAT binding proteins, IL-3 receptor, GM-CSF receptor and major basic proteins was also augmented^[56].

So far, no definite and detailed protocol has been established for the differentiation of eosinophils from human ESCs.

Production of neutrophils

A neutrophil differentiation protocol was documented and investigated by Lieber *et al.*^[57,58] in which mouse ESCs were used. The differentiation protocol followed was performed in three steps: firstly, ESCs were cultured on an OP9 feeder layer under conditions that elicited EB formation until the 8th day; secondly, the day 8 EBs were dissociated and placed in a new medium with added basic fibroblast growth factor (FGF), IL-6, kit ligand (KL), IL-11 and leukemia inhibitory factor (LIF); and the third step promoted the final differentiation into mature neutrophils by transferring the cells to a new medium supplemented with G-CSF, GM-CSF and IL-6^[57,58].

A neutrophil production protocol for human ESCs was more recently published. EB formation was stimulated by bone morphogenetic protein-4 (BMP-4), SCF, FTL-3L, IL-6, IL-6 receptor fusion protein and thrombopoietin. Further differentiation required G-CSF in order to attain mature neutrophils which expressed the lineage markers^[59].

Production of dendritic cells

Standard well-defined protocols for producing dendritic

Table 3 Summary and comparison of protocols employed for differentiation of embryonic stem cells and induced pluripotent stem cells

Hematopoietic lineage	Culture conditions for ESCs	Culture conditions for iPSCs	Cytokines used in ESC differentiation	Cytokines used in iPSC differentiation	Ref.
Erythrocytes	Cells grown initially on mitomycin-treated Mouse Embryonic Fibroblasts; BGM and Stemline II media are used; Final step was in co-culture with OP9 cells or human mesenchymal stem cells	Cells are grown in co-culture with human fetal liver-derived feeder layer	BMP-4, VEGF ₁₆₅ , FGF, thrombopoietin, FLT-3L, t-PTD-HoxB4 fusion protein, Epo, IL-3	IL-3, SCF, Epo, BMP-4, Insulin-like growth factor-1	[28,31,32,74]
Megakaryocytes	Cells are grown in co-culture with OP9 stromal cells	Feeder-free culture in serum-free Stemline medium or in OP9 or C3H10T1/2	IL-6, IL11 and thrombopoietin	BMP-4, VEGF, FGF, SCF, thrombopoietin, FLT-3L, IL-11	[35,75,76]
Mast cells	Cells are grown in co-culture with OP9 stromal cells	Mice iPSCs were initially co-cultured in on mitomycin-treated Mouse Embryonic Fibroblasts with LIF added. In the final step, OP9 cells were used as feeder layer	SCF, IL-6, IL-3 and FLT-3L	IL-3, IL-6 and SCF	[43,44,77]
Macrophages	Cells are grown in co-culture with OP9 stromal cells, but in an alternative method, no feeder layer was used, EBs were produced by the spinning method	Cells are grown in co-culture with OP9 stromal cells	IL-3 and M-CSF	FGF, BMP-4, VEGF, IL-3, IL-6, IL-11, SCF	[45,78]
T lymphocytes	Cells are grown in co-culture with OP9 stromal cells	Initial culture was done on irradiated SNL76/7 cells and further steps on OP9-DL1 cells	FLT-3L, IL-7 and SCF	FLT-3L, IL-5	[49-52,79]
B lymphocytes	Cells are grown in co-culture with OP9 stromal cells	Cells are grown in co-culture with OP9 stromal cells	FLT-3L, IL-7	FLT-3L, IL-3, IL-7 and SCF	[53-55,80]
Eosinophils	Cells are grown in co-culture with OP9 stromal cells	No established protocol	IL-5, IL-3, GM-CSF and Eotaxin	No established protocol	[56]
Neutrophils	Cells are grown in co-culture with OP9 stromal cells	Cells are grown in co-culture with OP9 stromal cells	BMP-4, SCF, FLT-3L, IL-6, IL-6 receptor fusion protein, thrombopoietin and G-CSF	VEGF, IL-3, SCF, thrombopoietin and G-CSF	[59,81]
Dendritic cells	Cells are grown in co-culture with OP9 stromal cells	Cell culture was feeder free, initially on mTeSR1 medium and posteriorly using X-VIVO 15 medium	GM-CSF, IL-4, TNF- α	BMP-4, VEGF, SCF, GM-CSF, IL-4	[60,61,82]
Natural killer Cells	Cells are grown in co-culture with M210-B4 cells initially and AFT024 cells in the final step	Cells are grown in co-culture with M210-B4 cells initially and AFT024 cells in the final step	IL-3, IL-7, IL-15, SCF and FLT-3L	IL-3, IL-7, IL-15, SCF and FLT-3L	[63,83]

ESCs: Embryonic stem cells; iPSCs: Induced pluripotent stem cells; FGF: Fibroblast growth factor; BMP-4: Bone morphogenetic protein-4; SCF: Stem cell factor; BGM: Blast-colony growth media; Epo: Erythropoietin; BSA: Bovine serum albumin.

cells (DC) from human ESCs are available. The procedure involves formation of EBs on an OP9 cell monolayer and requires the use of GM-CSF, IL-4 and tumor necrosis factor- α (TNF- α) as cytokines to induce differentiation. The process requires the formation of HPC before a final step that gives rise to a mature DC due to the presence of GM-CSF and IL-4^[60,61].

Production of natural killer cells

Natural killer (NK) cells have particular importance in the cytotoxic response of effective immunity. The modulation of these cells has been investigated as they may be useful tools in the treatment of neoplasms, which has been recently been explored^[62].

NK cell differentiation was done by culturing the ESCs initially on a monolayer of M210-B4, a murine bone marrow lineage, as feeder cells. CD34+ and CD45+ were isolated from the first step and differentiated to NK when co-cultured with another feeder cell, AFT024, on medium

supplemented with β -mercaptoethanol, ascorbic acid and the cytokines IL-3, IL-7, IL-15, SCF and FLT-3L^[63].

DIFFERENTIATION OF INDUCED PLURIPOTENT STEM CELLS TOWARDS BLOOD CELL PRODUCTION

iPSCs was the term coined to describe the first cell lineage produced by reverting the differentiated status of somatic cells by using defined factors and four transcription factors were found to be necessary to reprogram fibroblasts, oct-4, Sox-2, Klf-4 and c-Myc^[64]. The cells acquired could successfully differentiate into cells of the three germ lines and resembled the ESCs in several other morphological aspects as well as in the gene expression signature^[64]. The understanding of the underlying mechanisms of cellular reprogramming provided by Takahashi *et al.*^[64] allowed further studies to develop protocols to reprogram other

somatic cell lines and produce iPSCs^[8,65,66]. The advances in the iPSC subsidized studies focused on their use for tissue production through cellular differentiation. Several following works managed to develop differentiation protocols to be applied to iPSCs, including hematopoietic differentiation^[67-69]. Additionally, cellular reprogramming readily encouraged considerable advances in tissue engineering since the development and use of iPSCs is not bound by the same hindrances imposed by the ethical constraints inherent to ESCs^[64].

The differentiation of iPSCs may also circumvent the problems related to immunological incompatibility upon engraftments and transfusion as iPSCs can be produced in a patient-specific manner^[64,70,71]. However, the production of these cells still is highly costly and widely inefficient with the proportion of cells which are successfully reprogrammed. Safety issues also have to be taken into consideration since lentiviral vectors were employed by Raya *et al.*^[68] and most of the following attempts to produce iPSCs. Nevertheless, several steps have been recently taken towards a safer and more efficient production of iPSCs^[64-66].

Considering the lack of ethical hindrances, the possibility of patient-specific cellular reprogramming and the great differentiation potential of iPSCs, they are a great candidate for use in obtaining donor-free blood products^[67-69].

In 2009, Lengerke *et al.*^[72] cultured fibroblast-derived iPSCs under conditions similar to those used for ESC procedures, enabling expansion of a long period. In addition, when differentiation was induced by BMP-4, EB formation was evidenced from the first day and flow cytometry provided evidence of the hematopoietic profile of the cells obtained after day 17^[72].

Protocols for hematopoietic differentiation of iPSCs are currently being devised and tested for functionality and resemble the protocols used in ESCs. The already established protocols for differentiating iPSCs into hematopoietic cell lineages were recently reviewed by Lim *et al.*^[73]. In order to summarize the state-of-the-art on the matter, Table 3 displays the culture conditions and cytokines employed in order to achieve differentiation as well as to compare the protocols used for ESCs.

Apart from the previously stated advantages of employing iPSCs for the production of blood products, the cells obtained with cellular reprogramming technology have been reported as useful tools for progression in the field of immunotherapy.

In 2013, Themeli *et al.*^[84] successfully produced tumor-targeting T lymphocytes by differentiating iPSCs. Differentiated NK cells were also investigated for cancer immunotherapy^[85]. Although little has yet been produced, the available data regarding iPSC aspects of differentiation potential as well as the possibility of using patient-specific cells make iPSCs a promising alternative to generate immunotherapeutic blood products^[86,87].

Besides the applications cited above, the knowledge of cellular reprogramming may also be applied to cancer cells in order to produce iPSCs that can potentially predict the progression of the disease and serve as an *in vitro*

model^[88,89]. Miyoshi *et al.*^[89] published the attainment of cancer stem cells by transfecting defined transcription factors to gastrointestinal neoplastic cells in 2009. More recently, iPSCs were produced starting from pancreatic carcinoma cells^[90]. Considering that pluripotency has also been achieved from hematopoietic somatic cells^[91-93], reprogramming is a promising technology for studying the development of hematological cancers which are of great importance in the population^[94].

CONCLUSION

From what could be perceived from data in the literature, differentiation of blood cells from either ESCs or iPSCs is an on-going field of studies from which various applications can be investigated. Most hematopoietic cells are already being successfully produced from pluripotent stem cells; however, there is an ever-progressing search for more efficient protocols in order to achieve sufficient production in the number of cells for transfusion through a safe protocol that also yields functioning blood cells.

Apart from the enterprise towards acquiring blood products through ESC and iPSC differentiation, the hematopoietic differentiation of these cells can also be applied for other purposes. T and NK cell-based immunotherapy seems to be an alternative to cancer treatment with future applications, as well as the reprogramming of cancer cells that may be of great use in determining the pathways through which carcinogenesis occurs.

Abstract

Reprogramming somatic cells using exogenous gene expression represents a groundbreaking step in regenerative medicine. Induced pluripotent stem cells (iPSCs) are expected to yield novel therapies with the potential to solve many issues involving incurable

INTRODUCTION

In 2006, Takahashi *et al*^[1] established a novel method of reprogramming mouse somatic cells using exogenous expression of genes related to pluripotency. The cell lines established by this group were named induced pluripotent stem cells (iPSCs) and demonstrated the same pluripotency and self-renewal properties that are characteristic of embryonic stem cells (ESCs). The following year, the

same group also succeeded in generating iPSCs from human somatic cells^[2]. These groundbreaking steps have been expected to lead to novel regenerative cell therapies with the potential to solve many problems surrounding incurable diseases. In particular, the clinical application of iPSCs is expected to solve the problems of immune rejection and ethics that are currently key obstacles in the clinical use of ESCs. However, as research into iPSCs has progressed, new problems to solve have emerged before iPSCs can be established as cell sources for patients. In this review, we discuss the current technology and future problems surrounding human iPSC generation methods for clinical applications.

BENEFITS AND PROBLEMS OF ESCS AND IPSCS IN CLINICAL APPLICATION

For treating diseases that lack self-repairing cells, the transplantation of artificially generated cells is one attractive means for curing the diseases. In fact, regenerative cell transplantation therapies have been expected to treat incurable diseases, such as spinal cord injury^[3], neurodegenerative disease^[4], heart failure^[5,6], diabetes^[7], and retinal disease^[8].

ESCs have the capacity to self-renew and differentiate into cells of the three germ layers. The development of suitable cultivation systems for maintaining the pluripotency of ESCs marked their promise as a cell source for regenerative medicine since human ESCs were first generated in 1998^[9]. Numerous efforts have been made since then to realize the promise of making specific differentiated cells from ESCs. However, the ethical problem of needing human zygotes to generate human ESCs has remained unsolved. Additionally, immune rejection remains an issue because of the limited number of ESC cell lines and the ability of the cell lines to match the huge number of human leukocyte antigen (HLA) type combinations found in patients.

These problems with ESCs and the ongoing need for regenerative therapies drove further research efforts, such as Dr. Yamanaka's 2006 success in generating iPSCs from somatic mouse cells^[1] and reports in 2007 by Takahashi *et al.*^[2] and Yu *et al.*^[10] of the successful generation of human iPSCs. In the original mouse work, 24 transcription factors showing high expression in ESCs were chosen as candidate reprogramming triggers^[1]. Finally, the forced expression of *OCT3/4*, *SOX2*, *KLF4*, and *C-MYC* together with a retrovirus evoked mouse somatic cell reprogramming into the pluripotent state, and the same combination of four factors forced human fibroblasts into iPSCs^[2]. At the same time, Yu *et al.*^[10] successfully reprogrammed human fibroblasts using the combination of *OCT4*, *SOX2*, *NANOG*, and *LIN28*. These methods attracted much attention because these iPSC lines could potentially overcome the immune rejection and ethical issues hampering the development of ESCs for clinical use. Therefore, iPSCs showed promise as the breakthrough

technology in regenerative medicine.

COMBINATION OF REPROGRAMMING FACTORS FOR IPSC GENERATION

Since iPSC generation methods were first reported, numerous efforts have been made to adapt them to clinical applications^[5,11]. The reported generation methods vary in the combinations of reprogramming factors, vehicles for exogenous genes, and cell types to generate the iPSCs. Therefore, current discussions in the literature focus on selecting the most appropriate iPSC generation method for clinical use.

In relation to the combination of reprogramming factors for iPSC generation, the first reported combination of *OCT3/4*, *SOX2*, *KLF4*, and *C-MYC*, known as the Yamanaka factors, are generally used for iPSC generation. Combining only three of these factors and omitting *C-MYC* was also reported to achieve successful iPSC generation, although with reduced reprogramming efficiency^[12,13]. These alternative methods arose following concerns about using *C-MYC*, which is a known oncogene in human cells. Another group also reported the generation of mouse iPSCs, which showed more efficient germline transmission in chimeric formation experiments using the combination of *OCT3/4*, *SOX2*, *KLF4*, and *TBX3* as reprogramming factors^[14]. Subsequently, iPSC generation using *L-MYC* instead of *C-MYC* was reported with improved efficiency in both reprogramming somatic cells and germline transmission of generated iPSCs^[15]. Furthermore, *GLIS1* was also reported as a candidate alternate factor for *C-MYC* that showed high reprogramming efficiency, less incomplete reprogramming, and reduced tumor formation in iPSC-derived mice^[16]. Recently, improved iPSC quality was also achieved by introducing *Zscan4*, which is highly expressed at the zygotic genome activation stage. Forced expression of *Zscan4* in combination with the Yamanaka factors improved iPSC quality as demonstrated by tetraploid complementation^[17].

Recently, lineage-specific genes were substituted for *OCT3/4* or *SOX2*^[18]. In this report, *OCT3/4* was replaced with an early mesendodermal lineage marker, such as *GATA3*, and *SOX2* was replaced with an early ectodermal lineage marker, such as *ZNF521*, in reprogramming using the Yamanaka factors. This finding raised the possibility that *OCT3/4* and *SOX2* might act as lineage specifiers for cell reprogramming and showed that reprogramming factors are not limited to genes associated with pluripotency^[18].

Although methods for checking the quality of iPSCs such as germline transmission experiments are not applicable to human iPSCs, such studies can be useful for seeking the best combination of reprogramming factors to generate human iPSCs that are of sufficient quality for clinical use.

GENE-DELIVERY VEHICLES FOR IPSC GENERATION

Gene-delivery vehicles are also an important for selecting a suitable method of iPSC generation for clinical use, and to date, many gene delivery vehicles have proven to be applicable to iPSC generation. Initially, retrovirus vectors, such as pMXs^[2,19,20], pLib^[21] or pMSCV^[22,23], were used for the delivery of reprogramming factors into somatic cells. Importantly, transgenes introduced with retrovirus vectors have been known to be silenced in pluripotent states^[22,24], and therefore, silencing of transgene expression in iPSCs has been thought to be an important result of successful reprogramming^[25]. Lentiviral vectors have also been used for successful iPSC generation because lentiviral vectors achieve a higher efficiency of infection than retrovirus vectors^[10,26]. Importantly, transgenes introduced by lentiviral vectors are more resistant to being silenced in pluripotent states than those transgenes introduced by retrovirus vectors^[27].

The genomic integration of transgenes that occurs as a result of these virus vectors was thought to be a problem for the clinical use of iPSCs because the delivered transgenes have the potential to be reactivated after cell reprogramming and thus drive oncogenesis in the iPSC-derived cells^[28]. Furthermore, these transgenes have the potential to disrupt functional genes, even if they are silenced and not expressed. Therefore, many efforts have been made to generate iPSCs without the genomic insertions. For example adenovirus vectors are routinely used to introduce transient gene expression in target cells. Furthermore, a replication-defective pHIHG-Ad2 vector, was used to successfully reprogram somatic cells into iPSCs^[29]. Therefore, although adenoviral vectors still integrate into the genome of target cells at extremely low frequencies^[30] and the reprogramming efficiency is significantly lower than that with retrovirus, this method generates iPSCs that do not transfer residual transgenes into the host genomes.

More recently, a Cre-deletable lentivirus system was used for the successful generation of iPSCs^[31]. However, although these systems can avoid transgene reactivation, the risk of gene breaks being introduced near the insertion site is present because the LoxP sequence remains in the host genome after removing the insert sequence by Cre recombinase^[32].

In addition to virus vectors, the Sendai virus was also successfully used to generate iPSCs^[33,34]. The Sendai virus genome is negative-sense single-stranded RNA. Because replication occurs in the cytoplasm, this virus vector does not pose a danger of genome insertion. Therefore, this method solves both problems of gene disruption near the insertion site and reactivation of transgenes. Additionally, the residual Sendai virus RNA can be removed from the infected cells using siRNA^[35], and temperature-sensitive mutations^[36] were also reported, improving the potential clinical suitability of this iPSC generation method.

As another approach for safe iPSC generation, a virus-

free reprogramming method has received attention. For example, an iPSC generation method using episomal vectors has also been developed^[37-40]. The early attempts using this method yielded lower efficiencies of successful reprogramming than those achieved using retrovirus, and only a low percentage of iPSC lines generated using this method had no plasmid integration. However, later modifications of the episomal vector method yielded a higher reprogramming efficiency using a combination of plasmids encoding *OCT3/4*, *SOX2*, *KLF4*, *L-MYC*, *LIN28*, and shRNA for *TP53*^[41,42].

Generating iPSCs using a piggyBac transposon was reported as another method to avoid the reactivation of residual transgenes and gene breaks in the host genome^[43-45]. The piggyBac transposon is a moth-derived DNA transposon^[46] that is highly active in mammalian cells and able to be completely eliminated from the host genome using the piggyBac transposase^[47]. Despite generating integration-free iPSCs by this method, the reported reprogramming efficiency was lower than that with retrovirus, and thus further improvements are needed^[43-45].

As another way to avoid introducing genetic material, introducing reprogramming factors such as RNAs or proteins has attracted much attention. Indeed, the direct delivery of synthetic mRNAs has been shown to successfully reprogram somatic cells to a pluripotent state^[48]. In this study, *in vitro* transcribed RNAs were modified to avoid the endogenous antiviral cell defense. As a result, this method achieved a higher iPSC generation efficiency than the original retrovirus system^[48]. Successful reprogramming of somatic cells has also been achieved using microRNAs^[49], whereby expression of the *miR302/367* cluster containing five different miRNAs, *miR302a/b/c/d* and *miR367*, reprogrammed human fibroblasts more efficiently than previous retrovirus systems^[49]. Such RNA-based reprogramming avoids both breaks in existing genes and the reactivation of transgenes. Therefore, these methods hold much promise as novel iPSC generation methods that could be applicable for clinical use.

Similarly, recombinant proteins were also reported as a successful means of gene introduction for generating iPSCs^[50,51]. These protein-based methods are also attractive for clinical application because of the absence of breaks in existing host genes and the reactivation of transgenes; however, the generation efficiencies remain lower compared to those in the existing retrovirus systems^[50,51].

Finally, small-molecule drugs have been investigated for establishing safe methods of iPSC generation for clinical application because they are nonimmunogenic, cost-effective, and easy to handle^[52]. Recently, successful reprogramming of mouse somatic cells without transgene introduction was achieved with small-molecule drug combinations^[53]. This strategy has many merits for applying the iPSC generation method for clinical use, and therefore, further research into applying this method to human somatic cells is expected in the near future.

TYPES OF DONOR CELLS FOR IPSC GENERATION

Generating iPSCs in clinical practice also requires the consideration of the most appropriate type of donor cells. At first, iPSCs were generated from mouse fibroblasts^[1], followed by successful reprogramming of mouse hepatocytes and gastric epithelial cells^[54]. Subsequently, terminally differentiated somatic cells have also been reprogrammed, including mouse B lymphocytes^[55] and pancreatic beta cells^[56]. With respect to human cells, iPSCs have been generated from human dermal fibroblasts^[2,10] and many types of human somatic cells^[5].

As a matter of course, clinical applications of cell therapies require that tissue collection from patients be as minimally invasive as possible, and harvesting human dermal fibroblasts by biopsy leaves a small scar on the patient's body. Recently, iPSCs were generated from human keratinocytes induced from plucked hair, a process that is much less invasive than biopsy^[23,57]. However, several hairs are needed to obtain the successful cell outgrowth of keratinocytes in some cases, and therefore, a more stable protocol for primary culture is needed for routine clinical practice.

Dental tissue has also been proposed as a unique cell source for iPSC generation. Dental stem cells^[58,59] and mesenchymal stromal cells derived from human third molars^[60] were successfully reprogrammed and thought to be potentially useful material for clinical iPSC generation. Oral gingival^[61] and oral mucosa fibroblasts^[62], which can be obtained less invasively, were also investigated for iPSC generation. These methods are advantageous for clinical application because they involve a minimally invasive approach for the patients.

Cord blood was also reported as another cell source for generating iPSCs^[63,64]. Early studies with cord blood yielded lower reprogramming efficiencies than those achieved with lentivirus or retrovirus systems. However, a modified method involving the knockout of p53, which was previously shown to increase the efficiency of reprogramming^[65-70] for iPSCs, increased the efficiency of generating iPSCs from CD34-positive cells which were sorted from cord blood cells^[71]. Additionally, gene introduction using Sendai virus vectors successfully reprogrammed CD34-positive cord blood cells more efficiently than lentiviral or retroviral vector used to reprogram cord blood cells^[36]. Cord blood cells have attracted much attention because cord blood-derived cells do not require laborious mobilization or an invasive biopsy before introducing reprogramming factors. Using cord blood cells for iPSC generation also avoids the risk of transferring over accumulated genetic mutations into iPSC. Additionally, banked cord blood cells are relatively uncomplicated for use in iPSC generation because their immunological information is already available in cord blood banks^[72].

Peripheral blood cells are also an attractive cell source because the method for cell sampling from patients is less

invasive. Peripheral blood cells are more easily accessible as a cell source than the dermal fibroblasts obtained by skin biopsy. In the first study to generate iPSCs from human blood cells, the donor needed to be injected for 3 days with G-CSF to mobilize the CD34-positive cells, and the reprogramming efficiency was not higher than that of previous studies^[73]; however, since then there have been many efforts to effectively generate iPSCs from peripheral blood cells. For example, less invasive methods have since been reported for generating iPSCs from peripheral mononuclear blood cells^[34,74-77], whereby mononuclear blood cells from donors or frozen samples were induced using the Yamanaka factors with a retrovirus^[74,77], lentivirus^[75,76], or Sendai virus^[34]. In these experiments, the majority of iPSCs generated from mononuclear cells had TCR gene rearrangements, indicating that these cell lines were derived from T lymphocytes, and the reprogramming efficiencies with the Sendai virus were similar to those with the previous retrovirus system^[34]. Additionally, to avoid generating iPSCs containing genome rearrangements, methods were developed in which iPSCs were generated from peripheral mononuclear cells cultured under conditions that inhibit the proliferation of lymphocytes^[78,79] and from CD34-positive cells that were mobilized without additional drug administration to the donors^[80]. Sampling of peripheral blood is one of the least invasive procedures available, and therefore, generating iPSCs from peripheral blood could be one of the most appropriate methods for the clinical applications of iPSCs.

REMOVING ANIMAL PRODUCTS FROM CULTURE SYSTEMS

One of the most important issues to address in applying iPSCs to clinical therapy is that the culture systems for generating iPSCs contain animal-derived products with potential and unpredictable risks to patients^[81]. The initial culture system for ESC generation contained fetal calf serum in the culture medium and mouse embryonic fibroblasts as a feeder layer. These animal-derived products conferred a risk of transferring exogenous antigens, unknown viruses, or zoonotic pathogens to the generated cell populations^[9]. Thus, many investigations have been conducted to reduce such risks by establishing animal product-free culture systems for human iPSCs.

First, human-derived feeder cells have proven to be a useful alternative to mouse cells for human iPSC generation^[82]. However, these feeder cell preparations need significant time and effort, and in the case of clinical therapies requiring the mass culture of human iPSCs in some situations, using human-derived feeder cells for culturing human iPSCs is not an optimal strategy. As an option for culturing human iPSCs without feeder cells, Matrigel has proven to be a useful alternative that enables the stable culture of human pluripotent stem cells^[83-85]. Although Matrigel allows the generation of human iPSCs without animal-derived feeder cells^[86,87], Matrigel itself was derived from Engelbreth-Holm-Swarm mouse

sarcoma cells^[88]. Therefore, other types of matrices, such as CellStart^[89,90], recombinant proteins^[91-93], and synthetic polymers^[94,95], which do not contain animal-derived agents, have been tested and used as feeder-cell substitutes for the successful maintenance and generation of human pluripotent cells.

Developing animal product-free medium for iPSC generation is also an important practice for achieving safe therapy using iPSCs. The culture media used in the early generation of human ESCs contained fetal bovine serum^[9]. To remove unpredictable agents that might cause the differentiation of human ESCs, knockout serum replacement (KSR) has now been established as a defined material for maintaining human ESCs^[96] and is also used for human iPSC generation^[2]. Additionally, mTeSR1 medium was developed as a chemically defined medium for maintaining human pluripotent cells and is used for defined condition cultures of human pluripotent stem cells^[97]. However, because KSR and mTeSR1 also contain animal-derived products, new media have now been commercially developed as xeno-free media for maintaining human pluripotent stem cells and have already been used successfully for iPSC generation; these media include TeSR2^[98], NutriStem^[99], Essential E8^[91], and StemFit^[100].

SELECTING THE MOST APPROPRIATE IPSC LINE FOR CLINICAL USE

One of the most intractable problems for applying iPSCs to clinical therapy is the variety of iPSC lines with respect to differentiation tendency and tumorigenic risk. Additionally, the laboratory in which the iPSCs are generated could influence global gene expression patterns of those iPSCs due to small possible differences in the culture conditions^[101]. Therefore, how to select iPSC lines that are appropriate for a specific clinical use in terms of safety and differentiation ability remains a topic of intense discussion.

As described above, in contrast to generating iPSCs with Yamanaka factors, introducing *TBX3*^[14], *L-MYC*^[15], or *GLI1*^[16] instead of *C-MYC* has yielded high-quality iPSCs with respect to the efficiency of germ line transmission and prognosis of iPSC-derived mouse cells. These reports implied that selecting suitable combinations of reprogramming factors was an important consideration for clinical therapy using iPSCs. However, these reports were derived from mouse experiments, and how these findings translate to human iPSCs remains unknown. Of course, the quality index of iPSCs using chimeric formation is not applicable to human iPSCs. Therefore, another index of iPSC quality that is applicable to human iPSCs is required.

With respect to assessing the effects of the type of donor cell on the quality of generated iPSCs, the teratoma-forming propensity of neural stem and progenitor cells derived from mouse iPSCs was shown to differ depending on the donor cell type^[102]. This finding suggested that the quality of the iPSCs should be considered when the type of donor cell is selected. Since that early report, an epigenetic

memory of tissue of origin donor cell type that affected the differentiation tendency of iPSCs was reported^[103,104]. Importantly, the effect of epigenetic memory was not demonstrated when pluripotent stem cells generated by nuclear transfer were used. Additionally, another recent study showed that human iPSCs contain more CpG sites that retain the DNA methylation pattern of the parental donor cells than human ESCs generated by nuclear transfer^[105]. Although the fact that the differentiation tendency derived from epigenetic memory will not remain after long-term culture^[103], these reports also suggested the importance of selecting the donor cell type when applying iPSCs clinically.

The effect of donor cell type on differentiation tendency was also reported in human iPSCs^[106], but experiments that compared donor cell type, gene vehicle type, and volunteers on hepatic differentiation tendencies of iPSCs showed that the differentiation tendency of iPSCs depended on the volunteer from which the iPSCs were generated^[107]. Interestingly, in this latter study, hepatic differentiation tendencies that were derived from donor cells were not observed, implying that such differences derive from the volunteer cell donor when epigenetic memory does not remain after long-term culture.

With respect to the tumorigenic tendencies of human iPSCs, a study of gene expression and DNA methylation in 21 human iPSC lines and 2 human ESC lines showed activated expression of genes containing specific LTR7 sequences in some human iPSC clones that showed a neural differentiation-defective phenotype and formation of teratomas when they were differentiated into dopaminergic neurons and transplanted in mouse brains^[108]. Another report on 21 human iPSC lines and 6 human ESC lines indicated that certain human iPSC clones were in a pro-oncogenic state, as shown by the ectopic presence of secretory tumor tissue during *in vitro* cartilage differentiation^[109]. These reports together implied that a marker foreseeing pro-oncogenic differences in iPSC lines would be required for establishing safe therapy using iPSCs.

AUTO-TRANSPLANTATION AND ALLO-TRANSPLANTATION OF IPSCS

One of the most important advantages expected of iPSCs for transplantation therapy is avoiding immune rejection and therefore avoiding combination immunosuppressive treatment. Indeed, autologous iPSCs were used in the first human clinical trial of iPSCs started by Dr. Masayo Takahashi at the RIKEN Center for Developmental Biology in Kobe in 2013 for treating age-related macular degeneration with iPSC-derived sheets of retinal pigment epithelium. With respect to the immunogenicity of autologous iPSCs, in the first report that aroused discussion on its credibility, immunogenicity showed in the case of iPSCs was not observed in the case of ESCs^[110,111]. Subsequently, experiments with isogenic transplantation of mouse iPSCs revealed the successful engraftment of iPSC-derived tissue without immunosuppressive treatment and

verified the advantages of using auto-transplantation of iPSCs for avoiding immunosuppressive treatment^[112,113]. However, a recent study demonstrated immune rejection upon transplanting autologous undifferentiated mouse iPSCs *in vivo*, and rejection was imperceptible upon transplanting autologous terminally differentiated mouse iPSCs^[114]. Although this report supports the presence of immunogenicity in undifferentiated iPSCs^[91] and conflicts with the successful autologous engraftment of undifferentiated iPSCs in other reports^[93,94], it supports the advantages of using auto-transplantation of iPSC-derived terminally differentiated cells for avoiding immunosuppressive treatment. On another front, whether the immunogenicity in undifferentiated iPSCs contributes to removing contaminated undifferentiated cells from iPSC-derived cell populations and avoiding tumorigenesis after transplantation in the same manner as removing undifferentiated cells from cell populations before transplantation^[115-117] remains to be clarified.

Allo-transplantation of iPSC-derived cells was also expected to provide a useful strategy for transplantation therapy using iPSCs due to saving cost and time in generating autologous iPSC lines for transplantation. Furthermore, as described above, selecting appropriate iPSC lines on a patient-by-patient basis will require significant numbers of studies for verification. Therefore, although the transplantation of iPSC-derived cells from an allogenic donor with foreign HLA requires lifelong immunosuppressive treatment of the recipient, the concept of homozygous HLA-typed iPSC banks may be feasible for achieving generalized therapy using iPSCs^[41,118,119] and, indeed, this type of approach is already progressing^[120].

CONCLUSION

The invention of iPSCs was groundbreaking for novel regenerative medicine and has been expected to lead to regenerative therapies with the potential to advance the treatment and management of incurable diseases. Importantly, iPSCs could overcome the problems of immune rejection and ethics that remain with ESCs. However, each strategy of using autologous or allogenic iPSCs has advantages and disadvantages, and the choice of appropriate strategy may vary depending on the intended use. Additionally, there remain many factors that affect establishing transplantation therapy using iPSCs. To avoid tumorigenesis and establish effective differentiation into the intended cells, further investigation is needed to clarify which iPSC line is the most suitable and how these lines can be best selected.

recover neurological deficits, it is still under development so as not to show significant treatment effects in clinical settings. In this review, we discuss the scientific and clinical basics of adult neural stem cells (aNSCs), and their current developmental status as cell therapeutics for neurological disease. Compared with other types of stem cells, aNSCs have clinical advantages, such as limited proliferation, inborn differentiation potential into functional neural cells, and no ethical issues. In spite of the merits of aNSCs, difficulties in the isolation from the normal brain, and in the *in vitro* expansion, have blocked preclinical and clinical study using aNSCs. However, several groups have recently developed novel techniques to isolate and expand aNSCs from normal adult brains, and showed successful applications of aNSCs to neurological diseases. With new technologies for aNSCs and their clinical strengths, previous hurdles in stem cell therapies for neurological diseases could be overcome, to realize clinically efficacious regenerative stem cell therapeutics.

Key words: Adult neural stem cell; Neurological diseases; Stem cell therapy; Preclinical trial; Clinical trial

Core tip: In this review, we compare advantages and disadvantages of various types of stem cells for regenerative therapy in neurological disease, and discuss the preclinical and clinical developmental hurdles of stem cell technologies. While at present, adult neural stem cells (aNSCs) have clinical advantages, technical issues in the isolation and expansion of aNSCs prevent active preclinical and clinical applications of aNSCs. However, several papers have recently reported scientific breakthroughs, on the basis of which broad application trials using aNSCs could be performed. In this review, we also summarize the current status of preclinical and clinical applications of aNSCs for various neurological diseases.

Abstract

Over the past two decades, regenerative therapies using stem cell technologies have been developed for various neurological diseases. Although stem cell therapy is an attractive option to reverse neural tissue damage and to

Nam H, Lee KH, Nam DH, Joo KM. Adult human neural stem cell therapeutics: Current developmental status and prospect. *World J Stem Cells* 2015; 7(1): 126-136 Available from: URL: <http://www.wjgnet.com/1948-0210/full/v7/i1/126.htm> DOI: <http://dx.doi.org/10.4252/wjsc.v7.i1.126>

STEM CELL THERAPY FOR NEUROLOGICAL DISEASES

Neurological diseases are derived from the loss of functional neurons in the central nervous system (CNS). Although acute localized neurodegeneration could result from a temporal localized injury, such as stroke and trauma, chronic neurodegeneration usually develops over a long period of time, and has unclear multifactorial causes. Functional neurological deficits in chronic neurological diseases originate from either loss of a specific neuronal subtype, or universal brain damage. Alzheimer's and Huntington's diseases result in non-specific death of neurons in the brain, whereas Parkinson's disease is characterized by the specific and localized damage of dopaminergic neurons located in the substantia nigra. In the brain and spinal cord, amyotrophic lateral sclerosis (ALS) and traumatic spinal cord injury induce diffuse motor neuronal loss and localized nonspecific neural tissue damage, respectively. Although these neurodegenerative conditions have unique morphological pathologies, the molecular mechanisms for the neuronal death are complicated and ambiguous, making the development of mechanism-based therapeutic modalities elusive. Since functional loss of neural cells is the common final pathway of various neurological diseases, regardless of specific etiologies, regenerative treatment using stem cells that could repair damaged neural tissue is a viable and non-specific therapeutic option.

TYPES OF STEM CELLS AND THEIR APPLICATIONS TO NEUROLOGICAL DISEASES

Stem cells have two important characteristics: proliferation capacity, and differentiation potential into multiple cellular lineages. According to the source, stem cells can be classified into embryonic, fetal, and adult stem cells (ESCs, FSCs, and ASCs, respectively). Pluripotent ESCs are obtained from the blastocyst of fertilized egg^[1]. ESCs proliferate robustly and have multi-potent differentiation potentials into three germ layer cells, which consist of the whole body^[2]. However, ethical concerns^[3-5], and risks of adverse effects, such as immune rejection and tumor formation^[6] prevent their clinical applications. Recently, it was reported that somatic cells could be reprogrammed into pluripotent state, by overexpression of Oct4, Sox2, Klf4, and c-Myc^[7,8]. Although these induced pluripotent stem cells (iPSCs) maintain the merits of ESCs, iPSCs still

have limitations, such as low efficient generation, and the formation of teratomas or tumors *in vivo*. These critical limitations provoke hesitation in the use of ESCs and iPSCs as clinical therapies. As other sources of stem cells, fetal organs that contain FSCs have been suggested. In spite of the advantages of FSCs, including proliferation capacity, limited differentiation potential, and lack of teratoma formation^[9], ethical problems of using fetal tissues still remain.

ASCs are classically defined as multi-potent cells that originate from various tissues within the adult body, including the bone marrow, skeletal muscle, central nervous system, and adipose tissue^[10,11]. The important benefit of ASCs is possible autologous transplantation, in which stem cells can be primarily cultured from and applied to the same patient. This benefit bypasses the ethical problems that ESCs and FSCs harbour. However, in spite of these advantages of ASCs, their limited differentiation and proliferation ability interrupts their widespread use.

Therefore, in the current status, technical and ethical considerations indicate that compared with other stem cells, ASCs are the most clinically applicable.

ADULT NEURAL STEM CELLS FOR NEUROLOGICAL DISEASES

Among various ASCs, mesenchymal stem cells (MSCs) are the most widely used, and furthest progressed in preclinical and clinical trials^[12]. The strengths of MSCs are relatively simple isolation, and *in vitro* expansion techniques. However, there are concerns about the clinical applications of MSCs^[13]. First of all, in the culture methods of MSCs, bovine serum should be used. Because the dangers of bovine serum have not been well characterized, potential risks in clinical applications still exist^[14]. Although xeno-free culture methods for MSCs have been developed, their quality needs to further study. Moreover, many previous studies suggested that the beneficial effects of MSCs for neurological diseases might originate from their paracrine effects involving immune modulation and/or secretory growth factors, and not from direct neuroregenerative effects producing functional neural cells^[15-17].

Compared to MSCs, NSCs are cultivated and expanded in media containing low, or no bovine serum^[18-22]. Many preclinical studies using NSCs suggest that NSCs not only have beneficial paracrine effects in the regeneration and repair of neural tissue, but also direct differentiation potential into diverse neuronal lineages, to form networks with surrounding neuronal cells^[23-25]. Since the ultimate goal of regenerative treatment for neurodegenerative diseases is the functional repair of damaged neural tissues, NSCs seem to be a more optimal choice for neurological diseases.

Adult NSCs are tissue-resident multi-potent neural progenitor cells that have self-renewal capacity, so long as they

can be maintained undifferentiated. NSCs have the potential, under appropriate culture conditions, to differentiate into multiple neural cells, such as neurons, astrocytes, and oligodendrocytes. NSCs are observed in the developmental stage and mature CNS of mammalian species^[26-29], specifically in the subventricular (SVZ) and subgranular zones (SGZ)^[30-32]. The neurogenic niche surrounding SVZ and SGZ represents a unique microenvironment that regulates the survival and differentiation of NSCs^[28,33].

TECHNICAL HURDLES AND RECENT BREAKTHROUGHS IN THE USE OF ADULT NEURAL STEM CELLS FOR NEUROLOGICAL DISEASES

Depending on the types of neurological diseases, undifferentiated NSCs themselves, or differentiated neural cells, have been applied to verify their efficacy in preclinical animal models. However, *in vitro* expansion of differentiated neural cells to acquire the necessary amount of cells for transplantation is very difficult, because differentiated cells cannot proliferate well. Therefore, regardless of transplantation cell types, aNSCs first need to be properly isolated, and effectively expanded *in vitro*. Compared with other stem cells, such as ESCs, fetal NSCs, and MSCs, aNSCs reside in restricted areas of the adult CNS^[31,32], and have limited capacity to proliferate^[34,35]. Therefore, difficulties in the primary isolation and stable *in vitro* expansion of aNSCs are major technical obstacles to be resolved, for the utilization of aNSCs.

Up to now, several research teams have addressed these difficulties, using various scientific and technical approaches. Surgical samples from the adult CNS are usually very small (1-2 mL). As the number of resident aNSCs within the tissue is also very small, isolation techniques have been optimized to increase the success rate of the primary isolation of aNSCs. To acquire aNSCs, CNS tissues are physically minced, and enzymatically digested into single cells. Among them, the enzymatic digestion is a critical step, because it directly affects the survival of aNSCs. The compositions of dissociating enzymes and incubation times are various among investigators. Papain, trypsin, and collagenase have usually been used, and in some reports, papain dissociation was suggested to be most optimal for the primary isolation of aNSCs^[36,37].

After the mechanical and enzymatic dissociation of CNS tissues, the resulting single cells have been cultured by two alternative methods: the neurosphere, and adherent culture methods. Conventionally, the neurosphere culture method has been used for *in vitro* culture of NSCs^[38-47]. This method was first used in the primary isolation of NSCs from murine brains. The neurosphere culture method was also applied to maintain aNSCs from human brains. However, difficulties in the stable *in vitro* expansion of aNSCs using suspension culture methods resulted in the need for another culture method to be developed.

Moreover, a single neurosphere may not be derived from a single NSC^[48]. The possible heterogenic origin of neurospheres could not guarantee the homogeneity of *in vitro* expanded aNSCs in the suspension culture conditions^[49-51].

To overcome the weak points of the neurosphere culture method, others, as well as ourselves, developed alternative adherent culture methods for NSCs^[18-21,44,52-54]. Each group used their own coating plates to attach NSCs to the plates, and various culture medium compositions. Laminin and poly-L-ornithine (PLO) have frequently been used to coat plates, which increase the adherent efficiency of NSCs. To maintain stemness and proliferation of NSCs, the amount of EGF and basic FGF have been optimized^[55]. For example, we expanded aNSCs from temporal lobectomy samples of epilepsy patients without any neoplastic diseases, on PLO-coated plates in a DMEM/F12 media supplemented with 1% B27, 1% penicillin/streptomycin, EGF (50 ng/mL), bFGF (50 ng/mL), and 0.5% fetal bovine serum (Table 1)^[18]. Using the adherent culture method, aNSCs were expanded *in vitro* from 10⁴ to 10¹² cells within 8 subcultures for 2 mo. Moreover, the expression of Nestin and Sox2 as NSC markers was stably maintained^[18]. If the number of aNSCs required for transplantation is 10⁷ per patient, at least one hundred thousand patients could be treated with a primary culture of aNSCs.

Table 1 summarizes various primary culture and *in vitro* expansion techniques for aNSCs. As indicated in Table 1, major obstacles in the primary isolation and stable *in vitro* expansion of aNSCs have been, or are being resolved, which would increase their clinical applicability.

CURRENT THERAPEUTIC STATUS OF ADULT NEURAL STEM CELLS FOR NEUROLOGICAL DISEASES

Since technical breakthroughs for the preclinical and clinical utilization of aNSCs were introduced relatively recently, scientific results showing treatment effects of aNSCs against neurological diseases are, at present, limited^[18,56-59]. However, many previous reports have indicated that NSCs, compared with other stem cell types, are optimal for neurological diseases, since neural functional recovery requires direct neural cell supplementation, besides indirect paracrine effects. With brief presentation of the current developmental status of stem cell therapeutics for individual neurological disease, Tables 2 and 3 summarize preclinical and clinical results, respectively, of aNSCs against various neurological diseases.

Ischemic stroke

Various human stem cells and their derivatives can differentiate into neurons restoring functional losses in the rodent stroke model^[60,61]. In particular, human ESC-derived NSCs, injected into the ischemic penumbra region in rat brains with ischemic stroke, have been reported to

Table 1 Isolation and *in vitro* culture methods for adult neural stem cells

Culture methods	Cell source	Dissociating method	Media composition	Plate coating	Maximal <i>in vitro</i> culture	Ref.
Adherent culture method	Temporal lobe	Physical Mincing and enzymatic digestion with papain	DMEM/F12 supplemented with 10 ng/mL bFGF, 20 ng/mL TGF α , 2.5 μ g/mL heparin, 2% B27 (without retinoic acid), 10 mmol/L hepes, and 1% FBS			[54]
	Temporal lobe	Mechanical trituration and enzymatic dissociation using papain and DNase I	DMEM/F12 supplemented with 1% B27, 50 ng/mL EGF, 50 ng/mL bFGF, and 0.5% FBS	Poly-L-ornithine	18 passages	[18]
Neurosphere culture method	Hippocampal and lateral ventricle wall tissue	Mechanical dissociation and enzyme digestion using hyaluronic acid, kynurenic acid, and trypsin	DMEM/F12 supplemented with 10 ng/mL EGF, 20 ng/mL EGF, B27, and 2 mmol/L glutamine			[39]
	Temporal lobe	Enzymic digestion with trypsin	N2 medium supplemented with 5% FBS	Poly-2-hydroxyethyl methacrylate		[40]
	Hippocampus Amygdala Frontal cortex Temporal cortex	Enzymic digestion with hyaluronidase, kynurenic acid, and trypsin	DMEM/F12 supplemented with 0.6% glucose, 2 mmol/L glutamine, 3 mmol/L sodium bicarbonate, 5 mmol/L HEPES buffer, 25 mg/mL insulin, 10 mg/mL heparan sulfate, 100 mg/mL transferrin, 20 nmol/L progesterone, 60 mmol/L putrescine, 30 nmol/L selenium chloride, 20 ng/mL EGF, and 20 ng/mL bFGF-2			[41]
	Temporal lobe from 11-wk-old postnatal male Hippocampus, ventricular zone, motor cortex and corpus callosum from and a 27-year-old male	Enzymic digestion with papain, DNase I, and neutral protease	Initially, DMEM/F-12 supplemented with glutamine and 10% FBS After 24 h, DMEM/F12 supplemented with BIT-9500 (bovine serum albumin, transferrin, insulin, 20 ng/mL bFGF, 20 ng/mL EGF, and 20 ng/mL PDGF-AB) and 25% conditioned medium from rat stem cells that produces secretory bFGF and glycosylated form of cystatin C	Fibronectin	More than 70 population doublings in the 11-wk-old postnatal male More than 30 population doublings in the 27-year-old male	[42]
	Temporal lobe	Mechanical dissociation and enzymic digestion with DNase I and trypsin	DMEM/F12 supplemented with 1 mol/L HEPES, 2% B27, 0.1% EGF, and 0.1% bFGF		11 mo	[43]
	Temporal lobe	Enzymic digestion with Papain and DNase I	DMEM/F12 supplemented with bFGF and EGF		3–6 wk	[44,114]
	Lateral ventricular roof	Mechanical dissociation and enzyme digestion with DNase I and trypsin	DMEM/F12 supplemented with bFGF, EGF, and B27		3–7 wk	[45]
	Hippocampus containing hilus, temporal cortex, and subventricular zone including anterior horn and segmented lateral ventricle	Physical mincing and enzyme digestion with trypsin	DMEM/F12 supplemented with N2, 35 μ g/mL bovine pituitary extract, 5% fetal calf serum, 40 ng/mL EGF, and 20 ng/mL bFGF		> 60 population doublings	[46]
	Biopsies from filum terminale below conus medullaris	Physical mincing and enzyme digestion with trypsin	DMEM/F12 supplemented with B27, 10 ng/mL LIF, 10 ng/mL bFGF, and 20 ng/mL EGF	Ultra-low attachment dish		[47]

TGF α : Transforming growth factor alpha; DMEM/F12: Dulbecco's Modified Eagle Medium/Nutrient Mixture F-12; FBS: Fetal bovine serum; bFGF: Basic fibroblast growth factor; EGF: Epidermal growth factor.

move to the lesions, and improve motor performances^[62]. Moreover, human adult temporal lobe-derived NSCs, grafted into the contralateral ventricle of the rat brains with focal cerebral stroke, significantly reduced the

infarction area, and showed recovery of motor function^[18]. When human fetal NSCs were transplanted into ischemic lesions of rodent brains, they migrated toward the injured regions and differentiated into neurons^[63,64].

Table 2 Preclinical results of adult neural stem cells against neurodegenerative diseases

Targeted disease animal model	Cell source	Injection method	Result	Animal species	Ref.
Demyelinated spinal cord injury	Frontal cortex, temporal cortex, hippocampus, and subventricular/subependymal zone of frontal lobe	The midline of the dorsal columns of the spinal cord at three longitudinal sites	The cells elicited extensive remyelination with a peripheral myelin pattern similar to Schwanncell myelination The remyelinated axons conducted impulses at near normal conduction velocities	Rat	[56]
Multiple sclerosis (lyssolecithin-demyelinated brain)	Temporal lobe	Local injection to demyelinated brain regions	Transplanted cells migrated to lesions without extending into normal white matter. Implanted progenitors matured as oligodendrocytes, and developed myelin-associated antigens	Rat	[57]
Global brain ischemia	Temporal lobe	The posterior periventricular region above the hippocampus	Adult human NPCs survived, migrated into ischemic regions, and differentiated into functional neural cells No information about therapeutic effects	Rat	[58]
Global brain ischemia	Temporal lobe	Left hippocampus After <i>in vitro</i> differentiation	Injected cells migrated preferentially into an ischemic lesion, which was mediated by SDF-1 α and CXCR4 signaling pathways No information about therapeutic effects	Rat	[59]
Focal ischemic stroke	Temporal lobe	Contralateral lateral ventricle	Transplanted cells reduced infarction volumes and enhanced motor activity	Rat	[18]

Initial clinical trials with stem cells have been completed in stroke^[61]. Unfortunately, no significant clinical outcomes were observed when autologous MSCs were injected intravenously into ischemic patients^[65]. Although other clinical studies adopting intravenous or intra-arterial administration of autologous bone marrow-derived stem cells in stroke patients are in progress or planning^[23], NSC-based regenerative treatment with both paracrine and neuronal supplementation effects would be more effective. Recently, a clinical trial for stroke with immortalized NSCs generated from human fetal cortex was planned in the United Kingdom^[23], which would yield scientific data that might possibly demonstrate the superior regenerative and treatment activities of NSCs.

Although there are scientific data demonstrating the therapeutic effects of aNSCs on ischemic stroke, aNSCs have not applied to clinical trials for ischemic stroke yet. In contrast, clinical trials using MSCs for ischemic stroke are continuously planned and performed world widely. Compared with MSC clinical trials, the most different feature of NSC trials is the injection route; while MSCs are usually injected intravenously, NSCs are stereotactically transplanted in the brain. Since the penetration of MSCs across brain-blood barrier is still controversial, direct implantation of NSCs into the brain would potentiate the therapeutic effects against ischemic stroke.

Spinal cord injury

Human NSCs transplanted into a mouse model of spinal cord injury were observed to differentiate into neurons and oligodendrocytes to lead the recovery of locomotion^[66]. Treatment mechanism study indicated that neurons derived from transplanted stem cells integrated into the host neuronal circuitry and mediated functional recovery^[19,67]. On the other hand, the functional recovery after NSC transplantation into spinal cord injury models was proportional to the number

of transplanted stem cell-derived oligodendrocytes and the amount of regenerated myelin^[68]. Those preclinical results indicate that the supplementation of mature neural cells by implanted stem cells would also be important in clinical settings, for the functional recovery of spinal cord injury patients.

Highly refined oligodendrocyte progenitor cells (OPCs) generated *in vitro* from human ESCs differentiated into oligodendrocytes, and induced remyelination of the demyelinated spinal cord of mouse^[69]. Based on these observations, a first phase I clinical trial using human ESC-derived OPCs is under planning by the United States company, Geron^[23]. This first clinical trial has raised worries about the risk for tumorigenicity, which is difficult to determine in preclinical situations^[70]. Since the results from animal models could not be directly translated into human, the possible risks need to be further validated. Moreover, utilization of aNSCs, instead of fetal origin stem cells, would reduce the possible tumorigenicity, due to their limited proliferation potential.

Parkinson's disease

Human embryonic mesencephalic tissue which contains many post-mitotic dopaminergic neuroblasts was tried clinically, which have showed proof of concept that regenerative approach could have therapeutic effects in Parkinson's disease (PD) patients^[71]. Dopaminergic neuroblasts for preclinical animal models have been cultured from various different stem cell sources, including ESCs^[72-79], fetal NSCs and precursors of embryonic ventral mesencephalon^[80-83], adult NSCs from the SVZ^[84], bone marrow stem cells^[85], and fibroblast-derived iPSC cells^[86].

Although a small portion of dopaminergic neurons derived from transplanted cells contain disease-specific Lewy bodies 11 to 16 years after transplantation^[87,88], implanted cells remained viable^[23,89]. However, definitive

Table 3 Current clinical trials of neural stem cells against neurodegenerative diseases

Disease	NSC source	Brief title	Trial ID	Condition	Location	Period	Cell source	Route	Phase
ALS	Fetal NSCs	Human neural stem cell transplantation in amyotrophic lateral sclerosis	NCT01640067	Recruiting	Italy	2012-07-09 -2016-09	Fetal neural stem cells	Spinal cord	I
	Adult NSCs	Dose escalation and safety study of human spinal cord derived neural stem cell transplantation for the Treatment of amyotrophic lateral sclerosis	NCT01730716	Enrolling participants by invitation only	United States	2012-11-06 -2014-09	Spinal cord of a single fetus 8 wk of gestation	Spinal cord after laminectomy	II
		Human spinal cord derived neural stem cell transplantation for the treatment of amyotrophic lateral sclerosis	NCT01348451	ongoing	United States	2011-04-28 -2015-12	Spinal cord of a single fetus 8 wk of gestation	Spinal cord after laminectomy	I
Stoke	Commercial NSC	Pilot investigation of stem cells in stroke	NCT01151124	ongoing	United Kingdom	2010-06-09 -2015-03	CTX0E03 DP allogeneic neural stem cells	Putamen region of the brain	I
	Adult NSCs	Pilot Investigation of stem cells in stroke phase II efficacy	NCT02117635	Recruiting	United Kingdom	2014-04-16 -2015-12	CTX0E03 DP allogeneic neural stem cells	Intracranially via stereotaxic	II
SCI	Adult NSC	Safety study of human spinal cord-derived neural stem cell transplantation for the treatment of chronic SCI	NCT01772810	Recruiting	United States	2014-08 -2014-05	Human spinal cord-derived neural stem cell	Direct injections into spinal parenchyma	I
	Adult NSCs	Study of human central nervous system stem cells in Patients with thoracic spinal cord Injury	NCT01321333	Ongoing	Canada, Switzerland	2011-03-21 -2015-05	Human central nervous system stem cells	Thoracic spinal cord	I , II
		study of human central nervous system stem cell transplantation in cervical spinal cord injury	NCT02163876	Recruiting	United States	2014-10 -2017-05	Human central nervous system stem cells	Cervical spine	II

NSCs: Neural stem cells; ALS: Amyotrophic lateral sclerosis; iPSCs: Induced pluripotent stem cells.

successful clinical trials have not yet been reported in the case of human stem cell-derived dopaminergic neurons. In contrast, a group of patients who had embryonic mesencephalic graft showed dyskinesia^[90-92]. Those reports have provoked major concern about the possible side effects of transplanted ESC cell-derived dopaminergic neuroblasts^[77], and the need for safer stem cell sources, such as aNSCs.

Amyotrophic lateral sclerosis

Amyotrophic lateral sclerosis (ALS) is a lethal neurodegenerative disease with premature degeneration of motor neurons in the CNS^[23,93]. For the regeneration and/or supplementation of motor neurons, motor neurons were generated *in vitro* from ESCs^[94-97], fetal NSCs^[98-100], and iPSCs^[101,102].

Recently, transplantation of fetal spinal cord- or iPSC-derived NSCs was reported to be effective in slowing down the disease progression of ALS animal models^[103,104]. Based on the preclinical results, a phase I clinical trial of intra-spinal cord injection of fetal NSCs into ALS patients was attempted in the United States. Clinical outcomes from 6 to 18 mo after the transplantation showed that the intervention did not accelerate disease progress^[105]. In contrast, their

efficacy could not be determined, although higher dose of injection showed better results in some evaluating factors. On-going and/or planned phase II and III clinical trials would further determine the optimal therapeutic dose, and their therapeutic efficacy against ALS^[106].

Until now, there have been few preclinical and clinical trials using aNSCs for ALS. However, ALS could be a good treatment target of aNSCs, having regard to its fatality, and lack of proven therapeutic options for it.

Alzheimer's disease

Alzheimer's disease (AD) is the most frequent neurological disease, which is characterized by the increased amyloid plaques and neurofibrillary tangles in the brain^[107]. Amyloid plaques are extracellular aggregations consisting of amyloid-peptides. Neurofibrillary tangles are intracellular aggregations of hyperphosphorylated tau, a microtubule-associated protein within neuron^[108]. The causative relationship between amyloid plaques/neurofibrillary tangles and AD is still under investigation^[109]. Widespread non-specific neuronal death in the AD brain makes stem cell-based regeneration challenging. For effective cell therapy for AD, NSCs need to migrate to multiple regions

Figure 1 A diagrammatic summary of the approaches/strategies of adult neural stem cells and their pros/cons. aNSCs: Adult neural stem cells.

of the brain and then differentiate into numerous multiple subtype neural cells^[110]. Moreover, the effect of amyloid plaques on the survival, migration, and differentiation of injected stem cells should be taken into consideration^[111].

Human NSCs transplanted into the brains of AD animal models showed little neurogenesis, but unwanted gliosis around the plaque-like structures^[112]. Therefore, stem cell-based regenerative therapies need to be further developed preclinically, before clinical applications to AD. The disappointing preclinical data have resulted in few clinical trials using NSCs against AD. However, MSC is in relative advanced clinical trial stages. For example, human umbilical cord blood-derived MSCs are currently in a phase I clinical trial. Most trials using MSCs hire one-time direct injection of MSCs into the patient's brain. As AD is a progressive disease, long term investigations are necessary, to examine the lasting effects, as well as the safety of transplanted stem cells^[113].

PERSPECTIVES

Based on few scientifically proven treatment modalities for neurological diseases, and the regenerative potentials of stem cells, cell therapies using various stem cells have been preclinically and clinically applied to neurological diseases. There are many controversies about the therapeutic effects of stem cell treatments and their treatment mechanisms. The controversies could be derived from the diverse types of stem cells, and from their unique pros and cons.

Compared with other stem cell sources, aNSCs have several advantages, such as differentiation potential into functional neural cells, limited proliferation capacity, and few ethical problems (Figure 1). Although difficulties in the isolation and *in vitro* expansion of aNSCs prevent the active applications of aNSCs to neurological diseases, the technical obstacles have been continuously resolved. Therefore, at the current status, aNSCs can be attractive stem cell sources, to be introduced into the preclinical and clinical trials targeting various neurological diseases.

Abstract

Recent advances in stem cell biology have shed light on how normal stem and progenitor cells can evolve to acquire malignant characteristics during tumorigenesis. The cancer counterparts of normal stem and progenitor cells might be occurred through alterations of stem cell fates including an increase in self-renewal capability and a decrease in differentiation and/or apoptosis. This oncogenic evolution of cancer stem and progenitor cells, which often associates with aggressive phenotypes of the tumorigenic cells, is controlled in part by dysregulated epigenetic mechanisms including aberrant DNA methylation leading to abnormal epigenetic memory. Epigenetic therapy by

targeting DNA methyltransferases (DNMT) 1, DNMT3A and DNMT3B *via* 5-Azacytidine (Aza) and 5-Aza-2'-deoxycytidine (Aza-dC) has proved to be successful toward treatment of hematologic neoplasms especially for patients with myelodysplastic syndrome. In this review, I summarize the current knowledge of mechanisms underlying the inhibition of DNA methylation by Aza and Aza-dC, and of their apoptotic- and differentiation-inducing effects on cancer stem and progenitor cells in leukemia, medulloblastoma, glioblastoma, neuroblastoma, prostate cancer, pancreatic cancer and testicular germ cell tumors. Since cancer stem and progenitor cells are implicated in cancer aggressiveness such as tumor formation, progression, metastasis and recurrence, I propose that effective therapeutic strategies might be achieved through eradication of cancer stem and progenitor cells by targeting the DNA methylation machineries to interfere their "malignant memory".

Key words: Cancer stem and progenitor cells; DNA methylation; Epigenetic therapy; Aza-cytidine; Aza-deoxycytidine

Core tip: Several types of cancers can be developed from genetic and/or epigenetic instabilities of stem and progenitor cells. Epigenetic abnormality involving dysregulation of DNA methylation has been reported to implicate in cancer aggressiveness. Inhibition of DNA methyltransferase activity by DNA methylation inhibitors has shown promising results toward treatment of myelodysplastic syndrome, a disease associated with leukemic stem cells. This review summarizes evidences which are pertinent to the antitumorigenic potential of DNA methylation inhibitors 5-Azacytidine and 5-Aza-2'-deoxycytidine on cancer stem and progenitor cells including those of leukemia and other solid tumors.

progenitor cells by targeting DNA methylation machineries. *World J Stem Cells* 2015; 7(1): 137-148 Available from: URL: <http://www.wjnet.com/1948-0210/full/v7/i1/137.htm> DOI: <http://dx.doi.org/10.4252/wjsc.v7.i1.137>

INTRODUCTION

The study of stem cell biology, especially that of hematopoiesis, has provided an insight into the biology of cancers^[1,2]. In particular, normal stem cells and cancer cells share one of their characteristics, which is an ability to proliferate without differentiation, the property known as self-renewal. Three concepts of cancer biology are proposed based on the study of hematopoietic stem cells and their tumorigenic counterparts as the paradigm: (1) normal stem cells and cancer cells might possess similar mechanisms to control their proliferation or self-renewal; (2) cancer cells can be derived by differentiation of normal stem cells *via* mutation of transit-amplifying cells or progenitors; and (3) there might be cancer stem cells inside tumors where the tumorigenesis occurred with normal stem cells^[3]. Leukemia, which is the cancers of hematopoietic system, has provided the best evidence that normal stem cells are the target of oncogenic evolution, and that leukemogenesis is driven by cancer stem cells. For example, the tumor initiating cells of myelodysplastic syndrome (MDS), which can develop into acute myeloid leukemia (AML), are cancer stem cells, at least those with genetic deletion of chromosome 5q^[4]. Cancer stem and progenitor cells have been suggested to involve with relapse in many types of cancers^[5-13]. This tumorigenic recurrence of cancer stem and progenitor cells, which often associates with more aggressive phenotypes compared with differentiated cancer cells, can occur *via* accumulation of genetic mutations and/or epigenetic defects leading to selective advantage and hence the oncogenic evolution of cancer stem and progenitor cells.

DEFECTS OF DNA METHYLATION IN CANCERS

Gene expression must be tightly regulated by both genetic and epigenetic mechanisms in non-cancerous normal cells, thereby avoiding malignant transformation. Both genetic- and epigenetic-dependent mechanisms ensure that expression of genes, whose function is involved in cell proliferation, apoptosis, self-renewal and differentiation, is normally controlled in temporal- and spatial-dependent manners. Deregulated epigenetic mechanisms have been shown to implicate in tumorigenesis. One epigenetic mechanism, which has been prominently focused in cancer research, is DNA methylation which also represents one of the most active fields of epigenetic research.

DNA methylation is one of the most common defects in epigenetic regulation observed in tumorigenesis. Earlier studies have suggested that cancer cells possess global DNA hypomethylation, which results in chromosomal

instability^[14]. However, in the past decade most cancer epigenetics studies have paid attention to regulatory region-associated DNA hypermethylation^[15]. DNA hypermethylation of CpG dinucleotides has been well-documented in many types of cancer such as leukemia and colon cancer, and has been proposed as a hallmark of tumorigenesis^[16]. Specifically, DNA hypermethylation at promoters of tumor suppressor- and differentiation-associated genes has been frequently reported. The DNA hypermethylation of those genes then leads to a reduced gene expression, which in turn provides a selective advantage to cancer cells. Thus, down-regulation of the genes by DNA hypermethylation might result in the emergence of cancer stem and progenitor cells^[17,18].

DNA methylation has been widely accepted to mediate malignant memory of cancer cells due to its stable inheritance during cell division. Gene regulatory network specific to cancer stem and progenitor cells might play a direct role in dysregulation of DNA methylation. For example, the pluripotency-associated transcription factors OCT4 and NANOG have been shown to directly up-regulate expression of the maintenance DNA methyltransferase (DNMT) DNMT1 in mesenchymal stem cells^[19]. In fact, maintenance of DNA methylation has been reported to be critical for cancer stem cell properties in leukemic, colon and lung cancer stem cells^[20-22], which might be required to suppress expression of differentiation- and apoptosis-related genes. For instance, *p16* and *MLH1* are frequently hypermethylated in certain types of cancer. Of interesting is *MLH1*, which is a member of DNA mismatch repair pathway. Thus the epigenetic instability of *MLH1* might be a cause of genetic instability of cancer stem and progenitor cells. The epigenetic defects of other genes involved in different pathways related to cell migration, hormone receptors, and cell cycle control, have also been described in tumorigenesis^[18]. Different patterns of DNA hypermethylation have also been found in different types of cancers, which might be explained by cellular function of the cells in respective tissues^[16]. In addition, the pattern of DNA hypermethylation might be influenced by an interaction between DNMTs and polycomb repressive complex 2 (PRC2) protein subunits^[23], since different tumors also have different patterns of PRC2 binding^[17,24,25]. Epigenetic therapy based on DNA methylation inhibitors including 5-Azacytidine (Aza) and 5-Aza-2'-deoxycytidine (Aza-dC) has promised a therapeutic regimen to patients with DNA hypermethylation-induced cancer diseases^[15]. Therefore, understanding how DNMTs transfer a methyl group to genomic DNA, how they function in cancer cells, and how the drugs inhibit DNMT activity is crucial for development of superior anti-cancer therapy.

MOLECULAR MECHANISM UNDERLYING DNA METHYLTRANSFERASE ACTIVITY

DNA methylation is responsible for multiple chromatin-related processes including regulation gene expression by adding a methyl group from S-adenosyl methionine

(SAM) to the C5 position of a cytosine base mostly within CpG dinucleotide context at gene regulatory regions such as promoters and CpG islands. The CpG methylation is catalyzed by DNMTs. Five DNMT family proteins, *i.e.*, DNMT1, DNMT2, DNMT3A, DNMT3B and DNMT3L, have been identified in mammalian genomes^[26]. Among these, DNMT2 does not function as a methyltransferase for DNA but as a RNA methyltransferase^[27,28]. In addition, DNMT3L does not possess the methyltransferase catalytic domain^[29], leaving only DNMT1, DNMT3A and DNMT3B that are functional DNA methyltransferases^[30]. Two mechanisms underlying DNA methylation have been reported. The first mechanism is maintenance DNA methylation pattern, of which all three DNMTs have the ability to copy DNA methylation pattern from DNA template to daughter DNA strand^[31-37]. In one study, Sharma *et al*^[34] have proposed a homeostatic inheritance system for maintenance of DNA methylation, whereby high levels of 5-methylcytosine stabilize DNMT3A and DNMT3B and prevent them from proteolysis^[34]. The second mechanism is *de novo* DNA methylation which can only be performed by DNMT3A and DNMT3B. Apart from repressing gene expression *via* methylation at gene promoters, DNA methylation also plays important roles in many epigenetic phenomena involved in development for example genomic imprinting, X chromosome inactivation and higher-order chromatin organization^[38,39]. Hence, apart from cancers, dysregulation of DNA methylation are also implicated in pathogenesis of many diseases.

Several DNMT domains play important role in the methylation catalysis. Region IV harbors a prolyl-cysteinyl dipeptide that functions as the active site (Figure 1). Regions I and X share amino acid residues, which are critical for binding of SAM. Region V contains glutamyl/asparaginyl residue, which functions to protonate nitrogen 3 (N3) of targeted cytosine during the methyltransferase reaction. The enzymatic mechanism of DNA methylation begins with flipping cytosine out of the DNA helix upon binding with a DNMT. The conformational change of the cytosine nitrogenous base ensures that carbon 5 (C5) of the base aligns at the catalytic pocket with a bound SAM, and that C6 is at close proximity to a cysteine residue at the active site of the enzymes. The base flipping leads to formation of a covalent bond between C6 of the cytosine in DNA and the cysteine residue mediated by nucleophilic attack of sulfhydryl group of the cysteine to the C6 resulting in a change from C5 = C6 double bond into C5-C6 single bond (Figure 2A). The chemical bonding between C6 and cysteine then leads to an increase in electron flow toward C5 position of cytosine. At the same time, a methyl group from SAM is transferred to C5 generating C5-CH₃ of the cytosine and S-adenosyl-homocysteine as the products. The proton at C5 position is then abstracted due to its weak bonding with C5 resulting in β -elimination at the C5-C6 single bond and in the reformation of the C5 = C6 double bond, which return a single electron to the cysteine of DNMT and discharge to the enzyme^[30]. The C5-cytosine is now become methylated giving rise to methylcytosine.

INHIBITION OF DNMTS BY AZA-DC

The ability of Aza and Aza-dC to induce not only cell death but also differentiation had encouraged the exploitation of the compounds for treatment of cancers associated with stem/progenitor cells such as leukemia^[40,41]. Unlike Aza which can be incorporated into both DNA and RNA, Aza-dC is only incorporated into DNA and is therefore a specific inhibitor for DNA but not RNA methyltransferases^[42,43]. Consequently, the difference between the two epigenetic drugs results in differential cellular responses and causes distinct changes in the gene expression patterns of cells treated with Aza-dC and Aza^[44,45].

Intracellular uptake of Aza-dC is mediated by the human concentrative nucleoside transporter 1 HCNT1, also known as SLC28A1^[46]. Once inside cells, Aza-dC is then phosphorylated by deoxycytidine kinase yielding Aza-dCMP. Aza-dCMP is further phosphorylated to Aza-dCDP and subsequent Aza-dCTP, the active substrate form for DNA replication, by dCMP kinase and diphosphokinase, respectively. Hence the irreversible inhibition of Aza-dC on DNA methylation takes place only if Aza-dCTP is used as a substrate by DNA polymerases during DNA replication at S phase of the cell cycle, but not from free Aza-dC itself. Within DNA and with the presence of DNMTs, which bind to genomic DNA, the Aza-dC base can make a covalent bond with a DNMT enzyme (Figure 2B), disrupting the function of the enzyme. Mechanistically, because the nitrogen atom at position 5 (N5) of Aza-dC has a higher electronegativity than C5 of cytosine, the incorporated Aza-dC can covalently trap the DNMT enzyme. A single bond between N5-C6 is formed upon the nucleophilic attack of sulfhydryl group to the C6. However, unlike C5 in cytosine, the N5 can abstract a proton, and hence stably form a single bond to the proton with a strong affinity due to its high electronegativity. The DNMT is therefore trapped with the incorporated Aza-dC through a covalent bond between C6 and the cysteine residue leading to a DNA-DNMT adduct. Thus only in the presence of DNMTs can Aza-dC function to inhibit DNA methylation activity^[47]. At chromatin level, gene reactivation activity of Aza-dC has been mechanistically demonstrated by Jones *et al*^[31]. The authors devised a novel technique called *Accesible/ble*^[48]. They find that approximately 2% of chromatin regions, which are demethylated after Aza-dC treatment in a colon cancer cell line, govern a feature of open chromatin^[48] possibly associated with deposition of the histone variant H2A.Z^[49]. Importantly, they show that of all genes reactivated by Aza-dC treatment, 90% of them possess DNA demethylation and chromatin accessibility supporting the role of the DNA methylation inhibitor as a gene reactivator. Interestingly, many reactivated genes are also tumor suppressor genes^[48].

Several reports have demonstrated that depletion of DNMT1, DNMT3A or DNMT3B can counteract the cytotoxic and apoptotic effect of Aza-dC on treated cancer cells, confirming the essential role of DNMTs in mediating the Aza-dC response^[47,50-52]. In contrast to

the apoptotic response mediated by DNMTs, whether DNMTs also mediate stem cell differentiation induced by Aza-dC is not well understood. Epigenetic therapy by induced differentiation offers an option for treating malignancies, in which cancer tissues contain both cancer stem/progenitor cells and differentiated cancer cells, such as chronic leukemia, teratocarcinoma, and other solid tumors. Thus elucidating how cell differentiation can be triggered by Aza-dC or Aza could have an enormous impact on epigenetic therapy targeting cancer stem and progenitor cells.

INHIBITION OF EPIGENETIC PATHWAYS IN CANCER STEM AND PROGENITOR CELLS

Leukemia

Leukemia is considered to be the prototypical model for development of epigenetic therapy. MDS together with AML have been identified for being diseases of cancer stem and progenitor cells^[4,53], which might contribute to relapse and resistance of chemotherapies. In fact, the DNMT inhibitor Aza is the first epigenetic drug which is approved by the Food and Drug Administration for treatment of MDS. Aza and Aza-dC have initially been shown to induce differentiation of Friend erythroleukemia cells^[54]. In this study, the authors show that Aza-dC has a greater effect on reduction of cell proliferation compared

with Aza when used at the same concentration, which might be associated with an increase in iron uptake and heme biosynthesis^[55]. Later on, Pinto *et al*^[56] have reported the first evidence of Aza-dC as a differentiation inducing agent of primary cells derived from patients with AML^[56]. The differentiation inducing effect of Aza and Aza-dC has proven them to be promising therapeutic approaches aiming at induction of leukemic stem and progenitor cells toward non-malignant differentiated cells^[57,58].

