Abstract

Rotator cuff tears are frequent shoulder problems that are usually dealt with surgical repair. Despite improved surgical techniques, the tendon-to-bone healing rate is unsatisfactory due to difficulties in restoring the delicate transitional tissue between bone and tendon. It is essential to understand the molecular mechanisms that determine this failure. The study of the molecular environment during embryogenesis and during normal healing after injury is key in devising strategies to get a successful repair. Mesenchymal stem cells (MSC) can differentiate into different mesodermal tissues and have a strong paracrine, anti-inflammatory, immunoregulatory and angiogenic potential. Stem cell therapy is thus a potentially effective therapy to enhance rotator cuff healing. Promising results have been reported with the use of autologous MSC of different origins in animal studies: they have shown to have better healing properties, increasing the amount of fibrocartilage formation and improving the orientation of fibrocartilage fibers with less immunologic response and reduced lymphocyte infiltration. All these changes lead to an increase in biomechanical strength. However, animal research is still inconclusive and more experimental studies are needed before human application. Future directions include expanded stem cell therapy in combination with growth factors or different scaffolds as well as new stem cell types and gene therapy.

Core tip: Current surgical techniques in rotator cuff repair do not achieve good tendon-to-bone healing. The use of stem cells to improve healing is a promising alternative. Different *in vivo* animal studies have shown

good results in achieving restoration of the native enthesis. However, human studies are scarce so the use of stem cell therapy in rotator cuff repair should still be considered and experimental technique. Further basic and clinical research is needed.

INTRODUCTION

The rotator cuff is a structure formed by the tendinous insertions of a group of muscles that dynamically stabilize the glenohumeral joint. Rotator cuff disease is the most common condition of the shoulder for which patients seek treatment and can be found in 30% to 50% of the population aged older than 50 years^[1,2]. However, it also affects athletes and active individuals regardless of age and activity level.

Rotator cuff tears often require surgical treatment in order to increase function and decrease pain^[3,4]. The objective of the treatment is the repair of the damaged tendons. Whether or not healing of the tear is a prognostic factor on function and pain after rotator cuff repair has been controversial. However, most of the authors have found that tear recurrence determines lower functional scores and a decrease in patient satisfaction^[5-7]. In an attempt to improve the strength of the surgical repair, new materials and surgical techniques that aim to reproduce the anatomical footprint of the rotator cuff have been proposed^[8,9]. Despite these significant technical advances, several studies have shown a persistently high failure rate of tendon to bone rotator cuff repair that ranges from 30% to 94%^[6,10,11].

The main problem with failure in rotator cuff repair is probably biologic, as it is well known that the delicate and highly specialized fibro-cartilaginous transition zone between the rotator cuff and the bone does not regenerate after repair^[12,13]. Standard tendon to bone repair techniques attain only a fibro-vascular scar tissue that has relatively poor mechanical properties^[14]. Thus, the focus in research has changed from mechanical improvement of the repair techniques to finding ways to improve the biological environment around that repair^[15-22]. This would include growth factors (GF), bone morphogenetic proteins (BMPs) as well as stem cells. The hypothesis is that biological therapies might facilitate the regeneration of the normal tendon-to-bone insertion microarchitecture and limit the amount of scar tissue. In this direction, isolated GF or platelet rich plasma has been recently used with variable results but stems cell are a more

Table 1 Main biochemical and histological characteristics of the four areas of the enthesis^[28]

Zone	Histological characteristics	Collagen type	Extracellular matrix composition
Zone 1	Tendon	I	Decorin
Zone 2	Non-mineralized fibrocartilage	II and III (small amounts of I, IX and X)	Aggrecan and decorin
Zone 3	Mineralized fibrocartilage	II (small amounts of X)	Aggrecan and mineral component
Zone 4	Bone	I	Mineral component

promising alternative^[23-25].

Stem cells have demonstrated great potential in enhancing the biologic healing process based on their influence in angiogenesis and the inflammatory pattern^[26]. However, several questions still remain before they can be used clinically for augmenting tendon to bone healing. The purpose of this paper is to outline the current knowledge on the role stem cell therapy might have in dealing with rotator cuff tears and the future implications of the ongoing research's results.

ENTHESIS: TENDON TO BONE HEALING IN THE ROTATOR CUFF

Tissue regeneration in the tendon-to-bone interphase is a complex process. The stiffness difference between tendon and bone is responsible for significant mechanical stress in the regeneration zone^[27]. The enthesis represents a transitional tissue that allows for efficient energy transmission due to the gradual changes that occur in its microstructure, its histological characteristics and its biomechanical behaviour.

The enthesis has been divided into four zones: tendon, non-mineralized fibrocartilage, mineralized fibrocartilage and bone^[28] (Figure 1 and Table 1). In the tendon area (zone 1) there is a predominance of type I collagen fibres together with a small amount of decorin which is a small cellular or pericellular matrix proteoglycan; In the non-mineralized fibrocartilage area (zone 2), type II and III collagen fibres are predominant and small amounts of type I, IX and X collagen fibres have also been detected. Aggregans and decorine are also present. Zone 3 is constituted by the mineralized fibrocartilage, with a highly specialized mineralized content and type I collagen fibres. Lastly, zone 4 is characterized for a bone-alike composition, as it corresponds to the bony insertional area. As previously mentioned, it has been demonstrated that this specialized tissue does not regenerate after injury and repair. The fibro vascular tissue that substitutes the native enthesis is characterized by a predominance of type III collagen due to the excessive formation of scar tissue and the absence of fibrocartilage.

The reparative process can be divided into 3 phases (inflammatory, reparative and remodelling) and numerous cells and cytokines have been

Figure 1 The normal enthesis (longitudinal image and diagram of the bone-tendon junction of the supraspinatus tendon of a rat; hematoxylin-eosine, $\times 10$): the supraspinatus tendon (T) approaches the humeral bone (B) immediately adjacent to the normal cartilage (C). The normal tendon (zone 1) gradually transforms into a fibrocartilaginous tissue with large mononucleated cells (zone 2). As the fibers progress into the bone the extracellular matrix is progressively calcified (zone 3) until it turns into normal bone (zone 4). Further explanation of the biochemical environment of these zones is shown in Table 1.

implicated^[13,29,30]. Diaz-Heredia *et al.*^[30] have studied the gradual variation of vascular endothelial growth factor (VEGF), interleukin-1 (IL-1) and transforming growth factor- β 1 (TGF- β 1) in an animal model of rotator cuff tears in rats. Some authors have pointed out that the inability to regenerate the native enthesis could be caused by the incomplete expression of the genes implicated in its formation^[28]. During embryogenic development, healing occurs without expression of TGF- β 1 but with expression of TGF- β 3, which determines an absence of scar tissue. On the contrary, during postnatal life, TGF- β 1 is active during the three phases of the healing process^[13,30,31]. Another important group of factors widely studied are BMP-12, 13 and 14 as well as fibroblast growth factor- β (FGF- β) and insulin like growth factor-1 (IGF-1). Matrix metalloproteinases are multi-domain proteinases regulated by tissue inhibitors of metalloproteinases (TIMPs) and play a determinant role in the remodelling phase.

The enthesis structure is developed successfully during embryogenic period so knowledge of the biological mechanism of its development could help in pinpointing which factors are relevant in trying to regenerate the native transitional tissue^[28]. Galatz *et al.*^[32] found that the mature fibrocartilage does not appear until 21 d after birth. Supraspinatus fibroblasts expressed type I collagen during all the process. Type II collagen was expressed firstly in the non-mineralized fibrocartilage and at 7 d in the mineralized fibrocartilage, where it persisted until 56 d. Type X collagen was initially seen in mineralized collagen at 14 d and it persisted until 56 d. There was a change in the presence from TGF- β 3 to TGF- β 1 at 15 d. The gradual expression of different factors present in the development of the physal plate as (sex determining region Y)-box 9, Scleraxis, Patched 1, Parathyroid hormone-related protein (PTHrP) and Indian Heddegog (Ihh) has also been studied^[32-34]. It has been proposed that the stratification in the structure and composition along the different zones of the enthesis could be a

consequence of the gradual expression of these and other factors. For example, the amount of mineral deposit in the mature enthesis could be determined by the presence of osteogenic factors such as runt-related transcription factor 2 (Runx2) and bone morphogenetic protein-2 (BMP2). On the other hand, the formation of fibrocartilage could be related to a greater expression of PTHrP, Ihh and Sox9. Lastly, tendon development would be conditioned by the expression of BMP-12, tenomodulin and scleraxis^[32]. Scleraxis is a protein member of the basic helix-loop-helix superfamily of transcription factors.

BIOLOGIC APPROACH

In the past decades, as mentioned before, numerous biology-based strategies have been developed in order to improve the rate and quality of healing in rotator cuff models. The main areas of research, apart from stem cells, are matrix metalloproteinase (MMP) inhibitors and GF.

MMP inhibitors

MMP expression is increased in degenerative rotator cuff tissue and it is known to cause progressive weakness in extracellular matrix. They are involved in tumoral growth, aneurysmatic disease and post-surgical tissue remodelling in the rotator cuff^[35-37]. Tissue metalloproteinase inhibitors are thus, potential biological tools. In particular, inhibition of MMP-13, a MMP that is increased in degenerative rotator cuff tears, allows for higher amount of fibrocartilage formation, better collagen fiber organization and higher load to ultimate failure in the enthesis^[36,38].

GF

GF factors are key in the development of the different enthesis zones. The regeneration of the most specialized zone, the mineralized fibrocartilage, can be stimulated by osteoinductive factors^[39]. The GF are

usually delivered with a vehicle, such as augmented sutures, fibrin gels or collagen sponges^[16,40,41]. Rodeo *et al.*^[16] developed an animal model of supraspinatus repair in sheep in which they used BMP-2 to 7, TGFβ1, TGFβ2, TGF-β3 and FGF. They detected better histologic and biomechanical properties^[16]. Other investigators have obtained similar results with BMP-12^[42], BMP-13^[17], BMP-14^[43], FGF^[40,44], IGF-1^[45] and PDGF-b^[15]. Some of these factors seem to play different roles depending in which zone of the enthesis they act or the timing of their effects.

The most widespread treatment, however, is platelet rich plasma (PRP) obtained from autologous blood^[46]. It has been proposed that PRP facilitates coagulation and homeostasis, stimulates wound closure, restores intraarticular hyaluronic acid, equilibrates angiogenesis, promotes glucosamine synthesis and serves as a cellular support for migration and differentiation^[23]. Despite the variable results obtained, it has been used for muscular, ligamentous, tendinous or cartilaginous injuries^[47-50]. With regards to its application in rotator cuff tears, the results have also been controversial. Neither Sánchez Márquez *et al.*^[24] or Ruiz-Moneo *et al.*^[51] found any relevant clinical improvement with the use of PRP to augment suture in massive tears. However, other investigators support the use of PRP in selected cases^[52]. For example, Randelli *et al.*^[25] in a prospective randomized clinical trial, found less postoperative pain and accelerated healing rate in patients with non-massive rotator cuff tears but there were no differences in functional scores and re-rupture rate. Due to the chronic nature of these injuries, it has been suggested that PRP application should be serial in order to enhance its benefits^[53]. Another explanation for this fact is that the expression of growth factors is ephemeral. In this context, stem cell and gene therapies could be a more definitive and long-lasting treatment.

STEM CELL THERAPY: ANIMAL STUDIES

The use of stem cell therapy in the regeneration of musculoskeletal tissue is a very dynamic field. MSCs of different origins, with their innate ability to differentiate into several mesenchymal tissues including bone, fat, muscle and tendon have been used extensively in tissue repair. Applications in which its usefulness has been confirmed are: treatment of bone defects, cartilage regeneration, meniscal regeneration and healing, management of tendinopathies and management of muscle lesions^[54-56]. Investigators usually prefer adult MSCs over embryonic or fetal stem cells as the former are usually locally available and easier to obtain for the treatment of these non-life-threatening problems. Furthermore, the low immunogenicity of MSCs allows for the use of allogenic strains^[57].

Some authors have also performed extensive research in animal bone-to-tendon healing models. Until recently the most widespread model reproduced

the integration of anterior cruciate ligament tendinous grafts in a bone tunnel. In this animal model, the hamstring grafts are introduced into bony tunnels in both femoral and tibiae bones and pull out strength is tested. Lim *et al.*^[58] have used MSCs in this model in rabbits and found a significant increase in maximum load to failure.

It was not until 2009 that MSC therapy was applied to a rotator cuff model, since then the available literature has grown consistently. MSCs of different origins have been used for rotator cuff repair. Different tissue sources have been identified: bone marrow, adipose tissue, muscle, synovia, periosteum, tendon, dermis and umbilical cord or peripheral blood, have all been evaluated as sources of multipotent and pluripotent cell^[26]. Although generally speaking MSCs of different origins have similar biological potential, there is increasing knowledge that certain MSC populations are better than others for specific tissue regeneration^[59-61]. Table 2 shows the main animal investigations performed on rotator cuff repair.

Bone marrow MSCs

The principal source for stem cell-enhanced healing of the rotator cuff has been autologous bone marrow (BM-MSCs). Gulotta *et al.*^[20] performed an experimental unilateral detachment of supraspinatus tendon and a transosseous repair in rats. BM-MSCs were harvested by performing lavage of intramedullary canals of long bones with Hank's Balanced Salt Solution (Gibco, Gaithersburg, MD). They showed that MSCs were present at the repair site and that they were metabolically active. Although they did not find significant differences in between the treated and untreated groups, at 4 wk, there was a higher amount of fibrocartilage formation and better orientation of fibrocartilage fibers.

In order to reproduce rotator cuff surgery, Kida *et al.*^[62] designed a study in which they performed additional drilling to the greater tuberosity to release bone marrow and allow bone marrow cells to migrate into the suture zone. They tested chimeric rats that expressed green fluorescent protein in the bone marrow cells and looked for the expression of this protein after a period of 2, 4 and 8 wk. It seems that drilling and the subsequent migration of stem cells might improve maximum load to failure at 4 and 8 wk.

More recently, Gulotta *et al.*^[63-65] have used genetically modified MSCs in order to express scleraxis and produce MIT1 and BMP-13 with promising results. MSCs genetically modified to over-express MT1-MMP might be useful for augmenting suture as it has demonstrated improved biomechanical strength at 4 wk based on a higher presence of fibrocartilage^[63]. Results of studies with application of MSCs genetically modified to overexpress BMP-13^[64] were not that successful. On the contrary, MSCs genetically modified with Scx demonstrated to promote better biomechanical

Table 2 Rotator cuff repair animal models using mesenchymal stem cells

Ref.	Animal	Type of cells	Tendon repair model	Method of delivery	Results
Gulotta <i>et al</i> ^[20]	Rat	Allogenic BM-MSC	Supraspinatus tendon Acute repair	Fibrin glue carrier	No differences in structure, composition or strength at the repair site
Gulotta <i>et al</i> ^[63]	Rat	Allogenic BM-MSCs transduced with MT1-MMP	Supraspinatus tendon Acute repair	Fibrin glue carrier	Improved fibrocartilage Improved biomechanical strength
Gulotta <i>et al</i> ^[64]	Rat	Allogenic BM-MSCs transduced with human BMP-13	Supraspinatus tendon Acute repair	Fibrin glue carrier	No differences in structure, composition or strength at the repair site
Gulotta <i>et al</i> ^[65]	Rat	Allogenic BM-MSCs transduced with scleraxis	Supraspinatus tendon Acute repair	Fibrin glue carrier	Improved fibrocartilage Improved mechanical resistance and stiffness
Shen <i>et al</i> ^[74]	Rabbit	Allogenic T-MSCs	Supraspinatus tendon Acute repair	Seeded scaffold (silk-collagen)	T-MSCs differentiated into tenocytes Improved collagen content Improved biological environment Less inflammation
Kida <i>et al</i> ^[62]	Rat	Autologous BM-MSC	Supraspinatus tendon Acute repair	Transosseous drilling	BM-MSCs infiltrated the repaired tendon Improved mechanical resistance
Oh <i>et al</i> ^[71]	Rabbit	Allogenic A-MSCs	Subscapularis tendon Chronic repair	Injection	Improved muscle function Improved tendon healing Decreased fatty infiltration

Different types of cells have been used: Bone marrow derived MSCs (BM-MSCs), Tendon derived MSCs (T-MSCs) or Adipose derived MSCs (A-MSCs). MT1-MMP: Metalloproteinase inhibitor-1; BMP-13: Bone morphogenetic protein-13; MSCs: Mesenchymal stem cells.

characteristics at 2 wk^[65].

Adipose tissue MSC

Adipose Tissue derived stem cells (AMSC) have also shown multipotentiality *in vitro*^[66]. Due to its mesodermal origin, they can differentiate into adipose lineage cells^[67], osteogenic cells^[68], chondrogenic cells^[59] and myogenic cells^[69]. *In vivo*, they have also demonstrated their capacity to differentiate into adipose tissue using different scaffolds as polyglycolic acid, collagen sponges or fibrin gel^[54,70,71].

Recently, Oh *et al*^[71] have published the first study in a rotator cuff model using AMSCs. Four groups were compared for a suture of the subscapularis tendon in rabbit using saline, saline and AMSCs, only AMSCs and only suture. They found better healing properties and a capacity of regeneration after fatty infiltration of the muscle.

MSCs of other origins (non-hematopoietic)

Muscle-derived stem cells (M-MSCs) have been isolated using a modification of a method known as the preplate technique^[72]. Pelinkovic *et al*^[73] have shown that the injection of M-MSCs into the supraspinatus tendon of athymic rats resulted in the engraftment of transplanted cells in a pattern with a morphology comparable to resident tendon fibers. The authors suggest that more studies are necessary before assuming that M-MSCs can improve rotator cuff healing.

Lastly, Shen *et al*^[74] performed a study using tenocyte-derived stem cells (T-MSCs) proliferated *in vitro* and obtained from human fetal Achilles tendon samples. Implantation of this type of cells in the rabbit rotator cuff defect did not elicit an immunologic

response but increased fibroblastic cell ingrowth and reduced infiltration of lymphocytes.

Choice of scaffold for MSCs deployment

Cell adhesion to the scaffold depends on the interaction that is established in between the scaffold microstructure and the cell surface receptors denominated integrins. Transmembrane contacts are key factor for MSC survival, proliferation and differentiation^[75]. Numerous studies have investigated the behaviour of stem cells in different scaffolds and have demonstrated that the scaffold can determine the differentiation capacity into one or other lineages^[75]. Two different types of interactions have been described: physical and biochemical. Vehicles that maintain the rounded shape of the cells and avoid contact in between them, promote the chondrogenic differentiation and avoid expression of type I collagen. Porous gelatine vehicles or those that use fibrin favour a fibro cartilaginous phenotype due to the expression of collagen types I and II^[76].

STEM CELL THERAPY: HUMAN STUDIES

Although there is a lack of consensus on whether the application of stem cells to enhance the rotator cuff healing is effective or not, some authors have started developing different strategies for the clinical application of the experimental findings.

Beitzel *et al*^[77] studied the quantity and characteristics of BM-MSCs obtained from proximal humerus and distal femur bone marrow aspiration and found them comparable, supporting the previous experimental research by Kida *et al*^[62]. Rotator cuff derived MSCs have been isolated and compared to BM-derived stem

cells. It seems that the myogenic potential of MSCs derived from rotator cuff cells is higher than for BM-MSCs^[78]. Randelli *et al.*^[79] could isolate tenocyte-derived stem cells from supraspinatus tendon and long head of biceps tendon. Utsunomiya *et al.*^[80] also studied the subacromial bursa as a potential source for MSCs and found that the synovial cells found in the bursa were a good cell source.

Ellera Gomes *et al.*^[81] published their work in 14 patients with a complete tear of the rotator cuff that was repaired in a trans osseous fashion through a mini-incision augmenting the suture with mononuclear stem cells from iliac crest bone marrow aspirate. At 12 mo, 12 of the 14 tears had healed according to clinical and magnetic resonance imaging results^[81]. This is the only published investigation on clinical application of stem cells in rotator cuff tears.

Lastly, Beitzel *et al.*^[75] have also focused their attention in how different scaffolds behave in humans in order to extrapolate results obtained from experimental research. MSCs adhesion, proliferation, and scaffold morphology were evaluated by histologic analysis and electron microscopy. According to their findings, significant differences existed: non cross-linked porcine collagen scaffolds showed superior results for cell adhesion and proliferation, as well as on histologic evaluation.

FUTURE ALTERNATIVES

Advanced stem cell therapy and gene therapy represent the most feasible option in order to improve rotator cuff healing^[21]. A better knowledge of the molecular phases of embryogenesis of the enthesis as well as the injury and healing patterns have allowed to identify the growth factors and proteins to target^[13,28].

A combination of stem cells, modified before implantation, using exposure to different growth factors or modifications to the culture conditions to generate a desired phenotype is one of the most investigated pathways^[26]. Moreover, the newly recognized anti-inflammatory and antiapoptotic impact of MSCs on tissue healing may provide a great potential for functional restoration^[76,82].

On the other hand, specific growth factor supplementation, in the form of transgenic therapy may allow longer-term tendon repair and potential return to function. Fetal-derived embryonic stem cell-like cells have recently been evaluated for tendon and ligament repair. More recently, induced pluripotent stem cells, developed by genetically reprogramming adult-sourced cells, may be particularly beneficial in the challenging environment of rotator cuff injury. Generation of iPS cells can use viral or, more recently, nonviral vector delivery of reprogramming genes. However, these transgenic therapies lack safety clearance when it comes to oncologic and teratogenic risks^[26].

Lastly, stem cells associated to bio or nanotechnology can control the proliferation and differentiation

into complex, viable 3D tissues. So we might be able to use biodegradable polymer scaffolds to promote cell growth and differentiation and formation of 3D structures. This could be useful in order to avoid scarring during the healing process.

CONCLUSION

Current literature regarding the clinical use of stem cells in rotator cuff tears is limited. Although in vivo animal studies have shown promising results to enhance tendon-to-bone healing, the use of stem cell therapy in rotator cuff should still be considered an experimental technique. Further basic and clinical research is needed.

is established and maintained by the coordinated interaction between transcription factors and epigenetic regulators which control stem cell fate. Epigenetic mechanisms are heritable alterations in genome function that do not involve changes in DNA sequence itself but that modulate gene expression, acting as mediators between the environment and the genome. At the molecular level, those epigenetic mechanisms comprise chemical modifications of DNA such as methylation, hydroxymethylation and histone modifications needed for the maintenance of NSC identity. Genomic imprinting is another normal epigenetic process leading to parental-specific expression of a gene, known to be implicated in the control of gene dosage in the neurogenic niches. The generation of induced pluripotent stem cells from NSCs by expression of defined transcription factors, provide key insights into fundamental principles of stem cell biology. Epigenetic modifications can also occur during reprogramming of NSCs to pluripotency and a better understanding of this process will help to elucidate the mechanisms required for stem cell maintenance. This review takes advantage of recent studies from the epigenetic field to report knowledge regarding the mechanisms of stemness maintenance of neural stem cells in the neurogenic niches.

Abstract

In the adult mouse brain, the subventricular zone lining the lateral ventricles and the subgranular zone in the dentate gyrus of the hippocampus are two zones that contain neural stem cells (NSCs) with the capacity to give rise to neurons and glia during the entire life of the animal. Spatial and temporal regulation of gene expression in the NSCs population

Core tip: Neural stem cells (NSCs) are capable of extensive self-renewal while preserving the ability to generate cell progeny that can differentiate into different cell types from the nervous system. Intrinsic mediators as well as extrinsic cues provided by the neurogenic niche (microenvironment where NSCs reside *in vivo*) are important for stem cell self-renewal and differentiation. Epigenetic changes, including alterations in DNA methylation, histone modifications and imprinting alter

the way a gene interacts with the cell transcribing machinery, turning genes “on” or “off”. These heritable changes must be reversible and context-dependent being responsible of stem cell plasticity.

NEURAL STEM CELLS AND THE NEUROGENIC NICHES

Adult stem cells have the ability to divide, self-renew and generate functional differentiated cells that replace lost cells throughout an organism's lifetime. The existence of adult stem cells was first described in tissues with high proliferation rates, such as the hematopoietic system and the intestine. Since then, stem cells have been found in almost all adult tissues including the nervous system^[1]. In the adult mouse brain two main regions continue to generate new neurons throughout adulthood: the subventricular zone (SVZ) in the walls of the lateral ventricles^[2] (Figure 1A-C) and the subgranular zone (SGZ) in the dentate gyrus (DG) of the hippocampus^[3] (Figure 1D-F). Adult neurogenesis is supported by multipotent neural stem cells (NSCs) deriving from embryonic radial-glia and thus expressing astroglial characteristics^[4,5]. Astrocytic-like stem cells are relatively quiescent and can be identified by the expression of the glial fibrillary acidic protein (GFAP), the stemness-related transcription factor Sox2 [Sex determining region Y (SRY)-box 2], and the neural progenitor marker Nestin^[2,6,7]. Moreover, their slow division rate can be detected by the label retention of thymidine analogs incorporated during DNA replication^[6,8,9]. NSCs can also be isolated from their natural niche and cultured *in vitro* in the presence of the epidermal growth factor (EGF) and basic fibroblast growth factor (bFGF) mitogens. In culture, NSCs form free-floating aggregates called “neurospheres” (Figure 1C). Self-renewal and multipotency characteristics of NSCs are assessed *in vitro* by clonal analysis in which single cells give rise to neurospheres^[10,11] (Figure 1C).

SVZ and the olfactory bulb system

The SVZ is located lining the walls of the lateral ventricles and constitutes a complex microenvironment or niche in which proliferation and self-renewal of NSCs are strongly regulated by multiple extracellular factors such as EGF, bFGF, bone morphogenetic protein and pigment epithelium derived factor^[12-14]. This significant extrinsic signaling is possible because of the special cytoarchitecture of the niche that allows NSCs to be

in direct contact with the cerebrospinal fluid (CSF) produced by the choroid plexus in the ventricles, with the vasculature and with other cells from the niche like astrocytes or microglia^[15,16]. Subventricular NSCs (also known as type B1 cells) present a radial glia-like morphology, with an apical primary cilium contacting the ventricular lumen and a basal process reaching the basal lamina and the vascular structures^[17,18] (Figure 1A). The walls of the lateral ventricles show a typical organization where the small apical process of one or more type B1 cells are surrounded by a rosette of epithelial ependymal cells that form structures known as pinwheels at the surface^[19]. There is another astrocyte-like type B cell that is more frequently located close to the underlying striatal parenchyma known as type B2 cells^[20]. When activated, these slowly dividing NSCs give rise to fast cycling cells called transit-amplifying progenitors (TAP or type C cells). TAP cells contribute to reducing the number of cell division rounds that NSCs have to undergo to preserve their genome integrity. Mash1-positive type C cells generate neuroblasts (type A cells) that migrate along the rostral migratory stream (RMS) into the olfactory bulb (OB) where they differentiate and integrate into interneurons (Figure 1B). These chains of polysialylated neural cell adhesion molecule (PSA-NCAM) and DCX (doublecortin) positive neuroblasts reach the core of the OB, where they detach from the RMS and migrate radially into the granular and periglomerular layers^[21-23]. These immature neurons then integrate and differentiate into inhibitory interneurons, playing an important role in rodent olfaction. In addition of being a neurogenic region, the SVZ can serve as a niche of oligodendrocytes although generated in much lower numbers than neuroblasts. Thereby, Olig2-positive transit amplifying cells give rise to oligodendroblasts that migrate to the corpus callosum and striatum while tightly associated with blood vessels^[24], where they differentiate into myelinating and nonmyelinating oligodendrocytes^[25].

SGZ of the hippocampus

Along with the SVZ, the subgranular zone in the dentate gyrus of the hippocampus constitutes the other main neurogenic niche in the adult mouse brain^[26-28]. The SGZ is also a complex microenvironment in which the vasculature plays an important role. Dividing stem cells in the SGZ are in close proximity to an extensive network of interconnected blood vessels and parenchymal astrocytes that can regulate their proliferation and differentiation *via* paracrine signaling^[29]. The SGZ is located between the granular layer and the hilus of the DG and the SGZ NSCs constitute a subpopulation of GFAP-positive cells that are analogous to subventricular type B1 cells^[30]. In this region, two types of neural progenitors can be identified according to different expression of molecular markers and their morphologies^[23] (Figure 1D and E). Type I progenitors exhibit a radial process spanning the granule cell layer and arborizing profusely in

Figure 1 The neurogenic niches in the adult murine mammalian brain. D: Coronal view showing the adult mouse subgranular zone (SGZ) and the newborn neurons (red) being integrated in the granular cell layer (gr). Enlarged view of the dentate gyrus (DG): Type I stem cells (blue) are GFAP+ and show a radial single prolongation through the granular layer; Type II precursors give rise to neuronal lineage-restricted progenitor cells type III cells (red) that differentiate into neurons in the granular layer; E: Schematic drawing showing the lineage progression in the SGZ; F: Confocal images showing immunostaining in the DG for the astrocyte marker GFAP in green, for the progenitor precursor marker T-box brain protein 2 (TBR2) in red and for the neuronal precursor marker Doublecortin (DCX) in red. DAPI is used to stain DNA. Scale bar in C: Top left panel 100 μ m, rest 10 μ m; In f: 10 μ m.

the molecular layer^[27]. These cells express nestin, GFAP, and Sox2^[31]. Type II hippocampal progenitors have short processes and contrary to type I cells, express TRB2 but not GFAP (Figure 1F). There is evidence suggesting that type II cells may derive from type I cells but a lineage relationship study is still lacking^[31]. In the adult SGZ, precursors give rise by asymmetrical divisions to intermediate neuronal lineage-restricted progenitor cells and in a minor number, to glial lineage-restricted progenitor cells (both of them are GFAP-negative cells). Compared to the SVZ, few oligodendrocytes are generated in the SGZ. Type II cells generate in turn type III cells, which are neuronal precursors that express markers of immature migrating neurons, such DCX and PSA-NCAM (Figure 1F). These differentiated cells integrate neuronal circuits into the hippocampal CA3 region forming dendrites and spreading their axons^[22]. In addition to the production of granular neurons, a low percentage of activated NSCs divide asymmetrically to give rise to astrocytes. The latter migrate into the hilus and the molecular layer where they lose their stem cell identity and cause the depletion of the pool of NSCs^[32,33] thus explaining the possible decrease in hippocampal neurogenesis associated with ageing.

EPIGENETIC REGULATION OF GENE EXPRESSION IN THE NEUROGENIC NICHES

Epigenetic is defined as the study of heritable altera-

tions in genome function that do not involve changes in DNA sequence itself^[34,35]. These epigenetic marks modulate gene expression either by directly altering the chromatin structure or by creating bindings sites for chromatin and transcription regulatory subunits. Two general classes of epigenetic regulation can be defined: covalent modifications to DNA and post-translational covalent modifications to the histones (H) around which the DNA is bound, influencing whether DNA is accessible or not for gene transcription^[36,37] (Figure 2A). Moreover, the three-dimensional structure and arrangement of chromatin within the nucleus are both regulated by and contribute to the establishment and maintenance of epigenetic states^[34]. These different classes of epigenetic modifications are intimately related, resulting in multiple layers of control allowing cells to maintain their identity over time^[34,38]. Dysregulation of these mechanisms leads to new cellular phenotypes by causing altered gene expression without a change in genotype. In the neurogenic niches, epigenetic regulators and the associated transcription factors play an important role in the control and maintenance of NSC stemness.

DNA methylation

DNA methylation involves the addition of a methyl group to the fifth carbon in the cytosine pyrimidine ring (Figure 2B). In most mammalian genes, CpG dinucleotides are methylated and concentrated in clusters called "CpG islands" which often have regulatory functions and tend to be found in the promoter and first exon regions of genes^[39] where it promotes a closed chromatin structure and aids the prevention

of expression^[34,40]. DNA methylation marks repress gene expression either by attracting DNA methyl-binding domain proteins (MBDs) such as methyl-CpG binding protein 2 (MeCP2) which recruit repressors and chromatin remodeling molecules to generate an inactive chromatin environment or by directly inhibiting transcription factor binding^[41-43]. MBD proteins have been suggested to play a role in neurogenesis. For example, mice deficient in MBD1 show decreased neurogenesis and hippocampus-related behaviour defects. Indeed, *Mbd1* deficient NSCs generate a reduced number of neurons when compared to wild-type cells, suggesting a role for MBD1 in neuronal fate commitment^[44].

DNMT3b, important for normal embryogenesis and development and responsible for the establishment of methylation patterns. The other type is maintenance methylation mediated by DNMT1 that effectively maintains CpG methylation upon DNA replication and provides the heritable “memory” of the methylation state of the parent cell^[45,46]. DNMT1 is highly expressed in the embryonic, perinatal and adult CNS in both dividing neural progenitors and mature neurons where it maintains DNA methylation^[47-49]. A lack of DNMT1 alters neuronal excitability and increases apoptosis in post-mitotic cortical neurons^[50]. In support of this, mice deficient for *Dnmt1* specifically in neural progenitors at embryonic stages exhibit deficits in neuronal function and die postnatally, suggesting a requirement for methylation in brain development^[51]. DNMT3a and DNMT3b are highly expressed in postnatal

NSCs and are required for neurogenesis and neuronal maturation^[48,49,52,53]. Loss of DNMT3a results in gene silencing^[53] and depletion of DNMT3b leads to deficient neuronal differentiation *in vitro*^[54].

DNA is hypomethylated in neural progenitor cells and methylation is progressively increased during lineage commitment^[55]. The suppression of astrogliogenesis during neuronal specification is also associated with changes in DNA methylation^[56,57]. This silencing is attenuated later in development resulting in the generation of astrocytes which correlates with the suppression of neurogenesis. Demethylation and expression of the genes coding for the astrocytic markers *Gfap* and the calcium binding protein *S100β* during astrocytic maturation, correlates with methylation and downregulation of neurogenic genes such as Neurogenin 1^[58-60]. Activation of the *Gfap* promoter requires binding of the signal transducer and activator of transcription 3 (STAT3) to a consensus sequence. Early progenitors are refractory to astrocyte differentiation due to methylation of the STAT3 binding site. At later development stages, loss of STAT3-binding element methylation is associated with *Gfap* promoter activation^[60,61]. A similar alteration in methylation pattern occurs at another STAT3 binding site in the *S100β* promoter^[58].

Hydroxymethylation

DNA methylation marks are reversible through both passive replication-dependent demethylation and active demethylation which probably involve the recently characterized 5-hydroxymethyl (5hmC) intermediate^[62] (Figure 2B). In mammals, three members of the ten-eleven translocation (TET) family of enzymes have been identified: TET1, TET2 and TET3^[63,64]. TET hydroxylases may catalyze active DNA demethylation by oxidation of 5mC to 5hmC^[65-67] (Figure 2B). 5hmC is relatively abundant in mouse embryonic stem cells (ESCs), the early embryo and in adult brain^[68,69]. In the brain, 5hmC is enriched at active genes, associated with the strong depletion of 5mC from these regions^[70]. It has been proposed that TET enzymes in the blastocyst and ESCs are involved in pluripotency by maintaining the hypomethylated state of key regulatory regions^[69,71]. Recent studies have also shown that TET1 is involved in the epigenetic regulation of neural progenitor cell proliferation in the adult hippocampus^[72-74]. Mice lacking *Tet1* exhibit impaired hippocampal neurogenesis accompanied by poor learning and memory^[72-74]. However, the full role and importance of hydroxymethylation in the brain remains to be elucidated.

Histone modifications as regulators of adult neurogenesis

In eukaryotic cells, a histone octamer including two H2A-H2B dimers and a H3-H4 tetramer acts as a scaffold around which DNA is wrapped to form a nucleosome^[75,76]. The interaction between histones and DNA is mediated by an N-terminal tail of histone

proteins available for post-translational modifications that control the chromatin structure^[75] (Figure 2C). These covalent modifications in the histone tails alter the interaction between adjacent nucleosomes and/or between histones and the DNA, changing the three-dimensional chromatin structure. Modifications in the body of histones have also been shown to alter chromatin structure influencing gene expression^[77]. Histone modifications are divided into repressive and active marks according to how they correlate with levels of transcriptional activity. For example, histone acetylation of lysine residues of histones, catalyzed by histone acetyltransferases enhances the recruitment and activation of the transcriptional machinery and is generally associated with areas of active gene transcription^[78]. However, histone deacetylases (HDACs) remove acetyl groups promoting the condensation of chromatin^[79] (Figure 2A). HDAC1 is expressed by GFAP-positive cells within the SVZ whereas HDAC2 is found in migrating neuroblasts and in TAP cells within the SVZ^[80]. Deletion of HDAC2 in the SVZ results in a defective neurogenesis to the OB^[81] and neurospheres treated with class I and II HDAC inhibitors promotes neuronal differentiation^[82] suggesting a role for this enzyme in neuronal fate determination. Furthermore, oligodendrocyte fate commitment is accompanied by a decrease in histone deacetylation at transcriptional repressors of oligodendrocytic differentiation such as *Sox11*^[83] and at neuronal genes such as *Sox2*^[84].

Histone methylation is associated with both active and silent chromatin and is catalyzed by histone methyltransferases (HMTs). Trimethylation of lysine (K)-27 and lysine 9 of histone H3 (H3K27me³ and H3K9me³) tends to associate with regions of inactive gene transcription, whereas H3K4, H3K36 and H3K79 methylations are associated with active transcription^[85]. Histone demethylases (HDMs) also have a key role in regulating neural development^[86]. During neural stem cell commitment, H3K27 methylation decreases in key developmental genes following downregulation of the HMT *Enhancer of Zest homolog 2* (EZH2) and upregulation of the HDM Jumonji domain containing-3 (JMJD3). Indeed, deletion of *Ezh2* in SGZ progenitor cells results in cell proliferation restriction leading to a reduced number of neurons that ultimately leads to impairment in spatial learning and memory^[87]. Additionally, JMJD3 is upregulated in neuroblasts, and *Jmjd3* deletion targeted to SVZ NSCs in both developing and adult mice impairs neuronal differentiation. JMJD3 regulates neurogenic gene expression *via* interaction at not only promoter regions but also neurogenic enhancer elements such as *Dlx2*^[88]. Moreover, H3K9me³ is enriched in the adult murine SVZ and it has been recently shown that its repression in undifferentiated cells is engaged in the maintenance of cell type integrity in this neurogenic niche^[89]. MLL1, another HMT that methylates H3K4, has been associated with the trithorax group of transcription factors. In mice where *MLL1* is knocked out in NSCs, neurogenesis is impaired.

Mll1 is associated with the promoter of the homeobox transcription factor *Dlx2* and although loss of *Mll1* does not affect the methylation of H3K4, it does increase H3K27me³ on the promoter indicating that *Mll1* is recruiting a H3K27 demethylase^[90]. In summary, the above studies indicate that different chromatin modifiers have a critical role in adult neurogenesis^[91].

Genomic imprinting and control of gene dosage

Imprinted genes are expressed predominantly from one chromosome in a parental-origin dependent manner. While most genes are expressed from both alleles, imprinted genes are functionally monoallelic and are expressed from either the maternally or the paternally inherited chromosome^[92]. In mammals, this affects around 100 genes that are found in clusters. Imprinting control regions (ICRs) regulate the parental allele-specific pattern of gene expression and have differentially methylated regions (DMRs) on the two parental chromosomes. ICRs can be divided into those which are methylated on the paternally inherited copy and those with maternally inherited methylation^[93]. DMRs are also characterized by the asymmetrical accumulation of different histone modifications on the two parental chromosomes and the recent identification of a "tri-mark", comprising the trimethylation of H3K4 and H3K9 and the trimethylation of H4K20 at all known ICRs^[94]. The majority of imprinted genes are expressed in the brain and several exhibit brain-specific imprinting. Their monoallelic expression makes these loci very vulnerable as mutation of the expressed allele can compromise expression and lead to severe developmental defects. For example, human congenital imprinting syndromes including Angelman syndrome and Prader-Willi syndrome are all characterized by neurological and behavioral impairments and learning difficulties^[95]. Evidence is suggesting that selective regulation of imprinting is a normal mechanism of modulating gene dosage and is associated with the control of stem cell potential in the neurogenic niche. For instance, relaxation of imprinting of the gene for the atypical NOTCH ligand delta-like homologue 1 (*Dlk1*) usually expressed from the paternally inherited chromosome has been shown in the neural stem cells and niche astrocytes within the SVZ^[96]. Notably, this selective absence of *Dlk1* imprinting is associated with acquisition of DNA methylation at the germline-derived imprinting control region^[96]. *Igf2* is also an imprinted gene expressed only from the paternally-inherited allele although it is specifically biallelically expressed in postnatal human and mouse choroid plexus epithelium and leptomeninges^[97,98]. Thus, CSF produced from the choroid plexus and blood vessels is a biallelic source of neurogenesis-promoting IGF2^[99].

Epigenetic changes during NSCs reprogramming to induced pluripotent stem cells

Epigenetic reprogramming consists in the transition from one cell type to another, permitted by the loss

of the molecular characteristics of the cell of origin and the acquisition of an entirely new molecular identity without changing the genomic sequence^[100]. Reprogramming involves changes in the transcriptome and chromatin state of the reprogrammed cell type to that of a pluripotent cell^[101-103]. This implicates different levels of changes in DNA factor binding, transcription and chromatin state^[103]. Since the discovery by Takahashi and Yamanaka in 2006 that the introduction of four transcription factors, *Oct3/4*, *Klf4*, *c-Myc*, *Sox2* (known as OKMS) could reprogram mouse embryonic and adult fibroblasts into induced pluripotent stem cells (iPSCs)^[104], the field of reprogramming has considerably evolved and several studies have reported the use of sets of these transcription factors in various combinations to reprogram mouse and human somatic cells^[105-108]. More recently, murine B lymphocytes, liver, stomach and pancreatic β -cells were showed to reprogram into iPSCs using the combination of factors OKMS^[109-111]. In 2008, Eminli *et al.*^[112] reported the generation of iPSCs from murine NSCs by retroviral infection of the same combination of factors. Since neurosphere cultures express *Sox2* and *c-myc*, a considerable advance consisted in showing that they could be reprogrammed only with *Oct4* and *Klf4* at similar efficiency to the reprogramming rate of murine fibroblasts with the original four factors^[112-114]. Finally, the forced expression of *Oct4* alone was shown sufficient to reprogram murine NSCs, albeit with a ten-fold lower efficiency than with two factors^[113]. Because NSCs are originally closer to the pluripotency state than somatic cells and require fewer factors to be reprogrammed, they constitute a more simple and attractive system to study epigenetic mechanisms occurring during the acquisition of pluripotency. Importantly, iPSCs derived from human and murine NSCs exhibited markers of ESCs, showed demethylation of pluripotency genes, formed teratomas, and contributed to viable chimeras^[112-114].

Reprogramming factors and epigenetic mechanisms

Reprogramming of somatic cells is a stochastic event^[115]. However, in NSCs, *Oct4* only seems sufficient to repress genes responsible for NSCs molecular identity and activate the pluripotency genes, suggesting that epigenetic of NSCs renders them easier to reprogram and that the combination of factors necessary for reprogramming is dependent on cellular context^[112]. iPSCs have lower levels of methylation than somatic cells, suggesting that demethylation is an important chromatin feature to achieve pluripotency^[116]. During reprogramming, it is stipulated that reprogramming factors interfere with methylation of the newly synthesized DNA by binding to specific promoters or enhancer regions leading to demethylation and activation of the pluripotency genes. In addition, active DNA demethylation mechanisms could be required for the reactivation of pluripotency genes^[117]. Recent studies in NSCs have shown the importance of methy-

lation level in the context of reprogramming. Undifferentiated neurospheres highly express DNMT1 and contain methylated chromatin suggesting the role of methylation for the maintenance of the quiescent or undifferentiated state of NSCs^[118]. It is then probable that NSC chromatin is dynamically remodelled and that DNA methylation modification is essential for reprogramming to a pluripotent state. For instance, histone methyltransferase G9a is responsible for the downregulation of Oct4 during NSC differentiation and its inhibition results in iPSC formation after overexpression of exogenous Klf4 and c-myc only^[119]. In addition, interference with DNMT1 promotes iPSC formation, also supporting that DNA methylation is a feature limiting reprogramming to pluripotency^[101]. All reprogramming techniques involve demethylation of the genome thus appearing as a crucial process for successfully achieving pluripotency^[120,121].

Loss of epigenetic memory

During reprogramming, NSCs downregulate specific genes like *Nestin* and progressively express the markers of pluripotency *Oct4*, *Nanog*, *Fgf4*, *Zfp42*^[113,114]. In addition, efficiency and timing of reprogramming highly depends on the differentiation state of the initial cell type. Importantly, comparative studies with ESCs reported that efficiently reprogrammed iPSCs show transcriptional pattern and epigenetic marks highly similar to ESCs. For instance, Oct4 and Nanog promoters are demethylated and histones H3 lysine 4 (K4) and lysine 27 mostly exhibit patterns of trimethylation^[101,106,122]. However, reprogramming of NSCs into iPSCs is often incomplete and leaves epigenetic marks including DNA methylation, chromatin modification and transcriptional regulation in the resulting iPSC genome^[123,124] known as epigenetic "memory". Partially reprogrammed cell lines are characterized by an absence of complete downregulation of the exogenous reprogramming factors and partial demethylation and reactivation of pluripotency genes^[101,104]. During reprogramming, somatic markers get progressively downregulated demonstrating the importance of silencing its differentiation program as a step towards pluripotency. Treatment of partially reprogrammed iPSCs with inhibitors of ERK1/2 and GSK3b signaling^[125], induced genome demethylation of 30% explained by decreased levels of DNMT3a/b and their targeting factor DNMT3L^[126-128]. The two inhibitors repress DNMT3A/B expression inducing demethylation of certain genomic regions in ESCs. Thus, DNA demethylation of the reprogrammed cell type as a way to remove epigenetic marks is important for complete reprogramming into iPSCs. Reprogrammed iPSCs often present the limitation of not being fully reprogrammed thus keeping epigenetic traces of the tissue of origin. Future generation of iPSCs without epigenetic memory is an important challenge in the field to ensure that differentiation decisions are not affected by events from the past^[116].

FUTURE PERSPECTIVES

Determining the mechanisms by which neural stem cells maintain self-renewal capacity and at the same time generate differentiated progeny is a central challenge in stem cell biology. Several recent studies have demonstrated that epigenetic gene regulation plays a crucial role in the control of stem cell behaviour. Epigenetic mechanisms include changes in chromatin structure that provides a way for coordinately activating or repressing genes during proliferation and differentiation. Extracellular signaling from the micro-environment or niche in which NSCs reside *in vivo* interacts with these diverse epigenetic mechanisms, thus regulating transcription factors and intracellular pathways. These changes in gene expression are often heritable and reversible, features that support stem cell plasticity such as the ability to dedifferentiate or become reprogrammed under certain conditions. Finally, aberrant epigenetic mechanisms are known to be involved in the development of many neurological diseases. Characterizing epigenetic changes associated with a particular neural pathology may be used as biomarkers of disease and the manipulation of those epigenetic mechanisms holds great promise as a potential therapeutic strategy.

pending in tissue engineering. The loss of hair follicles caused by injuries or pathologies such as alopecia not only affects the patients' psychological well-being, but also endangers certain inherent functions of the skin. It is then of great interest to find different strategies aiming to regenerate or neogenerate the hair follicle under conditions proper of an adult individual. Based upon current knowledge on the epithelial and dermal cells and their interactions during the embryonic hair generation and adult hair cycling, many researchers have tried to obtain mature hair follicles using different strategies and approaches depending on the causes of hair loss. This review summarizes current advances in the different experimental strategies to regenerate or neogenerate hair follicles, with emphasis on those involving neogenesis of hair follicles in adult individuals using isolated cells and tissue engineering. Most of these experiments were performed using rodent cells, particularly from embryonic or newborn origin. However, no successful strategy to generate human hair follicles from adult cells has yet been reported. This review identifies several issues that should be considered to achieve this objective. Perhaps the most important challenge is to provide three-dimensional culture conditions mimicking the structure of living tissue. Improving culture conditions that allow the expansion of specific cells while protecting their inductive properties, as well as methods for selecting populations of epithelial stem cells, should give us the necessary tools to overcome the difficulties that constrain human hair follicle neogenesis. An analysis of patent trends shows that the number of patent applications aimed at hair follicle regeneration and neogenesis has been increasing during the last decade. This field is attractive not only to academic researchers but also to the companies that own almost half of the patents in this field.

INTRODUCTION

Regenerative medicine aims to create living, functional tissues that repair or replace lost or damaged organ function resulting from disease, injury, congenital defects or aging.

The main challenge of tissue engineering is the reconstitution of fully organized and functional organ systems from dissociated cells that have been propagated under defined tissue culture conditions.

Skin is the largest organ in the human body, acting as a barrier with protective, immunologic and sensorial functions. Deep skin injuries produce a complete destruction of skin regenerative elements. These wounds heal by contraction, with epithelization from the edges only and extensive scarring, resulting in reduced joint movements and cosmetic defects^[1]. Moreover, if these lesions are too extensive, the healing process is unsuccessful and they become life-threatening for the patient. Tissue engineering has emerged as a new interdisciplinary field combining scaffolds, cells and biomolecular signals towards the treatment of skin lesions. This useful strategy may contribute not only to the treatment of deep skin injuries but also to the understanding of skin regeneration.

The main goal of tissue-engineered skin grafts is to restore lost barrier function. Many dermal-epidermal composites or skin equivalents have been described for use in the clinic^[2] but the inability of these skin constructs to regenerate skin appendages as hair follicles has limited their use. Although the ability to reconstitute adult skin with functional skin appendages has long been a major clinical objective, the regeneration of epidermal appendages, such as hair follicles, and sebaceous and sweat glands, is a challenge that is still pending.

Recent studies clearly demonstrate that there are

multipotent stem cells with the capability to regenerate hair follicles and sebaceous glands in adult mammalian skin and this multipotency can be maintained in cell culture^[3,4]. The hair-differentiation potentiality of epidermal stem cells can be activated by inductive dermal cells. As will be extensively reviewed in this article, co-grafting of those cellular components from mice allows complete hair reconstitution^[5]. The successful regeneration of hair follicles in immunodeficient mice suggests that creating human hair follicles in tissue-engineered skin grafts is feasible. However, regeneration of human hair in a similar manner has not been reported.

Skin appendages cannot be restored in healed wounds by current tissue-engineered skin grafts^[6] mainly because of their limited self-regeneration capability in adults^[7], the lack of appendage structures in the human skin grafts and probably an improper molecular microenvironment. Many strategies still need to be explored, particularly enriching isolated cells with trichogenic capability, maintaining this capability during processing, and providing the cells with proper environmental signals.

The lack of skin appendages by skin wounds and by pathologies such as different kinds of alopecia not only affects the patients' psychological well-being^[8], but also endangers the inherent functions of the skin.

Skin appendages cannot regenerate on their own after damage^[7]. For the fully functional regeneration of ectodermal organs, it has been proposed that a bioengineered organ could be developed by reproducing the embryonic processes of organogenesis.

This review summarizes current advances in the different experimental strategies to regenerate or neogenerate hair follicles, *in vitro* and *in vivo*, with emphasis on approaches that include the neogenesis of hair follicles in adults from isolated cells and by tissue engineering as well as an analysis on patent trends in this field.

ANATOMY AND BIOLOGY OF HAIR FOLLICLES

The skin consists of three layers: epidermis, dermis, and hypodermis. The epidermis is in fact a multi-layered epithelium extending from the basement membrane that separates it from the dermis to the air. The dermis is located below the epidermis and is a connective tissue comprised of extracellular matrix, fibroblasts, vascular endothelial cells, and skin appendages.

Skin appendages, including hair follicles, sebaceous glands and sweat glands, are linked to the epidermis but project deep into the dermal layer. A human has around five million hair follicles with two types of hair, terminal hair (long, thick pigmented) and vellus hair (thin, unpigmented)^[9].

Hair follicles are composed of an outer root sheath

(ORS) that is contiguous with the epidermis, an inner root sheath (IRS) and the hair shaft (HS). The matrix surrounding the dermal papilla (DP), in the hair root, contains actively dividing and relatively undifferentiated cells that are essential for follicle formation.

In embryogenesis, the skin begins as a single layer of epidermal stem cells. Then, mesenchymal cells populate the skin to form the underlying collagenous dermis^[10]. Human hair follicles start to develop through complex morphogenetic processes resulting from highly coordinated series of bidirectional epithelial-mesenchymal interactions^[11]. Hair follicle development is initiated by the appearance of a thickening in the embryonic ectoderm called placode resulting from the condensation of the underlying mesoderm that will form the DP^[12]. The DP becomes a permanent part of the follicle base^[13] enveloped by the hair bulb. It is considered the commander of the hair follicle determining the hair thickness, length, and life cycle^[8]. Signals from the condensed mesoderm induce the proliferation of the placode which forms mature hair follicles by a systematic series of differentiation and proliferation processes of epithelial cells. The hair follicle becomes fully mature when its bulb nears the bottom of the dermis. At this point, the proliferative cells (matrix) at the follicle base continue to divide, producing progeny cells that terminally differentiate to form the growing hair that emerges from the skin surface. The inner layers begin to differentiate into concentric cylinders to form the central HS and the surrounding channel, the IRS.

These tissues undergo continual rejuvenation and, in response to injury, they must be prepared for wound repair. The capability of the skin for maintaining tissue homeostasis, regenerating hair, and repairing the epidermis after injury resides in its stem cells.

HAIR FOLLICLE STEM CELLS AND THE HAIR CYCLE

Stem cells are undifferentiated cells that are ultimately responsible for the constant renewal of the skin due to their distinguishing properties of self-renewal for the entire life span of an organism and their ability to differentiate into a variety of specialized cells.

A pool of progenitor cells is located on the basement membrane of the skin. These cells contribute to epidermal homeostasis undergoing continuous self-renewal and differentiation to keratinocytes that migrate towards the surface of the skin where they undergo terminal differentiation and maturation providing the skin's barrier properties.

Another reservoir of slow-cycling multipotent stem cells that gives rise to a range of differentiated cell types in skin is located in a specialized region of the ORS in the hair follicle, known as the bulge^[3,4,14-16]. Early work showed that these slow cycling multipotent stem cells not only contribute to the growth of hair

follicles themselves and of the sebaceous glands^[3] but also can be activated and migrate out of hair follicles in order to repair the damaged epithelium^[17]; however, they contribute little to the turnover of the intact epidermis. In the absence of these hair follicle stem cells (HFSC), hair follicle and sebaceous gland morphogenesis is blocked, and epidermal wound repair is compromised^[18]. The epithelial-mesenchymal interactions with the underlying DP play a pivotal role in embryonic hair genesis^[12], in the regulation of post-natal hair follicle cyclical activity, and in the repair of wounded skin^[19-22].

Unlike most organs, hair follicles do not reach homeostasis once they mature. Each mature hair follicle is a regenerating system, which physiologically undergoes cycles of growth (anagen), regression (catagen), and rest (telogen) numerous times in adult life^[23]. In catagen, hair follicle stem cells are maintained in the bulge. Then, the resting follicle re-enters anagen (regeneration) when proper molecular signals are provided. During late telogen to early anagen transition, signals from the DP stimulate the hair germ and quiescent bulge stem cells to become activated^[24]. Many paracrine factors are involved in this crosstalk at different hair cycle stages and some signaling pathways have been implicated^[3,19,25]. In anagen, stem cells in the bulge give rise to hair germs, then the transient amplifying cells in the matrix of the new follicle proliferate rapidly to form a new hair filament^[26].

Even if it is generally believed that hair follicles do not form after birth in humans^[27], the formation of vellus hair follicles from the reconstituted epidermis of an abraded area of facial skin was described in 1956^[28]. However, the great challenge of skin tissue engineering and skin wound regeneration remains to be its inability to reliably reconstitute skin appendages, most notably hair follicles and sweat glands. The information about the mechanisms that generate and maintain skin appendages provided by recent studies with skin-derived progenitor cells, may be the basis of new therapies that could help to overcome these limitations.

CAUSES OF HAIR LOSS AND REGENERATION OF THE HAIR FOLLICLE

Hair loss responds to different causes ranging from mild traumas, such as hair fiber plucking, to severe traumas such as partial- or full-thickness skin lesions. Pathological processes, such as cicatricial or non cicatricial alopecia, can also be responsible for hair loss. After plucking, if HFSC and DP remain, a new hair filament would be spontaneously regenerated. Some label retaining studies have shown that hair follicle stem cells in the bulge remain intact after hair plucking^[29,30] whereas others reported bulge stem cells suffering apoptosis after plucking which are replaced by label retaining cells coming from hair germ^[31].

It was also observed that the slow-cycling bulge cells (CD34 positive cells in mouse) are involved in normal hair homeostasis and wound healing, whereas regeneration after hair plucking involved actively cycling cells from the lower ORS^[26]. However, the cell dynamics in this process is less clear than in the physiological renewal and further studies are required to understand this process.

However, when the cellular niches are completely lost, it is necessary to generate a completely new hair follicle in a process called hair follicle neogenesis.

Based on the knowledge on the epithelial and dermal cells, and their interactions, during the embryonic hair generation and adult hair cycling, different experimental approaches have been designed to regenerate hair follicles or generate new ones by the neogenesis process.

These hair regeneration and neogenesis attempts are recapitulated in this article, and can be classified into 4 categories: (1) reversion of pathological intra- and/or extra-follicular environment, for instance androgenetic alopecia (AGA); (2) regeneration of complete hair follicles from the recombination of hair follicle parts; (3) neogenesis of hair follicles from isolated cells; and (4) neogenesis of hair follicles by tissue engineering.

Reversion of pathological intra- and/or extra-follicular environment

Hair follicle cycle and growth can be affected and deregulated by paracrine factors from the follicle itself and/or from the surrounding dermal tissue, or by endocrine factors^[32,33] leading to hair loss. Many factors have been described as molecular mediators of hair follicle growth^[11]. Some of them, such as PDGF^[33] and Wnt proteins^[34], are positive regulators while others, such as BMPs^[35], suppress hair growth. Many paracrine factors involved in the epithelial-mesenchymal crosstalk at different stages of the hair cycle, and some implicated signaling pathways, have also been studied^[3,19,25].

In addition, endocrine factors, such as sexual hormones, have both physiological and pathological effects on hair growth as in human male beard, and androgenetic alopecia respectively. Androgenetic alopecia^[36] is a common, progressive disorder in which large, terminal scalp hairs are gradually replaced by smaller hairs following a defined pattern. The DP is the site through which androgens act on follicle cells by altering the regulatory paracrine factors involved in the differentiation and proliferation of HF stem cells. DPs from balding scalp have higher levels of androgen receptor and 5- α reductase. Dihydrotestosterone can induce DP to secrete factors including, TGF- β 1 and DKK-1 which down regulate keratinocytes growth^[37,38].

A functional crosstalk between the androgen receptor and Wnt signaling pathways in DPCs has been described in target tissues^[39]. Moreover, our group has demonstrated that androgens regulate secreted factors involved in normal HF stem cell differentiation via the

inhibition of the canonical Wnt signaling system in androgen sensitive DPCs. We provided evidence that androgen activation of GSK-3 β would be responsible for the inhibition of Wnt/ β -catenin signaling^[40]. The current pharmacological treatment for AGA includes androgen metabolism modulators, such as the 5- α reductase inhibitor finasteride and the antiandrogen agent flutamide. Nevertheless, the results of these treatments are not only variable and patient-dependent, but can also cause undesirable side effects. Therefore, therapies acting on specific molecular targets are necessary to treat this pathology downstream from the actual antiandrogenetic pharmaceutical modulators. The crosstalk between the androgen receptor (AR) and Wnt/ β -catenin signaling pathways could be one alternative therapeutic target, among many others recently reviewed^[41].

In these experimental approaches, modulation of the intra-follicular microenvironment and the extra-follicular macroenvironment could contribute to promote growth of the existing hair follicles but not to increase their number by the formation of new ones.

Regeneration of hair follicles by recombination of hair-follicle parts

Taking into account the inductive ability of DP and the current knowledge on epithelial-mesenchymal interactions, different recombination of dermal and epidermal tissue have been employed for hair follicle regeneration. In the early 1960s, researchers showed that whole follicle end bulbs and isolated whole whisker papillae (containing dermal and epidermal components) remain viable and may produce whisker hair follicles in a new site^[42]. The most surprising finding was that isolated DPs (without epidermal components) were capable of inducing the generation of new hair follicles recruiting epithelial cells from the implantation sites. The same results were obtained when epidermis from different origins were transplanted together with whisker DP^[43]. Regeneration of hair follicles was also observed in both mice^[43-45] and humans^[46] when dermal sheath tissue was used, which was sufficient to regenerate also the DP structure. After implantation, the whisker DP was capable of inducing hair follicle regeneration retaining the information to determine hair fiber type and follicle size^[47].

Neogenesis of hair follicles in adult individuals from isolated cells

Grafting of dermal-inductive tissue is limited by the fact that it is not possible to generate more hair follicles than the obtained from the donor tissues. To overcome this limitation different approaches and experimental models using freshly or cultured isolated cells from both dermal and dermal/epidermal origin were tested. Most of them involved neonatal and embryonic murine cells. One of the first models used was the chamber assay (Figure 1) in which dermal and epithelial cells are seeded inside a chamber consisting of a cylinder

Figure 1 Hair follicle neogenesis using isolated epithelial and dermal cells. Inductive-dermal and Epithelial Cells can be obtained from adult tissue or embryonic sources. Isolated cells by enzymatic digestion of living tissues, or monolayer cell cultures (A) can be used in the trichogenic assays (D): Chamber assay; Patch assay; and flap assay. Moreover, isolated cells can be cultured in 3D-conditions, allowing them to create their own extracellular matrix as in the case of homotypic and heterotypic spheroids and hair germs (B). Also, cells can be seeded on a precast scaffold used for cellular support or used to produce a bioengineered composite skin (C). Any of these constructs can be evaluated by the trichogenic assays (D): Flap assay; and Bioengineered composite skin grafting. All these trichogenic assays are mainly performed in the back-skin of athymic mice in order to avoid immune rejections and to take advantage of its bare-skin (E). DPCs: Dermal papilla cells; DSCs: Dermal sheath cells; HFSC: Hair follicle stem cells.

inserted through a full-thickness skin lesion in mouse dorsal skin, covered by a dome. In former studies using this device in nude mice^[48], it was showed that hair buds obtained from neonatal mice combined with fresh neonatal dermal cells or with immortalized clones from vibrissae rat DPCs produced mature and cycling hair follicles. Using the same chamber assay, hair bud preparations without any additional inductive dermal component were unable to form hair follicles resulting in a scarring reparative tissue, a thin epidermis and a dermis without appendages^[49]. On the other hand, the combination of hair buds with fresh dermal cell preparations or early passages of cloned vibrissae cell lines resulted in skin with normal epidermal and dermal layers.

Although these studies confirmed the trichogenic potential of dissociated dermal cells, particularly DPCs, the conditions of the chamber assay correspond to a wound healing environment and do not represent the physiological status. Other approaches allow studying the trichogenic potential of isolated cells in a more physiological environment, as is the case of the patch assay (Figure 1). This assay consists in injecting dissociated murine neonatal epidermal and dermal cells hypodermically into adult mouse skin. This system, originally described by Zheng

et al^[50], showed the formation of cell clusters that resulted in "infundibular cysts" which generated hair germs, followed by pegs that grew to differentiate into cycling mature pilosebaceous units. Surprisingly, whereas patch hair follicles were in anagen phase, the host skin hair follicles were in telogen and vice versa, suggesting that follicle cycling depends on the trichogenic cells and not on the host skin hair cycling. Even when the shaft grows inside an intradermal cyst that tends to extinction by inflammatory processes, none of the other already described systems at that moment showed to be so efficient to evaluate the trichogenic potential of isolated cells. A variation of this method is called tracheal grafting method. It consists in inoculating rat tracheas with fresh or cultured keratinocytes from newborn mice together with newborn fibroblasts or cultured DPCs and implanting them subcutaneously in athymic mice for four weeks. In this assay hair follicles and sebaceous glands were generated using cultured keratinocytes from newborn mice and fresh newborn fibroblasts^[51]. Although adult mice keratinocytes successfully produced a two layered epithelium, they failed to generate hair follicles or sebaceous glands^[51].

Other strategy to evaluate the hair inductive capability of dermal cells is the "flap assay" (Figure 1). This

approach originally described by Qiao *et al.*^[52] consists in: (1) generating a skin flap in the dorsal skin of nude mice; (2) locating an embryonic epidermis supported by a silicone sheet in direct contact with the muscle with the basal side of the embryonic epidermis facing upwards; (3) seeding embryonic murine dermal cells or cultured DPCs onto the basal face of the graft-epidermis; and (4) pulling over the graft and suturing the flap edges. In this configuration the graft-dermal cells were layered between the graft-epidermis and the host connective tissue. When fresh embryonic dermal cells were used, abundant hair was developed four weeks after grafting. The induced hairs were oriented vertically down towards the silicone sheet. After surgical flap inversion, the formed hairs were exposed in the host skin surface and survived for more than 12 mo.

Neogenesis of hair follicles by tissue engineering

Although the assays described above provided much information respect to the hair neogenesis process and the cells involved in it, the high number of cells required, the need of *in vivo* animal models and the poor results obtained with human cellular sources make these procedures not applicable for clinical uses in the near future. The development of new strategies has become necessary and begun to emerge. They are mainly focused on tissue engineering-based follicle neogenesis, including three-dimensional (3D) cell culture conditions generated by the cells themselves or by the use of biocompatible scaffolds.

Lee *et al.*^[53] developed a simplified procedure to reconstitute hair-producing skin. They obtained both epidermal and dermal cells from newborn mice, and mixed them in different ratios. A high density cellular suspension was prepared in drops of minimal volume on tissue culture inserts or wells. They allowed the cells to settle until gel consistency was obtained. Alternatively, they seeded the cells on the collagen-side of the IntegraTM matrix (porous matrix of cross-linked bovine tendon collagen and glycosaminoglycan and a silicone layer). Both constructs were grafted in full thickness skin wounds generated on the back of athymic mice. After grafting, the epidermal cells formed a basal layer and some epidermal microcysts could be observed. Dermal cells started to form dermal condensations adjacent to the epidermal layer or cysts. Eight days after grafting hair germ started to appear and progressed to hair peg, observing complete hair follicles four days later that kept the ability to continuously cycle for at least one year. This method would allow preparing constructs with specific sizes and shapes useful to treat alopecia by tissue implants.

Two separate reports^[54,55] showed hair follicle neogenesis using hair germs obtained by the previously described "organ germ method"^[56]. One of them^[54] generated bioengineered hair germs mixing epithelial and mesenchymal cells derived from mouse embryos within a collagen gel drop. In these culture conditions, the two cellular types generated a structure with

two cellular layers separated by a translucent region they called hair germ. When these hair germs were transplanted ectopically into subrenal capsules, the presence of mature hair follicles was observed. These bioengineered hair follicles had a normal histological structure with the concentric epithelial layers of ORS and IRS, DP, hair matrix, and sebaceous glands. These follicular units transplanted intracutaneously in nude mice (Figure 1), were connected to the arrector pili muscle and nerve fibers and were able to produce hair shafts and cycling.

In addition, a fully functional orthotopic hair regeneration was demonstrated via intracutaneous transplantation of bioengineered hair follicle germs generated by epithelial and mesenchymal cells derived from mouse embryos^[55] (Figure 1). These bioengineered hairs responded to hair cycles and had the correct structure of natural hair follicles and shafts, and the proper connections with surrounding host tissues. Qiao *et al.*^[57], using embryonic dermal cells and hair-peg-derived keratinocytes, generated cellular aggregates by hanging drop methods. These aggregates cultured in methylcellulose coated wells elongated, and after seven days, acquired hair follicle features. These structures termed "proto hairs", showed a morphological structure more developed respect the previously described "hair germs"^[54,55]. They presented hair-like characteristics as an inner mass of cells similar to the DP structure surrounded by matrix-like keratinocytes and a partially keratinized substance that could represent intent to produce a hair shaft. After implantation into shallow incisions in nude mice (Figure 1), black-pigmented hair fibers were observed emerging from epidermis. These hairs persisted throughout the experimental period (6 mo) and were shown to regrow after plucking.

Although embryonic tissues are used as cellular sources, these studies showed the potentiality of dissociated cells to form hair follicle germs or proto-hairs able to generate mature hair follicles both by ectopic and orthotopic implantation. Collectively, these studies provide a proof of concept for the use of Follicular Cell Implantation to restore hair in patients suffering from hair loss.

As it was already mentioned, dermal cellular components from the skin, such as DPCs or dermal sheath cells (DSCs), have the potential to induce hair formation in *in vivo* assays and also induce *in vitro* differentiation of hair follicle stem cells to hair lineage^[25,40]. Even if it is possible to isolate and culture DPCs, the inductive ability tends to fade with time in 2D cultures^[6,58]. Considering that the hair follicle neogenesis requires a large number of DPCs, it is necessary to look for new strategies to maintain their inductive potential in culture in order to use them in skin bioengineering and hair follicle neogenesis.

The niche generated by the extracellular matrix (ECM) of DP probably plays a key role in keeping DPC inductive activity. Accordingly, the loss of ECM throughout culture time could be responsible for the

fading of DPC inductive properties.

DPCs are naturally aggregated at the hair-bulb base. In proper culture conditions, these cells tend to aggregate^[13,59] and their inductive activity is preserved after they are grafted in this state. It has been demonstrated that it is possible to generate dermal papilla spheroidal microtissues using different methods including rotation, two-step rotation and flotation, and hanging drop^[60-62]. Osada *et al.*^[63] artificially prepared DPC spheres by aggregation of mouse vibrissae follicle DPCs in a round-bottom 96-well low-binding plate. These spheres expressed higher amounts of versican, an indicator of inductive capability, than DPCs in monolayer cultures. In a "patch assay" (Figure 1), together with embryonic-epidermal cells, they induced hair follicle neogenesis, keeping their inductive capability for at least twenty-six passages.

However, these methods are labor intensive and the microtissues obtained have a very variable size and cell number content, which reduces reproducibility. DPCs can self-assemble into dense spheroids when seeded on controlled biomaterial surfaces such as poly (ethylene-co-vinyl alcohol) (EVAL)^[64] or polyvinyl alcohol (PVA) membranes^[65]. The DPC microtissues generated on EVAL surface^[64] expressed DPC-markers such as neural cell adhesion molecule (NCAM)^[66] and α -smooth muscle actin^[67]. Alkaline phosphatase activity, which correlates with hair follicle inductive ability of DPC^[68], was higher in spheroid microtissues than in monolayer cultured cells. Finally, the spheroids mixed with newborn mouse epidermal cells and injected into the hypodermis of nude mice in a "patch assay" (Figure 1) were able to generate new hair follicles.

The use of PVA as substratum material enhanced DPC aggregation^[65], preventing cellular attachment and spreading. Using this material and reducing culture surface it is possible to control the number, size and compaction of spheroidal microtissues. DPCs quickly aggregated into a single spheroid whose diameter decreased progressively due to tissue compaction. The expression of DPC-inductive capability markers, versican^[69] and alkaline phosphatase^[68], were present in spheroids of various sizes. All these experiments were made both with adult DPCs from rat vibrissae, and human scalp hairs, giving similar results. The hypodermal injection in nude mice of eighty spheroids altogether with keratinocytes from newborn mice induced HF neogenesis. These results are very promising given that transplantation of dispersed cultured human DPCs had shown very low efficiency in inducing new hair follicles^[70]. Using the same approach, heterotypic folliculoid microtissues or hair follicle-like organ germs were produced using dissociated adult epithelial and mesenchymal cells by self-assembly on EVAL coated wells^[71]. Keratinocytes and DPCs seeded together grew into floating or loosely attached multicellular spheroids. Histological analysis showed that the spheroids are composed by

a core of DPCs surrounded by keratinocytes. These keratinocytes expressed keratin 6, a cytokeratin preferentially expressed by ORS *in vivo*^[72], and DPCs expressed versican, a marker associated to HF-inductive ability. Using "patch assays" (Figure 1) disperse DPCs and keratinocytes did not form new hair follicles, whereas heterotypic folliculoid microtissues did. These last experiments would contribute to the development of new strategies for scalable production of organoid microtissues of epithelial organs for hair follicle neogenesis by bioengineering approaches.

Altogether, these results strongly indicate that the hair-inductive capability of DPCs can be restored by three-dimensional spheroid cultures.

Hair follicle neogenesis using human cells

During embryogenesis, dermal mesenchymal cells drive HF development and a condensate of these cells remains during adult life forming hair follicle DP. These cells retain the capability to induce hair follicle regeneration and neogenesis^[21,73] as reviewed by Ohyama *et al.*^[5] and Yang *et al.*^[6]. However, most of these experiments were performed using murine and embryonic cells, whereas DPC from human origin showed many difficulties to maintain inductive capability in culture^[74].

As discussed above, rat cultured DPCs self-aggregate within the dermis forming a papilla-like structure that synthesizes its own extracellular matrix^[13]. However, such behavior was not observed with cultured human DPCs, highlighting specie-specific differences. Human keratinocytes from ORS and DPCs cultured in Matrigel™ (3D network of extracellular matrix proteins and collagen) have shown to form tubule-like structures in this skin-equivalent *in vitro*^[75] and organize themselves into epidermoid cyst-like spheroids^[72,76], but did not form complete hair follicles. Similarly, Sriwiriyanont *et al.*^[77], observed neofollicle formation in nude mice grafted with engineered skin substitutes containing murine DPC and human keratinocytes in a collagen-glycosaminoglycan matrix, but not in those containing human DPC and human keratinocytes.

Ehama *et al.*^[78] reported the formation of hair follicle-like structures using human primary cultures of foreskin- or adult-derived epidermal cells co-grafted with murine DPCs by a chamber assay (Figure 1). The innermost regions were similar to the hair cortex and medulla of mature human follicles. Hair shaft-like fibers occasionally emerged at the skin surface, and structures, reminiscent of the DP, at the follicle bottom were also observed. However, these structures showed no bulge region, nor all the follicular epithelial layers, and the DP-like tissue failed to express the anagen DP marker versican. These hair follicle-like structures correspond to the initial follicle formation suggesting that the differentiation process was altered.

Using the "flap assay"^[52] (Figure 1), Qiao *et al.*^[79] showed that DPCs from human scalp combined with epidermis from mouse embryo produced mature

hair follicles that persisted and grew. The authors reported that the inductive potential of DPCs could be maintained using keratinocyte-conditioned medium. These DPCs were able to form DP and dermal sheath *in vivo*.

Spheroids microtissues were also obtaining by culturing human DPCs in a 96-well low-binding plate, and implanted intradermally into nude mice using the "patch assay" (Figure 1)^[80]. This combination of human DPC spheres with murine neonatal epidermal cells generated new hair follicles. In contrast, hair follicles were never observed when monolayer DPC cultures were used.

Cultured human DPCs do not induce hair neogenesis unless changes in the culture conditions are made. In this sense, the formation of DPC-microsphere tissues has shown to improve hair-inductive properties of rodent cells as well as the expression of cell-markers associated with these properties^[63-65]. Therefore, all these observations encouraged investigators to look for new strategies intended to achieve the first step toward human hair follicle neogenesis that is, providing culture conditions that confer hair-inductive ability to human DPCs. Higgins *et al.*^[74] evaluated the human DPC-transcriptome observing that monolayer DPC cultures showed the most important changes immediately after early outgrowths from DP explants. These changes involved 3729 transcripts, including several involved in hair follicle development. This large number of differentially expressed transcripts shows the physiological changes that 2D culture conditions do on the molecular signature of DPCs. The generation of DPC spheroids by the hanging drop method partially restores the intact DP signature. These human-DPC spheres induced hair follicle neogenesis when placed in between foreskin epidermis and dermis and grafted onto nude mice (Figure 1). These hair follicles showed a DP and dermal sheath highly positive for alkaline phosphatase, hair specific keratin markers disposed in concentric layers and blood vessel formation around follicles. Nevertheless, neither sebaceous glands nor hair fibers emerging from the skin surface were seen. These results suggested that human DPC spheroids would be able to initiate hair follicle morphogenesis but the production of a complete hair follicle requires additional signals.

Recently, Miao *et al.*^[81] produced DPC-spheroids from cultured DPCs on a MatrigelTM scaffold. As reported by Higgins *et al.*^[74], the DPC spheres were shown to restore DP-signature gene expression of NCAM, versican and α -smooth muscle actin (α -SMA), lost during monolayer culture. The authors also claimed that these DPC-spheres, combined with hair germinal matrix cells, onto Matrigel-coated plates produced colorless fiber-like structures *in vitro*.

Other alternative to culture dermal mesenchymal cells in 3D conditions is the organotypic method consisting in culturing cells inside a scaffold. Using this method, Wu *et al.*^[82] prepared a collagen gel with

human DPCs or dermal sheath cells (DSCs). This gel was seeded with keratinocytes from interfollicular skin, superior ORS or inferior ORS obtaining *in vitro* a bilayered skin. Nonetheless, only the constructs containing superior ORS keratinocytes showed hair follicle-like structures. That is, an outer root sheath, nearly ten layers of concentric epithelial cells, a middle layer IRS-like and some keratinoid substances in the center, similar to a hair fiber. When these constructs were transplanted into nude mice (Figure 1), only the organotypic cultured tissue containing superior ORS keratinocytes and DPCs exhibited hair follicle structures.

In a recent study^[83], composite skin substitutes were generated by seeding human neonatal foreskin keratinocytes onto a dermal equivalent structure cultured in air-liquid interface condition. This dermal equivalent was composed of DPCs from human scalp contained in a collagen-I gel. Eight weeks after grafted onto nude mice (Figure 1), these constructs presented hair follicles showing bulb, dermal sheath, hair matrix and cortex. Histological analysis showed concentric layers of IRS and ORS, sebaceous glands and hair shaft. Immuno-histochemistry assays revealed that both epithelial and dermal cells from neo-follicles were from human origin, and that DPCs and DSCs expressed human nestin and versican.