The induction ability of myeloid differentiation by Aza-dC in myeloid leukemic cells correlates with an up-regulation of CD15, myeloperoxidase, lysozyme and the tumor suppressor p15^[59]. Several mechanisms have been proposed to underline Aza- and Aza-dC-induced differentiation of myeloid leukemia. For example, Aza-dC facilitates tumor necrosis factor alpha-induced monocytic differentiation of two AML cell lines NB4 and U937 by demethylation of *DIF2* (also known as *IER3*) promoter and thus up-regulation of the gene^[60]. Similarly, an upstream regulatory element within PU.1 promoter has been shown to be demethylated by Aza leading to an up-regulation of PU.1 and its target genes^[61]. Co-treatment of CD34⁺ cells derived from MDS patients by Aza and granulocyte colony-stimulating factor led to myeloid differentiation^[61]. Another study has shown that Aza-dC induces expression of olfactomedin 4 (*OLFM4*), of which an over-expression led to apoptosis and differentiation HL60 cell line^[62]. Treatment of myeloid leukemia cells with Aza-dC also led to an induction of

Figure 2 Mechanism of DNA methylation and its inhibition by 5-Aza-2'-deoxycytidine via covalent trapping. A: Cytosine methylation by a DNMT is initiated by the formation of a covalent bond between the cytosine base and a cysteine residue at the active site of the methyltransferase. SAM then transfers a methyl group to the cytosine generating a methylcytosine. B: A DNMT is covalently trapped by the DNA-incorporated 5-Aza-2'-deoxycytidine (Aza-dC) adduct. The sulfhydryl group of the cysteine residue at the active site of DNMT forms a covalent bond with C6 of the Aza-dC in DNA. However, the active methyl group from SAM cannot be transferred to Aza-dC by DNMT. This covalent trapping mechanism then leads to a gradual loss of free DNMTs, because they are covalently linked with Aza-dC within DNA. Therefore, the loss of free DNMTs then precedes passive DNA demethylation. Thus cells expressing high levels of DNMTs will respond to Aza-dC at a higher extent compared with cells expressing low levels of DNMTs (see Figure 3). R: Methionine/cysteine; R': Adenosine; Dr: Deoxyribose-5-phosphate; DNMT: DNA methyltransferases.

differentiation-associated genes including the erythroid-lineage transcription factor GATA1, which inhibits proliferation of the cancer cells^[20]. A link between DNA hypermethylation and AML1/ETO-mediated repression of microRNA expression has been suggested as a means to inhibit apoptosis and differentiation of leukemic stem and progenitor cells^[63,64]. In AML and chronic myeloid leukemia cell lines, Aza treatment reactivated expression of microRNA-193a, which suppresses translation of oncogenes including c-kit. Furthermore, an ectopic over-expression of microRNA-193a in primary cells of AML blasts led to apoptosis and differentiation of the cells^[63]. Remarkably, Tsai *et al*^[65] have recently shown that application of Aza or Aza-dC at low and non-acute toxic doses has successfully reduced stem cell characteristics of leukemia and also other cancer stem and progenitor cell lines and of primary tumors, without adverse effects on normal human bone marrow cells^[65]. The low concentrations of the epigenetic drugs can demethylate both CpG island- and non-CpG island-containing promoters, which up-regulate expression of tumor suppressor- and differentiation-associated genes.

Recently, a failure of Aza to eradicate cancer stem and progenitor cells in patients with MDS and AML has been reported^[66]. However, it has yet to be determined the mechanisms underlying this failure in order to improve new strategies of Aza treatment, and to design new drugs and clinical regimes that can completely diminish the cancer stem and progenitor cells of MDS and AML, either through an induction of cell death or

differentiation. Interestingly, tranylcypromine, an inhibitor targeting histone H3 lysine 4 demethylase LSD1 (also known as KDM1A) which is pivotal for maintaining the stem cell state of AML cells^[67], shows a promising result when combined with retinoic acid to induce myeloid differentiation of AML cells^[68]. Therefore, combination therapies between DNA methylation inhibitors, preferentially with low doses^[65], and other molecules which induce apoptosis and/or differentiation of cancer stem and progenitor cells of MDS and AML cells might offer an alternative direction to target the malignant cells in MDS and AML patients.

Although the effect of DNMT inhibitors on cytotoxicity and differentiation of lymphoblastic leukemia is less studied, a recent finding has suggested the role of Aza-dC in induction of apoptosis and differentiation of B-cell acute lymphoblastic leukemia (B-ALL) cell line NALM-6 and T-cell acute lymphoblastic leukemia (T-ALL) cell line CCRF-CEM^[69]. The apoptotic induction by Aza-dC in B-ALL cells might be due to reactivation of *HES5* gene, which has been shown to be hypermethylated in primary B-ALL cells^[70]. Further investigations are needed to ascertain whether Aza and Aza-dC induces differentiation of primary B-ALL and T-ALL cells, and to elucidate mechanisms responsible for the eradication of cancer stem and progenitor cells of B-ALL and T-ALL by DNMT inhibitors.

Medulloblastoma

Medulloblastoma is the most common malignant

brain tumor found in children, and is a disease of cancer stem cells which possess activity of cell signaling pathways resemble to that of embryonic stages of neural progenitors^[71]. Recent genome-wide DNA methylation analyses have suggested that DNA methylation plays a major role in the pathogenesis of medulloblastoma by repression of genes involved in developmental regulation thus avoiding cellular differentiation^[72,73]. In addition, DNA methylation might also be important for medulloblastoma to avoid cell death, since an inhibition of DNA methylation sensitized medulloblastoma cell lines to undergo apoptosis induced by interferon gamma and TNF-related apoptosis-inducing ligand (TRAIL)^[74]. Treatment of medulloblastoma cell lines by Aza-dC has been shown to induce expression of *SPINT2*, which is an inhibitor of hepatocyte growth factor signaling and is hypermethylated in a number of patients with medulloblastoma^[75]. Interestingly, an ectopic expression of *SPINT2* led to a decrease in proliferation, colony survival and cell migration of medulloblastoma cell lines. Moreover, mice transplanted with *SPINT2* over-expressing medulloblastoma cells show a prolonged survival compared with controls suggesting that *SPINT2* functions as a tumor suppressor *in vivo*^[75]. Similar to *SPINT2*, expression of *CRABP2*, which encodes a retinoic acid binding protein, is silenced by DNA methylation in medulloblastoma. Treatment of the cancer cells by Aza-dC restored expression of *CRABP2*, which in turn allowed neuronal differentiation of medulloblastoma cells induced by retinoic acid^[76]. Co-treatment of Aza-dC and the histone deacetylase (HDAC) inhibitor valproic acid also resulted in a reduction of medulloblastoma formation in *Patched* mutant mouse models, and extended survival of the mice^[77]. Thus further preclinical studies on combined therapies using DNA methylation inhibitors and HDAC inhibitors might be worthwhile for treatment of patients with medulloblastoma.

Glioblastoma

While medulloblastoma is the most prevalent brain tumor in children, glioblastoma is the most common and aggressive brain tumor found in adults. The role of DNA methylation in repression of genes involved in differentiation seems to be similar between glioblastoma and medulloblastoma. For example, DNA hypermethylation has been reported at CpG island upstream of *CRABP2*. Inhibition of DNA methylation by Aza-dC treatment in primary glioblastoma resulted in activation of *CRABP2* expression and differentiation of the cells^[76,78]. However, in contrast to medulloblastoma^[74], treatment of glioblastoma stem-like cells by Aza-dC failed to sensitize the cells toward TRAIL-induced apoptosis, although expression of caspase-8 was induced by Aza-dC^[79]. A connection of DNA methylation with p53 pathway has been described, in which Aza-dC treatment led to demethylation at p53 promoter. As the result, p53 then directly binds to the promoter region of the G protein-coupled formylpeptide receptor, and represses its expression leading to differentiation of glioblastoma

cells^[80]. Aza-dC has also been reported to induce expression of microRNA-137, which is involved in anti-proliferation and differentiation of glioblastoma stem cells^[81].

Neuroblastoma

Neuroblastoma has been proposed to develop from undifferentiated neural crest progenitor cells, which possess the potency to differentiate into peripheral neural and mesenchymal lineages^[82]. It is a pediatric cancer, which might be explained by the embryonic origin of neural crest progenitor cells. DNA methylation has been reported to epigenetically silence expression of caspase-8, which is a mediator of apoptosis in neuroblastoma^[83]. Co-treatment of Aza-dC and either chemotherapeutic drugs cisplatin or etoposide induced cell death possibly through caspase-8 reactivation^[84]. In addition, as mentioned above for medulloblastoma^[74], the same study also shows that a combined treatment of Aza-dC and interferon gamma led to apoptotic induction *via* TRAIL pathway in neuroblastoma cell lines^[74]. It would be of interest to further investigate whether Aza-dC and interferon gamma might synergistically and extensively induce differentiation of the cancer progenitor cells as neuroblastoma have been shown to differentiate by Aza-dC treatment^[85,86].

Prostate cancer

Androgen receptor (AR) is an important survival factor in prostate cancer. However, in some cases of prostate cancer, AR can function as a tumor suppressor gene^[87]. The inhibitory role of AR in aggressiveness of prostate cancer is supported by loss of AR expression *via* promoter DNA methylation^[88-91]. Interestingly, expression of AR is also reduced in prostate cancer stem cells particularly with high CD133 expression level^[92]. Treatment of prostate cancer stem cells with Aza-dC led to an up-regulation of AR and a decrease in proliferation and tumor formation. Moreover, Aza-dC treatment also induced differentiation of the cancer stem cells, which is correlated with a reduced expression of stem cell-associated genes *OCT4* and *NANOG*^[92]. Thus, this study suggests that the inhibition of DNA methylation might be clinically translated for patients having prostate cancers with androgen-independent feature.

Pancreatic cancer

Pancreatic cancer stem cells have been shown to be sensitive to Aza-dC, which reduces tumor sphere formation and induces apoptosis of the cancer stem cells through activation of caspase-3 pathway^[93]. The tumor suppressor activity of Aza-dC on pancreatic cancer stem cells is due to its ability to induce expression of microRNA-34, which in turn suppresses expression of the growth factor VEGF-B^[93]. In addition to the apoptotic induction effect, Aza-dC has also been demonstrated to induce differentiation of the pancreatic cancer progenitor cell lines MIA PaCa-2^[94] and PANC1^[95]. Further investigations on how Aza-dC induces differentiation of pancreatic cancer stem and progenitor cells at molecular level are important toward its clinical translation.

Figure 3 5-Aza-2'-deoxycytidine induces apoptosis of human teratocarcinoma stem cells but not their differentiated counterparts. Human nullipotent embryonal carcinoma (EC) cells, the stem cells of teratocarcinoma, are highly sensitive to 5-Aza-2'-deoxycytidine (Aza-dC), which induces apoptosis of the cancer stem cells. On the other hand, OCT4-knockdown differentiated nullipotent EC cells are resistant toward Aza-dC treatment. In human pluripotent EC cells NTERA2, DNMT3B mediates apoptosis induced by Aza-dC, whereas the enzyme mediates differentiation of human ES cells induced by the inhibitor. DNMT: DNA methyltransferases; ES: Embryonicstem; OCT4: Octamer-binding transcription factor 4.

Testicular germ cell tumors

Germ cell tumors (GCTs) with stem cell characteristics comprise of seminoma and non-seminoma, which belong to type II testicular GCTs. Seminoma and non-seminoma have been proposed to develop from carcinoma *in situ*, also known as intratubular germ-cell neoplasia unclassified lesion or testicular intratubular neoplasia, which is the malignant counterpart of gonocytes^[96,97]. Although the human seminoma-like cell line TCam-2 is resistant to Aza-dC even applied at 10 $\mu\text{mol/L}$ ^[98], human embryonal carcinoma (EC) cells, the stem cells of teratocarcinoma, are extremely sensitive to the epigenetic drug of which only 10 nmol/L is sufficient to reduce viability of EC cells. This cytotoxicity of Aza-dC on human EC cells is mediated by DNMT3B, which is a marker of human pluripotent stem cells^[99] and is highly expressed in human EC cells^[51]. Subsequently, DNMT3B has been reported to play a significant role in activation of DNA damage response and expression of p53 target genes induced by Aza-dC in human pluripotent EC cell line NTERA2^[100].

Albeit having the cytotoxic effect on the cancer stem cells, Aza-dC fails to induce apoptosis of differentiated cells derived from human nullipotent EC cells, which can be isolated from teratocarcinoma more frequently than their pluripotent counterparts^[52]. Although human nullipotent EC cells undergo apoptosis induced by Aza-dC, they do not differentiate. On the other hand, Aza-dC induces both differentiation and apoptosis of human pluripotent EC cells and also human embryonic stem (ES) cells. The ability to induce apoptosis of Aza-dC depends on DNMT3B in human pluripotent EC cells but not in their nullipotent counterparts (Figure 3). Similarly, the ability to induce differentiation of Aza-dC in human ES cells also depends on DNMT3B, supporting the role of DNMT3B in facilitating differentiation of human ES cells^[101]. The failure of Aza-dC to induce differentiation of human nullipotent EC cells suggests that mechanism(s) other than DNA methylation is responsible for maintaining the stem cell state of nullipotent EC cells^[102], which

might still possess a remnant of germ cell memory^[103]. Therefore, to effectively eradicate teratocarcinoma comprising of EC cells and their associated teratoma tissues, combined therapies between Aza-dC and agents that target the differentiated cancer cells should be considered.

CONCLUSION

Progresses in an understanding of normal stem cell biology have revolutionized the concept of cancer stem and progenitor cells, which might be the key toward success in treatment of a number of cancer diseases by targeting at cancer stem and progenitor cells. Aza and Aza-dC, although being the drugs currently used for treatment of hematologic malignancy, have held a great promise for treatment of solid tumors^[65]. Future studies on mechanisms underlying differentiation and/or apoptosis induced by Aza and Aza-dC on cancer stem and progenitor cells are required for effective treatment of the epigenetic drugs. Several questions emerge including; (1) Do gene regulatory networks, which are specifically associated with cancer counterparts of stem and progenitor cells, up-regulate expression of DNMTs? (2) Which signaling pathways and their downstream target genes are functionally perturbed by Aza and Aza-dC treatment? (3) Are cell death pathways other than apoptosis involved in the anti-proliferation effect? (4) Are Aza and Aza-dC effective to eradicate cancer stem and progenitor cells in xenograft tumors? (5) In case of relapse, do recurrent cancer stem and progenitor cells evolve a distinct "malignant memory" at epigenomic levels compared with the cancer cells isolated before admission? and, if so, (6) Does the oncogenic evolution lead to more aggressive phenotypes such as a reduced differentiation potential of cancer stem and progenitor cells? Treatments with Aza and Aza-dC can lead to certain toxicity and side effects to hematopoietic, nervous as well as metabolic systems^[104-107]. Nevertheless, they have been recognized as having lower toxicity compared

to traditional chemotherapy. In fact, low-dose treatment of Aza-dC in patients with MDS^[108] and solid tumors^[109] resulted in complete response of the patients. Thus using low-dose DNA methylation inhibitors may provide a safe therapeutic choice^[65] especially for elderly patients^[107,110]. Whether long-termed treatments of low-dose Aza and Aza-dC would perturb fates of stem and progenitor cells without side effects and toxicity in patients have yet to be elucidated. Addressing these questions will not only provide an understanding of cancer stem cell biology but also shed light on development of novel clinical regimes.

Abstract

In facing the mounting clinical challenge and suboptimal techniques of craniofacial bone defects resulting from various conditions, such as congenital malformations, osteomyelitis, trauma and tumor resection, the ongoing research of regenerative medicine using stem cells and concurrent advancement in biotechnology have shifted the focus from surgical reconstruction to a novel stem

cell-based tissue engineering strategy for customized and functional craniofacial bone regeneration. Given the unique ontogenetical and cell biological properties of perinatal stem cells, emerging evidence has suggested these extraembryonic tissue-derived stem cells to be a promising cell source for extensive use in regenerative medicine and tissue engineering. In this review, we summarize the current achievements and obstacles in stem cell-based craniofacial bone regeneration and subsequently we address the characteristics of various types of perinatal stem cells and their novel application in tissue engineering of craniofacial bone. We propose the promising feasibility and scope of perinatal stem cell-based craniofacial bone tissue engineering for future clinical application.

Key words: Craniofacial bone regeneration; Bone tissue engineering; Extraembryonic tissue; Perinatal stem cells

Core tip: Given the unique ontogenetical and cell biological properties of perinatal stem cells, emerging evidence has suggested these extraembryonic tissue-derived stem cells to be a promising cell source for extensive use in regenerative medicine and tissue engineering. In this review, we summarize the current achievements and obstacles in stem cell-based craniofacial bone regeneration and subsequently we address the characteristics of various types of perinatal stem cells and their novel application in tissue engineering of craniofacial bone. We propose the promising feasibility and scope of perinatal stem cell-based craniofacial bone tissue engineering for future clinical application.

INTRODUCTION

The craniofacial bone has an essential role in supporting the adjacent soft tissues, providing anchorage for dental structures, maintaining structural stability for many physical functions and composing the esthetics of the human body. Craniofacial bone defects resulting from various conditions, such as congenital malformation, trauma, osteomyelitis and tumor resection, often lead to large psychomedical burdens as well as difficult reconstructive challenges for both patients and craniofacial surgeons^[1-5]. Current treatments for such skeletal defects often require invasive and technically challenging operations such as alloplastic reconstruction, bone grafting from various anatomic areas like the iliac crest and fibula and microvascular free-flap techniques^[3,4,6-8]. While these procedures have been proven to be reliable and effective, they also result in secondary donor site defects, associated intra- and post-operative complications and extended hospitalization. Furthermore, these techniques were largely limited by the scarcity of donor bone graft volume and patient physical conditions and struggled to restore pre-operative form and function. Suggested by recent clinical studies, stem cell-based bone tissue engineering has been recognized as a promising strategy for both aesthetic and functional reconstruction of craniofacial bone defects^[9-14].

To date, several stem cell sources, such as adult mesenchymal stem cells or mesenchymal stromal cells (MSCs), embryonic stem cells (ESCs) and induced pluripotent stem cells (iPSCs), have displayed promising osteogenic potential *in vivo* and *in vitro* and thus have been proposed as a potential cell source for bone tissue engineering^[9,11-13,15,16]. However, the limitations associated with these stem cell sources are also significant^[13,17-20]. In the last decade, the list of putative human stem cell sources was amended to include human perinatal extraembryonic tissues, such as amniotic fluid, fetal membranes (amnion and chorion) and umbilical cord^[21-23]. Due to their unique ontogenetic relationship to fetal development, the extraembryonic perinatal stem cells represent an intermediate cell type which has recently been described to combine qualities of both their adult stem cell counterparts and ESCs and possess immunoprivileged characteristics, as well as a broad multipotent plasticity^[24-29]. Most importantly, these cells, simply isolated from extraembryonic tissues which are normally discarded after birth, effectively avoid ethical issue involvement. All these attractive characteristics make perinatal stem cells a promising and noncontroversial source of stem cells for extensive use in craniofacial bone tissue engineering (CBTE).

In the present review, we summarize the current research progress on stem cell-based craniofacial bone regeneration and subsequently we address the characteristics of various perinatal stem cells and their novel application in CBTE.

CRANIOFACIAL BONE TISSUE ENGINEERING AND STEM CELLS

Craniofacial bone tissue engineering

As an alternative to surgical reconstruction, multidisciplinary developments in cell and molecular biology, developmental biology, materials science and bioengineering promoted the tissue engineering approach, which was composed of stem/progenitor cells, biocompatible scaffolds and biochemical signals, to regenerate large tissue defects^[30]. The ongoing tissue engineering strategy offers several potential benefits, including the avoidance of secondary donor site defect, reduction of hospitalization and medical burdens and most importantly, the ability to closely restore the normal anatomic structure and function. Among the variety of current tissue regenerative indications based on the tissue engineering strategy, craniofacial bone defect is particularly suited to be tissue engineered. In fact, stem cell-based bone tissue engineering has already entered many preclinical or clinical applications in the craniofacial region.

Adult MSC-based craniofacial bone tissue engineering

Currently, one of the most well-defined and utilized stem cell types in CBTE is the adult MSCs. These stem cells have been isolated and identified from various tissues such as bone marrow, adipose, muscle, dental pulp and periodontal ligament^[9,11,12,14,31,32]. In 2001, Shang *et al.*^[33] showed augmented healing of sheep cranial defects with calcium alginate gel containing autologous bone marrow-derived MSCs (BMSCs). In 2004, Cowan *et al.*^[34] first demonstrated that hydroxyapatite-coated polylactic-co-glycolic acid scaffolds seeded with adipose-derive MSCs (AMSCs) promoted bone regeneration of critical-size calvarial defects using a rodent model^[34]. More recently, a stem cell-based temporomandibular joint (TMJ) condylar bone graft using a tissue engineering strategy was reported, which suggested the possibility of generating an entire articular condyle in the same shape and dimensions of a human TMJ *in vivo*, with both cartilage and bone layers from a single population of MSCs^[35]. These observations were constantly supported in various craniofacial defect models of mouse, rabbit and canine, with the utilization of different MSC and biomaterial scaffolds^[9,11,12,14,36-42]. In clinical experiments, autologous BMSCs were seeded onto bioscaffolds and transplanted to repair the mandible or alveolar defect in patients and showed satisfied ossification at the regenerated site in terms of both esthetic and functional outcome^[10,43-45]. In 2009, Mesimäki *et al.*^[46] reported the first use of a microvascular custom-made ectopic bone flap developed from a preformed titanium cage filled with autologous AMSCs, β -tricalcium phosphate (β -TCP) granules to reconstruct a maxillary defect. Most recently, Thesleff *et al.*^[47] described a novel method to reconstruct critical-sized calvarial defects of adult patients using autologous AMSC and β -TCP granules, providing evidence that AMSCs combined with β -TCP can be used

to regenerate calvarial bone, with favorable clinical results. Although there have been many reports of preliminary success using adult MSCs both in the laboratory and clinic for craniofacial bone regeneration, these stem cell sources are still significantly limited by their scarcity, invasive cell collection and cell aging^[15,16,19,48].

Pluripotent stem cell-based craniofacial bone tissue engineering

After the revolutionary discovery and characterization of ESCs and iPSCs, further advances have been made towards applying bone tissue engineering methods with these promising pluripotent stem cells^[15,16,19,20,49]. Harkness *et al.*^[50] reported a subpopulation of fibroblast-like ESCs which showed up-regulation of osteogenic specific markers and production of extracellular mineralization when cultured in osteogenic induction medium. The implantation of these cells in a critical-sized calvarial defect of immune deficient mice resulted in promoted new bone formation and partial repair of the calvarial defect^[50]. More recently, Ye *et al.*^[13] demonstrated de novo osteogenesis of iPSCs within a critical-sized calvarial bone defect^[13]. However, the application of ESCs and iPSCs in craniofacial regeneration are still at a preliminary stage and significantly limited by controversial political and ethical concerns, as well as genomic instability, tumorigenesis and immune rejection^[16-18]. The drawbacks of these stem cell types may restrict their utility and performance in further clinical practice, prompting increasing interest in alternative stem cell sources for bone tissue engineering.

PERINATAL STEM CELLS

Perinatal stem cell research has been attracting mounting interest worldwide in recent years. Various populations of stem cells, most of which are comprised within the category of mesenchymal stem cells, have been isolated from different extraembryonic-associated tissues.

Amniotic fluid-derived stem cells

Amniotic fluid (AF) is the nourishing and protective liquid located within the fetal sac throughout the gestational stage which contains heterogeneous cells originating from embryonic and extraembryonic tissues^[51,52]. Previously, cells obtained from AF were mostly used for diagnostic purposes, such as sex determination, detection of fetal infections and genetic diseases. During the last decades, different groups of researchers have provided evidence that human amniotic fluid could be a pool of stem cells. In 2003, Prusa *et al.* demonstrated that a distinct subpopulation of cells expressing OCT4, a key transcript factor for pluripotent human stem cells and preventing differentiation of stem cells, can be found in human amniotic fluid. In the same year, In't Anker *et al.*^[53] demonstrated that human amniotic fluid contained a fibroblast-shaped cell population positive for mesenchymal markers such as CD90, CD105, CD73 and CD166 but negative for the hematopoietic markers such as CD45, CD34 and CD14^[53]. Notably,

De Coppi *et al.*^[54] successfully isolated a multipotential subpopulation of stem cells in the amniotic fluid by fluorescence-activated cell sorting for c-kit positive cells. These amniotic fluid-derived stem cells (AFSCs) maintain a round shape for 1 wk after isolation and begin to change to a fibroblastoid morphology from the second week. Long term culture shows a high self-renewal capacity of these cells with > 300 population doublings, far exceeding Hayflick's limit. The doubling time of the undifferentiated cells is noted to be 36 h, with little variation during passaging. Analysis of stem cell markers shows that the AFSCs express pluripotent markers SSEA4 and OCT4, as well as typical mesenchymal markers, but they did not express the full complement of pluripotent markers, such as SSEA1, SSEA3, TRA1-60 or TRA1-81, indicating that AFSCs are not as primitive as ESCs and yet maintain greater potential than most adult MSCs^[54-56]. Later, the existence and multi-differentiation capabilities of AFSCs into cells and tissues from all three embryonic germ layers was widely confirmed by various independent reports^[54,57-63]. Promising results in terms of structural and functional outcomes highlight the true clinical potential of AFSCs in cell-based therapies and tissue engineering perspectives.

Amnion-derived stem cells

The amniotic membrane is the innermost fetal layer of the placenta which lines the amniotic cavity and assures the normal growth and development of the fetus during gestation. Normally, two types of stem cells can be isolated from the amniotic membrane through mechanical separation and the subsequent enzymatic digestion, namely amniotic epithelial cells (AECs) and the amniotic mesenchymal stem cells (AMMSCs)^[64]. What makes these cells especially attractive is that large amounts can be isolated from an uncontroversial material that is usually discarded after birth. AECs, developing from the central region of the epiblast, build a single layer adjacent to the amniotic fluid and display a cobblestone-like epithelial morphology^[64,65]. While AECs reside in the innermost layer of the amnion, AMMSCs differentiated from somatopleuric mesodermal cells reside in the stromal matrix of the amniotic membrane and exhibit a fibroblastoid morphology^[66-68]. Given their different ontological and cell biological characteristics, subpopulations from both cell types have been confirmed to express a wide range of pluripotency markers, such as OCT4, SOX2, SSEA4, SSEA3, as well as typical mesenchymal markers^[65-70]. Further *in vitro* and *in vivo* studies confirmed their multilineage differentiation potential into cells derived from all three germ layers, such as neuron-like cells, cardiomyocytes, chondrocytes, osteocytes and hepatocytes^[69,71-81]. Most importantly, the immunomodulatory capacity and immunoprivileged status of amnion-derived stem cells make them a promising candidate for allogeneic transplantation and stem cell based therapies^[2,25-27,82-91]. However, standardized collection, quality control and further preclinical and clinical research are still needed before safe amnion-derived stem cell banking products can be achieved^[92].

Chorion-derived mesenchymal stem cells

The chorionic membrane of human term placenta is a rich source of stem cells from which mesenchymal stem cells from chorionic villi and chorionic plate can be isolated^[24,93]. Notwithstanding the potential contamination of decidual maternal stem cells suggested by many studies of term chorionic cells with both fetal and maternal origin, or even pure maternal origin cells only, previous studies of these chorion-derived mesenchymal stem cells (CMSCs) have been focused on primary isolation and limited cell characterization^[24,66]. Like their stem cell counterparts from the placenta, CMSCs participate in placental tissue generation, maintenance, repair and possess a intermediate phenotype of adult MSCs and pluripotent stem cells^[93-95]. *In vitro*, the CMSCs have been reported to be more primitive than adult MSCs with evidence of greater self-renewal and potential to differentiate beyond mesenchymal cell lineages to other lineages such as hepatocyte-like cells and neuron-like cells^[24,93,95-98]. *In vivo*, the CMSCs have recently been reported to have a therapeutic effect on liver injury and osteogenesis imperfecta through not just direct hepatocyte and osteocyte differentiation, but also secretion of cytokines and inhibition of donor cell apoptosis^[97,98]. Very recently, Jones *et al.*^[99] reported that CMSCs isolated from first trimester but not term human placenta accelerated tissue repair in dermal excision skin wounds and improved bone quality and plasticity in osteogenesis imperfecta of mice. Interestingly, the first trimester CMSCs showed an earlier state of stemness, such as smaller size, faster kinetics, unique formation of embryoid bodies and higher expression levels of NANOG, SOX2, c-MYC and KLF4, than its term isolated counterparts. However, collection of CMSCs in the first trimester is technically challenging and usually requires early termination of pregnancy, an ethical obstacle to clinical applications.

Umbilical cord-derived mesenchymal stem cells

The umbilical cord (UC) is an elastic cord that connects the fetus to the placenta during pregnancy. Anatomically, the UC consists of two umbilical arteries (UA) and one umbilical vein (UV) embedded in a mucous connective proteoglycan-rich matrix called Wharton's jelly (WJ). Since more than a decade ago when two independent teams reported their successful isolation of mesenchymal like cells from porcine and human umbilical cord respectively^[100,101], there has been increasing interest in studying the potential of umbilical cord-derived mesenchymal stem cells (UCMSCs) for regenerative medicine. Generally, UCMSCs have been reported to be isolated from different parts of the UC such as UA, UV, WJ, umbilical-lining membrane and umbilical cord blood (UCB)^[102]. Based on the optimized methods to isolate, culture and cryopreserve human UCMSCs, a human UC-MSC bank complying with good manufacturing practices has been established^[103]. Given the controversy that exists on whether UCB or umbilical vessel-derived MSCs can be isolated, MSCs isolated from these various parts of UC have been shown

to resemble adult BMSCs while retaining some specific characteristics. *In vitro*, UCMSCs appear with a fibroblastoid morphology and display a greater expansion capacity and faster doubling time than adult BMSCs. Their morphology and proliferative characteristics did not change even after 30 passages^[100,101]. These cells consistently express typical mesenchymal markers as well as α -smooth muscle actin and low levels of pluripotency markers, such as Oct4, Sox2 and Nanog^[100,104,105]. Moreover, UCMSCs express a lower level of HLA-ABC than BMSCs and were negative for CD31, CD34, CD45, HLA-DR, CD80 and CD86^[106]. *In vitro* and *in vivo* studies confirmed their multi-differentiation potential of mesodermal lineages, such as osteocytes, chondrocytes and cardiomyocytes, as well as other lineages such as neuron-like cell and hepatocytes^[100,107-111]. Most importantly, UCMSCs possess immunomodulatory effects *in vitro* and *in vivo* and have been shown to be well tolerated in allogeneic transplantation experiments^[28,106,112]. Promising results of preclinical and clinical studies using UCMSCs for treatment of liver fibrosis, systemic lupus erythematosus, Sjogren's syndrome and GVHD have been reported which will further promote the therapeutic application of UCMSCs in cell-based regenerative medicine^[112-115].

APPLICATION OF PERINATAL STEM CELLS IN CRANIOFACIAL BONE TISSUE ENGINEERING

Due to their same ontogenetic origin, perinatal stem cells isolated from different extraembryonic tissues possess similar phenotypic and functional properties. In fact, AFSCs, AECs, AMMSCs, CMSCs and UCMSCs have been shown to exhibit osteogenic differentiation capacity both *in vitro* and *in vivo*^[77,93,97,116-119]. In limited comparative studies, perinatal stem cells such as AFSCs and UCMSCs have been shown to display lower basal levels of bone-related genes, higher proliferation rate and much later senescence than BMSCs, resulting in a delayed but robust osteogenic differentiation capacity, which render them a promising candidate for cell banking and stem cell-based bone tissue engineering^[120-122].

In face of the mounting clinical demand and suboptimal techniques for craniofacial skeleton reconstruction, perinatal stem cells may be particularly useful for autologous or allogeneic CBTE for newborns and children and may also be used for adult patients after banking at later stages of life (Figure 1). Although preclinical applications of perinatal stem cells in craniofacial bone regeneration are still limited, recent research progress of these cells revealed multiple possibilities for their potential applications in CBTE.

One of the most advanced applications of perinatal stem cells in CBTE was demonstrated by the use of UCMSCs in restoring rat cranial defects. Chen and colleagues investigated the *in vitro* and *in vivo* bone regenerative performance of human UCMSCs and BMSCs with RGD-modified macroporous calcium phosphate cements (CPC), using a critical-sized athymic rat parietal bone defect (8 mm in

Figure 1 Schematic illustration of the perinatal stem cell-based craniofacial bone tissue engineering. Generally, perinatal stem cells are easily harvested with no harm to the baby or mother and hold a most promising perspective for extensive application in tissue engineering. In the most visionary view, through sophisticated control of perinatal stem cells, biocompatible scaffolds and a signaling system, we will finally be able to bring the perinatal stem cell-based bone tissue engineering strategy to the customized and functional clinical reconstruction of craniofacial bone defects resulting from congenital malformations, osteomyelitis, trauma and tumor resection.

diameter) model^[123]. They observed similarly high expressions of osteogenic specific genes and high percentages of live cells and cell density on CPC for UCMSCs and BMSCs. After implantation for 24 wk, the new bone tissue of UCMSC-CPC and BMSC-CPC groups *in vivo* exhibited similarly higher bone mineral density, new bone amount and vessel density compared to the CPC control group. Notably, this observation was in agreement with a former study by Liu *et al.*^[124] using human UCMSCs and partially demineralized bone matrix for reconstruction of critical-sized parietal bone defects (5 mm in diameter) in athymic rats. Interestingly, Barboni *et al.*^[125] reported AEC-enhanced bone regeneration using an ovine maxillary sinus augmentation model. Calcium-phosphate synthetic bone substitutes, alone or engineered with ovine AECs, were grafted bilaterally into maxillary sinuses of six adult sheep. After implantation, the scaffold integration and bone deposition are positively influenced by allotransplanted AECs. Sinus explants derived from an AEC-scaffold group displayed a reduced fibrotic reaction, a limited inflammatory response and an accelerated process of angiogenesis compared with the control group. In addition, a direct osteogenic differentiation of ovine AECs *in vivo* was observed at 45 d post operation, suggested by the presence of AECs-derived osteocalcin-expressing osteocytes entrapped within the newly deposited bone matrix. The general concept of perinatal stem cell-based bone tissue engineering has also

been validated using ASCs in several craniofacial bone defect models. A commercial magnesium-enriched hydroxyapatite (MgHA)/collagen-based scaffold seeded with or without ovine AFMCs was implanted in the bilateral maxillary sinus of sheep models for up to 90 d. Results showed that application of AFMCs increased new bone deposition and stimulated a more rapid angiogenic reaction^[126]. In another study, researchers developed two combined constructs by seeding dental pulp stem cells (DPSCs) and AFSCs onto silk fibroin scaffolds respectively. The AFSCs-scaffold construct as well as DPSC-scaffold construct promoted early bone regeneration in the critical-sized rat parietal bone defects compared with scaffold alone^[127]. However, the relative long-term outcome of AFSCs in craniofacial bone repair was still in question and the optimal scaffold composition for this particular application remains to be defined^[128,129]. In addition, suggested by most of the discussed studies, perinatal stem cells may play an essential role in new vessel formation in the regeneration site, which indirectly promotes the restoration of craniofacial bone defects^[123,125,126,128].

CONCLUSION

The ontological and anatomical origins of stem cells have profound influences on their biological properties and performance in regenerative medicine. Promoted

by the developments in cell and molecular biology, developmental biology and tissue engineering, the unique and advanced properties of perinatal stem cells have been largely unveiled within the last decade: (1) the collection, preparation and application of perinatal stem cells are scarcely involved with ethical issues; (2) most perinatal stem cells are easily harvested and manipulated with no harm to the baby or mother; (3) compared to adult MSCs which decreased in cell number, proliferation ability and differentiation capacities with age, perinatal stem cells are initially available in substantial numbers and exhibit greater proliferative activity than BMSCs, indicating the advantage for rapid expansion and consequent downstream application; (4) with an intermediate multipotency between pluripotent stem cells and adult MSCs, perinatal stem cells do not form a teratoma while maintaining a broad multi-differentiation capacity *in vitro* and *in vivo*; and (5) in terms of their involvement in materno-fetal immunotolerance, perinatal stem cells exhibit low immunogenicity and potentially high immunomodulatory capacity, indicating a clinical prospective of allogeneic cell transplantation. However, the mechanisms underlying the immunoprivileged and immunosuppressive effects of perinatal stem cells have not yet been clearly defined.

Despite the problems researchers still face in translating scientific concepts from the bench to the bedside, these exciting experimental and preclinical achievements from intense research efforts suggest perinatal stem cells may offer a most promising scope and will continue to produce new and exciting progress for the novel cell-based CBTE in the future.

Abstract

In this review, we discuss about current knowledge about stem cell (SC) therapy in the treatment of retinal degeneration. Both human embryonic stem cell and induced pluripotent stem cell has been growth in culture for a long time, and started to be explored in the treatment of blinding conditions. The Food and Drug Administration, recently, has granted clinical trials using SC retinal therapy to treat complex disorders, as Stargardt's dystrophy, and patients with geographic atrophy, providing good outcomes. This study's intent is to overview the critical regeneration of the subretinal anatomy through retinal pigment epithelium transplantation, with the goal of reestablish important pathways from the retina to the occipital cortex of the

INTRODUCTION

The retina is the light sensing, innermost part, in a multilayered structure that relays information to the occipital cortex of the brain *via* the optic nerve. The photoreceptors layer is located in the outer retina, and plays a major part in light perception and the phototransduction^[1,2]. The retinal pigment epithelium (RPE) is placed between the adjacent photoreceptors, and the underlying pentalaminar Bruch's membrane^[3]. It provides both metabolic and

functional support of photoreceptors, replenishing bleached photopigments that, after a photon is absorbed, initiates the phototransduction, through an active participation from the RPE and the photoreceptors^[1,2]. The RPE forms with the photoreceptors a functional unit, and its optimal functioning is critical to sight^[1,4]. Loss of the integrity of this unit, promotes apoptosis or degeneration of the photoreceptors^[1,2].

Retinal degeneration occurs in several forms, such as age related macular degeneration (AMD), Stargardt's macular dystrophy and retinitis pigmentosa (RP)^[2,4,5]. The AMD has a multifactorial pathophysiology, which results in photoreceptors degeneration in the macula. However, the inner retina remains intact, becoming suitable to the possibility of photoreceptors replacement as a potential therapy^[2]. Therapeutic options that could substitute affected retinal layers, aim to replace lost or injured retinal components, and reestablish the interaction concerning RPE and photoreceptors^[2,5,6]. Autologous full thickness grafts have been used most commonly in humans, but the pursuit for the best method to replace RPE is still ongoing^[7].

STEM CELLS AND CELL REPLACEMENT

After recent advances in regenerative medical treatment, the stem cell (SC) therapy started to be actively explored for eventually blinding retinal conditions. SC could be defined as pluripotent, with ability of self renewal, and able of differentiate or just be maintained quiescent, in order of a damage, following injury or stress^[8,9]. The introduction of the concept of SC therapy, after bombings in Hiroshima and Nagasaki, discovered that bone marrow (BM) transplanted into irradiated animals produced hematopoiesis. Hematopoietic SC (HSC) were identified in 1961, and their ability to migrate and differentiate into multiple cell types was documented^[8-10].

SC transplants may be xenogenic (from another species), allogenic (from another individual) or autograft (from the same individual)^[2,4]. The immunological ocular privilege provides, both allogenic and xenogenic intraocular grafts, a long term survival, when compared with similar grafts^[11]. The human embryonic (hESC) and the induced pluripotent (iPSC) consist, at this moment, as the major forms of retinal SC therapy^[4]. The hESC are derived from blastocysts, left from procedures of "*in vitro*" fertilization. They can remain undifferentiated, or develop into a settled differentiated population. Takahashi and Yamanaka, reprogrammed peripheral normal adult fibroblasts and lymphoblasts, into human iPSC^[11,12]. Both hESC and iPSC have similar characteristics and potential for retinal differentiation, with morphological similarities to the RPE, bringing a total new horizon for retinal degenerations, producing RPE in possibly unlimited amounts^[1,4,7].

Human iPSC are normal fibroblasts or lymphoblasts, and can be obtained from any adult individual, including the patient itself^[1,4]. The first findings about the hESC suggest that there was no sign of abnormal proliferation or

growth, such as no immune mediated transplant rejection in the patients. However, the possibility of immune rejection, teratogenicity and ethical restrictions need to be firmly established before bringing hESC into clinical application^[5].

The most common techniques of delivering SC are the intravitreal and the subretinal injections. The first approach resulted in a higher survival of SC, according prior reports. The subretinal pathway directs the material to targeted retinal regions with indicated treatment, promoting maturation of hESC RPC to photoreceptors^[2]. Unfortunately, lack of integration is a problem when using a suspension as orientation, resulting in unsuccessful outcomes^[2,7].

TARGET DISEASES

Loss of highly differentiated photoreceptors and RPE, is a common end point in retinal degenerations^[12,13]. First described in medical literature in 1874, AMD still has no permanent solution. The dry form of AMD refers to the condition in which the retina accumulates amorphous deposits, called drusen, with gradual degeneration of the RPE^[2,5]. In the wet form, CNV grow progressively, disrupting visual function. It may result in hemorrhagic alterations and fibrosis, affecting the macula^[13]. In both types of AMD, loss of photoreceptors has been documented^[5]. Current therapeutic options to the wet form include, photodynamic therapy (PDT) and, mainly, antivascular endothelial growth factor (anti VEGF) therapy^[5]. The dry form remains an unmet medical need with no available treatment^[5,12]. Hereditary retinal degenerations, including RP and Stargardt's macular dystrophy are important blindness related disorders^[8,13]. RP is an inherited disorder in which rod photoreceptors degenerate initially, but all photoreceptors frequently become involved as well, leading to total blindness^[2]. Stargardt's macular dystrophy was firstly described by Karl Stargardt, in 1905, and is the most common pediatric macular degeneration^[12,14]. Patients with this condition usually present with macular atrophy^[14].

RPE CELLS REPLACEMENT

The RPE is a hexagonal, monolayer of polarized pigmented cells, densely adherent to one another, as well as to the underlying Bruch's membrane. Among its many functions, it plays a major part in photoreceptor renewal^[2,4,12,13]. The AMD is frequently pictured as a local disruption of the RPE photoreceptor unit. Moving photoreceptors to intact underlying regions of the retina had demonstrated good results^[14,15]. Transplant rejection was not so manifested in dry form, as in other forms of this disorder^[4]. The RPE replacement, prior the development of advanced stages, may signify a crucial alternative, requiring refined surgical methods^[5]. The autologous RPE replacement is usually applied from RPE suspension, or autologous full thickness RPE and choroid transplantation. A clinical trial concluded that both had similar results^[4,5]. RPE suspensions may product underprivileged orientation and survival, which is an important factor to be considered^[2,4,5].

The transplantation of RPE polarized monolayer on a scaffold may provide higher integration and function^[4,5]. So far, the parylene membrane has been the only scaffold experienced for subretinal delivery, resulting in a good biocompatibility in RCS rats after implantation^[4,12,13]. The RCS rat is a model used in disorders involving the outer retina^[11,13]. Genetic studies have demonstrated that Mer is essential for RPE function, and its absence results in inherited abnormal phagocytosis of the photoreceptor outer segment, photoreceptor degeneration and retinal atrophy within 2 mo of birth^[1,5,16,17]. Prasad *et al*^[17], in 2006, demonstrated the action of Mer, suggesting that the Protein S is a biologically relevant ligand.

The natural formation of hESC into RPE is the most commonly used process to generate this material^[18]. Reestablishment of the normal interface had demonstrated good results^[14,15]. The hESC initially overgrows in a supplemented hESC medium, until formal contact of its borders. At this point, it is performed the removal of bFGF, and changed until they start to show RPE as a truly small, hexagonal and pigmented morphology^[11,13]. In 2004, Haruta demonstrated the generation of RPE derived from hESC, indicating functional recovery and biological function of phagocytosis^[1,2,16]. The hESC RPE not only display consistent structure with adult RPE, but also exhibit resemblances, as the ability to phagocytose photoreceptor outer segments. The hESC RPE in animals improved functional performance, after comparing with controls, and significant similarity compared to what is found in adult humans^[6,8,9]. The United States FDA recently approved a I / II clinical trial, currently ongoing with hESC, for the treatment of GA and Stargardt's macular dystrophy^[7,19]. Pan *et al*^[12], reported the first subretinal replacement of hESC RPE in subjects with Stargardt's and GA^[2,5]. A clinical study reported absence of immune rejection 4 mo after transplantation in a group of patients^[1,16]. Still, it is hard to find clinical trials showing the results of RPE suspension injection therapy. Ribeiro *et al*^[20] conducted a study to determine whether transplantation of a polarized monolayer of hESC RPE, supported on a nondegradable parylene membrane, into the subretinal space of 69 rats, would lead to RPE survival and tumorigenic effects, compared to suspension injection^[20]. Polarized monolayers of hESC RPE showed 12 mo survival of 50% and 25% in the hESC RPE suspensions, with no signs of tumoral formation. This survival was confirmed by robust antiTRA185, and antiRPE65 staining^[11,20]. Ribeiro *et al*^[20] showed that the confocal nearinfrared (NIR) 830 nm imaging modality, capable of visualizing subretinal pathology, was, also capable to identify the “*in vivo*” hESC RPE in the parylene membrane, with subsequent histological confirmation^[20].

Possibility of teratomas, management of immune rejection and histocompatibility with the hESC, turns it into a difficult clinical application^[11-13]. The iPSC is an interesting alternative to avoid immune rejection, but it is important to point out that iPSC may become immunogenic after reprogramming^[14,6,8,21]. It is predictable that the “autogenous” iPSC RPE transplantation could improve results in patients with retinal degeneration^[16]. The iPSC therapy is a possibility

for retinal replacement, though remaining problems to be solved, until applying it to daily practice. Thus, both hESC and iPSC, under certain biological conditions, may distinguish into actual RPE^[4].

PHOTORRECEPTORS REPLACEMENT

The degeneration of RPE always promotes the induction of photoreceptor damage. But when the loss of photoreceptors is settled, the resulting deficit is permanent. As such, replacing the injured RPE through SC therapy may help to reestablish the integrity of this functional unit^[2,11,13]. The generation of photoreceptors has garnered particular interest, probably related with the growing number of patients affected with macular degeneration and inherited disorders in the United States^[21]. Several groups have demonstrated successful photoreceptors' transplantations in animals, performing synaptic connections between grafts and host retina, and significant functional improvements^[2,22].

Retinal SC (RSC) has been cultured from the peripheral mammalian retina^[6]. RSC transplanted subretinally into animal models develop into photoreceptors after integration, with long term survival^[2,6]. The hESC may, also develop the RSC^[2,8]. In 1998, Reynolds *et al*^[1] cultured hESC from human blastocysts. In 2009, with the permission of the FDA, the first hESC clinical trial was approved for spinal cord injury.

The RPC exist in a more advanced ontogenetic stage than hESC, and constitutes the active component of fetal retinal transplants^[2,8]. Aftab *et al*^[23] showed that human RPC (hRPC), depending of the gestational period, exhibit optimal proliferative dynamics under certain conditions^[23]. After the transplantation of human fetal retina, opsin and recoverin could be also developed by the photoreceptors, improving patients' vision transiently^[6,8]. The use of hRPC from fetal retina was limit by the low capacity to expand “*in vitro*”. Baranov *et al*^[24] showed that hRPC expanded in culture conditions submitted to hypoxia, maintaining its multipotency and self renewal characteristics^[24,25].

Photoreceptors transplantation requires integration into both outer and inner retina, reforming functional synapses, and acting as an anatomical replacement therapy. This direct contact provides the differentiation of photoreceptors “*in vivo*”, which is hard to replicate “*in vitro*”. The inner retina of the transplant, including the outer limit membrane, act as a barrier to donor photoreceptors, and its removal may improve the success involving full thickness retinal grafts^[2]. In addition, the induced differentiated cells are not similar to photoreceptors in structure and morphology. A recent study successfully molded structures similar to outer segment from hESC^[16]. Although the production of phototransduction initiating protein, rhodopsin, it has been difficult to induce electrophysiological responses under light stimuli using the patch clamp technique, indicating a functional defect^[2,16]. Researchers treated ESC with Wnt and Nodal antagonists to differentiate SC^[2,16]. The inhibition of Notch signaling, also significantly promoted photoreceptor differentiation^[16]. In 2006,

Table 1 Clinical trials using stem cell for retinal therapy currently registered on ClinicalTrials.gov

Injury or disorder	Sponsor	Type or source of cells	Delivery	Identification
Stargadt's, AMD (GA)	Advanced cell technology, recruiting	hESC RPE	Subretinal transplantation	NCT01469832
AMD (GA), RP, ischaemic retinopathy	University of Sao Paulo recruiting	BMSC	Intravitreal injection	NCT01518127 NCT01560715 NCT01518842
AMD	Pfizer, ongoing	hESC RPE	Subretinal transplantation	NCT01691261
AMD (GA), RP, RVO, DR	UC Davis recruiting	BMSC	Intravitreal injection	NCT01736059
Stargadt's, Fundus Flavimaculatus, Juvenile Macular Dystrophy	Advanced cell technology, recruiting	hESC RPE	Subretinal transplantation	NCT01469832
Retinal and optic nerve damage	Retinal associates of South Florida, recruiting	BMSC	Retrobulbar, subtenon and intravenous injection	NCT01920867
AMD	Advanced cell technology, recruiting	hESC RPE	Subretinal injection	NCT01344993
AMD	Al-Azhar University, recruiting	BMSC	Intravitreal injection	NCT02016508
RP	Chaitanya Hospital, recruiting	MSC	Not informed	NCT01914913
RP	Mahidol University, recruiting	MSC	Intravitreal injection	NCT01531348
Myopic Macular Degeneration	UC Los Angeles, ongoing	hESC RPE	Subretinal transplantation	NCT02122159
Best disease	Mayo Clinic, recruiting	iPSC RPE	Not informed	NCT02162953
AMD	CHA Bio and Diotech, recruiting	hESC RPE	Subretinal transplantation	NCT01674829
Stargadt's	Advanced cell technology, recruiting	hESC RPE	Subretinal transplantation	NCT01345006
Stargadt's	CHA Bio and Diotech, recruiting	hESC RPE	Subretinal transplantation	NCT01625559

Legends^[29]. AMD: Age related macular degeneration; GA: Geographic atrophy; RVO: Retinal vein occlusion; DR: Diabetic retinopathy; SC: Stem cells; hESC RPE: Human embryonic stem cells derived RPE; iPSC: Induced pluripotent stem cells; BMSC: Bone marrow stem cells; RP: Retinitis pigmentosa; MSC: Mesenchymal stem cells.

Lamba *et al*^[1] promoted the formation of RPC, and generated photoreceptors from hESC in a culture with supplementation of IGF1, noggin (inhibitor of BMP pathway) and Wnt inhibition^[1,10,16]. Reynolds *et al*^[11], in 2009, implanted photoreceptor derived from hESC, with the objective of testing hESC to photoreceptor replacement in an animal model. They demonstrated the migration following intraocular injection of hESC derived material, settling into the appropriate layers, and expressing markers, included related to photoreceptors. After transplantation, there is differentiation into functional photoreceptors and restore light responses to the animals^[2].

The injection of RPC was promising, but, although it demonstrated robust integration, they did not produce photoreceptor appropriately. Fernandes *et al*^[2] demonstrated the subretinal delivery method promote maturation of hESC RPC to photoreceptors. Concluding, alternative approaches and techniques need to be explored to direct RPC transplantation as a therapeutic option, aiming significant survival after transplantation, integration into host retinas and photoreceptor specific differentiation^[2]. Scaffold delivery strategy has been shown to enhance the cell survival and differentiation in a variety of retinal degeneration models^[24].

RETINAL GANGLION CELL REPLACEMENT

The retinal ganglion cell (RGC) is the primarily part of the retina damaged by glaucoma^[26]. In general, the most successful transplantations mentioned before, aiming to

repair damaged retinas, restored photoreceptor cells, but not RGC^[2]. Nevertheless, RGC production from ESC cultures has been reported^[12,13]. Reconstructing the optic nerve through the regeneration of RGC may reestablish sight in glaucoma or traumatic optic nerve injury^[2].

NON NEURAL SC REPLACEMENT

The transplantation of nonneural SC, such as BM derived SC (BMSC), UCSC, HSC or MSC has been documented^[2,14]. BM transplants still consists in adjunct therapy in cancer patients^[8]. The injection of BMSC improves retinal circulation, enhancing survival of outer retina, bringing benefits in retinal degeneration^[2]. The BMSC is an important tool in regenerative therapy, directly related to HSC production^[6]. HSC is an accepted therapy today. It is a group of multipotent SC, obtained by directly removal^[8,9]. BM is supplemented as SC by peripheral blood or cord blood^[27]. The HSC therapy performed globally, such as the demand for donors, has progressing annually^[28]. Nevertheless, HSC transplantation is still related to significant morbidity and mortality, has a high cost and requires multidisciplinary infrastructure. The identification of small ESC in BM supports the notion that, if transplanted together with HSC, it would be able to participate in regeneration^[8,9,27].

CONCLUSION

Several ocular SC clinical trials ongoing have the objective of establish the safety and efficacy of this therapy in humans (Table 1). Additional sources of funding are

therefore imperative to maintain the research programs and integrate these basic and preclinical discoveries and launch early phase clinical trials within the coming years. Although the recent controversy involving changes in strategy planning and funding of the Center of Regenerative Medicine, from the United States NIH, studies of SC therapy for macular degeneration will not be affected.

interesting source of multipotent stem cells has led to many studies exploring the clinical potential of these cells in cell-based therapies. Recent advances in understanding the secretory capacity of adipose tissue and the role of adipokines in the development of obesity and associated disorders have added a new dimension to the study of adipose tissue biology in normal and diseased states. Subcutaneous adipose tissue forms the interface between the clinical application of regenerative medicine and the establishment of the pathological condition of obesity. These two facets of adipose tissue should be understood as potentially related phenomena. Because of the functional characteristics of adipose stem cells, these cells represent a fundamental tool for understanding how these two facets are interconnected and could be important for therapeutic applications. In fact, adipose tissue stem cells have multiple functions in obesity related to adipogenic, angiogenic and secretory capacities. In addition, we have also previously described a predominance of larger blood vessels and an adipogenic memory in the subcutaneous adipose tissue after massive weight loss subsequent to bariatric surgery (ex-obese patients). Understanding the reversibility of the behavior of adipose stem cells in obese and in weight loss is relevant to both physiological studies and the potential use of these cells in regenerative medicine.

Core tip: In this mini-review, we summarize recent aspects regarding obese subcutaneous adipose tissue with a focus in adipogenic and secretory capacities of adipose stem cells. In particular, we discuss how the occurrence of obesity and weight loss could alter the properties of stem cells and the consequences of using adipose-derived stem cells in regenerative medicine.

Abstract

The discovery that adipose tissue represents an

Our previous results reveal that, after massive weight loss subsequent to bariatric surgery, stem cells retain an adipogenic memory besides a predominance of larger blood vessels in subcutaneous adipose tissue. Inflammatory subcutaneous adipose tissue microenvironment found in obese patients and even the massive weight loss could alter adipose tissue-derived stem cells phenotype to a non-healthy state.

INTRODUCTION

The discovery that adipose tissue represents an interesting source of multipotent stem cells has led to many studies exploring their clinical potential in cell-based therapies. Recent advances in understanding the secretory capacity of adipose tissue and the role of adipokines in the development of obesity and associated disorders have added a new dimension to adipose tissue biology under normal and diseased states. In the present mini-review, we summarize different aspects of adipose tissue stem cells and the role of these cells in obese subcutaneous adipose tissue. In addition, we discuss how the occurrence of obesity and weight loss after bariatric surgery could alter the properties adipose-derived stem cells and the consequences of using these cells in regenerative medicine.

OBESE SUBCUTANEOUS ADIPOSE TISSUE

White adipose tissue is highly complex and is composed of various cell types that interact dynamically with each other through the secretion of adipokines, including hormones, cytokines and chemokines. This tissue is now recognized as being equivalent to an endocrine organ^[1]. White adipose tissue is mainly divided into two fat depots: internal or visceral and subcutaneous. In humans, a major contribution of visceral adipose tissue to the development of insulin resistance and to the cardio-metabolic complications in obesity was proposed^[2]. The differences observed between visceral and subcutaneous adipose tissues are supported by studies showing that visceral and subcutaneous fat depots exhibit differential gene expression profiles^[3]. A recent study has suggested a common embryonic origin from mesothelium and mesothelium-derived cells for up to six internal fat depots, but not for the subcutaneous fat depot^[4].

Visceral and subcutaneous adipose tissues can significantly alter their mass according to the amount of triglycerides stored in adipocytes, however is more evident in subcutaneous fat tissues. Some authors assume that the

visceral fat depot is associated with metabolic syndromes, while subcutaneous fat has a metabolic buffer function, which means that an increase in the subcutaneous fat depot in the presence of a positive caloric balance is protective^[3,5]. However, during the development of obesity, the enormous increase in the subcutaneous fat mass results in a dysfunctional tissue. Tissue homeostasis is disrupted due to adipocyte hypertrophy, decreased adipogenesis and angiogenesis^[6].

The cellular content of subcutaneous adipose tissue includes a major population of specialized cells, the adipocytes, and a stromal vascular fraction (SVF) composed of preadipocytes, pericytes or multipotent stem cells, vascular wall and endothelial cells, macrophages^[7], lymphocytes^[8], eosinophils^[9], neutrophils^[10], mast cells^[11] and hematopoietic progenitor cells^[12]. It was initially proposed that adipocyte hypertrophy is the major mechanism by which subcutaneous adipose tissue expands. However, adipocyte hyperplasia also contributes to tissue expansion through the activation of multipotent stem cells, leading to the generation of new cells to sustain the demand for fat storage^[13,14]. Therefore, the capacity to dynamically expand or shrink throughout adult life is mediated by adipocytes, preadipocytes and multipotent cells with a regenerative capacity.

Lipid accumulation is not the only trigger for the development of obesity. One of the most important discoveries regarding the development of obesity was the description of the establishment of an inflammatory state characterized by an increase in the levels of local and systemic inflammatory cytokines and macrophage infiltration into subcutaneous adipose tissue^[15-18]. Besides, endoplasmic reticulum dysfunction is being given as evidence of adipocyte stress^[19], playing an upregulation role in inflammatory scenario of adipose tissue. The accumulated macrophages contribute to the production of inflammatory mediators, thus amplifying the inflammatory state of the adipose tissue and thereby representing an important factor in promoting insulin resistance^[17,18]. The macrophage population within inflamed obese adipose tissue can switch phenotypes between inflammatory and non-inflammatory states^[20]. Adipose tissues also secrete osteopontin, which also plays a role in the migration and differentiation of cells of the immune system^[21-25].

It has been suggested that preadipocytes of mouse adipose tissue could be responsible for most of the secretion of MCP-1^[22,24,25], which has been classically described regarding the role of this cytokine in monocyte mobilization from the bone marrow and the migration of monocytes through the peripheral circulation. Therefore, it was proposed that the inflammatory process that is established during the development of obesity could be initiated by preadipocytes that were affected by adipose tissue growth. In this case, both adipocytes and the preadipocytes would be responsible for the migration and, possibly, the activation of macrophages in adipose tissues.

The cellular events that lead to the establishment of this scenario have not been fully elucidated, and

Figure 1 Annual number of publications referenced in the PubMed database between 2000 and 2014 with the sentence “adipose stem cell in obesity”.

the mechanisms by which obesity is associated with other metabolic disorders are not well understood. Because multipotent stem cells are directly involved in subcutaneous adipose tissue homeostasis, it is reasonable to postulate a pleiotropic role for stem cells in the vicious cycle of inflammation. In fact, since 2000, the number of scientific articles in the adipose stem cell field within the context of obesity has been increasing (Figure 1). However, there is only a few analyzing subcutaneous adipose tissue samples after massive weight loss^[26-30]; two of them with focus on multipotent stem cells^[26,30].

HEALTHY AND NON-HEALTHY ADIPOSE STEM CELLS

The term mesenchymal stem cells (MSC) was first used for a multipotent cell population that dwells in adult bone marrow stroma. Based on the concept of bone marrow MSC, this population of perivascular cells has been described in a variety of other adult tissues^[31-36], including adipose tissue^[37]. MSC contribute to tissue homeostasis, repair and regeneration^[38,39]. Data collected during the last 10 years suggest that MSC represent a specific adult tissue stem cell population, the plasticity of which is essential. It is not clear whether all the MSC populations, derived from different tissues throughout the body, represent a substantially similar cell category. Among the different sources of MSC already described, the adipose stem cells have attracted the attention of many scientists and physicians due to the frequently large amounts of subcutaneous adipose tissue that can be easily harvested using liposuction. In addition to being an important tool for tissue regeneration, due to their secretory capacity, adipose stem cells also represent possible regulators in the development of obesity. While many studies have reported on the participation of inflammatory and non-inflammatory macrophages, little is known about the events in obesity that involve resident stem cells.

The *in vitro*-amplified stem cell population derived from adipose tissue is now termed adipose tissue-derived stem cells (ASC)^[40]. ASC share common features with

MSC derived from other tissues, which are primarily based on the paracrine activity of these cells. ASC are similar to MSC derived from bone marrow, including the capacity to sustain hematopoiesis^[12] and immunomodulatory activities, but most importantly, ASC display specific features, among which are higher angiogenic and adipogenic potentials^[41]. Regarding the surface marker profile, ASC are distinguished by CD34 expression^[42].

In fact, results from *in vitro* assays and animal models have supported a beneficial role for ASC in tissue regeneration and immunomodulation *via* paracrine activity^[43]. However, ASC are responsive to inflammatory stimulus. Hoogduijn *et al.*^[44] showed in C57BL/6 mice that intravenously infused ASC home to the lung where they first induce an inflammatory response that in turn leads to immunomodulatory effects. Furthermore, after lipopolysaccharide stimulation ASC increases their inflammatory cytokines secretion^[45] with clones exhibiting varying degrees of paracrine activity^[46]. Stressful conditions on tissue homeostasis can lead to extreme cell behavior changes^[47], and specifically in subcutaneous adipose tissue it has been reported that some diseases can alter ASC function. For example, autologous ASC therapy treatment in a mouse model of multiple sclerosis showed no positive results on the disease progression^[48]. The angiogenic potential^[49,50] and wound healing^[51] capacity of ASC is altered by Diabetes.

There is a positive correlation between high body-mass index (BMI) and some types of malignant tumors^[52]. MSC may favor tumor development through the release of soluble factors and by direct cell contact, promoting proliferation, survival, and drug resistance. It is postulated that the inflammatory tumor microenvironment could change the phenotype of infiltrating MSC to a pro-inflammatory state^[53]. We could speculate that the tumor-derived MSC is in fact a non-healthy state, since they promote tumor progression.

In addition to producing new adipocytes and to participation in the growth of the vascular tree^[41], ASC could contribute in other ways to the development of obesity. First, these cells could generate macrophages by direct differentiation or indirectly, by supporting their generation from resident hematopoietic progenitor

Figure 2 Multipotent stem cells as key players in tissue homeostasis disruption in obesity. The enormous increase in subcutaneous fat mass leads to an increase in secreted molecules such as monocyte chemoattractant protein 1 (MCP-1), which causes monocyte infiltration and subsequent macrophage differentiation (blue lines). Inflammatory cytokines may change multipotent stem cells to a non-healthy phenotype (blue lines) that in turn impairs (red lines) the normal adipogenesis of subcutaneous adipose tissue.

cells^[12]. Murine ASC have a phagocytic activity, both *in vitro*^[54] and *in vivo*^[55]. Human ASC also have this capacity^[56]. Recently, a macrophage population that expresses CD34 and is plastic-adherent and multipotent, similar to ASC, was identified in human white adipose tissue^[7]. Therefore, the idea that a significant proportion of the inflammatory macrophages present in the adipose tissue of obese patients may be generated *in situ* cannot be ignored^[57]. Second, ASC could also participate in obesity *via* cytokine secretion function. The endocrine function of adipose tissue depends upon the activity of the adipocytes and the cells from the SVF. Adipocytes are the main source of leptin and adiponectin, while inflammatory cytokines such as IL-6 and TNF- α , are mostly secreted by the stromal-vascular cells^[13,17,58], among which are ASC and preadipocytes. Consequently, ASC can be key players in obese subcutaneous adipose tissue as secretory cells.

Oñate *et al.*^[59] showed a low capacity for adipogenic and angiogenic differentiation and an upregulation on inflammatory genes^[60] in the ASC from obese patients. Once ASC and preadipocytes are exposed to inflammatory adipose tissue microenvironment, they may react in several possible ways including cytokines secretion, dedifferentiation and migration, aiming to reduce tissue damage^[47]. In this microenvironment, inflammatory cytokines secretion by non-healthy ASC could represent a failure to evade stress. Indeed, the cellular and molecular events in obesity may alter ASC producing a non-healthy and even inflammatory phenotype that in turn impairs the normal cellular physiology of the subcutaneous adipose tissue (Figure 2). Once a disruption in adipose tissue homeostasis begins, the metabolic buffer function

of subcutaneous adipose tissue^[3,5] can be lost, thereby worsening the systemic chronic inflammatory condition of obese patients.

This opens a new and fascinating pathway for modulating obesity through the possibility of manipulating the functional capacity of ASC^[61]. Massive weight loss after bariatric surgery reduces the inflammation as measured by C-reactive protein and IL-6 plasma levels^[62] and even the stress in endoplasmic reticulum of adipocytes^[63], however if ASC isolated from subcutaneous adipose tissue could return their healthy state is still unknown.

ADIPOSE STEM CELLS AFTER MASSIVE WEIGHT LOSS: IMPLICATIONS FOR REGENERATIVE MEDICINE

ASC are now considered to be regenerative cells that promote tissue repair and regeneration *in vivo*, which may occur *via* different mechanisms, including indirectly by the production of soluble factors or directly by the differentiation of the ASC themselves. The first clinical trial that used expanded ASC involved the treatment of fistulas in Crohn's auto-immune disease^[64-66]. More than a decade's worth of animal model studies and clinical trials using ASC^[67] suggest that cell therapy approaches lead to the reestablishment of function and the remodeling of tissue after injury, mostly *via* a paracrine mechanism. Paracrine factors include a set of growth factors that once released by the transplanted stem cells may abrogate local apoptosis and stimulate the proliferation and activation of resident cell progenitors^[45,46].

Figure 3 The enrichment of preadipocytes and the density of blood vessels in the adipose tissues of ex-obese patients may play roles in accelerated weight regain. Even after massive weight loss, ex-obese adipose tissue does not return to a normal cellular state. This adipose tissue is characterized by a higher percentage of CD34 cells and a greater number of small and large blood vessels^[26].

Obesity is an inflammatory disease, and relevant changes in the cytokine release profile are expected when comparing obese and non-obese patients and even after massive weight loss (ex-obese patients). In fact, it is known that epigenetic modifications could play a role in chronic diseases^[68,69]. The alterations in cellular behavior caused by the inflammatory microenvironment in obese subcutaneous adipose tissue could be partially maintained even after the decrease of inflammation because of the accumulation of epigenetic modifications. Therefore, it is critical to investigate the biology of ASC to understand their potential use in particular therapeutic approaches. If ASC are isolated from ex-obese patients, the regenerative potential of these cells may be modified, and distinct from that observed in the cell populations present in and derived from non-obese patients. Although massive weight loss has been associated with reduced inflammatory markers in plasma^[62], bariatric procedures could produce metabolic abnormalities, including the increase of bone resorption^[29]. It has been reported that after massive weight loss, subcutaneous adipose tissue returns to a non-inflammatory state with a significant decrease in inflammatory cytokines^[28,58] and immune cells infiltration^[27,29]. These cytokines are produced mainly by SVF and their decrease was observed during weight stabilization period^[58].

Mitterberger *et al.*^[30] have showed no alterations in ASC after massive weight loss; however we analyzed few days of adipogenic induction in contrast to previous studies^[26,59,60]. We have described a predominance of larger blood vessels in the subcutaneous adipose tissues derived from ex-obese patients (BMI 25-29.9 kg/m²), who had lost weight after treatment with bariatric surgery, compared to that from control patients (BMI 25-29.9

kg/m²), who had never developed morbid obesity. In the same study, ASC isolated from ex-obese patients attained a mature adipocyte phenotype faster than those obtained from non-obese patients^[26], suggesting an enrichment of the preadipocyte population.

We currently propose to find a potential biomarker to predict the adipogenic commitment of ASC and, therefore, a biomarker to predict the potential regaining of subcutaneous adipose tissue mass. Recently, Joe *et al.*^[70] have described two major subpopulations, based on CD34 surface marker expression, that dwell in murine skeletal muscle tissue. Using cell sorting techniques, the authors have shown that Lin^{neg}Sca-1^{pos}CD34^{pos} cells contain adipogenic progenitors, while Lin^{neg}Sca-1^{neg}CD34^{neg} cells contain osteogenic and chondrogenic activity. In a mouse model of acute lung injury, freshly isolated human umbilical cord blood CD34-positive cells are protective against the inflammation induced by a lipopolysaccharide challenge^[71].

The role of the CD34 surface molecule in ASC physiology has been recently discussed^[72]. In subcutaneous adipose tissue, the population of preadipocytes can be identified by flow cytometry using the following combination of cell surface markers: CD45^{neg}, CD146^{neg}, CD31^{neg}, CD34^{pos}^[42]. Our preliminary results have shown an accumulation of CD34-positive cells in subcutaneous adipose tissue of ex-obese patients. Furthermore, a novel adipose tissue macrophage subpopulation (CD45^{pos}/CD14^{pos}/CD34^{pos}/CD206^{pos}) had characteristics similar to ASC, including adherence, localization, morphology, and mesenchymal multipotency. This subpopulation may have migrated from the bone marrow and, once in the adipose tissue, may play an important role in tissue maintenance^[7] and also in the development of obesity.

The mechanisms by which the ASC from ex-obese patients are committed to the adipogenic lineage are unknown, but some results point to the existence of circulating preadipocytes that can be recruited and participate in the enlargement of the adipose tissue mass^[73]. Another possible mechanism for the preadipocyte accumulation in ex-obese adipose tissue relies on the fact that adipocytes can dedifferentiate *in vitro*^[41,74]. Considering that patients treated with bariatric surgery massively decrease food intake and increase energy expenditure through physical exercise, hypertrophied adipocytes tend to mobilize lipids through lipolysis and could dedifferentiate into preadipocytes (Figure 3). The enrichment of preadipocytes in the adipose tissues of ex-obese patients and the fact that the blood vessels in these tissues do not return to a normal diameter^[26] may play roles in accelerated weight regain.

Due to the high demand for breast augmentation, replacing devices with autologous fat and ASC is a fair option^[75]. However, this approach cannot be followed if previous breast cancer has occurred. Moreover, if the ASC from ex-obese patients have an adipogenic memory of obesity development, we could also postulate an inflammatory memory or even altered inflammatory properties. It is thus reasonable to consider that the ASC from ex-obese patients may worsen the evolution of a tumor.

Due to ASC plasticity, studies of the function and contribution of ASC during the development of obesity are fundamental to developing new therapeutic approaches to prevent or treat obesity and its complications. Evidence of the alteration of ASC function during the development of obesity is beginning to be evaluated^[59,60], but information is still scarce^[61], specially related to patients who lost weight after bariatric surgery. In fact, inflammatory subcutaneous adipose tissue microenvironment could change ASC phenotype to a non-healthy state, possibly maintained by epigenetic alterations even after massive weight loss. We believe that the use of cell sorting approaches is imperative to validate the use of ASC from obese and ex-obese patients for autologous cellular therapy.

CONCLUSION

In conclusion, subcutaneous adipose tissue forms the interface between the clinical application of regenerative medicine and the establishment of the pathological condition of obesity. These two facets of adipose tissue should be understood as potentially related phenomena. Due to their functional characteristics, ASC represent a fundamental tool for understanding how these two facets are interconnected and could be important for therapeutic applications. Efforts to increase the understanding of the biology of ASC isolated from adipose tissues with normal physiology and in disease states may thus lead to the appropriate use of these cells in regenerative medicine and will provide novel therapeutic insights regarding obesity and weight regain.

Abstract

Pluripotent stem cells (PSCs) are able to differentiate into several cell types, including pancreatic β cells. Differentiation of pancreatic β cells depends on certain transcription factors, which function in a coordinated way during pancreas development. The existing protocols for *in vitro* differentiation produce pancreatic β cells, which are not highly responsive to glucose stimulation except after their transplantation into immune-compromised mice and allowing several weeks for further differentiation to ensure the maturation of these cells *in vivo*. Thus, although the substantial improvement that has been made for the dif-

ferentiation of induced PSCs and embryonic stem cells toward pancreatic β cells, several challenges still hindering their full generation. Here, we summarize recent advances in the differentiation of PSCs into pancreatic β cells and discuss the challenges facing their differentiation as well as the different applications of these potential PSC-derived β cells.

Key words: Embryonic stem cells; Induced pluripotent stem cells; Insulin-secreting cells; *In vitro*; *In vivo*; Differentiation; Maturation

Core tip: Pluripotent stem cells (PSCs) including induced PSCs and embryonic stem cells are valuable sources for cell replacement therapies and disease modeling of diabetes. Although several studies reported the differentiation of PSCs into pancreatic β cells *in vivo*, still their response to glucose is very limited *in vitro* due to their immature nature. In this review, we summarize the current knowledge about the differentiation of PSCs into pancreatic β cells and discuss the challenges facing the differentiation and application of PSC-derived β cells.

INTRODUCTION

Diabetes mellitus (DM) is a common disease, characterized by hyperglycemia caused by insufficient insulin production and/or resistance to insulin. Two different kinds of DM are

well characterized, type 1 (T1D) and type 2 (T2D). T1D is an autoimmune disease in which insulin-secreting β cells in pancreatic islets are permanently damaged by autoimmune attack, resulting in a lack of insulin production^[1]. T2D occurs when the pancreas produces insufficient amounts of insulin and/or the tissues of the body become resistant to normal or even high levels of insulin^[2]. Thus, T1D and T2D patients suffer from insulin insufficiency and damage of insulin-secreting β cells by distinct mechanisms^[3,4].

Pluripotent stem cells (PSCs), including embryonic stem cells (ESCs) and induced PSC (iPSCs) have the ability to differentiate into all cell types of the body^[5,6], which make them valuable sources for cell replacement therapies and other applications. Several reports have showed the generation of iPSCs from patients with different forms of diabetes^[7-12]. Also, the generation of patient-specific ESCs has been recently generated from somatic cells of diabetic patients^[13]. Thus, generation of functional β cells from human PSCs represents the most promising approach to treat diabetes. In addition to their high potential in cell therapy, β cells derived from patient-specific PSCs can be used as a disease model, where they provide a new approach to culture cells with a disease genotype and re-establishing pathogenesis *in vitro*. Disease modeling with such cells has the potential to give insights into the molecular mechanisms underlying diabetes and enable new cell-based drug discovery as well as autologous transplantation^[13,14].

Several studies reported the generation of pancreatic β cells from ESCs^[15-18] and iPSCs^[7,8,12,15,19]. However, a number of obstacles have arisen that render the generation of fully functional pancreatic β cells from PSCs^[14]. Therefore, in this review we summarize the current knowledge about the differentiation of ESCs and iPSCs into pancreatic β cells and discuss the challenges facing the differentiation and application of PSC-derived β cells.

DIFFERENTIATION OF PLURIPOTENT STEM CELLS INTO INSULIN-SECRETING β CELLS

It has been well documented that both human ESCs (hESCs) and human iPSCs (hiPSCs) share the same characteristics and properties and are able to differentiate into various types of cells under certain cultural conditions^[6,20,21]. Among these cells, insulin-secreting β cells differentiation from both hESCs and hiPSCs has been studied using similar differentiation protocols (Figure 1)^[8,15-17,19]. However, variation in the efficiencies of differentiation has been reported between different hPSC lines^[22,23]. These variations might occur due to the use of different protocols and different cell lines. The process of β cells differentiation is controlled by a complex network that depends on transcriptional regulation of genes involved in the development of the pancreas, the type and number of the differentiation factors, and the type and conditions of stem cell culture. Although many factors are important for successful generation of pancreatic insulin-secreting β cells

from PSCs, successful manipulation of culture conditions stands out as one of the more critical factors. Several initial studies have used the step-wise approach to differentiate insulin-secreting cells from hESCs. Under these cultural conditions, hESCs generate up to 12% pancreatic β cells; however, the ability of these differentiated cells to produce insulin in response to glucose was very limited^[16,18,24]. Therefore, a number of modifications in culture conditions have been done to improve the efficiency of β cell differentiation^[16,18,25,26]. These modifications include, but are not limited to, monolayer cultures^[16-18,25,27,28] or embryoid body (EB) technique^[29,30]. Also, several studies have used xeno-free culture system to generate pancreatic β cells from PSCs *in vitro*^[31-34]. Furthermore, *in vitro* modifications of cultural conditions to regulate signaling pathways demonstrated the vital role of specific pathways in the enhancement of β cell differentiation (Nostro *et al.*^[29], 2011). In hESCs, the regulation of transforming growth factor β (TGF β) signaling produces high yields of insulin-secreting cells that reaches up to 25%^[29]. Importantly, it has been proven that such critical refining in pancreatic differentiation protocols efficiently enhances the differentiation and maturation of hESC-insulin-secreting cells *in vivo*. These generated insulin-secreting cells showed several properties of functional β cells and were capable to respond efficiently to glucose stimulation in engrafted mice^[25].

Differentiation of pluripotent stem cells into definitive endoderm

Similar to embryonic pancreatic development, PSCs differentiation into pancreatic lineage is excised in several steps that start with the differentiation into definitive endoderm (DE) (Figure 1), which is recognized by the expression of specific markers. Previous studies showed a high percentage (60%-80%) of hESC-differentiated cells express a panel of specific DE endodermal markers such as SOX17, FOXA2, CXCR4, and GSC, but not the visceral endodermal marker, SOX7^[15,16,25,35-37]. The initiation of DE differentiation is properly induced in hESCs and hiPSCs by NODAL and WNT signals^[15,18,35,38]. NODAL signals have been previously reported to be the main inducer of endogenous endoderm^[39] and is activated by one of the members of TGF β family, activin A. Notably, the dose of activin A appears to be crucial for Nodal signaling activation and in-turn DE differentiation. A previous study showed that the use of activin A in a concentration of (50-100 ng/mL) leads to an efficient DE differentiation as compared to lower concentrations^[30,40]. In association with activin A, other factors have been shown to play an important role in DE differentiation. A recent study showed that treatment of hESCs with a combination of activin A, wortmannin (PI3K inhibitor), and CHIR99021 improves the percentage (90%) of the generated SOX17-positive cells^[41]. Furthermore, it has been previously shown that the combination of activin A with sodium butyrate^[16], PI3K pathway antagonists^[15,38], or Wnt signaling activators (WNT3A or CHIR9902) enhances the efficiency of DE differentiation in PSCs. It is worth to note that CHIR99021 has been found to be more potent

Figure 1 Schematic representation of the differentiation of pluripotent stem cells into pancreatic β cells. Pluripotent stem cells (PSCs) can be differentiated *in vitro* into pancreatic β cells after a step-wise differentiation protocol into definitive endoderm (DE), pancreatic progenitors (PP), pancreatic endocrine (PE) progenitors, and β cells. Transplantation of pancreatic progenitors derived from PSCs into immune-compromised mice induces their differentiation into glucose responsive pancreatic β cells (mature β cells). During pancreatic β cell differentiation, specific transcription factors are expressed at different stages. PDX1: Pancreatic and duodenal homeobox 1 gene; NGN3: Neurogenin 3; OCT4: Octamer-binding transcription factor 4; SOX: SRY (sex determining region Y)-box 2; FOXA2: Forkhead box protein A2; BMP: Bone morphogenetic protein; GLUT2: Glucose transporter 2.

in promoting SOX17- and FOXA2-positive endodermal cells than Wnt3A^[28]. Like wise, treating hESCs with GSK3 β inhibitor instead of WNT3A increases DE generation^[42]. Also, another TGF β family member, GDF8 (myostatin), has been found to be effective for stimulating DE^[43]. However, the efficiency of DE differentiation not only depends on GDF8, or activin A and its associated factors but also is enhanced by small molecules such as IDE1 and IDE2, which has been found to significantly induce the differentiation of approximately 80% of ESCs into SOX17-expressing DE cells^[44].

It is well known that DE eventually generates both pancreatic and hepatic tissues. To direct DE cells towards pancreatic differentiation *in vitro*, the alternative hepatic lineage differentiation is inhibited by treating the cells with different types of growth factors inhibitors, such as SU5402 (FGF receptor antagonist) and Noggin (BMP antagonist)^[36]. It has been shown that BMP signaling exerts two opposite

effects during pancreatic differentiation^[45]. In the dorsal endoderm, BMP signaling inhibition has been found to be required for specific differentiation into pancreatic lineage, whereas it is presence after the formation of pancreatic cells is essential to maintain pancreatic and duodenal homeobox 1 gene (*PDX1*) expression^[45].

Differentiation into pancreatic progenitors and endocrine cells

In the dorsal endoderm, BMP signaling inhibition has been found to be required for specific differentiation into pancreatic lineage, whereas its presence after the formation of pancreatic cells is essential to maintain pancreatic and *PDX1* expression^[45]. *PDX1* is a transcription factor that is expressed on all pancreatic precursor cells and has been shown to be essential for early pancreatic development^[46]. It has been found that the expression of *PDX1* is correlated with the pancreas developmental stages. During the early stages of endocrine specification, *PDX1* expression becomes restricted, whereas at later stages during β cells development its expression is upregulated as the protein enhances β cell function and is involved in insulin secretion^[46]. The differentiation of *PDX1*-expressing cells *in vitro* is regulated by several factors that range from signaling pathways inhibitors to protein kinase activators. For example, in hESCs, the differentiation of pancreatic progenitors expressing *PDX1* is induced by a small molecule, Indolactam V, that activates protein kinase C^[17], and enhanced by retinoic acid and dorsomorphin (a BMP type 1 receptor inhibitor) treatments^[28], whereas its proliferation is increased by inducing epidermal growth factor signaling^[15]. Two other signaling pathways, NOTCH and HEDGEHOG, have been shown to be involved in the DE differentiation into pancreatic endocrine cells^[16] (Figure 1). The inhibition of HEDGEHOG-signaling by Cyclopamine or KAAD cyclopamine induces the generation of *PDX1*-expressing cells^[17,18,25,27,29], whereas Fibroblast growth factor 10 activates NOTCH signaling, which is involved in the proliferation of *PDX1*-expressing pancreatic progenitors.

Another transcription factor to consider as a marker for late pancreatic cell development is neurogenin 3 (NGN3). NGN3 expression peaks during endocrine differentiation stage, which is subsequent to the generation of *PDX1* pancreatic progenitors. It has been previously shown that the capacity of PSCs to differentiate into pancreatic endocrine cells is highly affected by the seeding density of initial cultures. For example, Gage *et al.*^[47] demonstrated that high density hESCs led to remarkable increase in that rate of cell differentiation into *PDX1*- and NGN3-positive cells as compared to low density cultured cells. In contrast to *PDX1*, NGN3 expression is stimulated by a reduction in NOTCH signaling. It has been previously shown that the blockage of NOTCH signaling at this stage may be driven by DAPT (the gamma secretase inhibitor) treatment and thus drive NGN3-expressing cells formation^[17,18,27]. Interestingly, these cells have been found to be differentiated from *PDX1*-expressing pancreatic progenitors after specific treatments. A recent study used a xeno-free culture system

showed that a high NOGGIN concentration is crucial for inducing the differentiation of iPSCs into pancreatic progenitors (PDX1-positive) and then pancreatic endocrine progenitors (NGN3-positive cells)^[34]. A previous study showed that TGF β type 1 receptor inhibitor (SB431542) stimulates the differentiation of hESC-derived PDX1-positive pancreatic cells into NGN3-positive pancreatic endocrine progenitors^[28,48]. Another recent study reported the generation of NGN3-positive endocrine precursors after the inhibition of vesicular monoamine transporter 2 by reserpine and tetrabenazine in PDX1-positive cells^[49].

Differentiation into pancreatic β cells

The generation of mature pancreatic β cells from hESCs and hiPSCs is characterized by the expression of a panel of different factors, such as PDX1, MAFA, NKX6.1, NEUROD, ISL-1, and GLUT2, C-peptide, and INS (insulin)^[15]. Of these factors, NKX6.1 expression has been shown to be essential for the production of functional mature β cells. This significant role of NKX6.1 was remarkably clear in the *in vivo* studies done by Rezanian *et al.*^[50], where they showed that hyperglycemia significantly reduced in diabetic mice engrafted with cells expressing substantial amounts of NKX6.1. On the other hand, diabetic mice transplanted with cells expressing low levels of NKX6.1 remains hyperglycemic. In another study, it has been demonstrated that mice lacking NKX6.1 does not develop pancreatic β cells. However, re-expression of Nkx6.1 in pancreatic progenitors (PDX1-positive) restores the development of pancreatic β cells^[51]. It has been also reported that overexpression of some pancreatic development-transcription factors enhance pancreatic β cell differentiation^[52-54]. In human ESCs, enforced expression of the transcription factor PAX4 significantly promotes cell differentiation into pancreatic β cells^[55]. Also, overexpression of human PAX4 in hESC-derived pancreatic progenitors increases the number of insulin-secreting β cells, which produce only one hormone (insulin) by suppressing the expression of ARX and glucagon^[56]. In contrast, overexpression of PDX1 induces pancreatic endocrine cell differentiation, but not *in vitro* β -cell formation during the differentiation of hESCs into EBs^[57].

Several treatments, forskolin (an adenylate cyclase activator) and dexamethasone (a synthetic adrenocortical steroid)^[28], hepatocyte growth factor, insulin growth factor 1 and glucagon-like peptide 1^[9], have been used to enhance pancreatic β cell maturation *in vitro*. Several studies have previously reported the successful production of insulin-secreting cells *in vitro* from either hESCs or hiPSCs^[15,16,18,19,24,25,29,30,36,58-60]. However these differentiated β cells showed little ability to respond to glucose, which is considered one of the well-known and important parameters that recognize functional and mature β cells. These differentiated cells also lack the expression of specific mature pancreatic β cell markers such as NKX6.1 and MAFA^[19], that categorize them as immature non-functional β cells. Moreover, hPSC-derived β cells co-express multiple hormones such as INS, GCG (glucagon), and C-peptide

instead of secreting only insulin hormone, which is secreted only by mature β cells. Therefore, controversy exists as to the ability of PSCs to differentiate into fully functional pancreatic β cells^[61]. A previous study showed that endocrine precursors could be differentiated into glucose responsive β cells^[49], which is considered one of the major challenges during β cell differentiation process.

In vivo maturation of pluripotent stem cell-derived pancreatic β cells

Despite these contentious *in vitro* evidences, mentioned above, *in vivo* microenvironment is likely to be important for pancreatic β cells maturation. Several transplantation studies have demonstrated the differentiation of immature pancreatic β cells or pancreatic progenitors into mature β cells *in vivo*. In either healthy^[25,30] or streptozotocin (STZ)-induced diabetes mice^[62], functional and mature pancreatic β cells are successfully developed from hESC-derived pancreatic progenitors transplanted either under the mouse kidney capsule or fat pad. Interestingly, another study showed that pancreatic progenitor cells are still capable to differentiate into mature pancreatic β cells that efficiently secrete insulin within macroencapsulation devices that have been transplanted into diabetic mice^[63]. Like wise, in two different mouse models that mimic human T1D and T2D^[64,65] *in vivo*, transplanted iPSC-derived β cells efficiently differentiate into glucose-responsive pancreatic β cells. In these studies as well as another study that has used monkey iPSC-derived β cells^[48], the generated functional pancreatic β cells were found to improve hyperglycemia in the transplanted mouse models. Other studies reported that transplantation of pancreatic progenitors derived from PSCs into mice induces the differentiation of polyhormonal cells into glucose responsive pancreatic β cells (Figure 1). Interestingly, it has been found that such transition into mature β cells is associated with dynamic chromatin remodeling^[58,66-68].

Moreover, it has been found that urocortin 3 (Ucn3), which is a corticotropin-releasing factor, is highly expressed in pancreatic β cells and regulates glucose-stimulated insulin secretion^[69]. Although Ucn3 expression is detected in pancreatic β cells after *in vivo* maturation, it has not been detected after *in vitro* differentiation, suggesting the difference between *in vitro* and *in vivo* differentiation^[70]. Interestingly, the level of Ucn3 expression increases more than sevenfold between immature and mature pancreatic β cells^[70]. Thus *in vivo* maturation is critical for both the functionality and maturity of PSC-derived pancreatic β cells, indicating that there may be specific signals at the transplantation sites that induce and enhance β cell differentiation and maturation.

CHALLENGES AND FUTURE PERSPECTIVES

Several challenges need to be addressed before using PSCs in clinical applications and disease modeling. Differentiation of PSCs into mature, glucose responsive β cells is required for proper cellular therapies as well as for re-establishing the

disease phenotypes *in vitro* to understand the mechanisms underlying different forms of diabetes. Pancreatic β cell maturation is defined based on glucose-stimulated insulin secretion (GSIS). To date, although several reports showed an improvement in generating glucose-responsive insulin-secreting β cells *in vivo*, still their response to glucose is very limited *in vitro* due to their immature nature^[8,15-17,19]. A recent study has reported that insulin-secreting β cells differentiated from hPSCs are highly similar to human fetal pancreatic β cells than adult β cells^[71]. Also, it has been suggested that the inability of pancreatic β cells to produce adequate insulin is due to the gradual loss of a specific group of transcription factors, which is important for insulin secretion and glucose responsiveness. Previous studies reported that dysfunctional pancreatic β cells derived from hESCs fail to secrete PDX1, NKX6.1, and MAFA^[18,25,72], indicating that restoring the transcription factors is essential to recover β cell functions. Another study found that some genes related to early embryonic development (DPPA4, LIN28A, and LIN28B) continue to be expressed in the cells differentiated from PSCs, suggesting that the cells differentiated from PSCs are similar to the cells found in the very early stage of human development^[73]. Notwithstanding the above findings, transplantation of pancreatic progenitors derived from PSCs into immune-compromised mice induces their differentiation into glucose responsive mature β cells^[7,50,58,66-68]. Thus, future studies should focus on the signaling pathways regulating the maturation of pancreatic β cells *in vitro*.

Another problem hindering cell therapies of PSCs in diabetes is the low efficiency in producing insulin-secreting β cells. The current protocols are still lacking critical signals required for efficient generation of insulin-secreting β cells. Therefore, future studies should focus on studying the molecular mechanisms, guiding normal pancreatic development and to develop highly efficient differentiation protocols to obtain large number of insulin-secreting β cells.

Furthermore, one of the problems facing the stem cell therapies is the potential for unwanted cell growth. Undifferentiated PSCs are characterized by their ability to produce teratoma *in vivo* due to their high pluripotential capabilities. Previous studies suggested that encapsulation of the transplanted cells prevents overgrowth^[74,75]. In addition, encapsulation was found to be crucial to differentiate PSCs into pure culture of insulin-secreting β cells to avoid their contamination with undifferentiated cells. To use the functional pancreatic β cells to cure T1D, the repair of self-tolerance or eliminate the influences of autoimmunity must be considered, thus the immune system cannot destroy the newly transplanted insulin-secreting β cells. Therefore, several studies reported the use of encapsulated devices to protect pancreatic β cells from immunological attack. Glucose responsive insulin-secreting grafts have been generated from encapsulated CyT49-luc hESC-derived pancreatic epithelium and found that maturation occurs without an increase in cell biomass^[75]. Thus, encapsulation is considered as a possible tool to overcome some of the grand challenges in diabetes treatment by stem cell therapy.

Another challenge is related to the use of ESCs in

cell therapy due to ethical concerns and immune rejection problem. The use of patient-specific ESCs, which are immunologically compatible to the patient, would overcome the immune rejection issue since ESCs can be generated from the somatic cells of the patients using SCNT^[13,76].

In conclusion, there is a lot of work need to be done to obtain fully functional pancreatic β cells *in vitro*. For example, a genome-wide transcriptional analysis should be performed in each stage during pancreatic β cell differentiation to recognize the defects in the transcription factors. Also, comparing *in vivo* pancreatic development with *in vitro* pancreatic differentiation is important to identify the difference in gene expression, which may account for the functional differences. Finally, different differentiation protocols should be applied to understand the signaling pathways controlling the differentiation process *in vitro*.

Abstract

It has been a decade since the monumental discovery of resident stem cells in the mammalian heart, and the following studies witnessed the continuous turnover of cardiomyocytes and vascular cells, maintaining the homeostasis of the organ. Recently, the autologous administration of c-kit-positive cardiac stem cells in patients with ischemic heart failure has led to an incredible outcome; the left ventricular ejection fraction of the cell-treated group improved from 30% at the baseline to 38% after one year and to 42% after two years of cell injection. The potential underlying mechanisms, before and after

cell infusion, are explored and discussed in this article. Some of them are related to the intrinsic property of the resident stem cells, such as direct differentiation, paracrine action, and immunomodulatory function, whereas others involve environmental factors, leading to cellular reverse remodeling and to the natural selection of "juvenile" cells. It has now been demonstrated that cardiac stem cells for therapeutic purposes can be prepared from tiny biopsied specimens of the failing heart as well as from frozen tissues, which may remarkably expand the repertoire of the strategy against various cardiovascular disorders, including non-ischemic cardiomyopathy and congenital heart diseases. Further translational investigations are needed to explore these possibilities.

Key words: Regeneration; Heart failure; Cell therapy; C-kit; Cardiac stem cells; Cellular reverse remodeling; Miracine

Core tip: The autologous transplantation of cardiac stem cells appeared to be safe and surprisingly effective for a small group of patients with chronic ischemic cardiomyopathy. Their specific feature as resident stem cells, the interaction with the surrounding tissue, and the natural selection during the cell culture process potentially contributed together to the outstanding consequences.

INTRODUCTION

The advancement of emergency medicine enabled us to

rescue many patients with acute myocardial infarction, but they may eventually develop and suffer from chronic heart failure later in life. Accordingly, the demand of alternative approaches to chronic ventricular dysfunction is increasing dramatically. For decades, the mammalian heart was recognized as a postmitotic terminally differentiated organ, in which the number of cardiomyocytes was believed to be constant throughout the life span of organisms. Early this century, however, the existence of resident cardiac stem cells (CSCs) was unveiled^[1], questioning the validity of the long-lasting theory. The uninterrupted renewal of human myocardium in physiological and pathological circumstances has been depicted^[2], promoting our understanding of the self-renewing characteristic of the heart. This paradigm shift not only shook the biological dogma but revealed the possibility of an unprecedented therapeutic strategy for devastating diseases.

CLINICAL APPLICATION OF CARDIAC STEM CELLS

By virtue of the explorations following the discovery of resident CSCs, the human heart has been characterized by the persistent renewal of its components, muscles and vessels. Moreover, by utilizing animal models, c-kit-positive CSCs are shown to regenerate the diseased myocardium of ischemic and non-ischemic origins^[3-5]. Subsequently, in 2009 the first clinical use of autologous CSCs began; in this SCIPIO trial, the subjects with severe ischemic heart failure received an elective coronary artery bypass graft surgery, during which a tiny piece of the right atrial appendage was resected as the source of stem cells. Four months after the operation, only those with the left ventricular ejection fraction (LVEF) worse than 40% were included in the trial and randomly assigned to the control or cell-treated groups. While the cardiac function did not change in the control group, the LVEF dramatically improved in the treated patients, from 30% at the baseline to 38% after one year and to 42% after two years of cell administration^[6,7]. The infarct size evaluated by an MRI remarkably reduced following the cell therapy, and the symptom improved as well. It should be noted that the major adverse cardiac event rate was unchanged with or without this therapeutic intervention^[8].

DIRECT DIFFERENTIATION VS PARACRINE ACTION

A single intracoronary injection of one million CSCs, as described above, appeared to be safe and effective for 2 years or longer. How does this work? There are accumulated evidences suggesting that most cell types applied for heart failure, including skeletal myoblasts, bone marrow-derived cells, and cardiosphere-derived cells^[9,10], function through paracrine mechanisms^[11-13]. In this regard, CSCs are found to work through the sequential processes of engraftment, proliferation, and direct differentiation into various cardiac cell types^[14], in addition to the paracrine action^[15,16]. Actually,

a recent study showed that the injection of 200 million human mesenchymal stem/stromal cells (MSCs) and that of one million c-kit-positive CSCs into a two-week-old infarcted myocardium were similarly effective, revealing the great regenerative potential of resident stem cells^[17]. Interestingly, the combined usage of these distinct cells resulted in a synergistic effect, formulating an attractive regimen for myocardial infarction.

REGULATION OF IMMUNE RESPONSE

The environment of the host tissue is not always favorable for the transplanted cells to engraft, especially when allogeneic ones are used. Historically, MSCs were found to be immune privileged, due to their lack of major histocompatibility complex class II antigen. In fact, the endomyocardial injections of autologous and allogeneic bone marrow MSCs were similarly effective as a treatment for ischemic heart failure patients^[18]. More recently, Di Trapani *et al.*^[19] have demonstrated that certain stem cells of various sources, including CSCs, are able to regulate the immune response of the recipient^[19]. Such properties may have a role *in vivo* in enhancing their regenerative ability, especially in inflammatory circumstances. These reports would support the enthusiasm for the “off-the-shelf” usage of allogeneic CSCs. The obvious advantages include minimizing the lot-to-lot variation of cell therapy and its applicability to the acute phase of the disease. Following the differentiation of engrafted CSCs *in vivo*, however, the immune system of the host may reject them, just like in the case with rat MSCs^[20]. Although this particular study was carried out with rodents, stem cells of any given species would become immunogenic upon the acquisition of myogenic phenotypes. In the setting of allogeneic transplantation, therefore, the long-term benefit depends essentially on the paracrine action of the administered cells. Further evaluations would be needed to compare the advantages and disadvantages of respective therapeutic strategies.

REVERSE REMODELING AT CELLULAR LEVEL

As stated above, while the administered cells may affect the circumstance, the microenvironment within the host would also influence the destiny of the exogenous cells. Based on the studies using immunosuppressed animals, human CSCs can create more cardiomyocytes than the lost myocytes of the recipient, within one month after injection^[21]. Assuming a comparable growth behavior of the autologous CSCs, it might be unlikely that these cells divided continuously and frequently for more than 2 years. Instead, it would be reasonable to speculate that each differentiated progeny gradually matured to improve the global function of the organ. Lately, it was shown that microRNAs (miRs) can traverse gap junctions and influence the fate of the cells receiving these miRs. Specifically, miR-499, which is abundant in cardiomyocytes

and essentially absent in CSCs, can be transferred from myocytes to resident stem cells *via* gap junction channels, resulting in the enhanced differentiation of the primitive cells toward myocytic lineage^[22]. Therefore, it can be presumed that the presence or absence of matured myocytes in a microenvironment determines the destiny of stem cells *in situ*. Actually, this theory is consistent with the previous observation in which CSCs engrafted in remote myocardium, full of surviving mature cells, progressively differentiate to become indistinguishable from its surrounding myocytes within five weeks^[23]. On the contrary, at the infarcted/regenerated area, cardiomyocytes derived from injected CSCs tend to hold fetal/neonatal characteristics for the same period of time. Once committed to the myocytic lineage, CSCs themselves start to express miR-499, and the quantity increases as the differentiation process advances, which in turn may have an influence on neighboring immature cells through the mircrine mechanism. This cascade of progressive maturation may be called “cellular reverse remodeling”.

CONSEQUENCE OF CELL EXPANSION

Another essential factor can be pointed out in the cell preparation procedure. The necessity of CSC cultivation prior to injection basically excludes the autologous implantation at the acute stage, and this is generally considered to be a major drawback of somatic stem cell treatments. This inevitable culturing step, however, may hold an advantageous aspect as well. Because rapidly multiplying “juvenile” cells grow faster than “senile” ones on the dish, this maneuver practically functions as a natural selection process. Conversely, when cells harvested from a body are used directly to treat an acute illness, the cell population may be heterogeneous by nature within the patients as well as among the preparations for various patients. Needless to say, it is unlikely that a longer culturing period gives a better outcome; there should be a certain threshold. Accordingly, CSCs should be characterized better, in order to pick the right timing and method for the cell preparation step.

PERSPECTIVE

The clinical applications of resident CSCs began only five years ago. Due to the limited number of subjects and the relatively short observational period, we still do not yet know whether this therapy will improve hard endpoints such as the survival of patients. Also, the treatment was mainly applied to patients who required cardiac surgery. However, a recent research indicated that tiny pieces of the failing heart, approximately 5 mg in weight, are sufficient for CSC preparation^[24]. Moreover, our group has lately succeeded in culturing CSCs from small surgical specimens kept frozen for longer than a year; the isolated cells possessed properties comparable to that of those derived from fresh tissues (unpublished observation). This is clinically relevant and important, in light of the

potential repetitive treatment of a single patient and/or applications to adult congenital heart diseases. We have to investigate further to see whether such repeated CSC injections and its usage for pediatric patients are safe and effective as expected. This endeavor will be able to salvage a large number of patients who do not have adequate therapeutic options at the present time.

Abstract

In the past few years, stem cells have become the focus of research by regenerative medicine professionals and tissue engineers. Embryonic stem cells, although capable of differentiating into cell lineages of all three germ layers, are limited in their utilization due to ethical issues. In contrast, the autologous harvest and subsequent transplantation of adult stem cells from bone marrow, adipose tissue or blood have been experimentally utilized in the treatment of a wide variety of diseases ranging from myocardial infarction to Alzheimer's disease. The physiologic consequences of stem cell transplantation and its impact on functional recovery have been studied

INTRODUCTION

In recent years, stem cells have become a focus of regenerative medicine. Adult stem cells, harvested directly from bone marrow, adipose tissue or blood have the ability to undergo mitosis as well as multipotent differentiation into a variety of cell lineages. The goal of stem cell therapy is to replace or replenish diseased tissue through the localized differentiation of transplanted stem cells into cells which advance the healing process or directly restore the tissue physically. Despite the years of research elucidating the physiology and the processes of stem cell differentiation, both the survival as well as the physical

and biochemical control over the stem cells when implanted into a body remains a challenge. Advances in material sciences have aided tremendously in providing a three-dimensional environment for the cells within a scaffold which allows for both the local retention of cells where they are intended to operate and simultaneously allowing the diffusion of nutrients to enable cell survival. Advances in genetic engineering on the other hand have allowed the modification of stem cells to induce the expression of selective growth factors to further aid in tissue reconstruction. Several challenges in spine surgery have been addressed by experimental ventures into stem cell therapy. Degenerative spinal disorders such as Degenerative Disk Disease have been sought to be addressed through the biological reconstruction of the disk by a variety of stem cells and growth factors, thereby potentially circumventing the need for surgery. The potentially devastating consequences of Spinal Cord Injury have been moderated through the implantation of stem cells to aid in the recovery of nerve cells. Spine surgery itself has been the focus of tissue engineers primarily to achieve bony fusion in the spinal fusion of vertebrae to attain stability. The iatrogenic injury of peripheral nerves and skeletal muscle surrounding the spine, which inevitably occurs during spine surgery whilst access to the spine is being prepared, although not as dramatic in its effect on the disability of the patient in the long-term has been addressed by many scientists. Overall, stem cell therapy, despite being in the experimental phase in most sub-disciplines, promises exciting opportunities to improve spine care and decrease the morbidity due to spine surgery in the future.

APPLICATION OF STEM CELLS IN SPINE SURGERY

Spine fusion

Spine fusion is performed to address the pain, deformity or neurologic deficit caused by degenerative conditions, spinal tumor, vertebral fractures and spinal deformities such as scoliosis and kyphosis amongst other indications. The bony fusion between two or more vertebrae eliminates the pain caused by aberrant motion of the vertebrae through immobilization. Lumbar fusion has been reported to have increased at a rate of 220% from 1990, more than the increases for knee and hip arthroplasty combined^[1]. Ambulatory lumbar spine surgery has been demonstrated to increase at a larger rate relative to inpatient surgery^[2]. Cervical and thoracolumbar fusions have also reportedly increased at a rate of 89% and 31%, respectively, mirroring the rapid increase in the utilization of the procedure^[3]. The introduction of new surgical technology has not proven to reduce reoperation rates^[4]. The vital elements in bony fusion are an adequate quantity of bone-forming cells (osteogenesis), an appropriate microenvironment directing bone synthesis through a variety of growth factors (osteinduction), and a scaffold or cage in which the growth of bone is well positioned (osteoconduction).

Despite the recent advances in cage design and bone fusion extender materials, pseudoarthrosis remains a pressing issue occurring in 13%-41.4% of patients^[5-8]. Risk factors for pseudoarthrosis have been reported to be older age, thoracolumbar kyphosis, smoking, diabetes mellitus, metabolic bone disease and female gender^[6,8-11]. As patients more than 60 years old represent the demographic with the largest increase in the rate of fusion surgery, the medical community has begun investigating alternatives to support the process of bone growth and fusion, for example with the implantation of stem cells^[1]. The gold standard for creating a bony fusion is the use of autograft bone from the iliac crest; however, this has been associated with increased morbidity. Allograft or synthetic bone graft extenders carry the osteoconductive, and to a different extent, the osteoinductive properties, but no cells that will bring the fusion together. Mesenchymal stem cells (MSCs) harvested from the bone marrow, adipose tissue, periosteum or skeletal muscle have been confirmed to differentiate into osteoblasts both *in vitro* and *in vivo*^[12-17]. Adipose derived stem cells (ADSCs) harvested from fat pads, although less commonly utilized in experimental models, are multipotent cells that can differentiate into adipocytes, osteoblasts, chondrocytes, or myocytes when cultivated in the correct microenvironment^[17-21]. Both types of cells have been demonstrated to have a significant effect on spinal fusion in a multitude of settings including a variety of culturing mechanisms, scaffolds and added growth factors. Bone morphogenetic protein-2 (BMP-2) is a growth factor which is increasingly used in spinal fusion, mostly on an off-label basis, which may be the reason for the increased incidence of complications associated with its utilization^[22]. Genetically modified MSCs which were induced to express BMP-2 were reported to induce spinal fusion in mice after injection into the paraspinal musculature comparable, in terms of rigidity, to the fusion achieved with instrumentation^[23,24]. Fu *et al*^[25] addressed the concern of complications associated with BMP-2 by examining if a reduced amount combined with MSCs would still yield acceptable fusion rates. They found that the group with MSCs seeded on alginate with a low dose of BMP-2 achieved equal fusion rates to the group treated with an iliac crest autograft in a rabbit model^[25]. Additional evidence that MSCs may potentially serve as a substitute for autograft or BMP-2 has been presented, however, slightly lower fusion rates were reported for the group treated with MSCs *vs* the group treated with BMP-2 in a rabbit model^[26]. Seo *et al*^[27] attempted to induce higher fusion rates in a rat model by transplanting MSCs seeded on hydroxyapatite in addition to fibroblast growth factor-4, but found that the group treated without the addition of the growth factor achieved the highest fusion rate^[27]. Other than selection of the appropriate growth factor, the level of osteogenic differentiation of the cells may also play a role. One study reported that 80% of rabbit spines treated with MSCs cultured in osteogenic differentiation medium fused *vs* only 33.3% of spines treated with cells that had been cultured without

the addition of differentiation medium^[28]. The efficacy of MSCs transplanted without amendments to culturing protocols, the addition of genetic engineering or growth factors has been less encouraging in a variety of animal models utilizing beta-tricalcium phosphate graft or porous ceramics^[29-31]. Recently, stem cells derived from adipose tissue have become popular in the tissue engineering community, in part due to the ease of cell harvesting from fat pads through liposuction. ADSCs expressing bone morphogenic proteins have proven effective for spinal fusion in animal models of metabolic bone disease^[32,33]. In a study comparing MSCs and ADSCs expressing BMP-2 seeded on collagen sponges, fusion rates were encouraging and not significantly different in the two groups of rat models^[34]. Due to the relatively easier clinical access to ADSCs in the patient, greater attention to their potential role in spinal fusion is warranted. Overall, the use of stem cells in clinical spine fusion has been restricted due to the limited number of cells which may be harvested through liposuction or bone marrow puncture. Cellular *in vitro* expansion is necessary to increase the number of viable pluripotent cells. This represents the greatest burden in the bench to bedside translation of stem cells in spine fusion, as two separate procedures, the availability of sophisticated instrumentation and educated personnel decrease the cost-effectiveness of the intervention^[35-37].

Disc regeneration

Degenerative Disk Disease results from a complex process regulated by biomechanical forces and molecular changes within the disk. A healthy disk consists of the nucleus pulposus rich in collagen type II fibers with a high content of proteoglycan and aggrecan to aid in the resistance to compression^[38,39]. It is surrounded by the annulus fibrosus, rich in collagen type I fibers which are arranged in a parallel fashion to withstand bending and twisting forces. A healthy disk is aneural and avascular due to the high proteoglycan content of the nucleus pulposus, receiving most of its nutrients by diffusion through the vertebral endplate^[40]. Starting at the second decade of life, the progressive calcification of the endplate results in a decrease in the nutrient supply to the disk^[41]. This has been hypothesized to result in phenotypic changes leading to decreased synthesis of proteoglycan and collagen type II, and increased synthesis of collagen type I and III as well as an increase in matrix metalloproteinase activity^[41-44]. Overall, the change in the biochemical composition of the disk results in gross morphologic changes and decreased disk height which contribute to the impingement of nerves^[45-47]. The clinical manifestation of Degenerative Disk Disease in the form of lower back pain is usually focused on conservative management including lifestyle- or work modifications, physical therapy, pain medication, acupuncture and epidural injections. If the symptoms are persistent, cause progressive deformity or neurologic compromise, surgery in the form of disc replacement or spinal fusion is considered^[48]. Growth factors, inflammatory cytokine antagonists and intracellular regulatory proteins are among the factors which have

been demonstrated to result in encouraging regeneration of nucleus pulposus cells *in vitro* and *in vivo*^[49-53]. The utility of these therapies in humans may be limited due to the rapid *in vivo* degeneration of the molecules used for the treatment. Gene therapy, although successfully utilized in animal studies, has significant risks concerning the vectors used for gene transduction. Stem cell therapy for Degenerative Disk Disease is based on the premise of reconstruction of the nucleus pulposus matrix. Nishimura and Mochida were the first to reimplant autologous nucleus pulposus cells in a disk herniation rat model and reported decreased degeneration of the annulus fibrosus, the endplate and the remaining nucleus pulposus when compared to the control group^[54]. As with bony fusion, most scientists have focused on MSCs for Degenerative Disk regeneration. MSCs can differentiate into cell lineages populating bone, cartilage, skeletal muscle and ligamentous tissue^[15]. As the exact phenotype of nucleus pulposus cells has yet to be determined, confirmation of the possibility of MSCs to differentiate into nucleus pulposus cells capable of proteoglycan production does not exist. Nonetheless, researchers have demonstrated that various environmental stimuli and genetic manipulations may result in an MSC differentiating into a nucleus pulposus-like cell. Richardson *et al*^[55] transfected MSCs using the transcription factor, SOX-9, and found that they differentiated into chondrocyte-like cells with the deposition of nucleus pulposus matrix markers collagen type II and aggrecan^[55]. Risbud *et al*^[56,57] experimentally cultured immobilized MSCs under hypoxic conditions with transforming growth factor-beta and found that these conditions prompted MSC differentiation towards nucleus pulposus-like cells^[56,57]. Similar differentiation of stem cells into cells which expressed nucleus pulposus-like phenotypic markers has been observed in rabbit studies. Sakai *et al*^[58,59] studied the effect of the transplantation of MSCs into both healthy and degenerated disks. They found that the implanted cells differentiated into nucleus pulposus-like cells, producing collagen type II and proteoglycan without harm to the rabbit^[58,59]. The degenerated disks showed significant improvement in height and hydration^[60]. Allogenic MSCs were transplanted into the intervertebral disk in a rat model, and demonstrated viability and proliferation^[61]. However, concerns regarding an immune reaction to allogenic stem cells in humans have limited the utilization of such cells in clinical trials. Orozco *et al*^[62] transplanted autologous MSCs into ten patients diagnosed with Degenerative Disk Disease^[62]. They found improvements in pain and disability within three months of treatment. Their study had severe limitations regarding the average age of the patients (35 years) and the number of patients (10). Nonetheless, these results exemplify the importance of arranging larger clinical trials to ease the translation of stem cell therapy from bench to bedside for patients suffering from Degenerative Disk Disease.

Spinal cord injury

Spinal cord injury (SCI) results from traumatic damage to the spinal cord which may have devastating consequences

or result in death^[63]. The most common causes of traumatic SCI are motor vehicle accidents, sports injuries, falls at home, and traumatic injury in the workplace^[64]. A total of 15-40 cases per million people are estimated to suffer a SCI every year, with most cases occurring in males 16-30 years of age^[65-67]. SCI consists of several complex phases which are yet to be elucidated fully on a molecular level. The primary or acute phase consists of the physical disruption and contusion of the nerves and the tissues surrounding the spinal cord^[68]. The force of the traumatic disturbance correlates directly with the amount of cell death^[69]. As a consequence, the spinal cord swells and concomitantly with the commonly associated hemorrhage impedes blood flow, causing hypoxia^[70-74]. The second or sub-acute phase of SCI is characterized by overlapping phases of sustained inflammation, oxidative and immune events. Excessive glutamate levels, the formation of reactive oxygen species and lipid peroxidation cause widespread neuronal and glial death, and axonal degeneration^[75-79]. The scar tissue which is generated during the third or chronic phase presents a physical and biochemical barrier for axonal regeneration, complicating recovery^[80,81]. Scientists have experimented with stem cell transplantation in the hope of promoting functional recovery after SCI. The intervention may be targeted at different phases, but should ideally enhance neuron and axon regeneration and remyelination through the creation of a favorable microenvironment or the direct physical replacement of cells^[82]. This may best be achieved through suppression of the inflammatory cascade resulting in cell apoptosis and necrosis^[83]. Embryonic stem cells, pluripotent cells derived from the inner cell mass of an embryo, have been considered as a treatment option for SCI^[84]. Although these cells can divide infinitely and have greater differentiation potential than adult stem cells, their use is highly controversial^[85-89]. A Chinese surgeon who claimed to have cured SCI in hundreds of patients without complications by injecting them with olfactory ensheathing cells isolated from aborted fetuses was received with great skepticism and sparked fierce debates about the ethicality of such research^[90-93]. The Gevron Corporation is the first company to have received approval to initiate a clinical trial assessing a human embryonic stem cell-derived candidate therapy for severe spinal cord injuries in the United States^[94]. Adult stem cells have more commonly been used in both *in vitro* and *in vivo* experimentation due to the ethical concerns regarding embryonic stem cells. MSCs are favored by many scientists due to the ease of cell harvest, isolation, expansion, and preservation^[35,95-97]. To date, no reports of immunologic reactions to allogeneic *vs* autologous cell transplants have been observed, making MSCs a very practical solution for cellular therapy^[98,99]. MSCs have been demonstrated to promote axonal regeneration and suppress demyelination^[100]. Several different studies in rat models found that MSCs induce nerve regeneration, modulate the production of inflammatory cytokines such as TNF- α and IL-6 and reduce myeloperoxidase activity^[101-105]. Menezes *et al*^[106] hypothesized that laminin may play a pivotal role in neuron and axon preservation and regeneration after finding deposits of the glycoprotein on the lesion site

in a rat SCI model^[106]. All of these studies reported that transplanted MSCs operate mainly through the creation of a favorable microenvironment by means of the secretion of a variety of neurotrophic factors^[107-111]. However, the *in vivo* differentiation of MSCs into neuron-like cells has been documented to be inefficient^[108-110]. Therefore, MSCs are as of now, not capable of directly repopulating and physically restoring the damaged tissue in SCI. Neural stem cells (NSCs) were sought as an option for stem cell therapy, specifically for their ability to overcome this deficit. NSCs are harvested from the subventricular zone and are capable of differentiation into neurons, oligodendrocytes and most commonly astrocytes^[112,113]. Nemat *et al*^[114] reported that the transplantation of NSCs into a contusion SCI in a monkey model facilitated hind limb performance recovery^[114]. Lee *et al*^[115] documented similar functional recovery in terms of hind limb recovery paired with reduced lesions and an increased density of axons and dendritic spines surrounding the transplanted NSCs in a rat model^[115]. Piltti *et al*^[116] examined the survival rates, migration and sensory fiber sprouting of transplanted NSCs in a rat model in the secondary or subacute phase *vs* the tertiary or chronic phase of SCI. They found that the number of surviving transplanted cells was lower in the group treated during the tertiary phase, but that these cells had a stronger effect by increasing the number of mature oligodendrocytes^[116]. The experimental utilization of stem cell therapy in SCI has been very limited to date. Several studies have reported sensory and motor improvements after 1-3 mo of stem cell transplantations combined with various other cells and growth factors^[117-121]. In contrast, Karamouzian *et al*^[122] stated that despite the feasibility and safety of cellular transplantations, the improvements in terms of functional recovery were not statistically significant in their study^[122]. The low numbers of patients in these studies make it difficult to provide a definitive statement on the clinical potential of stem cell transplantation for SCI.

CONCLUSION

Additional areas of interest which have not been clinically addressed with stem cell therapy are iatrogenic nerve and muscle injury caused by spinal surgery. Additional considerations are warranted with respect to the ethics and the cancerogenous risk of embryonic stem cell therapy, the potential immune reaction to autologous cell transplantation as well as the clinical morbidity of adult stem cell harvest. Overall, greater standardization of *in vitro* experimentation and animal models may aid the speed of translation of stem cell therapy in spinal surgery from bench to bedside.

Abstract

AIM: To investigate the potential for early gestation placenta-derived mesenchymal stromal cells (PMSCs) for fetal tissue engineering.

METHODS: PMSCs were isolated from early gestation chorionic villus tissue by explant culture. Chorionic villus sampling (CVS)-size tissue samples (mean = 35.93 mg)

were used to test the feasibility of obtaining large cell numbers from CVS within a clinically relevant timeframe. We characterized PMSCs isolated from 6 donor placentas by flow cytometry immunophenotyping, multipotency assays, and through immunofluorescent staining. Protein secretion from PMSCs was examined using two cytokine array assays capable of probing for over 70 factors in total. Delivery vehicle compatibility of PMSCs was determined using three common scaffold systems: fibrin glue, collagen hydrogel, and biodegradable nanofibrous scaffolds made from a combination of polylactic acid (PLA) and poly(lactic-co-glycolic acid) (PLGA). Viral transduction of PMSCs was performed using a Luciferase-GFP-containing lentiviral vector and efficiency of transduction was tested by fluorescent microscopy and flow cytometry analysis.

RESULTS: We determined that an average of 2.09×10^6 (SD $\pm 8.59 \times 10^5$) PMSCs could be obtained from CVS-size tissue samples within 30 d (mean = 27 d, SD ± 2.28), indicating that therapeutic numbers of cells can be rapidly expanded from very limited masses of tissue. Immunophenotyping by flow cytometry demonstrated that PMSCs were positive for MSC markers CD105, CD90, CD73, CD44, and CD29, and were negative for hematopoietic and endothelial markers CD45, CD34, and CD31. PMSCs displayed trilineage differentiation capability, and were found to express developmental transcription factors Sox10 and Sox17 as well as neural-related structural proteins NFM, Nestin, and S100 β . Cytokine arrays revealed a robust and extensive profile of PMSC-secreted cytokines and growth factors, and detected 34 factors with spot density values exceeding 10^3 . Detected factors had widely diverse functions that include modulation of angiogenesis and immune response, cell chemotaxis, cell proliferation, blood vessel maturation and homeostasis, modulation of insulin-like growth factor activity, neuroprotection, extracellular matrix degradation and even blood coagulation. Importantly, PMSCs were also determined to be compatible with both

biological and synthetic material-based delivery vehicles such as collagen and fibrin hydrogels, and biodegradable nanofiber scaffolds made from a combination of PLA and PLGA. Finally, we demonstrated that PMSCs can be efficiently transduced (> 95%) with a Luciferase-GFP-containing lentiviral vector for future *in vivo* cell tracking after transplantation.

CONCLUSION: Our findings indicate that PMSCs represent a unique source of cells that can be effectively utilized for in utero cell therapy and tissue engineering.

Core tip: In this study we characterize mesenchymal stromal cells derived from early gestation human placenta chorionic villi (PMSCs) for the purpose of fetal tissue engineering. We examine cell expansion in early passages from chorionic villus sampling-size tissue samples, as well as PMSC surface marker expression, multipotency, intracellular protein expression, protein secretion, and compatibility with delivery vehicles and tracking methods often used for *in vivo* experimentation. We show that early gestation PMSCs are excellent candidates for future tissue engineering studies, particularly as it applies to in utero therapy for congenital anomalies.

Early gestation chorionic villi-derived stromal cells for fetal tissue engineering. *World J Stem Cells* 2015; 7(1): 195-207 Available from: URL: <http://www.wjgnet.com/1948-0210/full/v7/i1/195.htm> DOI: <http://dx.doi.org/10.4252/wjsc.v7.i1.195>

INTRODUCTION

Over the past three decades, fetal surgery has emerged as an effective treatment option for congenital diseases, including spina bifida, congenital diaphragmatic hernia, sacrococcygeal teratoma and cardiac malformations^[1,2]. *In utero* intervention allows clinicians to treat disease quickly after its onset and prevent debilitating symptoms before they ever occur^[3,4]. Mesenchymal stromal cell (MSC) therapy can augment existing *in utero* surgical techniques, and treatment with MSCs has been shown to promote wound healing^[5,6], protect damaged tissues^[7-11], and modulate the immune system^[12-15]. Cells obtained *via* methods such as chorionic villus sampling (CVS) allow for the potential development of cell therapies that are autologous (derived from the patient's cells) to the fetus^[16-18]. Autologous therapies are potentially preferable to allogeneic (not patient specific) therapies, as using the patient's own cells in a therapy should not elicit an immune response^[19]. However, where autologous therapies are not required, allogeneic

early gestation chorionic villus tissue can be an outstanding cell source for cell therapy as well.

The chorionic villi of early gestation placenta present an ideal source of autologous and allogeneic stromal cells. Placenta-derived mesenchymal stromal cells (PMSCs) are analogous to the MSCs routinely obtained from bone marrow in both surface marker expression and multipotency^[20,21]. Investigators interested in utilizing PMSCs or other fetal-derived mesenchymal stromal cells have demonstrated their potential for engineering bone^[22-24], cartilage^[25-27], and muscle^[28-30], as well as pancreatic^[31], neural^[17,17] and cardiac tissues^[18,32-34]. The gestational age of the source tissue may affect the therapeutic capabilities of the cells. One study comparing cells obtained from term chorionic villus tissue *vs* those from first trimester tissue noted that the cells from earlier gestation tissue had more stem-like properties, faster growth kinetics, and improved wound-healing capability *in vivo*^[35]. These data indicate that cells obtained from earlier gestation chorionic villus tissue may be preferential to term cells for tissue engineering purposes.

In this study we isolate PMSCs from chorionic villus tissue of early gestation placenta (GA 12-18 wk). We detail the initial growth phase of cells isolated from CVS-sized tissue samples using an explant culture method. PMSCs were characterized by flow cytometry immunophenotyping, multipotency assays and immunofluorescent staining for stem cell related transcription factors and intracellular markers, as well as by examining secreted proteins by membrane array. We demonstrate that these cells are compatible with multiple delivery matrices critical to their local distribution upon surgical transplantation. Lastly, PMSCs are shown to be efficiently transduced with a Luciferase-GFP-containing lentiviral vector which allows for cell tracking data to be obtained from *in vivo* transplantation experiments. These data provide further support for the use of early gestation PMSCs for *in vivo* tissue engineering purposes, and sets the stage for further investigation of the therapeutic profile of transplantable cell-seeded matrices.

MATERIALS AND METHODS

Isolation and culture of PMSCs from human early gestation placenta

Donated placental tissues were collected at the UC Davis Medical Center with approval from the Institutional Review Board. PMSCs were isolated from placentas of varying ages early in gestation (GA 12-18 wk) using an explant culture method. Chorionic villus tissue was dissected into small pieces (roughly 5 mm) and washed in sterile 1X phosphate-buffered saline (PBS) containing 100 UI/mL of penicillin, 100 µg/mL of streptomycin. Tissue was then dissected into even smaller pieces and evenly spread across tissue culture-treated dishes. Cells were allowed to migrate from tissue onto the dish before being harvested for subculture. Cells were cryopreserved in a freeze media containing fetal bovine serum (FBS) and 10% dimethyl sulfoxide beginning at passages 3-5 and

thawed for later characterization. Our standard culture media for all experiments was DMEM high glucose with 5% FBS, 100 UI/mL of penicillin, 100 µg/mL of streptomycin, 20 ng/mL recombinant human bFGF (Peprotech) and 20 ng/mL recombinant human EGF (Peprotech).

Early passage growth from CVS-size samples

Cell growth curves were generated from PMSCs obtained from CVS-size tissue samples in order to test the feasibility of obtaining significant cell numbers from a limited tissue mass. Early gestation chorionic villus tissue was carefully dissected and washed in sterile 1X PBS containing 100 UI/mL of penicillin and 100 µg/mL of streptomycin. Dissected tissue was then further cut into smaller pieces (about 20-50 mg) analogous to the amount of tissue obtained in routine chorionic villus sampling (CVS). The CVS-size samples were weighed before being further dissected and spread evenly across an individual well of a 6-well cell culture plate previously coated with CELLStart xeno-free substrate for 1 h at 37 °C. When cells reached 70%-80% confluence, individual wells were passaged and villus tissue removed. Cells were counted at each passage up to the third passage.

Flow cytometry immunophenotyping of PMSCs

Cells were detached for flow cytometry using Accutase (Invitrogen) and viable cell counts obtained using Trypan Blue staining. Cells were then fractioned into tubes containing approximately 1×10^6 cells per sample before staining with the following antibodies: FITC-CD44 (560977), PECy5-CD90 (555597), PE-CD73 (561014), Alexa Fluor 647-CD105 (561439), PE-CD29 (561795), PE-CD34 (560941), Alexa Fluor 647-CD31 (561654), FITC-CD45 (560976) or appropriate isotype controls (all from B.D. Biosciences). Prior to antibody staining, viability staining was completed using LIVE/DEAD® Fixable Aqua Dead Cell Stain Kit (Molecular Probes) to detect dead cells. After viability and antibody staining, cells were fixed in 10% formalin for 30 min prior to analysis. Cell samples were analyzed on a BD Fortessa LSR Cell Analyzer and further data analysis and gating was performed using FlowJo software (Treestar, Inc).

Multipotency assays

Trilineage differentiation capability of PMSCs was assessed using the assays described below.

For osteogenic differentiation, PMSCs were grown in media consisting of DMEM containing 10% FBS, 10 mmol/L β-glycerol phosphate (Sigma Aldrich), 0.1 µmol/L dexamethasone (Sigma Aldrich) and 200 µmol/L ascorbic acid (Sigma Aldrich) for a minimum of two weeks. Upon differentiation cells were fixed in formalin and osteogenesis confirmed using Alizarin Red staining (Sigma-Aldrich).

For chondrogenic differentiation, PMSCs were grown as cell pellets in suspension in media consisting of DMEM containing 10% FBS, 10 ng/mL transforming growth factor

beta-3 (Peprotech), and 200 µmol/L ascorbic acid (Sigma Aldrich) for a minimum of 3 wk. Chondrogenic pellets were then fixed in formalin before subsequently being embedded in Optimal Cutting Temperature compound (Fisher Scientific) and frozen prior to sectioning. Pellet cross sections were then stained with Alcian Blue (Sigma-Aldrich) and Nuclear Fast Red (Sigma Aldrich) to confirm presence of glycosaminoglycans.

For adipogenic differentiation, PMSCs were grown in media consisting of DMEM containing 10% FBS, 1 µmol/L dexamethasone (Sigma Aldrich), 10 µg/mL insulin (Sigma Aldrich), 5 µmol/L isobutylxanthine (AdipoGen), and 200 µmol/L indomethacin (MP Biomedicals) for a minimum of 3 wk. Upon differentiation cells were fixed in formalin and stained with Oil Red O (Sigma-Aldrich) to identify lipid formation followed by hematoxylin to stain cell nuclei.

Immunofluorescent staining of PMSCs

Cells were fixed in formalin and permeabilized using 0.5% Triton X-100 in PBS prior to immunofluorescent staining. Non-specific binding of primary antibodies was blocked with 1% bovine serum albumin (BSA) in 1X PBS for one hour at room temperature. Primary antibody staining consisted of an overnight incubation with each of following primary antibodies at 4 °C in a solution of 1% BSA in PBS: Sox10 (R and D Systems, MAB2864), Sox17 (R and D Systems, MAB1924), Nestin (Millipore, MAB5326), S100β (Sigma-Aldrich, S2532), or NFM (Santa Cruz Biotech, SC-16143). Following primary antibody incubation, cells were then incubated with AlexaFluor 546-conjugated secondary antibodies (Molecular Probes, A10040) for 1 h at room temperature. Lastly, cell nuclei were counterstained using DAPI (Biotium, 40011). Stained samples were imaged using a Carl Zeiss Axio Observer D1 inverted microscope and post-processed with ImageJ software.

Cytokine array analysis of PMSC secreted proteins

Secreted factors were analyzed from the culture supernatant of PMSCs from a single donor (14 wk GA) using two cytokine array kits (Human Cytokine Array Panel A and Human Angiogenesis Array, both from RD Systems). PMSCs were seeded at a density of 7.5×10^5 per 100 mm culture dish. Culture supernatant was collected at 96 h, centrifuged to remove particulates and then the assays performed according to the manufacturer's instructions. Stained membrane blots were imaged on a Bio-Rad ChemiDoc MP, and images were analyzed using ImageJ software with the Dot Blot Analysis plugin. Integrated density values obtained from membrane images were then plotted using Microsoft Excel.

Delivery vehicle compatibility testing

A single PMSC line (15 wk GA) was tested for compatibility in three delivery vehicles: collagen and fibrin hydrogels, as well as aligned nanofiber scaffold made from synthetic polymers. Fibrin gels were formed using EVICEL® Fibrin Sealant kit. PMSCs were resuspended in DMEM and mixed

Figure 1 Early passage growth of placenta-derived mesenchymal stromal cells from chorionic villus sampling-size tissues. Placenta-derived mesenchymal stromal cells (PMSCs) were isolated and expanded from chorionic villus sampling (CVS)-size tissue samples ($n = 6$). A: Photograph of a representative CVS-size mass of human early gestation chorionic villus tissue. The average tissue mass used in this experiment was 35.9 mg; B: Cell expansion data from the first three passages show that an average of 2.09×10^6 cells were obtained by the third passage; C: Average days *in vitro* until passages 1, 2, and 3 were 18.83, 23.5, and 27 d, respectively.

with 70 mg/mL fibrinogen solution and 1000 U/mL thrombin. The final composition of fibrin hydrogel was 5 mg/mL fibrinogen, 5 U/mL thrombin and 8.3×10^4 cells/mL. Fibrin gel with embedded cells were seeded in 96-well plates at a volume of 100 μ L per well and incubated at 37 °C for 1 h to ensure complete gelation. After gelation was complete, 100 μ L of culture media was added to each well to cover the hydrogel layer. Collagen hydrogel was prepared by mixing stock 5 mg/mL bovine collagen I solution (Advanced BioMatrix) in DMEM containing PMSCs, yielding a final concentration of 2 mg/mL collagen I and 1.5×10^5 cells/mL. The collagen/cell solution was then seeded in 24-well plates at a volume of 500 μ L per well and allowed to gel at 37 °C for 1 h before the addition of 500 μ L culture media to cover the hydrogel. Aligned nanofiber scaffold has a two-layer structure and was prepared using electrospinning technology. The scaffold consists of polylactic acid (PLA) and poly(lactic-co-glycolic acid) (PLGA) polymers each of them making up 15% weight/volume of the final product. A rectangular piece of nanofiber scaffold (150 mm² surface area) was attached to the bottom of a 35 mm culture dish using double sided bonding tape 5 × 10⁵ cells in 400 μ L of DMEM were carefully pipetted on the membrane and incubated at 37 °C for 1 h to allow cells to adhere. After 1 h, 1 mL of culture medium was added to the 35 mm dish to cover the scaffold

with cells. Cell viability in each system was assessed using LIVE/DEAD® Viability/Cytotoxicity Kit (Molecular Probes) after 24–72 h. Stained constructs were imaged using a Carl Zeiss Axio Observer D1 inverted microscope, and images further processed with ImageJ software.

Lentiviral vector transduction

To allow for long term labeling for future *in vivo* transplantation applications, PMSCs from a single donor (17 wk GA) were transduced using a Luciferase-GFP-containing lentiviral vector. The viral vector used was a pCCLc-MNDU3-LUC-PGK-EGFP-WPRE construct obtained from the UC Davis/CIRM Institute for Regenerative Cures, Sacramento, CA. Cells were seeded overnight at a density of 7.5×10^5 cells per 100 mm dish, and the next morning were treated with transduction media containing 8 μ g/mL protamine sulfate and 10 μ L/mL viral vector for 6 hours. After incubation with the viral vector, cells were washed twice and normal culture media reintroduced. Cells were imaged with fluorescent microscopy to detect successful GFP expression using a Carl Zeiss Axio Observer D1 inverted microscope. At 5 d post-transduction the GFP expression was quantified by flow cytometry using a BD Fortessa LSR Cell Analyzer and collected data further analyzed using FlowJo software (Treestar, Inc).

Figure 2 Placenta-derived mesenchymal stromal cells express typical mesenchymal stromal cells surface markers and are multipotent. A, B: Placenta-derived mesenchymal stromal cells (PMSCs) were found to be mostly positive for well-established MSC markers CD29, CD44, CD73, CD90, and CD105, and mostly negative for hematopoietic and endothelial cell markers CD31, CD34, and CD45 ($n = 6$); C: Cells were multipotent and were capable of differentiating into adipocytes, osteocytes and chondrocytes *in vitro*. Images in the left column show negative control samples (normal media only) while those on the right display cultures grown in induction media. Yellow boxes provide a magnified view of the selected area. Scale bar = 50 μ m.

RESULTS

Early passage growth from CVS-size Samples

Cell growth from CVS-size tissue samples demonstrated the feasibility of obtaining cells from biopsied early gestation chorionic villus tissue within a timeframe meaningful for autologous *in utero* cellular therapy, as shown in Figure 1. Expansion of PMSCs from CVS-size tissue samples (mean = 35.93 mg) was found to yield over 2×10^6 cells on average by the third passage ($n = 6$ samples). The first passage of cells to a monolayer occurred at an average of 18.8 d with a minimum and maximum time of 14 and 23 d until passage one, respectively. The cultures reached passage three by day 27 on average, and the longest culture time until passage three was observed to be 29 d.

PMSC display typical MSC surface marker profile and multipotency

Flow cytometry immunophenotyping displayed a profile for PMSCs similar to that typically assigned to mesenchymal stem cells from various sources. As shown in Figure 2A and 2B, cells were observed positive for well-established MSC surface markers CD105 (97.13%), CD90 (96.98%), CD73 (99.28%), CD44 (98.93%), and CD29 (99.58%). Additionally, they were mostly negative for hematopoietic and endothelial-related surface markers CD31 (0.62%), CD34 (1.96%), and CD45 (0.53%) ($n = 6$). Trilineage differentiation potential was observed for all cell lines assayed and results displayed in Figure 2C. PMSCs

exposed to induction media for 2 wk were capable of differentiating into osteocytes and adipocytes, confirmed by Alizarin Red staining to observe calcium deposition and Oil Red staining for lipid accumulation, respectively. In addition, PMSCs were capable of forming chondrocytes when cultured as pellets in induction-specific media for 3 wk, as confirmed by Alcian Blue staining. These results indicate that these cells are multipotent, which is another widely accepted hallmark of traditionally characterized MSCs.

Immunofluorescence staining of PMSC reveals stem cell phenotype

PMSCs were probed for developmentally significant transcription factors and stem cell-related intracellular proteins in order to describe their phenotype in a developmental context. All cell lines examined displayed positivity for transcription factors Sox10 and Sox17, as well as for intracellular stem cell-related proteins Nestin, S100 β , and neurofilament medium (NFM) (Figure 3).

Robust cytokine and angiogenic protein secretion by PMSCs

Supernatant from one PMSC line was collected and secreted cytokines were detected using two cytokine array kits together capable of probing for over 70 cytokines. A total of 34 factors with spot density values above 10^3 were detected in the culture supernatant in both assays combined (Figure 4). Density values for each array showed

Figure 3 Immunofluorescence staining of placenta-derived mesenchymal stromal cells reveals stem cell phenotype. Placenta-derived mesenchymal stromal cells (PMSCs) were probed using immunofluorescence and found to express intracellular structural proteins Nestin, NFM, and S100 β that are often associated with neural-lineage phenotypes. Additionally, PMSCs were positive for developmental transcription factors Sox10 and Sox17. Scale bar = 100 μ m. NFM: Neurofilament medium.

variable range, with negative control spots having values of around 500. Density maximums were near 57000 in both kits (IL-8 for the angiogenesis array and MCP-1 for

the Panel A array). With the angiogenesis array we found 13 of the 30 detected factors (43.3%) to have densities above 10000, compared to 6 of 7 detected factors

Figure 4 Robust paracrine secretion by placenta-derived mesenchymal stromal cells. A, C: Results from the human angiogenesis array kit detected 30 secreted factors with integrated density values above 10^3 . A: Original membrane image from the Angiogenesis array, and C: corresponding graph showing measured integrated density values of detected spots. Functions of proteins identified here include modulation of angiogenesis, chemotaxis, stimulation of cell proliferation, blood vessel maturation, blood coagulation, and extracellular matrix remodeling. B, D: Results from the panel A array kit detected 7 secreted factors with integrated density values above 10^3 . B: Original membrane image from the Panel A array; D: Corresponding graph showing measured integrated density values of detected spots. Many of these proteins have distinct functions related to the cell chemotaxis and immune response. TGF: Transforming growth factor; IL: Interleukin; VEGF: Vascular endothelial growth factor; GRO α : Growth regulated oncogene alpha; MCP-1: Monocyte chemoattractant protein 1; uPA: Urokinase-type plasminogen activator.

(85.7%) detected in the Panel A array. The functions of these factors are quite expansive and are detailed in Table 1. Among the most highly detected factors for both kits were cytokines and angiogenic factors such as MCP-1, IL-8, IL-6, GRO α , MIF, HGF, Angiopoietin-1, FGF-7, coagulation factor III and VEGF. Inhibitors of angiogenesis such as TIMP-1, Thrombospondin-1, and Pentraxin-3 were notably present as well, indicating the cells can modulate angiogenesis. IGF-binding proteins 2 and 3 were also highly detected, as was extracellular matrix degradation protease μ PA and its inhibitor Serpin E1. The presence of an additional 18 factors was observed at lower levels (integrated density < 10000). While most function in some way to modulate angiogenesis, many also have specific function beyond this process. Some of the more unique functions include vessel homeostasis and maturation (Angiopoietin 1 and 2), ribonuclease activity (Angiogenin), and initiating coagulation (Coagulation Factor III). Additional capabilities such as chemotaxis, stimulation of cell growth, and immunomodulation are shared among many of the detected factors.

PMSCs are compatible with delivery vehicle matrices and transducible for in vivo tracking

Cell loading experiments demonstrated that PMSCs are viable on both biological and synthetic delivery vehicle systems. Viable non-transduced cells were observed with green fluorescence in all vehicles tested as well as the two-dimensional control culture (Figure 5A). PMSCs seeded on the scaffolds had normal morphology indicating that cells were well adhered. Little to no red fluorescent staining was observed in each condition, indicating that cells seeded on each matrix remained viable with few, if any, dead cells. Additionally, PMSCs were readily transduced with the lentiviral vector (97.3% of total cell population) as confirmed by microscopy images for GFP-expression as well as by flow cytometry analysis of transduced and non-transduced cells (Figure 5B).

DISCUSSION

Early gestation chorionic villus tissue is a unique cell source, yielding robust mesenchymal stromal cells well-

Figure 5 Placenta-derived mesenchymal stromal cells are compatible with biological and synthetic delivery vehicle matrices. A-D: Cell viability was assessed using Molecular Probes Live/Dead fluorescent assay kit for PMSCs cultured in various delivery vehicles. Results show that PMSCs were viable when culture in A: two-dimensional culture (control); B: 2 mg/mL collagen hydrogel; C: 5 mg/mL fibrin glue; D: an aligned PLLA/PLGA nanofiber scaffold. E-G: PMSCs can be efficiently transduced with Luciferase-GFP-containing lentiviral vector; E: phase contrast; F: green fluorescence images from the same field of view of transduced PMSCs; G: Flow cytometry analysis of transduced PMSCs indicate that they were transduced with an efficiency of 97.3%. Scale bars = 100 μ m. PMSCs: Placenta-derived mesenchymal stromal cell.

suites for autologous and allogeneic *in utero* cell therapy and tissue engineering. PMSCs isolated from CVS-size samples were consistently able to generate populations on the order of 10^6 cells in less than four weeks, indicating that simple explant culture provides feasible means of obtaining cells for an autologous fetal cell therapy or tissue engineering. For example, *in utero* repair of spina bifida typically occurs before 26 wk gestational age^[36], and our data show that CVS tissues obtained early in the second-trimester can produce sufficient cell numbers well before they are needed for the repair. Additionally, other structural and congenital defects such as cardiac malformations and congenital diaphragmatic hernia (CDH) may also be potential targets for autologous, tissue engineered constructs populated with PMSCs^[18,32,37].

The *in vitro* characteristics of early second-trimester PMSCs presented in this study are analogous to those of MSCs isolated from various source tissues^[38] in terms of surface marker expression and multipotency. The data also corroborate previous studies aimed at characterizing chorionic villus stromal cells from first and third trimester placentas^[20,39,40], showing that PMSCs described here

contain similarities to cells typically obtained from placentas younger and older in gestation.

Immunofluorescent staining revealed that PMSCs expressed developmentally significant transcription factors Sox10 and Sox17. Sox10 is critical for neurogenesis and maintenance of multipotency^[41-43], while Sox17 functions in the development of definitive endoderm and vasculogenesis^[44,45]. The uniformity of expression of these transcription factors in PMSC cultures may reflect the developmental origins of these cells and could serve as predictors of some related functional properties. All examined PMSC lines also expressed structural proteins Nestin, NFM, and S100 β . These proteins are often associated with a neural phenotype, but their appearance in cultures of non-fetal MSCs has been previously reported elsewhere^[46,47]. Taken in total, these results provide a characteristic phenotypic profile of these cells similar to that of traditionally studied bone marrow MSCs. Still, more work is necessary to better understand how the expression of proteins described above may impact the cell function after *in vivo* transplantation.

It is widely understood that MSCs derive many of

Table 1 Functions of placenta-derived mesenchymal stromal cells secreted factors

Factor	Array	Function	Ref.
Amphiregulin	Angiogenesis	Related to EGF, autocrine mitogen, cancer cell inhibition	[51,52]

their therapeutic properties from paracrine signaling^[48,49]; thus we employed cytokine array assays in order to examine PMSC cytokine secretion. This approach allowed us to identify an abundance of secreted factors with a wide array of functions. Many of the factors function directly or indirectly in the process of angiogenesis, either to stimulate or inhibit its onset. This seems to indicate that PMSCs are able to modulate the angiogenic process, possibly in response to other environmental cues. Indeed, the enormous variety of function in the factors detected seems to indicate that these cells are capable of exerting an extensive paracrine effect on their environment. In the context of the field of tissue engineering where it is necessary to “restore, maintain, or improve tissue function”^[50], PMSCs delivered locally to damaged tissue may be capable of enhancing the endogenous wound response through their paracrine function.

Cell fate and a suitable delivery vehicle must be determined in the course of developing a new cell therapy. Of crucial importance in this study is the examination of cell compatibility with several delivery systems capable of carrying and supporting PMSCs for transplantation. We have found that PMSCs are exceptionally well-suited

for seeding in several systems capable of delivering cells such as collagen hydrogel and fibrin glue, as well as nanofiber scaffolds made of synthetic polymers. These materials have distinct physical properties in terms of rigidity and biodegradability, making them ideal for tailored approaches to tissue engineering with cell-seeded matrices. These data demonstrate cell attachment and survivability on each of these matrices, which is critical to their effective use for *in utero* tissue engineering. Support for further investigation into the use of PMSCs for tissue engineering purposes is given by the efficiency at which they can be transduced with viral vectors. We show here that PMSCs are readily transduced (97.3% of total cell population) with a luciferase-GFP-containing lentiviral vector that can aid in tracking the cells after *in vivo* transplantation. PMSCs transduced with this viral vector can be tracked in two ways: by detection of luciferase expression in live animals injected with the luciferin substrate, and by GFP expression in histological sections after the transplanted animal is sacrificed. Future investigations into the therapeutic function of PMSCs *in vivo* are enhanced by this technique in that it may allow researchers to gain insight into the ultimate fate of

transplanted cells.

In this report, the characterization of early gestation PMSC populations establishes some basic properties of the cells in their surface marker expression and multipotency. Early gestation PMSCs appear to be an excellent candidate cell source for an autologous *in utero* cellular therapy, especially given their compatibility with several delivery vehicles. However, much work still needs to be completed to determine their potential therapeutic applications and to optimize relevant parameters for transplantation, such as delivery vehicle and cell dosage. In addition, more detailed characterization of cytokine secretion across various cell lines and gestational ages is needed in order to determine the optimal time frame for tissue collection and *ex vivo* cell expansion. It will also be necessary to characterize changes in cell secretion patterns for cells seeded on delivery vehicles in comparison to normal two-dimensional culture. Still, there is abundant potential for PMSCs to be utilized as a therapeutic cell source for transplantation, especially in the form of an autologous *in utero* cell therapy.

COMMENTS

Background

In utero surgery has emerged in recent years as an effective option for early repair of many congenital anomalies and malformations. Additionally, many diseases for which *in utero* surgery is available may be amenable to augmentation with tissue engineered repair strategies using mesenchymal stromal cells (MSCs). MSCs have been shown to promote wound healing, protect damaged tissues, and modulate the immune system via paracrine secretion. The placenta has recently been described as an ethically unobjectionable and minimally invasive source of fetal MSCs.

Research frontiers

As the field of *in utero* surgery continues to expand, it is likely that future advances in regenerative medicine such as tissue engineering, stem cell and gene therapy will in turn be incorporated into clinical practice. The placenta represents a unique cell source for both autologous and allogeneic fetal stem cell therapies. Due to the developmental nature of many congenital malformations, fetal-derived cells may confer greater benefit to the fetus than traditional adult multipotent cells such as bone marrow or adipose-derived MSCs.

Innovations and breakthroughs

Early gestation placenta-derived mesenchymal stromal cells (PMSCs) were shown to be expandable to clinically relevant populations from chorionic villus sampling (CVS)-sized samples on a timeline applicable to autologous *in utero* therapy for disorders treated mid-gestation. The sheer variety of factors secreted by PMSCs reported here underscores their ability to affect a broad number of physiologic and cellular processes. Additionally, their compatibility with numerous delivery vehicle systems demonstrate that PMSCs can be surgically applied locally to damaged or injured tissues.

Applications

The results obtained in this study suggest that PMSCs have the potential to be highly therapeutic when used to augment current fetal surgical procedures.

Terminology

The chorionic villi are a functionally and anatomically distinct portion of the placenta. They consist of small, tree-like projections that facilitate nutrient transportation between the maternal and fetal blood supplies. CVS is a technique

by which a small portion of chorionic villus tissue can be obtained in a minimally invasive procedure as early as 8 wk of gestation.