The analysis of all these reports leads to the conclusion that hair follicle neogenesis using human epithelial and dermal cells is a very difficult task that requires special culture conditions, somehow recreating the normal or embryonic skin environment, and the use of embryonic or neonatal cells.

Very recently, we prepared in our laboratory a dermal-epidermal skin substitute by seeding an acellular dermal matrix with cultured hair follicle epithelial stem cells and DPCs, both obtained from adult human scalp^[84]. These constructs were grafted into a full-thickness wound generated on nude mice skin (Figure 1). In only fourteen days, histological structures reminiscent of many different stages of embryonic hair follicle development were observed in the grafted area. These structures showed concentric cellular layers of human origin, and expressed k6hf, a keratin present in epithelial cells of the companion layer. Although the presence of fully mature hair follicles was not observed, these results represent, up to our knowledge, the first report showing that both epithelial and dermal cultured cells from adult human scalp in a dermal scaffold were able to produce *in vivo* structures that recapitulate embryonic hair development.

ANALYSIS OF PATENTS TRENDS IN HAIR FOLLICLE REGENERATION AND NEOGENESIS

So far, we have made a concise review of the scientific

literature describing the attempts to regenerate the hair follicle. We have also mentioned a number of reviews on academic articles dealing with hair regeneration or wound induced follicle neogenesis that have been published in recent years^[85]. However, reviews on tissue engineering and hair regeneration patents are less common. Many of these strategies have been combined in different methods intended for use in active applications. In this section, we review and analyze published patents on hair regeneration^[86-150], as a measure of the interest in the industry for this area of research, identifying the currently available technical developments, favorite research strategies and main points of interest. Parameters analyzed include not only chronological patent publishing trends, but also the most cited patents, top patent owners (assignees), most cited documents, and the classification of patents among technology areas according to the International Patent Classification (IPC). Moreover, hair regeneration applications that have been patented throughout the years are screened (Figure 2).

LITERATURE STUDY

Patent search was performed using the Thomson Innovation Database, a collaboration platform for searching and analyzing global patents, integrated with analytics and workflow tools which allow access to more than 40 databases from different countries. For each particular group of hair regeneration, specific keywords (descriptors) were selected. Descriptors were chosen based on the synergy of two approaches: the search of specific keywords and concepts used in academic publications, and the selection of additional descriptors from specific patent vocabulary. Therefore, the keywords are: Stem cell; progenitor cell; precursor cell; repair; growth; wound; regeneration; neogenesis; skin; tissue engineering; dermis; epidermis; dermal; hair follicle; sebaceous gland and sebaceous unit. The presence of the chosen descriptors was checked in the title, abstract and claims of existing patents, considering documents published between years 1990 and 2014. More than forty technology patent and patent application databases were used for patent search, including the Spanish OEPM, the American USPTO, the worldwide WIPO, the European EPO, the patent offices of France, Germany, Great Britain and the Far-Eastern patent offices of Japan, China and South Korea. Besides the keywords, the search process was completed with the use of the IPC codes under which the patents of interest could be framed. The combination of the search approaches previously mentioned offered a universe of about 475 patent families, which were manually reviewed and filtered, setting aside those directed to gene therapies, mesenchymal, embryonic stem cell, osteoblast, neuron and hematopoietic cell and others. The result of this process was the identification of 65 patent families^[86-150]. The selection of the document to be considered in patent trends was the first published.

It is important to note that patent applications can be published in different countries under different national numbers. This is called the family of the patent. In the search performed for the present study, care was taken to include just one patent per family.

Tables showing patents that are most frequently cited take into account all the patents in the family, since it may occur that the earliest document is not necessarily the most cited one.

Competitive dynamics

The competitive dynamics indicator shows the distribution of patents among the different organizations, providing a general picture of the tissue repair regeneration industry and their relative positioning. On the basis of this information we can identify the most prolific applicants for hair regeneration technology patents in the world, by establishing the number of applications filed by each company.

Table 1 lists the applicants that have filed more than one application, which will be our "Reference Group". Most of the members of this group are manufacturing companies, indicating that this technology belongs to the industrial sector. The highest percentile is shared by a small number of applicants with five patents each, while a second group includes a wide range of companies with no clear technological leadership.

The group of companies of the first percentile shown in Table 1, are the leading hair regeneration manufacturers Shiseido Co Ltd and Aderans Research Institute, which own more than five published patents each, and which own almost 20% of all filed applications in this field.

The second percentile of institutions having one or two applications each could offer a favorable scenario for technology transfer.

It should be highlighted that there are over 20 institutions or about 40% patent applications from non-profit institutions including universities and foundations. The most prolific institutions are: Jilin University, University of Pennsylvania, University of Southern California and National Taiwan University, which gives an idea that this field is very prolific in academic institutions.

Technology trends

The patent technology trends indicator introduces the serial number of patent applications showing how technology has evolved over time as well as its appropriation by companies and non-profit institutions in the field of hair regeneration. This technological area has experienced constant growth. In the 90's an average of 2.5 patent applications were filed per year, and in the first decade of the 21st century the average increased to 6 patent applications per year (Figure 2).

The years 2011 and 2012 stand out as the ones with the most patent applications, 10 and 16 respectively.

Table 1 Owners of hair regeneration patents and patent applications matching all the descriptors found in academic literature

Assignee	No of patent applications	Percentage
Shiseido Co Ltd	5	7.69%
Aderans Research Institute Inc	5	7.69%
Hospital for Sick Children	2	3.08%
Biointegrence Inc, phoenixbio Co Ltd	2	3.08%
Follica Inc	2	3.08%
Organ technologies Inc	2	3.08%
University of Jilin	2	3.08%
University of Southern California	2	3.08%
National University of Taiwan	2	3.08%
Aderans Research Institute Inc, Bioamide Inc	1	1.54%
Agency for science, technology and research	1	1.54%
Alvi Armani Genomics Inc	1	1.54%
Anticancer Inc, Li L, Yang M	1	1.54%
Beijing Yonghe Hair Transplant Technology	1	1.54%
Biomaster KK	1	1.54%
Chen B, Gao Q, Zeng Q	1	1.54%
Chinese Academy of Science Institute of Zoology	1	1.54%
Total No of patent applications	65	100.00%
No of Entities	50	

Own investigation using patent data base Thomson Innovation.

Aderans Corp Company filed most patent applications from 2005 to 2008. Shiseido and Follica, as well as the University of Pennsylvania have filed patent applications in recent years.

From this general perspective, it can be inferred that the technological field is, at present time, in a developmental stage, with an annual growth rate of 10%, based on the number of patent documents filed since 2010.

From another perspective, Figure 3 shows the cumulative patent families published in the last 20 years. As it can be seen, since 2005 there has been a remarkable increase of attraction in the area: while 50% of the patents required 15 years to be generated, the remaining 50% has been filed over the past five years.

The analysis of patent application-trends shows that, at the present time, the development of hair regeneration technology is evolving positively, making this technological field attractive to companies that start producing and selling products as a result of the development of hair regeneration technology.

Technological leadership indicator

The technology leadership indicator identifies specific companies with the most consolidated and developed technologies in this specific field. The Patents which have received the highest number of citations are considered to have the highest degree of technological progress or impact. The analysis of patent citations allows the identification of patents which have been most useful for later researchers and for the development of newer technologies and may illustrate the diffusion of technical knowledge and its different practical applications throughout the years.

Just as those patents that have received most

citations are not always the most relevant ones, and those most relevant are not always the most cited ones; a number of empirical studies demonstrate a strong correlation between those variables. In Table 2 the 10 most cited institutions as references are listed.

Up to the present, New York University and Pennsylvania State University have received the highest number of citations with 29 citations which reflects the importance of the works of Lavker *et al*^[86] previously described. Following these institutions, companies like Biointegrence Co and Phoenixbio Co Inc, and Anticancer Inc have 17 citations. The Hospital for Sick Children, Aderans Research Institute Inc, Sci Torico Innovations Inc and Trichoscience Innovations Inc are among the most innovative companies.

Skin substitutes were among the earliest products to be developed using principles of tissue engineering, and their success is evident in the clinical use of several commercially available products. However, skin substitutes capable of performing all the functions of normal skin are not currently available, which limits their use in patients. Hair follicle neogenesis is not observed using current skin substitutes. Thus, the efforts in hair and skin bioengineering continue to be in a leading place in regenerative medicine. Furthermore, hair restoration is one of the fastest growing areas of cosmetic therapies for both men and women.

Hair follicles are important not only for appearance, skin hydration, barrier formation, and protection against pathogens but also in wound healing. As hair follicles store epidermal stem cells, skin with hair follicles heals faster. In addition, bulge stem cells are less susceptible to loss through minor trauma and damage through ultraviolet light. Thus, treatments that involve neogenesis of normal hair follicles would find much wider application for restoring normal skin

Figure 2 Evolution of the number of patent applications related to hair regeneration (time frame 1990-2014). Own investigation using patent data base Thomson Innovation.

function and appearance.

Methods and compositions capable of generating morphologically-correct, fully-developed human hair follicles, useful for treating conditions such as full- or partial-thickness skin loss, wounds, burns, scars, and hair loss have been developed in order to fulfill this necessity. In this analysis, only patents aiming to hair follicle regeneration or neogenesis have been selected. As reviewed, it has been determined that both epithelial cells and mesenchymal cells are essential for hair follicle regeneration. The regeneration of chimeric hair follicles comprised of mouse DPC and human epithelial cells has been shown to be possible, however it is still not possible to regenerate completely human hair follicles. One of the reasons for this is the difficulty to obtain an adequate number of human DPCs having the ability to induce hair follicle formation to be used

for transplantation. Consequently, most of the patents filed in this field provide cellular compositions capable of hair neogenesis and regeneration or methods for isolating progenitor skin cells as well as the culture conditions that will allow them to keep their inductive properties to promote hair neogenesis or regeneration.

The first most cited patent listed in Table 2 (WO1995001423), published in 1995, described a method of culturing and modulating subpopulations of follicular keratinocytes from upper portions of hair follicle to be used for identifying agents which stimulate hair growth or prevent hair loss and useful for follicular reconstruction and transplantation as well as wound coverage in burns and skin ulcer^[86].

In 2005 a patent application (WO2005053763A1) developed a method for transplanting the dermal papilla or dermal papilla cells and outer skin epidermis

Table 2 Most cited patents from 1990 to present

Publication number	Title	Assignee	Inventor	Publication year	Count of citing patents	Ref.

Own investigation using patent data base Thomson Innovation.

tissue or epidermal cells to hairless scalp to regenerate hair^[94].

Different tissue engineered-hair follicle grafts were also patented; a scaffold constructed to mimic the architecture of the native hair follicle and for percutaneous implantation facilitating the follicle neogenesis process^[90] (US20050214344), a hair graft comprising plucked hairs having adhered epidermal stem cells and follicular dermal cells for implantation into wounded skin^[105] (US20070122387A1) and a hair graft comprising a scaffold, and tissue engineered epidermal and dermal layer with hair follicle progenitor cells (WO2007062386A2)^[98].

Several methods for isolating skin-derived precursor stem cells from hair follicles or dermal papillae as well as the culture conditions or the delivery into the skin of these cells in order to induce hair growth are also among the most cited patents (WO2002060396A, WO2005071063A1 and US20070092496A1)^[88,91,99].

Finally, among the most cited patents are those describing methods for isolating hair follicle mesenchymal stem cells useful for treating alopecia and gene therapy (WO2003104443A2)^[89] or useful for hair loss, burns or skin replacement as well as for treating neurological or degenerative disorders (WO2003-024406A2)^[87].

The rest of the patents analyzed whose content is not mentioned, can be found in the References section^[86-150] at the end of this review.

CONCLUSION

Although a successful strategy to generate human hair follicles from adult cells has not yet been reported, the results presented in this review suggest the issues that need to be addressed before success can be achieved. Perhaps the most important of those issues is to provide cells with a three-dimensional structure that simulates the natural scaffold. Herein the cells should develop and interact among themselves or with other cell types in the epithelial-mesenchymal interactions. Improving culture conditions that allow the expansion of these cells without losing their natural properties, as well as selecting the appropriate epithelial stem cells, should give us the tools needed to face the challenge of regenerating human hair follicles.

These efforts in hair and skin bioengineering are also visible in the growing number of patent applications filed during the last decade, indicating that this technological field is not only attractive to academic research but also to the companies that own almost half of these patents.

for regeneration of damaged tissues. Stem cells have attracted much interest in tissue engineering as a cell source due to their ability to proliferate in an undifferentiated state for prolonged time and capability of differentiating to different cell types after induction. Scaffolds play an important role in tissue engineering as a substrate that can mimic the native extracellular matrix and the properties of scaffolds have been shown to affect the cell behavior such as the cell attachment, proliferation and differentiation. Here, we focus on the recent reports that investigated the various aspects of scaffolds including the materials used for scaffold fabrication, surface modification of scaffolds, topography and mechanical properties of scaffolds towards stem cells differentiation effect. We will present a more detailed overview on the effect of mechanical properties of scaffolds on stem cells fate.

Core tip: Application of stem cells in tissue engineering and regenerative medicine has attracted many researchers and it is considered as a hot topic of research. The research was mostly aimed towards the fabrication of a suitable scaffold with appropriate physical, chemical, biological and mechanical properties to guide the differentiation of stem cells to specific lineages of interest. This paper reviews the previous researches on effect of chemical structure, surface modification, topography and mechanical properties of scaffolds on stem cells behavior. Fabrication of scaffolds with desirable properties can open new strategies for cell therapy using tissue engineering technique.

Abstract

Tissue engineering is a multidisciplinary field that applies the principles of engineering and life-sciences

INTRODUCTION

Autologous cells obtained from adult patients might deliver a less difficult route to regenerative-cell therapies. In the past, many tissues were assumed incapable of self-regeneration upon its damage, mainly because they do not possess any endogenous stem cells. However, recent discoveries show that more adult tissues harbor cells with capacity for regenerative repair^[1]. Tissue engineering comprises of suitable cells, scaffolds and appropriate biochemical/physical factors, such that it function as a strategy towards the engineering of tissues and cellular delivery. Encapsulating stem cells within biocompatible scaffolds provide a matrix which result in cell adhesion, migration and differentiation suitable for transplantation and tissue regeneration^[2-4].

Stem cells have uncovered a new perspective as therapeutic tools in regenerative medicine. These cells with the ability to proliferate indefinitely (*in vitro*) and the capacity to differentiate into any somatic cell type are a potential cell source. Stem cells are originated in the early embryo, the fetus, placenta, umbilical cord, and it occurs in many different tissues of the body. Also they have been engineered from somatic cells, termed as induced pluripotent stem cells (iPSCs). iPSCs give rise to different cell types including the neural cell types (neurons, oligodendrocytes, and glia), cardiomyocytes, osteoblasts, hepatocytes, and haemopoietic progenitors cells^[5-8]. The two main stem cell types are the embryonic stem cells (ESCs) and the adult stem cells. ESCs are derived from fetal tissue or from the inner cell mass of the blastocytes with ability for unlimited growth in culture that could be associated to a high risk of teratoma formation. Several researches have been done on ESCs pluripotency to obtain specific cell lineages for tissue engineering and regenerative medicine, as well as for therapeutic treatments^[8-13]. Adult stem cells are specialized cells including the mesenchymal stem cells (MSCs), hematopoietic stem cells (HSCs), and neural stem cells (NSCs)^[9]. MSCs are self-replicating cells that are capable of differentiating in multidirectional pathways, resulting in cell lineages such as the osteoblasts, chondrocytes, myocytes, marrow stromal cells, tendon-ligament fibroblasts, adipocytes, neural cells, oligodendrocytes and haemopoietic cells^[9,14,15]. These cells have been used for the engineering of different tissues such as the cardiac^[16], tendon^[17], cartilage^[18-20], vascular^[11,21] Meniscus^[22], bone^[23], Ligament^[24], myocardia^[25], fat^[26], and neural tissues^[5,16,17,27].

While a routine source of human MSCs is the bone marrow, they have been also derived from multiple adult tissues comprising of adipose tissue (ADSCs), umbilical cord blood, placenta, thymus, and dental pulp^[28]. In comparison to MSCs derived from the bone marrow^[29], ADSCs have several advantages such that they are easy to obtain after minor donor site morbidity, possess high proliferating capacity and can be preserved for longer period of time in cell banks^[30]. Under appropriate culture conditions, ADSCs can differentiate to classical mesenchymal lineages, which include adipogenesis, chondrogenesis, osteogenesis, and myogenesis^[31,32]. Moreover, the ability of ADSCs differentiation to numerous lineages when seeded into polymeric scaffolds has been well documented in several literatures^[33,34].

The sources of HSCs are bone marrow, peripheral blood, umbilical cord blood, fetal hematopoietic system^[35], ESCs and embryonic germ cells^[11]. These cells are also a suitable cell source for blood vessel engineering^[12]. Avoidance of anaesthesia without the need for hospitalization or blood transfusion, and low risk of serious adverse events are the major advantages of the peripheral stem cells, which make them the favourable source of stem cells worldwide. On the other hand, NSCs are defined as self-renewing multipotent progenitors existing in the developing and adult CNS. Generally, they are considered by their capacity to symmetrically self-renew and their ability to discriminate into neurons, oligodendrocytes, and astrocytes through asymmetrical fate-committed division^[27]. Neural stem or progenitor cells can be obtained in different approaches such as direct isolation of these cells from embryonic or adult brain tissue^[36,37]. NSCs have been used for tissue engineering of different tissues such as multiple cell types of the adult nervous system^[5,38]. It was shown in several studies that stem cells behavior such as their adherence, proliferation and differentiation on scaffolds, depends on the material itself. Additionally, the surface chemistry, surface geometry/micro architecture of scaffolds, and the mechanical properties of scaffolds^[39-42] play a significant role in determining the cellular responses after culture of stem cells on them^[43].

Therefore, recent studies have focused on the selection of an appropriate biomaterial, whit focusing on the surface modification of the scaffolds, creating appropriate microstructures and controlling the mechanical properties of scaffolds to recapitulate the *in vivo* microenvironment suitable for regenerating tissues or for the differentiation stem cells to specific cell lineages^[44].

This review will discuss on the influence of different aspects of scaffolds including scaffold composition, surface modification, micro-nano architecture of scaffolds and mechanical properties of scaffolds pertaining to stem cells differentiation. An emphasis is also given to the effect of mechanical properties of

scaffolds towards stem cells differentiation.

EFFECT OF SCAFFOLD COMPOSITION ON STEM CELLS DIFFERENTIATION

The interaction of stem cells with their surrounding microenvironment is fundamental to multiple processes such as cell migration, proliferation, lineage specificity, and tissue morphogenesis^[45]. Biomaterials play an important role in directing tissue growth and chemical properties of the scaffolds have been shown to influence the behavior of stem cells whereas the scaffold composition has an significant role in stem cells differentiation towards preferred lineages^[42,43,45]. The ability to selectively guide stem cells differentiation by merely changing the properties of an underlying biomaterial scaffold is a smart approach in tissue engineering, which can help compliment or potentially eliminate the use of exogenous differentiation inducers like the viral gene vectors and small molecule drugs^[46].

Natural polymers such as the collagen, fibrinogen, hyaluronic acid, glycosaminoglycans, cellulose, chitosan, silk fibroin, *etc.*, consist of components found in the native extracellular matrix, such that they can assist cells to attach to cell surface receptors and provide a physical environment to control cell function compared to synthetic materials^[40,47]. However these materials suffer from fast degradation rates, difficulty in sterilization and purification, high variability, high contamination potential, and induce immune response upon implantation, while synthetic materials offer the potential for improved control, repeatability and safety^[40,47]. Scaffolds fabricated by synthetic materials can be chemically modified by natural materials to carefully regulate the differentiation of stem cells^[47]. Immune response is an important concern in synthetic biomaterials used for scaffold fabrication and it can be reduced by selection of materials which are inert inherently or by modification of scaffolds to avoid detection by the immune system. Hydrophobic materials usually tend to increase monocyte adhesion compared to hydrophilic materials leading to a local immune reaction at the scaffold site^[48].

Awad *et al.*^[34] compared the chondrogenic differentiation of human adipose-derived adult stem cells seeded in alginate, agarose and gelatin scaffolds and their findings revealed that the growth and differentiation potential of adult stem cells seeded on the scaffolds varied and the cells on gelatin scaffolds showed better proliferation and differentiation. Collagen has attracted much interest as a biomaterial for fabrication of scaffolds in tissue engineering as a key structural protein found in the extracellular matrix of many connective tissues^[49,50]. In spite of the several advantages of collagen as a biodegradable, biocompatible, safe and multifunctional material, its potential to evoke immune response has raised concerns as an animal-derived biomaterial^[51].

Meinel *et al.*^[52] investigated the osteogenic differentiation of human MSCs on different protein substrates including unmodified collagen with fast degradation rate, cross-linked collagen with slow degradation rate and silk; in both static and dynamic culture conditions. Under dynamic condition, MSCs on cross-linked collagen and silk scaffolds deposited more calcium and had a higher alkaline phosphatase activity than MSCs on unmodified collagen scaffolds indicating the importance of scaffold properties in causing osteogenesis of the cultured MSCs^[52].

Jäger *et al.*^[39] cultivated MSCs on the D,D,L,L-poly lactide (PLLA), collagen I/III, and polygalactin-910/polydioxanone (PGPD) scaffolds and their results showed significant differences in the proliferation, differentiation, and Ca^{2+} accumulation of MSCs on different scaffolds. Cell adhesion on PGPD was lower compared to the cell adhesion on PLLA and collagen I/III scaffolds, which was related to the significant biodegradation rate of PGPD scaffolds compared to other scaffolds. They found significantly higher cell numbers on collagen I/III membrane compared to that for PLLA scaffolds after 4 h cell culture while the differences were less significant after 28 d of cell seeding. Lower cell number on PLLA scaffolds compared to collagen I/III after 4 h could be attributed to the hydrophobic nature of PLLA while an increasing deposition of serum proteins from culture media on the PLLA scaffold may reduce the effect of its hydrophobic nature and decreased the quantitative differences in cell attachment between collagen I/III and PLLA scaffolds after 28 d cell seeding^[39].

PEG is a relatively inert, biocompatible and hydrophilic polymer^[53]. Hwang *et al.*^[41] encapsulated MSCs in PEG based hydrogels containing type I collagen, type II collagen and hyaluronic acids (HA) which are the main components of musculoskeletal tissue matrix. Chondrogenic differentiation of MSCs was slightly enhanced in collagen-matrix-based hydrogels, whereas osteogenic differentiation was induced in HA-containing hydrogels suggesting the potential of ECM components to modulate the fate of MSCs differentiation^[41].

Ravichandran *et al.*^[54] fabricated a composite scaffold containing PLLA and Poly-benzyl-L-glutamate (PBLG), a polymer of glutamic acid in which the carboxyl groups have been benzoylated, by electrospinning. Nanohydroxyapatite (n-HA) was also deposited on the surface of the nanofibers by calcium-phosphate dipping method. Their results proved that the incorporation of PBLG along with n-HA deposition on the surface of scaffolds promoted greater osteogenic differentiation of ADSCs in the absence of an induction medium highlighting the chemical composition of the scaffold as a determinant factor towards ADSCs differentiation^[54].

Shah *et al.*^[46] reported selective differentiation of NSCs into oligodendrocytes by seeding NSCs in PCL nanofibrous scaffolds coated by graphene oxide (GO).

Higher concentration of GO was found to promote NSCs differentiation into mature oligodendrocytes without introducing differentiation inducers in the culture media. Their results showed that the presence of GO in the structure of nanofibrous scaffolds was a crucial factor that determined the stem cell-scaffold interactions in directing NSCs towards oligodendrocyte differentiation^[46].

One of the major challenges in cartilage and disc-tissue engineering using MSCs is the rapid expression of type X collagen as a marker of chondrocyte hypertrophy associated with endochondral ossification. Nelea *et al.*^[55] used polypropylene and nylon-6 polymers for the fabrication of scaffolds and modified the surface of scaffolds by glow discharge plasma treatment in ammonia gas to investigate the potential of each polymer in its ability to inhibit the expression of type X collagen. They cultured MSCs on modified and unmodified polypropylene and nylon-6 and evaluated the chondrogenic differentiation pathway using aggrecan and types I, II, and X collagens. Their results showed that MSCs did not adhere to unmodified PP while they observed cell adhesion on modified PP, nylon 6 and unmodified nylon 6 and concluded that the nature of the surface should be vital for the interaction of MSCs. Both modified and un-modified nylon-6 suppressed the expression of type X collagen, while the modified polypropylene scaffold almost completely inhibited its expression indicating the impact of polymer type and surface characteristics on the fate of stem cells^[55].

Hosseinkhani *et al.*^[56] encapsulated DNA nanoparticles into collagen sponge reinforced with poly (glycolic acid) fiber for bone tissue engineering. More osteogenic differentiation of MSCs and formation of homogeneous bone upon implantation of scaffolds containing DNA nanoparticles was observed by these researchers^[56].

In yet in another study, semi-interpenetrating polymer networks made of collagen type I fibers combined with fibronectin or laminin were fabricated to investigate the effect of matrix composition towards ESCs differentiation. Results showed that scaffold composition has an important role in ESCs development and differentiation whereas the presence of fibronectin in collagen scaffolds strongly induces endothelial cell differentiation and vascularization. On the contrary, laminin stimulated ESCs to differentiate into beating cardiomyocytes^[57]. Costa-Pinto *et al.*^[58] prepared chitosan-poly (butylene succinate) scaffolds in different weight ratios of chitosan (50%, 25%, and 0%) and compared the potential of osteogenic differentiation of human bone marrow stromal cells on these scaffolds. Their results revealed higher cell viability, adhesion, proliferation, and osteogenic differentiation on scaffolds with more ratios of chitosan^[58]. Overall, it was clear that the scaffold material and its properties played a critical role in directing the stem cells towards differentiation, with proteins and peptides had a positive influence towards this effect.

EFFECT OF SURFACE MODIFICATION OF SCAFFOLDS ON STEM CELLS DIFFERENTIATION

Cell-biomaterial interactions has a significant role on the growth and differentiation of stem cells within scaffolds^[34]. It is well known that the surface properties of scaffolds have an important role in stem cells-biomaterials interactions, ultimately controlling the stem cell adhesion, proliferation, and differentiation after its attachment on the surface^[59,60]. Stem cells differentiation can be regulated by presenting suitable biological or chemical signals within the structure of the scaffolds^[47]. Therefore the chemical and biological modification of the scaffolds can affect stem cells behavior which is also defined by the substrate properties and their degradation rate, eventually manipulating the signal transduction pathways in stem cells^[47]. It can be concluded that the surface chemistry of materials can affect protein adsorption and the binding of different integrins and influence the cell behavior^[59]. Surface modification of scaffolds is therefore an important issue in tissue engineering in order to control the cellular behavior^[59]. More recently different methods have been established for the modification of scaffolds thorough incorporation of biomolecules within the scaffold structure by method like simple physical adsorption or by covalent conjugation^[47,61].

Ayala *et al.*^[45] demonstrated the influence of interfacial matrix hydrophobicity on stem cells behavior. They fabricated tunable synthetic scaffolds with control over the hydrophobicity of the scaffolds, by copolymerizing acrylamide with acryloyl amino acids and their results showed that the small changes in matrix hydrophobicity can dramatically alter the cell-matrix interaction and can influence various cellular behaviors^[45].

Chua *et al.*^[62] investigated the effect of surface-functionalized polyethersulfone (PES) scaffolds including the hydroxylated, carboxylated and aminated PES nanofibers and films and their results showed that the surface-bound amino groups highly influenced the proliferation and differentiation of hematopoietic stem/progenitor cells. The effect of coating of polycaprolactone-co-lactide scaffolds with collagen I (coll I) and coll I/chondroitin sulfate (CS) on osteogenic differentiation potential of ovine bone marrow MSCs has been investigated. The results showed surface modification of scaffolds using coll I/CS induce osteogenic differentiation of cells, without using any differentiation supplements such as dexamethasone, revealing the osteoinductive characteristics of the modified scaffolds^[63].

Rim *et al.*^[64] fabricated electrospun PLLA nanofibrous scaffolds and coated scaffolds with polydopamine through immersion in an aqueous solution of dopamine with mild shaking for 1 h. Their results showed more

Figure 1 Quantitative analysis of initial cell adhesion from human mesenchymal stem cells cultured on the fibers. Relative adherent cell numbers and spreading area of human mesenchymal stem cells (hMSCs) cultured on PLLA and PD-PLLA fibers were analyzed after 12 h of culture. ^a $P < 0.05$, PD-PLLA vs PLLA group. Adherent morphology of hMSCs on PLLA and PD-PLLA fibers was observed by confocal microscopy. Scale bars represent 100 μm. Reproduced with permission from Rim *et al*.^[64] PLLA: Poly(L-lactide); PD-PLLA: Poly(L-lactide) (PLLA) fibers coated with polydopamine.

adhesion and proliferation of MSCs cultured on surface modified nanofibrous scaffolds with dopamine relative to cells seeded on unmodified scaffolds (Figure 1). More osteogenic differentiation as well as angiogenesis was also observed for MSCs seeded on modified scaffolds compared to unmodified scaffolds^[64].

In yet another study, electrospun PCL nanofibers were coated using polydopamine by simple immersion of substrates in an alkaline dopamine solution. RE-1 silencing transcription factor (REST) was then absorbed onto PCL nanofibers coated with polydopamine to induce scaffold-mediated gene knockdown for enhanced neuronal differentiation of neural stem/progenitor cells. The results showed significant enhanced neuronal commitment and decreased glial cells differentiation due to presence of the silencing of REST^[44]. Controlled release of insulin-like growth factor I (IGF-I) from silk fibroin scaffolds for chondrogenic differentiation of human MSCs has been studied by Uebersax *et al*.^[65] and the results showed that IGF-I loaded silk fibroin scaffolds have the potential to provide chondrogenic stimuli to human MSCs, thus beneficial for cartilage repair.

In yet another study, copolyester of 3-hydroxy-butyrate-cohydroxyhexanoate (PHBHHx) scaffolds were fabricated and coated with PHA granule-

associated proteins (PhaP) and PHA granule-associated proteins PhaP fused with RGD peptide (PhaP-RGD) for investigating the effect of surface modification towards chondrogenic differentiation of human bone marrow mesenchymal stem cells (hBMSCs). Their results showed that the surface modification of scaffolds with PhaP-RGD promote chondrogenic differentiation of hBMSCs compared to PhaP coated or uncoated scaffolds even without the presence of chondrogenic induction medium (Figure 2). Hyaline cartilage regeneration, and inhibited fibrocartilage formation in hBMSCs derived chondrocytes was also observed on PhaP-RGD coated PHBHHx scaffolds indicating suitability of this substrate for cartilage tissue engineering compared to the uncoated ones^[61].

In yet another study, poly (ethylene glycol) (PEG) hydrogels were functionalized with heparin and osteogenic differentiation of human MSCs was evaluated. The results through increased ALP production and gene expression of osteopontin and collagen type I showed that functionalization of hydrogel with heparin induce osteogenic differentiation which is likely due to improvement of cell-scaffold interactions due to the presence of heparin^[66]. Surface modification of poly-(lactic-co-glycolic acid) (PLGA) (75:25) scaffolds with RGD peptides also enhanced the human

Figure 2 Confocal microscopic imaging of human bone marrow mesenchymal stem cells grown in uncoated, PhaP and PhaP-RGD coated 3-hydroxybutyrate-co-hydroxyhexanoate scaffolds after 4 or 72 h of incubation, respectively. Phalloidin-fluorescein isothiocyanate was used to F-actin of cells grown in the scaffolds (Green). Reproduced with permission from You *et al*^[61]. PhaP-RGD: PhaP binding protein fused with arginyl-glycyl-aspartic acid.

osteoprogenitor differentiation and osteogenesis^[67]. While RGD peptide immobilized macroporous alginate scaffolds showed enhanced chondrogenesis properties of human MSCs compared to the un-modified ones^[68].

In vitro osteogenic differentiation of human MSCs was also observed on RGD peptide functionalized PLLA nanofibers by Paletta *et al*^[69]. Their results showed more osteogenic differentiation of human MSCs on modified scaffolds revealing the osteoinductive effect of the scaffolds functionalized with RGD^[69].

Kuo *et al*^[70] fabricated PLGA /chitosan scaffolds and functionalized it with type I collagen, whereby these researchers were able to improve the cell adhesion and viability on PLGA/chitosan/collagen scaffolds. Moreover, MSCs differentiated towards osteoblasts in the modified scaffolds without induction procedures, while neural differentiation was observed on the scaffolds by the induction MSCs with neuron growth factor (NGF)^[70].

In another study Yang *et al*^[71] fabricated porous poly L-lactide-co- ϵ -caprolactone (PLCL) and did surface modification *via* crosslinking of chitosan on the surface of scaffold. Their finding showed elongated morphology of MSCs on modified scaffolds while cells on unmodified scaffolds showed more spherical morphology with lower spreading. Moreover, the surface modified scaffolds provide surfaces for early differentiation of MSCs with more *in vitro* cartilage tissue formation revealing more chondrogenic differ-

entiation of MSCs on modified scaffolds compared to the unmodified PLCL scaffold^[71].

In yet another study, Budiraharjo *et al*^[72] obtained carboxymethyl chitosan scaffolds (CMCS), coated with hydroxyapatite and compared the behavior of osteoblasts and human MSCs on both modified and un-modified scaffolds. Coating the scaffold with HA substantially enhanced the osteogenic differentiation of the human MSCs.

Surface modification using plasma has been frequently used to improve surface properties of scaffolds fabricated with synthetic polymeric materials through formation of functional groups on the surface^[73]. Lin *et al*^[74] investigated the effect of modification of PLLA scaffolds by gas plasma towards the differentiation of ADSCs and their results showed that the cells seeded on modified scaffolds displayed significantly increased differentiation into endothelial cells^[74].

Wang *et al*^[60] fabricated porous nanocrystalline HA/chitosan scaffolds using a lyophilization technique, further treated them with cold atmospheric plasma as a simple, quick, and inexpensive method to modify the surface of scaffolds. Their results showed enhanced stem cell growth and osteogenic differentiation on modified scaffolds, which might be due to higher amounts of protein adsorption on the scaffold surfaces due to improves surface roughness and wettability after its modification^[60].

An ideal bone implant should recruit osteoblasts or

progenitor cells from the adjacent native tissue and induce cell proliferation and osteogenic differentiation for new bone formation. Hu *et al.*^[75] modified Ti6Al4V (TC4) implants using biofunctional multilayer coating of gelatin, chitosan, gelatin and human recombinant BMP2. *In vitro* results showed that such modifications of the implant surface stimulated the adhesion and osteogenic differentiation of MSCs and *in vivo* results showed improved induction of new bone formation at the interface of bone and implant and the integration of the implant within the surrounding living tissues^[75].

EFFECT OF SCAFFOLD TOPOGRAPHY ON STEM CELLS DIFFERENTIATION

The topography of the extracellular matrix is known to influence cell attachment, morphology, proliferation and differentiation^[76]. Topography can also enhance differentiation of progenitor cells into their programmed pathways^[77].

Topographic surfaces with micro and nano scale structures have been shown to stimulate the cell alignment, polarization, elongation, migration, proliferation, gene expression, *etc.*, while the mammalian cells have been shown to react to nanoscale structures on a synthetic surface^[77,78]. Nano scale topographies are obtained by different fabrication methods such as electrospinning, polymer phase separation, photolithography, chemical vapor deposition, electron beam lithography, *etc.*^[2]. The similarity of electrospun nanofibers to the morphology of native extracellular matrix has attracted interest in the application of these scaffolds as a substrate for stem cell attachment and differentiation^[2].

Smith *et al.*^[79] compared the *in vitro* osteogenic differentiation of ESCs on nanofibrous scaffolds and traditional scaffolds with two and three dimensional structure without the nanofibrous features. The results showed that the nanofibrous features enhanced the osteogenic differentiation and mineralization of ESCs compared to traditional substrates. Moreover, the osteogenic differentiation was observed on nanofibrous scaffolds without osteogenic supplements, while cells on other scaffolds required osteogenic supplements and growth factors for osteogenic differentiation^[79].

Ragety *et al.*^[80] evaluated the chondrogenic differentiation of MSCs on chitosan microfibrillar scaffolds and chitosan sponges. More chondrogenesis differentiation was observed on chitosan microfibers compared to that on sponges indicating the effect of scaffold microstructure towards the cell behavior^[80].

Christopherson *et al.*^[81] evaluated the effect of topographical features of nanofibrous scaffolds in view point of fiber diameter on rat adult neural stem/progenitor cell (rNSC) differentiation and proliferation. They fabricated different nanofibrous scaffolds with average fiber diameters of 283 ± 45 nm, 749 ± 153 nm and 1452 ± 312 nm and their findings showed that the fiber diameter of PES nanofibrous scaffolds significantly

influenced the differentiation of rNSCs, whereas by decreasing of fiber diameter, more cell spreading and proliferation was observed. Additionally, the differentiation of stem cells towards oligodendrocytes was observed on nanofibrous scaffolds with fiber diameter of 283 ± 45 nm while morphology similar to neuronal progenitors was observed on nanofibers with fiber diameter of 749 ± 153 nm. Although, the number of cells on nanofibers with fiber diameter of 1452 ± 312 nm was found to be low which may be due to the difficulty of adhesion and migration of rNSCs on fibers with large diameter. However, the cells present within these nanofibrous scaffolds showed the morphology of neurons or neuronal progenitors^[81].

In yet another study, aligned PLLA nanofibrous scaffolds with a mean diameter ranging from 307 to 917 nm and random PLLA nanofibrous scaffolds with a mean diameter ranging from 327 to 1150 nm were fabricated and the behavior of NSCs were evaluated on these scaffolds. The results showed that the depending on the fiber diameter and pattern, NSCs behaved differently revealing that the fiber alignment and diameter had significant effects on cellular behavior^[82].

Yin *et al.*^[76] examined the effect of alignment of PLLA nanofibrous scaffolds on differentiation of stem cells from human tendon and the differentiation of the cells seeded on aligned nanofibrous scaffolds was found to be higher with either normal or osteogenic media than on the randomly-oriented nanofibers^[76].

Subramony *et al.*^[83] also evaluated the effect of PLGA nanofiber alignment and mechanical stimulation towards MSCs differentiation. Their results showed fibroblastic differentiation of MSCs in the absence of chemical induction factors on aligned nanofibers together with mechanical stimulation under tensile loading. No fibroblastic differentiation was observed on the non-aligned scaffolds even after the application of mechanical stimulation, indicating the effect of topography of scaffold towards stem cells differentiation^[83].

Bakeine *et al.*^[84] investigated the effect of nanoscale surface topography on adhesion, proliferation and neural differentiation of mouse ESCs by fabrication of thin films of gold with different root mean square (RMS) surface roughness of 10, 21, 30 nm and 50 nm. Their results showed that surface topography influenced the neural differentiation whereas highest differentiation was observed on gold films with RMS surface roughness of 21 nm after five days of cell seeding without addition of the traditional soluble neurotrophic factors^[84].

The effect of topography with different sizes (groove width: 350 nm/ $2 \mu\text{m}$ / $5 \mu\text{m}$, depth = 300 nm) on the differentiation of human induced pluripotent stem cells (hiPSCs) towards neuronal lineage was studied by Pan *et al.*^[78]. Their results showed the obvious effect of topography on directing differentiation of hiPSCs towards neuronal lineage with noticeable up-regulation of neuronal marker expression on surfaces with nanostructured topography^[78].