Peer reviews

This report from Lankford et al demonstrates the extraction of stromal cells from chorionic-villi suitable for manipulation, expansion, and reimplantation with the ultimate goal of tissue engineering and repair of multiple congenital disease, namely those of the heart and spinal cord. These findings are particularly relevant to the translational field of medicine, as heart conditions and spinal bifida have recently been described as promising targets of *in utero* repair; thus the cells described here would be an excellent source for repair of these congenital anomalies. The authors have detailed an exciting area of research with solid findings that will be of significant interest to multiple investigators and clinicians in the field.

gene expression was analyzed.

METHODS: Gene expression of MSCs and diffuse-type GC cells were analyzed by microarray. Genes related to stem cells, cancer and the epithelial-mesenchymal transition (EMT) were extracted from human gene lists using Gene Ontology and reference information. Gene panels were generated, and messenger RNA gene expression in MSCs and diffuse-type GC cells was analyzed. Cluster analysis was performed using the NCSS software.

RESULTS: The gene expression of regulator of G-protein signaling 1 (RGS1) was up-regulated in diffuse-type GC cells compared with MSCs. A panel of stem-cell related genes and genes involved in cancer or the EMT were examined. Stem-cell related genes, such as growth arrest-specific 6, musashi RNA-binding protein 2 and hairy and enhancer of split 1 (Drosophila), NOTCH family genes and Notch ligands, such as delta-like 1 (Drosophila) and Jagged 2, were regulated.

CONCLUSION: Expression of RGS1 is up-regulated, and genes related to stem cells and NOTCH signaling are altered in diffuse-type GC compared with MSCs.

Key words: Mesenchymal stem cells; Gastric cancer; Stem cells; Gene; Epithelial-mesenchymal transition

Core tip: Recent studies have revealed that epithelial-mesenchymal transition (EMT) regulators play important roles in cellular phenotypes. This study has shown that EMT-related genes are regulated in diffuse-type gastric cancer and mesenchymal stem cells (MSCs). Regulator of G-protein signaling 1 (RGS1) was significantly up-regulated in diffuse-type GC compared with MSCs. These results are interesting and

Abstract

AIM: To investigate the genes regulated in mesenchymal stem cells (MSCs) and diffuse-type gastric cancer (GC),

provide insights about the mechanisms of the stem cell phenotype transition and gastric cancer progression. These insights will examine the novel role of EMT-related genes and RGS1.

INTRODUCTION

It is a mystery how the epithelial-mesenchymal transition (EMT) and cancer stem cells (CSCs) are correlated^[1,2]. Although it is known that the EMT is related to cancer migration and shares similar molecular characteristics with CSCs, whether the EMT occurs in CSCs or if there is any threshold for this phenotype between stem and cancer cells is largely unknown. The EMT is the cellular process involving the cell phenotype transitioning from an epithelial phenotype to a mesenchymal phenotype. Cancer cells experience the EMT when adhesion is less important, and the cells can freely migrate throughout the body. This mechanism is thought to be important in cancer cell invasion and migration and CSC development. The stem cell phenotype transforms from a differentiated stage to an undifferentiated stage and vice versa during the development of tissues and organs and during different disease states. Investigating stem cell-regulated genes is a highly important issue to elucidate the mechanisms of CSCs.

It has been shown that mesenchymal stem cells (MSCs) can promote the expression of an EMT phenotype in cancer cells *via* CD44, lysyl oxidase and TWIST^[3]. The relationship between MSCs and cancer cells, including the mechanism of stemness exhibited by cancer cells, remains unclear. Moreover, the self-renewal of colorectal cancer initiating cells is considered to be a new therapeutic approach^[4]. It is important to uncover the gene signature of stem and cancer cells to further understand the stemness of these cells. Studies to reveal the stemness phenotype have already been performed. A marker of the putative stem cell region of human intestinal crypts has been identified using a Fourier transform infrared microspectroscopy approach^[5-7]. Genes, such as necdin homolog (mouse) (*NDN*), EPH receptor A5 (*EPHA5*), nephroblastoma overexpressed gene (*NOV*) and runt-related transcription factor 2 (*RUNX2*), have been correlated with MSC passage numbers^[8]. Molecular signatures have also been investigated, and a prediction model of bone marrow stromal cell senescence has been discovered^[9]. Even gene expression at the single cell level can be determined using a recent technique^[10]. These new approaches, including a physical theory, may be important for the advancement of stem cell therapeutics.

Gastric cancer is classified into diffuse and intestinal types^[11,12]. Diffuse-type gastric carcinomas supposedly originate from nonmetaplastic gastric epithelium, and the intestinal type originates from the regenerating epithelium in chronic atrophic gastritis^[12]. Diffuse-type gastric cancer (GC) are known to correlate with the EMT^[13]. We have previously shown that diffuse-type GC can be distinguished with combination of cadherin 1, type 1, E-cadherin (epithelial) (*CDH1*) and cadherin 2, type 1, N-cadherin (neuronal) (*CDH2*) gene expression in MSC and diffuse-type GC associated with the EMT^[14]. Considering that hepatoma cells are converted into human induced pluripotent stem cell-like cells using microRNAs, the difference between stem cells and cancer cells should be deeply investigated^[15]. Breast CSCs show both mesenchymal-like and epithelial-like phenotypes and transition between EMT- and mesenchymal-epithelial transition-like states^[16]. Diffuse-type GC has been reported to be involved in the remodeling of the pulmonary artery, which suggests cancer niche formation by diffuse-type GC^[17]. Considering the finding that MSCs provide microenvironment for CSCs, the features of MSC and cancer cells should be investigated^[18].

In this article, MSC gene expression has been investigated and compared with diffuse-type GC cells that exhibit a mesenchymal phenotype more than intestinal-type GC cells do, and panels of regulated genes in MSCs and diffuse-type GC have been generated to clarify the important molecular patterns that distinguish stem and cancer cells.

MATERIALS AND METHODS

Cell culture

MSCs from human bone marrow were cultured according to the manufacturer's protocol (Lonza Walkersville, Inc., Walkersville, MD, United States). Detailed methods have been previously described^[8]. Briefly, MSCs were cultured *in vitro* in mesenchymal stem cell growth medium (Lonza Catalog #PT-3001; mesenchymal stem cell basal medium plus SingleQuots™ of growth Supplements) at 37 °C in a CO₂ (5%) incubator. Each number in the MSC sample name indicates the passage number.

Total RNA extraction

Diffuse-type GC samples were surgically resected and obtained from the National Cancer Center Research Institute. Detailed information on total RNA extraction has been previously described^[14,19]. Briefly, total RNA was obtained by suspending the cells in ISOGEN lysis buffer from surgically resected samples, which were provided by the Central Hospital or East Hospital at the National Cancer Center^[14,19]. Total RNA of MSCs were purified using RNeasy kit (QIAGEN, Düsseldorf, Germany) as previously described^[8].

Microarray analysis

MSC gene expression data are available to the public *via* the NCBI Gene Expression Omnibus (GEO)^[8]. Diffuse-

type GC gene expression data are also available *via* the NCBI GEO^[14]. The accession numbers of data used for gene expression analysis are GSE7888 and GSE42252 for MSCs and diffuse-type GC, respectively. Briefly, total RNA from MSCs and diffuse-type GC was analyzed using a GeneChip® Human Genome U133 Plus 2.0 Array (Affymetrix, Inc., Santa Clara, CA, United States). Probe set and Gene Ontology information is based on annotation version na34. Cluster analysis was performed using NCSS 2007 (NCSS, LLC., Kaysville, UT, United States).

Statistical analysis

All data are presented as the mean $\pm$ SE. Statistical significance was calculated with GraphPad Prism® 6 or Microsoft® Excel® using the unpaired Student's t test or one-way ANOVA with Bonferroni's multiple comparisons test.

RESULTS

Regulated genes in diffuse-type GC and MSCs

Genes regulated in diffuse-type GC and MSCs were investigated and analyzed using cluster analysis (NCSS) (Figure 1). Probe sets that have a more than a 50-fold significant difference between MSCs and diffuse-type GC ($P < 10^{-9}$ in the equal variance hypothesis and $P < 0.01$ in the non-equal variance hypothesis) are shown in Figure 1. Each panel shows the gene expression in 30 probe sets. Panels A, B and C show the up-regulated probe sets in diffuse-type GC compared with MSCs, whereas panel D shows 29 up-regulated probe sets and one down-regulated gene, pentraxin 3, long (*PTX3*). In this analysis, regulator of G-protein signaling 1 (*RGS1*) was the most up-regulated gene in diffuse-type GC compared with MSCs (Figure 2A). *RGS4* gene expression was down-regulated in diffuse-type GC compared with MSCs (Figure 2B). The regulated RGS family genes are shown in Table 1. Additional up-regulated genes in diffuse-type GC compared to MSCs included spleen tyrosine kinase (*SYK*) and *CDH1*, which have been suggested to be mutated in cancer, based on an assessment of the public database Cancer Gene Census (<http://cancer.sanger.ac.uk/cancergenome/projects/census/>).

Stem cell gene panel

The expression of genes related to stem cells was investigated (Table 2). Considering that gene combination is important to understand stem cell phenotype, several genes involving to stem cells have been analyzed^[20]. *NANOG* and *SUZ12*, which have been found by gene expression analysis to be involved in MSC invasion was up-regulated in diffuse-type GC compared to MSCs^[21]. Gene expression of tumor necrosis factor receptor superfamily, member 19 (*TNFRSF19*), tended to decrease in diffuse-type GC compared with MSCs, but it was not significantly altered in MSCs and diffuse-type GC (Figure 3). The gene expression of *TNFRSF8*, also known as

CD30, was slightly up-regulated in diffuse-type GC compared with MSCs. The gene expression of growth arrest-specific 6 (*GAS6*), musashi RNA-binding protein 2 (*MSI2*) and hairy and enhancer of split 1, (*Drosophila*) (*HES1*), which have stem cell terms in the Gene Ontology biological process, were regulated in diffuse-type GC and MSCs (Figure 4).

Investigation of EMT markers

To examine the cellular phenotype of cancer and stem cells, the expression levels of EMT-related genes were investigated (Table 3). The gene expression of the *TWIST*, *ZEB* and *SNAI* families were examined because these genes have been reported to be associated with the EMT and cancer regulation^[22]. The gene expression of twist family bHLH transcription factor 1 (*TWIST1*) and paired related homeobox 1 (*PRRX1*) were down-regulated in diffuse-type GC compared with MSCs. The gene expression of zinc finger E-box binding homeobox 2 (*ZEB2*) was up-regulated in diffuse-type GC compared with MSCs. Previously, high mobility group AT-hook 2 (*HMGAT2*) has been shown to be involved in the EMT, *WNT*/ β -catenin signaling and malignant cancer^[23,24]. *HMGAT2* gene expression was down-regulated in diffuse-type GC compared with MSCs. The gene expression of one of the probe sets for catenin (cadherin-associated protein), beta 1, 88 kDa (*CTNNB1*) was up-regulated in diffuse-type GC compared with MSCs. The gene expression of the other two probe sets for *CTNNB1* was stable. Sp1 transcription factor (*SP1*) and lymphoid enhancer-binding factor 1 (*LEF1*) were up-regulated in diffuse-type GC compared with MSCs. *SP1* is known to be an important factor for cell cycle regulation and is up-regulated in various cancers^[25]. The *AKT* gene family is known to be important in cancer and has been suggested to regulate the EMT and stem cells in cancer cells^[26]. Three *AKT* isoforms were examined, and the gene expression of v-akt murine thymoma viral oncogene homolog 2 (*AKT2*) was up-regulated. However, some of the probe sets recognizing *AKT3* showed a down-regulation of *AKT3* gene expression. The gene expression of stratifin (*SFN*); F11 receptor (*F11R*); gap junction protein, beta 2, 26 kDa (*GJB2*); occluding (*OCN*); coxsackie virus and adenovirus receptor (*CXADR*); and keratin 8 (*KRT8*) were up-regulated in diffuse-type GC compared with MSCs.

Messenger RNA expression of NOTCH signaling-related genes

NOTCH signaling-related genes are involved in cancer, and *NOTCH* signaling is one of the target signaling pathways of CSCs^[27-30]. Next, *NOTCH* messenger RNA (mRNA) expression was examined (Table 4). *NOTCH1*, 3 and 4 gene expression was up-regulated, whereas *NOTCH2* gene expression was down-regulated in diffuse-type GC compared with MSCs (Figure 5A). The gene expression of delta-like 1 (*Drosophila*) (*DLL1*) and Jagged 2 (*JAG2*) were up-regulated in diffuse-type GC compared with MSCs

To confirm that the up-regulation of *RGS1* was not stomach specific, *RGS1* gene expression in normal tissues was investigated using various data in the database, such

Figure 2 Regulator of G-protein signaling 1 and regulator of G-protein signaling 4 gene expression was up-regulated and down-regulated, respectively, in diffuse-type gastric cancer. A: regulator of G-protein signaling 1 (*RGS1*) gene expression was up-regulated in diffuse-type gastric cancer (GC) compared with early-stage mesenchymal stem cell (MSC) cultures [$n = 5$ in early-stage MSC cultures (B#4, C#4, F#5, G#4, and H#4), $n = 5$ in late-stage MSC cultures (B#28, C#24, E#28, G#28, and H#28), and $n = 5$ in diffuse-type GC (GC16, GC40, GC54b, GC60, and GC23s)]. Results represent the mean $\pm$ SE. $^bP < 0.01$ using a one-way analysis of variance with Bonferroni's multiple comparisons test; B: *RGS4* gene expression was down-regulated in diffuse-type GC compared with MSCs. Results represent the mean $\pm$ SE ($n = 12$ in MSC cultures and $n = 5$ in diffuse-type GC). $^bP < 0.01$ and $^cP < 0.001$ using Student's *t* test with the non-equal variance hypothesis.

Genes related to stem cells in the literature are shown with their gene expression alterations in MSCs and diffuse-type GC. *NANOG* and *SUZ12*, which have been found by gene expression analysis to be involved in MSC invasion was up-regulated in diffuse-type GC compared to MSCs. RGS: Regulator of G-protein signaling; MSCs: Mesenchymal stem cells; GC: Gastric cancer.

Figure 3 Tumor necrosis factor receptor superfamily, member 19 gene expression. Tumor necrosis factor receptor superfamily, member 19 (*TNFRSF19*) gene expression tended to decrease in diffuse-type gastric cancer (GC) but was not significantly altered compared with early-stage mesenchymal stem cell (MSC) cultures. *TNFRSF19* gene expression in late-stage MSC cultures was significantly down-regulated compared with early-stage MSC cultures. Results represent the mean $\pm$ SE [$n = 5$ in early-stage MSC cultures (B#4, C#4, F#5, G#4, and H#4), $n = 5$ in late-stage MSC cultures (B#28, C#24, E#28, G#28, and H#28), and $n = 5$ in diffuse-type GC (GC16, GC40, GC54b, GC60, and GC23s)]. * $P < 0.05$ using a one-way ANOVA with Bonferroni's multiple comparisons test.

spinal cord but not in the stomach.

DISCUSSION

Gastric cancer progression is associated with *Helicobacter pylori* and gastric stem cells are suggested to involve in the progression from chronic atrophic gastritis to gastric cancer^[33]. It may be assumed that *RGS1* plays a role in regulating G protein signaling and mitogen-activated protein (MAP) kinase signaling during gastric cancer progression, which may provide some hypotheses in which *RGS1* promotes stem cell transition into CSCs, CSCs induce *RGS1* expression in gastric cancer, or *RGS1* orchestrates with other molecules in EMT. In gastric cancer cells, *CDH1* isoform is found to increase gastric cancer cell invasion and angiogenesis, and some inflammatory mechanism is suggested to be

involved in *CDH1* regulation^[34]. Analysis of *Rgs1*(-/-) has shown that B cell responses to chemokines, plasma cell localization, and immune tissue architecture are disturbed when *Rgs1* is deleted^[35]. In our studies, *RGS1* was up-regulated in diffuse-type GC compared to MSC, which may suggest that *RGS1* plays a role to response cancer cells and indicate the possibility to involve in cancer immunity. It may be possible that *RGS1* protects the cells from cancer progression by enhancing anti-cancer immunity, or promote cell phenotype transition to cancer. The possibility that diffuse-type GC sample contains a variety of cells in cancer microenvironment should be considered. It may also be possible that *RGS1* is up-regulated in some cancer microenvironment cells. Because the dedifferentiation of epithelial cells into stem cells may play a role in regenerative medicine or diseases, including cancer, investigating the genes regulated in stem and cancer cells is important^[36]. Changes in the gene expression profiles of early- and late-stage MSC cultures have provided evidence regarding the importance of studying gene combinations to understand cellular phenotypes^[8]. Cell surface antigens, such as SSEA4 or TRA-1-81, should also be included for future quality control in stem cells^[37-39]. Furthermore, cell type-specific transcriptional profiles have been suggested for neural lineage cells, hepatic lineage cells, embryonic stem cells and induced pluripotent stem cells (iPSCs)^[40]. Interestingly, insulin-like growth factor-1 receptor signaling and EMT crosstalk is sufficient to down-regulate erlotinib function in cells, while exon 19 of the erlotinib-sensitive epidermal growth factor receptor is mutated in non-small cell lung carcinomas^[41]. Many cell-based iPSC models that are derived from patient cells have been investigated^[42], and successful genetic or epigenetic reprogramming of cellular identity is crucial for the development of these stem-cell based disease models^[42]. The investigation of the molecular combinations associated with different cell types is important for determining cellular phenotypes.

RGS1 has been shown to be related to cancer in some studies^[43-45]. In late-stage non-small cell lung cancer, single nucleotide polymorphisms in *RGS1* have been shown to

interacting with the immune system may be future targets for anti-cancer therapy^[47]. Considering that *RGS1* is up-regulated in diffuse-type GC compared with MSCs, *RGS1* may be a potential target for cancer treatment. *RGS1* is involved in an adenylate cyclase-inhibiting G-protein coupled receptor signaling pathway, immune response, positive regulation of GTPase activity, and termination of a G-protein coupled receptor signaling pathway in the Gene Ontology biological process [Traceable author statement (TSA)]; Inferred from electronic annotation (IEA) (NCBI). From the investigation of EMT-related genes and *RGS1*, this study may suggest the possibility of future gene applications, including *RGS1*, to evaluate cancer cells to their sensitivity to treatment. microRNAs have been reported to be involved in *RGS5* regulation in neuroblastoma^[48]. Further assessments are needed to examine the possibility that *RGS1* could be a marker for responsiveness to cancer treatment.

NOTCH gene expression was altered in diffuse-type GC and MSCs. Gene expression of *NOTCH1*, 3 and 4 was up-regulated in diffuse-type GC compared with MSCs, whereas *NOTCH2* was down-regulated in diffuse-type GC. Upon Notch ligand cellular stimulation, the intracellular domain of the Notch receptor (NICD) translocates into the nucleus and regulates gene transcription, which leads to cell communication in signaling^[49,50]. The regulation of *NOTCH* family gene expression may play an important role in the

transcriptional regulation of cell phenotype transitions. *NOTCH1* expression is increased in gastric cancer^[51]. It has been shown that *NOTCH1* is associated with gastric cancer with non-cardia location and diffuse type^[51]. The up-regulation of *NOTCH1* in diffuse-type GC compared to MSCs in our studies is consistent with the results in previous reports. *NOTCH2* has been reported to be a candidate marker for prognosis of neoadjuvant-treated gastric cancer^[52]. Combination of expression of *GSK3B*, *CTNNB1*, *NOTCH2* was suggested to be correlated with patient survival. The previous study indicated that *NOTCH2* may be involved in chemotherapy resistance in GC^[52]. Considering that CSCs may be involved in drug resistance, the role of *NOTCH2* should be investigated in CSCs or EMT. *NOTCH2* expression was increased in post-therapeutic tumors^[53]. Since *NOTCH2* was down-regulated in diffuse-type GC compared to MSCs, *NOTCH2* may mark some cancer phenotype in different stages. *NOTCH3* was found to be increased in diffuse-type GC^[51,53]. The previous reports are consistent with the results in this study indicating that *NOTCH3* is up-regulated in diffuse-type GC compared to MSCs. Interestingly, *NOTCH4* is suggested to be related to gastric carcinogenesis targeted by microRNA *miR-181*^[54]. Our data indicating *NOTCH4* up-regulation in diffuse-type GC compared to MSCs is consistent with the previous findings suggesting involvement of *NOTCH4* in gastric carcinogenesis. *NOTCH1* and *NOTCH2* exhibit opposite functions and play important roles in cancer as oncogenes or cancer suppressors depending on the cancer species. The relationship with *NOTCH* signaling and gastric cancer signaling should be investigated in the future (Figure 6A). In the EMT hypothesis, it is possible that epithelial-phenotype cells expressing *NOTCH1* transition to mesenchymal-phenotype cells that express *NOTCH2* (Figure 6B). Integrin beta 1 expression is important for the cancer cell population, and the insights into the mechanisms of cell phenotype conversion by gene regulation may provide fundamental understanding of cancer development^[55]. Several pathways, including the claudin family genes and MAP kinase signaling pathways, have been investigated by gene set enrichment analysis, which may be the next step for the precise investigation of cancer drug response signaling^[56].

A: The gene expression of *NOTCH1*, 3 and 4 was up-regulated in diffuse-type gastric cancer (GC) compared with mesenchymal stem cell (MSCs), whereas *NOTCH2* was down-regulated. Results represent the mean $\pm$ SE ($n = 12$ in MSC cultures and $n = 5$ in diffuse-type GC). ^a $P < 0.05$, ^b $P < 0.01$, and ^d $P < 0.001$ using Student's *t* test; B: *DLL1*, a *NOTCH* ligand, was up-regulated in diffuse-type GC compared with MSCs. Results represent the mean $\pm$ SE ($n = 12$ in MSC cultures and $n = 5$ in diffuse-type GC). ^b $P < 0.01$ using Student's *t* test; C: Jagged 2 (*JAG2*), a *NOTCH* ligand, was up-regulated in diffuse-type GC compared with MSCs. Jagged 1 (*JAG1*) was up-regulated in diffuse-type GC compared with MSCs. Results represent the mean $\pm$ SE ($n = 12$ in MSC cultures and $n = 5$ in diffuse-type GC). ^a $P < 0.05$ and ^b $P < 0.01$ using Student's *t* test.

COMMENTS

Background

Mesenchymal stem cells (MSCs) exhibit mesenchymal features and are useful in regenerative medicine. Gastric cancer (GC) can be classified into two types, including diffuse-type GC that has mesenchymal features and intestinal-type GC that has epithelial features. The epithelial-mesenchymal transition (EMT) is an important mechanism in cancer development. The EMT is known to be involved in cancer cell migration and malignancy. Cancer stem cells (CSCs) are known to be resistant to anti-cancer drugs and involved in cancer recurrence.

Research frontiers

Gene regulation in MSCs and diffuse-type GC may provide new insights into CSCs. In this study, regulator of G-protein signaling (*RGS*) has been identified to be up-regulated in diffuse-type GC compared with MSCs. It is a novel hypothesis where *RGS* signaling may be involved in the EMT pathway.

Innovations and breakthroughs

Recent progress in genome-wide analysis in cancer has revealed that the gene signature is important for cancer diagnosis and exploring the targets of cancer therapy. CSCs are one of the targets for cancer treatment because these cells

tend to be resistant to anti-cancer drugs and are involved in cancer recurrence. This study is the first to demonstrate that *RGS1* may distinguish diffuse-type GC and MSCs.

Applications

By understanding how *RGS1* is involved in the EMT and CSC signaling, this study represents potential future strategies for GC including diffuse-type GC treatment and prediction.

Terminology

RGS1 is protein involved in G-protein signaling and the regulation of GDP dissociation from the G alpha subunit and GTP binding to form trimetric G proteins. The EMT is the mechanism by which epithelial cells change into mesenchymal cells with a migratory capacity. Several adhesion molecules are involved in the EMT, and *RGS1* may contribute to the changes in signaling.

Peer review

The authors described a global gene expression analysis in comparison between MSCs and diffuse-type GC cells. The authors found that *RGS1* gene was upregulated in diffuse-type GC cells compared with MSCs, and that genes related to stem cells and *NOTCH* signaling were altered in diffuse-type GC cells compared with MSCs. The results may provide some insights in correlation

- between the EMT and CSCs. This paper summarizes important and actual data, it fulfils all criteria and demands put on articles published in World Journal of Stem Cells.

mesenchymal stem cells (MSCs) and effects on stemness *in vitro* and function as a cell therapy *in vivo*.

METHODS: Bone marrow-derived adult and fetal MSC were isolated from an equine source and expanded in monolayer tissue culture. Polyethylenimine (PEI)-mediated transfection of pcDNA3-eGFP or adenoviral transduction of green fluorescent protein (GFP) was evaluated in fetal MSCs. Adenoviral-mediated transduction was chosen for subsequent experiments. All experiments were carried out at least in triplicate unless otherwise noted. Outcome assessment was obtained by flow cytometry or immunohistochemistry and included transduction efficiency, cell viability, stemness (*i.e.*, cell proliferation, osteogenic and chondrogenic cell differentiation), and quantification of GFP expression. Fetal and adult MSCs were then transduced with an adenoviral vector containing the gene for the bone morphogenic protein 2 (BMP2). *In vitro* BMP2 expression was assessed by enzyme linked immunosorbent assay. In addition, MSC-mediated gene delivery of BMP2 was evaluated *in vivo* in an osteoinduction nude mouse quadriceps model. New bone formation was evaluated by microradiography and histology.

RESULTS: PEI provided greater transfection and viability in fetal MSCs than other commercial chemical reagents. Adenoviral transduction efficiency was superior to PEI-mediated transfection of GFP in fetal MSCs ($81.3\% \pm 1.3\%$ *vs* $35.0\% \pm 1.6\%$, $P < 0.05$) and was similar in adult MSCs ($78.1\% \pm 1.9\%$). Adenoviral transduction provided significantly greater expression of GFP in fetal than adult MSCs (7.4 ± 0.1 *vs* 4.4 ± 0.3 millions of mean fluorescence intensity units, $P < 0.01$) as well as significantly greater *in vitro* BMP2 expression (0.16 pg/cell-day *vs* 0.10 pg/cell-day, $P < 0.01$). Fraction of fetal MSC GFP positive cells decreased significantly faster than adult MSCs ($1.15\% \pm 0.05\%$ *vs* $11.4\% \pm 2.1\%$ GFP positive at 2 wk post-transduction, $P < 0.05$). Cell proliferation and osteogenic differentiation *in vitro*

Abstract

AIM: To investigate adenoviral transduction in

were not affected by Ad transduction in both fetal and adult MSCs, but fetal MSCs had reduced chondrogenic differentiation *in vitro* when compared to adult ($P < 0.01$). Chondrogenic differentiation was also significantly reduced in Ad-GFP transduced cells ($P < 0.05$). Ad-BMP2 transduced adult MSCs induced new bone formation in more thighs than Ad-BMP2 transduced fetal MSCs (83% *vs* 17% of the six treated thighs per group, $P < 0.05$) and resulted in increased femur midshaft diameter due to greater extent of periosteal new bone (1.57 ± 0.35 mm *vs* 1.27 ± 0.08 mm, $P < 0.05$).

CONCLUSION: Fetal MSCs may be genetically manipulated *ex vivo* with adenoviral vectors. Nonetheless, the abbreviated expression of the exogenous gene may limit their applications *in vivo*.

Key words: Adenovirus; Bone morphogenic protein 2; Fetal; Green fluorescent protein; Mesenchymal stem cell; Gene transfer technique

© The Author(s) 2015. Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: Fetal mesenchymal stem cells (MSCs) can be genetically manipulated *ex vivo* with adenoviral vectors without major effects on stemness. Their greater expression of exogenous genes than adult MSCs is promising for MSC-mediated gene therapy. MSC-mediated bone morphogenic protein 2 gene delivery provides osteogenic induction *in vivo*, which could have clinical applications in bone regeneration. Nonetheless, the abbreviated expression of the exogenous gene provided *via* adenoviral transduction may limit their applications *in vivo*.

Fetal *vs* adult mesenchymal stem cells achieve greater gene expression, but less osteoinduction. *World J Stem Cells* 2015; 7(1): 223-234 Available from: URL: <http://www.wjgnet.com/1948-0210/full/v7/i1/223.htm> DOI: <http://dx.doi.org/10.4252/wjsc.v7.i1.223>

INTRODUCTION

The best-characterized source of human mesenchymal stem cells (MSC) to date is bone marrow (BM)^[1]. Transplantation of BM-derived MSCs has been studied as a potential therapy for myocardial ischemic injury^[2,3], autoimmune diseases^[4], and musculoskeletal conditions such as osteoarthritis^[5]. MSCs could be useful in the active regeneration of joint and cartilage tissue because of their multipotency and fast proliferation, as a cell therapy acting to replace lost lineages and to modify existing cells. However, in certain degenerative diseases, such as osteoarthritis, MSCs are depleted and have reduced ability to differentiate and proliferate^[6]. As an alternative source of MSCs, young cells such as fetal (f) MSCs could be harvested from the umbilical cord, placental stroma, and

the amnion^[7-9]. Ethical concerns regarding the isolation of MSCs from fetal sources are minimized, as these tissues are normally discarded after birth^[1].

Zhang *et al*^[10] demonstrated that human fMSCs are a superior cellular candidate for bone tissue engineering applications. This related to their superior proliferation capacity, more robust osteogenic potential, and lower immunogenicity, as compared to MSC from postnatal sources^[10]. Nevertheless, the permissiveness to gene delivery and the effect of genetic engineering on stemness in these young cells has not been extensively studied. Gene delivery to fMSCs may differ from adult (a) MSC due to immaturity of gene expression cellular pathways and cell surface receptors, such as the coxsackievirus adenovirus receptor required for adenoviral transduction^[11]. To our knowledge, only two original research studies have evaluated gene delivery on fMSCs. Campagnoli *et al*^[12] demonstrated that fMSCs could be retrovirally transduced with high efficiency without selection. Also, Chan *et al*^[13] showed that human fMSCs retain their proliferative and differentiation capacities after stable lentiviral transduction. The paucity of studies addressing gene delivery in fMSCs, and the lack of studies on transient gene delivery in these young cells, highlights the need for more studies in these topics.

We chose to study the transient transduction characteristics of adenoviral vectors (Ad) in fMSC. Adenoviral vectors' lack of insertional mutagenesis result in a desirable safety profile, which added to their capacity to achieve high levels of transgene expression^[14], make them attractive for gene delivery particularly for bone regeneration. Our study addressed the effectiveness of Ad-mediated transduction of equine fetal bone marrow-derived MSCs. We hypothesized that Ad-mediated transduction will be efficient in fMSCs without affecting measures of cell stemness. In addition, Ad-transduced equine MSC-mediated bone morphogenic protein 2 (BMP2) gene delivery was studied to assess its ability to induce bone formation in a mouse model.

MATERIALS AND METHODS

Ethics

The use of animals in this study was carried out in accordance to regulations by The Ohio State University Institutional Animal Care and Use Committee (IACUC) in compliance with national guidelines. The IACUC reviewed and approved our Protocol 2009A0119.

Study design

Both bone marrow-derived aMSCs and fMSCs were isolated and expanded in monolayer tissue culture. Low passage MSCs were immunophenotyped by CD90 and CD34 surface expression by flow cytometry. Polyethylenimine (PEI)-mediated transfection of pcDNA3-egreen fluorescent protein (GFP) or Ad transduction of GFP were evaluated in fMSCs. Ad-mediated transduction was chosen for subsequent experiments. Outcome assessment included transduction efficiency, cell viability, stemness (*i.e.*,

cell proliferation, osteogenic and chondrogenic cell differentiation), and quantification and duration of *GFP* and *BMP2* gene expression. All experiments were carried out at least in triplicate unless otherwise noted. *In vitro* *BMP2* gene expression was assessed by ELISA. MSC-mediated *BMP2* gene delivery was then evaluated *in vivo* in an osteoinduction nude mouse quadriceps model.

Isolation and culture of MSCs from equine bone marrow

Adult MSCs were obtained from equine bone marrow of the sternum of adult horses (age range 2-5 years old) using methods described by Ishihara *et al.*^[15]. Fetal MSCs were isolated following a similar protocol from a 20-wk-old equine fetus. The mare was euthanized for terminal problems, while the fetus was apparently healthy. Isolated cells were then resuspended in 1 mL of 90% fetal bovine serum with 10% dimethyl sulfoxide for cryopreservation. Prior to each experiment, preserved cells were allowed to thaw at 37 °C, rinsed in Dulbecco's modified Eagle medium (DMEM; Gibco, Grand Island, NY, United States), and were grown separately in T-75 flasks in DMEM supplemented with 10% fetal bovine serum (Sigma, St. Louis, MO, United States), 100 U/mL penicillin, and 100 µg/mL streptomycin (Gibco). Cells were incubated at 37 °C and 5% CO₂. Medium was changed every 2-3 d. Cells were trypsinized when confluency was above 80% with Trypsin-EDTA (Gibco) after a washing step with Dulbecco's phosphate buffered saline (PBS, Gibco). MSCs were evaluated by microscopy for homogenous elongated spindle-shaped morphology. Cells were also immunophenotyped by flow cytometry for expression of CD90 after incubation with phycoerythrin (PE)-conjugated anti-hCD90 antibody (561970, BD Biosciences) detected with a 585/40 nm optical filter. Lack of expression of CD34 was assessed with allophycocyanin (APC)-conjugated anti-hCD34 antibody (555824, BD Biosciences) detected with a 675/25 nm optical filter.

Amplification and purification of plasmid DNA

Escherichia coli DH5α were transformed with a plasmid consisting of a pcDNA3 backbone containing a gene for the enhanced GFP. The transformed cells were amplified in lysogeny broth medium at 37 °C overnight at 225 rpm in a shaker incubator. Isolation and purification of the plasmid was carried out with a Midiprep kit (K2100, Life Technologies) according to the given protocol. The concentration and purity of the plasmid were determined by the 260/280 ultraviolet absorbance method with a Nanodrop 2000 (Thermo Scientific). The purified plasmid was stored at -20 °C.

PEI/DNA complex preparation

A 1 mg/mL transfection reagent solution was made from 50 mg of linear PEI (23966, Polysciences) in 50 mL of PBS adjusting the pH to 4.5 with HCl and dissolving at 70 °C, followed by filter sterilization and storage at 4 °C. On the day of transfection a stock solution was made with 100 µL of warm PBS, 5 µL of 1 mg/mL PEI, and 2

µL of the pcDNA3-eGFP plasmid, which is sufficient for transfection in one well in a 6-well plate. The transfection solution was upscaled as needed.

Adenoviral production and titering

Replication-deficient, E1-A-deleted adenoviral vector encoding either a 1547 base-pair open reading frame segment of human BMP2 (Ad-BMP2) or GFP (Ad-GFP) under the control of the cytomegalovirus promoter were previously generated^[16]. These were amplified in 80% confluent HEK 293A cells (R70507, Invitrogen) and titered by plaque assay following the methods described in the provided user guide by Life Technologies. Aliquots were stored at -80 °C.

Fluorescent microscopy and flow cytometry

A fluorescent Olympus 1X51 microscope was used to evaluate the PEI-mediated eGFP transfection and Ad-GFP transduction efficiency of MSCs in monolayers at various time points. Fluorescent and phase contrast images were merged using ImageJ.

Green fluorescence after gene delivery into aMSCs and fMSCs was assessed in an Accuri C6 BD Biosciences flow cytometer, excited by an argon 488 nm laser and detected by use of a 533/30 nm optical filter. The mean fluorescence intensity (MFI) data were collected from these cell populations. All data was analyzed with a minimum of 15000 events setting the respective negative control to less than 1% in BD CFlow software.

Transient gene delivery optimization

MSCs were seeded at a density of 6×10^4 cells/well in a 12-well plate to 75% confluency with 2 mL of DMEM per well. PEI, FuGENE 6 (Promega), and Lipofectamine (Invitrogen) were tested for *GFP* gene transfection in fMSCs. Transfection conditions were optimized for the three reagents. Transfection efficiency and viability were qualitatively assessed at 48 h post-transfection. In addition, transduction with Ad-GFP was tested at MOI of 0.5, 3, 15, 25, and 50 in fMSCs.

Transgene expression, proliferation, and viability of MSCs post-transduction

Adult MSCs or fMSCs were seeded at 1×10^5 cells in triplicate in T-25 flasks and transduced 24 h later or kept as control cells. Ad-GFP transduced cells (Ad-GFP-MSC) and control cells were evaluated by flow cytometry at 48 h, 1 wk, and 2 wk post-Ad-GFP transduction at MOI of 25. Outcome assessment included transduction efficiency, MFI, cell confluence to calculate cell proliferation, and cell viability by staining with 7-AAD (559925, BD Biosciences) detected with a 670 nm long pass filter. Cell morphology and GFP expression were documented with fluorescent microscopy.

Differentiation post-transduction

Chondrogenic and osteogenic differentiation was carried out following Lonza's protocol (AA-2501-16). The

Figure 1 Morphology and immunophenotyping of fetal mesenchymal stem cells and adult mesenchymal stem cells. (A) fMSCs and (B) aMSCs were evaluated by microscopy for homogenous elongated spindle-shaped morphology. Scale bar = 100 µm; C and D: Corresponding positive expression of CD90 and absent CD34 as measured by flow cytometry. fMSCs: Fetal mesenchymal stem cells; aMSCs: Adult mesenchymal stem cells.

cultures were stained with Von Kossa stain and toluidine blue for evaluation of osteogenesis and chondrogenesis, respectively, of Ad-GFP-MSCs compared to control MSCs. Images were evaluated in ImageJ software.

In vitro BMP2 expression and osteoinduction in vivo

MSCs at 80% confluency were transduced at MOI of 25 with Ad-BMP2 or used as control. On the following day, ascorbic acid was added to both, transduced and control cells, in the DMEM to a final concentration of 50 µg/mL. At day 3 after transduction, samples from the media were evaluated for BMP2 expression using methods described for the BMP2 Quantikine ELISA Kit (BD Biosciences, DBP200). BMP2 expression per cell was estimated through quantification of BMP2 standard provided with the kit and using media from untransduced cells as background.

Ad-BMP2 MSCs and control cells were trypsinized at day 3 post-transduction and trypan blue exclusion count was performed to confirm viability of at least 90%. The cells were washed twice with PBS and resuspended in 0.9% NaCl to a concentration of 2×10^6 cells/0.1 mL. Thighs from twelve 6-wk-old mice (BALB/c *Foxn1 nu/nu*, Taconic Farms, Hudson, NY, United States) were randomly assigned to five groups: aMSC, Ad-BMP2-aMSC, fMSC, Ad-BMP2-fMSC, or saline. Anesthesia was induced with 5% isoflurane (IsoFlo, Abbott Animal Health, North Chicago, IL, United States) in 100% oxygen and maintained with 0%-2% isoflurane delivered by a precision vaporizer. Cranial thigh injection sites were disinfected with three alternating scrubs of povidone iodine and 70% isopropyl alcohol. Mice received one intramuscular injection in each thigh of 0.1 mL cells

or saline using a 25 G needle. All mice recovered from anesthesia uneventfully. Three weeks after injection, mice were euthanized by CO₂ followed by cervical dislocation. The hind limbs were harvested, and the skin was removed.

Diagnostic imaging

Digital microradiography (Model LX-60, Faxitron Bioptics, Tucson, AZ, United States) was performed separately for each experimental group. Lateromedial views of the hind limbs were obtained at 30 kV for 10 s and analyzed with ImageJ at 40% contrast. Outcome measurements included: number of mineralized bodies (*i.e.*, ossicles), lateromedial area (mm²) of the ossicles, extent of periosteal new bone formation, and midshaft diameter (mm). Extent of periosteal new bone was scored as 0, 1, 2, 3, or 4 corresponding to no formation, new bone in less than 50% of the cranial aspect of the femur, more than 50% cranial, less than 50% involving both the cranial and the caudal aspects of the femur, or more than 50% cranial and caudal aspects involved, respectively.

Histological examination

Harvested limbs were fixed in 10% neutral buffered formalin for 4 mo. Samples were decalcified in 14% EDTA neutralized solution, overnight. The samples then underwent procedures for embedding, incising, and staining with toluidine blue or hematoxylin and eosin.

Statistical analysis

Data were reported as the mean $\pm$ SD. Group means were compared with two-tailed sample *t* test or One-way ANOVA. Relationships between categorical variables

Figure 2 Chemical transfection of fetal mesenchymal stem cells. Representative merged photomicrographs for (A-D) FuGENE 6, (E-H) Lipofectamine and (I-L) PEI mediated transfection of pcDNA3-eGFP into fMSCs at 3:1, 3:2, 6:1, and 5:2 reagent (μL): DNA (μg) ratio, respectively. In combination, qualitative transfection efficiency and viability reveal that PEI was superior at all the tested conditions. fMSCs: Fetal mesenchymal stem cells; PEI: Polyethylenimine.

Figure 3 Optimization of E1-A-deleted-green fluorescent protein transduction and viability of fetal mesenchymal stem cells post-transduction. Transduction efficiency and viability as a function of MOI at 48 h post-transduction with Ad-GFP. Ad-GFP: E1-A-deleted-green fluorescent protein.

were tested by the chi-square method. Statistical analysis was performed using StatPlus. A value of $P \leq 0.05$ was deemed significant.

RESULTS

Morphology and phenotypic expression of MSCs in vitro

Cultured fMSCs and aMSCs displayed an elongated spindle-shaped population and maintained their morphology during subsequent passages (Figure 1A and

B). MSCs were more than 90% positive for CD90 and negative for the hematopoietic stem cell marker CD34 (Figure 1C and D).

Screening for a transient gene delivery reagent for fMSCs

A qualitative analysis of fluorescent photomicrographs 48 h after pcDNA3-eGFP transfection revealed that FuGENE 6 resulted in the lowest transfection efficiency (Figure 2A-D) and Lipofectamine resulted in the lowest viability (Figure 2E-H), while PEI provided superior transfection efficiency (Figure 2I-L) in fMSCs than FuGENE 6 or Lipofectamine transfection reagents at 3:1, 3:2, 6:1, and 5:2 μL of reagent to μg of DNA ratio.

Optimized PEI-mediated transfection of pcDNA3-eGFP (5:2 μL of reagent/μg of DNA ratio) resulted in a maximum efficiency of $35.0\% \pm 1.6\%$ as assessed by flow cytometry. No significant decrease in viability was observed at either of the tested MOIs when compared to control untreated cells (Figure 3). Ad transduction at MOI of 25 resulted in transduction efficiency above 70% with similar viability to control cells (Figure 3). Thus, Ad transduction at an MOI of 25 was selected for succeeding experiments.

GFP expression and cell proliferation of MSCs post-transduction

Ad-GFP transduction at MOI of 25 resulted in transfection efficiency of $81.3\% \pm 1.3\%$ in fMSC, which was not statistically different from the efficiency of $78.1\% \pm 1.9\%$

Figure 4 Percent green fluorescent protein positive MSCs and mean fluorescence intensity following E1-A-deleted-green fluorescent protein transduction. Representative merged photomicrographs for (A-C) fMSCs and (E-G) aMSCs following Ad-GFP transduction at 2, 4, and 10 d post-transduction, respectively. Scale bar = 100 μ m; (D) GFP positive cells over the period of 2 wk post-transduction and (H) mean $\pm$ SD fluorescence intensity. Ad-GFP: E1-A-deleted-green fluorescent protein; fMSCs: Fetal mesenchymal stem cells; aMSCs: Adult mesenchymal stem cells.

Figure 5 Mesenchymal stem cells viability and proliferation post-transduction. A: Mean $\pm$ SD percent of viable cells as determined by 7-AAD positivity in flow cytometry at the indicated days post-transduction with Ad-GFP; B: Cumulative relative number of cells of Ad-GFP-MSCs and control MSCs. An estimated cell proliferation rate of 45 h and 29 h for aMSC or fMSCs, respectively, was determined from the slope of the curves; not significantly different between treated and control cells. Ad-GFP: E1-A-deleted-green fluorescent protein; fMSCs: Fetal mesenchymal stem cells; aMSCs: Adult mesenchymal stem cells.

in aMSCs. There was a greater decrease of GFP positive cells in fMSC than aMSC within 2 wk post-transduction (Figure 4A-G). Mean fluorescence intensity (MFI) was $7.43 \pm 0.08 \times 10^6$ and $4.40 \pm 0.25 \times 10^6$ channel numbers in fMSCs and aMSCs, respectively, at 48 h post transduction (Figure 4H). Ad-GFP-fMSCs retained superior gene expression intensity compared to Ad-GFP-aMSCs at one and two weeks post transduction.

Cell viability of both fMSCs and aMSCs in culture was not significantly affected by exogenous administration of GFP gene *via* Ad-transduction at MOI of 25 when compared to control untransduced cells (Figure 5A).

Number of cells was similar in both Ad-GFP-MSCs and control MSCs, with fMSCs showing a greater number of cells than aMSCs (Figure 5B), which in combination with results on viability reflect greater proliferation capacity of about 1.5 times faster proliferation than aMSCs (doubling time of 29 h *vs* 45 h). The latter, in combination with data on % GFP positive expression, suggests that Ad genome is gradually diluted out as cell division occurs.

Differentiation capacity post-transduction

Chondrogenic differentiation *in vitro* was significantly less for fMSCs than aMSCs and decreased post Ad-

Figure 6 Chondrogenic and osteogenic differentiation of control mesenchymal stem cells and E1-A-deleted-green fluorescent protein-mesenchymal stem cells. A-D: Chondrogenic cell pellets, differentiation induced with chondrogenic medium and TGF β 3, scale bar = 250 μ m; E-H: Osteogenic differentiation induced in monolayer culture of MSCs, scale bar = 100 μ m. monolayer cultures used for osteoinduction were evaluated for BMP2 expression. It was determined that Ad-BMP2-fMSCs transduced at MOI of 25 released significantly more soluble BMP2 than Ad-BMP2-aMSCs (0.16 pg/day-cell *vs* 0.10 pg/day-cell; Table 1). Also, BMP2 expression per injection of 2×10^6 transduced MSC was estimated at 3.28 and 1.85×10^4 pg/d with fMSCs and aMSCs, respectively (Table 1), consistent with the greater intensity of GFP expression in Ad-GFP-fMSCs than aMSCs.

***In vivo* MSC-mediated BMP2 delivery and osteoinduction**

Digital microradiography of the harvested thigh specimens revealed intramuscular bone ossicle formation, new periosteal bone, and femur cortical bone thickening in treated mice with Ad-BMP2-MSCs, but not in saline-injection control group (Figure 7A and B). Five of six thighs treated with Ad-BMP2-aMSC resulted in new bone formation, which was significantly greater than saline, untransduced, and Ad-BMP2-fMSC groups (Table

2). The Ad-BMP2-aMSC group also had significantly greater femur midshaft diameter due to cortical thickening and new periosteal bone when compared to saline, untransduced, and Ad-BMP2-fMSC groups (Table 2). Bone ossicles were identified in two of the six thighs treated with Ad-BMP2-aMSCs (Table 3 and Figure 7C) and of the other four thighs in the Ad-BMP2-aMSC group, 3 showed femur cortical thickening and new periosteal bone (Table 4 and Figure 7D), while no changes were found in the untransduced aMSC group (Figure 7E-F). One of the six thighs treated with Ad-BMP2-fMSCs showed ossicle formation (Figure 7G-H), none resulted in periosteal changes, and no changes were noted in the untransduced fMSC group (Figure 7I-J).

Histological examination confirmed new trabecular bone formation, normal in morphology, in the thighs of the Ad-BMP2-aMSC group (Figure 8A). This new trabecular bone contained highly cellular bone marrow (Figure 8B). A nodule of what appears to be our MSCs was identified in the untransduced aMSC group with no bone or cartilage formation (Figure 8C) as evaluated by H&E and toluidine blue stains, respectively (Figure 8D-E).

DISCUSSION

Our study confirmed that adenoviral vector-mediated transduction was efficient in fMSCs without affecting measures of MSC stemness. Chemical-mediated transfection was less efficient than Ad transduction, but PEI was superior and more effective in fMSCs than other commercial products. Fetal MSCs were not superior to aMSCs in osteoinduction *in vivo*. Both fMSCs and aMSCs were able to express BMP2 *in vitro* and to deliver BMP2 *in vivo*, which could have clinical applications in bone regeneration.

Figure 7 Osteoinduction *in vivo* by mesenchymal stem cell-mediated bone morphogenic protein 2 delivery. Twelve 6-wk-old SCID mice received a 100 μ L injection of 2×10^6 MSCs or saline into the quadriceps muscles. Muscle samples harvested from the mice were examined by microradiography, 21 d after treatment. Treatment groups consisted of (A-B) saline control; C-D: Ad-BMP2-aMSC injection; E-F: plain aMSCs; G-H: Ad-BMP2-fMSCs; I-J: injected with plain fMSCs. The white arrows point at ossicles. The green arrow points at cortical thickening and new periosteal bone. BMP2: Bone morphogenic protein 2; Ad-GFP: E1-A-deleted-green fluorescent protein; fMSCs: Fetal mesenchymal stem cells; aMSCs: Adult mesenchymal stem cells.

Scale bar = 100 μ m. BMP2: Bone morphogenic protein 2; aMSCs: Adult mesenchymal stem cells.

In the evaluation of chemical-mediated transfection, we found that PEI provided a significant level of transfection efficiency in fMSCs. Our results are in accordance with a study by Wang *et al.*^[17], which showed that genetic modification of human MSCs by PEI with a relatively low efficiency of 4% achieved biologically significant effects *in vivo*, with transfection efficiency proportional to cells in S phase^[17]. Our analysis further supported the use of PEI as a transfection reagent in

MSCs over other reagents. While we achieved around 35% transfection efficiency of pcDNA3-eGFP ratio, we found PEI to be relatively nontoxic in contrast to Lipofectamine and FuGENE 6. In conclusion, PEI offers an alternative to viral vector transduction and advantages over other chemical transfection reagents, especially when funding to support the use of viral vectors is not available.

Furthermore, the current study showed that Ad transduction provided superior efficiency to chemical

Table 4 Extent of periosteal new bone in E1-A-deleted-bone morphogenic protein 2-adult mesenchymal stem cell treatment group

Extent of periosteal new bone	Thighs (n)	Midshaft diameter (mm)

1	2	1.76
4	1	2.10

transfection, including PEI. It has been shown that lentiviral and retroviral-mediated transduction are effective in fetal MSCs^[12,13], however these are non transient and oncogenic such that their confirmed risk may be even greater when used in a stem cell. Our study was the first to test transient adenoviral mediated transduction in fetal MSCs. The present study confirmed that Ad transduction of fMSCs did not significantly affect measures of stemness, consistent with the previous studies addressing lentiviral and retroviral-mediated transduction of fMSCs. Viability was maintained above 90% for both fetal and adult MSCs, consistent with Ishihara *et al.*^[18] who reported equine aMSCs to not be sensitive to cytotoxic effects associated with Ad transduction at MOI of 100 or less. Our study also confirmed that fMSCs maintained a higher proliferative capacity than aMSCs post-transduction. This is again consistent with previous studies on viral vector-mediated stable transduction^[12,13]. Also, our observed greater proliferative capacity of fMSCs than their adult counterpart is consistent with studies in human fMSCs^[19]. These advantages of fMSCs would suggest advantages *in vivo*.

Ad-mediated transduction provided a similar efficiency in both fMSCs and aMSCs, but significantly greater intensity with greater decrease of the fraction of GFP positive cells in fMSCs compared to aMSCs. The greater proliferation of fMSC is sufficient to explain the greater reduction in GFP positive cells resulting in a gradual dilution of the adenoviral genome as cell division occurs^[20-22]. This is due to the fact that Ad transduction does not result in DNA integration into the host genome; therefore the delivered gene will be expressed only as long as the viral genome is present^[11,18].

Osteogenic differentiation capacity was not affected by Ad transduction *in vitro*. Our results are consistent with those of Zhang *et al.*^[10], who suggested that human fMSCs are a superior cellular candidate for bone tissue engineering applications than their adult counterpart because of their higher proliferation capacity, lower immunogenicity, and robust osteogenic potential as assessed *via* mineralization *in vitro*. On the other hand, the chondrogenic capacity of aMSCs was superior to fMSCs when inducing chondrogenesis with TGFβ3, and both decreased post-transduction with Ad-GFP. In fact, TGFβ3 was recently shown to induce chondrogenesis in aMSCs by phosphorylating SMAD3 but not in fMSCs^[23], which explains in part the lower differentiation of fMSCs into chondrocytes found in the present study.

In the evaluation of osteogenesis *in vivo*, the present

study showed that Ad-BMP2-aMSCs are capable of inducing regenerative bone formation more effectively than Ad-BMP2-fMSCs. Naïve fetal or adult MSCs alone were not osteoinductive *in vivo*. In fact, previous work by Zhang *et al.*^[10] have demonstrated that predifferentiation and a scaffold were necessary for osteoinduction by naïve MSCs. Although fMSCs showed higher BMP2 expression post-transduction *in vitro*, fMSC resulted in minimal new bone formation *in vivo*. These findings may be related to the shorter expression of the transgene in fMSCs. Alternatively, initial high BMP2 expression and release from fMSCs could have caused a transient increase in number of osteoclasts derived from hematopoietic stem cells^[24] but there was no evidence of bone remodeling in our histology to suggest this mechanism was at work. Based on our *in vitro* findings with fMSC, and recent work from our laboratory demonstrating superior outcomes of neocartilage growth with a mosaic of 90% naïve and 10% Ad-BMP2-transduced juvenile chondrocytes^[25], it was anticipated that the dilution of BMP2 expressing cells in the rapidly proliferating fMSC population may be an advantage *in vivo*. In addition, Brady and colleagues recently demonstrated that recombinant BMP2 can induce chondrogenesis in pellet culture of fetal but not adult MSCs^[23]. However, we were unable to demonstrate this potential as either enhanced endochondral ossification or chondrogenesis *in vivo* by fMSC, which could be due to difference in delivery method (recombinant BMP2 protein *vs* BMP2 gene transduction) or the fact that our study was *in vivo*. It is also possible that chondrogenesis would not be identified by microradiography and chondral ossicles may have evaded histologic sectioning, but, regardless, we saw minimal evidence of activity of fMSC *in vivo*.

In conclusion, the present study demonstrated adenoviral vectors as an effective method to transiently deliver genes into fMSCs. Nonetheless, the relative faster decrease in the fraction of cells expressing the exogenous gene when compared to transduced aMSCs may limit their applications. Our study also suggested fMSC-mediated BMP2 gene delivery and osteogenic induction *in vivo* was less robust than aMSCs at least in their capacity to induce bone formation. Both Ad-BMP2-aMSCs and Ad-BMP2-fMSCs were capable of expressing BMP2 *in vitro* and can be employed to deliver BMP2 for osteoinduction *in vivo* for the purpose of bone regeneration. Cell delivery may offer advantages over direct vector delivery. In addition, Ad vectors lack insertional mutagenesis, resulting in transient expression of the exogenous gene, which may be desirable over stable expression in applications involving bone morphogenic proteins to induce bone or cartilage regeneration. Further studies are necessary to elucidate differences in osteoinductive mechanisms of aMSCs and fMSCs *in vivo*.

ACKNOWLEDGMENTS

We thank the following for technical assistance: Heather Strange for guidance with laboratory equipment and

procedures, Hayam Hamzah Hussein for providing and guiding with the use of some of the MSCs and reagents, Juhnnei Vera for preparation of viral stocks, and Nathalie Reisbig for assistance with *in vivo* experiments.

COMMENTS

Background

In recent years, there have been hundreds of active clinical trials testing the use of mesenchymal stem cells (MSCs) in treating disorders such as myocardial infarction, osteoarthritis, spinal cord injury, and autoimmune diseases. Recent studies have demonstrated that fetal MSCs are a superior cellular candidate than adult MSCs for bone tissue engineering applications. While bone regeneration can be optimized with genetic engineering techniques, the permissiveness to gene delivery and the effect of genetic engineering on stemness in fetal MSCs has not been extensively studied.

Research frontiers

Bone regeneration is a complex process that requires interplay of molecular, cellular, and metabolic factors. In the area of bone tissue regeneration and MSCs, the current hotspot is genetic engineering, microenvironment, and homing of MSCs to optimize bone healing.

Innovations and breakthroughs

Previous studies have found that fetal MSCs can be retrovirally and lentivirally transduced with high efficiency and retain their proliferative and differentiation capacities. The present study demonstrated that adenoviral vectors are an effective method to transiently deliver genes into fetal MSCs and bone morphogenic protein 2 (BMP2)-transduced MSCs can be employed for osteoinduction *in vivo*.

Applications

The study results suggest that fetal MSCs can be genetically engineered with adenoviral vectors to deliver BMP2 and induce osteoinduction, with promising applications in bone tissue regeneration.

Terminology

MSCs are capable of self replicating and differentiating into mesenchymal tissues such as bone, cartilage, and adipose tissue. MSCs can be genetically engineered for applications in tissue regeneration. Adenoviral vectors can deliver genetic material into MSCs. These vectors lack insertional mutagenesis resulting in a desirable safety profile, which added to their capacity to achieve high levels of transgene expression make them attractive for gene delivery particularly for bone regeneration. BMP2 is a growth factor involved in signaling pathways for osteoinduction resulting in osteoblast differentiation of stem cells.

Peer review

The authors have asked some interesting questions and they have compared the fetal vs adult MSCs for their ability to express transgenes via viral and non-viral vectors, and their differentiation capability. It is a very good study. Conclusions are supported by their data.

ABOUT COVER

Editorial Board Member of *World Journal of Stem Cells*, Gavin Stewart Dawe, PhD, Department of Pharmacology, Yong Loo Lin School of Medicine, Centre for Life Sciences, Level 4, 28 Medical Drive, Singapore 117456, Singapore

AIM AND SCOPE

World Journal of Stem Cells (*World J Stem Cells*, *WJSC*, online ISSN 1948-0210, DOI: 10.4252), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJSC covers topics concerning all aspects of stem cells: embryonic, neural, hematopoietic, mesenchymal, tissue-specific, and cancer stem cells; the stem cell niche, stem cell genomics and proteomics, and stem cell techniques and their application in clinical trials.

We encourage authors to submit their manuscripts to *WJSC*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

INDEXING/ ABSTRACTING

World Journal of Stem Cells is now indexed in PubMed Central, PubMed, Digital Object Identifier, and Directory of Open Access Journals.

proliferation for cardiac disease, vascular disorders, cancer, and neurodegenerative disorders is receiving great enthusiasm, especially those that focus upon SIRT1, a mammalian homologue of the yeast silent information regulator-2. Modulation of the cellular activity of SIRT1 can involve oversight by nicotinamide/nicotinic acid mononucleotide adenylyltransferase, mammalian forkhead transcription factors, mechanistic of rapamycin pathways, and cysteine-rich protein 61, connective tissue growth factor, and nephroblastoma over-expressed gene family members that can impact cytoprotective outcomes. Ultimately, the ability of SIRT1 to control the programmed cell death pathways of apoptosis and autophagy can determine not only cardiac, vascular, and neuronal stem cell development and longevity, but also the onset of tumorigenesis and the resistance against chemotherapy. SIRT1 therefore has a critical role and holds exciting prospects for new therapeutic strategies that can offer reparative processes for cardiac, vascular, and nervous system degenerative disorders as well as targeted control of aberrant cell growth during cancer.

Key words: FoxO; Mechanistic of rapamycin; Apoptosis; Autophagy; Cardiovascular; Cysteine-rich protein 61, connective tissue growth factor, and nephroblastoma over-expressed gene; Neurodegeneration; Progenitor stem cells; SIRT1; Cancer

Core tip: SIRT1, a mammalian homologue of the yeast silent information regulator-2, holds exciting prospects for new therapeutic strategies that can offer reparative processes for cardiac, vascular, and nervous system degenerative disorders as well as targeted control of unchecked cell growth during cancer.

Maiese K. SIRT1 and stem cells: In the forefront with cardiovascular disease, neurodegeneration and cancer. *World J*

Abstract

Cardiovascular disease, nervous system disorders, and cancer in association with other diseases such as diabetes mellitus result in greater than sixty percent of the global annual deaths. These noncommunicable diseases also affect at least one-third of the population in low and middle-income countries and lead to hypertension, elevated cholesterol, malignancy, and neurodegenerative disorders such as Alzheimer's disease and stroke. With the climbing lifespan of the world's population, increased prevalence of these disorders is expected requiring the development of new therapeutic strategies against these disabling disease entities. Targeting stem cell

THE IMPACT OF CARDIOVASCULAR DISEASE, CANCER, AND NEURODEGENERATIVE DISORDERS

Life expectancy is increasing in developed countries such as the United States and has been accompanied by a one percent decrease in the age-adjusted death rate from the years 2000 through 2011^[1]. Yet, a number of disorders on a global scale continue to plague the population with increased morbidity and mortality from cardiovascular disease, disorders of the nervous system, and cancer. The World Health Organization reports that in 2008, greater than 60% of 57 million global deaths were primarily due to cardiovascular diseases, diabetes, cancer, and respiratory disorders^[2]. Almost 80% of these noncommunicable diseases (NCDs) occur in low and middle-income countries. These NCDs affect approximately 30% of the population under 60 in low and middle-income countries. In contrast, in high-income countries, 13% of the population under 60 is affected. Hypertension and elevated cholesterol are significant risk factors for cardiovascular disease with hypertension alone contributing to approximately 13% of all deaths^[3]. Disorders such as hypertension and elevated cholesterol also contribute to acute neurodegenerative disease such as stroke, the fourth leading cause of death^[4,5]. With the increasing lifespan of the world's population and advancing age, it is expected that the incidence of neurodegenerative disorders also will grow. As an example, ten percent of the global population over the age of 65 is now affected with the sporadic form of Alzheimer's disease, but this is expected to increase significantly^[6-8]. Continued development of new therapeutic strategies directed against the NCDs of cardiovascular disease, neurodegeneration, and cancer are necessary to increase our armamentarium against the complexity of these disease entities.

THE SIRT1 PATHWAY

In this arsenal directed against cardiovascular disease, neurodegenerative disorders, and cancer, multiple therapeutic strategies are being advanced that involve novel stem cell applications. Targeting stem cell proliferation is being considered for cardiac disease^[9], vascular disorders^[10,11], cancer^[12,13], and neurodegenerative disease^[14-16]. However, it is the investigation of stem cells that focus upon sirtuins, mammalian homologues of the yeast silent information regulator-2 (Sir2), that are proving to be extremely

exciting.

Sirtuins are histone deacetylases that transfer acetyl groups from ϵ -N-acetyl lysine amino acids on the histones of DNA to regulate transcription^[17-19]. This family of histone deacetylases also mediates post-translational changes of proteins involved with cellular proliferation, survival, and senescence^[20-23]. There are seven identified mammalian homologues of Sir2 that include SIRT1 through SIRT7. Of these, SIRT1 has been tied to the modulation of multiple cellular functions that include protection against oxidative stress^[24-28], development of atherosclerosis^[29,30], modulation of vascular survival and senescence^[17,20,21,31,32], proliferation of cancer cells^[33-36], changes in diabetic cellular metabolism^[33-36], control of vascular tone through the transient receptor potential cation channel A1^[37], promotion of neuronal survival and cognitive function^[21,38-41], and the extension of lifespan^[25,42,43]. Furthermore, SIRT1 appears to be necessary for efficient post-reprogramming of telomere elongation, the maintenance of pluripotency, and the modulation of differentiation in induced pluripotent stem cells^[44]. In differentiated cells, SIRT1 also controls telomere length and maintenance^[45].

SIRT1 is dependent upon NAD⁺ as substrate^[17,38,46,47]. Through the salvage pathway of NAD⁺ synthesis, nicotinamide phosphoribosyltransferase (NAMPT) catalyzes the conversion of nicotinamide to nicotinamide mononucleotide^[48]. Nicotinamide mononucleotide is subsequently converted to NAD⁺ by enzymes in the nicotinamide/nicotinic acid mononucleotide adenyltransferase (NMNAT) family. NAMPT is a rate-limiting enzyme in mammalian NAD⁺ biosynthesis pathway. Elevated levels of NAMPT activity increase cellular NAD levels as well as the activity of SIRT1 transcription.

The level of SIRT1 activity and its modulation in these cellular processes is considered to be an important factor in determining cell survival and protection against toxic insults. Insufficient SIRT1 activity can have a detrimental affect upon vascular cell survival^[22,23,49], protection against cardiovascular disease^[31], and prevention of neuronal injury^[28,50,51]. Yet, a reduction in SIRT1 activity also may be required to promote cellular survival in systems involving trophic factors such as insulin growth factor-1^[52].

Several biological systems can control the activity of SIRT1 (Figure 1). For example, NMNAT can modulate the deacetylating activity of SIRT1. In addition, mammalian forkhead transcription factors^[53] can bind to the SIRT1 promoter region that contains a cluster of five putative core binding repeat motifs (IRS-1) and a forkhead-like consensus-binding site (FKHD-L). As a result, forkhead transcription factors such as FoxO1 can govern SIRT1 transcription and increase SIRT1 expression^[54]. AMP activated protein kinase (AMPK) represents another pathway for the control of SIRT1 activity. AMPK is a member of the mechanistic

Figure 1 Schematic of SIRT1 pathways that can influence stem cell maintenance, proliferation, and survival. Several pathways can control SIRT1. For example, NMNAT can modulate the deacetylating activity of SIRT1, FoxO1 can govern SIRT1 transcription and increase SIRT1 expression, and AMPK can increase the cellular NAD⁺/NADH ratio leading to the deacetylation of downstream SIRT1 targets. SIRT1 subsequently can depress mTOR pathways and promote autophagy to preserve stem cell integrity during oxidant stress as well as promote neuronal growth. In addition, SIRT1 is necessary to initiate autophagy and transition cells from a quiescence state to an active state. WISP1 increases SIRT1 activity to protect cells from oxidative stress and apoptotic injury and blocks SIRT1 caspase degradation. NMNAT: Nicotinamide/nicotinic acid mononucleotide adenylyltransferase; mTOR: Mechanistic of rapamycin; AMPK: AMP activated protein kinase.

of rapamycin (mTOR) pathway that phosphorylates tuberous sclerosis protein 2 and inhibits the activity of mTORC1^[55,56]. AMPK can increase the cellular NAD⁺/NADH ratio leading to the deacetylation of downstream SIRT1 targets that include the peroxisome proliferator-activated receptor-gamma coactivator 1 α , FoxO1, and FoxO3a^[57]. AMPK also can increase NAMPT during glucose restriction that results in increased NAD⁺ and decreased levels of nicotinamide^[58], an inhibitor of SIRT1^[59]. Resveratrol, a SIRT1 activator, also has been shown to activate AMPK through SIRT1 dependent or independent mechanisms^[57,60].

STEM CELLS, SIRT1, APOPTOSIS, AND AUTOPHAGY

The impact of SIRT1 on cellular function is intimately associated with programmed cell death pathways that involve apoptosis and autophagy^[61-63]. Apoptosis leads to DNA degradation and caspase activation through an early phase that involves the loss of plasma membrane lipid phosphatidylserine (PS) asymmetry and a later phase that results in genomic DNA degradation^[64]. During the early phase of apoptosis, prevention of membrane PS externalization in injured cells is necessary to block the loss of functional cells that may

be removed by activated inflammatory cells^[56]. SIRT1 activation limits external membrane PS exposure during the early phases of apoptosis in mature cells^[22,23,65,66]. In endothelial progenitor cells, SIRT1 activity can counteract the “pro-apoptotic” effects of tumor necrosis factor- α (TNF- α)^[67]. During exposure to TNF- α , SIRT1 also has been shown to protect skeletal myoblast survival^[68]. Loss of SIRT1 activity in human mesenchymal stem cells yields a reduction of proliferation rate with increased apoptosis^[69]. During aging in the mouse auditory system, loss of SIRT1 in cochlear neurons and in the auditory cortex is associated with hearing loss^[70]. In addition, endothelial progenitor cell dysfunction with apoptotic cell death that can occur in smokers and chronic obstructive disease patients has been associated with the loss of SIRT1 expression^[71].

Stem cell survival with SIRT1 can be reliant upon forkhead transcription factors and mTOR (Figure 1). Although several studies involving differentiated cells support the premise that down-regulation of forkhead transcription factors by SIRT1 activation can protect against apoptotic cell death especially during oxidant stress^[22,23,65,72,73], other studies in embryonic stem cells suggest that SIRT1 down-regulation can lead to the acetylation/phosphorylation of forkhead transcription factor pathways such as FoxO1, and in association with phosphatase and tensin homolog (PTEN) and c-Jun N-terminal kinase (JNK), block oxidant stress induced apoptosis^[74]. However, in embryonic stem cells, the presence of SIRT1 also can be protective and appears to have an inverse relationship with mTOR^[35]. SIRT1 can depress mTOR mediated pathways as well as promote autophagy to preserve the integrity of embryonic stem cells during oxidant stress^[75]. SIRT1 can foster inhibition of mTOR signaling to promote neuronal growth^[76]. In addition, during high glucose exposure to mesangial cells, the loss of SIRT1 activity is necessary for mTOR to arrest mesangial cell senescence^[77].

It is important to note that during apoptotic cell injury with the induction of caspase activity, SIRT1 is susceptible to degradation by caspases. Although SIRT1 degradation also may be mediated by apoptotic pathways associated with p38^[78] and JNK1^[79], loss of SIRT1 activity can be the result of caspase degradation of the SIRT1 protein^[80] that can then accelerate further activation of caspases^[80,81]. In some systems that involve the cysteine-rich protein 61, connective tissue growth factor, and nephroblastoma over-expressed gene (CCN) family (defined by the first three members of the family that include cysteine-rich protein 61, connective tissue growth factor, and nephroblastoma over-expressed gene)^[12], the CCN member WISP1 increases SIRT1 activity to protect cells from oxidative stress and apoptotic injury^[28] (Figure 1). WISP1 also prevents SIRT1 degradation and oversees forkhead transcription activity with SIRT1 similar to other

cytoprotective pathways^[20,73,82] to block FoxO3a activity and prevent caspase activation that would otherwise lead to the degradation of SIRT1^[28,83-85].

In contrast to apoptosis, autophagy promotes tissue remodeling by recycling cytoplasmic components and eliminating no longer useful organelles^[62]. Macroautophagy is the classification of autophagy most commonly described^[86]. It involves the sequestration of cytoplasmic proteins into autophagosomes that fuse with lysosomes for degradation and are eventually recycled. In most cases, SIRT1 activation with the induction of autophagy appears to be vital to promote cell survival in mature cells. In differentiated chondrocytes during oxidant stress, knockdown of the forkhead transcription factors FoxO1 and FoxO3 result in cell death with decreased SIRT1 activity and reduced autophagic related proteins, suggesting that SIRT1 with the activation of autophagy is necessary for cellular protection^[24]. SIRT1 also plays a role in autophagic flux and promoting autophagy in mitochondria^[87] that may be required to maintain a healthy pool of mitochondria^[88]. In endothelial cells exposed to oxidized low density lipoproteins that can lead to atherosclerosis, SIRT1 up-regulation in conjunction with AMPK results in autophagy that is necessary for cellular protection^[89]. In models of cognitive loss with chronic intermittent hypoxia hypercapnia exposure, SIRT1 activation is able to block apoptotic cell injury, up-regulate autophagy, and improve cognitive performance^[90]. However, in pulmonary models of oxidant stress such as the exposure to cigarette smoke in bronchial epithelial cells, SIRT1 has been shown to prevent cell injury through the inhibition of autophagy^[91,92]. In regards to stem cells and the autophagic pathway, stem cells rely upon SIRT1 to modulate autophagic flux^[93]. In muscle stem cells, SIRT1 is necessary to initiate autophagy and transition muscle stem cells from a quiescence state to an active state^[94]. In endothelial progenitor cells, SIRT1 blocks apoptotic cell injury during oxidative stress through the induction of autophagy^[95].

STEM CELLS, SIRT1, AND THE CARDIOVASCULAR SYSTEM

In the cardiovascular system, SIRT1 expression can affect not only the survival of stem cells, but also the ability of stem cells to differentiate and the efficacy of these cells for therapeutic applications. Increased SIRT1 expression can improve the survival of cardiomyoblasts^[96] and prevent senescence and impaired differentiation in endothelial progenitor cells^[97]. In regards to treatment efficacy, mesenchymal stem cells that are subjected to SIRT1 over-expression exhibit increased blood vessel density in the area of cardiac infarcts, reduced cardiac remodeling, and improved cardiac performance in rodent models^[98], factors that may be associated with cardiac stem migration that is vital to tissue repair^[99]. SIRT1 also

can limit expression of aged mesenchymal stem cell phenotypes^[98]. Loss of SIRT1 in circulating endothelial progenitor cells that can occur during tobacco exposure or chronic obstructive pulmonary disease may lead to increased senescence and apoptotic cell death that presents increased risk for vascular disease or cardiac disease^[71]. SIRT1 also may improve the function of aged stem cells that are senescent. Aged mesenchymal stem cells that were exposed to pre-conditioning with glucose depletion exhibited increased expression of SIRT1 in addition to other proliferative entities such as growth factors and resulted in increased cardiac performance^[100].

STEM CELLS, SIRT1, AND NEURODEGENERATION

In the nervous system, SIRT1 has been tied to the differentiation, maturation, and maintenance of neurons. Loss of SIRT1 expression with the concurrent induction of heat shock protein-70 promotes neural differentiation, maturation of embryonic cortical neurons^[101], and the differentiation of human embryonic stem cells into motor neurons^[102]. SIRT1 also is considered a negative regulator of subventricular zone and hippocampal neural precursors in murine animal models. Knockdown of SIRT1 does not eliminate neural precursor numbers or proliferation but increases the production of neurons in the subventricular zone and the hippocampus^[103]. In the mouse cerebral cortex, repression of SIRT1 by the oncogene BCL6 leads to the conversion of neural stem cell/progenitor cells to become neurons^[104]. Neural stem cell differentiation also can be controlled through alternate pathways that involve SIRT1. In mouse neural stem cells, neuronal differentiation can be driven through the microRNA miR-34a that leads to decreased SIRT1 expression and DNA-binding of p53^[105]. Interestingly, in these studies, increased expression of SIRT1 enhanced the astrocytic subpopulation of cells^[105].