Yim *et al.*^[77] studied the proliferation and differentiation

Figure 3 TRITC-Phalloidin labeled F-actin (red), AlexaFluor 488 labeled vinculin (green), diamidino-2-phenylindole nuclear staining (blue) and overlaid fluorescent image of immuno-stained cellular components (merged) for the unpatterned (A) and patterned human mesenchymal stem cells (B and C). Samples were cultured in Dulbecco's Modified Eagle's Medium supplemented with 10% fetal bovine serum and 1% antibiotic/antimycotic solution for 4 d before they were fixed and stained. All images were taken with a 20 × objective lens. (Scale bar = 100 μm) (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.). Reproduced with permission from Tay *et al.*^[86].

rentiation of human MSCs on nano-gratings of 1 μm, 10 μm, 350 nm width and their results showed the alignment of cytoskeleton and nuclei of human MSCs along the nano-gratings. Significant up-regulation of neuronal markers was also observed on patterned surface compared to un-patterned and micro-patterned controls^[77].

Chaubey *et al.*^[85] evaluated the effect of the surface topography on the differentiation of multipotent mouse bone marrow stromal precursors (D1 cells) to adipocytes. They compared the differentiation potential of D1 cells on patterned PLLA films, plain PLLA films and tissue culture-plate and their results showed the impact of patterned surfaces on cell differentiation^[85].

Figure 4 Schematic depicting the normal variation in elasticity of the indicated tissue^[92].

Tay *et al.*^[86] printed fibronectin on PLGA thin films and investigated the differentiation of human MSCs on patterned and un-patterned scaffolds, where they revealed the differentiation of human mesenchymal stem cells (hMSCs) into myocyte like cells on the micropatterned films (Figure 3).

Shi *et al.*^[87] fabricated two nano-grating substrates with a period of 250 and 500 nm and with a depth of 120 nm on quartz, and investigated the effect of substrate nanotopography on differentiation of ADSCs into endothelial cells which play an important role in vascularization. Decreased cell proliferation along with enhanced endothelial gene expression of the ADSCs and *in vitro* angiogenesis was observed on nanograting suggested the role of nanotopography on ADSCs differentiation to endothelial cells^[87]. Oh *et al.*^[88] fabricated PCL cylindrical scaffolds with different pore size (90-400 μm range) along the longitudinal direction; and investigated the effect of pore size on the chondrogenic differentiation of ADSCs. Their results showed that the pore size of 370-400 μm provided a more suitable environment for chondrogenic differentiation than other pore size groups^[88].

Teo *et al.*^[89] applied nanotopography technique along with NGF controlled release from polydimethylsiloxane substrate for neuronal tissue engineering and their results showed enhanced expression of neuronal genes on nanopatterned substrate combined with NGF delivery^[89].

The influence on nanotopography, whether in the form of fibers, porous microstructures or pits and grates, was studied extensively by various researchers. However, comparison of the results between such studies was difficult due to the differences in various factors involved in each study, where some researchers used mechanical stimulation, while others used a specific biomolecule for the differentiation to take place. A systematic evaluation is therefore necessary, to clearly define the fiber length or the pore size that

might specifically cause the differentiation of stem cells to nerve, osteolineages or endothelial cells.

EFFECT OF CULTURE ENVIRONMENT ON STEM CELLS DIFFERENTIATION

Bioreactors have been used in tissue engineering to overcome the drawbacks of static culturing conditions and to obtain uniform distribution of cells within the scaffolds and provide sufficient levels of oxygen, nutrients, cytokines, and growth factors, and to expose the cultured cells to mechanical stimuli^[90]. Dynamic condition of cell culture has also been shown to influence stem cells differentiation.

Gomes *et al.*^[90] evaluated the effect of static and dynamic culturing conditions on the proliferation and osteogenic differentiation of rat bone marrow stromal cells seeded on two starch-based scaffolds. Calcium content analysis, VonKossa-stained sections, tetracycline fluorescence and histological analysis revealed the enhancement of osteogenic differentiation under dynamic condition created by flow perfusion bioreactor^[90]. Mauney *et al.*^[91] also showed increased levels of alkaline phosphatase activity, bone-specific protein transcript levels, and mineralized matrix production by human bone marrow stromal cells under dynamic culture condition indicating increase in osteogenic differentiation of human BMSCs using mechanical stimulation applied by bioreactor. However, the influence of mechanical stimulation towards stem cells differentiation is not studied highly and more investigations are required.

EFFECT MATRIX MECHANICAL PROPERTIES TOWARDS STEM CELL DIFFERENTIATION

Matrix stiffness varies with respect to different organs

present in the human body, and Figure 4 shows the difference in matrix stiffness of a few organs, as depicted by Vincent *et al.*^[92]. It explains how the matrix stiffness varies throughout the body: the brain is the softest tissue with an elasticity ranging between 0.2 to 1 kPa, while the precalcified bone is the hardest tissue with an elasticity value of more than 30 kPa^[87], explaining the differences in the tissue matrix stiffness. Cells of different lineages survive in distinct natural environment, and they possess different stiffness. This is also the main reason why we believe that the stiffness have a higher influence towards the differentiation of stem cells. For tissue engineering, the most considered factors are the structure and the components used for scaffold fabrication, which determine the physical, chemical and biological properties of the scaffolds, and these properties will furthermore affect the differentiation of stem cells.

Bone

Various strategies has been acknowledged and selectively chosen to alter the biomaterial surfaces or to create micro-environment to establish both mechanical and biochemical cues for the differentiation of stem cells, especially for application in regenerative medicine. Chemical factors have been individually studied, suggesting the ability of BMP-2 to promote pro-osteogenesis or IGF to promote tenogenic phenotype^[93,94]. However, aligning the mechanical properties of the scaffolds with the specific tissue of interest was an interesting strategy applied to hydrogels, nanofibers and ceramics, in order to advance the field of stem cell differentiation on bioengineered substrates. Among these, injectable biodegradable hydrogels eliminate the need for surgical interventions or they allow for minimally invasive procedures causing minimal harm to the patients. However, physically crosslinked hydrogels lack strength and stability, while the chemically cross-linked hydrogels are more appreciated due to their high mechanical strength and stiffness. Hydrogels are useful substrates that assist to determine the interplay between physical cues/stiffness and their relationship with the fate of stem cell differentiation. A thiolene chemistry was utilized by Gandavarapu *et al.*^[95] to functionalize poly(ethylene glycol) hydrogels with a pendant peptide moiety, c(RRETAWA) and gels with Young's Modulus (YM) of 2 kPa (soft) and 25 kPa (Stiff) were prepared. The stiffer substrate was found to give 3.5 fold higher hMSCs attachment. The ALP activity of hMSCs cultured on stiff gels containing 0.1 mmol/L and 1 mmol/L c(RRETAWA) increased by 2.5 and 3.5 fold, respectively after 14 d of cell culture. At the same time, the expression of osteopontin and collagen-1a for cells cultured on stiffer gels were higher, suggesting the application of high substrate stiffness gels for osteogenic differentiation of MSCs. In order to adjust the matrix stiffness, crosslinking of the thiol functionalized hyaluronic acid (HA-SH) and thiol functionalized recombinant human gelatin (Gtn-

SH), were performed by using varied amounts of poly (ethylene glycol) tetra-acrylate (PEGTA)^[96]. Further hMSCs were seeded on the hydrogels to assess their potential towards osteo-lineage differentiation. MSCs grown on gels with 1.5 kPa stiffness, was found to express the early bone protein, namely osteopontin, while the cells on stiffer (4 kPa) gel expressed late osteogenic gene or the bone sialoprotein (BSP). This highlights the potential of higher osteogenic differentiation on stiffer hydrogels, mainly because the focal adhesion structures might have increased and F-actin might have got organized on such substrates, supporting the differentiation of MSCs to osteo lineages.

In order to study the role of substrate stiffness towards cell differentiation, Sun *et al.*^[97] prepared crosslinked gelatin scaffolds, where by the influence of scaffold strength was demonstrated *in vitro* and *in vivo* during this study. Crosslinking of gelatin scaffolds was performed by these researchers, using 1-Ethyl-3-[3-dimethylaminopropyl] carbodiimide hydrochloride (EDC) to prepare three dimension gelatin scaffolds with high stiffness properties. The elastic modulus of the EDC crosslinked scaffolds (2.5 kPa) was significantly higher than those of the non-crosslinked scaffolds (0.6 kPa). High mechanical strength of cross-linked scaffolds was suggested to promote stem cell mediated bone regeneration *via* endochondral ossification process, than the non-crosslinked scaffolds. *In vivo* studies using Inbred C57BJL/6 mice, showed significantly high trabecular bone formation for the crosslinked gelatin implanted animals, by micro-computed tomography and histology analysis^[92]. Wang *et al.*^[98] prepared gelatin-hydroxyphenylpropionic acid-tyramine (Gtn-HPA-Tyr) conjugates to simulate osteogenic differentiation of hMSCs, by conjugation of Tyr to Gtn-HPA conjugate by means of carbodiimide/active ester mediated coupling reaction. Oxidative coupling of phenol moieties were further carried out by hydrogen peroxide (H₂O₂) and horseradish peroxidase (HRP), whereby the concentration of H₂O₂ was varied producing Gtn-HPA-Tyr hydrogels of varying storage modulus (G₀). Hydrogels with G₀ > 20000 was found suitable for the osteo-specific differentiation of MSCs, with osteocalcin upregulation and high calcium accumulation was observed on these gels compared to hydrogels with G₀ of 13500. Stiffer hydrogels were suggested beneficial for the repair of bone defects. In yet another attempt, the ability of cells to differentiate to osteogenic cells were studied on transglutaminase cross-linked gelatin (TG-Gel) of varying rigidity and these researchers found that the softer matrix promote cell proliferation, while stiffer matrix promote osteogenesis^[99]. Osteogenic differentiation was found to occur in 6% and 9% TG-Gels with rigidity of 13.51-2.13 kPa and 32.32-1.9 kPa, respectively than using 3% TG-Gels. However, little or no effect of BMP-2 was found in the case of stiffer (6% and 9%) TG-Gel towards MSC differentiation. The 9% TG-Gels with and without BMP-2 demonstrated high

calcium deposition with expression of osteogenic markers during *in vitro* studies. On the other hand, the ALP activity and early markers of osteogenic differentiation were observed in 6% TG-Gel and these cells differentiated to osteoblast-like cells at a later time point. Stiffer substrates are also demonstrated to direct the osteogenic differentiation of ADSCs, even in the absence of any growth factors^[100]. PDGF and BMP-2 were covalently immobilized to collagen-Glycosaminoglycan (CG) membrane in defined patterns, by combined photolithography-carbodiimide crosslinking strategy and the elastic modulus (stiffness) of the matrix was orthogonally manipulated. These researchers explained that by increasing the ratios of EDC:NHS:COOH, the stiffness of the CG got increased. Photoimmobilized BMP-2 was demonstrated to have a little effect on lineage-specific gene expression of ADSCs during this study, while the matrix stiffness had a higher impact. In yet another study, using BMP-2 modified poly(acrylamide-co-acrylic acid) hydrogels, BMP-2 was found to have little or no effect towards stem cell differentiation if grafted on softer gels^[101]. Hence the mechanical properties of the substrate dictated the potential for stem cell differentiation than the biochemical reagents, explaining the diversity of stem cell behaviors. Efforts to leverage approaches to explore a wider range of combinatorial environments and biochemical pathways, in a systematic manner is necessary, such that the results obtained by different kinds of material systems can be compared. In yet another study, CG scaffolds were prepared by cross-linking treatment *via* dehydrothermal and 1-ethyl-3-(3-dimethyl aminopropyl)carbodiimide methods, with varying stiffness of 0.5 to 1.5 kPa^[102]. MSCs differentiation studies on these scaffolds, showed higher level of RUNX2 expression on the stiffer scaffolds (1.5 kPa) indicating MSCs differentiation to osteogenic lineage. Chondroitin sulphate and hyaluronic acid was found to have a positive influence towards the MSCs differentiation towards osteogenic and chondrogenic lineages, respectively.

Actin filaments of cells are structures for force transmission in response to the substrate with which it comes in contact^[103,104]. Increased cell spreading in response to geometric features of the substrate, could result in enhanced actomyosin contractility associated with osteogenic differentiation^[103]. The expression of osteogenic markers was demonstrated as stiffness dependent, with maximum osteogenesis observed for fibronectin coated micropatterned polyacrylamide gels with stiffness of 30 kPa.

Studies on the rate of proliferation of mouse ESCs suggest higher proliferation on stiffer substrates of polyacrylamide hydrogels compared to the proliferation on soft substrates, favoring mESC colonization with high levels of Oct3/4 and the Nanog biomarker production^[105]. In maintaining the stemness of mESCs on soft hydrogels with varying topography, no significant advantages were observed, suggesting the

insensitiveness of topography effect towards mESC stemness. However, surface topography might have a role on substrates with hexagonal or pillar shapes topology or even on stiffer surfaces. It is also believed that either stiffness or topography might play an independent decision factor towards colony formation on 3D substrates. Geometric control of osteogenesis was also studied on polyacrylamide gels prepared by microcontact printing of adhesion proteins where cell spreading and cell geometry are suggested to have some influence towards MSCs differentiation^[106]. Stiffer matrices can assist to increase cell spreading, thus promote osteogenesis through enhanced actomyosin contractility and this was observed up to a stiffness of 30 kPa. However, the density of seeded cells were described to over-ride the effect of gel stiffness to cause osteogenic differentiation, according to Xue *et al.*^[107]. However, this effect was not pronounced on soft gel, where chondrogenic differentiation was induced. Overall, their study highlights the importance of cell-matrix and cell-cell interactions in causing MSCs differentiation. Substrate stiffness was also found to play a predominant role in regulating the growth of rat BM-MSCs, while substrate topography manipulate the cell morphology and spreading, with spherically shaped cells were observed on pillar substrates but not on grooved substrate^[108].

In general, studies using mechano-variant polyacrylamide substrates showed that the osteogenic differentiation reduced on substrates with low stiffness and ligand density. However, compared to fibronectin, BMSCs were demonstrated to have a higher binding affinity towards an equivalent bulk of collagen (Figure 5). Such comparisons were further delineated by Sharma *et al.*^[109], and they found the occurrence of osteogenic differentiation on fibronectin substrates, while tenoblast gene expression was only found on collagen substrates. Two entirely different microsystems namely, sponges and hydrogels were compared by Zhang *et al.*^[110] where they studied the behavior of MSCs and they found fast cell proliferation in sponges than in hydrogels. Sponges might have encouraged cell-cell and cell-matrix interaction and upon inducing them with media containing TGF- β 3, the chondrogenic differentiation of MSCs were better compared to those in hydrogels.

Nerve

From Figure 4 and the abovementioned researches, it can be indicated that for neural differentiation, scaffolds with relatively small stiffness is required. The fate of MSCs towards neural or glial lineages could be manipulated by adjusting the substrate stiffness. Three dimensional collagen-HA scaffolds (fabricated by lyophilization) with higher elasticity (E approximately 1 kPa) induced MSCs into neuronal differentiation, while those with less elasticity (E approximately 10 kPa) induced MSCs into glial differentiation. The elasticity was adjusted by using different concentration

Figure 5 (A) As the rigidity increased, so did cell attachment. Collagen elicited a greater degree of cell attachment, and increased bulk density of the ligand further enhanced this (B) Morphology on functionalized substrates at 8000 cells/cm² for 24 h. ^astatistical difference compared to fibronectin at 10 mg/mL, ^bdifference compared to collagen at 10 mg/mL, ^cdifference compared to preceding substrate compliance. Cells were stained with FITC-phalloidin. (Scale bar represents 50 µm). Reproduced with permission from Sharma *et al*^[109].

of the crosslinking agent, namely 1-ethyl-3 (3-dimethylaminopropyl) carbodiimide (EDC)^[111]. Tuning the modulus of hydrogels affects neurite outgrowth and ESCs differentiation; with higher modulus gels offered better substrate for neural differentiation and neurite outgrowth, while less modulus enhanced astrocyte formation and cell migration. Thus, ESCs differentiation into neural and glial lineages is influenced by the type, composition, architecture and stiffness of the matrix and the type and concentration of signaling molecules comprehensively^[112]. Neuronal differentiation was favored on softer surfaces such as the photopolymerizable methacrylamide chitosan hydrogel with Young's modulus less than 1000 Pa as confirmed by both immunohistochemistry and qRT-PCR. Oligodendrocyte differentiation was favored on stiffer scaffolds with Young's modulus more than 7000 Pa. However, myelin oligodendrocyte glycoprotein gene expression suggested that oligodendrocyte maturation and myelination was best on scaffolds with modulus less than 1000 Pa where more mature neurons were present. Astrocyte differentiation was only observed on scaffolds with modulus less than 1000 Pa and 3500 Pa and represented less than 2% of the total cell population^[113]. Elastic moduli, even in the range of neural tissue, would have a great impact on adult neural stem cell differentiation. The adult NSCs expressed a high level of the neuronal marker,

β -tubulin III, on variable moduli interpenetrating polymer networks of 500 Pa, which is similar to the physiological stiffness of brain tissue. Furthermore, under mixed differentiation conditions with serum, softer gels (approximately 100-500 Pa) greatly favored neurons, whereas harder gels (approximately 1000-10000 Pa) promoted glial cultures^[114].

To achieve the scaffold with favorable stiffness for nerve tissue regeneration, the fabrication method and the materials should be carefully considered. Hydrogels possess low modulus, and they are suitable as substrates for neuronal differentiation of stem cells. Alternatively, polymers with low modulus might be appropriate for this purpose. Within the category of the neuronal tissue structures, glial differentiation of stem cells might be gained on stiffer scaffolds, and neural differentiation can be achieved on softer scaffolds. By fine tuning the stiffness of the matrix, there is a great possibility to control the differentiation of stem cells into appropriate nerve cells.

Cardio-vascular

Lineage commitment of MSCs towards specific vascular cells (MSCs to ECs or MSCs to SMCs) on electrospun scaffolds could be manipulated by controlling the substrate modulus, from 2 to 15 kPa. Around 95% of MSCs seeded on soft scaffolds (3 kPa) showed Flk-1 endothelial markers within 24 h, while only 20% of

MSCs seeded on the rigid scaffolds (> 8 kPa) showed Flk-1 marker. In contrast, about 80% of MSCs seeded on rigid scaffolds (> 8 kPa) showed smooth muscle α -actin marker within 24 h, while fewer than 10% of MSCs seeded on soft scaffold (< 5 kPa) showed α -actin markers^[115]. Besides, the synergistic effect of scaffold elasticity and growth factors has been studied for the differentiation of MSCs. In one such study, MSCs were seeded on soft nanofibrous matrices with or without VEGF, and in Petri dishes with or without VEGF, where these researchers found that MSCs in soft matrices with VEGF showed significant increase in the expression of endothelial markers (vWF, eNOS, Flt-1, and Flk-1), with faster up-regulation of the endothelial markers. The results indicate that it is critical to control both mechanical factors and biochemical factors to regulate vascular endothelial regeneration of MSCs^[116]. MSCs gained very low rate of cardiogenic differentiation after transplantation to infarcted heart, partly because stiffer scar tissue lack the capacity to support cardiogenic differentiation. Thermosensitive and injectable hydrogels with different moduli (16, 45 and 65 kPa) were achieved by controlling the concentration of the hydrogel solution. After 14 d, more than 76% MSCs differentiated into cardiac cells in gels with 45 and 65 kPa, while MSCs in the 65 kPa gel had the highest differentiation efficiency^[117]. But the effect of stiffness towards the differentiation of stem cells might be time-dependent. Human embryonic stem cells are sensitive to substrate stiffness during early mesodermal specification, but not late fate choices during cardiac differentiation, when they are seeded on polyacrylamide hydrogels. An intermediate stiffness was most beneficial for cardiomyogenic differentiation than soft or stiff substrates^[118].

CONCLUSION

Selection of appropriate biomaterials for scaffold fabrication and their modification by incorporation of biological constituents, or by patterning, thus altering the topography and mechanical properties of the scaffolds, might have a significant effect on stem cells behavior. Major literature review shows that MSCs are in favor of soft substrate to differentiate to neuronal cells, with moderately stiffer materials promote myogenic differentiation and more stiffer substrates support osteogenic differentiation, suggesting the effect of substrate mechanical properties in influencing the differentiation of stem cells toward specific lineages. The stiffness of mature tendon range between 500-1000 MPa and bone falls in the range of 20 GPa and this might be a reason for such specific behaviors of stem cells on substrates with proportionate mechanical properties. Prioritizing the stiffness of the substrate alone might not serve as a smart approach, but the presence of specific ligands along with the matrix mechanical compliance, might assist for more specific stem cell differentiations. There exists great

difficulty in comparing the results obtained by different research groups, mainly because the parameters such as the ligand type, their concentrations, surface topology or matrix type and their mechanics, and even the cell numbers differ between studies. Hence more uniform and systematically organized studies, are required for a thorough understanding of the stem cell differentiation effect. The extent of differentiation or the % of differentiated cells is another parameter that deserves great attention, such that the cell-substrate can be used for its maximum potential.

The cells on a 2-D platform might be less sensitive to mechanical properties than when they are in 3-D environment. The 3-D structures might provide an additional dimension to mechanical properties, such that the cell related factors such as the integrin ligation, cell contraction, and associated intracellular signaling might be influenced.

biology has been successfully used to analyze multiple pathways, the approach is often used to develop a small molecule interacting at only one pathway in the system. A new model is emerging in biology where systems biology is used to develop a new technology acting at multiple pathways called “systems therapeutics”. A natural set of healing pathways in the human that uses SRM is instructive and of practical use in developing systems therapeutics. Endogenous SRM processes in the human body use a combination of SRM from two or more stem cell types, designated as S²RM, doing so under various state dependent conditions for each cell type. Here we describe our approach in using state-dependent SRM from two or more stem cell types, S²RM technology, to develop a new class of therapeutics called “systems therapeutics.” Given the ubiquitous and powerful nature of innate S²RM-based healing in the human body, this “systems therapeutic” approach using S²RM technology will be important for the development of anti-cancer therapeutics, antimicrobials, wound care products and procedures, and a number of other therapeutics for many indications.

Abstract

The degree to, and the mechanisms through, which stem cells are able to build, maintain, and heal the body have only recently begun to be understood. Much of the stem cell's power resides in the release of a multitude of molecules, called stem cell released molecules (SRM). A fundamentally new type of therapeutic, namely “systems therapeutic”, can be realized by reverse engineering the mechanisms of the SRM processes. Recent data demonstrates that the composition of the SRM is different for each type of stem cell, as well as for different states of each cell type. Although systems

Core tip: A fundamentally new type of therapeutic, namely “systems therapeutic,” can be realized by reverse engineering the mechanisms of the stem cell released molecules (SRM) processes. Recent data demonstrates that the composition of the SRM is different for each type of stem cell, as well as for different states of each cell type. Although systems biology has been successfully used to analyze multiple pathways, the approach is often used to develop a small molecule interacting at only one pathway in the system. A new model is emerging in biology where systems biology is used to develop a new technology acting at

multiple pathways called “systems therapeutics”.

Systems biology approach to developing S²RM-based “systems therapeutics” and naturally induced pluripotent stem cells. *World J Stem Cells* 2015; 7(4): 745-756 Available from: URL: <http://www.wjgnet.com/1948-0210/full/v7/i4/745.htm> DOI: <http://dx.doi.org/10.4252/wjsc.v7.i4.745>

INTRODUCTION

The initial few days following fertilization of the human egg, all stem cells in the developing egg are able to create any tissue in the human body, *i.e.*, the stem cells are totipotent. However, about four days following the fertilization of a human egg, the stem cells in the blastocyst begin to differentiate and become pluripotent instead of totipotent, thus being able to differentiate into a more limited set of adult cell types^[1]. At this point in time, many different stem cell types are beginning to form that will have unique function related to the development, maintenance, and healing of various tissues throughout the body. The degree to which stem cells differentiate into specific adult phenotypes is only recently beginning to be understood. For example, cell types, such as the progenitor cell preadipocyte and adipose-derived mesenchymal stem cells, each of which was previously classified as one cell type, have now been shown to have phenotypic differences depending on the location of the preadipocyte niches or mesenchymal stem cell niches^[2,3]. The signaling factors controlling the development and function of the stem cell types, and indeed the signaling factors that each stem cell type releases, are relatively unknown, but progress is being made. For example, we know that adult stem cells release hundreds of types of proteins within the molecular pool^[4], called the stem cell released molecules (SRM), and that each cell type will release a unique pool of molecules^[5,6]. These molecules in the SRM will prove to be important for developing many types of therapeutics, including, for example, immunoregulators for organ transplantation^[7].

The more differentiated the stem cell, the more specialized the SRM will become. Further, that unique pool of molecules from one stem cell type can change in composition, including the types of molecular species, depending on intrinsic and extrinsic regulatory factors. For example, intrinsic factors related to simple passage number of a stem cell will change the composition of the SRM^[8,9] and mesenchymal stem cells (MSCs) in different parts of the body will secrete unique pools of SRM^[10]. Telomere dysfunction, whether the cause is intrinsic or extrinsic, will change the nature of the SRM^[11]. Likewise, when MSCs derived from fat tissue are conditioned with TNF- α , a significant effect on the SRM is observed with an increased release of factors

such as Cathepsin L, interleukin (IL)-6, IL-8, monocyte chemotactic protein-1, matrix metalloproteinase (MMPs), and pentraxin-related protein 3^[12]. Further, signaling conditions during the immune modulating responses of human MSCs through Toll-like receptors (TLRs) on the MSCs leads to two basic phenotypic changes of the cells (MSC1 and MSC2) and a consequent dramatic difference in their SRM^[13]. Phenotypic changes in the MSC are consequent to: (1) low-level exposure of TLR4 agonists that drives hMSCs toward a pro-inflammatory MSC1 phenotype important for early injury responses; and (2) the TLR3 agonist exposure of hMSCs driving the phenotype to an immunosuppressive MSC2 phenotype that is important to later anti-inflammatory responses that help repair the wound. Culture conditions can also have dramatic effects on SRM. A significant increase in SRM [Vascular endothelial growth factor (VEGF), basic fibroblast growth factor (bFGF), phosphatidylinositol-glycan biosynthesis class F protein, and TGF- β] was observed after subjecting hMSCs to 72 h hypoxia compared with normoxic conditions^[14]. Serum deprivation is another model for ischemia, and was shown to increase the secretion of angiogenic factors released by hMSCs, although the results could have been attributed in full, or part, to differences in cell proliferation rates^[15]. Glucose levels have been shown to differentially affect the phenotype of endothelial progenitor cells and mesenchymal progenitor cells^[16]. Indeed, subtle variations in cell culture conditions can have significant consequences to the phenotype of stem cells^[17].

The state of the extracellular matrix in the stem cell niche is also an important regulator of stem cell phenotype, where, for example, the absence of the SPARC protein in the extracellular matrix (ECM) can drive hematopoietic stem cells into a state of quiescence^[18]. Antioxidants and FGF-2 were shown to cause rapid proliferation and a retention of stem cell properties in MSCs, and even enhanced their adipogenic and osteogenic potentials^[19]. Interestingly, new studies suggest that adult stem cells, and even somatic cells, may exist in a state of dynamic transition between different levels of potency^[20,21] that is dependent on many factors, including paracrine and autocrine factors in the SRM from surrounding stem cells in the same niche, and through the physical state of the surrounding stem cell niche^[22]. The state of the oxidative stress in the stem cell may be a contributing factor in phenotype, including the state of pluripotency where the antioxidants curcumin and sesamin were shown to decrease oxidative stress and increase pluripotency^[23]. Stem cell derived control factors for determining the fate of stem cells and the potency of cells, including the dedifferentiation of somatic cells, their proliferation, and subsequent differentiation, may include growth differentiation factor 11, a protein secreted by bone marrow mesenchymal stem cells^[24] that has been shown to be involved in stem cell fate

and proliferation^[25], and has recently been shown to induce a number of regenerative effects, including neurogenesis^[26]. Recent studies also demonstrate that NANOG, a pluripotency transcription factor in embryonic stem cells, is also present in at least some adult tissues further raising the possibility that a dynamic state of pluripotency is a naturally occurring process in adults^[27]. Again, these shifts in the state of pluripotency will have concomitant shifts in the composition of the SRM released from the stem cell.

Given the differentiation of stem cells into distinct phenotypes, each of which releases a distinct pool of molecules with each distinct pool of molecules inducing a specific set of functions, a knowledge base of the secreted factors (SRM) from each stem cell type and the resulting actions from each pool of molecules will be instructive in the development of therapeutics. The resulting therapeutics that can be developed using the combination of many types of molecules has been termed "systems therapeutics"^[28]. The "systems therapeutic" approach, where multiple molecule types target multiple pathways, is in contradistinction to the more traditional approach of small molecule development for perturbation of one pathway.

Moreover, as the stem cell types are cultured *ex vivo* in the laboratory and driven to state-dependent specific phenotypes through genetic, epigenetic, and other state-dependent variables, the concentration and composition of the SRM as a result can be experimentally manipulated for the purposes of therapeutic development. In addition, distinct pools of SRM from two or more stem cell types cultured in state-dependent conditions can be combined into a collective pool of molecules called S²RM, mimicking the collective actions of multiple stem cell types in their native state in the human body.

TWO OR MORE TYPES OF STEM CELL INDUCE HEALING

There are two basic forms of cell replacement and regeneration: (1) a maintenance function where renewal of damaged cells during tissue homeostasis (homeostatic growth) are restored; and (2) a response to external injury, such as traumatic wounding, burn, ulceration, or surgery. A given healing response will require many processes acting through a well-orchestrated concert of mechanisms and molecules in the given tissue, and the results of these processes depend on many factors, including the developmental age of the organism. Fundamental factors, such as caspases released from cells undergoing apoptosis, will activate both stem cells and progenitor cells in the wound healing process^[29], where apoptosis may be a key factor in cell proliferation during tissue regeneration^[30]. Wounds occurring in early to mid-gestational fetal skin have been shown to heal through regeneration without the formation of a scar^[31],

whereas adult wounds heal by a fibroproliferative response that emphasizes repair over regeneration. The complexity of this process, where fetal wounds differ from adult wounds in inflammatory responses, ECM components, growth factor expression and responses, and profiles of gene expression is exemplified by the observation that adult skin in a fetal environment will still exhibit scar formation^[32]. The state dependency of stem cells is so critical as shown in diabetes where the adipose stem cell niche *in situ* is altered, and the stem cells in the diabetic state are compromised in their ability to establish a vascular network both *in vitro* and *in vivo*^[33] where glucose itself has profound direct effects on stem cells^[34].

Following injury, wound healing begins rapidly and involves resident and migratory stem cell types, ECM, and soluble factors, including SRM. Stem cells and progenitor cells resident in the skin are certainly involved, but recruitment of stem cells from other sources, including bone marrow, is thought to be important^[35]. The mechanisms underlying wound healing include: (1) a rapid release of pro-inflammatory mediators; (2) cell to cell, and cell to extracellular matrix interactions that help mediate cell proliferation, migration, and differentiation; (3) a cascade of events including epithelialization, fibroplasia and angiogenesis^[36]; (4) contraction of the wound; and (5) remodeling of the tissue. These events begin at the time of physical injury and proceed continuously throughout the process of tissue repair. Although the processes of repair begin immediately after an injury in all tissues, and all wounds proceed with a similar cascade of healing, some tissues, for example, liver, skeletal tissue, and the eye have different forms of regeneration and repair with variations on the underlying mechanisms^[37]. Severe injury has been shown to increase the number of circulating stem cells^[38,39] and that these stem cells will participate in the wound healing process^[6].

At the onset of trauma bone marrow stem cells will sense histamine released from platelets at H1 receptors and change their phenotype to one of releasing more IL-6 and more IL-8. The increased IL-8 will attract polymorphonuclear neutrophil cells, and the increased IL-6 will facilitate their survival through antiapoptotic functions^[40]. When the trauma inducing the injury has stopped, and hemostasis is achieved with an immune response activated, the tissue repair phase will then begin^[41]. On the third day after wounding the proliferative phase starts and continues for two or more weeks thereafter. Proliferation begins with fibroblast migration and deposition of newly synthesized ECM, elaborating the initial network of tissue built by fibrin and fibronectin. This phase of wound healing can be clinically observed as an abundant formation of granulation tissue. The complex nature of the proliferative phase is briefly described below^[42].

First, fibroblasts and myofibroblasts in the tissue surrounding the wound are stimulated to proliferate for 3 d^[43]. The fibroblasts and myofibroblasts then migrate from the surrounding tissue into the wound, attracted by soluble factors TGF- β and platelet-derived growth factor (PDGF) that are released by platelets and inflammatory cells^[44]. Appearing in the wound on the third day after injury, the accumulation of fibroblasts in the wound requires their phenotypic modulation. Within the wound, the fibroblasts greatly proliferate, producing and locally releasing the matrix proteins hyaluronan, fibronectin, proteoglycans, and type 1 and type 3 procollagen^[45]. Abundant new ECM has accumulated at the end of the first week, further supporting cell migration that is essential for the repair process. Fibroblasts then change to a myofibroblast phenotype. The myofibroblast phenotype contains thick actin bundles that extend below the plasma membrane with pseudopodia attaching to fibronectin and collagen in the ECM. Wound contraction, critical to the reparative process by closing the wound margins, then takes place as the actin bundles begin to retract. Any overabundance of unneeded fibroblasts are then eliminated by apoptosis^[44].

The three phases of wound healing involve MSCs to varying degrees, whereby, for example, they recruit macrophages to the wound site^[46], induce the fibroblast response to injury^[47], and remodel the wound site^[48], including a preferential release of collagen type III at the site^[35]. While the MSCs contribute directly to wound repair by releasing molecules such as collagen to the wound^[35], the MSCs also act indirectly by releasing an instruction set to other cells thus initiating, for example, progenitor cell migration to the wound^[49]. The MSCs are key to the wound's ability to proceed beyond the inflammatory phase and not maintain a chronic wound state. A significant early component of the mechanism of action of MSCs is their attenuation of the inflammatory response. The addition of MSCs to an active immune response decreases secretion of the proinflammatory cytokines TNF- α and interferon- γ (IFN- γ) while simultaneously increasing the production of anti-inflammatory cytokines IL-10 and IL-4. These anti-inflammatory properties of MSCs impart a particular benefit to chronic wound treatment through SRM, given the SRM can restart healing in chronic wounds by advancing the wound past a chronic inflammatory state into the next stage of healing.

Many studies have shown that MSCs possess antimicrobial activity, critical for clearance of infection in the wound. The antimicrobial activity of MSCs is mediated by two mechanisms: (1) direct secretion of antimicrobial factors such as LL-37^[50]; and (2) indirect, by secreting immune-modulating SRM that will upregulate the bacterial killing and phagocytosis of immune cells^[51]. Further, the phenotype of macrophages can be regulated by MSCs into various M1 and M2 classes directed to either antimicrobial, phagocytic

activity, or one of controlling inflammation^[52].

Endogenous MSCs migrate to sites of injury in response to chemotactic signals where they can then modulate inflammation, repair damaged tissue, and facilitate tissue regeneration. Furthermore, bone marrow stem cells home to the injury where cells in the wounded area secrete a protease that interacts with collagen matrix to produce a homing agent^[53]. Differentiation and paracrine signaling are two key mechanisms used by MSCs for tissue maintenance and repair. While differentiation of MSCs contributes by directly regenerating damaged tissue, the paracrine signaling by MSCs regulates the local cellular responses to injury, including the differentiation process itself. However, studies of exogenous MSCs show that the contribution of differentiation of these stem cells is limited due to poor engraftment and survival of MSCs at the site of injury, whereas the activation of endogenous stem cells by SRM may provide better results for the differentiation pathway^[54]. Paracrine signaling by MSCs appears to be the primary mechanism for the beneficial effects of MSCs in wound healing, including the reduction of inflammation, enhanced angiogenesis, and induction of cell migration and proliferation^[55].

An analyses of the conditioned medium indicate that MSCs secrete many known SRM mediators of tissue repair including growth factors, cytokines, and chemokines, including VEGF, PDGF, bFGF, EGF, keratinocyte growth factor (KGF), and TGF- β . Stem cells are also known to release exosomes^[56], and exosomes from mesenchymal stem cells have been shown to contain factors, including miRNA, that switch cancer stem cells into a dormant state^[57]. Such a mechanism is important to dampen the cells in a wound from moving into a state of cancer^[58]. Many cell types, including epithelial cells, endothelial cells, fibroblasts, and keratinocytes are responsive to MSC paracrine signaling, where a number of different cellular responses including cell survival, proliferation, migration, and gene expression are regulated. The SRM from MSCs acts as a chemoattractant for dermal fibroblasts, macrophages, endothelial cells, and epidermal keratinocytes, *in vitro*. The presence of either MSCs or the SRM from MSCs have been shown to promote wound closure through the activation of dermal fibroblasts. MSCs also secrete mitogens, leading to the proliferation of keratinocytes, dermal fibroblasts, and endothelial cells *in vitro*. Further, dermal fibroblasts secrete increased amounts of collagen type I and alter gene expression in response to either MSCs in co-culture or the SRM from MSCs. These data suggest that SRM from MSCs stimulate proliferation and migration of the key cell types in the wound. In addition, the SRM of MSCs imparts anti-scarring properties to wound healing through the secretion of VEGF and hepatocyte growth factor (HGF), and through maintaining a normal balance between

TGF- β 1 and TGF- β 3. The pathways underlying MSC processes in wound healing are complex, and further details of these processes can be found in recent reviews. Stem cell niches in other regions of the body, including the hematopoietic stem cell niche, appear to be equally complicated as the skin stem cell niche with a rich interaction amongst many cell types, including a number of stem cell types and their respective SRM^[59].

NATURALLY INDUCED PLURIPOTENT STEM CELL WITHIN THE STATE DEPENDENT STEM CELL NICHE

Naturally occurring endogenous iPSCs, or naturally induced pluripotent stem cells (NiPSCs) occur within the state dependent stem cell niche. While induction to a totipotent state has not been realized, dedifferentiation seems to be an important adaptive mechanism in both the animal^[60] and plant kingdoms^[61] where cells can be induced to become pluripotent. In addition to the therapeutic development of embryonic stem cells and iPSCs, the use of adult stem cells and the molecules that they release have been intensively investigated and have current therapeutic applications. Further, SRM from stem cells or other molecules from neighboring cells, such as ciliary neurotrophic factor (CNTF), have been shown to dedifferentiate myoblasts into multipotent progenitor cells. The dedifferentiated myoblasts were then able to differentiate into several new phenotypes^[62].