STEM CELLS, SIRT1, AND CANCER

The cellular proliferative effects of SIRT1 also play a critical role in tumorigenesis. For example, SIRT1 activity can maintain acute myeloid leukemia stem cells and confer resistance against chemotherapy^[106], stimulate endometrial cell tumor growth through lipogenesis^[107], maintain neural stem cells and promote oncogenic transformation^[108], and foster hepatocellular carcinoma^[109]. As a result, SIRT1 and agents that modulate SIRT1 activity may represent new therapeutic strategies against tumorigenesis. For example, down-regulation of endoglin, a protein over-expressed in tumor associated endothelial cells, leads to apoptotic cell death, DNA damage, inhibition of several DNA repair genes including SIRT1, and enhanced chemotherapy sensitivity^[110]. In addition, pathways linked to SIRT1

also may provide new strategies against cancer. Activation of p53 through SIRT1 inhibition can result in apoptotic cell death for quiescent leukemia stem cells in chronic myelogenous leukemia^[111]. In breast cancer, estrogen receptor- α can lead to SIRT1 expression that activates pro-survival genes in breast cancer cells, such as catalase and glutathione peroxidase, and inhibits tumor suppressor genes, such as cyclin G2 (CCNG2) and p53. In these breast cancer cells, if SIRT1 is inhibited, estrogen receptor-induced breast cell growth is blocked through apoptotic cell death^[112].

FUTURE CONSIDERATIONS

Cardiac disease, vascular disorders, neurodegenerative disease, and cancer lead to significant disability and death in the global population. Development of stem cell strategies for these disorders and the targeting of SIRT1 to drive stem cell viability and function holds great promise for the future. In the cardiovascular system, SIRT1 through stem cell proliferation can drive angiogenesis, improve cardiac performance following ischemic injury, limit cell senescence, and enhance the function of aged stem cells. In the nervous system, SIRT1 can be a negative modulator of neural precursors with the loss of SIRT1 leading to differentiation and maturation of embryonic stem cells in the nervous system. During tumorigenesis, SIRT1 foster the development of acute myeloid leukemia stem cells, promote oncogenic transformation of neural stem cells, and lead to hepatocellular cancer. Vital to the clinical outcomes controlled by SIRT1 is its level of activity overseen by pathways that include NMNAT, mammalian forkhead transcription factors, mTOR, and CCN family members such as WISP1 that determine cell survival through apoptosis and autophagy. Future work that can target SIRT1 and navigate stem cell proliferation under required conditions to either cellular proliferation or cellular death can open new avenues for the treatment of cardiovascular disorders, neurodegenerative disease, and cancer.

Abstract

The capability of human pluripotent stem cells (hPSCs) to differentiate into a variety of cells in the human body holds great promise for regenerative medicine. Many substrates exist on which hPSCs can be self-renewed, maintained and expanded to further the goal of clinical application of stem cells. In this review, we highlight numerous extracellular matrix proteins, peptide and polymer based substrates, scaffolds and hydrogels that have been pioneered. We discuss their benefits and shortcomings and offer future directions as well as emphasize commercially available synthetic peptides

INTRODUCTION

Ever since the derivation of human embryonic stem cells (hESCs) from the inner mass of the blastocyst^[1], great effort has been placed on extending the benefits of these pluripotent cells to regenerative medicine^[2,3]. However, human pluripotent stem cells (hPSCs) which include human induced pluripotent stem cells (hiPSCs) and hESCs, have traditionally been cultured on mouse fibroblast feeder layers in the presence of animal cell-conditioned media or on Matrigel that pose inherent risk of pathogenic contamination^[4] as well as the presence of non-human immunogenic epitopes such as N-glycolylneuraminic acid (Neu5Gc)^[5]. Consequently, research has focused on developing xeno-free, chemically defined media and substrates that are

compliant with current good manufacturing practice (cGMP), scalable, maintain high degree of hPSC purity, colony homogeneity and pluripotency. Here, we review substrates that have been developed for maintenance of hPSCs for clinical applications.

EXTRACELLULAR MATRIX PROTEINS

Feeder free cultures for hPSC expansion rely on Matrigel which constitutes the basement membrane components derived from mouse Engelbreth-Holm Swarm (EHS) tumor. The EHS tumor can easily yield a hundred grams of basement membrane components that are abundantly found in Matrigel such as collagen IV, laminin, heparin sulfate proteoglycans and nidogen/entactin^[6]. In addition, minor components can also be found in Matrigel which include proteases such as 72 kDa matrix metalloproteinase-2, 92 kDa matrix metalloproteinase-9, urokinase, tissue-type plasminogen activator as well as growth factors, like transforming growth factor beta, fibroblast growth factor, epidermal growth factor, platelet-derived growth factor, insulin-like growth factors, and proteins (Amylase, Transferrin, Clusterin) in an undefined composition. Matrigel has been used as a substrate to study the long-term stability (40 passages) of hESCs^[7] as well as to derive and maintain new hESC lines for over 70 passages^[8]. Other studies have used Matrigel as an extracellular matrix (ECM) to induce hepatic differentiation of hESCs using hepatic growth hormone and activin A^[9], to expand hESCs on Matrigel-coated cellulose microcarriers in 3D suspension cultures^[10] and to study the effects of bone morphogenetic protein 4 on hESCs differentiation^[11]. As Table 1 highlights, the batch-to-batch variability and xenogeneic-origin makes Matrigel unsuitable for quality control or cGMP production of hPSCs. Consequently, various ECM protein components have been sought as alternatives to Matrigel.

Vitronectin

The N-terminal of the 75 kDa vitronectin protein consists of the binding sites for integrins *via* the Arg-Gly-Asp RGD sequence, which allows cell-vitronectin interaction^[12]. Braam *et al*^[13] have shown that recombinant vitronectin is as effective as plasma purified vitronectin for hESC expansion and mediates cell attachment *via* the α V β 5 integrins. In mTeSR1 medium, recombinant vitronectin supported several hESC lines for five passages while maintaining normal morphology, karyotype, differentiation potential and cell surface markers for stemness. However, other ECM proteins such as laminin, collagen I, collagen IV and fibronectin were only able to support cell growth in mouse embryonic fibroblast-conditioned media (MEF-CM)^[13]. The use of mouse myeloma cell line NS0 to obtain the recombinant vitronectin holds potential risk of sialic acid contamination but others have been

able to produce recombinant vitronectin in *Escherichia colivia* plasmid vectors^[14]. Prowse *et al*^[14] obtained recombinant somatomedin B (SMB) domain along with the RGD sequence of vitronectin (rVN SMB) and anchored the substrate to tissue culture plate through vitronectin's polyhistidine linker sequence.

Recently, a fully-defined, serum- and feeder-free medium called StemPro was developed for hPSC expansion and differentiation. The hESCs grown in an ascorbate (vitamin C) free StemPro media for over 10 passages showed similar binding affinity to another ECM protein purified from EHS tumor (called Geltrex) and pluripotency markers comparable to cultures grown on whole purified vitronectin and Geltrex^[14]. The surface density of human purified plasma vitronectin necessary for long term (> 30 passages) hESCs attachment, proliferation and differentiation was determined by Yap *et al*^[15] to be 250 ng/cm². However, the hESCs cultured on purified plasma vitronectin in mTeSR media showed slower (35 h) doubling time than Matrigel (25 h) but expressed normal pluripotency markers and karyotype^[15]. Another study examined the scale up potential of vitronectin and laminin-coated three dimensional (3D) substrates from traditional two dimensional (2D) tissue culture polystyrenes (TCPs) to 3D polystyrene microcarriers (MCs)^[16]. In this study, vitronectin was adsorbed onto TCPs and reached a surface density saturation of 510 ng/cm² compared with laminin at 850 ng/cm². Coating vitronectin and laminin to MCs allowed for a surface density saturation of 450 and 650 ng/cm², respectively. Even though, the two extracellular matrices showed similar adhesion and growth kinetics, the scale up to 3D culture resulted in a slower growth kinetics on the polystyrene MCs. This was explained by the hydrophobicity of MCs as well as the formation of large compact cell aggregates which deprive essential nourishments to the cells that are located in the center.

Laminins

Laminin provides adequate growth for hESCs *via* the integrin α 6 β 1 laminin specific receptor since it is the major type of integrin present on hESCs^[17,18]. The effect of various recombinant human laminin (rhLM) isoforms on hESC attachment and proliferation has been investigated. Miyazaki *et al*^[18] showed that hESC line KhES-1 cells adhere markedly to rhLM-332 as well as to rhLM-511 and rhLM-111 (least adherence) when compared to non-adherence on rhLM-211 and rhLM-411. In the study, KhES-3 cells were able to adhere to rhLM-211 and rhLM-411 but their growth rate was markedly lower on rhLM-332, rhLM-511 and rhLM-111^[18]. The primary reason for such a marked difference in adherence and growth is because rhLM-211 and rhLM-411 possess affinity for α 3 β 1 and α 7 β 1 which are laminin-binding integrin isoforms that are expressed on hESCs in a relatively low amount compared to α 6 β 1 integrins^[18]. This receptor specificity

Table 1 Benefits and shortcomings of Matrigel, extracellular matrix proteins, synthetic peptides, synthetic polymers and hydrogels

Substrate	Advantages	Disadvantages
Matrigel	Allows feeder-free cell culture Inexpensive Long-term hESCs culture ^[7,8]	Xenogeneic origin ^[6] Undefined components ^[6] Pathogenic contamination risk ^[4] Neu5Gc immunogenic epitope ^[5] Batch-to-batch variability ^[6]
ECM proteins	See subsections below	Batch-to-batch variability Degradation upon sterilization
Vitronectin		Pathogenic contamination risk
rhLM-332		Not-Scalable ^[30]
LM-E8		High production cost ^[30]
rh E-cadherins-Fc protein		Immunogenicity risk ^[17]
Fibronectin		Degradation upon sterilization
Vitronectin	Long-term hESC culture (> 30 passages) ^[15] α V β 5 integrin receptor mediated cell attachment ^[13]	Not-Scalable ^[16,30] High production cost ^[30]
rhLM-332	High α 6 β 1 integrin affinity ^[18]	
LM-E8	Smaller, easily purified, higher purity <i>vs</i> 780 ku laminins ^[20] Better stem cell adhesion than Matrigel and intact laminins ^[20] ROCK inhibitor Y-27632 not needed ^[20]	Not-Scalable ^[30] High production cost ^[30]
rh E-cadherins-Fc protein	hESC self-renewal, maintenance and pluripotency comparable to Matrigel TM ^[26]	Low cell adherence <i>vs</i> Matrigel ^[26]
Synthetic peptides	No batch-to-batch variation ^[36] Immunogenicity risk avoided ^[37] Since chemically synthesized Long-term hESCs culture ^[32,37,44]	High production costs ^[47,48] Sterilization difficulties ^[47] Easily degradable ^[47] Labor intensive cell passaging Limited scale-up potential of 2D platform ^[51]
Synthemax surface	Gamma irradiation sterilization ^[39] 2 yr shelf-life ^[39] hESCs cryopreserved and thawed on substrate ^[38] Scalable ^[38] Long-term hESCs culture ^[38-40]	
Synthetic polymers	Inexpensive ^[45,47]	Limited scale-up potential of 2D platform
PMVE-alt-MA	Easy and rapid fabrication ^[45,49]	
PMEDSAH	Highly manipulable ^[47]	
APMAAm	Long-term substrate stability ^[46]	
Polyacrylates		
Chitosan-alginate polymers		
(pDTEc) polymer scaffolds		
Hydrogels	<i>In-vivo</i> 3D type environment ^[58] Thermoresponsive and pH sensitive properties ^[54,55,58]	Difficult to analyze cells embedded in hydrogels
(AETMA-Cl)-DEAEA based		Enzymatic release of cells from hydrogel ^[57]
PDEAAm-based		
HA-based		
Alginate-collagen based		
PEG-based		
PPP-based		

hESC: Human embryonic stem cell; ECM: Extracellular matrix; LM: laminins; PMVE-alt-MA : Poly(methyl vinyl ether-alt-maleic anhydride); PMEDSAH: poly[2-(methacryloyloxy)ethyl dimethyl-(3-sulfopropyl)ammonium hydroxide]; APMAAm: Aminopropyl methacrylamide; pDTEc: Poly(desaminotyrosyl tyrosine ethyl ester carbonate); AETMA-Cl: 2-(acryloyloxyethyl) trimethylammonium chloride; HA: Hyaluronic acid; PDEAAm: Poly(N,N-diethylacrylamide); PEG: Polyethylene glycol; PPP: Platelet poor plasma; 2D: Two dimensional.

is further established by the fact that although laminin-332 is not expressed on hESCs, rhLM-332 was an adequate substrate for hESCs adherence and proliferation due to its affinity for α 6 β 1 integrins^[18].

Since laminin isoform-511/-521 are the major laminins expressed on hESCs, another study investigated hESC self-renewal of cell lines HS420, HS207 and HS401 on a rhLM-511 substrate in the mTeSR1 variant (O3) and xeno-free TeSR1 variant (H3) media^[19]. The cells proliferated for 28 passages and normal karyotype was observed after 20 passages while exhibiting OCT4, SOX2 and Nanog pluripotency markers at a higher level than Matrigel and comparable

to those grown on feeder cells. Importantly, rhLM-511 affinity of the cells was higher than cell-cell adhesion as demonstrated by cell spreading when the cells were passaged as individual clumps and this highlights the role of rhLM-511 in cell motility.

Further refinement to laminin-coated substrates has been achieved by using laminin E8 fragments (LM-E8) that are composed of the α , β and γ chains' C-terminal regions^[20]. These truncated proteins are smaller, easily purified in a short time period and yield a higher purity compared with the 780 kDa LMs. Miyazaki *et al*^[20] used LM-511-E8 and LM 332-E8 to achieve greater hESC and hiPSC adhesion than MatrigelTM and intact LM-511

and 332 in a TeSR2 medium. The three hESC lines and two hiPSC lines cultured on LM-E8-coated substrates underwent proliferation for 30 and 10 passages, respectively, where disassociated cells attached strongly to LM-E8 substrates as compared to weak adhesion on Matrigel, fibronectin and vitronectin substrates^[20]. Importantly, LM-E8 substrates did not require the use of ROCK inhibitor γ -27632 which is needed for some recombinant protein-based substrates.

E-cadherin

E-cadherin, which is a transmembrane glycoprotein is involved in calcium-dependent cell-cell adhesion in epithelial as well as embryonic stem cells^[21]. It is essential for the maintenance of pluripotent state of stem cells due to their critical role in cell-cell adhesions^[22] as well as cell survival and renewal^[23]. This E-cadherin mediated pluripotency is quickly lost, as measured by the levels of Oct4, Nanog and Sox2, when siRNA is used to suppress E-cadherin expression on cells^[24]. This in turn causes a decrease in hESC proliferation^[25] and emphasizes the critical role that E-cadherins play in cell-cell adhesion, survival, renewal, proliferation and pluripotency. Nagaoka *et al*^[26] used recombinant E-cadherin-Fc-coated culture dishes (rhE-cad-Fc) where E-cadherins are fused with an IgG-Fc domain to coat tissue culture plates on which hESCs were examined for their pluripotency and propagation characteristics. The study demonstrated that both hESCs and hiPSCs that were cultured on rhE-cad-Fc protein-coated surface for > 13 passages in mTeSR1 medium were indistinguishable from those that were cultured on Matrigel as far as the rate of proliferation, cell morphology, maintenance of pluripotency and the ability to differentiate into multiple cell types were concerned. However, the ability of cells to adhere was decreased as a result of protease digestion cocktails using Accutase. This problem can be circumvented by using enzyme-free Cell Dissociation Buffer for passaging the cells. Therefore, rhE-cad-Fc can be considered superior to Matrigel as a substrate because of the use of more defined chemical conditions that yield similar results for hESC self-renewal, maintenance and pluripotency. E-cadherins have also been linked with matrix rigidity where hESCs on rigid substrates were shown to co-express E-cadherins and were OCT4⁺. In contrast, the softer substrates had large hESC aggregates that had an increased tendency to differentiate. Furthermore, hESCs on rigid substrates exhibit increased cytoskeleton contractility related to E-cadherin expression among cells^[27].

Fibronectin

The 220 kDa fibronectin dimer interacts with hESCs *via* the α 5 β 1 integrin receptor such that only 25 percent of adsorbed fibronectin is needed for hESC renewal^[28]. However, the 120 kDa central-binding domain of fibronectin is necessary for attachment

and maintenance of hESCs pluripotency. Using a high throughput screening of various ECM proteins, Brafman *et al*^[29] discovered that high concentrations of fibronectin and laminin (500 μ g/mL) supported hESC proliferation commensurate with Matrigel in a concentration dependent manner and fibronectin, collagen I and laminin were each able to support a high degree of pluripotency.

SYNTHETIC PEPTIDES

Even though, the protein based substrates such as recombinant vitronectin, laminin and rhE-cad-Fc coated tissue plates may be feeder free, they are not xeno-free and as a result pose significant immunogenic and pathogenic hazards^[4]. Additionally, such substrates are not scalable and have significant manufacturing costs associated with them^[30]. Being protein-based, they can also undergo degradation following common sterilization techniques. Consequently, peptide-based substrates offer better alternatives for maintaining hPSCs pluripotency, self-renewal, growth, scalability and clinical applicability.

Heparin binding peptides promote cell adhesion and spreading through their interaction with cell-surface glycosaminoglycans (GAGs) which are involved in cell-cell recognition and adhesion, cell-matrix interactions and receptor-signal complexes^[31]. In a study conducted to determine the optimal peptides for hESC self-renewal, Klim *et al*^[32] discovered that surfaces which display heparin binding peptide GKKQRFHRNRKG, derived from vitronectin, supported adhesion and self-renewal of hESCs at the lowest peptide surface density (0.5%) while other surface presenting various heparin binding peptides did not allow for cell attachment. These heparin binding peptides exhibit increased levels of Oct-4 and SSEA-4 expression, exhibit similar rates of growth, long term stem cell propagation (17 passages) and differentiation capabilities that are equal to Matrigel. The heparin binding peptide GKKQRFHRNRKG has been used in polyacrylamide hydrogels of varying stiffness where H9 hESCs were cultured for 12 passages in mTeSR1 medium supplemented with 10 μ mol/L ROCK inhibitor Y-27632^[33]. Not only was the hESC self-renewal confirmed but it was found that GAG binding on stiffer materials conveyed mechanosensing information that allowed for F-actin polymerization and enabled cell adhesion. Additionally, the nuclear localization of transcriptional co-activators Yes-associated protein and transcriptional coactivator with PDZ-binding motif (TAZ) on stiffer matrices allowed for hESCs pluripotency^[33].

Self-assembled monolayers (SAMs) with peptide sequence TVKHPDALHPQ and LTTAPKLPKVTR have also been shown to promote hESC adhesion and proliferation for 3 passages^[34]. However, non-clonal abnormalities were detected in cells cultured on TVKHPDALHPQ SAMs while LTTAPKLPKVTR SAMs

did not exhibit karyotypic abnormalities. Similarly, 18 different laminin-derived peptides were also screened and five (including RNIAEIIKDI) were capable of supporting hESCs proliferation and pluripotency comparable to MatrigelTM[35]. The presence of relatively low receptor concentration on cells requires the presentation of laminin-derived peptides at a higher concentration despite being presented in a uniform density and specific orientation.

More recently, Au-coated glasses have been modified with poly[oligo(ethylene glycol) methacrylate] polymer brushes through surface initiated polymerization and peptides that are derived from vitronectin^[36]. A 0.75 mmol/L vitronectin peptide concentration is deemed necessary for hiPSC expansion for up to 10 passages in mTeSR1 medium. Using micro-contact printed polydimethylsiloxane stamp, cell adhesion was easily regulated only on the vitronectin peptide and pluripotency markers and self-renewal capabilities were observed to be similar to Matrigel. A more potent version of the RGD sequence in the form of cyclic RGD peptide has been used to modify surfaces on which hESCs can adhere more prominently than on linear RGD peptides at a 4 fold higher rate^[37]. Normal pluripotency markers, karyotype and differentiation potential similar to Matrigel have been observed for cells cultured for 10 passages as well as in mTeSR1 medium.

Peptide acrylate surfaces

Peptide acrylate surfaces (PAS) are synthetic surfaces that are composed of acrylates which are conjugated to biologically active peptides^[38]. One such platform is the so called Synthemax Surface where the synthetic surface is manufactured by covalently linking the vitronectin-derived RGD sequence to the acrylate surface^[39]. Melkounian *et al*^[38] have used this technique to deposit various peptide sequences, as well as the vitronectin sequence, onto acrylate surfaces in a process that deposits carboxylic acid containing acrylate onto the surfaces of cultures and then conjugates amine-containing peptides to these surfaces using 1-Ethyl-3-(3-dimethylaminopropyl)-carbodiimide/*N*-hydroxysuccinimide. Here, bone sialoprotein-PAS and vitronectin-PAS were used to culture hESC line H7 for more than 10 passages in a defined medium. The authors concluded that the hESCs grown on PAS system were not different to the cells that were grown on Matrigel when comparing cell viability, colony morphology, doubling time and hESC marker expression of OCT4, TRA-1-60 and SSEA-4. Furthermore, hESCs can be cryopreserved and thawed onto PAS in addition to their ability to undergo directed differentiation into functional cardiomyocytes. This research demonstrated the scalability of feeder free, xeno-free and chemically defined PAS substrate that are suitable for clinical applications. Jin *et al*^[40] further examined the expansion and differentiation capabilities of hiPSCs on synthemax surface. The authors concluded

that there is no significant difference between the doubling time and pluripotency marker expressions for hiPSCs cultured on Matrigel and Synthemax substrate. However, the cells cultured on the Synthemax substrate showed more compact morphology than Matrigel. The researchers were able to demonstrate definitive endoderm differentiation of hiPSCs and were able to decipher the specific binding of $\alpha V\beta 5$ receptors for Synthemax Surface while the Matrigel substrate bound to various integrin receptors. Lastly, cell-cell interfaces on Synthemax Surface showed broad and dense actin filaments as well as the up-regulation of zyxin which demonstrates the involvement of various cytoskeletal proteins in hiPSCs attachment and proliferation.

Synthemax Surface has also been used for retinal differentiation of hiPSCs^[41] and to show efficient single cell passaging of hPSCs, using ROCK inhibitor Y-27632, similar to the results obtained on LM-E8 substrates^[42]. It has been used to obtain oligodendrocyte progenitor cells (OPCs) from hESCs that express higher levels of OPC specific proteoglycan, NG2, as compared to OPCs grown on xenogeneic-derived ECM^[43]. The researchers concluded that Synthemax Surface can replace the xenogeneic-derived ECM for hESCs differentiation into OPCs. Recently, Synthemax Surface was used to expand hESCs for 10 passages and to obtain insulin-producing β cells within 21 d in a defined serum-free media^[44].

Nevertheless, the high production costs, degradation upon sterilization, labor intensive cell passaging and limited scale-up potential of 2D peptide surfaces have caused researchers to seek alternative substrates in the synthetic polymer arena.

SYNTHETIC POLYMERS

Poly(methyl vinyl ether-alt-maleic anhydride)

Brafman *et al*^[45] used a high throughput screening approach to identify supports for hPSCs self-renewal as well as optimal conditions for pluripotency and proliferation for hPSCs. The authors examined 90 polymers with different functional groups, chemical compositions and molecular weights. They discovered that poly(methyl vinyl ether-alt-maleic anhydride) (PMVE-alt-MA) is most capable of supporting both short and long term maintenance of hESCs for HUES1 and HUES9, as well as one hiPSC line for over five passages. PMVE-alt-MA and poly(acrylic acid) cause greatest hPSC proliferation rates at discrete molecular weights of 1.25×10^6 Da and 4.5×10^5 Da, respectively. Of the 16 polymers, cells on PMVE-alt-MA did not exhibit detachment or differentiation. Furthermore, one hiPSC line and two HUES 1/9 lines were successfully cultured for over five passages with expression of normal pluripotency markers and differentiation capabilities and showed an increased expression of $\alpha 5$ and αv integrin receptors. Importantly, the authors showed that hPSCs can

further secrete endogenous ECM proteins in the absence of exogenous ECM proteins in defined medium thereby highlighting the role of ECM proteins in hPSC self-renewal.

Poly[2-(methacryloyloxy)ethyl dimethyl-(3-sulfopropyl)ammonium hydroxide]

Long term hESC growth has been demonstrated on poly[2-(methacryloyloxy)ethyl dimethyl-(3-sulfopropyl) ammonium hydroxide] (PMEDSAH)-coated TCPs *via* surface initiated graft polymerization technique that grafts PMEDSAH onto ozone-activated surfaces of TCPs^[46]. For 25 passages, H9 and BG01 cells that were grown on PMEDSAH attached, proliferated, exhibited long term growth along with normal genetic and proteomic makeup as exhibited through Nanog, OCT3/4 and SOX2 expression and possessed differentiation potential. H9 cells exhibited higher cell-aggregate adhesions when grown in human cell conditioned medium as compared to BG01 cells. However, both these cell lines showed comparable cell doubling times, pluripotency and karyotype when compared with cells grown on Matrigel^[46]. Consequently, variability exists in the response of these cell lines to various media conditions. H9 hESCs grown on PMEDSAH were able to be cultured on chemically defined StemPro media for 10 passages. Additionally, hiPSCs grown on PMEDSAH have also been shown to proliferate in defined xeno-free conditions for 15 passages while retaining pluripotency markers, normal morphology and karyotype^[47]. However, the hiPSC-derived mesenchymal stem cell unequally preferred osteogenic and chondrogenic differentiation rather than adipogenic lineage.

Aminopropyl methacrylamide

Other synthetic polymer substrates such as the methacrylamide-based aminopropyl methacrylamide have been used to culture hESCs for over 20 passages in mTeSR1 media^[48]. The H9-hOct4-pGZs cells showed higher expression of pluripotency markers than Matrigel as well as higher proliferation rate at passage 1 and 22 but the proliferation rate slowed down at latter passages. Importantly, bovine serum albumin (BSA) remains crucial for hESC attachment, growth and proliferation since it was shown to be adsorbed onto the APMAA surfaces in an unfolded state^[48].

Polyacrylates

One study applied a high throughput screening approach to high-density polymer microarrays to obtain polymers with either 2-carboxyethyl acrylate or 2-(methylthio) ethyl methacrylate containing monomers that allowed cell adhesion at specific ratios^[49]. Furthermore, an equal ratio of 4-tert-butylcyclohexyl acrylate and n-butyl methacrylate was found in polymers supporting greatest adhesion. The study demonstrated short term (5 passages) pluripotency potential of hESCs cultured on these surfaces.

Chitosan-alginate polymers

As natural polymers that mimic GAG structure, chitosan-alginate (CA) 3D scaffolds have been used for hESC self-renewal^[50]. The cells grown on these scaffolds exhibit three times higher alkaline phosphatase activity and the expression of pluripotency markers were similar to hESCs grown on human fibroblast feeder layers. Additionally, hESCs which are recovered *via* EDTA and K₂HPO₄ solution express over 95% cell viability and the CA scaffolds allow for easy passaging of cells. Another study used alginate-chitin polymer based scaffold, which mimic the GAGs units of the ECM^[51]. Combined conditions of high cell seeding density, avoidance of fluid shear stresses *via* encapsulation as well as increased surface area to volume ratio of encapsulated cells, and cryopreservation with high cell viability (> 75%) allows for long term culture (10 passages) and quick non-cytotoxic harvesting of cells through enzymatic disassociation of microfibers with further scalability.

Poly(desaminotyrosyl tyrosine ethyl ester carbonate) polymer scaffolds

Synthetic scaffolds composed of poly(desaminotyrosyl tyrosine ethyl ester carbonate)^[52], a tyrosine derived polycarbonate polymer^[53], have been used to study the effects of geometries on hESCs self-renewal and proliferation. Carlson *et al.*^[52] discovered that microfibrillar architecture of poly-D-lysine pretreated scaffolds supports hESC survival and colony formation as this geometry allows cell-cell and cell-matrix contact and extensive ECM deposition of laminin and collagen IV with some collagen I deposition. The endogenous production of laminin was an essential factor for hESC adhesion and survival.

HYDROGELS

Although synthetic polymers represent a more economical approach with more quality control over the manufacturing process, the 2D topography does not mimic the *in vivo* cell-cell and cell-ECM interactions. Hydrogels, serve as viable alternatives to 2D cultures that hold the potential for clinical scale hESC production. Using acrylate and acrylamide monomers, one study used 2-(acryloyloxyethyl) trimethylammonium chloride (AETMA-Cl) and 2-(diethylamino) ethyl acrylate (DEAEA) in a 3:1 ratio to construct thermoresponsive hydrogels^[54]. The undifferentiated colonies can be passaged without enzymatic disassociation by reducing the temperature from 37 °C to 15 °C for 30 min, followed by gentle pipetting since hydrogel swelling alone was not sufficient for hESC removal. The hydrogel adsorbed BSA and cells that were grown on the hydrogel demonstrated slower growth and lower total expansion rate over 5 d compared to Matrigel. Additionally, microdeletions and duplications on some chromosomes were present in both Matrigel and hydrogel culture conditions. Nonetheless, hESCs were able to be cultured

for over 20 passages in mTeSR1 medium on glass coverslips coated with the hydrogel and expressed pluripotency markers.

Another acrylamide-based Poly(N,N-diethylacrylamide) (PDEAAm) thermoresponsive hydrogel uses pentapeptide YIGSR-NH₂ to mimic B1 chain amino acid sequence of laminin^[55]. Here, the hydrogel was further modified with (NH₄)₂SO₄ salt to yield highly porous interconnected (NH₄)₂SO₄-PDEAAm hydrogels that were able to support adhesion and growth of hESCs better than large NaCl generated random pores. The polyacrylamide hydrogels can also be used to direct the differentiation to specific lineages in microwells since microwells accumulate molecules above the hydrogel cut off range of 40 to 70 kDa^[56]. As a result, microwells direct stem cells to be differentiated into neural, ectodermal and endodermal lineages while relatively small mesodermal inducing factors diffuse away and large mesodermal inducing factors accumulate in the microwells.

Hyaluronic acid (HA) based hydrogels were used by Gerecht *et al.*^[57] to culture hESCs in MEF-CM. The encapsulated hESCs formed colonies of varying sizes and maintained doubling time similar to 2D cultures. After 20 d, undifferentiated colony morphology was observed but a high cell seeding density between 5-10 × 10⁶ is necessary to prevent apoptosis. The hydrogel allowed for enzymatic release (hyaluronidase) of cells that achieved cell viability of 76.5% ± 8%^[57]. Additionally, Ikonen *et al.*^[58] used HA with hydrophilic pH-sensitive hydrogels to demonstrate adhesion and expansion of hESC cardiomyocytes. Here, the collagen-mimicking hydrogel nanofibers allowed for cell adhesion and growth due to their hydrophilicity but HA further augmented the cell survival and provided a more structurally sound hydrogel. Furthermore, the thinnest nanofibers (4.2 nm) were supportive of hESC cardiomyocytes culture.

Clinical scale applications require microenvironments that not only self-renew hESCs but are also able to direct their differentiation. To this end, Dixon *et al.*^[59] have used alginate-collagen hydrogels such that self-renewal of hESCs is sustained on alginate dominated state but differentiation can be induced by "switching" to a collagen predominant microenvironment via EDTA/sodium citrate based treatment. This process further changes the elasticity of the matrix from approximately 21.37 ± 5.37 kPa to ~4.87 ± 1.64 kPa. Moreover, the early switching (day 3) correlates with ectodermal differentiation while day 5 switching results in mesodermal and endodermal commitment. This hydrogel configuration offers advantages, namely the preservation of hydrogel structure and the relatively high hESC cell density (approximately 2 × 10⁷) obtained before differentiation^[59].

Polyethylene glycol (PEG)-based hydrogel functionalized with vinyl sulfone (VS) macromers with multiarms have been shown to maintain hESC self-renewal where the 8 multiarm PEG-VS hydrogel (10% PEG) proved to be ideal for hESC self-renewal and stemness expression^[60]. However, the hydrogel needs to be optimized for specific

cell lines since some of the cells lines demonstrated weak stemness markers. Another PEG-based thermoresponsive substrate utilized recombinant protein factors as a poly(N-isopropylacrylamide)-co-poly(ethylene glycol) (PNIPAAm-PEG) hydrogel^[61]. Here, 10⁷² fold expansion over 60 passages was achieved in hPSCs using single cell passaging and stem cells were able to be further differentiated into dopaminergic neurons at even higher numbers.

Another novel hydrogel is derived from human platelet poor plasma (PPP) gelled in the presence of DMEM media, which contains calcium ions^[62]. The resulting coagulation cascade forms a stable hydrogel. HESCs were able to be cultured for 25 passages and fibronectin was speculated to play a role in hESC adhesion via α5β1 integrins^[63]. Despite being relatively inexpensive, the PPP-based hydrogel was not xeno-free due to the N2 and B27 supplements in the media. Furthermore, scalability may be an issue being that the system is donor dependent.

CONCLUSION

Although many substrates exist for the self-renewal and expansion of hPSCs, most of the substrates possess limitations hinder their clinical applicability. As summarized in Table 1, Matrigel is xenogeneic in origin, contains undefined components and can be immunogenic. The relatively high production costs, immunogenicity risks and difficulties with sterilization^[16,17,30] of ECM proteins limit their scalability potential while synthetic polymers, although being inexpensive and easily fabricated, have shown limited 3D scale-up capabilities. Hydrogels address the need for 3D *in vivo*-like environment but are not easily scalable.

Lastly, synthetic peptides are easily degradable^[47] and difficulties with sterilization and high production costs exist^[47,48]. Nevertheless, Synthemax Surface has shown to be capable for clinical applications since it can be sterilized via gamma irradiation, has a long shelf life of two years and can be stored at room temperature^[39]. Furthermore, hESCs can be cryopreserved and thawed on substrate and studies have demonstrated its capability for long term hESCs self-renewal and maintenance^[38-40]. Its scalability has also been demonstrated in T75 flasks^[38]. Therefore, we conclude that Synthemax Surface is an ideal substrate for clinical applicability.

FUTURE DIRECTION

Although feeder free, xeno-free and chemically defined media has been developed, the clinical applicability of hESCs depends on synthetic substrates that can easily and economically be manufactured, can undergo common sterilization methods without degradation (*i.e.*, reusability) and yield large number of cells as required for transplantation dosage (2 × 10⁸ cells/kg per dose)^[64]. Microcarriers and suspension cultures have

been used to meet these demands but their limitations in controlling aggregate size, passaging challenges, shear forces in stirred cultures and difficult cell extraction from microcarrier have caused researchers to seek alternatives. As a result, significant need exists for developing scalable synthetic substrates like Synthemax that can work with multiple cell lines (without conferring epigenetic modifications to cells), easily cryopreserved, are non-labor intensive (*i.e.*, automation), adaptable to induce differentiation conditions and require fewer exogenous factors to maintain hPSCs self-renewal and expansion.

Abstract

The tumor microenvironment (TME) is complex and constantly evolving. This is due, in part, to the crosstalk between tumor cells and the multiple cell types that comprise the TME, which results in a heterogeneous population of tumor cells and TME cells. This review will focus on two stromal cell types, the cancer-associated adipocyte (CAA) and the cancer-associated fibroblast (CAF). In the clinic, the presence of CAAs and CAFs in the TME translates to poor prognosis in multiple tumor types. CAAs and CAFs have an activated phenotype and produce growth factors, inflammatory factors, cytokines, chemokines, extracellular matrix components, and proteases in an accelerated and aberrant fashion. Through this activated state, CAAs and CAFs remodel the TME, thereby driving all aspects of tumor progression, including tumor growth and survival, chemoresistance, tumor vascularization, tumor invasion, and tumor cell metastasis. Similarities in the tumor-promoting functions of CAAs and CAFs suggest that a multipronged therapeutic approach may be necessary to achieve maximal impact on disease. While CAAs and CAFs are thought to arise from tissues adjacent to the tumor, multiple alternative origins for CAAs and CAFs have recently been identified. Recent studies from our lab and others suggest that the hematopoietic stem cell, through the myeloid lineage, may serve as a progenitor for CAAs and CAFs. We hypothesize that the multiple origins of CAAs and CAFs may contribute to the heterogeneity seen in the TME. Thus, a better understanding of the origin of CAAs and CAFs, how this origin impacts their functions in the TME, and the

temporal participation of uniquely originating TME cells may lead to novel or improved anti-tumor therapeutics.

Key words: Hematopoietic stem cell; Cancer associated adipocyte; Mesenchymal stromal cell; Tumor progression; Cancer associated fibroblast; Plasticity; Metastasis; Fibrocyte

Core tip: This review examines the roles of cancer-associated adipocytes (CAAs) and cancer-associated fibroblasts (CAFs) in remodeling of the tumor microenvironment (TME), presents evidence for a unique hematopoietic stem cell origin for both CAAs and CAFs, and discusses potential therapeutic implications of this novel origin. Studies highlighted herein emphasize the necessity of developing an understanding of the origins of cells in the TME and the importance of multipronged therapeutic targets directed at preventing both the incorporation and effects of stromal remodeling by the cells of the TME.

INTRODUCTION: THE TUMOR MICROENVIRONMENT

The "seed and soil" hypothesis suggests that an appropriate host microenvironment ("soil") must be present for the optimal growth of tumor cells ("seed")^[1-3]. Although this paradigm was initially proposed by Stephen Paget in 1889, research efforts have predominantly focused on the epithelial component of solid tumors and tumor cell-intrinsic factors leading to tumorigenicity. However, in the last decade, Paget's hypothesis has again come to focus and it has been recognized that the epithelial "seed" and stromal "soil" components co-evolve and interact during tumor progression^[4]. Seminal works from Weinberg's group have shown that this stromal compartment, often referred to as the reactive stroma or tumor microenvironment (TME), directly and indirectly supports tumor survival, growth, vascularization, escape from immune surveillance, drug resistance, and metastasis *via* extracellular matrix (ECM) remodeling and production of growth factors, cytokines, and chemokines (reviewed in^[5-7]). The TME is comprised of a variety of cell types including endothelial cells, perivascular cells, immune cells, adipocytes, and fibroblasts/myofibroblasts.

These cells interact with one another as well as with tumor cells to create an intricate network of cellular crosstalk and bidirectional regulation.

This crosstalk results in a heterogeneous population of tumor cells exhibiting varying degrees of differentiation, unregulated proliferation, the capacity to migrate and invade through surrounding tissue, and the ability to establish a dense irregular and leaky vascular network, all critical steps in metastatic tumor progression. Concomitantly, this crosstalk leads to changes in the local stromal populations, contributing to the heterogeneity of TME cells. The heterogeneity of the cells of the TME, the factors they contribute and their broad functional ability to promote all aspects of tumor progression make the "soil" a challenging and complex therapeutic target. Many factors contribute to the heterogeneity of these cell types, including exposure to the local tumor milieu, the plasticity between cells of the TME, and the multiple potential origins of each cellular population. Understanding the mechanisms behind this heterogeneity could lead to the identification of novel therapeutic targets for cancer. This review will focus on two stromal cell types, the cancer-associated adipocyte (CAA) and the cancer-associated fibroblast (CAF). The adipocyte is a stromal cell type that has recently been implicated in tumor initiation, growth, and metastasis (reviewed in^[8]). Several epidemiologic studies have linked obesity with multiple types of cancer^[9-11]. Recent clinical studies have reported a positive correlation between the presence of CAAs at the tumor margin and poor patient outcome, suggesting that CAAs contribute to the permissive pro-TME, particularly in adipocyte-rich tissues, such as the mammary gland^[12,13] (and reviewed in^[14]). CAFs, the most abundant cellular component of the TME in solid tumors, have a significant impact on tumor progression during multiple stages^[5-7]. While more extensively studied than CAAs, the numerous roles of CAFs in tumor progression and metastasis are still under investigation. Like CAAs, CAFs have clinically been correlated with tumorigenesis and poor prognosis in many cancer types^[15-18]. Similarities in the pro-tumorigenic functions of CAAs and CAFs suggest that these TME cell types may act in concert to promote tumor progression, indicating that therapeutic targeting of the TME may need to encompass both cell types. Herein, we will examine the phenotype and function of CAAs and CAFs in remodeling of the TME, present evidence for a unique hematopoietic stem cell origin for both CAAs and CAFs, and discuss potential therapeutic implications of this novel origin.

CONTRIBUTIONS OF CAAS AND CAFS TO TME REMODELING

Cancer has been likened to a perpetual wound

Figure 1 Multifactorial contributions of cancer-associated adipocytes and cancer-associated fibroblasts to tumor progression and metastasis. Research in the last decade has highlighted the importance of the tumor microenvironment in cancer progression. While there are numerous stromal cell types that contribute to the tumor microenvironment, this illustration depicts roles for cancer-associated adipocytes (CAAs) and cancer-associated fibroblasts (CAFs) in promoting the multiple stages of tumor progression and metastasis. ECM: Extracellular matrix.

healing process^[19] since both processes begin with the formation of a reactive stroma. During wound healing the reactive stroma resolves rapidly, but, during cancer progression, this actively remodeling, inflammatory state is perpetuated. CAAs and CAFs have been shown to play a role in a variety of tumor promoting processes including ECM deposition/degradation, inflammation and immune surveillance, tumor growth and survival, angiogenesis, invasion, and metastasis^[5,6,20-24], suggesting similarities in the pro-tumorigenic functions of these cells. As summarized in Figure 1, this section will discuss the CAA and CAF phenotypes and their roles in generating and maintaining the reactive stroma associated with cancer progression and metastasis.

The activated phenotype of CAAs and CAFs

Adipocytes, surrounded by fibroblasts, preadipocytes, pluripotent stem cells, endothelial cells, and immune cells, are the major components of the adipose tissue. Apart from their traditional function in energy storage, adipocytes are also considered endocrine cells, producing hormones, growth factors, cytokines and adipokines, including leptin, adiponectin, resistin, vascular endothelial growth factor (VEGF), tumor necrosis factor- α (TNF- α), and interleukin-6 (IL-6)^[25]. During interaction with cancer cells, adipocytes acquire phenotypic changes and are reprogrammed to an activated state during which they are referred to as CAAs^[26]. CAAs are generally located at the invasive front of tumors^[21]. Several reports suggest that cancer cells can induce metabolic changes in adipocytes,

resulting in enhanced lipolytic activity and an inability to properly store triglyceride^[27]. Moreover, transforming growth factor- β (TGF- β), secreted by cancer cells or local stroma, is a potent inhibitor of adipocyte differentiation^[28]. Thus, the associated morphological changes upon activation include loss of lipid content (delipidation) and acquisition of a fibroblast-like/preadipocyte phenotype (de-differentiation)^[21]. Functional alterations in CAAs include loss of terminal adipocyte markers and products (adiponectin, resistin, fatty acid binding protein-4 (FABP4), hormone sensitive lipase (HSL), and CCAAT/enhancer binding protein- α (C/EBP α)) and an increased production of pro-inflammatory cytokines IL-6, IL-1 β , plasminogen activator inhibitor-1 (PAI-1)^[21]. As detailed below, in this activated state, CAAs produce adipokines and inflammatory factors that have been shown to promote tumor progression in adipocyte-rich environments.

In non-malignant tissues, fibroblasts provide structure and ECM scaffolding for tissues. In a wound environment, these fibroblasts become activated, produce increasing amounts of ECM proteins and migrate to wound interfaces to cause wound contraction and closure. In both wound healing and the TME, fibroblast activation is marked by increased α -smooth muscle actin (α SMA) protein expression, along with increased expression of vimentin, desmin, fibroblast specific protein, platelet-derived growth factor receptor α and β (PDGFR α and β), fibroblast activation protein (FAP), or a combination of these markers. TGF- β is present in both the wound and TMEs and has been shown to both induce and suppress differentiation and

tumorigenesis in a dose and context specific manner^[29]. With respect to fibroblasts, TGF- β has been shown to upregulate α SMA expression^[30,31], induce expression of FAP^[32], and promote collagen synthesis^[33], hallmarks of activated fibroblasts. Like CAAs, activated fibroblasts in the TME are also characterized by increased and altered production of inflammatory cytokines, chemokines, ECM components, and growth factors. The clinical importance of this activated phenotype is highlighted by molecular profiling studies of CAFs and matched normal fibroblasts. Studies in non-small cell lung cancer^[16] and breast cancer^[34] revealed that the cancer-associated gene signatures in CAFs correlated to disease outcome.

CAAs and CAFs in ECM remodeling and establishment of a reactive stroma

CAAs have been shown to play an important role in stromal remodeling during tumorigenesis. Type VI collagen, a soluble ECM protein, was reportedly up-regulated in peritumoral adipocytes during tumorigenesis^[22] and was shown to promote early mammary tumor progression *in vivo*^[23]. The $\alpha 3$ chain cleavage product of type VI collagen, endotrophin, augmented fibrosis, angiogenesis and inflammation through recruitment of macrophages and endothelial cells^[23]. Rio and colleagues found that the native $\alpha 3$ chain of type VI collagen constituted a specific substrate for matrix metalloproteinase (MMP)-11, whose collagenolytic activity was functional in fat tissue ontogenesis as well as during cancer invasive steps^[24]. Interestingly, they also reported that invasive breast cancer cells induced the expression of MMP-11 in the neighboring CAAs^[20], suggesting that exposure to tumor cells promotes stromal remodeling abilities of CAAs.

CAF function to generate and remodel ECM through production of collagens, fibronectin, and laminin^[30,35], and proteases such as MMPs^[36,37]. Collagens, fibronectin, and laminin contribute to the stiffness and density of the stroma, give structural support to the tumor cells, and provide important mechano-signals in the TME. Additionally, the expression of α SMA by activated fibroblasts was shown to promote matrix contraction^[38-40], suggesting a direct effect on matrix stiffness. Like CAAs, CAFs also produce MMPs that degrade matrix collagens, fibronectins, and proteoglycans, profoundly contributing to structural remodeling of the TME. It has also been demonstrated *in vitro* that fibroblast overexpression of FAP, a serine protease selectively produced by CAFs, remodeled the ECM by increasing expression levels of α SMA, fibronectin, and collagen I^[41]. These data indicate that, orchestrated by the tumor-stroma crosstalk, CAAs and CAFs actively remodel the ECM to favor local tumor progression.

In addition to elaboration and remodeling of matrix, CAAs and CAFs may also promote changes in the local stroma by contributing to the inflammatory

state of the TME. As described above, CAAs have been shown to produce a variety of inflammatory cytokines including IL-6, IL-8, IL-1 β and TNF- α ^[8,26]. Through production of factors such as IL-1 β , IL-23, TGF- β , IL-6, and IL-8^[42-44], CAFs exert considerable influence over the inflammatory state of the TME. CAF production of ECM components such as hyaluronic acid further drive the inflammatory state by recruiting tumor-associated macrophages^[45] that promote tumor vascularization and proliferation. While the interactions between CAAs, CAFs and immune cells are only beginning to be explored, it is clear that cellular cross-talk modulates the inflammatory state of the TME, potentially influencing tumor-specific immunity.

Tumor growth and survival

Both CAAs and CAFs aid the tumor in meeting requirements for rapid growth by providing structural matrix as described above as well as directly promoting tumor cell proliferation and survival. Rapid, unchecked proliferation is characteristic of tumor cells, and as the cells of the TME remodel the reactive stroma, tumor cell proliferation is further accelerated. In addition to proteases and ECM constituents, CAAs provide their high energy content lipids to cancer cells resulting in accelerated tumor progression^[46]. In support of this, morphologically, CAAs at the tumor invasive front are smaller than those observed at a distance, which implies lipolysis. In the case of ovarian cancer, the cancer cell-adipocyte interaction initiated HSL-mediated lipolysis in the adipocytes, releasing fatty acids, which were then taken up by the ovarian cancer cells for energy production through β -oxidation^[46]. In a PC-3 model of prostate cancer, the translocation of lipid from adipocytes to prostate cancer cells was visualized by Fourier transform infrared spectroscopy^[47]. Together these studies suggest that in multiple cancer types, CAAs supply the TME with energy rich lipids that may act to promote tumor growth by supplying tumor cells with essential metabolites.

Furthermore, adipocytes secrete adipokines into the TME, such as TNF α , IL-6, IL-8, monocyte chemoattractant protein-1 (MCP-1/CCL2), and leptin which have been shown to enhance tumor growth locally and systemically in a variety of cancer types (reviewed in^[8]) including prostate^[48,49] and breast^[14,21] cancers. Another aspect of adipocyte pro-tumorigenic activity is their contribution to chemo/radio-therapy resistance. The antitumor effect of vincristine, daunorubicin and dexamethasone to acute lymphoblastic leukemia (ALL) was impaired under the influence of adipocytes, which augmented ALL cell survival due to increased expressions of Bcl-2 and Pim-2^[50]. Likewise, breast tumor cells co-cultivated with adipocytes or recombinant IL-6 exhibited radioresistance, an increase in the effector

kinase Chk1, and a decrease in cell death^[51]. Taking into account that CAAs secrete elevated levels of IL-6 in the TME, CAAs could promote chemoresistance *via* multiple mechanisms. These studies shed light on a new role of CAAs in fostering a chemo/radio-resistant phenotype in cancers and suggest targeting CAAs may increase effectiveness of conventional chemotherapy treatments.

CAFs also promote tumor growth through the production of factors that have been shown to be involved in proliferation of tumor cells, including TGF- α ^[52], TGF- β ^[53], hepatocyte growth factor (HGF)^[54], and others (reviewed in^[44,55]). Through production of MMPs, CAFs act to release stored growth factors from within the matrix, further contributing to an enriched host microenvironment and promoting proliferation of tumor cells (reviewed in^[37]). Studies have identified a novel mechanism of cellular respiration, coined the “reverse Warburg effect” that involves an interplay and exchange between tumor cells and stromal cells whereby tumor cells take up energy-rich metabolites from CAAs^[8] and CAFs^[56] for use in the mitochondrial TCA cycle. This may contribute to the rapid proliferation of tumor cells by directing cellular energy towards cell division rather than cellular respiration. CAFs, like CAAs, have been implicated in promoting tumor chemoresistance. The expression and organization of collagen type I has been inversely correlated with intratumoral uptake of chemotherapeutic agents *in vivo* as it contributes to increased interstitial fluid pressure, forming a barrier to trans-capillary transport of agents^[57]. DNA vaccine targeting of FAP on CAFs led to decreased deposition of a collagen I rich matrix and improved chemotherapeutic drug uptake in pre-clinical animal studies^[58]. Direct targeting of CAF-derived FAP also suppressed primary tumor cell growth in a pre-clinical murine model of multi-drug resistant breast cancer^[58]; however, this finding has not held in Phase II clinical trials. *In vitro* studies revealed that adherence of melanoma cells to fibroblast monolayers allowed for reduction of the cytotoxic effects of cisplatin, supporting a role for the CAF-induced ECM^[59] in tumor cell survival. CAFs from melanoma and prostate cancer were found to be less sensitive to etoposide and vincristine due to expression of a non-mutated but functionally deficient form of p53^[60]. Together, these findings suggest CAFs promote tumor growth and survival through multiple mechanisms and these effects may contribute to both the primary tumor and metastatic site.

Tumor vascularization

Angiogenesis is a critical step in tumor progression, without which tumors cannot maintain growth beyond 1-2 mm³^[61]. Many of the key factors required to initiate the angiogenic switch in solid tumors are produced by CAAs and CAFs. Adipocytes are known to produce multiple angiogenic factors [VEGF, fibroblast growth

factor-2 (FGF2)], adipokines (leptin, adiponectin, resistin) and cytokines (IL-6), all of which stimulate angiogenesis and contribute to an overall pro-angiogenic microenvironment for tumor progression^[62]. CAFs have been shown to produce angiogenic factors including stromal derived factor-1 (SDF-1)^[63], TGF- β ^[64], IL-6^[65] and VEGF^[66,67], which support endothelial cell proliferation and tumor vascularization. In addition to their production of angiogenic cytokines, CAFs may play a more direct role in tumor vascularization through their ability to serve as vascular support cells. CAF and myofibroblast expression of α SMA closely links this cell type with the pericyte, a fibroblast-like cell, which plays a supportive role for endothelial cells in both normal and tumor systems. Thus, CAAs and CAFs are a source for critical angiogenic factors and may be involved in flipping the hypothetical switch to a vascularized tumor site, thereby acting to support an essential early step in tumorigenesis.

Invasion and metastasis

One of the initial steps in metastasis of solid tumor is the migration and invasion of the tumor cell through the ECM and through the basement membrane. This is followed by intravasation of tumor cells into a local blood vessel and the extravasation of the tumor cell to colonize and proliferate at a distant site. CAAs secrete similar levels of MMP-2 and MMP-9 compared to normal adipocytes^[21], whereas MMP-11 is highly expressed by CAAs in the proximity of invading cancer cells, but not in normal resting adipocytes^[24]. The role of MMP-11 (stomelysin-3) in tumor biology is still unclear (reviewed in^[37,68]). However, MMP-11 has been shown to promote tumorigenesis and function through its proteolytic activity^[69,70], but only weakly degrades matrix molecules. CAFs have been shown to produce a variety of matrix metalloproteinases (MMP), including MMP-1, MMP-2, MMP-3, MMP-9, MMP-11, MMP-13, and MMP-14 (reviewed in^[36,37]). Degradation of ECM allows tumor cells to cross the structural barrier of the basement membrane, a key step in tumor metastasis (reviewed in^[37]). In an elegant imaging study, Gaggioli^[35], demonstrated that CAFs are able to degrade matrix to form tracks through the ECM that allow invading tumor cells to efficiently follow behind.

CAAs and CAFs also directly affect the migratory and invasive abilities of tumor cells through production of adipokines, cytokines, and chemokines. Adipocyte/CAA-secreted IL-6 has been shown to play a key role in mediating adipocyte-dependent invasive activity of both breast cancer cells and melanoma cells^[21,71]. FAP production by fibroblasts was linked to the increased invasion of pancreatic cancer cells in a β_1 -integrin/FAK mediated fashion^[41]. In breast cancer, CAFs were shown to increase the invasive ability of DCIS epithelial cells and this was related to their production of MMP-9 and MMP-14^[72,73]. In addition, these factors secreted by CAAs and CAFs may flood

Figure 2 Origins of cancer-associated adipocytes and cancer-associated fibroblasts. This drawing illustrates the complex and ever-growing understanding of the origins for cancer-associated adipocytes (CAAs) and cancer-associated fibroblasts (CAFs). CAAs and CAFs are generally thought to arise from resident tissue cells, the adipose stem cell (ASC) and resident fibroblast, respectively. However, alternative sources for adipocytes and CAAs have been demonstrated including cells of the bone marrow, specifically those of the myeloid lineage (e.g., macrophages, CFPs, and fibrocytes). In addition to resident fibroblasts, CAFs have been shown to be derived from myeloid progenitors (CFPs, fibrocytes), mesenchymal stromal cells (MSCs), ASCs, CAAs, epithelial cells, tumor cells, and endothelial cells. It is possible that these multiple sources are reflected in the morphological, phenotypic, and functional heterogeneity described for adipocytes and for CAFs. HSC: Hematopoietic stem cell; CFPs: Circulating fibroblast precursors.

the circulation with signals for distant metastatic sites to initiate their own expression of chemokines that will aid the tumor cell in homing to the metastatic site and preparing the site for colonization once the tumor cell arrives^[74]. Research conducted on human omental adipocytes indicates they secrete IL-6 and IL-8 and that antibody-mediated inhibition of either factor resulted in reduced homing of ovarian cancer cells *in vitro* and *in vivo*, although inhibition of IL-8 was more efficient at reducing homing of cancer cells *in vivo*^[46]. Once ovarian tumors are established on the omentum, they may convert adjacent adipocytes into CAAs, which results in a positive feedback loop leading to increased IL-6 production and further recruitment of cancer cells to the omentum. It has also been suggested that tumor cells do not metastasize alone, rather, they “travel” with stromal cells. Studies from Duda *et al.*^[75] demonstrated by cannulating primary tumor bearing mice, that tumor cells are shed with stromal cells in heterotypic “clumps” from the primary tumor. The stromal component, which included fibroblasts, acted to support the viability of the tumor cells while traveling through the circulation to the metastatic site. Together, these studies suggest that CAAs and CAFs promote the migratory and invasive phenotype in a variety of solid tumors and highlight the importance of elucidating mechanisms to target both CAAs and CAFs.

ORIGINS OF CAAS AND CAFS IN THE TME

Both CAAs and CAFs are generally thought to arise from tissues adjacent to the tumor; however, recent studies have begun to demonstrate alternative sources, including other resident stromal cells, epithelial cells, and bone marrow. This complex and ever-growing understanding of the origins for CAAs and CAFs can be appreciated in Figure 2. It is possible that these

multiple sources are reflected in the morphological, phenotypic, and functional heterogeneity described for adipocytes from different fat depots^[76] and for CAFs^[77,78]. Given that this heterogeneity is a significant hurdle in therapeutically targeting the TME populations, it will be essential to elucidate the multiple origins for these cells as well as to examine the impact these origins may have on cellular function.

Origins of CAAs

The expansion of adipose tissue is achieved *via* increases in size (hypertrophy) and/or number (hyperplasia) of adipocytes. Mature adipocytes are postmitotic, therefore, adipocyte hyperplasia requires new adipocytes be produced from their adipogenic precursors. A long-standing paradigm of adipocyte generation is that all adipocytes are differentiated from mesenchymal progenitor cells resident in the vascular stroma, referred to as adipose stem cells (ASCs), where the regional fat depots eventually form^[79,80]. However, these progenitor cells are found associated with adipose vessels^[79], bringing up the possibility that circulating progenitors, such as those provided by bone marrow, home to adipose tissue through the bloodstream followed by extravasation across the endothelium of blood vessels, subsequently undergoing adipogenic conversion. To test this hypothesis, several groups transplanted GFP-labeled bone marrow into wild-type mice^[81-83]. Two of these groups detected GFP-expressing adipocytes in the major adipose depots^[81,82], while one failed to detect these cells^[83], perhaps due to low marker expression or limited engraftment. When engrafted mice were treated with rosiglitazone or a high fat diet that stimulated adipogenesis, the number of GFP-expressing adipocytes was elevated, and cells were often found in clusters, suggesting clonal growth from bone marrow-derived progenitors^[81]. While these studies support a bone marrow origin for CAAs, it is unclear which bone

marrow stem cell serves as the CAA progenitor.

It is commonly held that the bone marrow contains two types of stem cells, the mesenchymal stromal cell (MSC) and the hematopoietic stem cell (HSC). MSCs are defined by their adherence to plastic and potential to differentiate into mesenchymal tissue cells such as bone, fat, muscle, cartilage, and fibroblasts^[84-87]. HSCs are defined by their capability of hematopoietic reconstitution *in vivo* and have also been shown to give rise to other tissue cell types including mast cells and osteoclasts. Our laboratory has developed a method for transplantation of a clonal population from a single sorted HSC defined as an EGFP⁺Lin⁻Sca-1⁺c-Kit^{hi}CD34⁻ cell. Using this single cell transplantation model, we have demonstrated that HSCs give rise to a variety of mesenchymal cell types including adipocytes^[88], osteocytes and chondrocytes^[89], cardiac valve interstitial cells^[90], circulating fibroblast precursors^[91], and fibroblasts and myofibroblasts in multiple tissues^[92-94] (reviewed in^[95]). Further use of our unique clonal cell transplantation model revealed the generation of adipocytes *in vivo* from clonally derived bone marrow HSCs^[88]. Similar to findings from Crossno *et al.*^[81], we found that rosiglitazone stimulated adipogenesis from the HSC^[88]. *In vitro*, clones giving rise to monocytes/macrophages under hematopoietic conditions were also able to generate adipocytes under adipogenic conditions, suggesting a differentiation pathway from HSCs-myeloid precursors-adipocytes^[88]. Similar results were obtained from the Klemm group who confirmed the *de novo* generation of a subset of adipocytes from bone marrow myeloid progenitor cells using a non-transplant transgenic mouse model in which LacZ expression was restricted to the myeloid lineage^[96]. Moreover, Sterieter and colleagues reported that circulating fibrocytes were capable of adipogenic differentiation both *in vitro* and *in vivo*^[97]. Due to the dual hematopoietic/mesenchymal nature of fibrocytes, they may be considered as an intermediate for myeloid-derived adipocyte population. These studies demonstrate the ability of the HSC to give rise to adipocytes through the myeloid lineage. While studies have not yet directly examined the role of HSC-derived CAAs in tumor progression, findings from our laboratory suggest that they can enhance tumor growth and tumor cell motility in breast cancer and melanoma models (unpublished data).

Origins of CAFs

Traditionally, CAFs are thought to arise from resident tissue fibroblasts^[98]. However, recent studies have suggested alternative sources including other resident stromal cells, epithelial cells, epithelial-mesenchymal transition or endothelial-mesenchymal transdifferentiation (EndoMT), and adipose tissue. Several studies have also suggested a bone marrow origin for myofibroblasts and CAFs^[99] (and reviewed in^[100-102]). As described above, the bone marrow provides a rich source for both MSCs and HSCs. Using

our model for transplantation of a clonal population from a single sorted HSC in conjunction with a variety of solid tumor models, we have demonstrated the presence of HSC-derived fibroblasts in tumor sections from mice transplanted with a clonal population of cells derived from a single, sorted HSC^[91,103]. Analysis of sections from Lewis lung carcinoma (LLC) and melanoma (K1735-M2) tumors harvested from clonally engrafted animals showed the presence of HSC-derived CAFs^[91,103]. These EGFP-expressing cells had a fibroblastic morphology and constituted 8%-28% of the tumor stromal cells^[103]. Characterization of these HSC-derived cells indicated that they were activated fibroblasts, based on expression of α SMA and mRNA expression of collagen I^[103]. Also prevalent in the specimens were EGFP⁺ pericyte-like perivascular cells, suggesting that HSCs contribute to tumor vasculature^[103].

Work from our laboratory has also identified a population of circulating fibroblast precursors (CFPs) that express markers of both hematopoietic cells (CD34, CD45) and fibroblasts [collagen I (Col I), discoidin domain receptor-2 (DDR2; a collagen 1 receptor)]^[91] (and unpublished data). The CD45⁺DDR2⁺ population was shown to differentiate along the monocyte/macrophage lineage, contain the CD34⁺Col I⁺ fibrocyte and rapidly differentiate to collagen 1⁺, α SMA⁺ cells with fibroblastic morphology. Using our clonal hematopoietic stem cell transplantation model, we conducted an *in vitro* examination of CFPs/fibrocytes derived from peripheral blood cells of clonally engrafted mice^[92]. In these studies, nucleated blood cells were cultured and the appearance of EGFP⁺ (HSC-derived), spindle-shaped or polygonal cells was detected by the seventh day. Flow cytometric time course analysis of the cultured cells demonstrated decreasing CD45 expression and increasing DDR2 expression. Our studies have demonstrated that CFPs may be stimulated to express markers of activated fibroblasts including collagen, vimentin, and α SMA by exposure to tumor conditioned media. This demonstrates a possible differentiation pathway from the HSCs-myeloid precursors-CFP and with exposure to tumor, HSCs-myeloid precursors-CFP-CAF^[91]. These findings are supported by our *in vivo* data demonstrating the activated fibroblast phenotype of HSC-derived cells recruited from the bone marrow to the tumor stroma^[91].

CAA and CAF common origins and plasticity

As summarized in Figure 2, multiple origins for CAAs and CAFs have been proposed. Evidence also suggests that CAAs and CAFs may share a common origin. Data from our laboratory using clonal cell lineage tracing demonstrated a monocyte lineage origin for adipocytes, specifically the Mac1^{lo} fraction of bone marrow^[88]. Similarly, lineage and gene expression analyses demonstrated that adipocytes and adipocyte progenitors arise from the hematopoietic stem cell *via* the myeloid lineage^[96]. Our studies of CAFs

and their circulating precursors demonstrated that these cells originate in the Mac1^{hi} population of peripheral blood and that their participation in tumor may be regulated by MCP-1^[91]. Additional evidence suggests plasticity between preadipocytes and macrophages, with preadipocytes being a source for macrophages^[104] and tissue macrophages being a source for preadipocytes^[105]. Histological evidence of a high ratio of adipocytes to fibroblasts at the tumor invasive front and an extremely high fibroblast-like cell to adipocyte ratio observed at the tumor center, suggests that CAAs may transition and/or give rise to CAFs as tumor progresses^[14]. Breast cancer cells were also shown to induce de-differentiation of adipocytes to a more fibroblastic phenotype^[21]. Human adipose tissue derived stem cells (hASCs) were found to give rise to CAF-like cells when cultured with conditioned media from MDA-MB-231 or MCF-7 breast cancer cell lines^[106]. Under tumor conditions, the hASC-derived CAF-like cells were shown to have a myofibroblastic phenotype, with increased expression of α SMA and tenascin C. This change in phenotype was found to be dependent upon TGF β signaling in the hASCs. Studies have yet to directly demonstrate a CAF to CAA conversion, however, we have observed *in vitro* that non-adherent bone marrow cells, enriched for hematopoietic progenitors, cultured in the presence of M-CSF and mouse serum give rise to lipid laden cells with a fibroblast-like morphology (unpublished observation). Together, these studies support an HSC origin for both CAAs and CAFs, suggesting plasticity exists between adipocytes, CAAs, and CAFs. This plasticity may be one mechanism by which heterogeneity of the TME is generated.

CONCLUSION

Evidence suggests that CAAs and CAFs play a critical role in tumor progression as well as patient prognosis and survival. It is thought that the metabolic changes associated with obesity underlie the increased risk of cancer and cancer-related mortalities. It has been estimated that excess weight and obesity were responsible for 20% of all cancer deaths in women in the United States^[107], consistent with poor outcome of cancer in overweight/obese patients (reviewed in^[108]). While no direct comparisons of CAAs derived from distinct sources have been conducted, it is clear that HSC-derived adipocytes represent a subpopulation distinct from conventional white and brown adipocytes based on their low expression level of leptin, low mitochondrial/peroxisomal content and oxidative capacity, and elevated inflammatory cytokine production^[96]. HSC-derived adipocytes also share numerous features with CAAs including low expression of terminal adipocyte markers and high expression levels of inflammatory cytokines, indicating that HSC-derived adipocytes may be considered "activated" contributors to the TME. Like CAAs, HSC-

derived adipocytes were found to be smaller in size than "resident" adipocytes (^[81] and our unpublished observation), but whether, as with CAAs, this is related to a higher rate of lipolysis in these cells requires further exploration. It has been noted that HSC-derived adipocytes preferentially accumulate in visceral adipose tissue (VAT) rather than subcutaneous adipose tissue (SAT)^[96]. Excess adiposity in VAT is specifically linked to type 2 diabetes and certain forms of cancer^[76]. As compared to adipocytes from SAT, VAT adipocytes exhibited higher rates of fatty acid turnover and lipolysis^[109] and produced more IL-6 and less adiponectin and leptin^[110]. These data could indicate that VAT and SAT adipocytes are generated from different progenitors, or functional changes in different depots are due to differential accumulation of adipocytes arising from distinct progenitors. Furthermore, the accumulation of HSC-derived adipocytes was increased in female mice over males, which may have important inference in human biology^[96], as women generally possess a higher percentage of body fat and tend to disproportionately gain fat in VAT following menopause. Coupled with preferential accumulation of HSC-derived adipocytes in VAT, this pattern of adiposity represents a higher risk of adipose-related gynecological cancers for postmenopausal women and suggests HSC-derived CAAs may represent a novel target these patients.

Several studies suggest that CAFs and their unique phenotypes are associated with increased malignant potential. In the case of breast cancer, women with denser breast tissue have an increased tendency to develop cancer^[15]. The presence of a fibrous stroma was found to be associated with poor prognosis in squamous cell carcinoma^[18]. In non-small cell lung carcinoma, molecular analysis revealed a gene signature for CAFs that was associated with patient prognosis^[16]. Interestingly, recent pre-clinical studies in pancreatic ductal adenocarcinoma have demonstrated a protective role for CAFs^[111,112], suggesting that the role of these cells is tumor-type dependent. CAFs are a heterogeneous population of cells that can differ based on both location within the tumor and between tumor types and demonstrate different phenotypes, activation states, and/or functions throughout tumor progression. This diversity may, in part, be due to the multiple proposed origins of CAFs, which have led to CAFs being referred to as a "cell state" rather than a specific cell type^[113]. A more in depth understanding of the origins of CAFs may shed light on the array of markers expressed by these cells, help to better define the "CAF", and elucidate their roles based on origin and tumor type.

Given the essential roles of the TME in tumor development, progression and metastasis, it is clear that successful anti-tumor therapeutics should include those directed at the support cells of the TME. A key step towards this goal is the gaining knowledge of the role(s) of the different TME cell types (*e.g.*, CAAs

Figure 3 Therapeutic implications. We hypothesize that the identification of pathways from the hematopoietic stem cell (HSC) to the cancer-associated adipocyte (CAA) and cancer-associated fibroblast (CAF) provides a potential opportunity to target these pro-tumorigenic cells both early in their differentiation and at multiple points in their maturation, which may lead to a more encompassing downstream inhibition of their contributions to tumor progression and metastasis.

and CAFs), their origins, their temporal participation and mechanisms by which they influence tumor. However, the complexity of the crosstalk between the cells of the TME, the broad impact of CAAs/CAF on the reactive stroma and their contribution to the evolving TME has made therapeutically targeting individual stromal cell derived factors difficult. For example, targeting fibroblast activation protein alpha (FAP α) produced by activated CAFs, while showing promise in preclinical studies^[58,114,115], was demonstrated to have no beneficial response in Phase II clinical trials for metastatic colorectal cancer and soft-tissue sarcoma patients^[116] (and reviewed in^[117]). However, we propose that targeting CAAs, CAFs and their precursors based on their origin may lead to significant advances in treatment by directly targeting the cells before their incorporation into tumor rather than targeting their varied products and multiple effects (Figure 3). We and others have shown that HSCs give rise to adipocytes *via* the myeloid lineage^[88,96]. Likewise, our studies demonstrate an HSC origin for CAFs *via* the same myeloid lineage^[91]. Studies have also demonstrated a myeloid lineage origin for the fibrocyte^[118] that also gives rise to adipocytes^[97] and fibroblasts^[92,119]. These HSC-derived CAAs (unpublished observation) and CAFs^[91,103] (and unpublished observation) contribute

to the TME and have a significant impact on tumor progression in mouse models. Identification of pathways from the HSC to the CAA or CAF provides a potential opportunity to target CAAs and CAFs both early in their differentiation and at multiple points in their maturation. For example, early inhibition of CFP/fibrocyte differentiation from the myeloid lineage would lead to fewer CAA and CAF precursors available for incorporation in the TME. Likewise, directly targeting CFPs/fibrocytes in circulation may prevent their incorporation into the local and metastatic TME as both CAAs and CAFs, essentially hitting two arms of pro-tumorigenic stromal cells. Given their ability to invade, circulate and extravasate, therapeutically targeting HSC-derived CFPs/fibrocytes may also directly affect the population of CAFs demonstrated to chaperone cancer cells to metastatic sites. Finally, the ability to isolate HSC-derived CAA/CAF progenitors in circulation, combined with their intrinsic ability to home to tumor^[91], may provide a novel modality for drug delivery vehicles for chemotherapy. Thus, targeting the precursors of CAAs and CAFs may lead to a more inclusive and encompassing downstream inhibition of their multiple contributions to tumor progression and metastasis. Taken together, these studies highlight the necessity of developing an understanding of the differences and similarities between TME cell types of multiple origins as well as research directed at elucidating the differentiation pathway of these populations for the ultimate goal of TME-based anti-tumor therapy.

Abstract

Recent regenerative medicine and tissue engineering strategies (using cells, scaffolds, medical devices and gene therapy) have led to fascinating progress of translation of basic research towards clinical applications. In the past decade, great deal of research has focused on developing various three dimensional (3D) organs, such as bone, skin, liver, kidney and ear, using such strategies in order to replace or regenerate damaged organs for the purpose of maintaining or restoring organs' functions that may have been lost due to aging, accident or disease. The surface properties of a material or a device are key aspects in determining the success of the implant in biomedicine, as the majority of biological reactions in human body occur on surfaces or interfaces. Furthermore, it has been established in the literature that cell adhesion and proliferation are, to a great extent, influenced by the micro- and nano-surface characteristics of biomaterials and devices. In addition, it has been shown that the functions of stem cells, mesenchymal stem cells in particular, could be regulated through physical interaction with specific nanotopographical cues. Therefore, guided stem cell proliferation, differentiation and function are of great importance in the regeneration of 3D tissues and organs using tissue engineering strategies. This review will provide an update on the impact of nanotopography on mesenchymal stem cells for the purpose of developing laboratory-based 3D organs and tissues, as well as the most recent research and case studies on this topic.

Key words: Nanotopography; Mesenchymal stem cells; Tissue engineering; Nanotechnology; Three dimensional organs/tissues; Scaffolds

Core tip: Tissue engineering and nanotechnology are both exciting fields that have enormous potentials to revolutionise medicine as we know it today. Use of nanotechnology is an attractive and effective way to control and direct biological events at cellular levels. Nanoscale architecture plays a pivotal role directing cellular activities. Here, the use of nanotopography for the purpose of 3D organ/tissue regeneration using mesenchymal stem cells (*i.e.*, their proliferation, differentiation and function), is reviewed by investigating the most recent, innovative, and effective studies in this field.

Role of nanotopography in the development of tissue engineered 3D organs and tissues using mesenchymal stem cells. *World J Stem Cells* 2015; 7(2): 266-280 Available from: URL: <http://www.wjgnet.com/1948-0210/full/v7/i2/266.htm> DOI: <http://dx.doi.org/10.4252/wjsc.v7.i2.266>

INTRODUCTION

It is becoming progressively evident that with an ever increasingly older population and high costs associated with meeting the healthcare demands^[1] as well as the shortage of organs and effective therapeutic methods^[2], the field of medicine has to move towards cutting edge, laboratory engineered techniques and devices if, we are to avoid a drastic world-wide healthcare collapse in the near future. To this end, the fields of nanotechnology, regenerative medicine and tissue engineering (TE) are expanding at a rapid pace. Recent regenerative medicine and TE strategies (using cells, scaffolds, medical devices and gene therapy) have led to fascinating progress of translation of basic research towards clinical applications^[1,3]. In the past decade, great deal of research has focused on developing various three dimensional (3D) organs, such as bone^[4], skin^[5], liver^[6], kidney^[7], and ear^[8], using such strategies in order to replace or regenerate damaged organs for the purpose of maintaining or restoring organs' functions.