The endogenous mechanisms of adult stem cells, and possibly somatic cells in the stem cell niche, seem to include the ability to reprogram themselves into more primordial states that are pluripotent. That is, the adult stem cell, and even somatic cells, may exist in a state of dynamic transition between different levels of potency that is dependent on many factors, including paracrine and autocrine factors in the SRM from surrounding cells in the stem cell niche, and by the physical, chemical, and electrical state of the stem cell niche^[63-65]. Recently, treatment with reversine, a type of purine, transformed 3T3-L1 preadipocytes into MSC-like cells, as evidenced by the expression of MSCs marker genes. The transform allowed differentiation of lineage-committed 3T3-L1 preadipocytes to osteoblasts under the osteogenic condition *in vitro*^[66]. Beyond transcription factors contained in the SRM, physical manipulation through the cytoskeleton is known to transmit signals to the chromatin^[67] and reprogram cells^[68], and may represent an additional biophysical, in addition to biochemical means, for driving cells to varying levels of potency. Reprogramming of differentiated cells to stem-like cells has been described in several tissues and is well studied in the epithelial-mesenchymal transition where a differentiated epithelial cell transforms to a mesenchymal cell with a stem cell-like phenotype. Thus, by understanding adult stem cell

function, we may develop the means to use these cells in many ways to maintain and heal the body, including a means of controlling naturally occurring iPSCs (NiPSCs).

The physical, chemical, and electrical state of the stem cell niche will have profound influences on stem cell function. Alterations of the stem cell niche in diseases such as diabetes will decrease the ability of endogenous stem cells, or autologous administered stem cells, to increase neovascularization and promote wound healing^[33].

In Figure 1, we see levels of interactions that may control the natural iPSC state. Considering wound healing as described in the aforementioned section, many factors, such as histamine, an important regulator of cell fate, including neurons^[69,70] are released at the site of injury. As an example of the actions of these factors, histamine will activate TRPM4 calcium channels in the mesenchymal stem cells and bias the dynamic transition of the stem cells toward differentiation into the needed mature cells types at the injury site^[71], including osteoclastogenesis^[72]. Similarly, exposure to sunlight will stimulate vitamin D3 levels and induce differentiation of stem cells, doing so through a downstream pathway that includes histamine^[73].

Reprogramming of cells to push the dynamic transition towards more potency has been specifically shown in mammalian cells whereby muscle cells^[74] and pancreas cells^[75] will dedifferentiate into a more pluripotent state following injury, and where fibroblasts were incubated in the SRM of adipose-derived stem cells. The fibroblasts displayed gene expression that was indicative of pluripotency in which repressive histone modifications were reduced, and increased global demethylation was present. The *Col1a1* and *Col1a2* genes, typically found in differentiated cells only, demonstrated reduced expression, and also demonstrated increased methylation in the 5'-flanking regulatory regions^[76]. Of the many factors released by mesenchymal stem cells, microRNA is one of the factors that have been shown to induce pluripotency in mouse and human somatic cells^[77]. In general, stress is a key factor that can naturally induce pluripotency. For example, simple isolation of mammalian cells from contact with other cells and their normal niche, originally exhibiting a limited differentiation potential, may become multipotent^[78]. Pluripotent cells can reside in the naïve state or the primed state where the naïve state is more potent than the primed state^[79]. Dedifferentiation under hypoxic conditions can drive committed cells beyond the primed state fully back to the naïve state of potency where the pluripotent cells are then capable of forming teratomas^[80].

Cancer cells and pluripotent stem cells follow certain common rules. Both cell types, when placed in a dysregulated extracellular matrix, will exhibit an increased state of potency. Cancer cells, when returned to a regulated ECM, will revert to a normal phenotype^[58,81]. Likewise, dedifferentiation of cells into

Figure 1 General model of wound healing. The wounded state sends a homing signal to bone marrow stem cells and disrupts the ECM. Disruption of the ECM will shift the dynamic transition of potency towards dedifferentiation and the more pluripotent state. The more pluripotent state will cause the cells to proliferate. After proliferation, the migration of bone marrow stem cells to the wound site will release stem cell released molecules, including GDF-11, that stops proliferation and induces differentiation allowing newly differentiated somatic cells to repair the tissue. Thus, in our model, GDF11 is released from BMSCs and is a master regulator of stem cell transcription that inhibits cell proliferation and migration by down-regulating the expression of numerous genes involved in both these processes^[93]. ECM-D: Extracellular matrix disruption; SC: Somatic cell; PPSC: Pluripotent stem cell; BMSC: Bone marrow stem cell; PSC: Potent stem cell.

a pluripotent state can occur when the cell is isolated and loses connections with other cells and the ECM^[78], and stem cells that have differentiated can revert to a more pluripotent state by changes in the concentration of the ECM associated protein, L-proline^[82]. Thus, induction of pluripotent stem cells is a naturally occurring phenomenon that can be controlled *in vivo* for therapeutic effect by manipulating the state of the stem cell niche.

CONCEPTS OF A SYSTEMS THERAPEUTIC

An abnormality in one pathway, or even at one level of the organism, such as at the level of genes, does not explain a disease. Rather, disease reflects the perturbations of the complex system of biological pathways acted on by a complex set of environmental regulators. Most previous work to understand disease and drug response traits have focused on single dimensions, and even single pathways, of the system. Achieving a more comprehensive and predictive understanding of disease and drug response requires examining living systems in multiple dimensions and

at multiple scales. Although biological engineering principles are necessary, with the requirement to remove superfluous complexity for the development of a particular therapeutic, the individual components of complex systems are highly coupled such that the individual components cannot be analyzed in isolation. This predicament in biology, such as the desire to place the sequencing of the genome as the singular predictor of disease, is similar to that dictum in physics where electrodynamics was broken down into the misbegotten particles and fields theorem by Bohr and his Copenhagen interpretation^[83]. Biological complexity is an extreme example of complexity, arising from a biological system that includes active, plastic components, nested feedback loops, flexible design principles, component multi-functionality, and multiple layers of system dynamics developed through evolutionary processes that are, at least partially, driven through the downward causation of environmental regulators. The power of the dynamic biological system has been recognized in engineering where, for example, neuromorphic engineering^[84] has become an important player in the development of new computer chip technologies such as TrueNorth^[85].

Despite the use of systems analysis in the fields

of biology and therapeutic development, therapeutic development has often remained as one using systems biology techniques for finding the one pathway, or the one target, that is best perturbed to develop the therapeutic. "Finding the magic bullet" is a common phrase that describes this common problem. A shift in mindset to one of finding the minimum set of pathways, or the minimum set of targets, using the "minimum molecule set" to perturb these targets in order to best develop a therapeutic is now needed. Thus, biological function results from a system, and a particular disease state is the result of multiple perturbations in that system, not just one perturbation. Therefore, through an understanding of complex pathways in normal and disease states, and using computationally intensive biological design-build-test-analyze cycles, with therapeutic molecule production batches based on this process, we can hope to develop safe and efficacious therapeutics. This will occur through a multi-targeted, "systems therapeutic" approach. The approach then is to use a system of molecules, the minimum molecule set, that is not overly reductionist so as to be ineffective, but instead use the optimal number of molecule species that are sufficient to realize a safe and efficacious therapeutic. Recognizing that diseases are the result of complex interactions among many networks has significant implications for drug discovery, leading to the design of combinations of molecular species that impact entire network states, rather than designing reductionist drugs that target specific genes that are associated, often weakly, with disease.

DEVELOPMENT OF SYSTEMS ANTIMICROBIALS

The attempt to develop animal-derived antimicrobials is not new. For example, in the 1990s great hope, and many dollars spent, was placed on the development of a small peptide from frog (*Xenopus laevis*) skin as an antibiotic^[86]. The observation that frog skin heals itself, despite the frog living in a very septic environment, led to the formation of Magainin Pharmaceuticals. After years, and millions of dollars, spent on development and Phase II clinical trials, today Magainin's assets are the auction block (Magainin changed names to Genera and then liquidated: <http://www.fiercebiotech.com/press-releases/genaera-corporation-announces-approval-plan-liquidation-and-dissolution-board-direct-0>). Why? Because the frog's skin does not heal itself through a reductionist approach with only one molecule (a peptide), and Magainin didn't fully learn the frog's lesson. The lesson not learned was that Magainin developed their antibiotic based on one peptide, a reductionist approach, instead of a mix of antimicrobial factors, a systems antimicrobial approach.

Lipids were first demonstrated by Koch^[87] to have antibiotic activity, and exists in human skin, for example, as a wide range of molecule types comprising

a significant part of the innate immune system^[88]. Like Magainin, a similar reductionist approach was used in the development of squalamine, a lipid compound (aminosterol) derived from the dogfish shark (*Squalus acanthias*). Squalamine was initially discovered on the basis of its anti-bacterial activity, and has broad spectrum antimicrobial activity against fungi, protozoa, and many viruses^[89]. Sadly, isolated squalamine was never approved for antimicrobial use and is now sold as a nutritional product by a number of companies in capsule form. Once again, the "Copenhagen reductionist" approach to therapeutic development has failed us. Here again, instead, an approach to developing antimicrobials using a collection of molecules, including peptides and lipids, is in development.

DEVELOPMENT OF CANCER SYSTEMS THERAPEUTIC

Cancer is strongly associated with a deregulated ECM^[58,90]. While cancer and stem cells are regulated by many factors, both cancer cells and pluripotent stem cells follow certain common rules such as regulation by the ECM. Both cell types, when placed in a dysregulated extracellular matrix, will exhibit an increased state of potency. Cancer cells, when returned to a regulated ECM, will revert to a normal phenotype^[58,81]. As beautifully explained by Mina Bissell at University of California Berkeley, during development, cells can spatially arrange themselves, differentiate, and change their SRM composition in response to a variety of signals in the microenvironment, including morphogens, biophysical manipulation, juxtacrine signals, and the ECM. All of these components in the microenvironment are sensitive to signals from other tissues and organs of the developing embryo as well as through downward causation from the macroenvironment. However, following organ formation, the microenvironment/ECM integrates and constrains the organ architecture and function, thus ensuring structural and functional homeostasis and therefore, a normal organ phenotype. However, when the organ architecture in adults is insulted by mutations and/or changes in the microenvironment such as ECM dysregulation and/or inflammation, that organ is transformed by the initiation of developmental and embryonic circuits. However, in the adult, the microenvironment is no longer embryonic in nature, and the ECM dysregulation and inflammation leads to a pluripotent state, *i.e.*, the cancerous state. Bissell argues that tumors become new evolutionary organs searching for homeostasis^[58]. Recent work fits the paradigm of Bissell, such as that of Liou *et al.*^[91] who describes the detailed steps that Kras-mutated acinar cells follow as they change into duct-like cells with a more potent state. They observed that Kras proteins in the acinar cells switched on

Figure 2 Regulation of the cancer/pluripotent phenotype by stem cells and extracellular matrix. The cancer/pluripotent cell phenotype can be regulated by the extracellular matrix (ECM) and stem cells, where cancer cells can be removed from a dysregulated ECM and placed into a normal ECM and the cancer/pluripotent phenotype will revert to a normal, somatic cell phenotype. Likewise, if a dysregulated ECM is reconstructed into a normal state, the cancer/pluripotent phenotype will revert to the normal somatic cell phenotype. Further regulation of the cancer/pluripotent phenotype can be regulated by a number of factors, including microRNA contained within exosomes that were released from mesenchymal stem cells serving to change the state of the cancer cell into one of quiescence. MBSC: BM-stroma cell.

intercellular adhesion molecule-1. This in turn attracts macrophages. The macrophages then release a variety of proteins, including MMPs that degrade ECM. Following dysregulation of ECM, the acinar cells then transform into the stem cell-like phenotype. Thus, the direct link between Kras mutations, the inflammatory environment, and dysregulated ECM that drive the initiation of pancreatic cancer is demonstrated.

Similar to the cancer state, dedifferentiation of cells into a pluripotent state can occur when the cell is isolated and loses connections with other cells and the ECM^[78], and stem cells that have differentiated can revert to a more pluripotent state by changes in the concentration of the ECM associated protein, L-proline^[82]. Given that that the ECM can act through mechanical and biochemical mechanisms to regulate the cancer phenotype, one important means to revert the cancer phenotype to the normal somatic cell phenotype is to use S²RM technology to reestablish a normal ECM microenvironment for the cancer cell. That is, using one progenitor cell type to release the building blocks of the ECM, such as collagen, and using another stem cell type to release other building blocks and the instruction sets to build the architecture of the ECM, the normal state of the ECM can be rebuilt and lead to the reversion of the cancer cell phenotype to a more normal somatic cell phenotype as depicted in Figure 2. Thus building on the model developed by Mina Bissell, our model suggests that that the microenvironment/ECM, which is largely comprised of, and developed by S²RM, is key to the regulation of the initiation and degree of pluripotency of cells, controls the "stop" signals for driving potency and then

initiates differentiation of the pluripotent stem cells. The S²RM thus controls homeostasis whereby the state of dynamic transition between different levels of potency^[92] is set to a proper level in which to produce enough new cells to maintain and heal tissue, but not too much so as to allow uncontrolled, cancerous growth of the tissue.

In summary, the S²RM technology provides a natural means for mimicking and stimulating the healing properties of the human body. Instead of using foreign molecules, natural molecules are used that will induce the initiation of natural processes with little or no side-effects. Further, instead of using a small molecule approach where one molecule interacts at one pathway underlying a multi-pathway disease is used, here the S²RM approach uses multiple molecules to perturb multiple pathways underlying the disease, thus yielding a more efficacious result than the one molecule-one pathway reductionist approach.

The S²RM approach will introduce all of the needed molecules to the tissue to induce a full wound healing cascade of events, unlike an approach using the molecules from one stem cell type that will introduce only a portion of the needed molecules and thus provide a fraction of the efficacy that the S²RM provides. And, S²RM uses the particular molecules from the particular stem cells types relevant to the particular tissue to be healed. This is distinct from the "one size fits all" approach where one stem cell type is used to develop therapeutics for the whole body. Therefore, S²RM provides all of the building blocks, such as the different collagen types, to rebuild the tissue, and also provides the instruction set molecules, such as microRNA, that

will deliver the needed architectural commands that will lay the building blocks in their proper places for that particular tissue. During this rebuilding process, the immune response will also be modulated by S²RM, so that inflammation is quelled, allowing the rebuilding to proceed within a normalized framework that is not swollen. The S²RM rebuilding process institutes two fundamental stem cell healing processes: (1) Mimicking the actions of multiple stem cell types and the molecules that they release in the relevant tissue, and (2) reconditioning the endogenous stem cell niche itself and driving the niche to a more primordial, potent state, allowing endogenous stem cell processes to better induce a healing response. Thus, a systems therapeutic approach using multiple molecules from multiple stem cell types called S²RM is used to develop a safer, more natural, and more efficacious therapeutic that both mimics and facilitates the natural adult stem cell healing processes of our body.

successfully isolated and characterized ovarian GSCs in postnatal mice. The ovarian GSCs are located in the ovarian surface epithelium and express markers of undifferentiated GSCs. When transplanted into mouse ovaries, mouse ovarian GSCs could differentiate and produce embryos and offspring. Similarly, in a recent study, ovarian GSCs were found to be present in the ovaries of women of reproductive age. Conversely, there is increasing evidence that stem cells responsible for maintaining a healthy state in normal tissue may be a source of some cancers, including ovarian cancer. Cancer stem cells (CSCs) have been found in many tissues, including ovaries. Some researchers have suggested that ovarian cancer may be a result of the transformation and dysfunction of ovarian GSCs with self-renewal properties. Drug resistant and metastasis-generating CSCs are responsible for many important problems affecting ovarian cancer patients. Therefore, the identification of CSCs will provide opportunities for the development of new therapeutic strategies for treatments for infertility and ovarian cancer. In this article, we summarize the current understanding of ovarian GSCs in adult mammals, and we also discuss whether there is a relationship between GSCs and CSCs.

Abstract

The field of reproductive biology has undergone significant developments in the last decade. The notion that there is a fixed reserve pool of oocytes before birth was established by Zuckerman in 1951. However, in 2004, an article published in nature challenged this central dogma of mammalian reproductive biology. Tilly's group reported the existence of ovarian germline stem cells (GSCs) in postnatal ovaries of mice and suggested that the bone marrow could be an extragonadal source of ovarian GSCs. These findings were strongly criticized; however, several independent groups have since

Core tip: This review provides an overview on postnatal ovarian germinal stem cells (GSC) of mammals. The characteristics of these cells and the last developments in the field of oogenesis have been presented. We also discuss the relationship between ovarian GSCs and ovarian cancer stem cells. The identification and characterization of these two types of cells are essential for a better understanding of tumor initiation, progression and treatment.

INTRODUCTION

The field of the reproductive biology was revolutionized ten years ago when Johnson *et al.*^[1] published a study in *Nature* that challenged the long-held dogma established by Zuckerman^[2] in 1951. Since that time, it has been generally believed that the ovaries of mammals do not possess renewable stem cells but instead contain a finite reserve of oocytes that diminishes through postnatal life. Although the existence of ovarian germline stem cells (GSCs) has been obviously demonstrated and fully accepted for adult females of non-mammalian species^[3-5] and for adult males of a majority of species^[6], the existence of ovarian GSCs in adult female mammals is still a subject of intense debate. In 2004, Johnson *et al.*^[1] demonstrated the existence of proliferative GSCs in the ovaries of adult mice, and recently, ovarian GSCs have been isolated and characterized in the ovaries of postnatal mice and reproductive-age women^[7].

Amid the controversy created by Johnson *et al.*^[1], the presence of cancer stem cells (CSC) in ovarian cancer was established by Bapat *et al.*^[8], and accumulating data have provided substantial evidence for the involvement of CSCs in ovarian cancer^[9-13]. Ovarian cancer (OC) is associated with enhanced tumor aggressiveness and metastasis, as well as drug resistance. The heterogeneous populations of cancer cells within an ovarian tumor tend to be more resistant to chemotherapeutic agents. In this context, the identification and characterization of CSCs in ovarian cancer is essential for a better understanding of the signaling pathways involved in tumor development and progression. In this review, we will focus on the latest developments in the field of oogenesis in the postnatal mammalian ovary. We will also discuss whether there is a link between ovarian GSCs and CSCs.

OVARIAN GSCS IN ADULT MAMMALS

Existence of ovarian GSCs

In 2004, Johnson *et al.*^[1] published a study that challenged the dogma established by Zuckerman^[2] in 1951. The authors demonstrated that ovarian GSCs are present in the adult mouse ovary, contrary to the principle established more than 60 years ago (Table 1). In a first series of studies, Johnson *et al.*^[1] counted the numbers of healthy (non-atretic) and degenerating (atretic) follicles in ovaries of mice to study germ cell dynamics in female mammals. The numbers of non-atretic quiescent (primordial) and early growing (primary, preantral) follicles in ovary was higher than expected and their rate of clearance in the immature ovary (day 1-day 4) was less than expected. According

to their experiments on the clearance of degenerative oocytes contained within immature follicles, from 1% to 33% of the immature follicle pool was atretic at any given time. The authors considered that the degeneration of this cell would deplete the primordial follicle reserve by young adulthood and that ovarian GSCs represent the source of oocytes produced *de novo*^[1].

By using unbiased assumption-free stereological methods to count follicles in the mouse ovary, Kerr *et al.*^[14] demonstrated the presence of actively dividing surface epithelial cells in prepubertal mouse ovaries and supported the concept of follicle renewal in postnatal and adult ovaries in mice. This study, published in 2006, confirmed the data from Johnson *et al.*^[1] (Table 1).

Johnson *et al.*^[1] reported the presence of large ovoid cells in the surface epithelium of juvenile and young adult mouse ovaries by histological analysis. These cells seemed similar to the germline cells of fetal mouse ovaries. Immunohistochemical staining for Mouse Vasa Homologue (MVH, also called Deadbox 4 or Ddx4), a gene expressed exclusively in the germ cells in both vertebrate and invertebrate species^[15], demonstrated that these large cells were of a germline lineage. Incorporation of 5-bromodeoxyuridine (BrdU) into the DNA of the MVH-positive cells demonstrated the proliferative capacity of these double-positive cells, which were localized to the ovarian surface epithelium. Moreover, postnatal ovarian expression of genes involved in the initiation of meiosis was determined by RT-PCR. Protein synaptonemal complex protein SCP3, the endonuclease Spo11, and the recombinase Dmc1 (required for the initiation of meiosis in mammals) were all detected at the mRNA level^[1]. These results confirmed the presence of proliferative germ cells in postnatal mouse ovaries. Supplemental evidence of continuous folliculogenesis during post natal life was provided by grafting experiments. Ovarian fragments from wild-type mice were grafted onto hemi-ovaries of transgenic mice with ubiquitous expression of green fluorescent protein (GFP). After 3-4 wk, follicles containing GFP-positive oocytes were detected in the wild-type ovarian fragments surrounded by unlabeled granulosa cells. These results suggested that transgenic germ cells had migrated into the grafted ovarian fragment and formed new follicles in adult mice. Collectively, these findings demonstrated that proliferative GSCs exist in the postnatal mammalian ovary. The GSCs support oocyte and follicle production in the postnatal mammalian ovary. This new concept challenged the dogma of a fixed reserve of oocytes.

Following the publication of this landmark article, Johnson *et al.*^[1] were confronted by criticism and skepticism^[16-20]. The main criticisms were related to the subjectivity of the scoring, the tissue fixation protocol, the mathematical model used to calculate the follicular dynamics, the toxicity of busulfan to follicles, the capacity of BrdU-MVH-double-positive cells for oocyte

Table 1 Articles in the field of ovarian germline stem cells and oogenesis

Ref.	Main findings
Johnson <i>et al</i> ^[1]	Ovarian GSCs are observed within the ovarian surface epithelium and provide the adult mouse ovary with oocytes
Johnson <i>et al</i> ^[25]	GSCs are detected in mouse bone marrow and provide the postnatal mouse ovary with oocytes
Kerr <i>et al</i> ^[14]	The follicle numbers remain constant in ovaries of juvenile and early adult mice. Follicle renewal in postnatal and adult mouse ovaries is suggested
Zou <i>et al</i> ^[29]	Mouse ovarian GCS are isolated by immunoselection and characterized. Ovarian GCSs transplanted into ovaries of infertile mice undergo oogenesis and produce offspring
Pacchiarotti <i>et al</i> ^[30]	The adult mouse ovarian GSCs are isolated by FACS. Long-term expanded mouse ovarian GSCs maintain their characteristics, telomerase activity and express germ cell and stem cell markers
White <i>et al</i> ^[7]	The ovarian GSCs are isolated by FACS. Xenotransplantation of human GCSs into NOD-SCID mice leads to the formation of follicles containing oocytes
Zhang <i>et al</i> ^[32]	No mitotically active female GSCs exist in postnatal mouse ovaries
Lei <i>et al</i> ^[33]	The adult female mouse ovary does not contain active ovarian GSCs. The number of follicles produced during fetal development is sufficient to provide ovaries with oocytes in adult life
Park <i>et al</i> ^[39]	Existence of mitotically active germ cells in the postnatal mouse ovary demonstrated by a genetic approach coupled with a GSCs selection strategy

GSCs: Germline stem cells; FACS: Fluorescence-activated cell sorting.

renewal, and the migration of GSCs to form new follicles in wild-type ovaries in the grafting studies.

Several groups criticized the methods used by Johnson *et al*^[1]. Moreover, some of them proposed alternative explanations for Johnson's findings. First, the numbers of preantral and antral immature follicles reported as atretic by Johnson *et al*^[1] were very high and in contrast to previous studies^[16]. Scoring atretic follicles represents a subjective and not reliable method for estimating the rates of follicular atresia^[16,17]. Moreover, the morphological appearance of the follicles can be modified by the use of a harsh fixative^[16,17]. Consequently, healthy and atretic immature follicles may have been misclassified in Johnson *et al*'s study, leading to an overestimation of the number of atretic immature follicles^[17]. The mathematical model of the dynamics of follicle progression was also questioned by several authors. Johnson *et al*^[1] were criticized for applying the rate of follicle disappearance from the CBA/Ca mouse strain, reported as a fast-depleting strain, in comparison to the C57Bl/6 strain^[16]. To verify Johnson *et al*'s results, Bristol-Gould *et al*^[18] proposed examining whether the initial population of follicles was sufficient to support fertility in adulthood by using a mathematical model of the dynamics of follicle progression. These authors counted the follicles in each stage from postnatal day 6 through to 12 mo in mice. The dynamics of the follicle population were simulated according to two distinct models: a fixed pool model and a stem cell model in the mouse ovary. The fixed pool model accurately reflected the experimental decrease in follicle numbers and allowed the authors to refute the concept of GSC replenishment in the adult ovary^[18]. Johnson's assumption that busulfan was only toxic to GSCs and does not kill primordial follicles was questioned by two groups^[16,17]. The loss of primordial follicles after busulfan treatment was considered to be a consequence of busulfan toxicity to primordial follicles and not due to the depletion of GSCs^[17]. The evidence that BrdU and MVH double-

positive cells in the epithelial layer of juvenile and young adult mouse ovaries represented functional GSCs was also challenged^[16-20]. The critics of Johnson *et al*^[1] findings suggested some alternative explanations for the detection of these cells in the ovarian surface epithelium. They asserted that these putative GSCs could be germ cells migrating out of the ovary, as had been reported for these cells in the past^[16,21]. Alternatively, these double-labeled cells could be oocytes from primordial follicles, released by the ovary^[16,20]. The grafting experiments were also subject to reinterpretation by opponents^[16,20] of the findings from Johnson *et al*^[1]. The plasticity of the mouse ovary has recently been demonstrated in experiments with chimeric ovaries^[22]. In addition, the mouse ovarian tissue has been shown to reaggregate after injury^[23]. The chimerism observed in the wild-type transplanted ovaries could result from the subsequent ovarian repair after the tissue trauma due to the transplantation rather than the generation of follicles *de novo*^[16,20].

In response to the critics, in a new study, Tilly and his group counted the numbers of atretic and non-atretic follicles in wild-type (WT) female mice and caspase-6 knockout female mice^[24]. They observed that the number of primordial follicles in caspase-6 deficient young adult females was nearly double the number of primordial follicles in WT females. As no decrease in the number of atretic follicles was detected, the authors interpreted the increase in the primordial follicle pool between birth and adulthood in caspase-6 mutant females as a consequence of neo-folliculogenesis.

Following this study, Skaznik-Wikiel *et al*^[24]s reinforced the validity of their findings and the concept of postnatal oocyte and follicle production in mammals.

Bone marrow as a source of GSCs

In 2005, Johnson *et al*^[25] proposed a new concept that further challenged the dogma of a fixed reserve of oocytes in the ovaries of postnatal females. They suggested that the bone marrow (BM) could be a

source of germ cells for the postnatal mouse ovary. The authors demonstrated that BM cells isolated from adult female mice expressed octamer-binding transcription factor-4 (Oct-4), MVH, deleted in azoospermia-like, a germ cell-specific RNA-binding protein (Dazl), Stella (a maternal factor) and Fragilis (Ifitm3, interferon-induced transmembrane protein 3), which are specific germline markers in mice. Transplantation of BM from adult wild-type female mice was performed with adult female mice treated with cyclophosphamide and busulfan to destroy the existing germ cell pools, and also into ataxia telangiectasia-mutated (Atm)-deficient female mice, which are unable to produce mature cells. After transplantation, oocyte-containing follicles at all stages of maturational development were detected in the ovaries of the chemotherapy-sterilized wild-type and Atm-mutant recipient mice. Moreover, oocytes and follicles were detected in the ovaries more than 11 mo after the initial BM transplantation. Johnson *et al.*^[25] and his group concluded that the putative BM-derived germline cells were able to support long-term oocyte production.

Consequently, they hypothesized that the BM-derived germ cells could be transported by the peripheral blood (PB) to replenish the ovaries. Transplantation of PB mononuclear cells from transgenic female mice with GFP expression driven by an Oct-4 promoter was performed with chemotherapy-sterilized wild-type and atm-mutant female mice. GFP-positive oocytes were observed in the ovaries of the chemoablated adult wild-type and atm-mutant female mice. Therefore, PB was capable of generating oocytes. GSCs derived from the BM could circulate in the PB to colonize the ovaries. Johnson *et al.*^[25] concluded that the BM could be considered as a potential source of germ cells that could support oocyte production in adulthood.

The criticism of this new concept developed by Johnson *et al.*^[25]'s group was again severe^[26,27]. A group of 16 authors published a short correspondence in which they questioned Johnson *et al.*^[25] findings. Their main criticisms concerned the expression of germ cell markers on BM and PB cells, the lack of a reciprocal experiment showing that mononuclear PB cells from wild-type mice could produce oocytes in Atm-Oct4/GFP mutant mouse ovaries, the capacity of generated oocytes to sustain fertilization and subsequent embryo development, and the recurrent question of ovarian failure in women treated by chemotherapy and subsequent BM or PB transplantation.

Subsequently, Johnson *et al.*^[28] published documented responses to the critics to clarify the misinterpretations of their studies. Among the different points discussed by Telfer *et al.*^[26], they defended the germline specificity of the markers used in their studies. They also clearly explained that GFP could not have been absorbed by oocytes from the blood because blood cells from GFP-transgenic males did not induce the generation of GFP-expressing oocytes in wild-type female recipients. The authors reported some cases of

fertility restoration in women treated with high-dose chemotherapy followed by BM or PB transplantation. They also suggested that the BM-derived stem cells involved in blood cell regeneration might be different from those that are able to promote de novo oogenesis, noting that the protocols are designed for the recovery of hematopoiesis and not oogenesis.

After the Johnson *et al.*^[25] publication, Eggan *et al.*^[27] performed parabiosis experiments with adult female mice to test the physiological relevance of BM-derived germ cells to contribute to oogenesis. To evaluate the capacity of circulating BM-derived GSCs to colonize ovaries, they examined ovulated oocytes from wild-type and ubiquitously-expressing GFP female mice that were surgically joined in parabiotic pairs at the age of 4-8 wk. The parabiotic pairs showed a high level peripheral blood chimerism after 6-8 mo (65% GFP-positive blood leukocytes in both mice).

After superovulation, no chimerism of the oocytes was observed in the parabiotic mice. Moreover, occasional GFP-positive cells associated with wild-type oocytes in the cumulus masses were positive for CD45, a pan-hematopoietic marker, demonstrating that these cells were circulating blood cells. The authors concluded that although these circulating cells could associate with ovulated oocytes in the ovary, they were not involved in the production of oocytes; the authors suggested that these hematopoietic cells may play an immune role in ovaries.

In subsequent studies, the investigators treated wild-type mice with cyclophosphamide and busulfan 1 d before joining them to GFP-expressing partners for a duration of 2 wk or 2 mo. In the treated and untreated control parabionts, PB and BM exhibited extensive leukocyte chimerism whereas no chimerism was observed in the oocytes. As indicated above, it was also shown that all GFP-positive cells associated with the ovulated cells were CD45 positive in both the treated and treated wild-type parabiotic mice. In addition, 2 mo after the chemoablative treatment, the ovaries still contained oocytes, revealing that the chemotherapy did not induce a complete depletion of oocytes in the treated parabionts.

The authors then suggested that a direct intravenous transplantation of bone marrow cells might introduce cells into the circulation that might be able to contribute to oogenesis. To investigate this possibility, wild-type mice were treated by chemotherapy (cyclophosphamide and busulfan) or sterilized by low-dose total body irradiation. The mice were injected or transplanted with GFP-transgenic BM cells and were superovulated after 2 mo. Chimerism was observed in hematopoietic stem cells in both chemotherapy-treated and irradiated recipient mice. However, no GFP-positive oocytes were detected. Furthermore, a small number of oocytes was ovulated in chemotherapy-treated mice. No oocytes were detected in irradiated mice.

In conclusion, these findings demonstrated that PB and BM cells did not directly contribute to the

Figure 1 Schematic diagram of isolation and differentiation of ovarian germ stem cells. DDX4: DEAD box polypeptide 4; FACS: Fluorescence activated cell sorting; MEF: Mouse embryonic fibroblast; SCP 1-3: Synaptonemal complex protein 1,2,3; ZP3: Zona pellucida protein 3.

formation of ovulated oocytes or their recovery after chemotherapy. Additionally, the BM-derived cells combined with oocytes belonged to the hematopoietic lineage, and oocytes in the adult mammalian ovaries could not be regenerated by circulating germ cell progenitors.

Isolation and characterization of GSCs from mouse and human ovarian tissues

Despite the controversies, the existence of GSCs was finally reported in 2009 by Zou *et al.*^[29]. They developed a strategy to isolate GSCs from neonatal and young adult mouse ovaries by immunoselection with the antigen MVH (Figure 1). The isolated MVH-positive cells were morphologically similar to type A spermatogonial cells (SSCs). They possessed large cell bodies with little cytoplasm and large nuclei. These MVH-positive cells were present in the ovarian surface epithelium. The isolated MVH-positive cells were cultured on mitotically inactivated mouse embryonic fibroblast (MEF) cell feeders. The MVH-positive cells incorporated BrdU in culture, and the BrdU-MVH double-positive cells were thus considered to be ovarian GSCs. After several passages, the MVH-positive cells formed compact clusters with blurred cell boundaries that did not resemble embryonic stem (ES) cell colonies. The nGSCs from neonatal mice

could be maintained in culture for more than 15 mo (68 passages) and maintained a morphology similar to that of freshly isolated nGSCs. GSC from adult (aGSCs) mice had been passaged in culture for more than 6 mo (more than 25 times). The cultured nGSCs and aGSCs expressed Oct-4, MVH, Dazl, Blimp-1 (a transcriptional repressor), Fragilis, Stella, and Rex-1 (zfp-42, zinc-finger protein 42), which are markers of undifferentiated GSCs (Figure 1). The cells did not express c-Kit (stem cell factor receptor), Figla (a meiosis-specific marker), Sox-2 (a key transcription factor that regulates stemness), Nanog (a pluripotency sustaining factor), synaptonemal complex protein 1,2,3 (Scp1-3), or zona pellucida protein 3 (ZP3), which are established markers of differentiated oocytes. This expression profile revealed that the cultured cells possessed undifferentiated GSC phenotypes. Moreover, the cultured cells showed high telomerase activity. After the transplantation of GFP-expressing GSCs into the ovaries of chemotherapy-ablated wild-type mice, the ovaries contained many GFP-positive oocytes at all stages of development. Moreover, the transplanted mice produced offspring after mating with a wild-type male. Eighty-two percent of nGSCs and 80% of aGSCs produced F1 offspring. The offspring were fertile and could also generate F2 GFP-transgenic progeny (Figure 1).

Furthermore, Pacchiarotti *et al.*^[30] used fluorescence-activated cell sorting (FACS) to isolate GSCs from the ovaries of a transgenic mouse model. In this model, GFP was expressed under the control of the Oct-4 promoter. The GFP-Oct-4-positive isolated cells were expanded on mouse MEFs for more than 1 year. GFP-Oct-4-positive cells formed round, flat colonies. These colonies maintained their telomerase activity and normal karyotype after 20 passages. The cells expressed germ cell and stem cell markers, such as germ cell nuclear antigen, c-kit, Oct-4, Nanog and GFR- α 1 (the receptor for GDNF), and they possessed a normal karyotype. In the presence of growth factors, these GSC cells formed embryoid bodies (EB) and expressed specific markers for the three germ layers. In the absence of growth factors, EBs produced oocyte-like cells. The authors' results thereby indicated the existence of GSCs in the postnatal mouse ovary.

In a recent study published in *Nature Medicine*, White *et al.*^[7] reported the isolation and characterization of ovarian germ stem cells from mouse and human ovarian tissue. GSCs were isolated and purified by FACS using the Ddx4 protein. Isolated mouse and human OSCs express high levels of Prdm1 (PR domain containing 1 with ZNF domain, referred to as Blimp1), Dppa3 (developmental pluripotency-associated 3, referred to as Stella), and Ifitm3, which identify primitive germ cell lines in mammals. Moreover, mouse and human OSCs express high levels of the catalytic subunit of telomerase (Tert), a feature of pluripotent stem cells and germ cells. The Ddx4-positive mouse and human ovarian GSCs were maintained on MEF-

free cultures. After 10-12 and 4-8 wk of culture respectively, the mouse and human ovarian GSCs formed actively dividing germ cell colonies. Gene expression analysis of cultured cells confirmed the maintenance of early germ line markers. Moreover, mouse and human ovarian GSC cells cultured *in vitro* spontaneously underwent oogenesis 24-48 and 72 h after each passage, respectively. Ploidy analysis of the cultured mouse and human GSCs detected 4n, 2n, and 1n populations of cells. These 1n cells were purported to be haploid germ cells.

Transplantation of GFP-expressing mouse ovarian GSCs into ovaries of non-chemotherapy-conditioned wild-type mice resulted in the formation of developing follicles containing GFP-positive oocytes. *In vitro* fertilization of the GFP-expressing oocytes led to the formation of embryos expressing GFP. In co-cultures of human GFP-transduced ovarian GSCs with adult ovarian cortical tissue, GFP-positive oocytes were found to be enclosed by GFP-negative somatic granulosa cells; these were present in tightly compact structures that resembled follicles within 24 h after seeding. GFP-expressing human GSCs injected into fragments of human adult ovarian cortical tissues were also transplanted into NOD-SCID female mice. Human ovarian grafts contained primordial and primary follicles with GFP-negative oocytes and also immature follicles containing GFP-positive oocytes.

After the publication of this new study, Oatley and Hunt published a brief commentary to raise some questions regarding these latest findings^[31]. They questioned whether the purported GSCs represented true stem cells. Oatley and Hunt also questioned the increase in haploid cells, indicating that oocytes completed both meiotic divisions *in vitro* and proposed that the oocytes underwent an abnormal maturation that does not occur *in vivo*. They also criticized the lack of studies on the normalcy of embryos derived from GFP-positive GSCs, arguing that the developmental potential and the genetic quality of the embryos needed to be tested.

Latest developments in the area of GSCs

After the publication of the above-mentioned studies, two different groups presented contradictory results^[32,33]. These investigators refuted the existence of GSCs in the adult ovary and provided evidence supporting the dogma of a fixed pool of oocytes after birth.

In 2012, Zhang *et al.*^[32] claimed that no mitotically active female germline progenitors existed in postnatal mouse ovaries. In their study, they challenged the existence of ovarian GSCs using a genetic approach. They developed a multiple fluorescent Rosa26rbw/+;Ddx4-Cre germline reporter mouse model to trace the development of Ddx4-expressing ovarian cells *in vitro* and *in vivo*. This model expresses GFP ubiquitously. The Ddx4-expressing germline cells

and the non-expressing Ddx4 somatic cells can be recognized by a difference in color. The authors tested the ability of adult mouse ovaries to support the formation of new follicles when provided with female primordial germ cells. Transplantation of enhanced GFP (EGFP)-expressing fetal ovarian cells into adult wild-type female mice led to the formation of fluorescent follicles at different stages of development in the cortex and the medulla of the recipient ovaries. Consequently, the adult mouse ovaries supported *de novo* follicular formation if progenitor cells that were able to differentiate into oocytes were provided. In addition, the adult mouse ovary cells did not transform into oocytes or granulosa cells, and no chimeric follicles were observed. Moreover, when the EGFP-expressing fetal ovarian cells were transplanted into the ovaries of chemotherapy-sterilized WT adult female mice, only newly formed EGFP-positive follicles were detected in the ovaries, which suggests that postnatal mouse ovaries are able to sustain *de novo* follicle formation when provided with exogenous germline progenitors.