Human organs are responsible for various important functions of the body including, but not limited to, digesting food, serving as a barrier against infections, recognising and coordinating the body's response to its internal and external environmental changes, and providing oxygen (to be used for cellular respiration) as well as removing excess carbon dioxide. They are also responsible for maintaining homeostasis, transmission of information and generating force^[3]. In cases when one or a few of the organs are severely damaged, to an extent that they are no longer capable of reconstructing or regenerating themselves, tissue engineering and nanotechnology based strategies, using previously established knowledge on cellular behaviour^[9,10],

could be employed to develop and construct tailored therapies, devices, or even whole organs. To this end, nanostructured, bio-inspired, or biological materials have attracted a great deal of attention as they poses unique chemical, mechanical and surface characteristics that could prove useful for organ or tissue TE.

The surface properties of a material or a device are key aspects in determining the success of the implant in biomedicine, as the majority of biological reactions in human body occur on surfaces or interfaces^[11]. Furthermore, it has been established in the literature that cell adhesion and proliferation are, to a great extent, influenced by the micro- and nano-surface characteristics of biomaterials and devices^[12,13]. In addition, it has been shown that the stem cells', mesenchymal stem cells (MSCs) in particular, functions can be regulated through physical interaction with specific nanotopographical cues^[3,14], further indicating the importance of surface characteristics at nanometre length scale. Therefore, guided stem cell proliferation, differentiation and function are of great importance in the regeneration of 3D organs and tissues using TE strategies.

This review will provide an update on the impact of nanotopography on MSCs for the purpose of developing laboratory-based 3D organs, as well as the most recent research and case studies on this topic.

NANOFABRICATION OF 3D SCAFFOLDS WITH STEM CELLS

Previously, most research and investigations focused on growing cells in a petri dish (2D). However, in nature cells use 3D template of extracellular matrix (ECM) to shape functional tissues^[15]. Micro- and nano-scale chemical and physical cues from the ECM environment control and direct various key cell behaviours including their adhesion, proliferation, migration and differentiation^[16-18]. Therefore, the construction of a synthetic system that mimics the natural ECM and its component has become a field of topical interest^[19].

Recent investigations have shown rapid success in TE of sophisticated and complex nanoenvironments suitable for 3D growth of stem cells for the purpose of organ and tissue regeneration^[19-22]. So far, various biofabrication techniques have been developed and employed to design an ideal 3D synthetic ECM-mimetic system that resembles the architecture and mechanical properties of the natural ECM^[3]. Natural or synthetic polymers are used as scaffold materials and, depending on their nature, suitable biofabrication techniques are used to create a 3D environment with nanotopographical cues that can lead to controlled and directed growth and differentiation of stem cells toward a specific tissue or organ regeneration. Numerous studies have covered the currently available fabrication techniques for natural or synthetic polymers^[15,23-27]. In general, the available fabrication techniques can

Table 1 Classification of various types of nanotopography (nanofabrication) methods

Energy source	Method	Mechanism and final outcome	Processable polymers
Thermal	Replica modelling	Creating negative shape of the mold by thermal cross-linking of cavity-filled pre-polymer	Thermocurable polymers, <i>e.g.</i> , poly(dimethyl siloxane)
	Nanoimprint lithography	Creating negative shape of the mold by plastic deformation of polymer above T _g	Thermoplastic, <i>e.g.</i> , polystyrene, poly(lactic acid), and conductive polymers, <i>e.g.</i> , polyaniline and polypyrrole
Optical	Block copolymer lithography	Creating nanoscale hole, line and lamellar structures by microphase separation of two immiscible polymers	Block copolymer, <i>e.g.</i> , polystyrene-block-poly(methyl methacrylate), styrenebutadiene-styrene
	Photolithography	Depending on mask design and selective UV exposure, solubility is changed	Photo curable polymers, <i>e.g.</i> , photoresist, polyurethane-based
	E-beam lithography	Formation of arbitrary patterns using different electron beam pathways and selective irradiation of focused electron beams to change solubility	E-beam sensitive polymers, <i>e.g.</i> , polymethyl methacrylate
	Direct laser writing	Formation of arbitrary patterns by selective cross-linking of the polymer by laser irradiation	Photo-curable polymers
Chemical	Microcontact printing	Creating extruded patterns of elastomeric stamp using relative surface energy difference needed for transferring materials	Proteins and self-assembled monolayers
	Dip-pen lithography	Formation of arbitrary patterns by direct writing of molecules with a sharp tip	Self-assembled monolayers
	Salt leaching/gas foaming	Formation of a block of polymer with voids by dissolution of salt particles (salt leaching) and/or bubble formation in the polymer block (gas foaming)	Solvent soluble polymers, <i>e.g.</i> , thermoplastic and conductive ones
Electrical	Electrochemical deposition	Forming negatively shaped molds by electrochemical reduction of the polymer	Conductive polymers
	Electrospinning	Drawing a three dimensional nanofibrous mesh from the polymer solution using an electric field	Solvent soluble polymers
Physical	Capillary force lithography	Formation of partially filled negative shape of the mold by capillary rise of thermoplastic polymer above T _g	Thermoplastic and solvent soluble polymers
	Micromolding in capillaries	Creating a negative shape of the mold by capillary-driven microchannel filling	Solvent soluble polymers
	Wrinkle	Formation of random or aligned micro- or nanolines using mechanical buckling Mechanical buckling between elastic substrate and rigid film	Elastomeric polymers, <i>e.g.</i> , polydimethylsiloxane
	Crack	Formation of aligned or inter-crossing line patterns by mechanical fracturing of the stiff film adhered onto elastic substrate	Elastomeric polymers

Adapted from Kim *et al.*^[3].

be classified into different categories based on their energy source, *i.e.*, thermal, optical, physical, chemical or electrical (Table 1). It is beyond the scope of this paper to review the different available techniques in each of these categories, however, a review conducted by Kim *et al.*^[3] could be referred to for further and in detail information on this topic.

CHARACTERISTICS OF MSCs AND THEIR APPLICATION IN TE OF 3D ORGANS

An extensive number of studies have demonstrated the great potentials of using MSCs for TE approaches^[28-33]. Among many advantageous characteristics of MSCs the fact that these cells can be isolated from several tissues and that they have the potential to be expanded in culture and exhibit multilineage differentiation (Figure 1) make MSCs a highly interesting stem cell source for TE and regenerative medicine research^[31]. Other interesting properties of MSCs include; their ability to self-renew, modulate immune responses, and their availability (they can be obtained from a small scale aspirate of bone marrow or adipose tissues)^[34-36]. Furthermore,

MSCs can be isolated from adults, therefore, allogeneic transplant of these cells would eliminate raising ethical issues in regards to their use in TE and regenerative medicine^[36].

Among most potential characteristics of MSCs, it is probably their ability of multilineage differentiation that is mostly exploited for TE and regenerative medicine purposes. The differentiation of MSCs is controlled by some regulatory genes and induction chemicals that lead to the specific differentiation of these progenitor cells^[37,38]. In addition to growth factors and induction chemicals, various biomaterials (*i.e.*, natural and synthetic polymers) are used to provide appropriate scaffolding for the proliferation and differentiation of MSCs for the purpose of reconstruction of several hard and soft tissues and organs, such as bone, cartilage, tendons, and skin^[39,40] (Figure 2).

THE ROLE OF NANOTOPOGRAPHY ON THE GROWTH AND PROLIFERATION OF MSCS

As mentioned earlier, surface nanotopography of

Figure 1 Potentials and sources of mesenchymal stem cells. Mesenchymal stem cells can be collected from various sources within human body and have the ability to differentiate into a variety of lineages.

Figure 2 Overview of tissue engineering strategy of incorporating scaffolds with mesenchymal stem cells. Mesenchymal stem cells (derived directly from the patient) are expanded in the laboratory, whereby the necessary environment for their growth has been prepared. These cells are then seeded onto a scaffold and either allowed to differentiate *ex vivo* pre-implantation or the scaffold is immediately implanted.

biomaterials can evoke specific cellular responses. Materials with unique nanotopographical characteristics offer properties, similar to growth factors, which can be used to induce specific biological performances of safe and cost effective manners in the human body^[41]. Previous studies show that various nanotopographical cues can potentially impact the adhesion^[42,43], orientation^[44], and cytoskeletal organisation^[45] of MSCs as well as their self-renewal^[46], proliferation and differentiation^[41]. Furthermore, nanotopographical cues could influence morphology, migratory capacity, gene expression and subsequently the fate of MSCs^[47,48].

It has been shown that nanofeatures including nanopits, nanogratings and nanoprotusions have the potentials to influence the cell morphology, proliferation and differentiation of MSCs^[49,50] (Figure

Figure 3 Comparison of different topography strategies employed to investigate the effects of anisotropic vs isotropic cytoskeletal tension on cultured mesenchymal stem cells. (A) nonpatterned substrates caused randomly oriented cell protrusions to be formed, while (B) alignment of elaborated processes in the direction of the grooves were induced by micropatterned surfaces, mimicking the native structure and orientation of the natural extracellular matrix proteins^[52].

3). For instance, it has been shown that homogeneously nanopatterned and chemically modified surfaces can have direct effect on cellular responses of MSCs, including their self-renewal abilities, control over their initial cell interactions and subsequently their cell phenotype, by creating arrays of nanodots using dip pen nanolithography^[51] (Figure 4). Furthermore, differentiation and proliferation of human MSCs (hMSCs) were investigated on nanogratings of 350 nm width combined with biochemical cues such as retinoic acid, and it was shown that synthetic nanostructures can induce hMSCs to differentiate into neuronal lineage^[52]. This study, conducted by Yim *et al.*^[52], also confirmed the significance of nanotopography as it revealed that retinoic acid alone on unpatterned surfaces did not lead to strong neuronal marker expression as it was shown on surfaces with nanogratings. Other nanopatterned structures, such as grooves, ridges, and pores as well as holes, nodes, or rods are of other commonly techniques currently employed to change unpatterned surfaces for MSCs to grow on and to direct their cellular responses^[53]. Such nanostructures have great applications to all areas of TE. For instance, Andersen *et al.*^[54] investigated adhering nanoparticles containing different small-interfering RNAs (siRNAs) into nanostructured scaffolds consisting of nanopores and reported of spatial retention of the RNAs within nanopores seeded with MSCs, which resulted in enhanced osteogenic and adipogenic differentiation of MSCs^[54]. This is an exciting finding as the ability of directing a single type of differentiation plays a crucial role in developing specific 3D organs. In another study, Watari *et al.*^[55] used topographically-patterned substrates containing anisotropically ordered ridges and grooves to modulate osteogenic differentiation in hMSCs^[55]. They reported that hMSCs cultured on 1400 or 4000 nm pitches, compared to those seeded on 400 nm pitch or planar control, exhibit better elongation

Figure 4 Nanopatterned gold surfaces examination for the effect of both the nanotopography and terminating chemical functionality. A: Nanopatterned surfaces used for mesenchymal stem cell control and differentiation exhibiting dot to dot pitch ($d\alpha$) and dot diameter ($d\beta$); B: Lateral Force Microscopy (LFM) image of small area 280 nm pitch array; C: LFM image of 140 nm pitch array; D-F: Atomic force microscopy topographical image of an alkanethiol resist array fabricated on gold surface following chemical etching. An average diameter feature ($d\beta$) of 70 nm was shown on the cursor profile^[53].

and alignment, while they showed a significant decrease in Runt-related transcription factor 2 (RUNX2) and bone gamma-carboxyglutamic acid-containing protein (BGLAP) expression. Their data also revealed that 400 nm pitch increased extracellular calcium deposition. Watari *et al.*^[55] concluded that specific size scale of topographic cues could directly influence the osteogenic differentiation of hMSCs both with and without osteogenic agents. This is another important finding that could enable one to manipulate and develop nanostructures that could lead to controlled and directed differentiation of stem cells for the purpose of TE of 3D organs. Very recently, the effect of topographical design, in the form of nano-pillar, nano-hole and nano-grill, on hMSCs were investigated by Wu *et al.*^[56] in which these nanotopographies were applied onto a polycaprolactone surface using thermal nanoimprinting. Their findings revealed that nanotopographical patterns trigger changes in the morphology and cytoskeletal structure of hMSCs. They

also found that, compared to non-patterned surfaces, nano-pillar and nano-hole topography determined MSCs chondrogenesis, resulting in specific cartilage formation. Furthermore, Kilian *et al.*^[57] showed that geometric nanotopography cues, that increase actomyosin contractility, could influence and direct the osteogenesis of bone marrow-derived hMSCs. Such geometric cues direct and control mechanochemical signals and paracrine/autocrine factors necessary for specific differentiation of MSCs, also observed during the *in vivo* investigation of the microenvironment of the differentiated cells.

CASE STUDIES ON THE APPLICATION OF NANOTOPOGRAPHY GUIDED TE OF 3D ORGANS/TISSUES USING MSCS

Bone

Reconstruction of large bone defects caused by

surgery, trauma or tumours are common deficiencies, which present a significant medical challenge^[58]. Autologous bone grafting is the gold standard for treating bone defects, but obstacles such as limited sources of tissue, and bone resorption before bone healing, have raised interests in synthetic materials as potential bone substitutes^[59]. Furthermore, bone grafting has proven challenging for large bone defects reconstruction^[60]. This is mainly due to difficulties in harvesting enough bone grafts from a healthy bone, potential postoperative pain, risk of infection, risk of hypersensitivity, risk of paresthesia, and time constraints^[61,62]. TE, using stem cells, provides the opportunity to avoid the established drawbacks of bone graft materials for the purpose of reconstructing or regenerating bone defects at variety of scales. MSCs, because of their interesting properties, have been demonstrated as an attractive cell source for bone TE applications^[63]. Controlled and directed differentiation of MSCs into osteoblasts (bone cells) is therefore a key aspect of this process. As mentioned above, nanotopographical cues could be used to influence MSCs cell behaviour and differentiation toward specific lineages. For instance, in a very recent study, McCafferty *et al.*^[64] demonstrated the use of nanotopography to induce osteogenic differentiation of human bone marrow derived MSCs. They sputter deposited thin films of bioactive calcium phosphate onto a polycrystalline titanium nanostructured surface. These sputter deposited surfaces supported high levels of bone marrow-derived hMSCs proliferation and adhesion, determined by DNA quantification. Moreover, they were also able to directly promote significant levels of osteogenic differentiation. In this study, gene expression, alkaline phosphatase activity and immunocytochemical localisation of key osteogenic markers showed that the nanostructured titanium surfaces and the bioactive calcium phosphate coatings could direct differentiation towards an osteogenic lineage. The addition of the calcium phosphate chemistry to the topographical profile of the titanium was found to induce increased bone marrow-derived hMSCs differentiation compared to that observed for either the titanium or calcium phosphate coating without an underlying nanostructure. Therefore, the results presented a clear benefit from a surface engineering strategy that combines a defined nanoscale surface topography with a conformal bioactive chemistry. In another study by de Peppo *et al.*^[65] osteogenic response of hMSCs to titanium-coated hemisphere-like topographic nanostructures of 50, 100, and 200 nm was assessed. Their aim was to look at the influence of different sizes of nanoscale topographies on the morphology, proliferation, and osteogenic differentiation of hMSCs *in vitro*. Here, the nanostructuring was fabricated using colloidal lithography and the desired structure sizes were achieved by etching the original 200 nm polymeric

particles (polystyrene particles) and further heat-treating them above the transition temperature of polystyrene (118 °C), to create semispheroidal nanoparticles to increase their surface attachment abilities. Their results showed that there is a direct relationship between the proliferation and osteogenic differentiation of hMSCs and the size of the underlying structures, demonstrating that by varying the scale of the nanotopographic features at nanoscale, one can control the osteogenic behaviour of hMSCs. de Peppo *et al.*^[65] concluded that colloidal lithography in combination with coating technologies can enable structuring well defined nanoscale topographies to control and direct hMSCs growth and differentiation. Dalby *et al.*^[66] also investigated the osteogenic response of hMSCs to semi-ordered and random nanotopographies performed by colloidal lithography and polymer demixing on silicon and showed that hMSCs react robustly to nanotopographic features down to 10 nm in size with a low aspect ratio^[66]. In this study, scanning electron microscopy of primary hMSCs on flat controls and scaffolds with nanotopographic structures showed that hMSCs exhibited strong reaction to nanofeatures as their filopodia extended and curled around these features (Figure 5). Dalby *et al.*^[66] concluded that their recorded osteogenic response of hMSCs to nanotopographies could be employed to construct and design scaffolds with an appropriate osteogenic “environment” instead of planar control structures in order to direct and control MSCs growth and differentiation.

Furthermore, Rosa *et al.*^[67] examined the osteoinductive potential of titanium (Ti) surfaces with nanotopographic features, yield by chemically treating polished Ti discs with H₂SO₄/H₂O₂, and cultured them with rat MSCs under osteogenic and non-osteogenic conditions. Untreated polished Ti surfaces were used as controls. Their findings revealed that Ti surfaces with nanotopography boosted cell proliferation and alkaline phosphatase (Alp) activity of rat MSCs under both osteogenic and non-osteogenic conditions (Figure 6). They also demonstrated that nanotopography upregulated the gene expression of major bone markers under both of the test conditions. Interestingly, they noticed that obtustatin, an α 1 β 1 integrin inhibitor, was able to reduce higher gene expression of key bone markers and Alkaline Phosphatase (ALP) activity on Ti Scaffolds with nanotopographic features. Therefore, suggesting that obtustatin signalling pathway plays a crucial role in determining the osteoinductive effect of nanotopography on MSCs, a finding that can be exploited as a novel mechanism of accelerating and/or enhancing MSCs osseointegration for the purpose of TE of complex organs or tissues in the future.

Cartilage

Cartilage defects, caused by osteoarthritis, trauma or sport, are considered serious clinical problems. So far,

Figure 5 Scanning electron micrographs of human mesenchymal stem cells cultured on control and test materials. A: On planar control materials cells showed normal morphologies; B, C: Filopodial of the human mesenchymal stem cells (hMSCs) interacts with the 3:1000 substrates (arrowheads); C: hMSC filopodia are curving around an island; D, E: Filopodial interactions with the 3:3000 substrates (arrowheads); E: A filopodia curving around an island is clearly observed; F: filopodial interactions with the hemi substrates (arrowheads); G: Filopodia curving around a hemisphere (arrowhead)^[68].

TE of cartilage has proven to be much more difficult than many other organs or tissues, due to cartilage's inherently poor regenerative ability^[68]. Therefore, developing a functional TE system, capable of improving the regenerative ability of this tissue, would be of great interest. Most research on this field have been focused on using polymeric scaffolds with stem cells, in particular MSCs^[8,68-70]. MSCs are considered the "gold standard" of stem cell source for cartilage TE as their

differentiation to chondrocytes can be easily controlled and directed using various techniques, in particular nanotopography^[8,56].

Previous studies have shown that a more rounded, spheroidal cell shape can enhance the rate of chondrogenesis, through increasing the expression of chondrocyte-related genes, markers, and proteins^[71,72]. Based on this, Zhong *et al.*^[73] attempted to create a microenvironment suitable for MSCs fibrochondrogenesis

Figure 6 Investigation of the effects of nanotopography on proliferation. (A), alkaline phosphatase (Alp) activity (B), and extracellular matrix mineralization (C) of mesenchymal stem cells differentiated into osteoblasts and cultured on nanotopography in an osteogenic medium compared to control Ti surfaces. A: The number of cells was significantly increased on Ti with nanotopography on days 10 ($P = 0.07$) and 17 ($P = 0.03$); B: Higher Alp activity was supported by Ti surface with nanotopography supported on days 4 ($P = 0.01$) and 10 ($P = 0.04$); C: The difference in the level of calcium mineralisation in the matrix (insets) was not statistically significant ($P = 0.13$) by comparing both surfaces. The data are presented as mean $\pm$ standard deviation ($n = 4$). ^aIndicates statistically significant difference^[67].

using simultaneously integrated nanotopography and flow stimulus. They developed a biomimetic microfluidic device consisting of aligned nanofibers of poly lactic-co-glycolic acid (PLGA), and micorchambers of different angles. The micorchambers were used to enable flow direction to create different angles with PLGA nanofibers. Their findings showed that the combination of fluid flow, nanotopography-induced cues, and the direction of flow in relation to the aligned nanofibers contributed towards the round shape morphology of MSCs, associated with fibrochondrogenesis during chondrogenic differentiation of these cells.

Although, most studies have shown positive contributions of various nanotopographical cues on MSCs growth and differentiation, a few studies have concluded that certain types of nanotopography could have adverse effect on the differentiation of MSCs into chondrocytes for the purpose of repairing

or regenerating cartilage. The study by Wu *et al.*^[56] is a good example on this statement as their findings revealed that MSCs experienced delayed chondrogenesis on samples with nano-grill topography. They observed radically different morphological, proliferation and chondrogenesis changes as well as significantly higher upregulation of type II collagen on nano-pillar and nano-hole surfaces compared to nano-grill surfaces, where the expression of collagen I marker was drastically higher (Figure 7). Similarly, Trujillo *et al.*^[74] reported of decreased chondrogenic differentiation of adipose-derived MSCs on nanowire surfaces. They used sintering and solvent-free nanotemplating to fabricate polycaprolactone (PCL, as control) and nanowire (NW) samples. After 4 and 7 d of culturing the samples with adipose-derived MSCs, both groups demonstrated positive support for cell attachment and proliferation. Once chondrogenic differentiation

Figure 7 The effect of nano-patterned surfaces on the expression of cartilaginous genes. Real time polymerase chain reaction was used to analyse mRNA expression levels of cartilaginous genes at week 2, 4 or 6 of chondrogenic differentiation, which was normalised to their respective glyceraldehyde-3-phosphate dehydrogenase expression and expressed as fold changes relative to undifferentiated mesenchymal stem cells. $n = 3$ per group, mean $\pm$ SD. ^a $P < 0.05$ which was considered statistically significant compared to non-patterned surface^[56].

media was supplemented to the cultures, alcian blue staining was used to confirm the presence of acidic polysaccharides, such as sulphated glycosaminoglycans, normally found in articular and hyaline cartilage tissue. At 3 wk, it was evident that there had been significantly higher production of polysaccharides on PCL compared to NW. The authors also investigated PCL and NW samples under adipogenic differentiation conditions and found the results to be reversed, *i.e.*, there was increased adipogenic differentiation of adipose-derived MSCs on the NW samples. These findings indicate that nanotopography can have bias and in some cases unexpected effects on the differentiation of MSCs towards a particular lineage. However, further research is required on this particular topic in the future, in order to better understand the underlying mechanism of such adverse events.

Skin

Millions of burn injuries occur worldwide that cause serious harm to skin and subsequently to the general health of patients, as the first line of a patient's defence is compromised. In cases where the injuries are too severe for the natural repair process to take place, skin TE is considered. Skin, with a surface area of 1.8 m², is the largest organ in the body, which consists of two layers: the outer protective epidermis and inner corium or dermis. Currently the main obstacle in front of skin TE is *in vitro* culture time required to grow epithelial sheets large enough to be used for severe cases. This is particularly dangerous as the longer the wound takes to heal, the patient is at higher risks of acquiring infection^[75]. Another issue is that epithelial cells are very sensitive and adhering them to the burned surfaces is very difficult^[76].

Like in other diseases, stem cells can help improve the healing and regenerating process of skin. Previously, bone marrow-derived MSCs have been shown to differentiate into epithelial cells of skin^[77], and promising results have been achieved in treating skin wounds,

especially chronic ones^[78,79]. Wounds treated using bone marrow-derived MSCs have shown accelerated wound closure with rapid re-epithelisation, cellularity and angiogenesis^[80]. Incorporation of these cells into a suitable scaffold, which closely mimics the native micro- and nanotopographical characteristics of the ECM of the skin, may offer improved opportunity to repair or regenerate skin^[81]. For this to happen, two events should take place; (1) MSCs should be directed to the sites of injury; and (2) they should differentiate into cells of skin lineage. This is achievable by designing scaffolds with specific nanotopographical features^[82].

Based on the highly oriented nanogrooved structures of natural ECMs in human body, Kim *et al.*^[83] designed nanotopographically variable grooved matrices, using UV assisted capillary force lithography, with curable polyurethane acrylate (PUA) polymer. The PUA nanogrooved matrices were then gelatine coated prior to cell culturing with hMSCs. In this study, the effect of nanotopographical density was investigated on hMSCs migration and proliferation for wound healing purposes. It was shown that hMSCs migrate into the target area (the wounded, cell free area) and that the hMSCs on nanogrooved matrices exhibited a significantly higher speed of cell migration than those on the flat controls. They also investigated various densities of nanogrooves and found that as the density of the nanogrooved matrices increases, the speed of hMSCs migration increases proportionally. Their analysis of hMSC proliferation on nanogrooved matrices, compared to flat ones, revealed no significant differences, hence concluding that proliferation of hMSCs may not be influenced by nanogrooves.

Recently, great deal of attention has been focused on electrospun nanofibrous for skin regeneration^[75,81,84,85]. Using various nanotopographical designs, highly porous meshes of ultrafine fibers could be fabricated that closely resemble the nanotopography of the natural ECM of human skin^[84]. Jin *et al.*^[86] investigated the *in*

Figure 8 Electron microscopy images of differentiated and undifferentiated mesenchymal stem cells on Coll/PLLCL nanostructured nanofibers. A: Mesenchymal stem cell (MSC) directed to differentiate along the epidermal lineage when cultured in epidermal induction medium; B: Epidermally differentiated MSC on the edge of a Coll/PLLCL scaffold (as shown by arrow); C: Electrospun Coll/PLLCL nanofibers seeded with undifferentiated MSC cultured in normal growth medium; D: MSC grown in normal growth medium on Coll/PLLCL nanofibers stained with Ker 10, after 15 d cell culture, imaged using laser scanning confocal microscope^[86].

vitro differentiation potentials of bone marrow-derived MSCs to epidermal cells on electrospun collagen/poly (L-lactic acid)-copoly (3-caprolactone) (Coll/PLLCL) nanofibrous scaffolds^[86]. To further mimic the structure of the natural ECM of human skin, they incorporated Coll/PLLCL nanofibrous scaffolds with collagen, at a ratio of 30:70, respectively. Their findings demonstrated that electrospun Coll/PLLCL nanofibers enhanced the level of MSC and scaffold interaction and that the electrospun scaffolds could mimic the native skin ECM. Furthermore, their results showed controlled and directed differentiation of MSCs along the epidermal lineage on Coll/PLLCL nanofibrous scaffolds (Figure 8), suggesting their potential use in skin TE applications.

POTENTIAL ADVERS EFFECTS OF ERODED NANOPARTICLES ON MSCS

Based on the evidence presented in this review, it is clear that nanotopography of a surface can have a great influence on the various cellular behaviours of MSCs including; their attachment, proliferation and most importantly their differentiation towards a specific lineage. However, based on the literature,

there have been various reports of the adverse effects of nanoparticles on the cellular behaviour of MSCs as the result of implant erosion over-time^[87-89]. This is especially a concern of biodegradable materials as they have been specifically designed to be deteriorated once implanted in their host. In long-term clinical application, the physiochemical properties of implants are influenced by their constant chemical, mechanical, and biological interactions with their host tissue and its surrounding environment^[90]. These factors cause the degradation of the implant and subsequently to the release microscale and/or nanoscale wear particles in their immediate vicinity. These released particles no longer exhibit any of the nanotopographical characteristic of the implant surface, prior to implantation.

Released nanoparticles, once exposed to tissues and bodily fluids, tend to absorb macromolecules in their vicinity and depending on the surface characteristics of the nanoparticles (e.g., their surface chemistry and surface energy), these macromolecules become attached onto the surface of the nanoparticles, leading to potential modification or functionalization of the surface of the nanoparticles^[91,92]. Attachment of such macromolecules could change the affinity of a nanoparticle to bind with a specific protein, on the surface of a particular type of cells, which in return could have serious unaccounted for or adverse toxic effects on the proliferation and/or differentiation of cells^[93]. For instance, there has been a report on serious DNA damage caused to MSCs when cultured with metallic silver nanoparticles, even at lower concentrations^[88]. Calcium phosphate nanoparticles, very commonly used for bone tissue engineering applications, have also shown to affect MSC proliferation in a size-dependent manner, with larger particles causing more serious harm^[87]. Furthermore, studies conducted by Hu *et al.*^[94] and Liu *et al.*^[89] showed that calcium phosphate nanoparticles could also affect MSC differentiation depending on their concentration and form of appearance. They reported that increasing the concentration of calcium phosphate nanoparticles, especially in the form of amorphous particles, rather than crystals, could negatively affect the osteogenic cell differentiation and matrix mineralisation of MSCs.

Other types of nanoparticles such as metallic ones are also of great concerns, as their release could lead to serious nanotoxicity in biomaterials and different cell lines. Various groups have investigated adverse systematic effects of titanium nanoparticles on different cell lines such as endothelial^[95], lymphoblastoid^[96], and fibroblasts^[97] cells and reported of inflammatory reactions, DNA damage, and induction of apoptosis, respectively. However, until a year ago, there was no concise report on the adverse effect of titanium nanoparticles on the cellular behaviour of bone marrow-derived MSCs, despite titanium implants majorly being used for medical applications, such as in bone TE. As the result, very recently, Hou *et al.*^[98] investigated

Table 2 Significant studies on nanotopography and mesenchymal stem cells for developing 3D bone, cartilage and skin

Tissue/organ	Nanotopographical cues	Description	Outcome	Ref.
Bone	Nano-ridges, and nanogrooves nanotopography surfaces	The effect of nanotopographic ridges and grooves on MSCs morphology, proliferation and differentiation to osteoblast cells were investigated	Osteogenic differentiation can be controlled and directed using specific size scale of topographic cues with or without osteogenic agents	Watari <i>et al</i> ^[55]
	Implementing nanostructures of different sizes	The effect of titanium-coated hemisphere-like topographic nanostructures of various sizes (50, 100, and 200 nm) on hMSCs cellular behaviour towards osteoblast lineage was investigated	Osteogenic differentiation of hMSCs is dependent on the size of the underlying nanotopographical structures. Colloidal lithography combined with coating technologies can have great potentials for fabricating nanoscale topography on scaffolds	de Peppo <i>et al</i> ^[65]
	Bioactive calcium phosphate thin films sputter deposited onto a polycrystalline titanium nanostructured surface	Calcium phosphate thin films were used to study the cellular response of hMSCs to nanostructured titanium surfaces with the aim of directing them towards osteogenic differentiation	Various <i>in vitro</i> studies revealed that the use of nanostructured titanium surfaces and the bioactive calcium phosphate coatings could allow for directed and controlled differentiation of hMSCs towards osteogenic lineage. The combination of the two materials together showed higher rate of osteogenic differentiation compared to that of each of these materials on their own	McCafferty <i>et al</i> ^[64]
	Polished Ti surfaces chemically treated with H ₂ SO ₄ /H ₂ O ₂ to create nanotopography	Chemically treated Ti surfaces with nanotopography and seeded with rat MSCs were used to investigate their osteoinductive potentials compared to untreated surfaces. Signalling pathways responsible for osteoinductive effect of nanotopography on MSCs were also investigated	Ti surfaces with nanotopography exhibited increased cell proliferation and alkaline phosphate activity. Gene expression of key bone markers was upregulated on nanotopography surfaces, under non-osteogenic conditions, compared to control	Rosa <i>et al</i> ^[67]
Cartilage	A biomimetic microfluidic device embedded with aligned nanofibers consisting of microchambers of different angle	A device was developed to create a microenvironment that integrates nanotopography and flow stimulus of the ECM of natural cartilage for the purpose of investigating the effect of microfluidic and nanotopography on the cellular behaviour and fibrochondrogenesis of MSCs	The angle of flow direction, in relation to the aligned nanofibers, affects MSCs behaviour. Fibrochondrogenesis of MSCs was evident when the flow direction was perpendicular to the aligned nanofibers	Zhang <i>et al</i> ^[76]
	Nanowire nanotopographic surfaces	Polycaprolactone nanowires surfaces were fabricated using a solvent-free gravimetric template technique to investigate their nanotopographical effects on the adhesion, proliferation, differentiation and ECM synthesis of adipose-derived MSCs	The results demonstrated that adhesion and proliferation of adipose-derived MSCs were enhanced on nanowire surfaces compared to the control. Nanowires also effected the morphology of these cells Interestingly, it was shown that nanowires supported adipogenic differentiation of these cells rather than chondrogenic differentiation	Trujillo <i>et al</i> ^[74]
	Nano-pillar, nano-hole and nano-grill nanotopography surfaces	Nano-pillar, nano-hole and nano-grill structures were formed on polycaprolactone surface using thermal nanoimprinting to investigate their effect on chondrogenic differentiation of hMSCs	Nanotopographical patterns have the ability to induce changes in MSC morphology and cytoskeletal structure towards a specific lineage, in this case chondrocyte cells. Delayed chondrogenesis was observed on nanogrill topography compared to nano-pillar and nano-hole topography, which enhance MSC chondrogenesis	Wu <i>et al</i> ^[56]
Skin	Electrospun nanofibrous scaffolds	Electrospun Coll/PLLCL and PLLCL nanofibrous scaffolds were prepared to investigate the proliferation and differentiation of MSCs to epidermal lineages	Cell proliferation was significantly higher on Coll/PLLCL nanofibrous scaffolds compared to PLLCL scaffolds. MSC morphology was also different on Coll/PLLCL nanofibrous scaffolds compared to control. Electrospun Coll/PLLCL exhibited similar properties to the native skin ECM	Jin <i>et al</i> ^[86]
	Nanotopographically variable grooved matrices	Nanotopographically variable grooved matrices, using UV assisted capillary force lithography, with curable PUA polymer were fabricated and then coated with gelatine to investigate the effect of nanotopographical density on hMSC migration and proliferation for wound healing purposes	As the density of the nanogrooved matrices increased, the speed of hMSCs migration increased proportionally. It was shown that hMSC proliferation was not significantly different on nanogrooved matrices, compared to flat control. Therefore, suggesting that proliferation of hMSCs may not be influenced by the nanogrooves	Kim <i>et al</i> ^[83]

PUA: Polyurethane acrylate; Coll/PLLCL: Collagen/poly(lactic acid)-co-poly(3-caprolactone); Ti: Titanium; hMSCs: Human mesenchymal stem cells.

the effects of titanium nanoparticles on adhesion, migration, proliferation and differentiation of MSCs and

reported of serious negative effects of the nanoparticles on MSC migration as particle size increased. They

also demonstrated that exposure of MSCs to titanium nanoparticles negatively affected their osteogenic differentiation^[98].

DISCUSSION AND FUTURE PROSPECTIVE

In this review, the role of nanotopography on controlling and directing cellular behaviour of various types of MSCs, with respect to specific tissues and organs, has been described. Based on the studies presented here, it can be established that various nanofabrication methods can be employed to design and fabricate nanostructured scaffolds with distinct nanotopographical cues to control and direct various cellular behaviours of MSCs including; their attachment, proliferation and most importantly their differentiation towards a specific lineage (Table 2). Therefore, incorporating nanotopography on the design of scaffolds would open doors to new generation of TE strategies for the development of functional organs and tissues.

The review of the literature demonstrated that most studies on this topic have been focused on bone TE applications. In most of these studies, such strategy seemed to improve the proliferation and differentiation of MSCs for repair or regeneration of bone. In most cases, authors have reported of controlled and directed osteogenesis of these cells on various polymeric based composite or nanocomposite scaffolds. However, there seems to be a clear lack of investigation into the potentials of using nanotopography for the development of more complex organs or tissues such as heart, kidney, or bladder. This is despite of the fact that some studies have confirmed the abilities of MSCs to differentiate into various other cell types; including muscle cells, stromal cells and fibroblast cells. Therefore, in the future, TE and regenerative medicine could greatly benefit from research focused on developing more complex organs or tissues using nanotopography guided differentiation of MSCs, while at the same time, there needs to be a more comprehensive investigation on the potential adverse effect of various types of nanoparticles, released from eroded nanotopographical surfaces, on the cellular behaviour of MSCs.

hypothesis is most widely accepted. This proposes that stem cells in the basal layer of the limbal epithelium, at the periphery of the cornea, maintain themselves and also produce transient (or transit) amplifying cells (TACs). TACs then move centripetally to the centre of the cornea in the basal layer of the corneal epithelium and also replenish cells in the overlying suprabasal layers. The LESC hypothesis maintains the corneal epithelium during normal homeostasis and become more active to repair significant wounds. Second, the corneal epithelial stem cell (CESC) hypothesis postulates that, during normal homeostasis, stem cells distributed throughout the basal corneal epithelium, maintain the tissue. According to this hypothesis, LESC are present in the limbus but are only active during wound healing. We also consider a third possibility, that the corneal epithelium is maintained during normal homeostasis by proliferation of basal corneal epithelial cells without any input from stem cells. After reviewing the published evidence, we conclude that the LESC and CESC hypotheses are consistent with more of the evidence than the third hypothesis, so we do not consider this further. The LESC and CESC hypotheses each have difficulty accounting for one main type of evidence so we evaluate the two key lines of evidence that discriminate between them. Finally, we discuss how lineage-tracing experiments have begun to resolve the debate in favour of the LESC hypothesis. Nevertheless, it also seems likely that some basal corneal epithelial cells can act as long-term progenitors if limbal stem cell function is compromised. Thus, this aspect of the CESC hypothesis may have a lasting impact on our understanding of corneal epithelial maintenance, even if it is eventually shown that stem cells are restricted to the limbus as proposed by the LESC hypothesis.

Abstract

In this review we evaluate evidence for three different hypotheses that explain how the corneal epithelium is maintained. The limbal epithelial stem cell (LESC)

Core tip: This review article evaluates the evidence for different hypotheses that have been proposed to explain how the corneal epithelium is maintained. It identifies core observations in favour of the conventional limbal epithelial stem cell (LESC) hypothesis and an alternative corneal epithelial stem cell hypothesis and describes how lineage-tracing experiments are helping to reconcile the two sets of conflicting evidence in favour of the LES C hypothesis.

West JD, Dorà NJ, Collinson JM. Evaluating alternative stem cell hypotheses for adult corneal epithelial maintenance. *World J Stem Cells* 2015; 7(2): 281-299 Available from: URL: <http://www.wjgnet.com/1948-0210/full/v7/i2/281.htm> DOI: <http://dx.doi.org/10.4252/wjsc.v7.i2.281>

INTRODUCTION

It is widely accepted that adult corneal epithelium is maintained by stem cells located in a region called the limbus, at the corneal periphery. However, this limbal epithelial stem cell (LESC) hypothesis has been challenged by an alternative corneal epithelial stem cell (CESC) hypothesis, based on experimental studies with mice^[1]. This accepts that LESCs exist but proposes that they only contribute to corneal epithelial repair in response to wounding and that, during normal homeostasis, the corneal epithelium is maintained solely by stem cells scattered throughout the corneal epithelium itself. It has also been proposed that, in the absence of a wound, the corneal epithelium is maintained entirely by proliferation of its own basal cells without any involvement of stem cells^[2]. The main purpose of this review is to compare the evidence for the alternative LES C and CESC hypotheses in order to identify where there is common ground and where differences need further experimental investigation. However, we also consider whether the experimental evidence is consistent with the possibility that the corneal epithelium is maintained without stem cells.

THE CORNEAL AND LIMBAL EPITHELIA

The cornea is the specialised, avascular, transparent, dome-shaped region of the anterior ocular surface, which refracts light through the pupil to the lens and provides a protective, impermeable barrier. It consists of three cellular layers: (1) the inner corneal endothelium, which, despite its name, is a type of epithelium; (2) the middle corneal stroma, comprising specialised fibroblasts, called keratocytes, embedded in a collagen and proteoglycan matrix; and (3) the outer, non-keratinised, stratified squamous epithelium, comprising 5-6 layers of keratinocytes, which is kept moist by the tear film. The corneal epithelium is a very dynamic tissue. Differentiated cells are continuously shed from the outer layer and replaced by cells

Figure 1 Diagrammatic representation of the tissues of the mouse ocular surface and eyelid.

produced in the proliferative basal layer. According to the conventional stem cell paradigm these proliferative basal cells are considered to be transient (or transit) amplifying cells (TACs) and are replenished by stem cells. The early generation TACs are sometimes referred to as progenitor cells.

The limbus is a narrow transition zone, which encircles the cornea (Figures 1 and 2). The stroma and epithelial layers of the cornea extend into the limbus where they become the limbal stroma and limbal epithelium. However, the corneal endothelium does not extend into the limbus and is replaced by the drainage channels of the trabecular meshwork. On the other side of the limbus, the stroma merges with the sclera, which forms most of the ocular surface (the white part of the human eye) and the limbal epithelium becomes the conjunctiva. The conjunctiva is an epithelium, which covers the anterior sclera, folds back to form the conjunctival sac and lines the inner surface of the eyelids (Figure 1). Thus, the conjunctiva attaches the eyeball to the eyelids and orbit and permits some rotation of the eyeball in the orbit. Unlike the transparent cornea, both the limbus and the conjunctiva are vascularised.

The human limbus contains radial fibrovascular ridges, called the palisades of Vogt, which project upwards from the stroma deep into the epithelium (Figure 2) but many species, including mice, do not have limbal palisade structures. Another anatomical difference between these species is that, in the mouse, the corneal epithelium is thickest in the centre of the cornea and has fewer cell layers in the peripheral cornea and limbus whereas, in humans, the limbal epithelium is thicker (about 8-10 cell layers) than the corneal epithelium (5-6 layers)^[3].

It is widely accepted that some basal limbal epithelial cells are stem cells^[4,5] and that the limbal stroma, vasculature and other associated cell types provides a suitable stem cell niche microenvironment, which is required to maintain the LESCs in a relatively undifferentiated state^[6,7]. The limbal palisades (Figure 2) increase the area of interface between the limbal

Figure 2 Palisades of Vogt. Diagram showing the arrangement of the palisades of Vogt (upward projections of limbal stroma into the limbal epithelium) in the human limbus in plan view (left) and how they might appear in differently orientated sections through the limbus (right). Only 16 palisades are shown but in reality there are many more. For anatomy see references^[114,115].

epithelium and stroma, so increasing the size of the region that is likely to harbour the LESC niches. Furthermore, it has been suggested that LESC niches may be particularly enriched in two types of epithelial crypts associated with the palisades. One type of crypt is formed by the regions of limbal epithelium between the upward-projecting stroma of the limbal palisades and these have been named "limbal crypts" (LCs)^[8,9]. The other type of crypt (named "limbal epithelial crypts"; LECs) are more sparsely distributed (only 6-7 per eye) and are formed from epithelial projections from the periphery of the limbal palisades, which extend either radially from the limbus into the conjunctival stroma or circumferentially within the limbus (perpendicular to the palisades)^[10,11]. However, many species do not have limbal palisades and associated crypts, which could, therefore, be considered to be species-specific adaptations, possibly related to eye size. Thus, if the limbus provides a niche microenvironment, presumably it is either not dependent on these structures or differs among species. Maintenance of the niche microenvironment is more likely to depend on the presence of the vasculature and other cell types that are present in the limbus in all species.

ALTERNATIVE HYPOTHESES OF CORNEAL EPITHELIAL MAINTENANCE

We consider two hypotheses, which propose alternative ways that stem cells may maintain the corneal epithelium, and a third hypothesis, which does not include stem cells. For the present purposes, we define a stem cell as an undifferentiated cell with high proliferative potential that is capable of renewing itself and also producing one or more differentiated cell types with lower proliferative potential. While most adult stem cells are multipotent, generating multiple cell types, stem cells that maintain the corneal epithelium are generally presumed to be unipotent,

only producing the corneal epithelial cells. Although one report shows that they may also produce the goblet cells that enter the corneal epithelium in response to large wounds^[12], we have not considered this possible additional role of the stem cells in this review.

Limbal epithelial stem cell hypothesis

According to the conventional LESC hypothesis (Figure 3A and D), LSCs act as a source of new basal corneal epithelial cells (the TACs) during normal corneal epithelial homeostasis and become more active during episodes of significant wound healing^[13], although small wounds may be healed without upregulating stem cells. In this scheme LSCs remain in the limbus where they maintain themselves and also generate the first generation of TACs. Some of these early TACs move to the overlying, non-mitotic suprabasal epithelial layers, and become terminally differentiated. Other early generation TACs continue to divide and move centripetally in the basal layer to maintain the corneal epithelium. Once cells leave the basal layer they differentiate and move rapidly through the suprabasal layers to the superficial layer from where they are shed. It seems that both daughter cells of a dividing basal cell usually share the same fate^[14] so that they either both remain in the proliferative basal layer or both move suprabasally. It is not known what determines whether cells leave the basal layer. For example, it could be a combination of declining suprabasal cell numbers, caused by cell loss, and overcrowding in the basal layer, caused by cell proliferation, as described for the *Drosophila notum*^[15].

Corneal epithelial stem cell hypothesis

The corneal epithelial stem cell (CESC) hypothesis accepts that there are stem cells in the limbus but proposes that these are only activated for repairing wounds and that during normal homeostasis the corneal epithelium is maintained by stem cells

Figure 3 Limbal epithelial stem cell vs corneal epithelial stem cell hypotheses. A: Diagram of human corneal epithelial maintenance according to the limbal epithelial stem cell (LESC) hypothesis showing active LESCs in the limbal epithelium in both a limbal crypt and a limbal epithelial crypt. The LESCs divide slowly replacing themselves and producing daughter transient (or transit) amplifying cells (TACs), which divide more quickly and move centripetally from the basal layer of the limbal epithelium to the basal layer of the corneal epithelium. After a final cell division TACs leave the basal layer, move through the suprabasal layers and are shed from the surface as terminally differentiated cells (TDCs); B: Histological section showing mouse cornea, limbus and part of the conjunctiva immunohistochemically stained for keratin 12 (K12; dark brown staining) to show the border between the corneal epithelium (K12 positive) and limbal epithelium (K12 negative); C: Drawing of photograph shown in (B) with different tissues labelled. The boxed area shows part of the limbal and corneal epithelia, equivalent to that represented in (D) and (E); D: Diagram of mouse corneal epithelial maintenance according to the LESC hypothesis. The principles are the same as described for (A); E: Diagram of mouse corneal epithelial maintenance according to the corneal epithelial stem cell (CESC) hypothesis. The CESC divide slowly replacing themselves and producing daughter TACs, which divide more quickly and move centrifugally as originally proposed^[1]. After a final cell division TACs leave the basal layer, move through the suprabasal layers and are shed from the surface. cb: Ciliary body; ce: Corneal epithelium; cj: Conjunctiva; cs: Corneal stroma; ir: Iris; le: Limbal epithelium; re: Retina; sc: Sclera. Table 1 Evidence discriminating between alternative hypotheses

Observations	Species	Ref.	Consistent with hypothesis?		
			LESC	CESC	GBL
Holocline-producing cells are present in limbus but not cornea	Human	[25]	++	±	±
Holocline-producing cells are present in limbus and cornea	Pig	[1]	±	++	±
Production of clonogenic spheres from limbus and central cornea	Human	[29]	±	++	±
Limbal epithelial cells are superior to corneal epithelial cells for corneal repair	Human	[32,33]	++	+	±
The central corneal epithelium can maintain itself when isolated from the limbus	Rabbit, mouse, human	[1,39-42]	+ ^a	++	++
Label-retaining cells are present in the limbus but not the corneal epithelium during normal homeostasis	Mouse, rabbit	[13,52-54,57]	++	+	0
After a 40-d chase ³ H-TdR-labelled cells are present in both the limbus and the corneal epithelium during normal homeostasis	Rabbit	[2]	+ ^b	+ ^b	+ ^b
Cells move centripetally from the periphery of the corneal epithelium during normal homeostasis	Human, mouse	[58,61-63]	++	± ^c	± ^c
Mosaic patterns change after birth and clones of labelled cells emerge from the limbus as radial stripes	Mouse	[27,72,77-79]	++	0	0
Distribution of rare stripes in corneas of <i>KRT5-LacZ</i> ^{+/+} transgenic mice	Mouse	[17]	++	±	±
Transplanted limbal tissue contributes to replacing experimentally debrided corneal epithelium	Rabbit, mouse	[1,76]	++	++	+
Transplanted limbal tissue does not contribute to the unwounded corneal epithelium	Mouse	[1]	0	++	++
More tumours arise from the limbal epithelium than corneal epithelium	Human	[80]	++ ^d	+	+
Diverse cell types and blood supply makes limbus a likely stem cell niche	All species	[6]	++ ^d	+	+
Distribution of markers associated with undifferentiated or stem cell phenotype	Human, mouse, rabbit	See Table 2	++	±	±
Lineage tracing studies show that limbal cells contribute to the unwounded corneal epithelium during normal homeostasis	Mouse	[64]	++	0	0

++: Expected for hypothesis; +: Consistent with hypothesis; ±: Not consistent with hypothesis unless specific assumptions are made or technical issues compromise the interpretation of the experiment; 0: Not consistent with hypothesis. ^aThis is compatible with the LES C hypothesis if self-maintenance of the central corneal epithelium is a back-up mechanism that is used when homeostasis is compromised and LESCs are unable to maintain the corneal epithelium. ^bThe chase period may not have been sufficient to identify label-retaining cells (see text). ^cThe CESC hypothesis, as originally stated^[1], proposed that corneal epithelial cell movement was centrifugal but this assumption is not necessary. However, it requires *ad hoc* assumptions to account for centripetal movement across the full radius. ^dEvidence is circumstantial. LES C: Limbal epithelial stem cell.

scattered throughout the corneal epithelium itself^[1]. This hypothesis is based largely on surgical transplantation experiments in mice. These experiments showed that labelled limbal epithelial tissue, transplanted to the limbus of immunologically compromised mice, only produced labelled clones in the cornea if the host corneal epithelium was subsequently removed. The authors reasoned that if LESCs were active during normal homeostasis, as the LES C proposes, the donor limbal tissue should colonise the cornea without being stimulated to do so by wounding. However, others have pointed out that the CESC hypothesis is not consistent with some of the earlier experimental evidence^[16-18].

Germinative basal layer hypothesis

A third possibility harks back to earlier explanations before the importance of tissue stem cells was recognised. Like the CESC hypothesis, this proposes that the corneal epithelium is normally maintained entirely from cells in the basal layer of the corneal epithelium but unlike the other two hypotheses it proposes there are no stem cells in either the limbal or corneal epithelia. Haddad *et al.*^[2] referred to the basal layer as the “germinative basal layer” and proposed this alternative mechanism for corneal epithelial maintenance to explain the results of their label-retaining cell experiment with rabbits. These

results are inconsistent with other label-retaining cell experiments, as discussed below. However, we have considered this hypothesis because there is evidence that some other adult tissues are maintained during normal homeostasis by proliferation of more differentiated cell types. In such cases, stem cells are either absent or only active during wound repair. For example, this type of tissue maintenance has been proposed for pancreas β -cells^[19], epidermis^[20], lung^[21] and liver hepatocytes^[22,23].

EXPERIMENTAL EVIDENCE AND EVALUATION OF ALTERNATIVE HYPOTHESES

The three alternative hypotheses are discussed below with respect to the available experimental evidence and evaluations are summarised in Table 1.

Cells with high proliferative potential

One of the hallmarks of stem cells is that they have a greater proliferative potential than TACs and this can be identified using *in vitro* colony-forming assays with cultured cells. The proliferation characteristics of cultures of explanted epithelial cells can be investigated in culture and clones derived from single cells can be classified as holoclones, mero clones and

paraclones. These are thought to represent *in vitro* descendants of stem cells, TACs and differentiated cells, respectively^[24]. (On indicator dishes in culture, holoclones form large, smooth-edged, fast-growing colonies with large numbers of small tightly packed cells. Meroclones form smaller colonies that are irregular in outline and include a mixture of small tightly packed cells and larger more loosely packed cells, which are predominantly at the edge. Paraclones form small, diffuse colonies and most cells are large, flattened and loosely packed). Clonal analysis of cells from the human ocular surface epithelia identified holoclone-producing cells in the limbal epithelium but not the corneal epithelium from a 54-year-old individual^[25], suggesting that stem cells are present in the limbal epithelium.

However, there is also evidence that some cells of the central cornea are self-sustaining and have high proliferative potential. Majo *et al.*^[1] showed that cultured corneal epithelial cells of many species produced colonies of cells *in vitro* although there were significant species differences. Pig corneal epithelial cells grew particularly well and clonal analysis of cultured pig cells identified holoclone-producing cells in the central corneal epithelium as well as the limbus. This suggests that stem cells are present in the central corneal epithelium of pigs as well as the limbus but this result cannot be evaluated fully as the age of pigs was not given and fetal cells with stem cell characteristics may persist in younger individuals^[26-28].

The production of clonogenic spheres of cells in culture has also been associated with the presence of stem cells and these have been isolated from the human limbus and central cornea, although isolation is most efficient from the limbus and from younger individuals^[29]. These culture experiments imply that both the limbal epithelium and the central corneal epithelium have cells that are able to behave like stem cells in clonogenic assays *in vitro* which argues against the LESC and germinative basal layer (GBL) hypotheses. However, if culture conditions unmasked proliferative potential of corneal epithelial cells, which is not expressed during normal homeostasis *in vivo*, this result would be compatible with all three hypotheses.

Despite their slow proliferation *in vivo* (see next section and reference^[30]), human limbal epithelial cells grow well in culture and have a higher mitotic rate than corneal epithelial cells^[31]. Furthermore, clinical observations indicate that human limbal tissue is superior to central corneal tissue for treating patients with severely wounded corneal epithelia, which is likely to reflect a greater proliferative potential. The corneal epithelium can be restored using grafts of human limbal epithelial tissue^[32,33] or cells cultured from explanted limbal tissue^[34-38]. Although the limbus is the preferred source of cells for clinical therapeutic use, this does not help determine whether LSCs are active during normal tissue homeostasis (LESC hypothesis)

or only during wound healing (CESC hypothesis).

There is also evidence that the central cornea of several species contains highly proliferative cells. For example, rabbit central cornea is able to survive for months after the limbus is removed or separated from the cornea^[39,40], although corneal integrity slowly degenerates and it does not heal properly after corneal wounding. Similarly, the mouse corneal epithelium was able to sustain itself for four months after the limbus was cauterised to destroy the limbal epithelium^[1]. It has also been reported that some patients with symptoms of total LESC deficiency retain central islands of normal corneal epithelium for several years^[41] and in one case this appeared to be sufficient to restore the corneal epithelium^[42]. These studies show that the central cornea can maintain itself to some extent when the limbus is eliminated or disconnected. This implies that the central corneal epithelium has cells that are able to act as progenitors, if LSCs are unable to maintain the corneal epithelium. However, again this does not show whether these cells act as progenitors during normal homeostasis so it does not provide conclusive evidence against the LESC hypothesis.

Cell division characteristics and identification of slow-cycling label-retaining cells

Stem cell populations maintain themselves and produce more differentiated cells throughout the lifetime of the organism. This is sometimes interpreted as requiring stem cells to divide asymmetrically (producing one stem cell and one TAC) but this does not mean that each division of every stem cell has to be asymmetric as long as the population average achieves this. There have been few attempts to identify asymmetrically dividing cells in the ocular surface^[43] and results are insufficient to discriminate among the three hypotheses.

A more widely studied characteristic of many stem cells is that they are relatively quiescent so divide infrequently. A slow cell division rate is not an obligatory phenotype of stem cells but it has been used to try to locate the stem cells that maintain the corneal epithelium. Slow-cycling cells (including putative stem cells) are usually identified as "label-retaining cells". These are cells that retain a DNA-label such as BrdU or ³H-TdR, or a chromatin label such as GFP-tagged histone-2B, after prolonged labelling and a chase period to dilute the label from more rapidly dividing cells. The prolonged period of labelling is to label as many cells as possible including relatively quiescent stem cells that divide infrequently. The chase period is calibrated to dilute label from most cells in the tissue but not any slow-cycling cells (which include putative quiescent stem cells). This method is useful for identifying the location of putative stem cells but is not specific and will also identify other slow-cycling cell types and cells that divide during the labelling

period and then stop dividing when they terminally differentiate.

The ocular surface is a suitable tissue for label-retaining cell experiments because the corneal epithelial TACs divide quite frequently so will readily dilute the label. (The average mitotic rate has been estimated for rats as 14.5% per day for the whole corneal epithelium^[44] and this equates to approximately 37% for just the mitotic basal layer, based on the relative basal and suprabasal cell numbers in mouse corneas^[45]). Similarly, BrdU experiments indicate that almost 50% of basal corneal epithelial cells are in S-phase of the cell cycle, during a 24-h labelling period^[46]. The effectiveness of the chase period is also helped by the constant loss of cells from the superficial layer, as stem cells will not be lost in this way. It has been estimated that once cells leave the basal corneal epithelial layer the time to cell loss (turnover time) is only about 7 d (range 3¹/₂ to 14 d) for mice, rats and humans^[45,47-50] but a longer turnover time of between 14 and 21 d has been estimated for rabbits^[51].

Most investigations have identified label-retaining cells in the basal limbal epithelium but not in the corneal epithelium either after wounding^[5,13] or during normal homeostasis in mice^[13,45,52-54], rats^[55,56] and rabbits^[57]. Two caveats about the exclusive location of label-retaining cells to the limbus in these experiments should be mentioned: (1) species differences in cell cycle kinetics and technical differences between studies may affect the number of cells that remain labelled so the chase period needs to be optimised for each species (for example, in these studies, chase periods for treatments without wounding varied from 4 to 11 wk); (2) using a relatively short chase period of 4 wk, Chen *et al.*^[56] showed that approximately 20% of the label-retaining cells were slow-cycling Langerhans cells rather than putative slow-cycling stem cells. (These Langerhans cells also shared two other characteristics of putative stem cells, discussed below, as they were positive for the marker ABCG2 and had a high nucleus to cytoplasm ratio). Nevertheless, the results of all these studies consistently identified label-retaining cells in the basal limbal epithelium but not in the basal corneal epithelium and it is likely that most of these will be stem cells. Thus, these studies favour the LESC hypothesis, unless there is an additional stem cell population in the corneal epithelium, which is not slow cycling. They also argue against the GBL hypothesis unless none of the limbal label-retaining cells are stem cells.

A completely different result was found for one study with rabbits^[2], which prompted the authors to conclude that the corneal epithelium is not maintained by LSCs but by virtually all the cells of the basal corneal epithelium (referred to here as the GBL hypothesis). Rabbits were given 3 intravitreal injections of ³H-TdR at intervals of 4 d. After a 41-d chase (49 d after the first injection) the labelling index was higher in the corneal epithelium (17.8%) than the limbal

epithelium (3.8%)^[2]. However, the high labelling index suggests that many of the labelled cells were TACs, rather than slow-cycling stem cells, and the chase period was insufficient to detect label-retaining cells. Paradoxically, the chase period was comparable to that used in an earlier experiment, which identified label-retaining cells in the limbus but not corneal epithelium of rabbits^[57]. In this experiment, BrdU was infused from an osmotic mini-pump for 14 d, the pump was removed at 17 d, and the rabbits were left for a further 38-d chase period (*i.e.*, until 55 d after the beginning of labelling). In the ³H-TdR study^[2], autoradiography was used to detect label in high quality semi-thin sections and it is possible that this is more sensitive than the BrdU immunofluorescence used earlier^[57]. If so, more cell divisions and a longer chase period would be required to dilute the ³H-TdR below detectable levels in the majority of cells in order to identify any label-retaining cells. It would, therefore, be worth repeating the ³H-TdR experiment with a longer chase period before drawing conclusions that contradict the other label-retaining cell studies.

Movement of corneal epithelial cells

Early experimental evidence showed that cells moved from the limbus to the cornea to repair a corneal wound in guinea pigs^[58]. The observation that donor corneal epithelial cells, transplanted to the centre of rabbit corneas, were replaced by host cells more quickly at the periphery of the transplant also suggested that new host cells were moving centripetally from the periphery of the cornea to replace the older donor cells^[59]. Other indirect evidence that cells move centripetally from the limbus during homeostasis of unwounded corneas is reviewed elsewhere^[60]. More importantly, direct observations of radial epithelial movement during normal corneal homeostasis have consistently demonstrated that cells move centripetally from the periphery to the centre of the cornea. This supports the LESC hypothesis, which proposes that LSCs remain in their limbal niche but TACs move centripetally to maintain the corneal epithelium.

These experiments also provided estimates of the rate of centripetal movement of corneal epithelial cells for the unwounded cornea. This was estimated to be 28 μ m/d from observations of one human subject over 24 h using *in vivo* confocal microscopy^[61]. For mouse corneas, the rate of centripetal movement has been estimated as 11-26 μ m/d using three different approaches involving direct observations of labelled cells. Corneal epithelial cells labelled with India ink moved 17 μ m/d over 7 d^[62], patches of brightly fluorescent cells moved 26 μ m/d over 7 wk in mosaic GFP transgenic mice^[63] and fluorescent clones of cells extended 11 μ m/d over 12 wk in K14-CreERT2;R26R-confetti transgenic mice (from 9 to 21 wk after tamoxifen-activation of the reporter transgene)^[64]. Furthermore, the evidence from the mosaic GFP

transgenic mice^[63] and tamoxifen-activated reporter transgenic mice^[64] demonstrated that the same clonal lineage of cells moved across the full radius from the periphery to the centre. This is in contrast to cells in the conjunctiva, which do not move significantly at all^[62,65].

When Majo *et al.*^[1] proposed the CESC cell hypothesis they also proposed that the corneal and conjunctival epithelia continuously expand towards the limbus, which they described as a zone of equilibrium, so any movement in the corneal epithelium was predicted to be centrifugal. This is inconsistent both with the absence of movement in the conjunctiva^[62,65] and the convincing, direct evidence that movement of corneal epithelial cells is centripetal not centrifugal^[62-64]. The evidence for centripetal cell movement in the corneal epithelium is inconsistent with the CESC hypothesis as originally proposed^[1] but there is no need to link the stem cell location and movement aspects of the original CESC hypothesis. In principle, it would be possible for the corneal epithelium to be maintained by stem cells, scattered throughout the tissue, without invoking centrifugal movement. It is likely that TACs produced by CESC would only move radially because evidence from various mosaics and chimaeras implies that lateral movement is constrained (discussed in the next section). In theory, radial movement of TACs could be either centripetal or centrifugal but, as noted above, evidence for centripetal movement is compelling.

The causes of centripetal movement are not known and suggestions include: (1) population pressure from the periphery due to production of new TACs by LESC^[66-68]; (2) preferential loss of epithelial cells from the central cornea^[30,60]; (3) differential stiffness of cornea and limbus^[69]; (4) chemotaxis^[62]; (5) stimulation by corneal nerves^[70]; and (6) response to endogenous electric currents^[71].

If the LESC hypothesis was incorrect, centripetal movement could still be explained by a mechanism other than population pressure from the limbus. However, if LESC were absent or only active during wound healing, a peripheral source of cells would be required to replace peripheral cells that move centripetally, during normal homeostasis. This might be provided by limbal TACs for the GBL hypothesis or CESC in or near the limbus for the CESC hypothesis. Thus, both the CESC and GBL hypotheses could account for centripetal movement of cells in separately maintained regions on the same radius. However, evidence from transgenic mice shows that a single clone of cells moves across the full radius^[63,64], implying that there is a single source of cells in the limbus or peripheral cornea, rather than multiple sources throughout the cornea. This is more difficult for the CESC and GBL hypotheses to explain unless it is argued that not all radial regions are maintained by a single CESC or progenitor TAC. Another problem for the CESC hypothesis is that the CESC would tend to

move centripetally with the TACs, and so accumulate in the centre, unless the CESC were somehow stabilised in unidentified niches and the TACs could move past them. Overall, centripetal movement strongly favours the LESC hypothesis and it is difficult to reconcile this with the other two hypotheses without *ad hoc* assumptions.

Change in mosaic patterns after birth

In addition to direct studies of cell movement in real time, changes in patterns in several types of mosaic mice have provided additional evidence that cells emerge from the limbus at the periphery of the corneal epithelium and continue to move centripetally across the cornea. Mosaic patterns in adult mouse and rat chimaeras and mouse X-inactivation mosaics (*XLacZ* mosaics) are arranged as radial stripes in the corneal epithelium^[27,72,73], which is consistent with either centripetal or centrifugal movement, without significant lateral dispersion. Similar radial stripes, have been observed with various endogenous markers in human corneas, including traces of pigment^[58] and various opacities, cell inclusions or drug-induced lipidosis associated with vortex keratopathy (cornea verticillata) or hurricane keratopathy^[60,66,74,75]. In many cases the stripes form a spiral-pattern in the centre, which fits well with the more direct evidence for centripetal movement, discussed above, because centripetal movement of labelled cells transplanted to the rabbit limbus sometimes formed a similar spiral^[76].

Before about 5 wk of age, the pattern in X-inactivation mosaics is completely different from the adult radial stripes and the β -gal-positive and β -gal-negative cell populations initially form randomly orientated patches^[27,72]. Groups of β -gal-positive and β -gal-negative cells emerge from the periphery by about 5 wk and extend as radial stripes across the cornea. The simplest interpretation is that the formation of stripes coincides with the onset of activation of stem cells in the limbus that generate new cells, which replace those produced during development^[27]. This is supported by similar observations with mosaic transgenic mice^[77,78] and lineage tracing with a GFP-tagged lentiviral marker^[79], as illustrated in Figure 4, and is consistent with the LESC hypothesis but not with the CESC or GBL hypotheses.

One problem with these mosaic systems is that similar proportions of labelled and unlabelled cells were present so many of the radial stripes may comprise more than one adjacent clone that are similarly marked. Observations on *KRT5-LacZ*^{+/-} transgenic mice showed that they had rare β -gal-positive stripes in a predominantly β -gal-negative corneal epithelium, so largely avoiding the problem of multiple adjacent clones^[17]. The distribution of β -gal-positive stripes was not consistent with predictions of centrifugal extension of clones of labelled cells from β -gal-positive CESC distributed randomly in the corneal epithelium and the simplest interpretation is that the stripes represent clonal lineages derived from LESC located

Figure 4 Transition from randomly orientated patches to radial stripes in corneal epithelia of different types of mosaic mice between 3 wk and adulthood. in the limbus. However, analysis of striped patterns in *KRT5-LacZ*^{+/-} corneas is not unequivocal and similar analyses with inducible lineage markers are required, as discussed below.

Transplantation experiments

Bradshaw *et al*^[76] labelled rabbit limbal tissue *ex vivo* and transplanted it back to the limbus of the donor rabbits after first debriding the corneal epithelium across the full diameter. The labelled cells quickly colonised the corneal epithelium but, as the corneal epithelium was completely removed, this is equivalent to wound healing rather than normal corneal homeostasis. Majo *et al*^[11] transplanted either β -gal-positive limbal or central corneal tissue from transgenic mice into the limbus of β -gal-negative, immunocompromised mice and both sources of tissue produced similar results. Consistent with the earlier experiment with rabbits^[76], labelled clones of donor cells moved centripetally into the corneal epithelium if the host corneal epithelium was removed but it failed to contribute to the corneal epithelium if the host cornea was left intact. Thus, although the transplanted limbal tissue contributed to corneal repair, it did not contribute to steady state corneal maintenance during normal tissue homeostasis, as predicted by the LESC

hypothesis. This was a key result, which prompted Majo *et al*^[11] to propose the CESC hypothesis.

Circumstantial evidence

In addition to the specific investigations discussed so far, there are two circumstantial observations that favour the limbus as a site for stem cells. First, tumours of the ocular surface commonly involve the limbus^[80] and for other systems it has been suggested that tumour cells may preferentially arise from stem cells^[81,82]. This provides only weak, circumstantial evidence in favour of the LESC hypothesis.

Second, it is generally agreed that stem cells need a specialised niche environment to maintain the stem cell phenotype and this is likely to involve interactions with several cell types^[6,83]. For example, signalling from the microvasculature plays an important role in the mouse neural stem cell niche^[84]. Undeniably, the limbus provides a more diverse population of cell types than cornea and this is enriched further by its blood supply and for this reason it seems arguably a more likely location for a stem cell niche than the cornea. As already mentioned, an additional issue is that a stem cell niche in the basal corneal epithelium might be unstable because of the continuous centripetal movement of TACs. These considerations also make

Table 2 Examples of marker gene expression differences between the basal limbal and corneal epithelia during normal homeostasis identified by immunostaining

Positive markers			Negative markers

¹ $\Delta Np63$ is not expressed in the human basal corneal epithelium^[107] but it is expressed in mouse and rat corneal epithelia^[27,112,113]. Positive markers are expressed in basal limbal but not basal corneal epithelium. Negative markers are expressed in basal corneal but not basal limbal epithelium.

it more likely that stem cell niches would be located preferentially in the limbus rather than the cornea.

Although some tissues are maintained during normal homeostasis by stem cells in the main body of the tissue, the limbus is not the only putative stem cell niche with a more peripheral location. For example, there are two types of stem cells that maintain the epithelium that lines the intestinal crypts and villi: crypt base columnar cells and position +4 reserve stem cells. These are both located near the base of the intestinal crypts, from where they produce TACs, which move up the crypt and generate the different functional cell types of the villus epithelium^[85]. Maintenance of the corneal epithelium by stem cells located in the limbal epithelium, as proposed by the LESC hypothesis, is essentially analogous to the way the intestinal epithelium is maintained. The circumstantial evidence that the limbus is a likely location for a stem cell niche supports the LESC hypothesis. However, it does not provide strong evidence against the CESC hypothesis, which accepts that LSCs exist, or the GBL hypothesis, which predicts there are no stem cells and so no niches.

Stem cell markers and phenotype

The Holy Grail of stem cell research is to find a phenotype or cell marker that allows the stem cells to be unequivocally distinguished from all neighbouring cells, including early generation TACs, and isolated for further study. This has not yet proved possible for the putative stem cell population(s) that maintain the corneal epithelium. Early evidence that the basal limbal epithelium contained stem cells was produced by an immunohistochemical study of keratin 3 (K3), which is considered to be a corneal differentiation marker^[4]. K3 is expressed in the basal and suprabasal layers of the rabbit corneal epithelium but only the suprabasal layers of the limbal epithelium, leading to the conclusion the basal limbal epithelium was less differentiated than the other epithelial layers. The

mouse has no K3^[86] but K12, which normally pairs with K3, is present and expression is restricted to the cornea^[87], as shown in Figure 3B. Several authors have also noted that cell morphology of cells in the basal limbal epithelium was more characteristic of stem cells (smaller, euchromatin-rich, high nucleus to cytoplasm ratio) than the corneal epithelium^[3,88] but, as already noted, Langerhans cells in the limbus also share this phenotype^[56]. These observations are consistent with the hypothesis that the limbus contains stem cells but no more than that.

The discovery of the K3 difference between basal limbal and corneal epithelia, as a whole, was followed by a quest for a specific cell marker to identify the LSCs within the limbal epithelium. Many candidate markers have been proposed based on differential expression studies (reviewed in reference^[18]) or conventional immunostaining (Table 2) but no definitive marker has been found, that is known to be expressed in putative stem cells in the limbus but not in neighbouring early generation TACs.

Some of the markers expressed in the limbal but not the corneal epithelium have been identified as putative stem cell markers in other tissues. ATP-binding cassette transporters (ABC transporters) are a family of transmembrane proteins whose functions include the transport of (potentially harmful) metabolic products out of the cells^[89]. Conceptually, they may form a component of the molecular mechanisms by which long-lived stem cells reduce the potential for genomic damage over their extended lives, and their expression has been correlated with stem cell activity^[90]. ABCG2 expression in the limbus is one such example and cells expressing this marker can be isolated as a "side population" by fluorescence-activated cell sorting (FACS)^[3,57,91-95]. However, as noted above, some of the ABCG2-positive, label-retaining cells with a high nucleus to cytoplasm ratio cells in the rat limbus have been identified as Langerhans cells rather than epithelial stem cells^[56].

It has recently been shown that ABCB5 appears to be a promising new marker for LESC and early TACs in both mice and humans, which should also allow enrichment by FACS sorting^[54].

Despite the absence of a marker that is only expressed in the stem cells, Δ Np63 α has proved useful for identifying cultures of human limbal cells with sufficient LESC and early TACs for clinical transplantation^[37,96].

RESOLVING THE LESC VS CESC DEBATE

Some of the evidence discussed so far (summarised in rows 1-15 of Table 1) is inconclusive. Evidence from holoclone experiments with pig and human tissues is inconsistent and, in any case, the critical thing is to understand how the corneal epithelium is maintained *in vivo* during normal homeostasis. Various studies have shown that some cells in the central corneal epithelium are capable of acting as long-term progenitor cells. On the face of it, this favours the CESC and GBL hypotheses. However, these observations are also consistent with the LESC hypothesis if some basal corneal epithelial TACs have a latent proliferative potential that is only used if LESC function is compromised so homeostasis is disrupted. Drawing attention to this latent proliferative potential is an important outcome of Majo *et al.*'s^[1] investigations even if the CESC hypothesis ultimately proves to be incorrect.

Other evidence provides better discrimination. There are several strong arguments against the GBL hypothesis. It is inconsistent with the consensus of results from label-retaining cell experiments and the evidence that mosaic patterns in the mouse cornea change after birth, when clones of cells emerge from the peripheral cornea and form radial stripes. The GBL hypothesis also has difficulty accounting for the convincing evidence that corneal epithelial cells move centripetally across the full radius. In our view, this evidence (summarised in Table 1) is sufficient to exclude the GBL hypothesis and it is, therefore, not considered further.