The ovaries of Rosa26rbw/+;Ddx4 Cre postnatal mice were dissociated, and single cells were cultured to determine the proliferation capacity of Ddx4-expressing cells (Red FP positive cells, RFP).

None of the RFP-positive ovarian cells underwent any cell divisions, and they rapidly died off. In long-term cultures on feeders, RFP-positive ovarian cells did not form any colonies. Some Ddx4-negative ovarian cells formed colonies of cells that were passaged stably, but the cells did not express germ cell markers. These cells did not participate in follicle formation after injection into adult wild-type ovaries. The authors concluded that these clonal cells presented a stem cell-like morphology, but they were not functional female germline progenitors.

Recently, another group published a study supporting the dogma of a fixed pool of oocytes after birth^[33]. By using a sensitive lineage-labeling system created in transgenic mice (Rosa26-YFP mice), Lei and Spradling affirmed that the primordial follicles generated during fetal life in mice are sufficient to support adult oogenesis. Moreover, female mouse ovaries do not contain active GSCs, and they do not produce new oocytes *in vivo*^[33].

In 2013, Woods *et al.*^[34] published a review on ovarian GSCs that took into consideration two commentaries^[31,35] released after the publication of the studies by White *et al.*^[7] and by Zhang *et al.*^[32]. Woods *et al.*^[34] responded to the comments, analyzed the findings of the Zhang *et al.*^[32] study, and, more importantly, defended their point of view on the existence of ovarian GSCs and oogenesis in postnatal life in mammals.

Woods *et al.*^[34] considered their strategy for the purification of mammalian GSCs from the postnatal ovary to be a validated and reliable method. The protocol using an antibody against the extracellular

epitope of the Ddx4 protein exposed on the surface of the plasma membrane of GSCs was also confirmed to isolate these cells from oocytes, which possess only cytoplasmic Ddx4. To respond to Oatley *et al.*^[31] about their doubts about the validity of the stem cell properties of the ovarian GSCs, Woods *et al.*^[34] explained that the GSCs expressed the same markers as primitive germ cells before and after culture, as described in their publication^[7]. In cultures lacking somatic granulosa cells, GSCs-derived oocytes can exit meiotic arrest and complete both meiotic divisions; thereafter, they exhibit a haploid status, similar to spontaneous oocyte activation *in vivo* when the regulation by somatic granulosa cells is disrupted by ovulation^[36]. With the support of data obtained from several groups^[29,30] Woods *et al.*^[34] claimed that GSCs have the capacity to differentiate into fully mature eggs that can be fertilized to generate normal and viable embryos and offspring in response to the criticisms expressed by Oatley and Hunt.

In the second part of their article, Woods *et al.*^[34] also questioned the results reported by Zhang *et al.*^[32]. They affirmed that the transgenic mouse model used by Zhang *et al.*^[32] possessed a permanent genetic alteration in cells that have activated the *Ddx4* gene promoter region. They stated that the fluorescent recombinant reporter gene would be expressed even if the endogenous *Ddx4* gene is not active anymore. Zhang *et al.*^[32] did not isolate GSCs from the ovaries of their recombinant mice using the methods reported by other groups because they refuted the existence of a *Ddx4* protein exposed on the extracellular surface of the plasma membrane. In experiments involving the transplantation of dissociated fetal ovarian cells into wild-type adult mice, Zhang *et al.*^[32] did not separate the fractions of purified germ line progenitors (primordial germ cells) and fetal follicular somatic cell progenitors to observe neofolliculogenesis in the adult ovary. A fetal somatic cell population or a fetal germ population transplanted separately could stimulate the adult ovary to recruit its own germ cell or somatic cell progenitors to sustain new follicle formation. Morphologic and genetic profiles of the RFP-positive postnatal ovarian observed in cultures were also questioned. The size of the *Ddx4*-expressing cells was significantly larger than that of the GSCs (5-8 mm in diameter). The method of selecting recombinant cells from mouse ovaries was discussed because Zhang *et al.*^[32] recovered the cells by the filtration of crude extracts of mice ovary with a size cutoff of 40 μm . Small immature oocytes present in postnatal mouse ovaries would not have been retained in the filter. The *Ddx4*-expressing cells observed in this study should have been considered as oocytes rather than putative GSCs, explaining their incapacity to proliferate in cultures. Identification of the *Ddx4*-expressing cells needed to be addressed by polymerase chain reaction (PCR)-based analysis of the gene expression patterns of GSCs and oocytes, which would have certainly given positive results for oocyte-

specific genes.

Finally, in the discussion of their article, Woods *et al.*^[34] compared their findings on ovarian stem cells with the observations established for the germinal stem cells in females of non-mammalian species, such as *Drosophila* and in males of mammalian species, such as mice. Although the reproductive period in women has a limited duration of 3 decades, Woods *et al.*^[34] argued that the presence of germinal stem cells in the ovaries should be accepted as it is in *Drosophila*, in which the GSCs persist after the failure of reproductive life^[37], or in male mice, in which the presence of germinal spermatogonial stem cells has been detected after spermatogenic failure^[38]. The authors defended the idea that mammalian females should not be excluded from that standard.

Following the puzzling questions about the Zhang *et al.*^[32] study, Park *et al.*^[39] decided to carry on experiments using transgenic *Ddx4*-Cre mice crossed with mice carrying a *Rosa26*^{tdTm/tdTm} fluorescent gene reporter to identify GSCs in adult mouse ovaries^[39]. In experiments performed according to the protocol used in the study by Zhang *et al.*^[32], Park *et al.*^[39] confirmed that cells collected from crudely dispersed ovaries from recombined mice at postnatal day 8 and selected by filtration were immature oocytes based on PCR analysis of oocyte-specific markers. Moreover, the tdTM/*Ddx4* double-positive cell population purified by FACS from dissociated *Ddx4*-Cre;*Rosa26*^{tdTm/+} ovaries expressed the primitive germ cell markers *Prdm1*, *Dppa3*, *Ifitm3*, *Tert*, and *Dazl* but did not express the oocyte-specific markers newborn ovary homeobox (*Nobox*), *ZP3*, and growth differentiation factor 9 (*Gdf9*). In addition, *Ddx4* mRNA was detected in freshly purified tdTM/*Ddx4* double-positive cells, although it was present at a low level. Cultures of the double-positive cells resulted fluorescent germ cell colonies that were mitotically active. In this study, Park *et al.*^[39] demonstrated that a genetic approach associated with a FACS cell selection based on extracellular *Ddx4* was a reliable and pertinent strategy for the isolation of GSCs from the adult mouse ovary.

From the studies described above, we can infer that the presence of GSCs in the adult ovary remains a subject of intense debate and controversy, and the field of ovarian biology is undergoing profound changes. Progress in ovarian biology has also been made since the discovery of ovarian CSC in 2005^[8]. The characterization of specific ovarian CSCs based on markers of stemness has also generated intense research and discussion. In the following section, we will focus on the characteristics of ovarian CSCs and their relationship with GSCs.

OVARIAN CANCER STEM CELLS: IS THERE ANY RELATIONSHIP BETWEEN GSCS AND CANCER STEM CELLS?

To date, the question concerning the cellular origin of

cancer is still debated. Two major hypotheses have been proposed regarding the formation of cancer: (1) Clonal evolution, or a stochastic model; and (2) a CSC model^[40]. In the first model, every cell within a tumor mass has the equivalent self-renewal capacity and multilineage potency to drive tumor development. In the CSC model, cancer originates from a small rare population of undifferentiated stem cells with self-renewal capacity. Given this theory, it is not surprising that the CSC hypothesis has gained considerable attention in recent years.

As it is known, CSCs share similar biological properties with normal somatic stem cells, including an extensive self-renewal capacity, expression of specific stem cell surface markers and genes and common signaling pathways. However, CSCs differ significantly from normal stem cells in their drug resistance and metastatic activities. Therefore, recent developments in the field of stem cell biology have led to the reconsideration of the definition of cancer. Many researchers suggest that cancer is a stem cell disease and focus on the CSCs theory to understand which cancer cells are responsible for the development of tumors, chemoresistance and high rates of recurrence.

Epithelial ovarian cancer (EOC) is the most lethal of all gynecological malignancies worldwide and the seventh leading cause of cancer-related death^[41]. It is generally often diagnosed at late stages of the disease. Greater than 90% of EOCs arise from the ovarian surface epithelium (OSC). The molecular and cellular mechanisms underlying EOC remain poorly understood because of the complexity and heterogeneity of the tumor development process^[42].

Accumulating experimental data have demonstrated that EOC is a stem cell-driven disease^[43,44]. Over the last few years, several studies have focused on the isolation, identification, and characterization of stem cells from ovarian cancer cell lines, primary tumor tissues and ascites from cancer patients. Although no universal single marker has been found to isolate ovarian CSCs, several putative markers have been identified by several groups (Table 2). However, the isolation and characterization of CSCs have been the subject of extensive studies and the experimental strategies are still a matter of debate.

The first evidence for the existence of a CSC population in EOC patients was reported by Bapat *et al*^[8]. The

authors isolated a single tumorigenic clone from the ascites fluid of an ovarian cancer patient and defined the characteristics of this cell clone, which was identified as a stem/progenitor cell. They suggested that ovarian cancer may be the result of transformation and dysfunction of stem cells in the ovary.

Subsequently, Szotek *et al*^[9] identified stem cell-like cells, or side population (SP) cells, in the murine transgenic epithelial ovarian cancer cell line MOVCAR-7, the human ovarian cancer cell lines OVCAR 3, SKOV-3 and IGROV-1 and ascites from a small group of ovarian cancer patients using the dye efflux marker SP. Then, they went on to characterize the cell surface markers of these cells by flow cytometry. The authors found that c-kit/117 and CD44 were expressed in the mouse SP cells. However, human SP cells were not further functionally characterized in this study.

In 2008, Zhang *et al*^[10] isolated and identified a self-renewing subpopulation of cancer-initiating cells from human ovarian primary tumor tissues for the first time. They showed that these cells expressed various stem cell markers, including stem cell factor, Nanog, ATP Binding Cassette G-member protein (ABCG2), and Oct-4. These cells also demonstrated chemoresistance to cancer therapeutics and were able to initiate tumors in mice, as determined by evaluating the CD44⁺/CD117⁺ phenotype. Subsequent studies have demonstrated that CD133(+) cells have higher clonogenic and proliferative potential than CD133(-) cells in primary ovarian tumors^[45,46]. This result is not consistent with a recently published study indicating the CD133 expression in tumorigenic ovarian cancer cells is heterogeneous^[47]. Similarly, contradictory results have been obtained using CD24 for the characterization of ovarian CSCs^[13,48].

Although the origin of CSCs has been debated for a long time, a common consensus on this issue has not been reached. While some authors support the hypothesis that CSCs originate from normal stem cells undergoing malignant transformation^[49,50], *in vitro* cancer models have shown that CSCs do not arise from normal stem cells^[51]. Although several putative ovarian CSC markers have been identified, these markers can also be found on normal stem cells^[52]. To understand the relationship between CSCs and normal stem cells, the gene expression profiles in human ovarian stem cells and ovarian cancer was analyzed, and the results showed that the expression of some genes is significantly reduced in malignant ovarian tumors but relatively unchanged in benign tumors compared to normal ovary^[53]. Surprisingly, in a more recent study, a link between normal stem cells and CSCs in ovarian cancer was established^[54]. The authors analyzed the expression patterns of the ovarian GSC marker DDX4 and the ovarian CSC marker CD133 in ovarian cancers using tissue microarrays. They found that the levels of both DDX4 and CD133 were significantly increased in ovarian cancer, and the expression pattern of DDX4 was similar to that of CD133. Even more interesting, they

showed that almost all CD133-positive cancer cells also expressed DDX4 whereas the CD133-negative cells did not.

The genetic program regulating the self-renewal and differentiation of CSCs plays a key role in cancer initiation, invasion and migration. A great body of evidence suggests that epigenetic changes and chromosomal alterations are responsible for tumor development including colorectal^[55], breast^[56], prostate^[57], and hepatocellular carcinoma^[58]. Epigenetic changes include altered DNA methylation, chromatin remodeling and non-coding small RNA (miRNA) expression. Recent developments in the understanding of the role of epigenetic mechanisms have shed new light on carcinogenesis. Taken together, similar to other cancers, determination of the epigenetic mechanisms involved in ovarian cancer opens promising new therapeutic avenues for treatment.

It has been emphasized that DNA methylation might play a seminal role in tumor formation, development and metastasis. DNA methylation of the cytosine residues of CG (also designated as CpG) dinucleotides is the most well-known epigenetic mechanism. Long-term silencing of genes in ES cells is under the control of the polycomb complex of proteins (PcG), and recent findings have shown that stem cell PcG targets are up to 20-fold more likely to have cancer-specific promoter methylation than nontargets, supporting a stem cell origin of cancer, including ovarian cancer^[59,60]. Moreover, Baba *et al.*^[52] demonstrated that CD133 expression, which is a somatic stem cell marker, in ovarian cancer is directly controlled by both histone modifications and promoter methylation. Additionally, specific methylated DNA markers can be detected in the serum, plasma and peritoneal fluid of ovarian cancer patients^[61].

MicroRNAs (miRNAs) are small noncoding RNAs that control gene expression post-transcriptionally and play pivotal roles in stem cell biology. Interestingly, emerging evidence suggests that some miRNAs are differentially expressed in CSCs and somatic cells and even in cancer cells, which indicates that these miRNAs may be involved in the regulation of cancer-related processes^[62-65]. Recently, the involvement of miRNAs in the tumorigenesis, metastasis and drug resistance of EOC has been increasingly reported; therefore, it has been proposed that miRNAs could present a novel therapeutic strategy for the management of ovarian cancer.

Guo *et al.*^[65] showed that miR-9 was downregulated in human ovarian cancer compared to normal ovary, and overexpression of miR-9 repressed cell growth. Li *et al.*^[66] examined the role of miR-27a in the development of drug resistance in ovarian cancer cells, and they found that inhibition of miR-27a decreased the expression levels of the multi drug resistance 1 (MDR1) gene and increased paclitaxel-induced apoptosis. Another recent study reported aberrant miRNA expression in ovarian cancers compared to normal ovary. Iorio *et al.*^[67] reported the overexpression of miR-

200a, miR-141, miR-200c, and miR-200b, as well as the downregulation of miR-199a, miR-140, miR-145, and miR-125b1, in ovarian cancer cell lines.

In light of these findings, it is clear that the CSCs play an important role in the development and maintenance of EOC, and epigenetic changes are responsible for the behavior of cancer progenitor cells and their progeny.

CONCLUSION AND FUTURE PERSPECTIVE

The field of reproductive biology is still divided over the possibility of neo-oogenesis in the mammalian adult ovary between the supporters of this new theory^[1,7,29,30] and the opponents who subscribe to the long-held dogma of a fixed number of follicles at birth^[32,33,68]. In addition, a recurrent question concerns the physiological role of GSCs in the adult mammalian ovary. Nonetheless, the isolation and characterization of GSCs from human ovaries open new perspectives to design protocols for producing mature, competent oocytes *in vitro* for clinical application in assisted reproduction techniques (ART).

During the past years, attempts to generate competent oocytes from ES cells and induced pluripotent stem cells have failed to meet expectations, and fertilization of ESC-derived oocytes remains to be demonstrated^[69,70]. Recently, stem cells derived from newborn mouse skin have been shown to produce oocytes when cultured in an appropriate environment, but these oocytes were not able to undergo complete maturation^[71]. Therefore, as a pure stem cell population that can be easily isolated, female GSCs provide a model to explore postnatal oogenesis in mammals. In addition, these cells may plausibly contribute to the preservation of sterility in women.

Many unanswered questions in the development of oocytes from GSCs remain to be addressed. Cultures of GSCs facilitate the characterization of factors that contribute to the development and regulation of oocytes^[72]. Importantly, the epigenetic program and modifications involved in *de novo* oocyte formation in the adult ovary need to be further established^[73]. A better understanding of these mechanisms of regulation may provide a means to stimulate the generation of oocytes in adult human ovaries *in vivo*.

The question of menopause also remains to be addressed. If ovaries can generate new oocytes during adulthood, it can therefore be suggested that the process of menopause may be the consequence of GSC and ovarian somatic cell aging and not the result of depletion of the oocyte pool. Aging GSCs may arrest to differentiate into oocytes, and/or the environment of the GSC niche may fail to sustain oocyte generation. Therefore, the issue of menopause occurrence is not incompatible with the concept of postnatal neo-oogenesis.

Translational applications of germinal stem cell-

based strategies in the field of infertility treatment in women may be achievable in the near future. Before the use of treatments that negatively impact fertility in women, samples taken from the ovaries could facilitate the isolation of GSCs for cryopreservation and/or for ex vivo expansion and subsequent differentiation into oocytes. Cultured GSCs could be transferred back into the ovaries after treatment to support neofolliculogenesis, or GSC-derived cultured oocytes could be fertilized in a program of *in vitro* fertilization^[74].

Although these potential clinical applications give hope for the future, we are a considerable way from using female GSCs in ART to treat infertility in women.

OC is the most lethal of all gynecological malignancies worldwide. To better understand cancers, researchers are now focusing on identifying the relationship between CSCs and normal stem cells. While both stem cell types have the ability to self-renew, common signaling pathways and similar gene expression profiles, these important properties make it difficult to isolate and distinguish these cells from each other. Additionally, the field faces major challenges, including the absence of specific cell surface markers, inadequate isolation and differentiation protocols, the paucity of genome-wide studies, and also ethical restrictions.

Taken together, it remains uncertain which ovarian cancer phenotype follows the stem cell model due to the complexity and heterogeneity of EOC. On the other hand, the initiation and progression of EOC is characterized by the activation of oncogenes and the switching of tumor suppressor gene expression by epigenetic mechanisms^[75-77]. More importantly, there is evidence on the epigenetic regulation of pluripotency transcription factors, signaling mechanisms and self-renewal pathways that play a critical role in the transformation of GSCs into CSCs in EOC. This knowledge provides us with not only a better understanding of how cancer cells may arise from germinal stem cells, but it also contributes to the development of new technologies or strategies in the management of EOC.

Over the last several years, a great body of evidence supports the idea that ovarian CSCs are responsible for metastasis and drug resistance after chemotherapy in this life-threatening disease. The lack of markers for early detection is the main obstacle to effective treatment strategies. A better understanding of the molecular pathogenesis of EOC is needed to develop new drug therapies and/or diagnostic biomarkers.

potentially sources of stem cells. Placenta-derived stem cells (p-SCs) are in between embryonic and mesenchymal stem cells, sharing characteristics with both, such as non-carcinogenic status and property to differentiate in all embryonic germ layers. Moreover, their use is not ethically restricted as fetal membranes are considered medical waste after birth. In this context, the present review will be focused on the biological properties, culture and potential cell therapy uses of placental-derived stem cells. Immunophenotype characterization, mainly for surface marker expression, and basic principles of p-SC isolation and culture (mechanical separation or enzymatic digestion of the tissues, the most used culture media, cell plating conditions) will be presented. In addition, some preclinical studies that were performed in different medical areas will be cited, focusing on neurological, liver, pancreatic, heart, muscle, pulmonary, and bone diseases and also in tissue engineering field. Finally, some challenges for stem cell therapy applications will be highlighted. The understanding of the mechanisms involved in the p-SCs differentiation and the achievement of pure cell populations (after differentiation) are key points that must be clarified before bringing the preclinical studies, performed at the bench, to the medical practice.

Key words: Fetal membrane; Placenta; Embryonic stem cells; Mesenchymal stem cells; Cell therapy

INTRODUCTION

Stem cell therapy is a promising approach to clinical healing in several diseases. Neurology^[1], orthopedics^[2] and cardiology^[3] are just a few medical branches in which the benefits of stem cell therapy have been mentioned. The prolific capacity of stem cells (either embryonic or mesenchymal), taken together with the ability to generate different cell lineages and its self-renewal property are the major features of these cells that allow their use and manipulation in biology and medicine^[4,5]. A great variety of tissues (bone marrow, adipose tissue, and endometrium) are potentially sources of stem cells and among them the placenta is a transient organ from which it is possible to obtain mesenchymal stem cells^[5].

The term placenta constitutes a very reliable rich source of fetal mesenchymal stem cells^[6-9]. These cells are capable of differentiating into multiple different cell types and have immunological properties that suggest their use in an allogenic transplantation setting^[10-12].

In this respect, it is important to remember that placenta has a fundamental role in maintaining fetomaternal tolerance and, therefore, the immunomodulatory properties of these cells have been investigated with the aim of exploring their applicability in cell therapy-based treatments^[11-13]. Their recovery does not involve any invasive procedures for the donor and their use does not create any ethical issue. In addition, the fact that placenta is generally discarded after birth as medical waste and is available in large supplies, makes placental-derived stem cells (p-SCs) excellent candidates for cell therapy. The current review is focused on the biological properties, culture and potential cell therapy applications of p-SCs.

P-SC

Biological properties

Animal development is initiated by fertilization of the egg with sperm, which is immediately followed by mitotic cell divisions, or cleavages, to generate blastomeres. For eutherians, such as the mouse and human, the first cell differentiation event is the establishment of two distinct cell lineages: the trophoblast (TE) and the inner cell mass (ICM)^[14].

TE engages in implantation by directly interacting with the mother's uterus, and gives rise to tissues in the placenta. It is only after implantation that the three germ layers form from the ICM, which ultimately generates all the tissues in the animal body^[14]. Pluripotency is a characteristic of the ICM and is related to the expression of octamer binding transcription factor 4 (Oct4). Oct4 is essential to prevent ICM from diverting towards the TE lineage. Another important transcription factor, caudal type homeobox 2 (Cdx2), is specifically expressed in TE. It was demonstrated that Cdx2 is necessary to repress the expression of Oct4 in TE^[15]. Moreover, Cdx2 null embryos exhibit high incidence of apoptosis^[16].

Embryonic stem cells (ESCs), which are ICM-derived cell lines, despite of showing pluripotency and self-renewal capacity, have ethical concerns restraints^[4], because of their tumorigenic potential. On the other hand, mesenchymal stem cells (MSCs) are not subject of these ethical restraints, but show multipotency, that means a lower capacity to multiply and originate different cell lineages^[5]. Surrogate systems to study early placental development in the human species have been tried using human and mouse embryonic stem cells under bone morphogenetic protein (BMP) 2/4 stimulus to trophoblast differentiation and spontaneous formation of embryoid bodies^[17,18]. MSCs are found in a lot of tissues, like the dentary tissue, adipocytes and bone marrow which culture provide inadequate cell numbers and have limitations like donor site morbidity and the need of aspiration to collect them, besides being a well-established culture. Attempts to overcome these problems were tried with alternative sources of MSCs and cells isolated from reproductive organs showed to be very useful. Thus, ovaries, uterus (endometrium) and specially the placenta^[19-21], because of its discarded as medical waste after delivery, are potential sources of MSCs that can be used without ethical restrictions.

The p-SCs, which are TE-derived cell lines, gather some features from adult and embryo cells: possible differentiation to originate each of germinative cells and absence of carcinogenicity^[22-27]. In the First International Workshop on p-SCs terminologies standardization have been made^[28], and according to the cell origin we should have amniotic epithelial or mesenchymal stromal cells, chorionic mesenchymal stromal or trophoblastic cells. In the present review it will be considered p-SCs in general, referring to any kind of them.

Cellular characterization

Immunophenotype characterization is the most common procedure used to distinguish different cell clusters, by means of surface marker expression, and some essays employed are immunolabeling^[29] and flow cytometry^[30]. The p-SCs show profiles merged with those found in embryonic and mesenchymal stem cells^[26]. None of these three cell lineages (embryonic,

mesenchymal, and p-SC as well) express the clusters of differentiation (CD) 11b, 34, and 45. Regarding CD expression, p-SCs are positive for 29, 73 and 166, and negative for 11b, 31, 34, 45. In addition, they are positive for human leucocyte antigen (HLA) A, B, C and negative for HLA-DR, DP, DQ^[26,31,32].

The p-SCs fulfill the essential characteristics to categorize MSC^[33] and are capable to originate ectodermal, endodermal, and mesodermal (adipocytes, osteocytes, and chondrocytes) lineages *in vitro*^[25,31]. Moreover, p-SCs express surface cell markers only expressed by embryo-derived cells, such as Oct-4, SRY (sex determining region Y)-box 2 (Sox 2), Nanog, stage-specific embryonic antigen (SSEA)-1, SSEA-4, germ cell tumor marker (GCTM)-2, Tra-1-60, and Tra-1-80^[22-24]. High levels of Oct-4, Sox 2 and Nanog were detected in p-SCs using q-PCR method^[25]. Musashi-1, vimentin, polysialylated-neural cell adhesion molecule, and Nestin were observed in cells from amniotic membrane, unlike other MSCs, when evaluated by immunofluorescence technique^[34].

Cell culture

Many different protocols for isolation of fetal membranes-derived stem cells are found in literature. For human beings and large animals, a separation of amniotic epithelial cells^[23,35], amniotic mesenchymal cells^[7] and chorionic mesenchymal cells^[8] are possible, meanwhile for small animals, such as rodents, such characterization is not possible^[31].

Fetal membranes are submitted to enzymatic disaggregation following different protocols, which differ among themselves particularly regarding enzymatic digestion and duration^[7,8,23,31,35]. In every protocol, the cells are incubated with trypsin-EDTA or other enzymes, at 37 °C, and then, are harvested through physical methods. Then cells are plated onto noncoated tissue culture dishes or flasks. Serum, like fetal bovine serum (FBS) ranging from 10% to 20%, must be added to the media. The most commonly used media are Roswell Park Memorial Institute (RPMI)-1640, Dulbecco's modified eagle medium (DMEM), Minimum essential medium (EMEM), and DMEM/F12. Also, media should be enriched with nonessential amino acids, L-glutamine, β -mercaptoethanol, sodium pyruvate, and antibiotics. Cells are raised at controlled conditions of air atmosphere and temperature. For maintenance of the cell culture, p-SCs must have their medium (such as DMEM or RPMI) changed every other day. To passage the cells, it should be used trypsin, and the cells are generally plated into T75 tissue culture flasks. Such culturing conditions are very similar with MSCs. On the other hand, ESCs need to be plated into mouse embryonic fibroblasts - MEFs - feeder layer or MatrigelTM and the medium (such as DMEM-F12 or mTeSRTM-1) must be changed every single day. To passage the cells, it should be used collagenase type IV or dispase, and the cells are generally plated into 6-well

plates.

Finally, p-SCs may be cryopreserved using different media containing various concentrations of dimethyl sulfoxide, FBS and DMEM. Viability and cell numbers must be evaluated after thawing.

CELL THERAPY USING P-SC

Basic considerations

Three characteristics are important for the clinical application of p-SCs: the lack of ethical restrictions, pluripotency and their low immunogenicity^[12]. An explanation for this is the low expression of MHC class II molecules, allowing these cells to be effectively employed in transplants^[26].

Regarding to cellular therapy we have to consider the existence of cell banking due to the large amount of cells needed. Thus, those cells must have essential properties like to keep stable in subcultures, availability, great prolificity, freezing resistance, and high viability after thawing. The p-SCs fulfill most of these requirements. It has been mentioned that p-SCs even at subculture 30 showed high cellular division rates keeping a steady karyotype^[25]. Different from p-SCs and ESCs, all other MSCs do not neither replicate nor exhibit high levels of cellular survival around subcultures 8 to 10.

Considering the freezing process, p-SCs require ordinary media (like MSCs, unlike ESCs), show intermediate resistance to low temperature (in between ESCs and MSCs) and show great viability after frozen-thawing (like ESCs, unlike MSCs).

Some of the p-SC uses in research are listed in Table 1, at the end of this section.

Neurological diseases

Human p-SC demonstrated neuroprotective effects after stroke in rats. Treatment of stroke with p-SCs (*via* intravenous administration) significantly increased vascular endothelial growth factor (VEGF), hepatocyte growth factor (HGF) and brain derived neurotrophic factor (BDNF) levels in the ischemic brain compared to controls (dextran vehicle or phosphate buffer saline) after middle cerebral artery occlusion^[36].

In Alzheimer's disease, β -amyloid peptide is considered to be its root cause. Also, the neuroinflammatory process mediated by β -amyloid plaque-induced microglial cells and astrocytes contributes to Alzheimer's disease pathogenesis. Thus, it was demonstrated that p-SCs transplanted into an Alzheimer's disease mouse model modulated the properties of microglial cells toward a β -amyloid peptide plaque-reducing anti-inflammatory response. Moreover, p-SCs injected mice, compared to phosphate-buffered saline controls, had higher levels of β -amyloid degrading enzymes, reduced levels of proinflammatory cytokines, increased levels of anti-inflammatory cytokines (TGF- β and IL-10), slower progression of Alzheimer's pathology, and

Table 1 Preclinical studies using placental-derived stem cells for different disease models

Disease	Animal model	Cells	Ref.
Stroke	Rats	p-SC	[36]

Bone lytic lesions	Mice	p-SC	[50]
Bone disease	rabbit	p-SC + scaffold	[51]

p-SC: Placenta-derived stem cell.

improved memory function^[37].

Liver disease

Cell therapy for liver diseases has also been investigated. Among other sources of MSCs, p-SCs showed the greatest potential for hepatogenic differentiation and proliferation *in vitro*. The p-SCs, mainly those from chorionic plate, expressed higher levels of hepatocyte growth factor after differentiation^[38].

In another study, chorionic-plate derived mesenchymal stem cells isolated from placenta could trigger autophagy to enhance regeneration in carbon tetrachloride injured rat liver model. After p-SC transplantation they observed reduction in apoptosis (caspase activity) and increasing levels for autophagy, survival and regeneration in liver cells^[39].

Pancreatic disease

Human placenta-derived mesenchymal stem cells (p-SCs) have the potential to differentiate into insulin producing cells^[40,41]. Also, p-SCs can form islet-like cell clusters which are capable of restoring normoglycemia when transplanted into streptozotocin-induced diabetic Balb/C mice^[42].

Heart disease

In order to evaluate whether human amniotic membrane could limit postischemic cardiac injury, a fragment was applied onto the left ventricle of rats that had undergone ischemia through left anterior descending coronary artery ligation. The authors observed that the amniotic membrane fragment onto ischemic rat hearts could significantly reduce postischemic cardiac dysfunction once the rats showed higher values of left ventricle ejection fraction, fractional shortening and wall thickening on echocardiographic examinations^[43].

In another study of myocardial infarction, pre-treated (with a hyaluronan mixed ester of butyric and retinoic acid - HBR) p-SCs were intramyocardial injected in a pig model. Treated animals showed

smaller infarct scar size and a significant improvement of the end-systolic wall thickening and circumferential shortening of the infarct border zone evaluated by magnetic resonance imaging^[44].

Muscle disease

First-trimester chorionic-villi-derived cells were evaluated for potential therapeutic use in Duchenne muscular dystrophy, which is a X-linked disorder characterized by the absence of dystrophin at the sarcolemma of muscle fibers. The p-SCs efficiently differentiated into myotubes after myogenic induction, at which point Nanog and Sox2 were down-regulated, whereas MyoD, myogenin, desmin and dystrophin were up-regulated. The p-SCs could be efficiently directed to differentiate *in vitro* into skeletal muscle cells that express dystrophin as the last stage marker of myogenic differentiation^[45].

The myogenic differentiation of fetal stem cells (p-SC, amniotic fluid stem cells, cord blood and wharton's jelly cells), were already reviewed and considerations about limitations and perspectives for therapeutically use were done^[46].

Pulmonary disease

On a mouse model of bleomycin-induced lung fibrosis, cellular therapy using p-SCs promoted a decrease in neutrophil infiltration and a significant reduction in the severity of fibrosis, compared to control^[47].

On a single centre, non-randomized, dose escalation phase 1b trial study, human patients with moderately to severe idiopathic pulmonary fibrosis received p-SCs *via* peripheral vein and they were evaluated follow up 6 mo. The variables analyzed were lung function (forced vital capacity and diffusing capacity for carbon monoxide), 6-min walk distance, gas exchange (assessed by resting PaO₂), and lung fibrosis score (assessed by high-resolution computed tomography chest). Compared to baseline, at 6 mo all parameters were unchanged, with no evidence of worsening fibrosis and no side effects reported in the patients who had received p-SC injections^[48].

Bone disease

Human fetal early chorionic stem cells (p-SCs) treatment was studied in a murine osteogenesis imperfecta model. It was demonstrated that intraperitoneal injection of p-SCs in osteogenesis imperfect neonates reduced fractures, increased bone ductility and bone volume, increased the numbers of hypertrophic chondrocytes, and upregulated endogenous genes involved in endochondral and intramembranous ossification^[49].

Regenerative medicine using p-SC for bone disease (large lytic lesions) secondary to multiple myeloma was investigated. The authors founded p-SCs inhibitory effects on myeloma bone disease and tumor growth were dose-dependent and intrabone engraftment of p-SCs inhibited bone disease and tumor growth in mice severe combined immunodeficiency-rab model.

The p-SCs also promoted apoptosis in osteoclast precursors and inhibited their differentiation, indicating a promising therapeutic approach for myeloma osteolysis using cytotherapy^[50].

Tissue engineering

The utility of p-SCs for bone tissue engineering has been investigated using different biomaterials and showing promising results. Transplantation of human p-SCs grown in a silk fibroin/hydroxyapatite scaffold into injured radius segmental bone in rabbits enhance tissue repair^[51]. A combination of p-SCs and polylactide/poly(ϵ -caprolactone)-poly(ethylene glycol)-poly(ϵ -caprolactone) fibrous scaffolds promoted good cellular response and excellent osteogenic potential *in vitro*^[52].

An elastic scaffold, obtained combining a poly-(ether)urethane-polydimethylsiloxane (PEtU-PDMS) semi-interpenetrating polymeric network (s-IPN) with fibrin, was used as a substrate for *in vitro* studies of human p-SC growth and differentiation. The s-IPN PEtU-PDMS/fibrin combined scaffold allowed a better proliferation and metabolic activity of p-SC cultured up to 14 d, compared to the ones grown on plastic dishes and also sustained the beginning of p-SCs differentiation process towards a cardiomyogenic lineage^[53].

As an alternative to corneal transplantation, researchers evaluated a biomaterial derived from fetal membranes to promote corneal repair. The pericellular matrix of decidua-derived mesenchymal cells was demonstrated to provide a xeno-free substrate for efficient culture of human corneal endothelial cells. The matrix enhanced corneal cell attachment, promoted cell proliferation, and suppressed apoptosis, offering a viable *in vitro* expansion protocol for human corneal endothelial cells^[54].

Cell-based therapy, using p-SC, combined with bioactive materials improved bone regeneration prior to dental implant. Amniotic epithelial cells, loaded on a calcium-phosphate synthetic bone substitute, displayed a reduced fibrotic reaction, a limited inflammatory response and an accelerated process of angiogenesis. In addition, the presence of p-SCs significantly stimulated osteogenesis by enhancing bone deposition, as suggested by the presence of p-SCs entrapped within the newly deposited osteoid matrix and by their ability to switch-on the expression of osteocalcin when transplanted into host tissues^[2].

CHALLENGES

A routine medical practice using stem cells is an exciting promise. And for this reason, any preclinical study regarding cell therapy must be considered cautiously. Besides the rapid evolution in differentiating stem cells into many different cell types, all protocols result in a mix cell preparations and how to get specialized cells in sufficient amount and purity is still a challenge. So, the really understanding of all the

mechanisms from culturing stem cells to transplanting differentiated ones into a patient is of great importance in order to let the dream comes true.

CONCLUSION

In summary, either the fetal or the maternal components of the placenta may be considered potential sources of stem cells once they share features from both cells of embryonic and mesenchymal origin. Phenotypically, these cells show common characteristics of embryo-derived and adult stem cells and do not express hematopoietic cell markers CD11b, CD 34 and CD 45. Different media to culture and stimuli to onward differentiation in p-SCs are under investigation and they have been used on research trials of cell therapy with promising results. Furthermore, it is important to get enough purity cells and to understand the mechanism of differentiation and engraftment of p-SC to improve cell-based therapy.

Abstract

AIM: To investigate whether fetal kidney stem cells (fKSC) ameliorate cisplatin induced acute renal failure (ARF) in rats and promote renal angiogenesis.

METHODS: The fKSC were isolated from rat fetuses of gestation day 16 and expanded *in vitro* up to 3rd passage. They were characterized for the expression of mesenchymal and renal progenitor markers by flow cytometry and immunocytochemistry, respectively. The *in vitro* differentiation of fKSC towards epithelial lineage was evaluated by the treatment with specific induction medium and their angiogenic potential by matrigel induced tube formation assay. To study the effect of fKSC in ARF, fKSC labeled with PKH26 were infused in rats with cisplatin induced ARF and, the blood and renal tissues of the rats were collected at different time points. Blood biochemical parameters were studied to evaluate renal function. Renal tissues were evaluated for renal architecture, renal cell proliferation and angiogenesis by immunohistochemistry, renal cell apoptosis by terminal deoxynucleotidyl transferase nick-end labeling assay and early expression of angiogenic molecules *viz.* vascular endothelial growth factor (VEGF), hypoxia-inducible factor (HIF)-1 α and endothelial nitric oxide synthase (eNOS) by western blot.

RESULTS: The fKSC expressed mesenchymal markers *viz.* CD29, CD44, CD73, CD90 and CD105 as well as

renal progenitor markers *viz.* Wt1, Pax2 and Six2. They exhibited a potential to form CD31 and Von Willebrand factor expressing capillary-like structures and could be differentiated into cytokeratin (CK)18 and CK19 positive epithelial cells. Administration of fKSC in rats with ARF as compared to administration of saline alone, resulted in a significant improvement in renal function and histology on day 3 (2.33 ± 0.33 vs 3.50 ± 0.34 , $P < 0.05$) and on day 7 (0.83 ± 0.16 vs 2.00 ± 0.25 , $P < 0.05$). The infused PKH26 labeled fKSC were observed to engraft in damaged renal tubules and showed increased proliferation and reduced apoptosis ($P < 0.05$) of renal cells. The kidneys of fKSC as compared to saline treated rats had a higher capillary density on day 3 [13.30 ± 1.54 vs 7.10 ± 1.29 , capillaries/high-power fields (HPF), $P < 0.05$], and on day 7 (21.10 ± 1.46 vs 15.00 ± 1.30 , capillaries/HPF, $P < 0.05$). In addition, kidneys of fKSC treated rats had an up-regulation of angiogenic proteins hypoxia-inducible factor-1 α , VEGF and eNOS on day 3 ($P < 0.05$).

CONCLUSION: Our study shows that fKSC ameliorate cisplatin induced ARF in rats and promote renal angiogenesis, which may be an important therapeutic mechanism of these stem cells in the disease.

Core tip: This study provides novel data on the therapeutic effect of culture expanded fetal kidney stem cells (fKSC) in acute renal failure (ARF). The fKSC represent primitive renal stem cells that express mesenchymal and renal progenitor markers. They exhibit *in vitro* angiogenesis and potential to differentiate into renal epithelial cells. On administration in ARF rats, they rapidly improve renal function and histology. The therapeutic effects of fKSC are accompanied with increased capillary density in kidney tissues suggesting that induction of renal angiogenesis may be an important therapeutic mechanism of these stem cells.

Fetal kidney stem cells ameliorate cisplatin induced acute renal failure and promote renal angiogenesis. *World J Stem Cells* 2015; 7(4): 776-788 Available from: URL: <http://www.wjgnet.com/1948-0210/full/v7/i4/776.htm> DOI: <http://dx.doi.org/10.4252/wjsc.v7.i4.776>

INTRODUCTION

Acute renal failure (ARF) is characterized by rapid loss of renal function due to damage of renal tubular epithelial cells by ischemia, nephrotoxins or other means. Some cases of ARF spontaneously recover from renal injury while in others the recovery process

is either delayed or does not occur at all, leading to chronic kidney disease (CKD), which is associated with high morbidity and mortality^[1,2]. Thus, it is very important to restore normal structure and function of the kidney after ARF using a suitable regenerative therapy in order to prevent its progression into CKD^[3]. Recent data suggest that injury of endothelial cells of small peritubular arterioles and capillaries plays a crucial role in the pathogenesis of ARF by mediating hypoxia and impairment of renal perfusion that eventually results in injury of renal tubular epithelial cells and thereby loss of renal function^[4-6]. Furthermore, reduction in renal capillary density following ARF may perpetuate the tubular epithelial injury leading to CKD^[7,8]. These observations suggest that neovascularization of the kidney and regeneration of damaged renal tubular epithelial cells may be potentially effective in recovery from ARF.

During the past decade, stem cell based regenerative therapy has emerged as a promising therapeutic strategy for ARF and stem cells derived from various sources are being extensively explored for the treatment of ARF^[9,10]. However, a suitable stem cell type for therapeutic application in clinical ARF has not yet been identified. Fetal kidney stem cells (fKSC) represent a novel stem cell type for treatment of ARF because they are multipotent stem cells with an inherent ability to differentiate into cells of renal lineage. In addition, few studies have shown that embryonic or fetal kidney also contains a subpopulation of endothelial and epithelial progenitors^[11-13] and hence fKSC may have an important role in neovascularization and the regeneration of the damaged kidney. However, there is a paucity of data on therapeutic effect of fKSC in ARF and no information is available about angiogenic role of these stem cells in mediating their therapeutic effect in the disease.

Therefore, the aim of the present study was to investigate the therapeutic effect of fKSC in cisplatin induced ARF in rats and to evaluate whether neovascularization in the damaged kidney has a role in the therapeutic efficacy of these stem cells in the disease.

MATERIALS AND METHODS

Animals

Experiments were performed on Sprague Dawley (SD) rats (220-250 g) purchased from Central Drug Research Institute, Lucknow, India. All animal experimental procedures in this study were performed as per guidelines of the Institutional Animal Ethics Committee and the Committee for the Purpose of Control and Supervision of Experiments on Animals (CPCSEA), India. The protocol was approved by the Animal Ethics Committee of Sanjay Gandhi Post Graduate Institute of Medical Sciences, Lucknow, India.

Isolation and culture of fKSC

The fKSC were isolated from SD rat fetuses at gestation

day 16. The kidneys were removed from fetuses of 10 pregnant female rats (8-12 fetuses/animal), minced, and digested with 1 mg/mL collagenase type-IV (Worthington Biochemical, NJ, United States) in serum free α -MEM (Gibco, NY, United States) medium for 40 min at 37 °C with intermittent stirring in water bath. After two washes with α -MEM, the digested tissue was cultured at 37 °C in a 5% CO₂ in 25 cm² tissue culture flasks (BD, New Jersey, United States) in complete culture medium consisting of α -MEM medium, 2 mg/mL of Glutamax (Gibco, NY, United States), 16.5% fetal bovine serum (Gibco, NY, United States) and bacteriostatic level of penicillin-streptomycin (Gibco, NY, United States). After 48 h of seeding of fetal kidney cells, the culture media containing non-adherent cells were replaced. On day 3 adherent cells were harvested by trypsinization with TrypLE Express (Gibco, NY, United States) and further cultured in complete culture media. The cells of 3rd passage were used for this study.

Characterization of fKSC

The fKSC were characterized by studying their expression of mesenchymal and renal progenitor markers. The expression of mesenchymal markers on fKSC was studied by flow cytometry. The fKSC at passage 3 were incubated for 30 min with following antibodies: Fluorescein isothiocyanate (FITC) conjugated CD90 (Abcam, MA, United States), CD44 (BD Biosciences, CA, United States), phycoerythrin conjugated CD45 (Abcam, MA, United States), MHC class II (Abcam, MA, United States) and with unconjugated CD29 (Abcam, MA, United States), CD73 (BD Biosciences, CA, United States), CD105 (Santa cruz biotechnology, inc. CA, United States). The corresponding FITC-conjugated secondary antibodies (Abcam, MA, United States) were added in CD29, CD73 and CD105 tubes. Isotype-identical antibodies (IgG) served as controls.

Expression of renal progenitor markers *viz.* Wilms tumor1 (Wt1), paired box2 (Pax2), SIX homebox2 (Six2) was studied by immunocytochemistry. The cells were fixed with 4% para-formaldehyde for 1 h at room temperature and incubated overnight at 4 °C with following primary antibodies: Wt1, Pax2 (both from Abcam, MA, United States) and Six2 (Santa cruz biotechnology, Inc. CA, United States). After washing with PBS, cells were incubated with corresponding FITC-conjugated secondary antibodies and counter stained with Hoechst dye (Sigma-Aldrich, MO, United States). The fKSC incubated with non-immune serum or IgG in place of primary antibodies were used as negative controls. The images were obtained using Nuance Multispectral Imaging System (CRI Inc., MA, United States).

In vitro differentiation towards epithelial lineage and angiogenic assay

To induce epithelial differentiation, fKSC (2×10^4 cells/well) were cultured on cover slips in 6 well plate

in complete culture medium containing 0.1 μ mol/L Retinoic acid, 10 ng/mL activin-A and 50 ng/mL Bmp7 (all from R and D Systems, MN, United States). After 7 d, cover slips with induced fKSC were fixed in 4% para-formaldehyde for 1 h at room temperature. The fixed cells were incubated at 4 °C overnight with primary antibodies *viz.* cytokeratin (CK)18 and CK19 (Abcam, MA, United States). After washing with PBS, cells were incubated with corresponding FITC-conjugated secondary antibodies for 1 h at room temperature and counter stained with Hoechst dye (Sigma-Aldrich, MO, United States). The fKSC cultured without induction medium were used as negative controls.

The tube-formation assay was performed to assess the angiogenic potential of fKSC. Briefly, fKSC (2×10^4 cells/well) were seeded onto the growth factor reduced matrigel (BD Biosciences, CA, United States) coated cover slips in 6 well plate and incubated overnight in standard culture condition with complete medium. The cells were examined by phase contrast microscopy and immunocytochemistry. For immunocytochemistry, cells were fixed with 4% para-formaldehyde for 1 h at room temperature. The fixed cells were incubated at 4 °C overnight with primary antibodies *viz.* CD31 (AbD serotech, Oxford, United Kingdom) and Von Willebrand factor (vWF) antibody (Abcam, MA, United States). After washing with PBS, cells were incubated with corresponding FITC-conjugated secondary antibodies for 1 h at room temperature and stained with Hoechst dye. The fKSC cultured without growth factor reduced matrigel were used as negative controls.

Development of ARF model and fKSC therapy

ARF was induced in male SD rats ($n = 36$) weighing 200-225g by cisplatin injection as described by Ozyurt *et al.*^[14]. Briefly, the animals were given a single intra-peritoneal injection of cisplatin (0.5 mg in 1 mL of saline, sigma, United States) at a dose of 7 mg/kg of body weight. A significant increase in blood biochemical parameters and renal damage were observed in rats on day 5 of cisplatin injection. Hence at this time point, rats were randomized into two groups *viz.* fKSC treated group ($n = 18$) and saline treated group ($n = 18$) for evaluation of the efficacy of stem cell therapy. In addition, a group of healthy rats ($n = 6$) was also included in the study as healthy controls to compare renal function and histology of fKSC and saline treated groups.

The fKSC were labeled with PKH26, a red fluorescent cell linker (Sigma-Aldrich, MO, United States) according to manufacturer's protocol. Labeling efficiency of PKH26 with fKSC and cell viability of labeled cells were > 95% and > 97% as revealed by fluorescent microscopy and trypan blue exclusion, respectively. On day 5 of cisplatin injection, a total of 2×10^6 PKH26 labeled fKSC in 150 μ L of saline or 150 μ L saline alone were injected intravenously through tail vein in each rat of fKSC treated or saline treated groups, respectively.

Animals were euthanized by barbiturate overdose

(intravenous injection, 150 mg/kg pentobarbital sodium) before fKSC therapy (day 0) and after three days (day 3) and seven days (day 7) of fKSC therapy. Blood samples were collected to determine blood urea nitrogen (BUN) and serum creatinine levels by using commercial Span diagnostic kits with an autoanalyser (BioSystems BTS-330). The kidney tissues were excised to perform the assays described below.

Histopathological and Immunohistochemical analysis

Ten percent of formalin fixed kidney tissues were cut into 5 μ m serial sections and stained with hematoxylin and eosin to evaluate sequential histopathological changes in saline and fKSC treated animals. Quantitative assessment of renal tubular necrosis was performed using the grading scores of Jablonski *et al.*^[15]. For immunohistochemical analysis, 5 μ m thick paraffin sections of kidneys were deparaffinized with xylene and rehydrated in a series of alcohol and water. After rehydration, tissue sections were incubated with primary antibodies *viz.* aquaporin (AQP)1, vWF (both from Abcam, MA, United States) and CD31 (AbD serotech, Oxford, United Kingdom) and proliferating cell nuclear antigen (PCNA; BD Biosciences, CA, United States). After overnight incubation, sections were washed with PBS and incubated with corresponding FITC-conjugated secondary antibodies and then counter stained with Hoechst dye. Images were taken by Nuance Multispectral Imaging System (CRi Inc., MA, United States). To determine the capillary density, CD31 stained capillaries were counted in 10 randomly chosen high-power fields (HPF; 20 μ m) using a fluorescent microscope and expressed as capillaries per HPF. To determine the number of proliferating cells in the kidney, PCNA positive nuclei were counted in 10 HPFs per section (20 μ m) in the cortico-medullary area under a Nuance Multispectral Imaging System (CRi Inc., MA, United States) and the proliferative index was expressed as average number of PCNA⁺ cells /HPF.

dUTP nick-end labeling

Apoptotic scores in kidney tissue sections were measured by the terminal transferase-mediated dUTP nick-end labeling (TUNEL) assay using an In Situ Cell Death Detection Kit (Roche, Mannheim, Germany) as per manufacturer's instruction. Briefly, kidney sections were deparaffinized, rehydrated, and digested with proteinase K and labeled with TUNEL reaction mixture for 60 min at 37 °C. TUNEL positive nuclei were counted in 10 HPF per section in the cortico-medullary area at 20 μ m magnification under a Nuance Multispectral Imaging System (CRi Inc., MA, United States) and the apoptotic index was expressed as average number of TUNEL⁺ cells /HPF.

Western blot

Expression of angiogenic signaling molecules in the kidneys of rats was evaluated by western blotting on day 3 after fKSC therapy. The kidney tissues of

animals were homogenized in RIPA buffer containing 1 mmol/L phenylmethanesulphonyl fluoride and 1% protease inhibitor cocktail (Sigma-Aldrich, MO, United States). Kidney tissue homogenate was centrifuged at 10000 *g* for 10 min and the supernatant was stored in -80 °C. 40 mg proteins were loaded and separated by 10% sodium dodecyl sulfate-polyacrylamide gel electrophoresis. After electrophoresis, separated proteins were transferred to polyvinylidene difluoride membranes. The membranes were blocked with 5% BSA for 1 h at room temperature and then incubated at 4 °C overnight against primary antibodies *viz.* vascular endothelial growth factor (VEGF), hypoxia-inducible factor (HIF)-1 α and endothelial nitric oxide synthase (eNOS) (all from Abcam, MA, United States). β -Actin antibody (Abcam, MA, United States) was used as a loading control. Primary antibodies were detected by corresponding horseradish peroxidase (HRP)-conjugated secondary antibodies using super signal west pico chemiluminescent substrate (Thermo scientific, IL, United States). The bands were quantified by densitometry using the Quantity One software (Bio-Rad, CA, United States).

Animal care and use

The animal protocol was designed to minimize pain or discomfort to the animals. The animals were acclimatized to laboratory conditions (23 °C, 12 h/12 h light/dark, 50% humidity, *ad libitum* access to food and water) for two weeks prior to experimentation. All animals were euthanized by barbiturate overdose (intravenous injection, 150 mg/kg pentobarbital sodium) for tissue collection.

Statistical analysis

Values were expressed as mean $\pm$ standard error (SE). The statistically significant differences between groups were analyzed by one way-analysis of variance (ANOVA) with Bonferroni multiple-comparison post hoc test. Statistical analysis was performed using GraphPad Prism Software Version 5 (GraphPad, San Diego, CA) and a *P* value of < 0.05 was considered statistically significant.

RESULTS

Expression of mesenchymal and renal progenitor markers by fKSC

The fKSC exhibited spindle-shaped and polygonal morphology in culture (Figure 1A). Flow cytometry analysis showed that fKSC expressed CD29 (37.59%), CD44 (32.76%), CD73 (51.72%), CD90 (68.71%) and CD105 (37.88%), whereas the expression of CD45 and MHC class II was < 5% (Figure 1B). Immunocytochemistry revealed that fKSC also expressed renal progenitor markers *viz.* Wt1, Pax2 and Six2 (Figure 1C).

In vitro epithelial differentiation and angiogenic potential of fKSC

On treatment with specific induction medium, fKSC

Figure 1 Morphology (A) and characterization of fetal kidney stem cells (B and C). A: Representative photomicrograph (Scale bars indicate 100 μ m) showing spindle-shaped and polygonal morphology of fetal kidney stem cells (fKSC); B: Phenotypic characterization of fKSC by flow cytometry showing expression of CD29, CD44, CD73, CD90, CD105, CD45, and MHC class II (green or red lines, detected with FITC - or phycoerythrin-conjugated antibodies, respectively) with isotype controls (black lines); C: Representative immunofluorescent photomicrographs (Scale bars indicate 20 μ m) showing expression of renal progenitor markers viz. Wt1, Pax2 and Six2 on

exhibited differentiation ability into epithelial cells as demonstrated by expression of CK18 and CK19 by immunocytochemistry (Figures 2A and B). When grown on matrigel, fKSC exhibited capillary-like tubular structures assessed by phase contrast microscopy (Figure 2C) and expressed endothelial markers viz., CD31 and vWF by immunocytochemistry (Figure 2D and E).

Improvement of renal function following fKSC therapy in ARF rats

On the 5th day of cisplatin injection, the rats exhibited a significant increase in levels of both BUN and serum creatinine as compared to healthy controls ($P < 0.05$). The same day (day 0 of therapy), the rats were randomized to receive fKSC therapy or saline alone. On day 3 of therapy, fKSC treated group had significantly lower levels of these blood biochemical parameters as compared to saline treated group ($P <$

0.05), but both groups had significantly higher levels as compared to healthy controls ($P < 0.05$). On day 7 of therapy, the serum creatinine and BUN levels in the fKSC treated group were comparable to healthy controls but they were still significantly higher in the saline treated group in comparison to healthy controls ($P < 0.05$) (Figure 3A and B).

Improvement of renal histology following fKSC therapy in ARF rats

The kidneys of ARF rats on the 5th day of cisplatin injection showed severe tubular necrosis, hyaline cast formation, loss of brush border in the proximal renal tubules and tubular dilatation (Figure 4B). On day 3 of fKSC therapy, the kidneys showed a significant attenuation of tubular injury as compared to saline treated rats (Figure 4C and D) and Jablonski grading score revealed significantly lower necrosis in the kidneys of fKSC treated as compared to saline treated

Figure 2 Epithelial differentiation (A, B) and angiogenic potential (C-E) of fetal kidney stem cells. A: Representative photomicrograph (Scale bars indicate 20 μ m) showing CK18 expression, Hoechst, overlay and untreated control cells with only Hoechst; B: Representative photomicrograph (Scale bars indicate 20 μ m) showing CK19 expression, Hoechst, overlay and untreated control cells with only Hoechst; C: Representative photomicrographs (Scale bars indicate 100 μ m) showing tubule like structure formation by fetal kidney stem cells (fkSC) cultured on matrigel and without matrigel as control; D: Representative immunofluorescent photomicrographs (Scale bars indicate 100 μ m) showing CD31 expression, Hoechst, overlay and fkSC cultured without matrigel as controls with only Hoechst; E: Representative immunofluorescent photomicrographs (Scale bars indicate 100 μ m) of fkSC cultured on matrigel showing Von Willebrand factor expression, Hoechst, overlay and fkSC cultured without matrigel as controls with only Hoechst.

rats (2.33 ± 0.33 vs 3.50 ± 0.34 , $P < 0.05$, Figure 4G). On day 7 of therapy, the kidneys of fkSC treated ARF rats showed disappearance of necrotic cells with almost normal architecture of tubules, whereas those of saline treated ARF rats still had necrotic tubular cells and hyaline casts (Figure 4E and F) and there was also a significant difference in Jablonski grading score between the fkSC treated and saline treated groups

(0.83 ± 0.16 vs 2.00 ± 0.25 , $P < 0.05$, Figure 4G).

Engraftment of infused fkSC in renal tubules

To study their engraftment, PKH26 labeled fkSC were evaluated in rat kidneys on day 7 of therapy. The fkSC were observed to engraft preferentially in renal tubules and capillaries stained with tubular epithelial marker AQP1 and endothelial marker vWF, respectively (Figure

Figure 3 Effect of fetal kidney stem cells therapy on renal function in rats with cisplatin induced acute renal failure. The changes in the levels of (A) blood urea nitrogen (BUN) and (B) serum creatinine in healthy control, saline treated and fetal kidney stem cells (fKSC) treated groups on day 0, 3 and 7 after fKSC therapy. Values expressed as Mean $\pm$ SE. ^a $P < 0.05$ for saline and fKSC treated vs healthy control group; ^c $P < 0.05$ for fKSC vs saline treated group.

5).

Administration of fKSC reduces apoptosis and promotes proliferation of renal tissues

On day 3 of therapy, the TUNEL-positive cells in the kidneys of fKSC treated rats were significantly lower than those in the saline treated rats ($P < 0.05$). On day 7, their numbers further decreased significantly in fKSC treated rats as compared to those in the saline treated rats ($P < 0.05$; Figure 6A). On days 3 and 7 of therapy, the number of PCNA-positive cells in the kidneys of fKSC treated rats were significantly higher as compared to those in the saline treated rats ($P < 0.05$, Figure 6B).

Administration of fKSC promotes renal angiogenesis

On day 3 of therapy, the morphometric analysis of CD31 labeled peritubular capillaries showed a significantly higher capillary density in the kidneys of fKSC treated than that in saline treated rats (13.30 ± 1.54 vs 7.10 ± 1.29 , capillaries/HPF, $P < 0.05$). On day 7 of therapy, the capillary density in the kidneys of fKSC treated rats was further significantly increased than that in saline treated rats (21.10 ± 1.46 vs 15.00 ± 1.30 , capillaries/HPF, $P < 0.05$; Figure 7).

To determine the early angiogenic effect of fKSC, the protein expression of angiogenic signaling molecules were studied on day 3 of fKSC therapy. The expressions of HIF-1 α , VEGF and eNOS in the kidneys of fKSC treated rats were significantly higher as compared to saline treated rats ($P < 0.05$; Figure 8).

DISCUSSION

The present study demonstrates that fKSC expressed mesenchymal as well as renal progenitor markers and exhibited the formation of CD31 and vWF expressing capillary-like structures and differentiation into CK18 and CK19 positive epithelial cells *in vitro*. The administration of fKSC in rats with cisplatin induced ARF resulted in rapid improvement in renal function

and histology. The infused fKSC were observed to engraft in renal tubules and promote proliferation and reduce apoptosis of renal tubular cells. In addition, the kidneys of fKSC treated rats exhibited increased angiogenesis and up-regulation of angiogenic signaling molecules. To our knowledge this is the first study showing therapeutic efficacy of *in vitro* expanded fKSC in cisplatin induced ARF model and role of angiogenesis in renal regeneration by these stem cells.

We have recently observed that fKSC have maximal growth at a seeding density of 1000 cells/cm², population doubling time of approximately 34 h and normal karyotype up to 3rd passage. In addition, these cells successfully differentiated into cells of all the three germ layers (communicated elsewhere). In the present study, we have observed that fKSC express mesenchymal (CD29, CD44, CD73, CD90 and CD105) as well as renal progenitor markers (Wt1, Pax2 and Six2). The Pax2 and Wt1 genes cross-regulate expression of each other during kidney development^[16]. However, we have observed a high expression of these markers in fKSC. A plausible explanation of this could be that a significant proportion of fKSC are a population of stem cells of metanephric mesenchyme which have been shown to express both Pax2 and Wt1 transcription factors^[13,17,18]. Similar to our observation high expression of Pax2 and Wt1 has recently been shown in human fetal kidney progenitors as well as human embryonal cells derived nephron progenitors^[19]. The fKSC could be induced to differentiate *in vitro* into CK18 and CK19 positive epithelial cells. In addition, they exhibited an angiogenic potential as shown by the formation of CD31 and vWF positive capillary-like tubular structures when plated on matrigel. Two previous studies have shown that stem cells derived from whole fetal kidneys express mesenchymal and renal progenitor markers, but they have not studied their *in vitro* angiogenic potential and differentiation into epithelial cells^[20,21]. However, corroborating with our data, one study has shown that human embryonic kidney derived CD24⁺ CD133⁺ stem cells exhibit *in vitro* differentiation into epithelial

Figure 4 Fetal kidney stem cells attenuate renal structural damage in rats with cisplatin induced acute renal failure (Scale bars indicate 20 µm). Figure 5 *In vivo* homing and engraftment of administered fetal kidney stem cells in renal tubules. Representative immunofluorescent photomicrographs (Scale bars indicate 20 μ m) showing engraftment of administered fetal kidney stem cells (fKSC) in renal tubules at day 7 of therapy, and expression of tubular epithelial and endothelial markers aquaporin (AQP)1 (A) and Von Willebrand factor (vWF) (B) respectively, with corresponding Hoechst, PKH26 labeled administered fKSC in injured kidney tissue respectively.

Figure 6 Effects of fetal kidney stem cells on apoptosis and proliferation of tubular cells in cisplatin injured kidney. A: Quantification of dUTP nick-end labeling (TUNEL)-positive cells in kidney sections of saline and fetal kidney stem cells (fKSC) treated groups at day 3 and 7 after fKSC therapy; B: Quantification of proliferating cell nuclear antigen (PCNA)-positive cells in kidney sections of saline and fKSC treated groups at day 3 and 7 after fKSC therapy. Values expressed mean $\pm$ SE. ^a $P < 0.05$ for fKSC vs saline treated group. HPF: High-power field.

and endothelial lineages^[22]. We did not evaluate the markers of other renal progenitors such as endothelial and epithelial ones on fKSC which may be a limitation of the present study.

To investigate their therapeutic effect in ARF, we infused intravenously PKH26 labeled fKSC in cisplatin induced rat model of ARF. On day 3 of therapy, we observed a significant improvement in the renal function and histology and on day 7 these parameters became comparable to healthy control rats indicating almost complete recovery. Similar to our data, culture expanded CD24⁺ CD133⁺ stem cells from human embryonic kidney have been shown to mediate a complete functional and structural recovery of glycerol induced ARF in SCID mice^[22]. We observed that PKH26 labeled fKSC engraft in the damaged areas of the kidney and express vWF and AQP1 showing the integration of infused fKSC into damaged renal vasculature and tubules, respectively. It is difficult to distinguish whether vWF and AQP1 are expressed by endothelial

and epithelial cells differentiated from infused fKSC or these markers represent fusion of administered fKSC with damaged kidney cells in the areas of engraftment. Similar to our observation, administration of human embryonic kidney derived CD24⁺ CD133⁺ stem cells in SCID mice with glycerol induced ARF and embryonic stem cell derived mesenchymal like progenitors in rats with cisplatin induced ARF have been shown to engraft into damaged renal tubules and vasculature of kidney^[22,23].

The kidneys of fKSC treated ARF rats were observed to have a higher capillary density correlating with their structural and functional improvement as compared to saline treated ARF rats. In addition, on day 3 of fKSC therapy, there was an increased expression of HIF-1 α and its downstream signaling molecules VEGF and eNOS in the kidneys of fKSC treated rats in comparison to saline treated rats, showing a role of early angiogenesis in the renal regeneration. It has been reported that HIF-1 α also activates expression of

Figure 7 Fetal kidney stem cells accelerate angiogenesis in rats with cisplatin induced acute renal failure. Representative immunofluorescent photomicrographs (Scale bars indicate 20 μ m) showing perivascular capillaries stained with CD31 in saline treated and fetal kidney stem cells (fKSC) treated groups on day 3 (A) and on day 7 (B) after fKSC therapy. C: Quantification of perivascular capillaries stained with CD31, expressed as capillaries per HPF, in saline and fKSC treated groups. Wt1, which in turn directly up-regulates VEGF and thus acts as an important regulator of angiogenesis^[24-27]. The fKSC that were infused in ARF rats were already expressing Wt1, so we did not study its expression in the kidney tissues but as fKSC therapy up-regulated HIF-1 α , it is likely that kidney tissues also have an up-regulation of Wt1. However, since the angiogenic role of Wt1 has mostly been reported in tumors, it is not

known whether Wt1 also has a similar role in normal tissues like kidney. Corroborating with our data, it has been shown that acetazolamide administration in mice with ischemic kidney results in up-regulation of angiogenic molecules HIF-1 α and eNOS in kidney tissue along with reduction in the apoptosis of renal tubular cells, increase in renal blood flow and improvement in renal function and histology^[28]. Similarly, the

Figure 8 Early angiogenic effect of administered fetal kidney stem cells in cisplatin injured kidney. Representative immunoblots showing the expression of hypoxia-inducible factor (HIF)-1 α , vascular endothelial growth factor (VEGF) and endothelial nitric oxide synthase (eNOS) in saline and fetal kidney stem cells (fKSC) treated groups on day 3 after fKSC therapy (A-D). Bar diagrams showing densitometric quantification of the expression of HIF-1 α (B), VEGF (C) and eNOS (D). Comparative gene expression ratio was calculated by referring each gene to β -actin as an internal control. Values expressed mean $\pm$ SE. ^a $P < 0.05$ for fKSC vs saline treated group.

VEGF has been shown to promote regeneration of cisplatin induced injury of renal tubular epithelial cells *in vitro* by inducing proliferation and reducing their apoptosis. In addition, administration of VEGF modified embryonic mesenchymal stem cells (MSC) in cisplatin induced ARF in rodents has been shown to reduce renal apoptosis and promote microcirculation and cell proliferation in the damaged kidney^[29]. There is no previous study showing angiogenic role of fKSC in ARF but in agreement with our study, it has been shown that a clonal cell line of MSC derived from kidney of adult Tie-2 green fluorescent protein transgenic mice exhibit *in vivo* angiogenesis and tubular regeneration by increasing epithelial proliferation and inhibiting apoptosis when administered in mouse model of renal ischemia^[30]. These studies suggest that the improved capillary density, proliferation and reduced apoptosis in renal tissue observed by us following fKSC therapy may be mediated by the up-regulation of VEGF, HIF-1 α and eNOS, and thus these molecules could play an important role in renal regeneration.

In conclusion, the present study shows that fKSC express mesenchymal and renal progenitor markers, exhibit an *in vitro* angiogenic potential and ability to differentiate into cells of renal epithelial lineage. The administration of fKSC in cisplatin induced ARF results in rapid recovery of renal function and histology, and promotes renal angiogenesis. Further studies on fKSC mediated renal angiogenesis and regeneration may lead to the development of novel pharmacological therapies for ARF.

ACKNOWLEDGMENTS

We would like to extend our sincere thanks to Dr. Rituraj Konwar, Scientist, Endocrinology Division, CSIR-Central Drug Research Institute, Lucknow, India and Dr. SK Mandal, Consultant Statistician, Center for Bio-Medical Research Lucknow, India for extending laboratory facilities to perform the Flow cytometry and review of statistical analysis, respectively.

COMMENTS

Background

Tissue specific fetal stem cells represent the most suitable stem cell type for tissue regeneration/repair due to their inherent ability of tissue specific differentiation. Thus, stem cells derived from the fetal kidney may be a novel cell type for renal regenerative therapy. The epithelial and microvascular damage are the main events in acute renal failure (ARF) and this led us to evaluate whether fetal kidney stem cells (fKSC) mediate their therapeutic effect by augmenting renal angiogenesis in cisplatin induced ARF in rats.

Research frontiers

The authors had demonstrated in the present study that fKSC differentiate into cells of epithelial lineage and exhibit angiogenic potential *in vitro*. Following infusion in ARF rats, they engraft in renal tubules and rapidly improve renal function and histology along with increased angiogenesis in the kidney tissues. It is thus logical to investigate whether induction of renal angiogenesis by fKSC is an important mechanism of renal regeneration and whether it is mediated by trans-differentiation of infused fKSC or their paracrine effect on resident kidney

stem cells.

Innovations and breakthroughs

To the best of our knowledge, this is the first study showing therapeutic efficacy of *in vitro* expanded fKSC in ARF model and their *in vitro* and *in vivo* angiogenic potential suggesting that induction of renal angiogenesis may be an important therapeutic mechanism of these stem cells.

Applications

The fKSC represent primitive renal progenitors expressing mesenchymal as well as renal progenitor markers and treatment of ARF rats with these stem cells results in rapid recovery in renal function and histology leading to their normalization. Further studies using human fKSC or human embryonic stem cell derived renal progenitors with similar characteristics may lead to the development of clinical therapy for ARF.

Terminology

The fKSC represent primitive renal progenitors and express mesenchymal as well as renal progenitor markers. They can be culture expanded to generate a requisite number of cells for therapeutic dose. They improve renal function and histology and lead to their normalization by inducing renal angiogenesis. It needs to be studied whether the angiogenesis observed in the kidney tissues in the fKSC treated rats is due to trans-differentiation of infused stem cells or by stimulation of resident endothelial cells or both.

Peer-review

It is a very interesting article about a possible protective role of fetal kidney stem cells in experimental model of acute renal failure.

ABOUT COVER

Editorial Board Member of *World Journal of Stem Cells*, Ling-Ling Hou, PhD, Associate Professor, College of Life Sciences and Bioengineering, School of Sciences, Beijing Jiaotong University, No.3 Shang Yuan Cun, Hai Dian District, Beijing 100044, China

AIM AND SCOPE

World Journal of Stem Cells (*World J Stem Cells*, *WJSC*, online ISSN 1948-0210, DOI: 10.4252), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJSC covers topics concerning all aspects of stem cells: embryonic, neural, hematopoietic, mesenchymal, tissue-specific, and cancer stem cells; the stem cell niche, stem cell genomics and proteomics, and stem cell techniques and their application in clinical trials.

We encourage authors to submit their manuscripts to *WJSC*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

INDEXING/ ABSTRACTING

World Journal of Stem Cells is now indexed in PubMed Central, PubMed, Digital Object Identifier, and Directory of Open Access Journals.

Abstract

Mesenchymal stem cells (MSCs) are progenitor cells capable of self-renewal that can differentiate in multiple tissues and, under specific and standardized

culture conditions, expand *in vitro* with little phenotypic alterations. In recent years, preclinical and clinical studies have focused on MSC analysis and understanding the potential use of these cells as a therapy in a wide range of pathologies, and many applications have been tested. Clinical trials using MSCs have been performed (*e.g.*, for cardiac events, stroke, multiple sclerosis, blood diseases, auto-immune disorders, ischemia, and articular cartilage and bone pathologies), and for many genetic diseases, these cells are considered an important resource. Considering of the biology of MSCs, these cells may also be useful tools for understanding the physiopathology of different diseases, and they can be used to develop specific biomarkers for a broad range of diseases. In this editorial, we discuss the literature related to the use of MSCs for diagnostic applications and we suggest new technologies to improve their employment.

Key words: Mesenchymal stem cells; Biomarkers; Next generation sequencing; Diagnostic tool; Tumor-initiating cells

Core tip: Mesenchymal stem cells have been considered potential tools for therapeutic applications in a wide range of pathologies. However, these cells may be used to develop specific biomarkers in a broad range of diseases and they could be considered useful tools to perform new strategies to get early diagnoses. Rare stem cell populations can be studied by recent technologies such as Next Generation Sequencing in order to develop specific marker for diagnostic and prognostic applications.

Valenti MT, Mori A, Malerba G, Dalle Carbonare L. Mesenchymal stem cells: A new diagnostic tool? *World J Stem Cells* 2015; 7(5): 789-792 Available from: URL: <http://www.wjgnet.com/1948-0210/full/v7/i5/789.htm> DOI: <http://dx.doi.org/10.4252/wjsc.v7.i5.789>

INTRODUCTION

Mesenchymal stem cells (MSCs) reside in many tissues during development, and their differentiation produces specific phenotypes such as osteoblasts, chondrocytes, adipocytes, and myoblasts. In recent years, MSCs have been considered an important source for cell therapy and tissue regeneration in many clinical applications. Tissue damage is followed by an inflammatory response, and pro-inflammatory factors can rescue MSCs and start the repair process. The process of regeneration is quite complex; MSCs interact with stromal and inflammatory cells, and derived factors play an important role in this process^[1]. MSCs are also involved in immunosuppression *via* inhibition of T cells, B cells, dendritic cells and natural killer cells^[2-5], and they may exert immunomodulatory activity during the co-transplantation process^[1].

In addition to cell therapy, MSCs are also a promising choice for other clinical applications because they can be used as diagnostic tools. The involvement of MSCs in many physiological or physiopathological aspects offers the possibility of targeting these cells, and their related molecular products, circulating in peripheral blood to obtain an early diagnosis by a non-invasive approach.

Diagnostic application of MSCs

In recent years, MSCs have been considered important "biomarkers" for a non-invasive prenatal diagnosis^[6]. Accurate prenatal diagnoses without fetal damage are needed to prevent genetic diseases, and MSCs have been identified in fetal blood during the first trimester, albeit at low concentrations. Despite 20 years of research in this area, technical challenges have produced many obstacles to reproducible fetal MSC isolation, and culture strategies have been developed. However, fetal MSCs have been observed in maternal peripheral blood, suggesting that fetal surface antigens could be considered promising biomarkers for a noninvasive prenatal diagnosis^[7], and the analysis of neural and MSCs in the amniotic fluid represents a useful tool for the identification of neural tube defects^[8].

Recruitment of progenitor cells in the blood stream in response to skeletal damage has been reported^[9], and we have shown that circulating MSCs are increased in patients affected by osteoporosis as a consequence of the impairment of osteoblast differentiation^[10]. Furthermore, the molecular analyses of genes involved in the differentiation process have revealed an abnormal level of expression of the transcription factor *runx2*, the master gene of osteogenic differentiation. These data suggest the possibility of using MSC analysis for the evaluation of bone diseases, and the identification of circulating MSCs could be proposed as a noninvasive diagnostic tool.

Circulating stem cells have been observed after

ischemic stroke in patients with myocardial infarction^[11,12], and this finding suggests that stem cells in the peripheral blood may provide a potential cell marker for prognosis and risk evaluation in patients with cardiac diseases.

Kim *et al.*^[13] showed that CD105 MSCs were mobilized in patients with cerebrovascular stroke, and, in particular, the authors demonstrated that the percentage of apoptotic CD105 cells, based on annexin V expression, was higher in patients with cerebral infarcts than that in normal control subjects.

The epithelial mesenchymal transition that occurs during cellular neoplastic transformation makes MSCs an important target for the diagnosis and prognosis of malignant tumors^[14]. Because cancer may originate from the neoplastic transformation of progenitors or related early differentiated cells, stem cell-like markers expressed in tumor cells could be of interest for biomarker identification.

New technologies for stem cells

Recent technologies have made possible the study of the molecular biology of cells at different levels (*i.e.*, the genome, epigenome, transcriptome, small RNAome and metabolome). However, the study of stem cells is still a major challenge due to their low numbers and their potency and plasticity. Currently, most stem cell studies reported in the literature apply microarray technology and focus on the gene expression profile analysis of MSCs^[7,15-19], cancer stem cells^[20-24], tumor-initiating cells^[25] and embryonic stem cells. The study of gene expression at the global level is generally a pitfall and an ordeal due to the presence of low expression levels of many genes, which occurs because stem cells need to be ready to undertake a variety of differentiation programs. Accordingly, the study of different individual gene expression profiles is very difficult. Such issues cause the true gene expression signal to be confounded by background noise. At present, more recent Next Generation Sequencing (NGS) technologies^[26] are entering the stem cell arena. NGS is based on massive sequencing, and it can be applied for several purposes, such as the detection of transcripts and estimation of their levels (transcriptome), the identification of genome sequence variants (exome, genome) or the examination of modified methylated nucleotides (methylome). It is noteworthy that epigenomic NGS applications^[27] can be used to study stem cells because they can be used to investigate gene regulation and genome function during the differentiation and reprogramming processes. Therefore, the Epigenomics Roadmap consortium has been formed by the NIH to create extensive maps of genomic and epigenomic elements in stem cells and *ex vivo* tissue^[28]. NGS methods can be used to sequence single cells (DNA and/or RNA) opening avenues to thoroughly investigate how differential gene expression in individual cells defines cellular differentiation, function and physiology^[22],

making it possible to study rare stem cell populations and to investigate the prevalence and differences of potential stem cell subpopulations in cancers or other types of tissue^[29].

CONCLUSION

Although several molecules such as Stro-1, CD271, SSEA-4 and CD146 are already recognized as markers for MCS cells^[30], it would be useful to have even more specific markers for stem cell potential before MSC cells can serve as reliable tools for standardized diagnostic methods. In conclusion, the analysis of MSCs and their related molecular products supported by new sequencing technologies may lead to the identification of potential biomarkers that could represent useful tools for noninvasive or less invasive diagnostic and prognostic applications for a wide range of diseases. In addition, the individualization of specific markers linked to MSCs could be used to develop new strategies to obtain early diagnoses and start therapeutic approaches for patients as soon as possible.

Certainly, further investigations are necessary to validate and improve the sensitivity of specific biomarkers linked to MSCs, and innovative and costly technologies are required considering the low number and plasticity of MSCs.

Abstract

Considering the complex nature of the adult heart, it is no wonder that innate regenerative processes, while maintaining adequate cardiac function, fall short in myocardial jeopardy. In spite of these enchaining

limitations, cardiac rejuvenation occurs as well as restricted regeneration. In this review, the background as well as potential mechanisms of endogenous myocardial regeneration are summarized. We present and analyze the available evidence in three subsequent steps. First, we examine the experimental research data that provide insights into the mechanisms and origins of the replicating cardiac myocytes, including cell populations referred to as cardiac progenitor cells (*i.e.*, c-kit⁺ cells). Second, we describe the role of clinical settings such as acute or chronic myocardial ischemia, as initiators of pathways of endogenous myocardial regeneration. Third, the hitherto conducted clinical studies that examined different approaches of initiating endogenous myocardial regeneration in failing human hearts are analyzed. In conclusion, we present the evidence in support of the notion that regaining cardiac function beyond cellular replacement of dysfunctional myocardium *via* initiation of innate regenerative pathways could create a new perspective and a paradigm change in heart failure therapeutics. Reinitiating cardiac morphogenesis by reintroducing developmental pathways in the adult failing heart might provide a feasible way of tissue regeneration. Based on our hypothesis "embryonic recall", we present first supporting evidence on regenerative impulses in the myocardium, as induced by developmental processes.