These same observations also argue against the CESC hypothesis. However, results of the label-retaining cell experiments could be accommodated by the CESC hypothesis if CESC were not slow cycling. Nevertheless, the CESC hypothesis is inconsistent with the developmental switch from randomly orientated patches to stripes that emerge from the periphery in various types of genetic mosaics in mice and then extend across the full radius to the centre. By the same token, the CESC hypothesis requires *ad hoc* assumptions to account for centripetal movement, if the same clone of cells moves across the full radius.

Conversely, the LESC hypothesis is inconsistent with the observation that when genetically marked limbal tissue was surgically transplanted to the limbus of immunocompromised mice, donor cells failed to

move into the cornea unless the corneal epithelium was removed^[1]. Thus, the LESC and CESC hypotheses each have difficulty accounting for one type of evidence. In each case, critical evidence is based on experiments with mice so there are no grounds for suggesting that maintenance of the corneal epithelium differs between mice and humans or other species.

Clinically, it may not matter whether the LESC or CESC hypothesis is correct as both agree that the limbus is a suitable source of stem cells for therapeutic use. However, we need to know where the stem cells that maintain the corneal epithelium during normal homeostasis are located in order to understand the biology of this process. The key issue that needs to be resolved is why evidence from mouse mosaics and transfection with lentiviral markers conflict with results of surgical transplantation experiments. Analysis of mosaics show that, during normal homeostasis, clones of cells appear at the corneal periphery at around 5 wk after birth and extend centripetally across the corneal radius, consistent with activation of LESC. In contrast, surgical studies in mice show that transplantation of labelled cells to the limbus fail to colonise the cornea in a similar way.

One possible explanation is that the transplanted limbal tissue failed to colonise the corneal epithelium because the surgical manipulation or other aspects of the experimental procedure somehow perturbed normal homeostasis and affected the outcome. In principle, one way of testing this would be to label individual cells in the limbus of adult mice, using a genetic switch rather than surgical transplantation and test whether any of the labelled cells produce long-lived clones of cells that colonise the corneal epithelium. Similar genetic labelling of cells in the adult basal corneal epithelium would also allow investigation of whether these produce long-lived clones of cells in the corneal epithelium. This requires lineage tracing experiments and some possibilities are discussed below.

It should be borne in mind that some of the apparent contradictions between the different hypotheses may be more imagined than real, and arise as a result of different research groups attempting to subdivide and label what is, perhaps, a continuum of biological situations. It seems certain that limbal stem cells exist, that they can contribute to regeneration of the cornea, and yet that the basal corneal epithelial cells themselves also have massive regenerative potential. There is no reason why the balance between limbal-mediated and corneal-mediated corneal regeneration should not shift over the lifetime of the animal, with age, disease and injury, and no reason why the balance should necessarily be the same in different species.

Although we talk about wounded and unwounded corneas as if they are separate entities, in fact the corneal epithelium is, of necessity constantly regenerating, because of normal desquamation of cells. Desquamation rate is modulated by rate of blinking,

tear film composition, irritants and abrasive dust in the environment, chronic abrasion caused by *e.g.*, contact lens wear and diseases such as trachoma, acute minor scratches, ranging through to significant physical or chemical injuries and acute infections such as Herpes simplex keratitis. This continuum of insults to the corneal surface may require different levels of limbal response to support the regenerative potential of the corneal epithelial cells. It may be that the genuinely uninjured cornea does not require limbal input, but the genuinely uninjured corneal epithelium does not exist. Experimentally, factors such as the abrasive nature of bedding and dust from food that laboratory mice are exposed to, may modulate corneal regeneration and be a source of variation between research institutes. Furthermore, the large circular central corneal wounds that are so widely used as models of induced regeneration do not really recapitulate any of the most common injuries that happen in life.

There may also be problems with the practical definition of stem cells, particularly with regard to their property of "immortality". We accept that TACs do not renew indefinitely and therefore have a finite lifespan, whereas stem cells do not have this constraint. However, outside the laboratory, a stem cell cannot outlive the individual. We do not know the maximum lifespan of a TAC but this is likely to vary stochastically. If the longer-lived TACs survive for 6 mo or more, this will encompass the effective lifespan of most laboratory mice used experimentally. At that stage, the difference between a long-lived TAC and a stem cell becomes blurred. On the other hand, in larger animals such as humans, a lifespan of 6 mo or a year for a TAC is utterly insignificant in terms of the lifespan of the individual. Differences such as this may start to explain why stem-like regenerative ability may be assigned to the corneal epithelium on experimental small animals, while at the same time the data do not reflect clinical experience in humans.

Lineage tracing experiments

To test whether any cells in the limbal and/or corneal epithelia can generate long-lived clones of cells that colonise the corneal epithelium, an inducible lineage tracing method is required that can label some of the putative stem cells in the adult at a chosen time without surgical intervention or disturbing homeostasis. Sophisticated, inducible lineage tracing methods using Cre/*loxP* transgenic mice are now available that can be used to throw a genetic switch to label a chosen cell population with a fluorescent or histochemical marker that will identify them and all their mitotic progeny. Such methods have been used to trace stem cell lineages in other tissues, including the hair follicle^[97], intestinal epithelium^[98-100] and ovarian surface epithelium^[101], and this approach could be used to help resolve the LESC vs CESC debate. A similar approach has already been used, in conjunction with a multi-coloured reporter construct, to trace clonal lineages in

the ocular surface of zebrafish and demonstrate that, as in mice, the initial patchwork of cells established in the embryo is replaced by a radial pattern of clones that extend from the limbus^[102].

We have begun to explore this Cre/*loxP* lineage tracing approach using transgenic mice in which a reporter transgene is ubiquitously expressed once the flanking *loxP* sites are recombined by active Cre recombinase to remove an upstream stop sequence. Cre recombinase is provided in the form of a CreER fusion protein, which is produced by another transgene under the control of a ubiquitous promoter. The CreER fusion protein is normally sequestered in the cytoplasm unless the mouse is treated with tamoxifen. This binds to the modified oestrogen receptor (ER) and translocates CreER to the nucleus, where it can recombine the *loxP* sites, so removing the stop sequence and activating the reporter transgene. Use of a ubiquitous promoter to drive expression of CreER provides an unbiased approach, which allows putative stem cells in the limbus or cornea (and any other tissue) to be labelled. However it is not specific for stem cells so initially most of the labelled cells will not be stem cells but, by including a chase period, short-lived clones founded by labelled TACs will be shed, leaving long-lived clones founded by labelled stem cells.

The genetic switch is activated when the mouse is injected with tamoxifen. Delaying tamoxifen treatment, until well after the adult stem cells are activated, should ensure that the genetic switch is thrown to label individual adult stem cells, during normal homeostasis. This avoids labelling ancestral cells, which could each generate multiple labelled stem cells. Furthermore, by titrating the dose of tamoxifen it should be possible to label a relatively small proportion of cells so only a few stem cells will be labelled per eye. Together, this will ensure that most of the clones of labelled cells that remain as stripes or patches after the chase period are individual clones produced by single stem cells. The predicted results for such an experiment are shown, for the LESC hypothesis and three versions of the CESC hypothesis, in Figure 5.

Tamoxifen-inducible labelling of a low proportion of stem cells in adults is a significant advantage over analysis of other types of mosaics, where the cells are labelled early in development and many patches and stripes of labelled TACs are likely to be derived from multiple adjacent labelled stem cells. This is because labelling a cell in the embryo will produce a large clone of labelled cells, some of which will remain close together throughout development. Later, when adult stem cells are specified, some adjacent stem cells will probably be clonally related making it difficult to identify TACs descended from a single stem cell in these mosaic systems.

Examples of results of a preliminary experiment of this type are shown in Figure 6 and indicate that the strategy suggested in Figure 5 is feasible. The cornea

A LESC hypothesis (centripetal movement)**B** Original CESC hypothesis (centrifugal movement)**C** Central CESC and centrifugal movement**D** CESC throughout cornea and centripetal movement

Time 1

Time 2

Time 3

Figure 5 Hypothetical results from a lineage tracing experiment to distinguish between the limbal epithelial stem cell and corneal epithelial stem cell hypotheses. In each figure the inner disc represents the corneal epithelium and the outer ring represents the limbal epithelium. If a reporter transgene is driven by a tamoxifen-inducible, ubiquitous promoter, a proportion of all the cell types in the ocular surface (and other tissues) will be labelled shortly after tamoxifen treatment. The frequency of labelled cells will depend partly on the dose of tamoxifen, which could be titrated to ensure only a few stem cells are labelled per eye. Time 1 is shortly after tamoxifen-treatment and the labelled cells may have divided to produce a small clone of labelled cells. By Time 2, the short-lived labelled clones produced by labelling transient (or transit) amplifying cells should have been shed from the corneal epithelium but long-lived labelled clones produced by long-lived labelled stem cells will remain. Expectations for distributions of labelled cells at Times 2 and 3 vary for the different hypotheses. A: The limbal epithelial stem cell hypothesis predicts clones of labelled cells will extend radially from the limbus and, by Time 3, clones of labelled cells will span the full radius; B: The original corneal epithelial stem cell (CESC) hypothesis predicts clones of labelled cells produced by labelled stem cells may also extend radially but will extend centrifugally from stem cells located throughout the corneal epithelium itself. Clones of labelled cells that do not arise from the centre of the cornea will not span the full radius; C: If the CESC hypothesis is modified so that all the CESC are at the very centre of the cornea, centrifugal movement will produce clones of labelled cells that span the full radius by Time 3 but at Time 2 there should be no labelled peripheral cells produced by stem cells; D: If the CESC hypothesis is modified so that the CESC are located throughout the corneal epithelium but movement is centripetal, clones of labelled cells that do not arise from the periphery of the cornea will not span the full radius. To distinguish between the various hypotheses it will be necessary to compare patterns of labelled clones at different times after tamoxifen treatment.

Figure 6 Preliminary results from a lineage tracing experiment to distinguish between the limbal epithelial stem cell and corneal epithelial stem cell hypotheses. Eyes from CAGG-CreER; R26R-LacZ mice that were injected with tamoxifen to induce LacZ reporter gene expression and stained for β -galactosidase (β -gal) activity after different chase periods. The pigmented iris is visible through the cornea and appears grey, whereas the β -gal staining is blue. A: Side view of a β -gal-stained eye, after a chase period of 9 wk and 4 d, with several radial β -gal-positive stripes and small patches in the cornea and numerous β -gal-positive patches in the conjunctiva. (The conjunctiva is torn near the limbus and hangs down at the bottom right of the photograph, so the sclera is visible between the limbus and conjunctiva.) Stripe 1 is a limbus-cornea (LC) stripe, with its more peripheral end in the limbus (arrow), consistent with expectations of the limbal epithelial stem cell (LESC) hypothesis (see Figure 5). It also appears to be aligned with other β -gal-positive patches towards the centre of the cornea so it may be part of a longer discontinuous stripe. Stripe 2 is a cornea-cornea stripe with both ends in the cornea, consistent with the corneal epithelial stem cell hypothesis. However, it is radially aligned with a small β -gal-positive patch in the limbus (arrow), which could be the location of a β -gal-positive LESC. If so, stripe 2 might be a discontinuous stripe, which extended from a LESC that was not continuously active (consistent with the LESC hypothesis); B: Anterior (frontal) view of a β -gal-stained eye, after a 14-wk chase period, with eight radial β -gal-positive stripes. All eight stripes are LC stripes with one end at the limbus and many extend the full radius and have a curved end, consistent with a central spiral pattern, as reported for other chimaeric and mosaic eyes^[27,72,73]. CAGG-CreER; R26R-LacZ mice were produced by crossing CAGG-CreER and R26R-LacZ mice [full names Tg(CAG-cre/Esr1*)5Amc and B6.129S4-Gt(ROSA)26Sortm1Sor/J; references^[116,117]]. LacZ reporter gene expression was induced at 12 wk by 3 injections of tamoxifen (100 μ g/g body weight per injection).

illustrated in Figure 6A was stained for β -gal activity after chase period of 9¹/₂ weeks. Stripe 1 has its peripheral end in the limbus and its more central end in the cornea so, using the stripe classification system described for mosaic *KRT5*^{LacZ/-} transgenic mice^[17], it is classified as a limbus-cornea (LC) stripe. This is consistent with expectations of the LESC hypothesis (Time 2 in Figure 5A), particularly as the stripe does seem to extend into the limbus itself (arrow in Figure 6A). A peripheral stripe could also be consistent with the original CESC hypothesis (Figure 5B) or the centripetal version shown in Figure 5D, although, in the latter case, peripheral stripes would be expected to be entirely within the cornea (CC stripes). This LC stripe fits less well with the hypothesis that all the CESC are located in the very centre of the cornea (Figure 5C) unless additional assumptions are made (e.g., stripes have already extended to the periphery by 9¹/₂ weeks).

Stripe 1 also appears to be radially aligned with other β -gal-stained tissue located more centrally so it may be a longer discontinuous stripe. Discontinuous stripes have been discussed elsewhere for *KRT5*^{LacZ/-} transgenic mosaics^[17] and also occur in mouse chimaeras and X-inactivation mosaics^[27,72,103]. The discontinuities in β -gal staining shown in Figure 6A could reflect: (1) separate clones of cells derived from β -gal-positive and β -gal-negative CESC or TACs that are radially aligned; (2) dispersal of a β -gal-positive clones by incursions from laterally adjacent β -gal-negative clones; or (3) alternating contributions of more than one stem cell to a single radial stripe if individual stem cells cycle through phases of activity

and quiescence.

Stripe 2 in Figure 6A is a cornea-cornea (CC) stripe with both ends in the cornea, consistent with the predictions of the original CESC hypothesis at Time 2 (Figure 5B) or the centripetal version shown in Figure 5D. However, it might also be consistent with the LESC hypothesis (Figure 5A) because this stripe is radially aligned with a small β -gal-stained patch in the limbus, which could mark the location of a β -gal-positive LESC. If so, stripe 2 might be a discontinuous stripe formed in two phases. During the first phase a β -gal-positive region might have extended from a β -gal-positive LESC, which was active during the early part of the chase period. This could have been followed by extension of a β -gal-negative region generated by an adjacent active β -gal-negative LESC, if the β -gal-positive LESC became inactive during the later part of the chase period.

The eye shown in Figure 6B was stained after a 14-wk chase period and has eight β -gal-positive stripes, all of which are LC stripes, consistent with the LESC hypothesis (Time 3 in Figure 5A) and both the original CESC hypothesis (Figure 5B) and the variant shown in Figure 5C. However, the variant CESC hypothesis shown in Figure 5D predicts that only a small proportion of stripes would extend right to the limbus. Some of these stripes span the full radius, consistent with the LESC hypothesis (Figure 5A) and the variant CESC hypothesis shown in Figure 5C. It could also be consistent with the original CESC hypothesis (Figure 5B) and the centripetal version, shown in Figure 5D, if full-radius stripes comprised several shorter stripes produced by β -gal-positive

CESCs aligned on the same radius. However, most of the cornea is β -gal-negative so it seems unlikely that the *LacZ* reporter would be activated in radially aligned CESCOs but not in many of the other CESCOs, located elsewhere in the corneal epithelium.

The preliminary results shown in Figure 6 and the alternative explanations of discontinuous stripes indicate that the interpretation of the stripe patterns may be more complicated than predicted in Figure 5, so detailed analysis of many more eyes and different chase periods will be required to resolve the LESC vs CESC debate. Nevertheless, this lineage-tracing approach appears to be a promising way of resolving the conflicting evidence from transplantation experiments and mosaics. Although important, the evidence from conventional mosaics is limited because the time of stem cell labelling cannot be controlled and occurs early in development. Even lineage tracing with a GFP-tagged lentiviral marker (Figure 4E and F) relied on marking one cell population before birth^[79]. In contrast, a tamoxifen-inducible transgenic reporter system enables cells to be labelled at a specific time in the adult without the risk of disturbing homeostasis with surgical intervention.

While this review was in preparation, a similar lineage tracing study was published online, in a preliminary form, and this has already been mentioned in the section on cell movement^[64]. This used K14-CreER^{T2}; R26R-confetti mice, where the keratin 14 (K14 or *Krt14*) promoter, rather than a ubiquitous promoter, was used to drive tamoxifen-inducible CreER^{T2}. The multi-colour "R26R-confetti" fluorescent reporter^[100] was used to identify labelled cells. This reporter is based on an earlier "brainbow" construct^[104] and is also similar to that used for the zebrafish cornea^[102]. According to the authors, immunofluorescence showed that K14 protein was present in basal epithelial cells in the mouse limbus but the central corneal epithelium had much lower levels. Thus, limbal epithelial cells will be preferentially targeted for labelling, making it difficult to test whether CESCOs exist. On the other hand, a chase period to remove short-lived clones formed by TACs rather than stem cells is less important than for the experimental design shown in Figure 5, where CreER is expressed ubiquitously.

Mice were treated with tamoxifen at 6 wk and corneas of the same mice were imaged repeatedly to allow changes in size and position of different clones to be tracked in real time. This elegant time-lapse study showed that labelled cells began to emerge from the limbus 5 wk after tamoxifen treatment and the same stripes were tracked at 9, 13, 17 and 21 wk, as they extended into the centre of the unlabelled cornea without overlapping. The frequency of labelled clones was higher than for the preliminary results illustrated for tamoxifen-treated CAGG-CreER; R26R-*LacZ* mice, shown in Figure 6. However, because the multi-coloured R26R-confetti reporter randomly labelled cells with one of up to ten different colours, individual

adjacent clones could be distinguished easily. In addition to the radial stripes, the authors reported the presence of some rare, small patches of labelled cells in the cornea, which they suggested might have arisen in the cornea itself.

This is an important study as it is the first lineage tracing investigation of the mouse cornea with an inducible marker that was activated in adults. In particular, the informative, real-time study with live mice proved that individual cells labelled in the adult limbal epithelium could form long-lived clones that extend centripetally across the complete radius of the cornea during normal homeostasis. This effectively provides a non-surgical equivalent of the limbal transplantation experiment described by Majo *et al.*^[11] and supports the interpretation that the outcome of the transplantation was adversely affected by the surgical procedures and homeostasis was perturbed. If so, this would undermine the evidence for the CESC hypothesis and reconcile the conflicting evidence from surgical transplantation experiments and conventional mosaics. In effect, all the available evidence would then be consistent with the LESC hypothesis. To further clarify the situation, additional investigations, driving CreER from a promoter expressed in the corneal epithelium, are now required to investigate whether long-lived clones can arise in the adult cornea as well as the limbus.

CONCLUSION

There is strong evidence that the corneal epithelium is maintained by stem cells rather than solely by proliferation of more differentiated cells in the basal corneal epithelium. Most evidence also favours the conventional LESC hypothesis, which proposes that limbal epithelial stem cells maintain the corneal epithelium during normal homeostasis. Although limbal transplantation experiments favour the alternative CESC hypothesis, this result could be reconciled with the LESC hypothesis if surgical transplantation perturbed normal homeostasis and affected the outcome. This possibility is supported by a recent non-surgical, lineage-tracing experiment, which demonstrated that clonal derivatives of cells in the limbal epithelium move into the corneal epithelium during normal homeostasis. Thus, the available evidence supports the conclusion that, during normal homeostasis, the corneal epithelium is maintained by stem cells in the limbus, which produce daughter TACs that migrate centripetally, rather than any stem cells in the corneal epithelium itself. However, if homeostasis is compromised, so the limbal epithelial stem cells are unable to maintain the corneal epithelium, it seems likely that TACs in the basal corneal epithelium can act as long-term progenitors and maintain the tissue for a considerable time in the absence of functional LESCOs.

ACKNOWLEDGMENTS

We thank Dr. Steven D Morley for helpful discussion and critical comments on the manuscript and Mr. Ronnie Grant for assistance with illustrations. We also thank Dr. Alan W Flake, Dr. Takayuki Nagasaki, Springer Science+Business Media, Developmental Dynamics, Molecular Vision and Molecular Therapy for permission to reproduce images as indicated in the figure legends. We are grateful to the Biotechnology and Biological Sciences Research Council and the Wellcome Trust for support for our own research.

Core tip: Both neural stem cells (NSCs) and imprinted genes participate in the same developmental processes. Here, we will explore the possibility that these two processes actually interact with each other. We will exemplarily consider the role of single imprinted genes in NSC biology based on their functional relationship to the imprinted gene *Zac1*, which is itself at the focus of this review due to its role in directing neuronal vs astroglial differentiation of NSCs and as a central hub of an imprinted gene network comprising genes important to NSC biology.

Abstract

Neural stem cells (NSCs) and imprinted genes play an important role in brain development. On historical grounds, these two determinants have been largely studied independently of each other. Recent evidence suggests, however, that NSCs can reset select genomic imprints to prevent precocious depletion of the stem cell reservoir. Moreover, imprinted genes like the transcriptional regulator *Zac1* can fine tune neuronal vs astroglial differentiation of NSCs. *Zac1* binds in a sequence-specific manner to pro-neuronal and imprinted genes to confer transcriptional regulation and furthermore coregulates members of the p53-family in NSCs. At the genome scale, *Zac1* is a central hub of an imprinted gene network comprising genes with an

INTRODUCTION

Neural stem cells (NSC), also known as neural precursor cells (NPC), are the common source of all neuronal and glial cells, including astrocytes and oligodendrocytes, in the developing and adult CNS. They arise from the neuroepithelial layers which line the spinal canal and forebrain ventricles at early embryonic stages and reside in circumscribed regions in the postnatal

brain to produce in a spatio-temporal controlled manner a variety of cell-types. Following a series of symmetric proliferative divisions, NSCs progress to asymmetric neurogenic divisions. Hereby, the parent cell maintains the progenitor state while the daughter cell migrates to its final destination, exits from the cell cycle, differentiates and participates in the formation of complex neural networks^[1]. Although the last decade has witnessed major progress on the pathways and genes coordinating NSC behavior, a potential role of imprinted genes has been largely ignored. In this review, we will consider current evidences for the general impact of imprinted genes in NSC cell fate decisions and differentiation with a particular focus on their relationship with the imprinted gene *Zac1*, as well as the role of *Zac1* itself, which encodes a versatile transcriptional regulator.

GENOMIC IMPRINTING

Although equivalent complements of paternally and maternally expressed autosomes are transmitted from parent to offspring, select autosomal regions can be lastingly silenced as a result of their parental origin. This process takes place in the respective parental germ cells and is known as genomic imprinting. Germline-derived imprints are preserved during fertilization and somatic development with few remarkable exceptions (see below). Some 120 genes with a verified imprinting status have been identified in mouse, which are largely conserved in human and correspond to less than 1% of the genome^[2]. A considerably larger number of genes with a strong bias in allele-specific expression has been recently detected in mice brains although an authentic imprinting status has still to be proven^[3,4]. In this respect we note that the reported number of genes showing allele-specific expression differences in mice actually matches general estimates on tissue-specific and allele-specific differences in human gene expression (approximately 10%) based on common genetic variations (*i.e.*, single nucleotide and copy number polymorphisms)^[5]. This observation speaks against the hypothesis that most of these allelic differences originate from genomic imprinting.

Multiple molecular mechanisms govern imprinted gene expression, they include CpG methylation of specific DNA sequences, ncRNAs, alterations in chromatin structure, and posttranslational histone modifications (*e.g.*, lysine acetylation, lysine and arginine methylation, serine phosphorylation, and covalent binding of the small peptide ubiquitin)^[6,7]. Above all, DNA methylation is at the center of the imprinting process and is thought to catalyze the establishment and life-long maintenance of genomic imprints. Differentially methylated regions (DMR), which harbor CpG-rich regulatory sequences, play a critical role in determining parental allele-specific expression. With few exceptions (*i.e.*, *Zac1*) imprinted

genes cluster in huge, conserved chromosomal domains throughout the genome, and their well-balanced expression enables regular development from fetus to early postnatal life^[8,9].

GENOMIC IMPRINTING AND THE BRAIN

Dysregulation of imprinted gene expression can elicit complex neurodevelopmental syndromes in humans, frequently associated with mental retardation [*i.e.*, Angelman syndrome (OMIM 105830) and Prader-Willi syndrome (OMIM 176270)]^[10]. Moreover, psychotic and autistic spectrum disorders possibly result from more subtle deregulation of imprinted genes. Indeed, mice harboring altered dosage of single or multiple imprinted genes showed various defects in higher brain functions ranging from learning^[11] and memory formation^[12] to social and nurturing behaviors^[13-15].

A ROLE OF IMPRINTED GENES IN NSCS?

On a historical ground, both NSCs and imprinted genes have been studied in the context of brain development. While our insight into the role of NSCs in brain development has largely expanded over the last decade^[1], the molecular targets and cellular pathways by which imprinted genes participate in brain development remain poorly defined. Importantly, the roles of NSCs and imprinted genes have been commonly investigated independently of each other although they apparently participate in the same developmental processes. Thus, new studies should explore possible reciprocal interactions between imprinted genes and NSCs during neurodevelopment. Here, we highlight recent evidences in the scientific literature on the critical role of imprinted genes in NSCs and major cellular processes they control.

INSULIN-LIKE GROWTH FACTOR 2

Insulin-like growth factor (*Igf2*) was the first mammalian gene shown to be maternally imprinted as a result of a differentially methylated imprinting control region (ICR) located nearby and upstream of *H19*, which is imprinted in the opposite direction (see below)^[16].

The product of *Igf2* is a potent growth factor promoting cell survival, proliferation, and differentiation by binding with high affinity to the insulin-like receptors *Igf1r* or *Igf2r*, but less efficiently to the insulin receptor (*Insr*). Hereby, *Igf2r* has no signaling function and is encoded by the paternally imprinted *Igf2r* gene. This antagonistic functional relationship together with the opposite imprinting of *Igf2* and *Igf2r* originally stimulated the genetic conflict hypothesis for genomic imprinting^[17].

During CNS development, *Igf2* is for the most part synthesized by the choroid plexus, and released into the cerebrospinal fluid (CSF), which contacts the primary cilia and apical surfaces of cortical progenitors.

There, CSF-borne Igf2 binding to the Igf1r stimulates neural precursors proliferation^[18].

Neurogenesis is maintained at a low level in the adult brain in so-called neurogenic niches, which comprise the subventricular zone (SVZ) of the lateral ventricles and the subgranular zone (SGZ) of the dentate gyrus (DG) of the hippocampus. Adult neurogenesis resembles in many aspects embryonic neurogenesis and raises the possibility of an additional role of Igf2 in stemness maintenance in the mature brain. In support of this hypothesis, transcriptome analysis of the SGZ evidenced substantially higher expression of Igf2 in stem cells than in immature neurons^[19]. Igf2 expression localized to radial-glia like NSCs (Nestin⁺, Sox2⁺, and Gfap⁺) and to a significant fraction of dividing cells (Ki67⁺). Interestingly, Igf2 enhances *in vivo* and *in vitro* the proliferation of NSCs isolated from the DG, but not from the SGZ, indicative of a site-specific effect. Finally, the secretion of Igf2 by Nestin⁺ progenitors in the external granule cell layer (EGL) potently stimulates neuronal cell proliferation whereas overexpression of Igf2 in granule neurons facilitates tumor formation in rodents^[20].

In sum, these reports show that *Igf2* enhances in a tissue- and age-dependent manner NSC proliferation and maintenance.

***H19* ncRNA**

The maternally imprinted *H19* locus localizes in tandem with the oppositely imprinted *Igf2* gene^[16] and encodes high levels of a 2.5 kb long RNA polymerase II-derived transcript. This large intergenic non-coding RNA (lincRNA) is not involved in the imprinting process^[21,22] but inhibits *in vitro* and *in vivo* tumor growth possibly due to its participation in and regulation of an imprinted gene network (IGN, see below).

Additionally, the first exon of *H19* encodes a micro RNA-containing hairpin that serves as a template for the miRNA 675, which reduces Igf1r expression and Igf2-signalling in the placenta^[23]. These self-restraining activities of the tandem *Igf2-H19* locus are necessary for normal embryogenesis and protect against parthenogenetic development in mammals^[24].

Erasure of imprinting at the *Igf2-H19* DMR is found in primordial germ cells (PGS) and associates with overexpression of *H19* RNAs at the expense of Igf2. This epigenetic switch-off is thought to safeguard PGS quiescence and prevent from teratoma formation^[25].

A similar strategy seems to be used by very small embryonic-like stem cells (VSELs), a population of very rare early-development cells with broad differentiation potential^[26]. VSELs can give rise to neurons, oligodendrocytes, and microglia among other cell types and possibly fulfill a role in physiological tissue rejuvenation and regeneration following cell damage.

In VSELs, the paternally silenced allele of select imprinted genes (*i.e.*, *Igf2-H19* and *Rasgrf1*) is reactivated by demethylation and results in biallelic expression. Conversely, select maternally expressed

alleles (*i.e.*, *Peg1*, *Igfr2*, and *p57^{Kip2}*) undergo deactivation and silencing by DNA methylation. Overall, this cell type-specific resetting of a limited number of genomic imprints supports growth-inhibition, cellular quiescence, and preservation of the stem cell population. On the other hand, methylation at the *Igf2-H19* DMR slowly increases with aging and has been suggested to facilitate increased insulin signaling and age-related depletion of the VSELs reservoir^[27].

Taken together, integrate imprinting at the *Igf2-H19* tandem locus critically controls growth and cell proliferation in the early embryo as well as in VSELs.

DELTA-LIKE HOMOLOG 1

The imprinted *Dlk1-Dio3* domain harbors the delta-like homolog 1 (*Dlk1*) and type III iodothyronine deiodinase (*Dio3*) genes which are expressed from the paternal derived chromosome. Similarly to the *Igf2-H19* locus, *Dlk1* and the close by *Gtl2* (gene trap locus 2, *alias* maternally expressed gene 3, *Meg3*) are imprinted in an opposite manner and locate 80 kb apart from each other. Three DMRs containing specific epigenetic signatures are hypermethylated on the paternal allele in somatic tissues^[28]. Hereby, those DNA methylation marks which are deposited in the paternal germline are confined to the central DMR. This region contains tandem repeats and localizes in the intergenic region of the tail-to-head orientated *Dlk1* and *Gtl2* genes (Figure 1).

Dlk1 encodes a transmembrane protein and closely resembles the Notch/Delta/Serrate type family of signaling molecules. Due to minor albeit important structural differences *Dlk1* is thought to compete with canonical Delta-like (DLL) ligands at the Notch receptor and to inhibit downstream signaling^[29].

Dlk1 is broadly expressed in developing mouse tissues and continues to be expressed in some adult neuronal tissues (*i.e.*, ventral striatum, septum, and ventral tegmental area) including the SVZ^[29,30]. Here, *Dlk1* is detected in NSCs (Nestin⁺, Sox⁺, Gfap⁺) and astrocytes (Sox2⁺, Gfap⁺, S100b⁺) localized to the germinal niche but not in differentiated parenchymal astrocytes (Gfap⁺, S100b⁺) and neuroblasts (β III-tubulin⁺). NSCs mainly express the membrane-bound form of *Dlk1* that is poorly active on its own but necessary for the response to secreted *Dlk1* produced by nearby astrocytes.

Postnatal deletion of *Dlk1* enhances NSC proliferation in the SVZ, causing the depletion of the quiescent NSC pool and reduced neurogenesis at later ages. Interestingly, this process takes place irrespectively of the parental origin of the deleted allele^[30], suggesting that *Dlk1* can be expressed from either parental allele. Indeed, both alleles of *Dlk1* are expressed from postnatal day 7 onward in NSCs and niche astrocytes as a result of an increase in methylation at the germ line targeted ICR of the maternal allele (Figure 1). This postnatal epigenetic switch at the *Dlk1* locus is

Figure 1 Genomic imprinting at the *delta-like homolog 1* locus is reset in the subventricular zone. A: *Delta-like homolog 1* (*Dlk1*) is monoallelically expressed from the paternal allele during development. Silencing of the maternal allele takes place in non-neuronal and various neuronal tissues such as the subventricular zone (SVZ) of the lateral ventricle (SVZ) and the medial septum (MS). At the molecular level, maternal silencing results from the absence of DNA methylation at the intergenic, germ line-controlled differentially methylated regions (DMR) (unfilled hexagon), which resides between the *Dlk1* and *Gtl2* genes and their associated DMRs (unfilled lollipops). Conversely, methylation at the intergenic DMR (filled hexagon), the 3' end *Dlk1* DMR and the *Gtl2* DMR (filled lollipops) associates with expression from the paternal allele. The same methylation patterns are present in the SVZ (left scheme) and MS (right scheme) at embryonic ages; B: *Dlk1* shows biallelic expression from postnatal day 7 onward towards adulthood in the SVZ, but not in the MS. Hereby, the maternal methylation pattern closely resembles the one on the paternal allele (*i.e.*, methylation at the 3' end *Dlk1* DMR, the intergenic DMR, but not the *Gtl2* DMR). At opposite, the methylation pattern in the MS is preserved and determines monoallelic *Dlk1* expression.

confined to the neurogenic areas, whereas all other tissues continue to express *Dlk1* exclusively from the paternal allele from embryogenesis to adulthood.

These findings suggest that genomic imprints at select loci (*i.e.*, *Igf2-H19* and *Dlk1*) are dynamically regulated in NSCs during specific developmental time windows, possibly to match the need for cell stemness vs cell differentiation.

NECDIN

Human and mouse *necdin* genes are maternally imprinted and localize to chromosome 15 q11.2 and a syntenic segment on chromosome 7, respectively^[10], within a cluster of paternally expressed genes.

Paternal deletion of this chromosomal segment in human underlies the neurodevelopmental Prader-Willi syndrome, which manifests with feeding anomalies, gross obesity, and hypogonadism^[10].

Necdin (*Ndn*) is broadly expressed in postmitotic neurons from early embryonic to adult ages with particular high expression in the developing hypothalamus, medulla oblongata, pons, and midbrain. Knock out mice show variable neonatal lethality, reductions in oxytocin and luteinizing hormone-releasing hormone producing hypothalamic neurons, impairments in serotonergic and catecholaminergic projections, and decreased tangential migration of neocortical interneurons from the basal forebrain^[31].

Ndn was originally discovered in a screen for

genes induced in neurally differentiated embryonic carcinoma cells^[32]. Functionally, Ndn potently inhibits proliferation in favor of differentiation by virtue of its interaction with various proteins critically involved in cell cycle progression and survival^[33,34]. Similar to the retinoblastoma tumor suppressor gene, Ndn binds to the carboxyl-terminal transactivation domain of E2F1 to repress its activity and consequently cell cycle progression^[33]. On the other hand, Ndn interacts with the amino-terminal transactivation domain of p53 to abolish its proapoptotic function without interfering with p53-dependent cell cycle arrest^[34]. Ndn also recruits the deacetylase sirtuin 1 to promote deacetylation of p53 leading to its inactivation and protection against DNA damage induced neuronal apoptosis^[35].

Furthermore, Ndn interacts and promotes the degradation of the hypoxia inducible factor-1 alpha (HIF) under normoxia^[36], whereas hypoxia enhances degradation of Ndn in primary NSCs through the HIF-associated ubiquitin-proteasome system^[37].

Interestingly, a growing number of reports (e.g.,^[38-40]) suggest that NSC proliferation is increased under hypoxia. Accordingly, Ndn-deficient NSCs show increased proliferation and apoptosis under normoxia, but not under hypoxia, which triggers degradation of endogenous Ndn in wild-type NSCs. Moreover, Ndn null mice show higher rates of NSC proliferation and apoptosis [e.g., in the embryonic (E14.5) ganglion eminence], strengthening Ndn's dual role in the suppression of proliferation and apoptosis^[33-35].

Ndn controls additionally the proliferation of NSCs in the ventricular zone of the embryonic cortex as evidenced by an upregulation of the stem cell marker Sox2, a downregulation of the cyclin-dependent kinase inhibitor p16^{Ink4}, and significantly increased proliferation rates in Ndn null mice^[41]. Interestingly, Ndn binds *in vitro* and *in vivo* to the polycomb protein Bmi1 and counteracts Bmi1-dependent inhibition of the p16^{Ink4} promoter and consequently promotes NPC proliferation. Conversely, overexpression of Bmi1 prevents Ndn-mediated inhibition of E2F1-driven Cdk1 promoter activity^[41].

Together, these findings suggest that Ndn controls NSC proliferation and apoptosis in an oxygen-dependent manner through interaction with various proteins driving cell proliferation (E2F1, Bmi1) and apoptosis (p53, Sirt1).

differentiation, quiescence, senescence, or apoptosis.

The formation of early progenitors from neuro-epithelial cells and the transition from proliferative symmetric to neurogenic asymmetric division is accompanied by a lengthening of the cell cycle, preferentially in G1-phase, implicating an involvement of CKIs^[42].

Paternally imprinted *p57^{Kip2}* gene encodes a cyclin-dependent kinase inhibitor (CKI)^[43] expressed in the VZ and SVZ, midbrain, thalamus, hypothalamus, cortical plate, septum, basal ganglia, cortex, and mantle zone of the hippocampus during development^[44,45]. By means of controlling cortical progenitor cell cycle exit, *p57^{Kip}* influences the migration and differentiation of neuronal precursors. Absence of *p57^{Kip2(+/-)}* during late embryogenesis and postnatal life gives rise to cortical hyperplasia. *p57^{Kip2(+/-)}* deficiency leads to an increased proliferation of radial glia cells (RGC) and intermediate precursors (IPC) and promotes re-entry into the cell cycle during corticogenesis^[46]. Cell cycle analysis of RGCs and IPCs evidenced an abnormal short cell cycle length favoring precursor proliferation and aberrant migration into cortical layers.

In mice adult hippocampus, *p57^{Kip2}* deficiency causes the severe depletion of the NSC reservoir by enhancing neuronal differentiation of NSCs at early stages of life^[47]. Moreover, consistent with a role of *p57^{Kip2}* in restraining NSC proliferation, neurogenic stimuli such as extensive running elicit a stronger activation of NSCs in mid-aged *p57^{Kip2(+/-)}* animals indicating that *p57^{Kip2}* might also play a critical role in the life long plasticity of brain functions^[47].

In addition to their canonical role in cell cycle control, CKIs have further functions including transcriptional regulation^[48]. As an example, nuclear *p57^{Kip2}* expression rises transiently during early telencephalic progenitor proliferation [embryonic day (E) 12.5] without inducing cell cycle exit. Instead, *p57^{Kip2}* interacts with the pro-neuronal basic helix-loop-helix (bHLH) factor Mash1 and blocks its transcriptional activity. As a result, *p57^{Kip2}* delays neuronal differentiation of telencephalic progenitors by antagonizing Mash1.

Taken together, *p57^{Kip2}* through inhibition of cell cycle progression and unrelated transcriptional mechanisms regulates many key processes in NSCs, including proliferation, cell cycle exit, differentiation, cell fate decisions, and stem cell quiescence in a cell type- and age-specific manner.

CYCLIN-DEPENDENT KINASE INHIBITOR *P57^{KIP2}*

The catalytic activity of cyclin-dependent kinases (CDK) is regulated by the binding of cyclins which oscillate periodically during the cell cycle and drive the orderly progression through consecutive phases. Conversely, inhibition of these complexes by CKIs induces transient or permanent cell cycle arrest,

ZINC FINGER PROTEIN REGULATING APOPTOSIS AND CELL CYCLE ARREST

The *Zac1* gene is maternally imprinted and maps on chromosome 10 in mice and chromosome 6q24 in human^[49,50]. The presence of a canonical C2H2 zinc finger domain and the potent induction of apoptosis and cell-cycle arrest in transformed tumor cells inspired originally the naming "*Zac1*"^[51].

An increased dosage of ZAC1 due to chromosomal anomalies or imprinting defects at the DMR is the most frequent genetic defect underlying transient neonatal diabetes mellitus (TNDM)^[52]. This disease manifests with intrauterine growth retardation (IUGR), dehydration, hypoinsulinemia, and early-onset hyperglycemia in term, newborn infants. Transgenic mice, which harbor an extra copy of the human ZAC1 locus, display key symptoms of the human condition and show at the cellular level an impaired proliferation and maturation of β -cell progenitors^[53]. In naïve pancreata, Zac1 is preferentially expressed in insulin-positive progenitor cells and increases strongly perinatally with the onset of terminal differentiation. At the same time, Zac1 confers repression following binding to specific DNA elements (see below) at the proximal promoter of the paternally imprinted *Rasgrf1* gene, an important modulator of various growth factor pathways. As a result, stimulus-induced activation of mitogen-activated protein kinase and phosphoinositide 3-kinase pathways and, ultimately, insulin secretion is impaired under conditions of increased Zac1 dosage^[54].

Zac1 confers transcriptional regulation either by DNA-binding^[50,55-57] or as coregulator of the nuclear receptor family, in particular of those members belonging to the subgroup of steroid receptors^[58], and furthermore, by coactivation of members of the p53 family^[59,60]. Transcription factors typically comprise separable, modular DNA-binding and transcriptional domains; the latter confer gene activation and repression in a context-dependent manner^[61]. Zac1 matches well to these criteria, whereby its diverse transcriptional functions are tightly controlled by the interaction of single zinc fingers at the level of protein-protein and protein-DNA interactions^[55,62].

The N-terminal zinc finger domain, containing seven canonical C2H2 zinc fingers, is highly conserved in mouse and human Zac1 proteins and across the *Zac1* gene family^[63]. Mouse and human proteins diverge, however, by a central region rich in proline residues and a C-terminal cluster of glutamic acid residues both of which exist exclusively in mice. The proline-rich region together with the adjacent upstream region, termed linker region, confers potent transactivation^[64]. This function is further enhanced by the simultaneous recruitment of the general coactivators p300/CBP through the C-terminus. In contrast to the separable function of multiple domains in mice, transactivation and p300 recruitment map indistinguishably to the C-terminus of human Zac1^[62].

Zac1 can bind as a monomer to GC-rich palindromic DNA-elements or as a dimer to direct and reverse repeat elements to confer transactivation. Conversely, Zac1 binding to a half-site of a repeat element causes repression^[55]. Mechanistically, the zinc fingers assist in the recruitment of p300 and regulate p300's catalytic activities in a manner dependent on the nature of the bound DNA element^[62]. Hereby, single zinc fingers can

participate selectively in DNA binding and/or regulation of coactivator activities.

Moreover, Zac1 can also act as a coregulator for unrelated transcription factors comprising nuclear steroid or thyroid hormone receptors or various members of the p53 family (including p53 itself, p63, and p73). All of these transcription factors bind to specific DNA elements at their target genes to critically control cell proliferation and differentiation in a cell type-specific manner^[58,59]. For example, Zac1 is recruited jointly with the coactivators p300 and PCAF by the tumor suppressor p73 at the *p21^{Cip1}* promoter during early neuronal differentiation (see below). In addition to serving as a scaffold for coactivator assembly, Zac1 furthermore regulates PCAF's catalytic functions similar to the ones of p300^[65]. Overall, this close relationship between Zac1 DNA-binding and enzymatic regulation of transcription might contribute to the precise and efficient regulation of target genes.

In brief, Zac1's transcriptional activities are coordinated by sequence-specific DNA binding or the coregulation of unrelated transcription factors.

Zac1 expression during neurodevelopment

Zac1 is highly expressed in progenitor/stem cells of neuroectodermal and mesodermal tissues during early embryogenesis^[66]. Zones of active cellular proliferation, comprising the telencephalic vesicles and the infundibular recess of the third ventricle (the origin of the neurohypophysis) show robust Zac1 expression at E9.5 and E12.5. Moreover, Zac1 is also detected in mitotically active regions of the developing nervous system including the neural tube at E9.5 and the neural retina at E10.5. At later stage of neurodevelopment, high levels of Zac1 expression appeared in the mitotically active cell layers lining the VZ of the 3rd and 4th ventricle, the EGL of the cerebellum, and different neuroepithelia (*e.g.*, infundibulum, ventral hypothalamic sulcus)^[67,68].

As noted before, Zac1 expression induced apoptosis and cell cycle arrest in transformed tumor cells^[50,51,56] raising the question of its function in neural progenitor cells. In this respect, the analysis of Zac1 deficient mice (*Zac1^{+/-}*) provided interesting insight into the role of Zac1 in the brain^[69]. Specifically, these animals revealed a high incidence of hydrocephalus, a significant decrease in brain size, and a substantial increase in the proliferation rate of progenitor cells in the germinative zones of the dentate gyrus, the RMS of the olfactory system, and the dentate gyrus^[70]. At the same time, the number of Nestin⁺ cells was largely unaffected, compatible with the view that Zac1 rather controls the proliferation of progenitor cells than of stem cells. Yet, a limitation to this work is the fact that Zac1 deficient mice develop IUGR, various skeletal anomalies, and postnatal lung failure pointing to additional defects at the level of single organs and whole systems that are likely to impact on brain development. As an alternative to the multilayered

phenotype of *Zac1* knock out mice, we conducted genome wide expression profiling (see below) in order to identify *Zac1* target genes and analyzed their roles in well-defined *in vitro* and *in vivo* systems to elucidate *Zac1*'s function at the cellular level.

***Zac1* target genes in NSCs**

Pituitary adenylate cyclase activating polypeptide receptor 1: The first *Zac1* target gene to be identified was the G-protein coupled receptor for the neuropeptide pituitary adenylate cyclase activating polypeptide (PACAP)^[51,57,71], which controls various neuroendocrine functions in addition to its role as potent neurotrophic factor^[72-74]. Mechanistically, *Zac1* binds to an imperfect palindromic DNA element localized in the proximal polypeptide receptor 1 (*Pac1*) promoter to confer transactivation in a cell-type specific manner and to compete at the same time with the estrogen receptor dependent activation of *PAC1*^[75].

PACAP and *PAC1* are broadly expressed in the fetal brain and reduce the proliferation rate of certain neural precursor populations. At E13 in rat, PACAP can be detected hippocampus, hypothalamus, cortex, amygdala, dorsal root ganglia, and spinal cord, whereas *PAC1* is expressed in the neural plate, the neuroepithelia of the mesencephalon and rhombencephalon at E9, and in the neuroepithelia of the cortex, hippocampal formation, and cerebellum at E11, and in the basal telencephalon and olfactory bulb from E13 and E16 forward, respectively^[76]. PACAP induces a sharp increase in *p57^{Kip2}* expression in embryonic cortical precursors resulting in decreased CDK2 kinase activity, S-phase entry, and DNA synthesis. Furthermore, PACAP promotes the association of *p57^{Kip2}* with the kinase complex supporting its anti-mitogenic activity in neural progenitors. In accord with the specific role of *p57^{Kip2}* in cortical neurogenesis (see above), the expression levels of CDK2, cyclin E, or of the CKIs *p21^{Cip2}* and *p27^{Kip1}* remain unaffected by PACAP.

Coregulation of *p53* and *p73* target genes: As noted before, *Zac1* can serve as a coregulator for *p53* and *p73* due to its scaffolding function and regulation of coactivator activities^[59,65]. The *p53* family consisting of *p53* itself, *p63*, and *p73* encodes transcription factors with a key role in proliferation, differentiation, apoptosis, stem cell renewal and cell fate commitment^[77].

Zac1 coregulation of *p53* has been originally discovered in a cervical carcinoma cell line^[59] and led us to investigate its potential role in NSCs. Consistent with previous studies^[78,79], we observed high levels of *p53* in the undifferentiated state in ESCs which reside primarily in the cytoplasm^[80] and decline upon differentiation^[65]. At the same time, *p53* binds to the promoter of the pluripotency genes *Nanog* and *Oct-4*^[81,82], represses their transcription, and triggers the transition from self-renewal to differentiation.

Although *Zac1* has been reported to co-repress nuclear receptors in a cell-type specific manner, no evidence exists for a comparable role towards members of the *p53* family^[58,59].

In the developing brain, *p53* is expressed in progenitor cells of the SVZ^[83] where it induces cell-cycle arrest, DNA repair and cell death following genotoxic stress^[84]. *p53*-deficient mice show higher cell proliferation in the SVZ and enhanced neurosphere formation *in vitro*^[83,85] consistent with a role of *p53* as negative regulator of NSC self-renewal. Moreover, *p53* seems to be involved in different aspects of NSC differentiation including repression of self-renewal and promotion of gliogenesis^[86,87].

Mounting experimental evidence indicates that endogenous reactive oxygen species (ROS) play a critical role in cell signaling and NSC physiology including appropriate timing of neurogenesis. In this respect, the pattern of ROS generation matches the one of *p53* immunoreactivity in the developing telencephalon. Similarly to *Zac1*, nuclear *p53* is detected in Nestin⁺ NSCs in E11 and E13 proliferative germinal zones, and its expression decreases towards the cortical plate^[88]. Loss of *p53* function causes enhanced ROS production and premature neurogenesis, which is partly reversed by reinstatement of *p53* or antioxidant treatment^[88].

Despite these interesting findings, a role of *Zac1* in any of these *p53*-dependent processes is presently unknown and future studies are needed to address this topic.

p73 has been recognized for its critical role in brain development as evidenced by the highly penetrant phenotype in *p73* null mice which display cortical hypoplasia, hydrocephalus, and hippocampal dysgenesis^[89,90]. The hippocampal anomaly corresponds with either a complete absence or truncation of the lower blade of the neurogenic DG and an abnormal gyration of the Ammon's horn. Isoform-specific *p73* knock-out mice showed that this phenotype results in major part from the absence of the activation-proficient *p73* protein (TAp73) as opposed to the activation-deficient *p73* protein (ΔNp73). The latter isoform lacks *Zac1* coactivation^[65] and is thought to act as a potent prosurvival protein in neurons by counteracting the proapoptotic function of *p53*^[91,92]. Therefore, it would be of interest to investigate the possibility of *Zac1*-dependent coregulation of TAp73 in NSC in greater depth.

Withdrawal of leukemia inhibitory factor (Lif1) potentially induces neuronal differentiation of ESCs and strongly upregulates *Zac1* and *p73* expression concomitantly to a rapid decline in *p53* mRNA and protein^[65]. At the same time, *p73* isoforms switch from activation-deficient ΔNp73, prevailing under the undifferentiated state, to activation-proficient TAp73 and caused a strong up-regulation of the *p21^{Cip1}* and *p57^{Kip2}* genes, two well-known direct *p73* target genes^[93]. As referred to above, DNA bound *p73* recruits *Zac1* to select target genes, where it

serves as a scaffold for coactivator assembly and enhancement of catalytic functions. As a result, *Zac1* enhances p73 transcriptional activities in a site-specific manner^[65]. These findings suggest a joint role for *Zac1* and p73 in inducing cell cycle exit of ESCs and in differentiation towards neural cells.

In vivo studies evidenced a reduced proliferation of neurogenic cells isolated from the E16 and E18 VZ/SVZ and a smaller size of the perinatal SVZ in p73 deficient mice when compared to controls. As a result, p73^(-/-) mice suffer from a depletion of the stem cell compartment at birth pointing to a role of p73 in NSC self-renewal and maintenance^[94]. This function of p73 extends also to the adult neurogenesis in the DG. At the molecular level, p73 deficiency elicits perturbations in the canonical Sox2 and Notch signaling pathways driving NSC proliferation^[95]. Additionally, a reduced transcription of *Hey2*, a negative regulator of activator bHLH proteins, impairs the long-term maintenance of neural precursors in the absence of p73^[95].

Because *Zac1* is expressed in embryonic and adult neural stem cells it could potentially interact with and coregulate TAp73 functions. Presently, the actual evidence remains limited to *Zac1* coactivation of TAp73 during neuronal differentiation of ESCs. However, further studies should address the role of *Zac1* coregulation for NSC self-renewal, maintenance and differentiation at different developmental stages though.

Suppressor of cytokine signaling 3: Genome-wide expression profiling in a cerebellar neural stem cell line (C17.2) using a Tet-off system led to the identification of suppressor of cytokine signaling 3 (*Socs3*), a negative regulator of Jak/Stat3 signaling, as potential *Zac1* target gene^[96].

The transition from neuronal cell types to glial subtype-specific precursors is critically controlled by preset developmental programs and extracellular signals like the cytokine driven Jak/Stat3 pathway, which is largely inactive at early, neurogenic stages and takes on at later gliogenic stages, when the expression of neurogenic factors progressively declines^[97].

Zac1 recognizes a cluster of GC-rich DNA elements in the proximal promoter and intronic region of the mice and human *Socs3* genes to confer transcriptional activation^[96].

Two radial glial-like NSC lines, derived from E15 or the adult SVZ of mice, showed a transient upregulation of *Zac1* mRNA and protein upon neuronal or astroglial differentiation, whereby transactivation of *Socs3* occurred solely under the latter condition indicative of a role of *Socs3* as a lineage-specific target gene. Consistent with this finding, DNA methylation at the *Socs3* gene decreased during astroglial differentiation but remained unaltered during neuronal differentiation. *Zac1* and *Socs3* are expressed simultaneously exclusively during the early

stage of astroglial differentiation and associated with a strong decline in receptor activation-dependent tyrosine phosphorylation of Stat3. In agreement with these results, *Zac1* and *Socs3* are highly expressed in the neocortical ventricular zone at E18, which corresponds to the onset of astroglial differentiation^[96].

Astroglial differentiation is triggered by various cytokines namely cardiotrophin-1, ciliary neurotrophic factor, or leukemia inhibitory factor, which activate Jak/Stat3 signaling^[97-100]. Conversely, genetic deletions in this pathway (*i.e.*, gp130, LIF and Stat3) reduce astroglial differentiation^[97,101,102]. Importantly, overexpression of *Socs3* inhibits Stat3 signaling and impairs astroglial differentiation^[103], whereas conditional deletion of *Socs3* leads to enhanced astroglial differentiation in neonatal mouse brain and primary neuroepithelial cells^[100]. These findings led us to investigate whether *Zac1*-dependent induction of *Socs3* could provide a negative feedback loop to inhibit Jak/Stat3 signaling during early astroglial differentiation of NSCs.

In accord with an inhibitory role in Jak/Stat3 signaling, *Zac1* overexpression delayed astroglial differentiation, independent of a simultaneous increase in the number of cells in transition into G₁ arrest^[96]. Conversely, knock-down of *Zac1* in NSCs facilitated astroglial differentiation and postponed cell cycle arrest. Although lengthening of the G₁ phase has been suggested to initiate differentiation, this mechanism seems not to apply to *Zac1*'s cell cycle arrest function in NSCs and supports the self-sufficient role of *Socs3* in the control of astroglial differentiation. Compatible with this view, knock-down of *Socs3* in *Zac1* overexpressing cells reinstated timely astroglial differentiation. Similar results were obtained in primary E18 NSCs strengthening the role of *Zac1*-dependent regulation of *Socs3* in early astroglial differentiation of NSCs^[96].

Overall, this study provides detailed insight into the molecular mechanisms by which an imprinted gene can fine tune cell-fate decisions and differentiation in NSCs and assigns to *Zac1* a critical role in the prevention of precocious astroglial differentiation (Figure 2).

Transcription factor 4: *Zac1* expression robustly increased under astroglial as well as neuronal differentiation, which led us to question *Zac1*'s function during the latter condition^[96]. The family of bHLH proteins plays a prominent role in cell fate decisions and differentiation. These proteins share the eponymic bHLH domain which is necessary for homo- or heterodimerization and for binding to a specific DNA sequence named E-box motif^[104]. bHLH proteins expressed in the brain can be classified into two groups; the so-called specification factors (*i.e.*, Math, Mash, neurogenin, and NeuroD), which are expressed in a spatiotemporally controlled manner, and their ubiquitously expressed dimerization partners, the E proteins^[105,106]. Under the undifferentiated, proliferative state proneural factors are weakly

Figure 2 Imprinted *Zac1* favors neuronal differentiation of neural stem cells. The *Zac1* gene is maternally imprinted and encodes a versatile transcriptional regulator. *Zac1* expression is strongly induced during neuronal and astroglial differentiation of embryonic and adult neural stem cells (NSCs). During neuronal differentiation (left scheme), *Zac1* binds to GC-rich DNA binding sites at the *Tcf4* promoter and first intron to confer synergistic transactivation. As a result, enhanced *Tcf4* expression promotes binding to and transactivation of the cyclin kinase inhibitor *p57^{Kip2}*, which induces G1 arrest. Moreover, *Zac1* binds to GC-rich DNA elements at the *Socs3* promoter during astroglial differentiation (right scheme). *Socs3* encodes a potent inhibitor of prodifferentiative Jak/Stat3 signaling and prevents precocious astroglial differentiation. The tataa-elements are boxed in light grey and the transcriptional start sites are symbolized by arrows. The first exon in the *Tcf4* locus is depicted as a green box (labeled E) and coding exons of *Tcf4* and *Socs3* as green and red boxes, respectively. *Tcf4* binds to various E-box motifs (light grey circles) localizing to the *p57^{Kip2}* regulatory region.

expressed, prior to a rapid increase in concert with the E-proteins at the initiation of neurogenesis. E-protein family members comprise two splice variants of *E2A* (*E12* and *E47*), *HEB*, and transcription factor 4 (*Tcf4*) (*alias E2-2*, *SEF2*, or *ITF2*), which upon heterodimerization with a specification factor, bind to the promoter of their target genes, in order to promote neurogenesis, and inhibit astroglial differentiation and NSC proliferation^[107,108].

Expression profiling in a NSC line (C17.2) based on inducible *Zac1* expression showed a robust upregulation of *Tcf4* mRNA and protein^[109]. Thereby, *Zac1* bound simultaneously to the proximal promoter and first intron of *Tcf4* and binding at either site was necessary to confer synergistic transactivation.

Neuronal differentiation of ESCs caused a strong *Zac1* and *Tcf4* upregulation and associated with *Zac1* binding at the *Tcf4* gene. As noted before, *Zac1* upregulation following differentiation of embryonic and adult NSC lines occurred under either astroglial

or neuronal differentiation, whereby induction of *Socs3* was confined to the astroglial lineage. Oppositely, *Zac1*-dependent upregulation of *Tcf4* was specific to neuronal differentiation, associated with an overall increase in active chromatin marks but no change in DNA methylation, at the *Tcf4* locus^[109]. *Zac1*-dependent *Tcf4* regulation was also confined to neuronal differentiation of primary NSCs; moreover, *Zac1* binding to and transactivation of the *Tcf4* locus occurred exclusively during periods of neuronal differentiation in the neocortical ventricular zone^[109].

Among known *Tcf4* target genes, *p57^{Kip2}* is of particular interest as it is co-regulated with *Zac1* in the framework of an imprinted gene network (see below), it critically controls differentiation and migration of radial glia cells, and shares with *Zac1* and *Tcf4* a cell cycle arrest function (see above).

Zac1 and *Tcf4* are broadly expressed in neuronal progenitor cell populations during early (E11) and midneurogenesis (E15) such as in the caudal brain

regions, the pallium, and the prethalamus eminence^[109].

$p57^{Kip2}$ expression is more localized and mapped strongly to the subpallium and peduncular hypothalamus where all three factors were detected.

Functionally, *Zac1* enhances G1-cell cycle arrest in NSC lines and primary NSCs (E15) during neuronal differentiation, by inducing $p57^{Kip2}$ expression through *Tcf4*^[109].

Taken together, these results suggest a role to *Zac1* in the prevention of precocious astroglial differentiation through *Socs3* induction and in advancing at the same time neuronal differentiation through *Tcf4* induction and *Tcf4*-mediated upregulation of $p57^{Kip2}$ (Figure 2).

ZAC1 IMPRINTED GENE NETWORK

Recent evidence indicates that many imprinted genes might work in an integrated network of imprinted genes. In this respect, Arima *et al.*^[110] noted that *Zac1* and $p57^{Kip2}$ show a conspicuously similar expression pattern in mesenchymal and neuroepithelial tissues, suggesting a functional interaction between these genes. Interestingly, the Beckwith-Wiedemann syndrome (loss of $p57^{Kip2}$ imprinting) and TNDM (loss of *ZAC1* imprinting) represent with partly opposite phenotypes including gigantism vs IUGR or hypoglycemia vs hyperglycemia.

At the molecular level, *ZAC1* binds in a methylation-sensitive manner within the promoter CpG island of *LIT1* (KCNQ1OT1), which encodes a paternally expressed, anti-sense RNA thought to repress $p57^{Kip2}$ in *cis*^[16]. *ZAC1* confers transactivation to *LIT1* promoter constructs suggesting that *ZAC1* might down-regulate $p57^{Kip2}$ via *LIT1* anti-sense^[110]. Oppositely, we demonstrated that *Zac1* upregulates $p57^{Kip2}$ via *Tcf4* in NSCs^[109].

Some aspects of the *Zac1* knock-out phenotype, such as growth retardation, perinatal death, and incomplete bone formation appear difficult to reconcile with *Zac1*'s antiproliferative activities^[69]. A possible explanation to this puzzle is provided by a meta-analysis of microarray data, which indicates that *Zac1* coordinates a network of genes that consists of a remarkable huge number of imprinted genes. These include *Igf2*, *H19*, *Dlk1*, *Ndn*, and $p57^{Kip2}$, which share an important role in NSC maintenance and differentiation, among others (*Grb10*, *Gnas*, *Meg3*, *Mest*, and *Sgce*). Moreover, *Zac1*-deficient liver tissue and *Zac1* overexpression experiments in neuroblastoma cells showed an opposite regulation of *Igf2*, *H19*, *Dlk1*, and $p57^{Kip2}$. Interestingly, *Zac1* bound to the downstream *H19* enhancer and conferred transactivation to both the *H19* and *Igf2* promoters (Figure 3).

More recently, Lui *et al.*^[111] showed that IGNs are possibly involved in mammalian somatic growth control. Early postnatal life is a period of fast somatic growth, which slows down with maturation and finally arrests in adulthood. A group of 11 imprinted genes involved in cell proliferation (including *Zac1*, *Igf2*, *H19*, *Dlk1*, *Ndn*, and $p57^{Kip2}$) and part of the *Zac1*-IGN is expressed in multiple tissues at levels that

correlate with trajectories of overall somatic growth and decrease coordinately with age. Although this study does not explicitly address the role of IGNs in NSCs, it importantly suggests that the function of IGNs is not reserved to embryonic life but potentially extends across lifespan.

Another recent study focused on gene expression profiling in murine long-term hematopoietic stem cells (LT-HSC) vs their differentiated progeny. These experiments showed that imprinted genes (including *Zac1*, *Igf2*, *H19*, *Dlk1*, *Ndn*, and $p57^{Kip2}$) were more uniformly expressed in progenitors when compared to the differentiated counterparts^[112]. Moreover, stem/progenitor cells from adult skeletal muscle and epidermis show a higher expression of these genes when compared to their differentiated derivatives.

Taken together, the *Zac1*-associated IGN network comprises, among others, imprinted genes that play a critical role in NSC maintenance and differentiation. Some of them, like *Igf2* and *H19* seem to be under the direct transcriptional control of *Zac1* while others like *Dlk1* might be regulated more indirectly as exemplified by *Zac1*-dependent upregulation of $p57^{Kip2}$ via *Tcf4* (Figure 3).

CONCLUSION

A wide range of genes acts in a concerted manner during brain development to regulate NSC proliferation, migration, and differentiation. Among these, imprinted genes have gained increasing apprehension in NSC biology due to their critical roles in quiescence, stemness, and cellular differentiation.

The molecular processes controlling both NSC fate and imprinted gene expression are manifold and include transcriptional regulation, epigenetic, and genomic interactions.

For instance, imprinted genes can regulate the expression or the transcriptional activities of proneural bHLH proteins in NSCs. *Zac1* activates *Tcf4* during neuronal differentiation of NSCs, while $p57^{Kip2}$ inhibits the transcriptional activity of *Mash1*. Conversely, the proneuronal bHLH-protein neurogenin regulates the imprinted *Dlk1-Gtl2* locus in the dorsal telencephalon^[113] indicating bidirectional interactions between imprinted genes and proneuronal proteins.

Genomic imprinting defects have been originally recognized for their role in early development of the embryo and placenta^[9] and more recently for postnatal life^[114]. New evidences suggest an additional role of variation in genomic imprinting in the mediation of environmental exposures, which is thought to associate with less severe consequences than those resulting from loss of genomic imprinting and might represent an important component of complex traits^[115]. For example, newborn of obese parents show altered DNA methylation profiles of multiple imprinted genes, which may be carried onto the next generation and confer an increased risk for metabolic diseases

Figure 3 Zac1-dependent transcriptional regulation of imprinted genes. Zac1 binds to the downstream enhancer of *H19* and transactivates *H19* and *Igf2* expression in neuronal cells. In pancreatic progenitor cell, Zac1 binds to the promoter of the paternally imprinted *Rasgrf1* gene and confers repression. Following neuronal differentiation of NSCs, Zac1 induces *Tcf4*, which binds at the promoter of the imprinted *p57^{Kip2}* gene and enhances G1 cell cycle arrest.

in adulthood^[116]. Moreover, the degree of methylation of *ZAC1* associates with pre- and postnatal growth in healthy infants as well as with maternal nutrition and lasts at least until the first year of life^[117]. Similarly, individuals prenatally exposed to famine showed 6 decades later less DNA methylation of *IGF2* compared with their unexposed, same-sex siblings^[118], although variation in DNA methylation at this locus is thought to increase as a result of the aging process itself^[119]. Collectively, these findings indicate the need for further studies on genetic and epigenetic variation at imprinted loci in response to environmental exposures and across lifetime.

Remarkably, in NSCs and other discrete stem cell populations, recent findings indicate that genomic imprinting can be epigenetically switched off at defined developmental time windows as shown for *Igf2-H19* and *Dlk1*. Such temporary changes in allele-specific transcription of imprinted genes alter gene dosage in a cell-type and tissue-specific manner and are required to prevent precocious depletion of the stem cell pool. The influence of various environmental exposures on epigenetic switches in NSCs is presently unknown and might contribute to brain function and aging in individuals at risk.

Interestingly, recent literature suggests that imprinted genes do not operate in isolation, but as complex network of genes, whose expression is dynamically controlled by epigenetic mechanisms that extend from prenatal to postnatal development and possibly during aging. For instance, *Zac1* is a central hub in an IGN comprising *Igf2*, *H19*, *Dlk1*, *p57^{Kip2}*, and *Ndn*, which share a role in NSC maintenance and differentiation.

Though, additionally studies are necessary to explore in more detail the role of IGNs in NSCs across lifespan as well as in response to environmental exposures and to elicit their molecular basis. Collectively, a better understanding of the complex interactions governing imprinted genes expression promises new insight into the biology of NSC and associated conditions ranging from imprinting disorders to age-related diseases.

unlimited self-renewal, and they can be triggered to differentiate into desired specialized cell types. These features provide the basis for an unlimited cell source for innovative cell therapies. Pluripotent cells also allow to study developmental pathways, and to employ them or their differentiated cell derivatives in pharmaceutical testing and biotechnological applications. *Via* blastocyst complementation, pluripotent cells are a favoured tool for the generation of genetically modified mice. The recently established technology to generate an induced pluripotency status by ectopic co-expression of the transcription factors Oct4, Sox2, Klf4 and c-Myc allows to extending these applications to farm animal species, for which the derivation of genuine embryonic stem cells was not successful so far. Most induced pluripotent stem (iPS) cells are generated by retroviral or lentiviral transduction of reprogramming factors. Multiple viral integrations into the genome may cause insertional mutagenesis and may increase the risk of tumour formation. Non-integration methods have been reported to overcome the safety concerns associated with retro and lentiviral-derived iPS cells, such as transient expression of the reprogramming factors using episomal plasmids, and direct delivery of reprogramming mRNAs or proteins. In this review, we focus on the mechanisms of cellular reprogramming and current methods used to induce pluripotency. We also highlight problems associated with the generation of iPS cells. An increased understanding of the fundamental mechanisms underlying pluripotency and refining the methodology of iPS cell generation will have a profound impact on future development and application in regenerative medicine and reproductive biotechnology of farm animals.

Abstract

Pluripotent stem cells are unspecialized cells with

Core tip: The generation of an induced status of pluripotency

in somatic cells by ectopic expression of core transcription factors allows to extending advanced genetic modifications and reproductive techniques to species, for which the derivation of genuine embryonic stem cells was not successful till now. The commonly employed viral gene transfer may be genotoxic and therefore non-viral methods for iPS cell derivation are intensively studied. In this review, we focus on the mechanisms of cellular reprogramming and current methods used to induce pluripotency.

INTRODUCTION

Induced pluripotent stem (iPS) cells are defined as differentiated cells that have been experimentally reprogrammed to an embryonic stem (ES) cell-like state. The first generation of murine iPS cells was achieved^[1] by retroviral transduction of four core reprogramming factors: Oct4, Sox2, Klf4, and c-Myc. Subsequently, human iPS cells were produced by viral transduction of adult fibroblasts^[2,3]. Also a combination of Oct4, Sox2, Nanog and Lin28, was effective for the generation of human iPS cells^[4]. An overview of reprogramming cells into iPS cells is shown in Figure 1.

Subsequently, the core reprogramming factors have been successfully used to derive pluripotent cells in various other species, including rhesus monkey^[5], rat^[6], pig^[7], dog^[8], cattle^[9], horse^[10], sheep^[11], goat^[12] and buffalo^[13]. A summary of the generation of iPS cells from different species of livestock is enumerated in Table 1. Importantly, iPS cells could be isolated from several species, in which the isolation of authentic ES cells was not successful despite several attempts since many years^[14,15]. In particular, for economically important species, such as farm animals, the availability of authentic iPS cells would have important consequences for reproductive biology and approaches for genetic modification. For agricultural purposes, iPS cells from farm animal species can serve as a valuable genetic engineering tool to boost the generation of livestock with advantageous genes that are important for economic, reproductive and disease resistant traits, or for the study of functional genomics in mammals.

So far, iPS cells have been successfully produced from fibroblasts^[16], pancreas cells^[17], leukocytes^[18], hepatocytes^[19], keratinocytes^[20], neural stem cells^[21], cord blood cells^[22], and other cell types. Together these data suggest that most cell types can be reprogrammed to a pluripotent state, and that the unidirectional lineage commitment can be experimentally overwritten.

Certain cell types, such as neuronal progenitors, which exhibit basal expression of one or more of the core reprogramming factors, seem to be ideal for reprogramming^[21].

Rodent iPS cells are almost identical to their ES cell counterparts, sharing typical hallmarks of pluripotency such as colony morphology, unlimited self-renewal, *in vitro* and *in vivo* differentiation potentials, and contribution to the germline^[23,24]. Most iPS lines from farm animal species have not been tested in chimera complementation assays; however some preliminary reports suggest that chimeras and germline transmission can be achieved in sheep and pig^[25,26]. iPS cells derived from rodents, humans, monkeys and farm animals share the features of high telomerase activity, expression of alkaline phosphatase, and expression of stemness genes, such as *OCT4*, *SOX2*, *UTF1* and *REX1*. The epigenetic status of murine iPS cells has been analysed by bisulfite sequencing and chromatin immuno-precipitation DNA-Sequencing (ChIP-Seq)^[27]. Thus the hallmarks for iPS cell characterisation can be enumerated as (1) unlimited self-renewal; (2) *in vitro* differentiation capacity; (3) *in vivo* differentiation capacity; (4) chimera contribution; and (5) subsequently germline transmission.

Apart from scientific and ethical hindrances, religious concerns restricted the derivation of human ES cells. To circumvent these concerns, alternative approaches to generate pluripotent cells have been assessed. The alternative approaches include culture of somatic cells with cell extracts isolated from ES cells^[28] or oocytes^[29], and fusion of somatic cell with pluripotent cell^[30]. However, extremely low efficiencies, high technical difficulties and aberrant ploidies of the resulting cells^[31,32] did reduce the enthusiasm for these attempts. At the moment, the derivation of iPS cells from human tissues seems to be the most promising alternative. Prior to clinical application of iPS-derivatives, cell survival, functional integration of the cellular transplant and safety of the cell products have to be assessed in informative animal models.

The progress in iPS cell development in farm animals lags behind those in rodents, but large mammalian models may be instrumental for pre-clinical tests of novel cell therapies (Table 2), enhanced pharmaceutical studies and regenerative studies, including the restoration of fertility.

HISTORICAL PERSPECTIVE

Ontogenesis of an organism and cellular differentiation were thought to be a unidirectional process, where stem and progenitor cells progressively develop to terminally differentiated cells, for example neurons, muscle, and epithelial cells. During ontogenesis the nuclear DNA of most cell types is unchanged, but different epigenetic marks, such as DNA methylation and histon modifications, are set, and lock the

Figure 1 Methodological toolbox for generating induced pluripotent stem cells. iPS: Induced pluripotent stem.

cellular potency and cell lineage commitment. This is depicted by the “epigenetic landscape” proposed by Waddington^[33].

Already in 1962, Gurdon^[34] questioned this view by amphibian cloning; he transplanted nuclei from intestinal cells into irradiated oocytes and obtained vital tadpoles. More than three decades later, the successful cloning of a sheep (Dolly) by SCNT of a mammary epithelial cell to an enucleated oocyte, showed that even mammalian cells can be reprogrammed^[35]. This success demonstrated that differentiated cells contain the genetic information to direct ontogenesis of an entire mammalian organisms, and that enucleated oocytes contain pivotal factors for reprogramming of differentiated cell nuclei. However, the identity of the oocyte reprogramming factors remained elusive.

The discoveries that ectopic expression of Antennapedia-a transcription factor was able and sufficient to induce leg structures in *Drosophila*^[36], and that ectopic expression of the mammalian transcription factor MyoD1 converted fibroblasts into myocytes^[37] led to the concept of “master genes”. A master gene was defined as a key transcription factor that in a hierarchical manner regulates a cascade of critical genes, which in a concerted action induce the cell commitment.

DISCOVERY OF INDUCED PLURIPOTENCY

In 2006, Takahashi *et al.*^[1] proved that not a single

master factor, but a combination of four reprogramming factors, Oct4, Sox2, Klf4 and c-Myc, was sufficient to induce the pluripotent status in somatic mammalian cells. The resulting cells were called iPS cells^[1]. This discovery offers new opportunities to study developmental biology, regenerative medicine, as well as reproductive biology and biotechnology of farm animals.

iPS cells from farm animals will likely serve as a bridging link between well developed rodent iPS and poorly characterised human iPS (Table 2), supporting the translation of innovative cell therapies from experimental studies to curative treatments. At the moment, human iPS cell application seems to be too risky because of basic lack of knowledge and ethical consideration which forbid certain tests such as chimera assays.

In contrast, research on iPS cells derived from farm animal species is not tainted with ethical concerns. Furthermore, the methodology for generation of iPS cells is relative simple and is thought to be easily transferable to other mammalian species. Thus farm animal models may turn out to be ideally suited to determine required cell doses, to assess long-term performance, tumorigenicity, applications methods and fate of transplanted cells^[38-41].

Recent advances in genetic engineering of farm animals allow the generation of precise genetic modifications^[42-47], such as the production of immunodeficient pigs^[48] which will be instrumental for further advances in preclinical testings of new cell therapies. A boost of recent

publications describe iPS cells from buffalo^[13], cattle^[9,49-53], dog^[8,54-56], goat^[11,57], horse^[10,58-62], pig^[7,63-71], rabbit^[72-74] and sheep^[11,75,76]. The majority of these iPS cells from farm animals showed typical hallmarks of pluripotency, such as differentiation *in vivo* and teratoma formation. However, most farm animal iPS cultures were not assessed for chimera contribution so far. Preliminary results that porcine iPS cells can contribute to chimera formation in blastocyst complementation were provided recently^[71]. Similarly, ovine iPS cells contributed moderately to chimeric lambs after injection into eight-cell stage embryos or blastocysts^[25]. These experiments represent an important step in the understanding of mechanistic nature of pluripotency in farm animals. The iPS technology may become instrumental for advanced transgenesis in large mammals (Figure 2).

METHODS TO DERIVE IPS CELLS

In recent years, several methods have been established for iPS cell generation (Figure 1), employing the core reprogramming factors as genes, mRNAs or proteins, and auxiliary chemical agents, which infer with the involved signalling pathways. Here, the main approaches for the generation of iPS cells are summarized.

Virally-induced iPS cells

There has been extensive amount of work carried out to obtain virally-derived iPS cells employing either retroviruses, lentiviruses, and non-integrating viruses. The first iPS cells have been generated through retroviral transduction of Oct4, Sox2, Klf4 and c-Myc^[1]. Disarmed, optimized retro- or lentiviruses can infect mammalian cells with high efficiencies. The use of the pantropic vesicular stomatitis virus G protein (VSVG) was instrumental for viral transduction of a broad spectrum of receptive cells. Interestingly, unstimulated T cells, B cells and hematopoietic stem cells could not be efficiently transduced with the VSVG lentiviruses^[77].

Retro- and lentiviruses integrate into the host genome allowing for high expression of the encoded cargo genes. The expression can be temporally confined by employing viral promoters, such as the 5' long terminal repeat, which are usually silenced by epigenetic mechanisms. Disadvantages of the viral approach include the limited cargo capacity of maximally 7 kb, the induction of immune responses and potential genotoxic effects. Retro- and lentiviral integrations do not happen randomly in the genome, but show a strong bias for promoter and exonic regions, which may result in dysregulation of endogenous genes. In a retrovirus-based clinical gene therapy of the X-linked

severe combined immunodeficiency (X-SCID), two of the treated children independently developed T-cell lymphomas due to viral integration in the neighborhood of the LIM domain only 2 gene^[78]. These data highlight the risks of viral-based therapies^[78]. Somatic cells derived from retrovirally reprogrammed iPS cells are apparently inconspicuous, provided that the c-Myc transgene is silenced^[19,79]. Retroviral reprogramming may evoke an immunogenicity of iPS cells^[80]. Human iPS cell-like cells can be formed through transduction with lentiviruses, which do not carry reprogramming factors. The “pseudo” iPS cells were induced by viral encoded microRNA expression^[81].

Alternative to integrating retroviruses, non-integrating adenoviruses can be used for reprogramming^[17,82]. Another non-integrating virus is represented by the Sendai virus system. Sendai viruses enable efficient production of iPS cells and later on elimination of the viral vector^[83]. Though viral mediated gene transfer offers high efficiency in generation of iPS cells, they require specific safety conditions for their handling.

Non-virally-derived iPS cells

The generation of iPS cells without viral transduction is preferable for regenerative medicine. Non-viral methods of reprogramming include episomal vectors^[84], minicircle DNAs^[85], plasmid vectors^[86], small molecules^[87], mRNAs^[88], recombinant proteins^[89] and transposons like piggyBac^[90] and Sleeping Beauty^[91]. In comparison to viral systems, non-viral approaches such as transposons are able to carry large DNA cargo into the host cell, they are non-infectious and do not evoke immune responses.

Episomal vectors

Episomal vectors for reprogramming of somatic cells were recently described^[84]. In this method, reprogramming of fibroblasts was carried out by transfecting with the episomal vector oriP/Epstein-Barr nuclear antigen-1. This vector was chosen because it can be removed after reprogramming by a drug selection method. The iPS cells generated through this method show similar morphology and expression patterns to ES cells. Further, they were able to form

teratomas in immunocompromised mice. As there was no integration into the host genome, transgene free iPS cells may be selected through further sub-cloning. Despite these advantages, this method yields low reprogramming efficiency in human fibroblasts at about three to six iPS colonies per 10^6 input cells^[84].

Minicircle vectors

Minicircle vectors are produced by the recombinatorial elimination of the bacterial backbone of the original plasmids. Minicircles containing the four reprogramming factors Oct4, Nanog, Lin28, and Sox2 in addition to an enhanced green fluorescent protein were used to obtain human iPS cells^[85]. The group excised the bacterial backbone from the plasmid by taking advantage of the PhiC31-based intramolecular recombination system, which cleaves away the undesired bacterial plasmid backbones, leaving minicircle DNA to be purified containing the desired reprogramming factors^[85]. It was claimed that minicircle DNA benefited from higher transfection efficiency compared to the parental plasmids. They also have longer ectopic expression, which is due to the lower activation of exogenous silencing mechanisms. Later, other groups reproduced the minicircle approach for reprogramming^[92,93].

Small molecules

Nowadays, small molecules and chemicals are assessed to enhance reprogramming efficiency and iPS cell generation. The idea behind their use is to substitute core reprogramming factors with small molecules, which will serve to enhance the reprogramming. Shi *et al.*^[94] showed that neural progenitor cells, which endogenously express Sox2, were reprogrammed only by ectopic expression of Oct4 and Klf4. They also showed that this process was supported by the G9a histone methyltransferase inhibitor, BIX-01294 (BIX). Ichida *et al.*^[95] used small molecules (RepSox2) for replacing transcription factors (Sox2) by inhibiting transforming growth factor- β signalling. In this direction, Lee *et al.*^[96] used magnetic nanoparticle-based transfection method that employs biodegradable cationic polymer PEI-coated super paramagnetic nanoparticles for iPS cells generation. Recently, the L-channel calcium agonist, BayK8644, was assessed to improve generation of iPS cells^[87] and it was claimed that BayK8644 does not directly cause epigenetic modifications as it works upstream in cell signalling pathways and can therefore avoid unwanted modifications. A more comprehensive list of small molecules involved in the iPS cells generation and their mechanism has been reviewed recently^[97].

Transposon systems

The recent development of hyperactive transposase enzymes makes transposon systems an interesting alternative to viral based methods. The commonly employed Sleeping Beauty, piggyBac and Tol2

transposon systems are relatively simple organized, and the essential components can be separated on two plasmids. One plasmid carries the inverted terminal repeats (ITR) flanking the transgene, the other plasmid carries an expression cassette for the respective transposase enzyme. Upon co-transfer of both plasmids into a cell, the transposase becomes expressed and subsequently transposes the ITR-flanked transgene into the genome. Importantly, only the desired transgenes becomes integrated by a cut-and-paste mechanism, whereas the plasmid backbones are degraded. On a genomic scale transposon integrations appear to happen at random, without a bias for promoter and gene-containing regions. The integrated transposon can be removed seamlessly by supplying the transposase in trans^[98], which makes the system more attractive and relevant in producing the safe and clean iPS cells. Up to six reprogramming factors have been connected by self-cleaving peptide sequences allowing for coexpression from a single cassette^[91,99-103]. Individual proteins are then produced by the self-cleaving peptide^[104-106].

Reprogramming with protein factors

The discussed transposon and episomal systems still require the introduction of cargo DNA into the cells^[106]. Delivery of reprogramming factors as proteins is an obvious alternative. In 2009, transgene-free iPS cells were produced with proteins of reprogramming factors^[107]. Therefor recombinant reprogramming proteins were produced as fusion proteins containing cell penetrating peptides. Repeated supplementation of the culture media of fibroblasts converted them to iPS cells. However, the protein-based reprogramming approach has not found widespread use, mainly due to relative low reprogramming efficiencies, and high costs for repeated treatments with protein factors.

mRNAs and microRNAs

The most recent trend in the field of non-viral iPS generation is reprogramming by using RNA molecules. Recently, modified mRNAs encoding reprogramming factors were employed to generate iPS cells with high efficiency^[108]. Messenger RNAs are an ideal vehicle for reprogramming, because they do not bear the risk of integrational mutagenesis, they can be transduced to cells with high efficiency, and they can be combined in desired ratios of the individual factor encoding transcripts^[108]. Disadvantages of mRNAs are the short half-life of -10 h, and that innate immune responses must be inhibited to allow for the full effects^[109].

Recently, it was shown that micro RNAs (miR) expression is sufficient to induce pluripotency^[110-112]. Two independent groups reported iPS cell generation by delivery of miR302, or miR200c, miR302, and miR369^[113,114]. These miR-derived iPS cells were indistinguishable from conventionally generated iPS cells. MicroR reprogramming seems to have advantages

for cellular reprogramming^[114-116], for example it avoids the need of transducing proto-oncogenic transcription factors^[117,118]. However, it needs to be assessed whether this approach will be successful in other species, since the underlying mechanisms are not well understood^[119].

MOLECULAR FACTORS REGULATING REPROGRAMMING

The core factors for reprogramming are Oct4, Nanog, Sox2, Klf4, c-Myc and Lin28. These genetic factors reprogram cells by regulating critical signalling pathways, epigenetic modifications and micro RNAs^[114].

Reprogramming by core transcription factors

Oct4 is the best studied regulator of pluripotency. Oct4 expression is confined to early embryonic cells, germ line cells and cultured pluripotent stem cells, where it activates the gene transcription of stemness gene^[120]. Oct4 protein cooperates with stemness factors such as Nanog and Sox2, but it also interacts with Polycomb group proteins^[120], which are important repressors of transcription. Sox2 is a transcription factor that acts as coactivator of Oct4^[121]. Binding of Oct4/Sox2 dimers to the promoter sequences of *Oct4* and *Nanog* genes upregulate their transcription^[122]. Nanog is a homeobox-containing transcription factor stabilizing the stemness network^[122]. Klf4 is a zinc finger-containing transcription factor which regulates the expression of Oct4, Sox2 and Nanog^[123-125]. Over-expression of Klf4 in ES cells increased the expression of Oct4 which further improve the self-renewal ability^[126]. c-Myc enhances the efficiency and speed of reprogramming^[127]. LIN28 promotes the expression of Oct4 at the posttranscriptional level by direct binding to its mRNA^[128]. Recently, Glis1 has been identified as a substitute for c-Myc^[129]. Glis1 transactivate the genes of Wnt ligands, Lin28a, Nanog, Myn, Mycl1, and Foxa2^[129].

The aspect of whether the species-specificity of reprogramming factors is relevant for proper reprogramming, is not well understood. In principle, the essential domains of the reprogramming factors are highly conserved between mammalian species, and several publications showed successful reprogramming with human and murine sequences in other species^[5-13,130].

APPLICATIONS OF IPS CELLS

Modeling of human diseases and preclinical trials

The potential applications of iPS cells will impact regenerative medicine, pharmaceutical industry, and animal biotechnology^[131]. Human iPS cells could be utilized for curative treatments, to studying onset and disease progression *in vitro*, and to test potential therapeutic in high throughput screens^[114,131,132]. The production of disease-specific iPS cells has found

widespread use in recent years^[133-136]. Disease-specific iPS cells provide a unique resource to obtain a molecular understanding of disease onset and progression^[131,132]. Induced PS-derived differentiated cells will allow to carry out *in vitro* drug screening (Figure 3), and to test therapeutic interventions^[131]. In mice, Fanconi anemia and sickle cell anemia have been successfully corrected by using iPS cells^[131,133-136].

However with regard to potential curative treatments, the functionality, safety, and lack of tumorigenicity of iPS-derived cells have to be assessed in appropriate animal models bearing significant physiological and anatomical similarities to humans (Table 2). Hence, animal models could be contributed tremendously to a better understanding of disease mechanisms and therapeutic interventions. In addition, iPS cells from monkey^[5], porcine^[41,26], canine^[8] and cattle^[9] would be useful in animal biotechnology such as making precise genetic engineering for improved production traits and products^[137,138].

Advanced transgenesis in large mammals

Transgenic farm animals can serve as excellent models of human diseases and during the past few years transgenic farm animals have gained renewed popularity. This is due to the availability of annotated genome depositories of the major domestic species and other organisms (for example: www.ensembl.org; or www.ncbi.nlm.nih.gov/genome), and due the introduction of active methods of transgenesis, which dramatically increased the success rates^[42,43]. The repertoire of molecular tools now allows the precise modification of large mammalian genomes at rapid pace and has led to a recent boost in this area. The development of genuine iPS cells from domestic species will contribute to these advances and allow to perform desired genetic modifications *via* high throughput screens *in vitro*, and then use either SCNT^[47] or blastocyst complementation for the generation of transgenic offspring (Figure 3). However at the moment most of the iPS cells cultures from different domestic species have not been tested for their capability to contribute to chimera formation, and only preliminary data are available^[25,26]. Thus reinforced efforts to assess the potential of current livestock iPS cell lines for chimera contribution and germ cell differentiation are required. The majority of current livestock iPS cell lines are generated with retro- or lentiviral reprogramming approaches (Table 1), and the opportunities to assess alternative non-viral approaches are not widely assessed^[10,56,106]. Also the potential of auxiliary small molecular inhibitors of stemness signaling pathway is not exploited for livestock iPS cells. Potentially, high throughput screens to identify small molecules with species-specific activity are required. It is anticipated that these approaches will lead to livestock iPS cells, which will make a significant impact for future genetic modifications of these species.

Figure 3 iPS cell technology contributes to disease modelling and drug discovery. iPS: Induced pluripotent stem.

Preservation of genetic resources and endangered breeds

The iPS technology has the potential to preserve endangered animals and highly valuable genotypes in the near future^[139]. Cryopreservation of cells and tissues is an important and useful approach for genetic preservation of valuable breeds and for conservation of endangered wild and domestic species. For highly endangered species, the derivation of iPS cells may become a method to prevent extinction. For example, iPS cells have been produced from endangered snow leopard^[140], drill and white rhinoceros^[139]. The iPS cells generated can be easily expanded for banking of genetic material, or used as donor cells for SCNT. Potentially, iPS cells from endangered species may be differentiated into mature oocytes and spermatozoa (Figure 4), which might be employed for *in vitro* embryo production^[139,140]. The differentiation of livestock iPS cells to functional gametes *in vitro* have not been achieved yet, however the current pace in developing fine-tuned protocols for *in vitro* differentiation of desired cell types, and the progress in inducing meiosis support the notion that the generation of fully functional spermatozoa and oocytes may be feasible. The possibility to obtain fully functional spermatozoa and oocytes from iPS cells of domestic and wild species would have far reaching consequences for maintenance of endangered species, as well as for breeding and genomic selection programs of domestic species. Even potential applications for infertility treatments in humans may become feasible^[141,142].

PROSPECTS OF FARM ANIMAL IPS CELLS IN PRECLINICAL STUDIES

The generation of iPS cells has opened new vista to

Figure 4 Application of induced pluripotent stem cells for *in vitro* generation of gametes. iPS: Induced pluripotent stem; IVF: *In vitro* fertilization.

understand pluripotency, disease onset and progression, and to develop regenerative medicine^[132]. However, before the clinical application of iPS cell-derived therapies can be envisioned, the low efficiency and kinetics of iPS cell formation, the risks of insertional mutagenesis, reactivation of silenced ectopic transgenes and potential tumor formation have to be assessed and solved^[131]. An important aspect is the biosafety of transplanted derivatives of iPS cells^[132]. A number of reports showed that iPS cell lines could contain genetic mutations, copy number variations, and epigenetic mutations^[132,143-145]. These aberrant changes may increase the tumorigenicity of iPS and iPS-derived cells. Retro- and lentiviruses are commonly used to introduce the reprogramming factors into differentiated cells, which can increase the immunogenicity^[146].

Farm animals represent informative model organisms, which seem to be suitable to assess obstacles and risks in longitudinal pre-clinical studies^[147]. In contrast to rodent models, they are more similar to humans with respect to life-span, physiology, metabolism and pathophysiology^[148,149]. Large mammalian models will allow to determine required cell doses to obtain therapeutic effects, to follow the fate of transplanted cells and their functional integration in the host tissue^[150]. Thus the research on pluripotent stem cells from farm animals will contribute to the development of innovative cell therapies for human patients.

has been carried out by expressing the mutated proteins in *in-vitro* heterologous systems. While these studies have provided a wealth of functional details that have greatly enhanced the understanding of the pathological mechanisms, it has always been clear that heterologous expression of the mutant protein bears the intrinsic limitation of the lack of a proper intracellular environment and the lack of pathological remodeling. The results obtained from the application of the next generation sequencing technique to patients suffering from cardiac diseases have identified several loci, mostly in non-coding DNA regions, which still await functional analysis. The isolation and culture of human embryonic stem cells has initially provided a constant source of cells from which cardiomyocytes (CMs) can be obtained by differentiation. Furthermore, the possibility to reprogram cellular fate to a pluripotent state, has opened this process to the study of genetic diseases. Thus induced pluripotent stem cells (iPSCs) represent a completely new cellular model that overcomes the limitations of heterologous studies. Importantly, due to the possibility to keep spontaneously beating CMs in culture for several months, during which they show a certain degree of maturation/aging, this approach will also provide a system in which to address the effect of long-term expression of the mutated proteins or any other DNA mutation, in terms of electrophysiological remodeling. Moreover, since iPSC preserve the entire patients' genetic context, the system will help the physicians in identifying the most appropriate pharmacological intervention to correct the functional alteration. This article summarizes the current knowledge of cardiac genetic diseases modelled with iPSC.

Abstract

Causative mutations and variants associated with cardiac diseases have been found in genes encoding cardiac ion channels, accessory proteins, cytoskeletal components, junctional proteins, and signaling molecules. In most cases the functional evaluation of the genetic alteration

Core tip: This paper revises the cardiac genetic diseases that have been modeled so far using the technology that starts from patient somatic cells, reprogram their fate to a pluripotent state, and then proceed to cardiomyocyte differentiation. We will describe the main steps of this procedure, from pluripotent stem cells to mature cardiomyocytes, and we will discuss the main features linked to the different cardiac pathologies that this model recapitulate in a cell culture dish.

INTRODUCTION

In 19th century, the Italian physician Giulio Bizzozero, founder of the Italian school of experimental pathology, proposed the classification of tissues depending on their regeneration rate. He divided human tissues in three categories: labile, stable, and perennial, where the labile are physiologically subjected to a continuous renewal, *e.g.*, keratinocytes, or bone marrow cells; stables, that are normally in a quiescent state but still retain the capacity to proliferate, *e.g.*, hepatocytes; and perennial, the so-called post-mitotic cells, that have completely lost their regenerative potential. The most representative cells in the latter case are neurons and cardiomyocytes, highly specialized cells that, apart from their duplication inability, share also the capacity, during development, to connect to sister cells and to build an organized network capable of an electric signal transmission.

During these years we learned the methods to cultivate and to maintain labile and stable cells in culture, but neurons and cardiomyocytes are still "problematic" cells, difficult to preserve in absence of their natural support, glial cells or cardiac fibroblasts, and, moreover, almost impossible to be obtained as sample from a healthy person.

Progress in this field came from studies of developmental biologist that were able to isolate, cultivate, and differentiate adult or embryonic stem cells (ESCs). These cells basically recapitulate *in vitro* the developmental process and ESCs in particular are indeed a continuous source of terminally differentiated post-mitotic cells that can be currently easily studied. The isolation and the use of human ESCs, although obtained from surplus of *in vitro* fertilization procedures, opened a serious and profound ethical issue. The great revolution came in 2006 when Shinya Yamanaka proposed a complex protocol designed to change cellular fate by forcing transcription factor expression^[1]. With this procedure, a murine

fibroblast was reprogrammed to a cell that assumed the main characteristics of an ESC: high proliferation rate as well as wide differentiation potential toward the three germ layers. Nevertheless, the search for an identical physiological counterpart has lead to the conclusion that these induced pluripotent stem cells (iPSCs), although very similar to ESCs, must be considered as artificial cells created in the lab. In 2007, the same process was applied successfully to human fibroblasts by Yamanaka's as well as Thomson's group^[2,3], thus creating cell lines that can be propagated almost indefinitely and can be used, in a close future, as a continuous source of differentiated cells for therapeutic purposes.

The application of this powerful technique to humans opened the possibility to reprogram fibroblasts isolated not only from healthy people but also from patients suffering of a genetic disease. The resulting human iPSCs (hiPSC) will keep the entire genetic information of the patient, including the mutation that has been linked to the pathology. The first examples of disease-related hiPSC involved patients with a range of human genetic diseases, whose DNA mutations, including the trisomy 21, were effectively maintained through all the reprogramming procedure^[4].

Since then, many laboratories started to model *in vitro* human genetic disease, succeeding to get a considerable number of post-mitotic cells for detailed functional studies. Indeed, this result is particularly important and useful when studying affected human cardiomyocytes or neurons, otherwise difficult to be obtained and maintained in culture. In most cases, despite the fact that hiPSC-derived cells are not exactly equal to the physiological counterpart, the system has attested successful *in vitro* replication of the main cellular characteristics already known to be associated with the modeled disease.

In this review we will discuss the important discoveries of the biological mechanisms underlying some genetic cardiomyopathies, made possible by the use of the cellular reprogramming technology.

FROM PLURIPOTENT STEM CELLS TO SPONTANEOUSLY CONTRACTILE CELLS

In vitro development of ESCs has been widely studied using murine ESCs (mESCs), whose differentiation procedure in culture implies the initial leukemia inhibitory factor (LIF) removal and the formation of cellular aggregates using the "hanging drop" method. These three dimensional (3D) structures, called embryoid bodies (EBs), replicate *in vitro* the different stages of murine embryonic development^[5]. Around differentiation day (dd) 8, clusters of spontaneously beating cells appear in culture; these cells express several transcriptional and structural cardiac markers and were therefore classified generically as cardiomyocytes^[6]. It should be noted that mESC differentiation starts by just removing LIF also in a 2D culture, but the resulting process does not strictly

Figure 1 Cardiomyocyte at day 16 post differentiation. A: Microscopical view of beating areas; B: Expression of cardiac troponin T (green), nuclei (DAPI) in blue; C: Cardiomyocyte sarcomeric structures evidenced by cardiac troponin T staining (green), nuclei (DAPI) in blue.

follow embryonic development (P. Dell'Era, unpublished results).

Since their isolation, human ESCs have shown different culturing needs from the murine counterpart, and their behavior revealed also minor differentiation plasticity. Cardiac differentiation is the most glaring example of this statement. The spontaneous 3D differentiation of mESC leads to the easy appearance of spontaneous beating foci in all the considered EBs, while in the case of both hESC and hiPSC, only a modest proportion of EBs contains contracting cells. This occurrence leads to the setup of different methods aimed to increase cardiac differentiation during *in vitro* development of pluripotent stem cells. While some of these procedures retain an initial 3D EB formation, others start from a confluent 2D monolayer.

Differentiation protocols

During gastrulation, cardiomyocytes emerge from mesodermal tissue, in particular from the anterior region of the primitive streak. Bone morphogenetic protein produced by the adjacent endoderm induces the cardiomyocyte fate, whereas WNT-mediated signals from the underlying neural tube and notochord suppress cardiomyocyte specification. Therefore the timed addition of inducers and/or inhibitors of the cited pathways would guide PSC differentiation toward: mesoderm, cardiomyogenic mesoderm, cardiac precursors, and cardiomyocytes. This is conceptually the summary of several protocols. At variance the required instructive signals can be provided by a visceral endoderm-like cell line that can be used as a feeder layer during the differentiation process^[7].

Within these years, several efforts have been made to identify a protocol that would give rise to high percentage of cardiomyocytes following differentiation of either hESC or hiPSC. All the attempts lead to the creation of several tools such as defined cultivation media that, avoiding animal components, will facilitate therapeutic use of pluripotent stem cells; recombinant single protein matrices such as vitronectin or laminin;

aggregation plates to standardize the production of EBs; and the more recent commercial cardiomyocyte differentiation media (StemRD and Life Technologies). The main differentiation protocols that have been used over the years are outlined in Table 1.

We tested several of these procedures using iPSC derived from patients' fibroblasts and adapted to grow on Matrigel-coated dishes; in our experience, we observed beating areas only when cells were treated with modulators of the Wnt pathway, while the general *TNNT2* expression was achieved in most protocols (Figure 1B). Of particular interest for therapeutic purposes the recent setup by BurrIDGE *et al.*^[8] that employs a chemically defined medium consisting of just three components on a dish covered by synthetic biological matrices. Indeed, using this protocol we strongly increased the number of beating cells in our culture up to 50%, but the best result, around 70%, was recently obtained using the PSC Cardiomyocyte Differentiation Kit (Life Technologies).

FROM SPONTANEOUSLY CONTRACTILE CELLS TO MATURE CARDIOMYOCYTES

In early development, the primitive heart tube is composed by small myocytes without distinct region of cells conducting and coordinating the stimulus. The contractile impulse begins with the primary pacemaker area in the primitive atrium that will later evolve in the sinoatrial node, where the fast beating pacemaker myocytes will reside. As development proceeds, also the conductive system will differentiate, generating CMs in anatomical different regions that will become the atrio-ventricular (AV) node, the AV bundles, and Purkinje fibers. Each of these CM subtype has its own electrical properties such as the presence and the form of the action potential (AP), the contraction rate, and the presence of specific currents that can be measured electrophysiologically.

However, CMs differentiated *in vitro* vary considerably from cells isolated from a mature human heart, because of the absence of humoral factors and organized

iPSC: Induced pluripotent stem cell; ESC: Embryonic stem cell; n.a.: Not available.

mechanical and electrical stress. In general, many of the features of hPSC-CMs are reminiscent of normal fetal cells. hPSC-CMs are spontaneously beating cells co-expressing atrial-, ventricular-, and nodal- markers, with unorganized sarcomeres, immature mitochondria, and an expression profile different from adult CMs^[9]. Our data indicate that, after 16 d of *in vitro* differentiation, iPSC-derived CMs start to segregate in the various subtypes, showing pronounced sarcomeric structures that reveal a certain degree of maturation (Figure 1C).

The CMs that arise during early hESC or hiPSC *in vitro* differentiation exhibit spontaneous AP, with a relatively depolarized resting membrane potential, probably due to the temporary absence of the inward rectifier potassium current (I_{K1})^[10].

The expression of the ion channels and, consequently, the ionic currents will undergo developmental maturation over time, as assessed by modifications in current density and property^[10]. hPSC-CMs immaturity is also reflected in their excitation-contraction machinery, lacking clear T-tubuli, disorganized sarcomeric striations, and immature Ca^{2+} handling^[11-13]. Unlike primary CMs that tend to undergo apoptosis or dedifferentiate, CMs derived from hPSC develop and maintain a functional phenotype in long-term culture^[14]. After surviving for 80 d, late-stage hESC-CMs show pronounced multinucleation that is accompanied by an increase in cellular perimeter, and area^[15]. Ultrastructural studies demonstrated that the sarcomere of hiPSC-CMs continue to mature through a 1-year culture^[16]. Young hiPSC-CMs contained a low number of unaligned myofibrils and immature high-density Z-bands. Within 6 mo the myofibrils became more tightly packed and formed parallel arrays accompanied by the appearance of mature Z-, A-, H-, and I-bands. M-bands were finally detected in 360-d-old

CMs, but expression levels of M-band-specific genes remained lower in comparison with those in the adult heart^[14].

Also a different gene expression accompanies these changes: late-stage CMs show increased levels of structural filaments MYH6 and MYH7, and of other specific molecules such as connexin 43, hyperpolarization activated cyclic nucleotide-gated potassium channel 4, and sarco(endo)plasmic reticulum Ca^{2+} ATPase^[14-16]. Finally, the electrophysiological profile of late-stage hESC-CMs show a significantly enhanced AP upstroke and a hyperpolarized maximum diastolic potential, and during maturation no differences were observed for AP duration (APD) to 50% or 90% (APD50, APD90) of repolarization^[15].

It must be noted that, while at early differentiation stages there are unspecified CMs that co-express different CM-subtype markers at later stages, around dd30, CMs acquire a more specific phenotype, expressing ventricular-, atrial-, and nodal-markers^[8]. The relative proportion of the three CM subtypes varies among the differentiation protocols that have been used, and can be additionally modulated by supplementing chemicals, microRNAs, or biological molecules to the culture^[17].

CARDIAC DISEASE MODELING

Despite all the discussed limitations, hPSC differentiation remains a powerful method to model *in vitro* genetic cardiac diseases, because of the capacity of these cells to give rise to terminally differentiated stable cardiac cells. The cardiac pathologies that have been modeled so far using hiPSC include some cardiomyopathies and arrhythmias, whose implicated

HCM: Hypertrophic cardiomyopathy; DCM: Dilated cardiomyopathy; BTHS: Barth syndrome; LQT: Long-QT; CPVT: Catecholaminergic polymorphic ventricular tachycardia; ARVC: Arrhythmogenic right ventricular cardiomyopathy; n.d.: Not defined.

genes are listed in Table 2.

hiPSC modeled cardiomyopathies

Familial hypertrophic cardiomyopathy: Hypertrophic cardiomyopathy (HCM) is a heterogeneous monogenic heart disease in which a portion of the myocardium is heavily hypertrophic. It is caused by more than 1400 mutations in at least 11 genes that encode thick and thin contractile myofilaments of the sarcomere or the adjacent Z-disc^[18]. HCM patients display abnormal thickening of the left ventricular myocardium in the absence of increased hemodynamic burden. Most people with familial HCM are symptom-free or have only mild symptoms, but their risk for clinical complications such as progressive heart failure, arrhythmia, and sudden cardiac death is strongly increased.

Efforts to elucidate the mechanisms underlying development of HCM have lead to the generation of patient-specific hiPSC-CMs that recapitulate *in vitro* a number of disease characteristics including cellular hypertrophy, and contractile arrhythmia^[19]. hiPSC were generated from a family cohort carrying a hereditary HCM missense mutation (Arg663His) in the MYH7 gene, and CMs were generated using the 3D spontaneous differentiation protocol^[20]. Mutant hiPSC-

CMs demonstrated not only cellular enlargement and multinucleation, but also other hallmarks of HCM including expression of atrial natriuretic factor, elevation of β -myosin/ α -myosin ratio, calcineurin activation, and nuclear translocation of nuclear factor of activated T cells^[19]. Using this model the authors were able to show that irregular Ca^{2+} transients and elevation of diastolic intracellular calcium $[\text{Ca}^{2+}]_i$ precedes the presentation of other phenotypic abnormalities, strongly implicating dysregulation of Ca^{2+} cycling in the pathogenesis of the disease. Pharmaceutical drug screening of mutant hiPSC-CMs further supported elevated $[\text{Ca}^{2+}]_i$ as a central mechanism for arrhythmia development. Indeed, only pharmaceutical blockade of Ca^{2+} and Na^+ entry mitigated contractile arrhythmia in HCM-CMs^[19].

Dilated cardiomyopathy: Dilated cardiomyopathy (DCM) represents the final common morphological and functional consequence of various pathological conditions in which a combination of myocyte injury and necrosis associated with tissue fibrosis results in impaired heart mechanical function. Nevertheless, primary familial forms of DCM represent a genetic condition in which the pathological involvement is predominantly limited to the myocardium. The main

hallmark of primary DCM is the presence of a left or biventricular dilatation with severely impaired systolic function in the absence of abnormal loading conditions or ischemic heart disease sufficient to cause global systolic impairment^[21]. Point mutations in 31 autosomal and 2 X-linked genes have been implicated in causing familial DCM (FDC) but account for only 30% to 35% of genetic causes^[22]. One of the more common genes identified in FDC is LMNA, which codes for lamin A/C proteins, intermediate filament proteins of the nuclear lamina^[23].

Several animal models of LMNA mutations have been generated to provide initial insights into the pathophysiology of lamin A/C-related DCM^[24]. Nevertheless the mechanism that links LMNA mutations with DCM remains uncertain.

Two different LMNA mutations have been modeled using hiPSC-CMs: an autosomal dominant non-sense mutation (R225X) in exon 4 of the lamin A/C and a GCCA insertion at base 50 in LMNA that creates a frameshift and premature stop codon, hence causing lamin A/C haploinsufficiency. LMNA^{R225X/WT} and LMNA^{Frameshift/WT} hiPSC-CMs showed normal phenotypes and basal electrophysiological properties as control hiPSC-CMs. However, when these CMs were subjected to electrical stimulation as in the cardiac environment, they exhibited typical nuclear abnormalities together with increased apoptosis^[25]. These two properties were replicated *in vitro* by shRNA knockdown of LMNA in control hiPSC-CMs, that was ineffective when the MEK1/ERK1/2 pathway was blocked pharmacologically^[25], thus identifying this pathway as a potential therapeutic target in LMNA-related DCM.

The same group also modeled a pathogenic phenotype of DCM due to a novel A285V Desmin (DES) mutation identified by whole exome sequencing (WES) using the hiPSC-CM system^[26]. Characterization of hiPSC-CMs carrying A285V-DES mutation revealed a poor co-localization of DES with several cytoskeletal proteins, including cardiac troponin-T, α -actinin and F-actin, and diffuse isolated aggregations of DES-positive protein^[26]. The electrophysiological analysis revealed that A285V-DES CMs exhibit significant functional abnormalities compared with the control-CMs as demonstrated by the diminished maximum rate of calcium ion re-uptake, slower spontaneous beating rate and failure to respond to the inotropic stress induced by isoproterenol^[26]. When control-iPSC-CMs were transduced with a lentivirus carrying the A285V-DES mutation, the resulting CMs simulated the phenotypes of DES-DCM-CMs, thus confirming the idea that abnormal DES-positive protein aggregates due to DES mutation can cause structural and functional abnormalities in cardiomyocytes. The relevance of this study is the demonstration that patient-specific hiPSC-CMs can be used to provide confirmation of a suspected genetic basis for DCM identified by WES.

Lastly, cardiomyocytes derived from patients in a

DCM family carrying a point mutation (R173W) in the gene encoding sarcomeric protein cardiac troponin T were analyzed^[27]. Compared to healthy individuals in the same family cohort, CMs from DCM patients exhibited altered regulation of Ca²⁺, decreased contractility, and abnormal distribution of sarcomeric β -actinin. When stimulated with a β -adrenergic agonist, CMs showed characteristics of cellular stress such as reduced beating rates, compromised contraction, and abnormal sarcomeric β -actinin distribution. Treatment with β -adrenergic blockers or overexpression of sarcoplasmic reticulum Ca²⁺ adenosine triphosphatase rescued the pathological phenotype^[27].

Barth syndrome: Barth syndrome (BTHS) is a rare, metabolic, and neuromuscular genetic disorder that occurs exclusively in males. Clinical features include variable combinations of pathologies including DCM, HCM, endocardial fibroelastosis, left ventricular non-compaction, ventricular arrhythmia, sudden cardiac death^[28]. The gene responsible for the disorder, tafazzin (TAZ), has recently identified: it is located on the long arm of chromosome X at Xq28, and encodes an acyltransferase that catalyzes the acylation of cardiolipin, the major phospholipid of the mitochondrial inner membrane^[28,29]. So far, more than 120 mutations have been described, but no correlation with specific phenotype has been observed^[28].

hiPSCs from two unrelated individuals with BTHS were generated, BTH-H and BTH-C, carrying TAZ frameshift (c.517delG) and missense (c.328T > C) mutations, respectively. CMs were generated by treating a cell monolayer with inducers and sorted for the surface marker vascular cell adhesion molecule-1 to obtain preparations highly enriched in CMs. Purified CMs were analyzed morphologically to evaluate sarcomere organization, and to assess mitochondrial functionality. CMs were then seeded onto thin elastomers with patterned lines of fibronectin, obtaining self-organized anisotropic myocardial tissues to study contractility properties^[30]. TAZ deficiency in BTHS-CMs impairs mitochondrial functionality as well as sarcomere assembly, generate contractile stress, and markedly increase reactive oxygen species (ROS) production. When linoleic acid (LA), an essential unsaturated fatty acid precursor of mature cardiolipin, was added to CM culture, the metabolic phenotype was corrected, the sarcomere organization and contractile defects were mitigated, and ROS production was strongly reduced^[30].

Using the hiPSC-derived model the authors showed that suppression of ROS, not only by LA but also by mitoTEMPO, normalized the metabolic, sarcomerogenesis and contractile phenotypes of BTHS- CMs, thus setting the basis for an effective pharmacological therapy of BTHS patients^[30].

hiPSC modeled arrhythmias

Long-QT syndromes: Long-QT syndromes (LQTS) are a group of heritable, usually autosomal dominant disorders with a estimated prevalence of 1:2500, characterized by an abnormally delayed or prolonged ventricular repolarization phase (prolongation of the QT interval on an electrocardiogram) and a propensity toward polymorphic ventricular tachycardia (often termed Torsades de pointes, TdP), syncope and sudden cardiac death in young patients^[31]. Clinically LQTS present a broad range of phenotypes even among family members with identical mutations, possibly as a result of genetic modifiers^[32]. To date, LQTS have been associated with over 500 different mutations in at least 13 genes encoding cardiac ion channel proteins, but the most prevalent forms are LQT1 and LQT2 caused by potassium channel mutations with a percentage of genotyped cases of > 50% and 30%-40%, respectively, and LQT3 caused by a sodium channel mutation that accounts for 10%-15%^[31].

LQT1 patients carry mutations in the *KCNQ1* gene (also known as KVLQT1 or Kv7.1), which encodes the pore-forming α -subunits of the channels generating I_{Ks} , an adrenergic-sensitive, slow outward potassium current, while LQT2 implicates hERG protein (encoded by *KCNH2* gene), which constitutes pore-forming α subunit of the rapidly-activating delayed rectifier potassium current (I_{Kr})^[33]. LQT3 is instead associated with gain-of-function mutations of the *SCN5A* gene, which encodes the α -subunit of the Na^+ ion channel $NaV1.5$ ^[34], while loss-of-function mutations in the same gene are associated with several other genetically heterogeneous disorders including Brugada syndrome, cardiac conduction disease, sick sinus syndrome sudden infant death syndrome and others^[35].

LQT1 was the first cardiac disease modeled using hiPSC and since then several hiPSC-CMs from patients carrying mutations in LQTS-associated channels have been considered^[36-42]. Indeed, patient-specific hiPSC-CMs represent a platform to investigate the functionality of ion channel mutations expressed in their complex genetic backgrounds and may provide unique insight into therapeutic approaches for disease management^[43].

LQT1: A family affected by LQT1 was screened and an autosomal dominant missense mutation R190Q in the *KCNQ1* gene was identified^[36]. hiPSC from two family members and two healthy controls were generated by retroviral vectors encoding the human transcription factors OCT3/4, SOX2, KLF4, and c-MYC (hOSKM). Using a 3D differentiation protocol, these cells were then differentiated into CMs. Spontaneously beating cells dissociated from LQT1 and control explants responded to pacing and generated three distinct types of APs, designated as "ventricular (V)", "atrial (A)", and "nodal (N)" on the basis of their similarity to the APs of human fetal heart CMs^[36].

Several disease-specific abnormalities were observed in LQT1-CMs: the duration and the rate adaptation of the AP, a 70%-80% reduction in I_{Ks} , as well as vulnerability to catecholaminergic stress^[36]. R190Q-KCNQ1 is a dominant mutation and indeed in hiPSC-CMs the mutated protein was absent on cell surface, but still retained in the endoplasmic reticulum. Similar results were obtained by expressing the wild type and the mutated protein in cardiomyoblast H9c2 cell line^[36]. Furthermore, electrophysiological studies confirmed the protective effect of β -blockade in the abnormal response to catecholamine stimulation, thus confirming the efficacy of the therapeutic approach for LQT1 patients^[36].

LQT2: The voltage-gated inwardly rectifying potassium channel that comprise KCNH2-encoded protein is composed of homo- or heterotetrameric complexes of pore-forming α subunits, like hERG, that associate with modulating β subunits. hERG consists of six transmembrane α helices, a pore helix, and N- and C-termini cytoplasmically located. The channel mediates the rapidly activating component of the I_{Kr} in heart^[44]. A large number of natural variants have been described, most of them in association with LQT2 syndrome (see <http://www.uniprot.org/uniprot/Q12809>).

A panel of control and LQT2-related hPSC were generated and characterized by several laboratories. hiPSC-CMs showing five different hERG mutations in genetically unrelated backgrounds were intensely characterized: R176W^[42], A561T^[38] and A561^[45], A614V^[37], and N996I^[46]. The aminoacids 176 and 996 reside in the N- and C-terminus cytoplasmic domains respectively, while the position 561 is in a transmembrane region of the protein, and the aminoacid 614 is located in the pore-forming segment.

Heterozygous KCNH2 mutations exert a dominant-negative effect on wild-type (WT) hERG channels associated I_{Kr} , by impairing trafficking pathways or altering channel kinetics of the resulting co-assembled hERG heterotetramers^[31,47]. Due to this behavior, it is possible to transfer them in a WT environment to verify their biological consequences in an unrelated genetic background.

The reprogramming and the following differentiation process were similar for all the laboratories: most of them used a retroviral transduction system, except for Mehta *et al.*^[45] that choose a viral-free episomal non-integrating approach, but the following differentiation involving EB formation and spontaneous differentiation was identical for all of them.

It must be pointed out that LQT2 is a disorder with incomplete penetrance where genetic background variations can confound disease traits. For this reason, the KCNH2 N996I mutation was deeply analyzed in (1) hiPSC-CMs from LQT2 patient; (2) hiPSC-CMs from LQT2 patient, previously corrected to wild-type using an homologous recombination system; and (3) NKX2.5eGFP/w hESC-CMs where the N996I-KCNH2

mutation was introduced using the same approach as before^[46].

Several observations were commonly reported to all LQT2-CMs: intracellular patch clamp recording of APD or extracellular measurement of field potential duration (FPD) using multi electrode array (MEA) showed prolonged intervals for both A-like and V-like cells^[37,38,42,45,46]. A summary of AP characteristic parameters measured by several authors in iPSC- or ESC-derived CMs is reported in Hoekstra *et al.*^[48]. Nevertheless, the AP increase was more restricted when isogenic cell lines were compared^[46], thus suggesting that a different genetic background can indeed over-estimate the differences between a control versus diseased CMs.

AP was modulated in LQT2-CMs by several drugs: pinacidil, a K_{ATP}-channel opener, significantly shortens APD₉₀, while Na-channel blocker, ranolazine, was ineffective^[37]; K channel enhancers, nicorandil and PD118057, caused AP shortening and in some cases could abolish early afterdepolarization (EAD)^[38]. In most of the papers some arrhythmogenicity of LQT2-CMs was reported, as evidenced by EAD events during spontaneous recordings^[37,42,45] or when challenged with the clinically used stressor, isoprenaline^[38].

As expected, the measurement of I_{Kr}, determined by adding the specific E4031 inhibitor, showed a reduction in LQT2-derived versus control CMs^[37,42,45,46].

Definitively, the genetic correction of the N996I-*KCNH2* mutation associated with LQT2 restores I_{Kr} density and normalizes APD in patient-specific LQT2-CMs, while the introduction of the same mutation in hESC-CMs reduced I_{Kr} and prolonged the AP duration^[46]. In addition, the molecular defects of hERG A561V and N996I mutants have been analyzed. In the NKX2.5-eGFP⁺ hESC-N996I cells, as well as in LQT2-N996I CMs, a trafficking defect was identified. Indeed, the 155-kDa protein band, representing the form transported to the cell membrane through the Golgi, was reduced by two-fold compared to the WT protein, while the 135-kDa band, which corresponds to the protein located in the ER, was unaffected^[46].

Similarly, hERG mutation A561V causes a reduced membrane localization of glycosylated/mature protein^[45]. Treatment of LQT2-A561V CMs with the calpain and proteasome inhibitor ALLN, not only increased membrane localization of mature hERG but also reduced repolarization, increased I_{Kr} and reduced arrhythmogenic events, thus suggesting a new therapeutic approach to treat LQT2 patients^[45].

LQT3: The α -subunit of the Na(v)1.5 cardiac sodium channel, encoded by *SCN5A* gene is composed by intracellular N- and C- terminus, and four homologous domains, attached one another by cytoplasmic linkers, forming a pore that conducts Na⁺ ions across membrane^[49]. In LQT3, the gain-of-function *SCN5A*-

mutations cause an increased persistent Na⁺ influx during depolarization that results in an enhanced late or persistent sodium current due to defective open-state inactivation of the channel^[35]. Four different *SCN5A* alterations have been modeled using hiPSC cellular system: a *de novo* heterozygous missense mutation F1473C associated with a polymorphism (K897T) in *KCNH2*, identified in a newborn patient with extreme prolonged QT interval^[50]. The second *SCN5A* modification was again a *de novo* heterozygous missense V1763M mutation, found in a Chinese girl^[51], and the last two V240M and R535Q alterations were from two LQT3-diagnosed patients^[52]. The F1473C mutation occurs in the channel inactivation gate of *SCN5A* while V240M and V1763M reside in transmembrane segments, and R535Q mutation occurs in the first cytoplasmic linker^[53].

In the first paper a lentiviral transduction of OSKM was used to reprogram fibroblasts, and a complex protocol rich in developmental modulators was used to achieve CMs differentiation^[50]. Ma *et al.*^[51] used instead an mRNA-based non viral non integrating reprogramming approach, followed by the spontaneous EB-based CM differentiation. Finally Fatima *et al.*^[52] used the classical retroviral infection, followed by a differentiation protocol guided by END-2 co-culture.

The data of hiPSC-CMs from the newborn and from the Chinese girl were compared with those obtained from hiPSC-CMs of healthy parents and of a healthy sister respectively that, because of the common genetic background with the patients, strengthened the obtained results^[50,51].

Terrenoire *et al.*^[50] reported a mutation-dependent increase in I_{NaL}, a right-shifted steady-state channel availability, and faster recovery from inactivation in all clones from the proband and none of the parents' clones. By using the hiPSC-CM system, the authors easily showed that the *KCNH2* heterozygous polymorphism T897 and K897, derived from homozygous parents, had no impact on electrophysiological pathology of the proband^[50]. Furthermore, the system allowed the pharmacological evaluation of the current patient's therapy, not so effective in controlling episodes of arrhythmia. Indeed, a more effective therapy has been identified as a result of the proposed study^[50].

Ma *et al.*^[51] observed significantly prolonged APD in patient-derived V-like CMs compared with control cells, while Fatima *et al.*^[52], showed a tendency to prolonged APD not statistically significant. Relevant to this point Terrenoire *et al.*^[50], comment that the relatively depolarized diastolic membrane potentials at this embryonic developmental stage inactivate sodium channels and consequently minimize contributions of sodium channel activity to AP^[53]. Relatively to sodium current Ma *et al.*^[51] found that TTX-sensitive I_{NaL} was significantly larger in patient-derived hiPSC-CMs compared with control hiPSC-CMs^[51], while Fatima *et al.*^[52]

showed that time-to-peak for sodium current and time to 90% of inactivation of the Nav1.5 were significantly longer in the LQT3-CM^[52]. In agreement with previous findings^[50], mexiletine reduced the late Na⁺ current and shortened the APD in patient hiPSC-CMs^[51].

LQT8/Timothy syndrome: Timothy syndrome (TS) is a multi-system disorder characterized by cardiac, hand, facial and neurodevelopmental features that include QT prolongation, webbed fingers and toes, flattened nasal bridge, low-set ears, small upper jaw, thin upper lip, and characteristic features of autism or autistic spectrum disorders (see www.orpha.net).

TS is caused by mutations in the *CACNA1C* gene and is inherited as autosomal dominant trait. The gene codifies for Cav1.2 channel, the main L-type channel in the mammalian heart that is essential for generating the cardiac action potential and for excitation contraction coupling^[54].

To date, just one paper reported the modeling of this syndrome using hiPSC: 16 iPSC lines from two TS patients, and 10 control lines from two unrelated individuals were generated using the classic retroviruses, and CMs were then obtained spontaneously from EBs^[55].

A prolonged AP was observed in TS-V-like CMs, while no differences were observed in A-like and N-like cells^[55]. The L-type Ca²⁺ channel current had significantly reduced voltage-dependent inactivation in TS-CMs compared to control cells^[55]. In addition, the TS-CMs exhibited a large number of depolarizing events that failed to trigger a full AP, similar to delayed afterdepolarizations (DADs) that arise after ectopic release of Ca²⁺ from the sarcoplasmic reticulum and which are associated with cardiac arrhythmias^[55]. Moreover, the Ca²⁺ elevations in spontaneously contracting TS-CMs were more prolonged and more irregular than those of control CMs^[55]. Finally, roscovitine rescued the electrophysiological properties of TS- CMs by increasing Cav1.2 voltage-dependent inactivation, reducing the APD, and decreasing the frequency of abnormal depolarizing events^[55].

Catecholaminergic polymorphic ventricular tachycardia: Another inherited cardiac disorder that was studied using hiPSC-CMs is catecholaminergic polymorphic ventricular tachycardia (CPVT) that is characterized by emotional and physical stress-induced ventricular tachyarrhythmia, syncope and sudden cardiac death in children and young adults. Two type of CPVT have been described: the autosomal dominant form (CPVT1) linked to mutations in the cardiac ryanodine receptor type 2 gene (*RYR2*) and a rare autosomal recessive form (CPVT2) caused by mutations in the calsequestrin-2 gene (*CASQ2*)^[56].

RYR2 gene encode for the principal Ca²⁺-releasing channel expressed in the membrane of the sarcoplasmic reticulum (SR). Studies based on *in vitro* expression of mutant *RYR2* in heterologous cell systems and

transgenic mice carrying specific *RYR2* mutations suggested that arrhythmias in CPVT1 are due to the diastolic Ca²⁺ leak from the SR following catecholaminergic stimulation^[57]. This leakage may lead to develop DADs through activation of the membrane Na⁺/Ca²⁺ exchanger, which can eventually result in triggered activity^[58].

The *CASQ2* gene encodes for a high-capacity, low affinity Ca²⁺ binding glycoprotein located inside the SR and involve in excitation-contraction coupling process^[59]. The functional alterations in intracellular Ca²⁺ handling resulting from the mutated *CASQ2* gene may cause DADs^[60]. In 2011, Fatima and his group described the hiPSC generation from a patient with CPVT1 carrying the mutation F2483I in *RYR2* gene^[61]. The authors differentiated hiPSC-CMs from fibroblasts of the CPVT patient and after 20-30 d of culture the cells were electrophysiologically analyzed. Frequent DADs and arrhythmias in CPVT-CMs exposed to adrenergic agonists were consistently observed. Furthermore, abnormal sensitivity to phosphorylation and cAMP-mediated regulation, together with the tendency for I_{Ca}-triggered Ca²⁺ release to continue following repolarization have been found^[61]. These first results using hiPSCs-based cardiac model validated the earlier hypothesis obtained only with animal models. Different groups have obtained similar results: Kujala has demonstrated that in addition to DADs, CPVT-CMs with P2328S *RYR2* mutation displayed also EADs which may be involved in cardiac arrhythmogenesis of their patients^[62]. Zhang reported specific analyses on calcium current (I_{Ca}) and Na⁺-Ca²⁺ exchanger current (I_{NCX}): in this case RyR2 F2483I mutant CMs have aberrant unitary Ca²⁺ signaling, smaller I_{NCX} reflecting smaller Ca²⁺-stores, higher I_{Ca}-gated Ca²⁺-release gains, and sensitized adrenergic regulation, consistent with functionally altered Ca²⁺-release profile of CPVT syndrome^[63]. Jung also reported the hiPSC generation of a 24-year-old woman with a diagnosis of familial CPVT1 with S406L missense mutation in the *RYR2* gene^[64]. In addition to presenting the electrophysiological properties of CPVT-CMs, the rescue capacity of dantrolene, which is believed to stabilize skeletal and cardiac RYRs by binding to a N-terminal sequence, is analyzed. Treatment with dantrolene restored normal Ca²⁺ spark properties in CPVT-CMs under basal conditions and corrected S406L-*RYR2* hyperactivity induced by adrenergic stimulation, with minimal effects in control cells; moreover, the same drug completely abolished DADs and triggered arrhythmias^[64].

Two more studies evaluated the effects of different drugs onto CPVT-CMs: Itzhaki reported the positive effects of flecainide, an antiarrhythmic agent, and thapsigargin, a β -blocker on CMs carrying the *RYR2* M4109R mutation^[65], while Di Pasquale *et al*^[66] reported the rescue of the arrhythmic phenotype induced by catecholaminergic stress by KN-93, an antiarrhythmic

drug that inhibits Ca^{2+} /calmodulin-dependent serine-threonine protein kinase II on CMs carrying the *RYR2 E2311D* mutation.

An additional study focused on the autosomal recessive form of the disease caused by the missense mutation D307H in *CASQ2*^[67]. In agreement with previous observations, isoproterenol stimulation caused DADs, oscillatory arrhythmic prepotentials and after-contractions, and diastolic intracellular calcium rising in *CASQ2*-derived CPVT model^[67]. Most importantly, electron microscopy showed that CMs derived from CPVT patients present an immature morphology with less-organized myofibrils, enlarged SR cisternae, and reduced number of caveolae^[67]. These data confirm previous findings derived from knock-out and knock-in *Casq2* mice that showed ultrastructural abnormalities in the SR^[68,69].

Arrhythmogenic right ventricular cardiomyopathy:

Arrhythmogenic right ventricular cardiomyopathy (ARVC) is a heritable primary cardiac disease characterized by the replacement of CMs with fatty or fibrofatty tissue^[70]. ARVC has an autosomal dominant trait with reduced penetrance; approximately 40%-50% of ARVC patients have a mutation identified in one of several genes encoding components of the desmosome, which can help confirm a diagnosis of ARVC^[71].

Also ARVC has been modeled using hiPSC by three independent groups starting from skin biopsies of five patients: retroviruses were used to transduce patient's-derived fibroblasts and CMs were differentiated with the spontaneous 3D differentiation protocol^[72-74]. The five patients carried different alterations in Plakophilin-2 gene (*PKP2*), a structural component of desmosome^[75]: a heterozygous L614P mutation^[72]; a heterozygous insertion resulting in a frame shift from amino acid 324 to a stop codon in position 335 (A324fs335X) and a heterozygous deletion resulting in replacement of threonine by serine in position 50 and in a frame shift leading to a stop codon in position 110 (p.T50SfsX110)^[73]; and, finally, a homozygous mutation that causes cryptic splicing with a 7-nucleotide deletion in exon 12, leading to frame-shift of the carboxy-terminal amino acids, whose results were further confirmed with cells carrying a heterozygous c.2013delC in exon 10 of *PKP2*^[74].

Common observations of ARVC-CMs carrying the heterozygous conditions reported specific down-regulation of *PKP2* and its interactor plakoglobin both at mRNA and at protein level^[72,73]. Transmission electron microscopy (TEM) analysis displayed larger ARVC-CMs with less organized, thicker and more pleomorphic Z-bands compared with the Z-bands in control cells^[72], as well as distorted desmosomes associated with accumulation of lipid droplets, that were strongly enhanced in lipogenic media^[72,73]. Relevant to this point, the addition of the GSK-3 β inhibitor BIO strongly suppress the effects of the

lipogenic stress^[73].

The phenotypic study of CMs derived from the patient carrying the homozygous mutation led to similar conclusions: an abnormal translocation of plakoglobin proteins associated with very low β -catenin activity^[74]. In addition, the culture of these ARVC-CMs, devoid of a correct *PKP2* carboxy terminus, in a lipogenic medium additionally containing PPAR- γ activating drugs, demonstrated exaggerated lipogenesis and pronounced apoptosis, that can be prevented by the addition of PPAR- γ antagonists^[74]. Similar results were obtained with CMs derived from the patient carrying a heterozygous c.2013delC mutation^[74].

The rescue of the pathogenic phenotypes was achieved by introducing the wild-type *PKP2* gene back into mutant hiPSC-CMs, thus suggesting that mutation of *PKP2* is sufficient to induce the pathological features observed in ARVC-CMs^[74].

Interestingly, the same cells were used by Cerrone *et al.*^[76] to verify a *PKP2*-mediated modulation of I_{Na} : indeed, as already shown using other cellular systems, ARVC-CMs showed drastically reduced I_{Na} and the deficit was restored by re-introducing the wild type *PKP2* gene.

CONCLUSION

Since the discovery of the cellular reprogramming method followed by *in vitro* CM differentiation, several findings regarding human cardiac cells, especially those exhibiting a pathological phenotype, have been made possible. We can discuss how close or how far is the relation between hiPSC-CMs and the normal counterpart, but surely the possibility to obtain human CMs in a culture dish is adding a missing item to the scientific community. Every model has its own limitations and this is true also for hiPSC-CMs. Indeed, data from the literature reports the most evident and predictable phenotypes, leaving aside those perhaps more interesting but still unexplainable. However, as shown, many patients' features are found in these hiPSC-CMs, starting from the prolongation of the APD corresponding to the elongation of the cardiac QT interval, or EAD or DAD events equivalent to arrhythmic episodes, or the presence of cellular lipid droplets primarily found in cardiac biopsies of patients with ARVC^[77].

Human CMs have been derived also from cells of patients carrying other genetic disorders involving cardiac pathologies such as Leopard syndrome^[78], Pompe disease^[79], Duchenne muscular dystrophy^[80], Friedreich's ataxia^[81], and Fabry disease^[82].

In all of the cases, patients-derived CMs showed the main characteristic traits of the related pathology: hypertrophic cells in Leopard^[78]; lower β -glucosidase activity, lower markers of metabolism, and higher glycogen content in Pompe^[79]; a dystrophic gene expression profile in Duchenne^[80]; impaired mito-

chondrial homeostasis in Friedreich's ataxia^[81]; and globotriaosylceramide accumulation in Fabry disease^[82]. Moreover, patients-derived CMs represent a powerful model to test type and dosage of clinically used drugs, laying the basis for a personalized therapy.

Increasing the number and diversifying the type of modeled patients will surely improve the understanding of the biological mechanism that leads to the considered disease. Nevertheless the big ongoing efforts reside in eliminating any kind of interaction of the reprogramming technology with patient's DNA and in identifying an easily reproducible protocol that leads to CM differentiation. Then, the non integrative Sendai-based reprogramming approach, followed by a chemical defined differentiation medium will surely solve the issue of reproducible cardiomyocyte differentiation.

Core tip: Inflammatory bowel diseases are inflammatory, chronic and progressive diseases of the intestinal tract. A limited experience is available with hematopoietic and mesenchymal stem cell transplantation for the treatment of these conditions. Research is ongoing with other cell lines which have been used in conditions alike to inflammatory bowel disease and which will possibly have a therapeutic role in this condition.

Stem cell therapy in inflammatory bowel disease: A promising therapeutic strategy? *World J Stem Cells* 2015; 7(2): 343-351 Available from: URL: <http://www.wjgnet.com/1948-0210/full/v7/i2/343.htm> DOI: <http://dx.doi.org/10.4252/wjsc.v7.i2.343>

Abstract

Inflammatory bowel diseases are inflammatory, chronic and progressive diseases of the intestinal tract for which no curative treatment is available. Research in other fields with stem cells of different sources and with immunoregulatory cells (regulatory T-lymphocytes and dendritic T-cells) opens up new expectations for their use in these diseases. The goal for stem cell-based therapy is to provide a permanent cure. To achieve this, it will be necessary to obtain a cellular product, original or genetically modified, that has a high migration capacity and homes into the intestine, has high survival after transplantation, regulates the immune reaction while not being visible to the patient's immune system, and repairs the injured tissue.

INTRODUCTION

Inflammatory bowel disease (IBD) mainly consists of two clinical conditions, Crohn's disease (CD) and ulcerative colitis (UC). It is mainly characterized by chronic, destructive inflammation of the gastrointestinal tract for which no curative treatment is currently available.

Its etiology is unknown, but it is accepted that it could be the result of loss of tolerance to intraluminal bowel antigens^[1]. Genetic, environmental, and microbiological factors are involved in its development,

together with morphological and functional changes in the intestinal barrier associated to an impaired immune response^[2]. Early data supporting genetic involvement in the pathogenesis of IBD come from familial clinical studies showing a greater incidence in twins^[3,4], first-degree relatives^[5,6] and given ethnic groups^[7,8]. Genome-wide association scan studies have allowed for identification of more than 163 loci associated to IBD^[9], 73 genes associated to CD and 47 to UC^[10], and overlapping genes for both conditions have also been found^[11]. Genetic factors would however account for less than 25% of cases^[12]. The exception is represented by a monogenic disorder referred to as IBD-like diseases, which are associated with severe colitis in childhood and have at most three loci alternatives^[13]. On the other hand the increase of the incidence of IBD suggests that environmental factors are more important than genetic factors in the development of IBD^[14].

Since IBD etiology is currently unknown, current treatment is intended to control the inflammatory intestinal process, thus avoiding irreversible structural damage. However, current therapeutic results are discouraging. Thirty-three percent of patients with CD do not respond to anti-TNF alfa therapy^[15-18], and one third of responders loss the response^[19]. Based on all the foregoing and on advances in understanding of the pathophysiological mechanisms involved in IBD development, new biological drugs and cell therapies are being investigated.

Future of the cellular-based therapy in IBD: Lessons from preclinical and clinical studies

Cell therapies are promising candidates for the treatment of IBD. However, inconsistent results have emerged from current clinical trials using both, hematopoietic stem cells (HSCs) and mesenchymal stem cells (MSCs). To establish the best stem cell type, the administration route and optimal dose of cells to achieve an effective therapy and to guarantee the safety of the patient, in-depth basic research is necessary. Therefore, preclinical studies using different animal models are necessary to understand the pathogenesis of IBD. These studies will facilitate a better design of preclinical stem cell therapies that will eventually become a suitable clinical therapy for IBD patients.

ADULT STEM CELLS

At present, HSCs and MSCs have been used in several clinical trials. However, up to now, the results are unpredictable. For additional information, the reader is referred to the recent review published by our group in 2014^[20].

Hematopoietic stem cells transplantation

Use of hematopoietic stem cells transplantation (HSCT) in IBD is restricted to severe CD with few therapeutic

options. These are patients who do not respond to standard treatment in whom surgery is not an option due to extent of disease. HSCT may also be used in monogenic diseases, such as interleukin-10 deficiency, where allogenic bone marrow transplant would correct the disease by reconstituting a new immune system.

Allogenic HSCT is not currently accepted for the treatment of CD because of its high mortality rate. Current studies focus on autologous HSCT, which is intended to "reset" the immune system of the patient. Once reactive T-lymphocytes and memory cells of the patient are eliminated by chemotherapy (lymphoablation), administration of autologous HSCs generates an immunotolerant system^[21-23]. Unfortunately, this effect will probably be transient until the patient cells start the inflammatory mechanisms again.

Clinical experience is limited (Table 1), with the Burt study^[25] reporting complete remission in all their 24 patients. We are currently waiting for the results of the ASTIC study^[28]. This is a phase III clinical trial comparing two treatment arms intended to clarify whether improvement is due to reset of the immune system or to transplantation. The first arm uses chemotherapy followed by early transplantation (30 d), and the second arm chemotherapy with late transplantation (13 mo). Results reported to date include a high adverse effect rate and appear to suggest efficacy of transplantation.

Mesenchymal stem cell transplantation

MSCs seem to be a promising therapeutic strategy for IBD because of their ability to selectively home in to injury/inflammation areas after systemic administration, and their immunosuppressive and tissue healing properties^[30,31]. However, the clinical data published about MSCs transplantation in IBD patients showed conflicting results. An explanation for these inconsistent results could be the different sources used to obtain the MSCs that could have distinct differentiation and regeneration capabilities and the variety of protocols used for their isolation and culture. A better understanding of the MSCs biology and mechanisms of action and the exploration of other sources of stem cells in preclinical models of IBD are necessary.

Bone marrow and adipose tissue are the main sources of MSCs for both experimental and clinical studies. However, these sources have several disadvantages such as the invasive procedure used for their isolation, the small number of MSCs isolated, and the low proliferation and differentiation capacities related to donor age. For this reason, in the last few years the search for alternative tissue sources for MSCs has become of vital importance. Placental tissues, both fetal (amniotic fluid, Wharton's jelly, amniotic membrane, chorionic villi) and maternal (decidua) represent an important source of MSCs with some advantages including the isolation of large number of cells in a non invasive way^[32,33]. In addition, like

bone marrow MSCs, placenta-derived MSCs are non-immunogenic and immunomodulatory stem cells with high expansion and differentiation capacity^[32-35].

An important issue in using MSCs is their safety. Although some studies supported that there is a risk of MSCs malignant transformation^[36,37], several recent studies using different types of MSCs supported that there is neither *in vitro* risk of development chromosomal aberrations after long term culture nor *in vivo* induction of tumors^[30,32,38,39].

For IBD treatment it is essential to increase the number of cells that migrate and home in to the intestine. A preclinical model of radiation enteritis treated with MSCs genetically modified to express the CXCR-4 receptor showed an increase of MSCs migration to intestinal site of injury and an improvement of symptoms^[40]. In the same way, MSCs coated with antibodies against vascular cell adhesion molecule VCAM-1 showed an increased cell migration of MSCs to inflamed colon and thereby an increased tissue repair capacity^[41]. A different strategy is to select a subpopulation of MSCs within the bone marrow that expresses high levels of EphrinB2. This subpopulation has an increased migration capacity to intestinal injury areas, and as a consequence, these MSCs would help to improve healing of intestinal injury^[42]. Once MSCs engraft in the intestinal damaged tissue they can proliferate and transdifferentiate into intestinal stem cells, or secrete cytokines and growth factors that will promote the proliferation and differentiation of intestinal stem cells in order to repair the injured areas of the intestinal tissue^[43].

Besides the migration, homing and tissue repair capabilities of MSCs, they also have an important function in modulating the inflammation and high

immune response within the injured tissues. These immunomodulatory properties of MSCs are of special importance in the treatment of IBD. Systemic administration of bone marrow MSCs in a mouse model of chemical-induced colitis^[43] and in a pig model of radiation-induced proctitis^[44], down-regulated autoimmune and inflammatory responses, and as a consequence, facilitated tissue regeneration.

The experience in luminal CD is limited (Table 2). Experience in UC is even smaller, and was mainly obtained in Russian studies about response of clinical activity^[50], changes in the pattern of systemic cytokines^[51] and elimination of cytomegalovirus after Mesenchymal stem cell transplantation (MSCT)^[52]. The most important work in this field is a phase III study^[48] that plans to include 330 patients who will be treated with MSCs at different doses, but final results are not expected until 2018. According to data reported to date, the safety profile appears to be favorable, and formation of aberrant tissue has not been detected.

As regards local treatment for perianal CD (Table 3), a single study using bone marrow cells is available^[55], and there is an 11-year experience of the Spanish group with MSCs taken from fat tissue (ASCs)^[53,54,56], initially autologous, except for a phase I / II trial using donor cells^[56]. We are currently waiting for completion of a phase III trial using donor cells which is planned to recruit a large patient sample. Two Korean studies using autologous ASCs have more recently been published. The first was carried out to evaluate the safety of the treatment^[57]. The second is a phase II study^[58]. A total of 43 patients were injected with ASCs. Among these, 33 were included in the modified per protocol analysis. The results showed complete sealing of 27 patients 8 wk after the final injection of

ASCs. No serious adverse effects were reported.

It is obvious that MSCs are a promising tool in the treatment of IBD. However, a large amount of work remains to be done to understand the mechanisms through which MSCs regulate the immune system, homeostasis and tissue repair. This knowledge will provide us with new tools to implement an effective MSCs-based treatment for IBD.

AMNIOTIC FLUID STEM CELLS

Amniotic fluid stem cells (AFSCs) are isolated from the excess of second-trimester amniotic fluid obtained during routine amniocentesis for prenatal diagnosis.

Recently, AFSCs were used in a neonatal rat model of necrotizing enterocolitis, one of the primary causes of morbidity and mortality in neonates, showed a decrease in intestinal damage, an increase in gut tissue repair and a higher survival^[59,60]. A better understanding of the AFSCs biology and mechanisms of action may help to develop strategies for their use in other IBD.

INDUCED PLURIPOTENT STEM CELLS

These are pluripotent cells derived from somatic cells by the introduction of reprogramming factors (Oct-4, Sox2, Klf4, c-Myc, Nanog and Lin28). These pluripotent cells can be differentiated to any

tissue specific cells to generate autologous cells for cell-replacement therapy^[61]. Human intestinal organoids have recently been generated from these cell lines^[62]. This will allow in the future for studying the pathophysiology of the disease and for testing new therapies, including generation of potentially viable tissues. Induced pluripotent stem cells (iPSCs) have been derived from somatic cells obtained from patients suffering a variety of diseases and important progress has been made in establishing preclinical iPSC-based disease models including IBD^[63]. Although iPSCs do not have the ethical problems of embryonic stem cells, there are many similarities between them and, as a consequence, iPSCs could develop teratomas following transplantation, hindering their use in clinical trials.

INTESTINAL STEM CELLS

Intestinal stem cells (ISCs) are a rare population of fast-cycling Lgr5⁺ cells and slow-cycling Tert⁺/Bmi1⁺ cells situated above them at the crypt base. ISCs are in charge of the renewal of the intestinal epithelium which is changed every 4-5 d and in the regeneration of the intestinal epithelium after injury or inflammation^[64]. It has been suggested that Lgr5⁺ cells and Tert⁺/Bmi1⁺ cells are two functionally different populations of ISCs^[65]. Lgr5⁺ cells are responsible for the maintenance of the normal homeostatis conditions, whereas Tert⁺/Bmi1⁺ cells are more quiescent cells responsible for the intestinal epithelium regeneration under injury or inflammation conditions^[66,67]. ISCs have proliferation and multipotency capabilities, *i.e.*, they are able to divide and later differentiate into all intestinal subtypes (enterocytes, goblet cells, Paneth cells and neuroendocrine cells). Recently, research in the ISCs field has advanced greatly and many ISCs markers have been identified^[68]. However, an exhaustive characterization of ISCs as well as the identification of specific markers still remains elusive^[64].

Transplantation of fetal and adult ISCs expanded *in vitro* presented a strong engraftment and healing potential in a colonic injury model in mice^[69,70]. However, ISCs in culture maintained as single cells have a very limited use in the study of the development of IBD and as a method for drug screening. Recently, intestinal organoids have been obtained from adult mouse and human ISCs^[66,71,72]. These organoids were able to engraft and repair murine and human epithelium and represent an important step forward in the treatment of IBD^[73]. Human organoids will be a very useful tool to study the pathological mechanisms of the disease from a specific patient and to test which is the best treatment to repair the intestinal epithelium for that patient. These organoids will be an important way to reach a more personalized medicine for IBD. These results highlight that those intestinal stem cells are a very promising source of stem cells for future patient-specific regeneration of the digestive tract^[68].

ENDOTHELIAL PROGENITOR CELLS

Besides local inflammation, IBD is characterized by anomalous angiogenesis/vasculogenesis and severe damage in epithelial cells^[74]. Important results have been obtained using endothelial progenitor cells (EPCs) for the treatment of hindlimb ischemia and myocardial ischemia. Recently, EPCs transplantation into fetal sheep showed an efficient migration and homing within the mucosal layer and a contribution to the vasculogenesis of the intestine^[75]. These results suggest that EPCs could represent an additional source of cells for IBD cellular therapy, on their own or in combination with other stem cells such as MSCs.

TOLEROGENIC IMMUNE CELL THERAPIES

In inflammatory disorders, special interest has been given to therapeutic strategies that could enhance the patient's tolerance response to intraluminal antigens. T-regulatory cells (Tregs) suppress immune responses of other cells and maintain tolerance to self-antigens. Tregs can be generated *ex vivo* by activation of both, murine and human CD4 T cells, suggesting that they could be an extra source of cells for cellular therapies in IBD. Intraperitoneal injection of induced Tregs in a mouse model of chronic colitis showed an attenuation of the preexisting gut inflammation response^[76,77].

Dendritic cells (DCs) are antigen-presenting cells involved in immunity and tolerance. DCs seem to be the most important regulators of immune tolerance in the gastrointestinal system, however, extensive studies are necessary to understand their role in this tissue and their mechanisms of action^[78]. Like MSCs, tolerogenic-DCs (tol-DCs) do not express neither MHCII nor the T-cell co-stimulatory molecules, and will not activate an immune response in the host. *Ex vivo* generated tolerogenic-DCs are available as a clinical grade product and used as therapeutic vaccines to restore antigen-specific tolerance in autoimmune diseases^[78]. Tol-DCs have been used in very few recent clinical studies such as rheumatoid arthritis and other not inflammatory diseases, and as a result conclusions about their clinical efficiency are still elusive. Several mouse models of colitis showed an important effect of tol-DCs in the prevention and reduction of symptoms of IBD^[79-83]. However, several questions must be resolved before tol-DCs can be used in IBD cellular therapy in humans, mostly due to the differences in IBD and tol-DCs between mice and humans^[84].

CONCLUSION

The goal for stem cell-based therapy is to provide a permanent cure for IBD. To achieve this, it will be necessary to obtain a cellular product (original or genetically modified) that has a high migration and homes into the intestine, has high survival after

transplantation, regulates the immune reaction which is not detectable to the patient's immune system, and will repair the injured tissue. Intestinal tissue is composed of several cell types and IBD are characterized by widespread damage. Cell-based therapies will probably be designed as a combination of several cell types that will produce a synergic therapeutic response.