Core tip: Unlike in primitive vertebrates, any regenerative effort in adult mammalian hearts after an acute event remains unsatisfactory. Most efforts to repopulate failing hearts with functioning and integrated cardiomyocytes have not achieved clinical importance. In this overview, after describing several options for endogenous myo-

cardial repair, we support the notion of a paradigm change towards inducible developmental processes in regeneration research. Major efforts have been made to convert tissues upstream in the Waddington scheme. Recently, stress transformed acquired pluripotency raised enormous expectations, but results and proof of concept were seriously questioned. We want to introduce pressure-controlled intermittent coronary sinus occlusion as a potential resource to decipher the unsolved equation of re-inducing the developmental processes in the human heart.

INTRODUCTION

Advances in therapeutic approaches to acute life-threatening cardiovascular conditions, such as early revascularization in patients with acute myocardial infarction (AMI), have contributed to a dramatic decrease in short-term mortality. Hence prolonged life expectancy coupled with the residual impairment of heart function and the progressive nature of cardiovascular diseases^[1] have exponentially increased the number of patients with chronic insufficiency of heart function. While aggressive medical therapy of severe chronic heart failure (HF) may alleviate symptoms, the ultimate treatment option for this growing patient group remains heart transplantation. However, due to infrastructural and technical constraints, heart transplantation could barely meet the needs of the vast population of patients with HF^[2], who have deleterious prognosis comparable to malignant diseases with the mortality rate as high as about 25% within the first year of diagnosis^[3,4]. In the United States the estimated prevalence of HF is > 5 million patients, annual incidence is > 500000 patients and annual mortality with HF as underlying cause is > 50000^[5], which makes paramount the development of a therapy regimen effective beyond the acute phase and available to a broad population of patients.

The pathophysiological substrate of heart failure is the loss of functioning cardiomyocytes during the overall process of remodeling of the heart tissue, which in turn leads to diminishing of the contractile function^[6]. Between the two ends of contemporary clinical reality represented by acute therapies, such as early revascularization, which are available to many, but effective mainly in improving short- and mid-term clinical outcomes, and heart-transplantation as ultimate treatment strategy for a failing heart, but available to only few, there is an unmet need to reverse the process of remodeling and foster myocardial regeneration.

The notion of replenishing lost cardiomyocytes is founded on the triad of rejuvenation, replacement and regeneration^[7] with the common goal of structural and functional heart repair. While the term rejuvenation refers to activation of myocardial self-renewal processes, replacement and regeneration are based on transplantation into the damaged host myocardium, of functional tissues and progenitor cells, respectively^[8].

First studies that tested the effects of transplantation of progenitor cells in patients with AMI or chronic ischemic heart disease while proving safe, showed modest improvement in clinical outcomes^[9,10]. The translation of this luring concept of repopulating heart with transplanted stem cells into every-day clinical practice has been challenged by the following issues: type and dosing of progenitor cells, ex-vivo processing and expansion, timing and route of administration, as well as timing of transplantation respective the stage and level of myocardial ischemia^[11]. Immunological response of the host-microenvironment that impacts long-term prognosis and possible ethical implications of transplanting pluripotent cells of embryonic origin have additionally burdened the research in the field of stem-cell based approaches to heart repair.

Opposite to the transplantation-based regimens, interventions aiming at rejuvenation of damaged heart tissue by activating innate cardiac repair pathways seem to provide a more holistic approach, while avoiding possible pitfalls of cell injection into the microenvironment of an ischemic heart. The development of such therapeutic strategies is supported by the evidence of postnatal formation of new cardiomyocytes, thus indicating the potential for endogenous myocardial regeneration^[12,13]. Since the effects of stem-cell therapies have been attributed not only to engraftment of transplanted cells and generation of new cardiomyocytes, by means of transdifferentiation or cell fusion, but to a considerable degree to paracrine effects^[14], the transplantation of cells could seem redundant in wake of a possible intervention succeeding in activation of endogenous repair pathways.

Our aim was to review the literature on the mechanisms of endogenous myocardial regeneration and to analyze the contemporary therapeutic approaches to activation of these inborn pathways of myocardial repair. We proceed in three subsequent steps by examining (1) the evidence for the self-regenerative capacity of the heart; (2) the initiation of endogenous myocardial repair mechanisms in a clinical setting such as acute or chronic myocardial ischemia; and (3) the results of the hitherto conducted clinical studies that investigated different methods of triggering endogenous myocardial regeneration in failing human hearts.

SELF-REGENERATIVE CAPACITY OF THE HEART

The axiom of regenerative medicine has been that

apart from intestinal epithelium, skin and bone marrow, no other tissue contained stem-cells capable of self-renewal^[15], with the predominant belief that in postnatal life cardiomyocytes respond with hypertrophy when exposed to stress^[16]. According to this view, from the birth on cardiomyocytes could only grow in size without any significant reproduction capacity, which is how > 20 fold increase in heart mass from birth to adulthood has been explained^[15,17-19].

The described axiom that cardiac myocytes could only grow in size, has been challenged by an early work that lists myocyte hyperplasia as mode of adaption to microenvironmental stimuli within the heart^[20]. Several contemporary experiments have contributed evidence in favor of a more dynamic view of myocardial cellular homeostasis, attributing cardiac myocytes the potential to increase in number^[21-24]. Of note, pathologic stimuli like acute myocardial infarction^[21] and chronic ischemia^[23] that lead to destruction and functional deterioration of myocytes, seem to concurrently provide the groundwork for their replenishment. It has been shown that during the initial stages of pressure overload hypertrophy the DNA synthesis in cardiomyocytes takes place^[25]. Cardiomyocyte hypertrophy and hyperplasia appear to be in no way mutually exclusive and both part of heart's defense strategy, with myocyte proliferation commencing with severe functional deterioration of the heart^[26].

In order to assess the clinical relevance of the posited myocardial self-regeneration capacity two issues need to be clarified. First, what is the expected magnitude of cardiomyocyte proliferation? Second, what is the origin of the newly formed cardiomyocytes?

Quantification of cardiomyocyte replication

A landmark study, that investigated cardiomyocyte proliferation based on carbon-14 integration in the DNA, reported that fewer than 50% of cardiomyocytes are renewed during a normal life span^[12]. The annual myocyte turn-over rate decreased from 1% at the age of 25 to 0.45% at the age of 75^[12]. On contrary, another study found aging to be associated with increased rates of cardiomyocyte turnover^[27]. In chronically failing hearts the presence of the proliferating cell nuclear antigen, a marker of DNA synthesis and cell proliferation, was documented in 49% ± 22% of the left ventricular myocytes^[26]. Quantitative analysis from the same study described 11 cardiomyocytes nuclei with mitotic images out of a million^[26]. After myocardial infarction, two out of a million of cells were observed to have images of mitotic divisions, predominantly in the adjacent zones^[26]. Another study documented the mitotic index after acute myocardial infarction of 520 cardiomyocytes out of a million, thus accounting for approximately 2 million cardiac myocytes in the mitosis within the left ventricle wall early after AMI^[24,28]. Further calculation that assumed the existence of 5.2×10^9 cardiac myocytes

in the left ventricle and the mitosis duration of approximately 1 h, showed that the presumed mitotic index of 11 per million^[26] would produce 10% new left ventricular myocytes in a year and would double the number of cardiac myocytes in the left ventricle over a period of 10 years^[29]. Of note, different studies estimated annual rates of cardiomyocyte turnover to be 1%-10%^[12,15,30,31]. The reported variability in estimated rates of cardiomyocyte replication translates into uncertainty regarding the true magnitude of myocardial self-regeneration and fuels the skepticism regarding the clinical relevance of the observed findings. The observed variability may have originated from different morphometric methodologies and different experimental settings (normal vs diseased heart).

Criticism of the theory of cardiomyocyte replication:

Although increased DNA synthesis in cardiomyocytes has been postulated as part of their adaptation to myocardial injury, many researchers remained skeptical of cardiomyocyte replication^[32]. Chien *et al.*^[33] reinforced the old tenet that cardiomyocytes were terminally differentiated and that the response to myocardial damage is mainly hypertrophy. Thereby, the experimentally obtained images of myocytes with clearly replicating DNA were ascribed to the fact that around 20% of heart muscle cells are multinucleated but still do not divide^[24,28].

It is clear that in order to prove the potential for self-regeneration of the myocardium one must show the actual mitosis and quantify the increase in actual cardiomyocyte numbers and not only show DNA synthesis, the more so as the ploidy formation in the hypertrophied heart has already been documented^[34]. Due to the fact that heart harbors a proportion of multinucleated myocytes accounting for 1/4 of the human cardiac myocytes^[29], it is important to mention that aging, cardiac hypertrophy and ischemic cardiomyopathy do not alter the proportion of mononucleated and multinucleated cardiomyocytes^[35]. It may thus be assumed that if the proportion is not changed under stress conditions, then cardiomyocyte hyperplasia could not be excluded. In this respect it has been pointed out^[25] that two studies have documented mitotic images in an experimental model of myocardial injury^[36,37].

Despite presented evidence for cardiomyocyte hyperplasia^[37,38], due to the methodological constraints and the fact that myocardial ischemia is followed by a vast loss of cardiomyocytes, the actual cardiomyocyte turnover may hardly be reliably assessed. Nevertheless, the contention that cardiomyocyte proliferate appears to be further strengthened by the aging-related telomeric shortening^[39]. On the other side, experiments with dog hearts exposed to acute heart failure documented increase in telomerase action^[40], which was interpreted as sign of ongoing regeneration^[41].

Endogenous origin of replicating cardiomyocytes

Similar to the true magnitude of the rate of cardiomyocyte renewal, uncertainty exists regarding the origin of the replicating cardiomyocytes. Besides circulating extracardiac progenitor cells that are homed into myocardium only upon a strong pathologic signal and to a very limited extent, two possible endogenous mechanisms have been postulated: (1) mitotic replication of pre-existing cardiac myocytes; and (2) development of heart tissue cells from a pool of multipotent stem cells residing within the heart^[15].

The long-standing contention that postnatal cardiomyocytes were unable to re-enter cell-cycle and undergo mitosis has been challenged by a study that posited the division of pre-existing cardiomyocytes to be the cornerstone of the observed myocardial renewal^[30]. On contrary, it has been reported that in response to injury, myocardium regenerates on the basis of residing progenitor cells with no significant contribution by division of pre-existing cardiomyocytes^[42]. Another study concluded that both resident stem cells and division of pre-existing cardiac myocytes contribute to myocardial regeneration, albeit the progenitor cells were attributed the leading role^[31]. In wake of the opposing results, it has been argued that different experimental techniques may have caused the controversy, while the most likely source for myocardial repopulation remain resident cardiac stem cells^[15].

Cell types: Endogenous cardiac stem cells appear to be a highly heterogeneous population of cells, each being defined by expression of surface markers. The hitherto described types include c-kit⁺ cardiac stem cells, Isl 1⁺ cardiac progenitors, cardiospheres and cardiosphere-derived cells, cardiac mesoangioblasts, side-population cells and cardiac resident colony-forming unit-fibroblast cells^[15,43,44].

In the heart, c-kit⁺ are located in significantly higher numbers in atria, as compared to left and right ventricles^[45]. Initial experiments showed the ability of c-kit⁺ cardiac stem cells to differentiate into cardiomyocytes, smooth muscle and endothelial cells^[46]. A recent study confirmed the potential of c-kit⁺ lineage to give rise to new cardiomyocytes in response to aging or myocardial injury, albeit not to a significant extent that could have an impact on heart function^[47].

A subgroup of CSCs, Isl 1⁺ progenitor cells have been identified as key factors in cardiac development, particularly concerning atria, the right ventricle and outflow tract^[48]. Despite their ability to differentiate into all three cardiac lineages, the role of Isl 1⁺ cells in myocardial regeneration is limited due to rapid decrease in number with the increasing age, with high levels exclusively during fetal and neonatal life^[49,50].

Cardiospheres are generated from endomyocardial biopsies and represent a heterogeneous population of endogenous cardiac origin^[51]. Primary cardiospheres are enzymatically digested and cultivated on fibronectin-coated dishes, to eventually give rise to cardiosphere-

derived cells (CDCs), which in turn form secondary cardiospheres when treated with epidermal growth factor (EGF)^[43]. The main characteristic of the myocardial tissue-derived cardiospheres is high heterogeneity of cells that mimics cardiac microenvironment, which apart from multipotency of so derived CSCs accounts for paracrine effects leading to generation of new cardiomyocytes^[52]. CDCs were shown to have superior paracrine effects when compared to exogenous stem cell types, such as bone-marrow derived mononuclear or mesenchymal and adipose-tissue derived mesenchymal cells^[53].

Recently, it has been debated that seemingly different types of CSCs essentially belong to a single cell type, based on a study that failed to detect differences between CDCs and c-kit⁺ cells in respect to surface-antigens and gene expression pattern^[54].

In any case, the observed potential to initiate cardiac regeneration seems not to translate into a clinically relevant effect on myocardial repair, due to limited number of residing CSCs^[44].

MYOCARDIAL INJURY AS THE SIGNAL FOR SELF-REGENERATION

Clinical applicability of endogenous myocardial regeneration is founded on the observation that myocardial injury serves as a trigger for activation of CSCs. In this context, progenitor cells within myocardium represent the prime therapeutic target, with an aim of boosting the heart's potential for self-renewal.

Several studies showed that under stress conditions such as ischemia or volume overload, myocardial tissue responds with initiating the pathways of regeneration^[13,21,25,55-57]. The experiments with bromodeoxyuridine (BrdU) labeled rat cardiomyocytes unveiled the tendency of myocytes to remain mitotically inactive once the adult values of the volume and pressure loads on the ventricle were reached, thus 3 or 4 wk after birth^[58]. The pressure and volume burden seemed to be strongly related to the cell cycle of the cardiomyocytes. In relation to this finding, Insulin growth factor (IGF-1) was found to be down-regulated within the postnatal myocardium. Thereafter the hypothesis was introduced that the IGF-1 and IGF-1 receptor (IGF-1R) system plays a crucial role in proliferation but not hypertrophy of cardiomyocytes^[58]. The upregulation of mRNA for IGF-1 and IGF-1R in cardiac myocytes was shown to be the direct consequence of ischemia. Interestingly, it was also documented that after the myocardial infarction the remaining viable myocytes expressed mRNA for IGF-1R. The fact that IGF-1/IGF-1R system ceases to be as abundantly represented within the myocardium as the time progresses and myocytes grow in volume, and the fact that the system seems to be reactivated during myocardial stress inspired the hypothesis of postnatal cardiomyocyte proliferation signaled in part by IGF-1^[25]. Interestingly, an over-

expression of IGF-1 in infarcted mice hearts was shown to attenuate the ventricular dilatation, wall stress and myocardial hypertrophy^[59].

Self-regenerative capacity of myocardium suffering from acute ischemia

Acute myocardial ischemia appears to set a strong proliferative impulse with a around 90% increase in DNA replication 2 d after the infarction and over 300% after 7 d. This marked up-regulation of the DNA synthesis was mainly observed in the myocytes adjacent to the necrotic myocardium^[25]. The authors commented that due to the consequent elevation of myocardial mass (hypertrophy), reduced "loading condition" on the myocardium temporarily takes away the trigger for the myocyte proliferation until the global functional deterioration reaches certain critical point where the DNA replication commences^[25].

The analysis of patients who died shortly after AMI revealed proliferating myocytes that were identified by the presence of Ki-67, a nuclear antigen associated with cell division and detectable during the phases G1, G2 and S of the cell cycle^[21]. The rate of Ki-67 presence was 4% in the border zones and 1% in the remote zones of myocardial infarction^[21]. Subsequent analysis showed that post-infarction myocytes from the border zones that express Ki-67 antigen are 84 times higher in number compared to the healthy myocardium. At the same time, remote myocardial portions contained 28 times more myocytes expressing Ki-67 in their nuclei as compared to the myocytes of a normally perfused heart^[21]. However, the extent of myocardial proliferation remains disputable due to different methodological approaches^[12,24].

Self-regenerative capacity of myocardium suffering from chronic ischemia

An experimental model of ischemic cardiomyopathy, produced by narrowing but not occluding coronary arteries, yielded similar observations as the described experiments with acute ischemia. One week after the intervention, the BrdU-labeled myocyte nuclei expended 7.31-fold, thus indicated an augmentation in DNA synthesis. After 3 mo this increase in DNA synthesis fell back to virtually the same rate as before the intervention^[25].

Cardiomyocyte loss, cellular hypertrophy and ventricular scarring are immediate histological sequelae of chronic myocardial ischemia leading to functional impairment of the left ventricle. Fibrosis is formed where the most severe myocyte loss occurs. Even though end stage ischemic heart failure would imply around 90% decrease in left ventricular cardiomyocytes only 30%-decrease was documented^[56,60]. In order to supply more evidence for the capacity of cardiomyocytes to proliferate, a study^[56] analyzed tissue samples of hearts of patients with chronic myocardial ischemia. Cardiomyocyte analysis of the failing myocardium

revealed higher mitotic indices of roughly 140 myocyte nuclei per million as compared to cardiomyocytes from the healthy myocardium.

Both acute and chronic myocardial injury may provide stimulus for myocardial self-regeneration. However, the magnitude of cardiomyocyte proliferation does not seem to compensate for the structural and functional myocardial damage.

FROM BENCH TO THE BEDSIDE:

RESULTS FROM CLINICAL TRIALS

The inadequacy of myocardial self-regenerative response has led to the development of therapeutic techniques that are based on isolation, *ex vivo* expansion and finally transplantation of endogenous cardiac stem cells.

Hitherto, three clinical trials assessing the effects of transplantation of cardiac-derived stem cells have been conducted (Table 1): the CARDiosphere-Derived aUtologous stem CELls to reverse ventricUlar dysfunction (CADUCEUS) study^[61], cardiac Stem Cell In Patients with Ischemic cardiomyopathy (SCIPIO) trial^[62] and AutoLogous Human cArDiac-Derived Stem Cell To Treat Ischemic cArDiomyopathy (ALCADIA) trial^[63].

CADUCEUS was a two-center randomized trial that assessed the effect of intracoronary infusion of cardiosphere-derived cells on infarct size reduction in patients after myocardial infarction, with left ventricular ejection fraction (LVEF) 25-45%. The autologous cardiac stem cells, cultivated from endomyocardial biopsies, were injected 1.5-3 mo after acute MI in 17 patients (control group consisted of 8 patients). At six months, magnetic resonance imaging (MRI) showed significant reduction in scar mass and increase in viable heart mass and regional contractility^[61].

SCIPIO was an open label trial that randomized post-infarction patients with left ventricular dysfunction who were scheduled for coronary artery bypass grafting (CABG) to either intracoronary infusion of autologous c-kit⁺ cardiac stem cells or placebo. In total, 16 patients received infusion of stem cells while 7 patients were controls. In 14 patients who had undergone follow-up four months after cell infusion there was a significant increase of LVEF (absolute difference vs baseline was about 8%), compared to no change in the control group. At one year the increase in LVEF was sustained (absolute difference vs baseline about 12%)^[62].

ALCADIA is an open label, non-randomized safety/feasibility study that evaluates intramyocardial injection of autologous cardiac-derived progenitor cells in combination with administration of basic fibroblast growth factor (bFGF), in patients with ischemic cardiomyopathy and heart failure. Cardiac progenitor cells were derived from endomyocardial biopsies and expanded for a month, prior to intramyocardial injection

Table 1 Clinical studies with endogenous cardiac stem cells

Study	Design	Population	Intervention	No. of patients receiving treatment	Primary endpoint	Conclusion
CADUCEUS	RCT	Post-MI with LVEF 25%-45%	Intracoronary infusion of CDCs	17	Occurrence of death, new MI, new cardiac tumour on MRI and/or admission for HF	Safety proven; MRI-scar reduction and increase in viable myocardium
SCIPIO	RCT	Post-MI with LVEF ≤ 40%	Intracoronary infusion of autologous c-kit+ CSCs	16	Short-term safety	Safety proven; LVEF improvement, infarct size reduction
ALCADIA	Non-randomized	Ischemic CMP with LVEF 15%-35%	Intramyocardial injection of autologous CSCs with bFGF	6	-	No adverse events; improvement of NYHA class and LVEF

RCT: Randomized controlled trial; CDCs: Cardiosphere-derived stem cells; MRI: Magnetic resonance imaging; HF: Heart failure; CSCs: Cardiac stem cells; bFGF: Basic fibroblast growth factor; CADUCEUS: CARDiosphere-Derived aUTologous stem CELls to reverse ventricUlar dysfunction; SCIPIO: Stem Cell In Patients with Ischemic cardiomyopathy; ALCADIA: AutoLogous Human CARDiac-Derived Stem Cell To Treat Ischemic cARDiomyopathy.

during CABG^[64]. So far 6 patients have been enrolled, one patient was excluded due to graft occlusion and one developed worsening heart failure symptoms.

Allogeneic Heart Stem Cells to Achieve Myocardial Regeneration (ALLSTAR) study is ongoing (ClinicalTrials.gov Identifier NCT01458405) and will randomize 274 patients to intracoronary infusion of either allogeneic cardiosphere-derived cells or placebo, 4-12 wk after anterior MI and successful primary percutaneous intervention for LAD coronary artery, if LVEF ≤ 45%.

The combined enrollment for all three trials has been 39 patients, with no major safety concerns. Common denominator of the three trials was the use of autologous cardiac stem cells that have been cultivated from endomyocardial biopsies. In SCIPIO trial, the so cultivated cells were then filtered to obtain the c-kit⁺ lineage. The number of cardiosphere-derived cells, used in CADUCEUS study, was limited due to their size (about 20 microns, as compared to the size of coronary capillaries of about 7 microns)^[64]. ALCADIA trial evaluated an interesting concept that combined cardiac stem cell transplantation with administration of a growth factor, with the purpose of enhancing the retention of the transplanted cells^[64]. Principal limitations of the hitherto conducted trials are the small number of included patients and the non-standardized cell therapy that varied both in respect to the cell type (cardiosphere-derived cells vs isolated c-kit⁺ cells) and the route of delivery (intracoronary vs intramyocardial). In addition, one study (ALCADIA) used bFGF to boost the retention of the transplanted cells.

The transplantation of cardiac-derived stem cells appears to at least in theory upgrade the hitherto developed cell therapies for treatment of myocardial injury (*i.e.*, bone-marrow derived cells), inasmuch as CSCs resemble the host myocardial microenvironment. However, the endogenous pathways of regeneration still remain largely enigmatic. As has been presented in the above sections of this review, there is still controversial evidence regarding the origin of the

newly formed cardiac myocytes (myocardium-specific progenitor cells vs self-replicating cardiomyocytes). The ambivalence in respect to the key factors behind the process of endogenous myocardial regeneration hampers clinical research, inasmuch as it makes the standardization of the therapeutic approach virtually impossible - the variety of scientific theories that are aiming at deciphering the endogenous signals is mirrored by the variety of clinical interventions and techniques (different cell types, routes of delivery, target populations, *etc.*, Table 1). In addition, there are significant constraints that are intrinsic to any process of cell transplantation, irrespective of how well the transplanted cells may fit to the host microenvironment and that could limit the effects of endogenous regeneration.

ACTIVATION OF MYOCARDIAL SELF-REGENERATION WITHOUT CELL TRANSPLANTATION

The process of cell transplantation presupposes stem cell isolation from the tissue of origin (*i.e.*, myocardium or bone marrow), *ex vivo* expansion and ultimately cell delivery into the host myocardium^[65] (Figure 1). Hence, the use of autologous stem cell renders acute treatment impossible, even though the issue of timing may be the crucial component of a successful myocardial regeneration. It has been shown that mice heart could regenerate if partial surgical resection is performed on day 1 after birth, while the ability of regeneration is lost by day 7^[66]. Genetic fate mapping showed that mainly the replication of preexisting cardiomyocytes was responsible for the myocyte replenishment^[66].

In situ activation of endogenous myocardial repair without cell transplantation (Figure 1) would help to avoid the inherent problematic issues associated with the transplantation of stem cells, such as long time periods and high cost of the preparation of cells, non-standard route of delivery (*i.e.*, intramyocardial

Figure 1 Transplantation of stem cells vs initiation of endogenous myocardial regeneration without cell transplantation. Depicted are two basic approaches to myocardial regeneration: (1) via transplantation of different types of stem cells into the damaged myocardium (on the left, in blue); and (2) by activation of endogenous pathways of cardiac repair, without cell transplantation (on the right, in red). Both sets of techniques are thought to ultimately exert their effects on the paracrine route and by replenishing lost cardiomyocytes. SCs: Stem cells; BMSCs: Bone marrow-derived stem cells; CPCs: Cardiac progenitor cells; VEGF: Vascular endothelial growth factor; FGF: Fibroblast growth factor; G-CSF: Granulocyte colony stimulating factor; EPO: Erythropoietin; GMT: Gata4, Mef2c, Tbx5; miRNAs: microRNAs; PICSO: Pressure-controlled intermittent coronary sinus occlusion.

injections) and insufficient regenerative response due to problematic retention of the transplanted cells. Thus, four criteria for successful regenerative therapy have been proposed: (1) available at all times; (2) safe and routine application, compatible with gold standard therapies, such as primary PCI; (3) affordable; and (4) effective in salvaging myocardium (at least 50-60 g of tissue) and thus preventing heart failure^[15].

The existence of endogenous reservoir of stem cells within myocardium warrants the development of therapeutic strategies directed at activating dormant salvage pathways and thus avoiding the costly and laborious process of cell transplantation.

Growth factor injection

The idea behind treating the diseased myocardium with growth factor injection rests on the observations that transplanted CSCs impact the host tissue microenvironment twofold, by differentiating into cardiac lineages and by exerting paracrine effects^[44,67]. Growth factors such as vascular endothelial growth factor (VEGF), fibroblast growth factors (FGF), granulocyte colony-stimulating factor (G-CSF), granulocyte-macrophage colony-stimulating factor (GM-CSF), erythropoietin (EPO), insulin-like growth factor-1 (IGF-1), hepatocyte growth factor (HGF), placental growth factor (PIGF),

stem cell factor (SCF) and angiopoietin (Ang) have been postulated as activators of endogenous stem cells within the myocardium and so as initiators of its self-regeneration^[68].

Intracoronary administration of the combination of IGF-1 and HGF in the infarct-related coronary artery has been associated with reduced ventricular remodeling and improved myocardial regeneration^[69]. However, the fact that IGF-1/HGF stimulated cardiomyocyte generation is a slow process may hamper the overall improving of the heart's function and the clinical implementation of this strategy^[15].

Initial trials on the effects of FGF in patients with coronary artery disease (CAD), via intracoronary delivery of adenoviruses, showed potential of this method to improve regional blood flow^[70]. However, further clinical studies failed to produce reliable favorable clinical outcomes in CAD patients, albeit the effect of FGF seemed to have been gender-specific with improvement in outcomes in women^[71].

Experimental studies have demonstrated the potential of G-CSF to improve LV function after MI, mainly by fostering arteriogenesis^[72]. Initial clinical application of G-CSF in MI patients indicated the potential to improve echocardiographic LV functional parameters^[73], but subsequent randomized trials

did not show improvement in clinical outcomes^[68,74]. Similarly, in patients with chronic occlusive CAD, subcutaneous injection of G-CSF improved neither myocardial perfusion nor LV function, albeit it appeared to reduce anginal symptoms^[75].

GM-CSF has been associated with mobilization of endothelial progenitor cells (EPCs) and ultimately neoangiogenesis^[68]. A clinical trial showed enhanced collateral flow following the subcutaneous injection of GM-CSF in CAD patients^[76]. However, the study raised a safety concern due to occurrence of acute coronary syndrome in patients on treatment with GM-CSF^[76].

The use of VEGF as a potential mediator of neovascularization has been extensively studied both experimentally and in clinical trials. Animal models of myocardial ischemia indicated the potential of VEGF to induce angiogenesis^[68]. Subsequent trials showed tendency toward improvement of functional parameters such as regional myocardial perfusion or wall motion, but with no significant effect on clinical outcomes^[77,78].

EPO is secreted in tissues under hypoxia and is posited to foster angiogenesis and progenitor cell development, while inhibiting apoptosis^[68]. Whereas animal studies indicated that EPO administration was associated with the decrease in infarct size^[79], a clinical trial in patients with acute MI did not show improvement of heart's function^[80].

Further growth factors such as PIGF, Ang and the ligand of c-kit, SCF, which have been proposed to induce neovascularization and mobilization of progenitor cells, showed their potential to regenerate damaged myocardium in animal models, but solid clinical evidence is still lacking^[68].

A common characteristic of the described growth factors and cytokines is that their potential to induce myocardial regeneration, mainly *via* paracrine effects, has been established in experimental models, but with no direct translation in the improvement of clinical outcomes.

Cell reprogramming

The idea of cell reprogramming to achieve structural and functional renewal of the damaged myocardium has been substantiated through the concept of induced pluripotency, whereby fibroblasts could be reprogrammed to assume pluripotency and further directed into the state of cardiac lineage cells^[81-83]. However, this process implies transplantation of such induced cells into the damaged myocardium (Figure 1). On the other hand, direct reprogramming of the scarred myocardium involves conversion of fibroblasts into functioning cardiomyocytes by delivery of the following transcription factors into the cells of heart tissue: Gata4, Mef2c, Tbx5 (GMT)^[83,84]. Despite its luring perspective, cardiomyocyte replenishment *via* GMT reprogramming has been hampered by a purported lack of efficiency, relating primarily to

the degree of molecular and electrophysiological development of the newly formed cardiomyocytes^[83,85].

Cell reprogramming has been enhanced by the delivery of microRNAs only^[86] or in combination with transcription factors^[87]. Furthermore, the delivery of sets of microRNAs that have been associated with cardiac developmental pathways may present another option of initiating myocardial regeneration without the need for cell transplantation^[88].

Pressure-controlled intermittent coronary sinus occlusion

Pressure-controlled intermittent coronary sinus occlusion (PICSO) is a technique that is based on repeated cycles of coronary sinus occlusion. PICSO alters the expressional pattern of endo- and perivascular cells by exerting shear stress and cyclic strain on endothelial cells. It has been shown that PICSO up-regulates the expression of VEGF and heme oxygenase-1 (HO-1)^[89]. In an animal model of myocardial infarction PICSO was shown to upregulate VEGF and VEGF-receptor 2 in the capillary endothelial cells of the remote zones of myocardial infarction^[90]. ICSO procedure, which differs from PICSO by not being controlled by coronary sinus pressure, was able to significantly reduce infarct size in experimental trials^[91]. In a clinical trial, PICSO significantly reduced occurrence in MACE in patients with acute MI treated with thrombolysis^[92].

It has been postulated that PICSO has the potential to elicit myocardial regeneration by activating innate regenerative pathways^[93,94]. Intermittent pressure elevation in the venous system of the heart results in shear stress and pulsatile stretch of the vessel wall, which in turn translates into gene expression on the way of mechanotransduction, thereby mimicking the pulsatile signal on the developing heart tube (Figure 2)^[95-98].

Intermittent pressure elevation in the coronary venous system may thus serve as a signal for the activation of endogenous cardiac stem cells *via* paracrine routes and induce dormant pathways of myocardial salvage *via* mechanotransduction, which mimics the structural and functional interplay of the developing heart.

The ease of the application of PICSO without biohazards and instant availability may help to collect clinical data in heart failure patients, thus giving an example that STAP (stress transformed acquired pluripotency) in spite of the unsolved questions in hitherto collected results, might not be an illusion.

CONCLUSION

Recent findings have overturned the classical contention that postnatal myocardium is terminally differentiated by providing evidence for the formation of new cardiomyocytes. The postulated origin of new cardiomyocytes is the population of resident cardiac stem cells that have the ability to differentiate into the

Figure 2 Hypothesis of embryonic recall. In embryos, the first heart beat is sensed by mechanotransduction of the endocardium, leading to a burst of developmental signals thriving cardiac morphogenesis. In analogy, elevated pressures in cardiac veins act *via* stretch and shear stress on perivascular cells, thus reiterating the same mechanotransductory signals in the adult failing heart. Pressure elevation in cardiac veins have to be pressure controlled not to increase arterial resistance to nutritive flow (PISCO).

three cardiac lineages. Myocardial injury provokes the initiation of the innate pathways of regeneration, but the extent remains insufficient to provide significant improvement of heart function. Isolation of cardiac-derived stem cells *via* endomyocardial biopsy and *ex vivo* expansion of stem cells are necessary steps in the process of cell transplantation. However, the transplantation of cardiac stem cells to repair the damaged myocardium is costly and time-consuming and of diminished efficacy due to problematic long-term retention of the transplanted cells. Hence, new therapeutic approaches such as growth factor injection and PISCO are under scrutiny with the proposed goal of activating endogenous progenitor cells and thus initiating myocardial regeneration.

Why does cardiac endogenous regeneration in mammals fail in contrast to reptiles and numerous regenerative signals? One very important aspect is the timing of these signals. Unlike morphogenesis of the developing heart, which is a controlled stepwise approach, regenerative pulses in necro-apoptosis are random in time and region. So one aspect would be to synchronize and amend the signals in order, presuming that we understand the full picture of the molecular signals involved. Therefore reviving a developmental process *via* an epigenetic stimulus like activation of vascular cells by mechanotransduction might initiate the plethora of morphogenetic pulses necessary to enforce and synchronize endogenous repair.

Morphogenesis of the heart seems to be a controlled

stepwise approach in tissue generation, alternating gene transcription and established physical functions which again initiate molecular growth signals. These "epigenetic" signals which could be explained as "morphometric windows" can be used as initiation of endogenous repair.

Abstract

Major advances are currently being made in regenerative medicine for cornea. Stem cell-based therapies represent a novel strategy that may substitute conventional corneal transplantation, albeit there are

many challenges ahead given the singularities of each cellular layer of the cornea. This review recapitulates the current data on corneal epithelial stem cells, corneal stromal stem cells and corneal endothelial cell progenitors. Corneal limbal autografts containing epithelial stem cells have been transplanted in humans for more than 20 years with great successful rates, and researchers now focus on *ex vivo* cultures and other cell lineages to transplant to the ocular surface. A small population of cells in the corneal endothelium was recently reported to have self-renewal capacity, although they do not proliferate *in vivo*. Two main obstacles have hindered endothelial cell transplantation to date: culture protocols and cell delivery methods to the posterior cornea *in vivo*. Human corneal stromal stem cells have been identified shortly after the recognition of precursors of endothelial cells. Stromal stem cells may have the potential to provide a direct cell-based therapeutic approach when injected to corneal scars. Furthermore, they exhibit the ability to deposit organized connective tissue *in vitro* and may be useful in corneal stroma engineering in the future. Recent advances and future perspectives in the field are discussed.

Key words: Cornea; Stem cells; Cell-based therapy; Limbal transplantation; Tissue engineering; Corneal endothelium

INTRODUCTION

The human cornea consists of 5 recognized layers, 3 of them are cellular (epithelium, stroma and endothelium) and 2 are interface layers (Bowman's layer and Descemet membrane)^[1]. Corneal epithelium is a stratified, non-keratinizing squamous layer characterized by extreme uniformity from limbus to limbus^[2]. Epithelial cells are regularly shed from the surface and replaced by new cells that are ultimately provided by stem cells located at the limbal area of the peripheral cornea^[2]. Corneal stroma provides the bulk of the structural framework of the cornea and comprises approximately 80% to 90% of its thickness. Keratocytes are the major cell type of the stroma and are involved in maintaining its extracellular matrix^[1]. An intricate collagen network in the extracellular matrix accounts for the cornea's shape, stability, mechanical strength and transparency^[3]. Posteriorly, a thin monolayer of polygonal cells constitutes the corneal endothelium. Since it is in contact with the aqueous humor, the endothelium regulates corneal hydration through active cell pumps, thereby being crucial to maintain corneal transparency^[4]. Except for oxygen, all corneal nutrients come from the aqueous humor through endothelial cells^[5].

Regenerative medicine for the cornea represents a novel treatment strategy for patients with corneal diseases. Enormous promise has been ascribed to this modality because it offers a paradigm shift from conventional corneal transplantation to stem cell-based therapeutic strategies^[6]. Cellular therapies are challenging given the singularities of each cellular layer of the cornea. To date, the most widespread clinical approach to regenerative medicine in the eye has been the utilization of limbal stem cells for ocular surface diseases. In 1989, Kenyon and Tseng^[7] reported successful autologous transplantation of limbal tissue from the healthy fellow eye in 26 cases of unilateral limbal stem cell deficiency. Many reports and studies of limbal stem cell transplantation have followed, from heterologous donors to *ex vivo* cellular cultures.

In the present article, we discuss the current status in corneal stem cell research and the perspectives regarding corneal regenerative therapies and tissue engineering.

CORNEAL EPITHELIUM

Corneal epithelial stem cells are located at the corneoscleral limbus and are the ultimate source for regeneration of the entire corneal epithelium under normal and injured states^[2,8,9]. Multiple diseases that destroy the limbal epithelial stem cell, its environment, or a combination of both can lead to a clinical condition known as limbal stem cell deficiency (LSCD)^[10]. The clinical picture of LSCD is a conjunctivalized corneal surface with neovessels and recurrent or persistent epithelial defects^[11]. As a result, patients with LSCD have decreased vision, photophobia, tearing, and recurrent pain episodes^[2,11,12].

The classic limbal stem cell transplantation procedure involves grafting of a healthy limbal biopsy onto the recipient corneal surface. The technique was developed in the late 1980s and early 1990s and proved useful in LSCD^[13]. Limbal grafts are obtained either from an unaffected fellow eye^[7,14], from a live relative^[14,15] or from cadaveric donors^[14,16,17]. For patients inflicted with unilateral total LSCD, where the entire limbal circumference is damaged in only one eye, transplantation of limbal stem cells from the fellow eye has shown success rates greater than 80%^[18,19]. Due to the autologous source of cells, there is no risk of immune rejection in these cases. Concerns regarding irreversible changes that may occur at the limbal site of the donor eye, as reported in rabbits^[20,21], prompted clinicians to consider cadaveric donors. However, in this procedure, there is an increased risk of allograft rejection and therefore systemic immunosuppression is mandatory^[14,16,17]. Although larger grafts can be procured from cadaveric eyes (360 ring grafts), a recent study^[22] found living-related limbal allografts to have better results in terms of vision gain and ocular surface restoration than cadaveric keratolimbal allografts. In a series of 39 eyes that received keratolimbal allografts from cadaveric donors, the overall survival of ambulatory vision, namely 20/200 or better, was 53.6% at 3 years, but a progressive decline of the visual outcome and graft survival became evident with time^[23]. The failure of the graft is related to loss of donor cells overtime, probably due to recipient's preoperative conditions such as dry eye and/or lid abnormalities, persistent inflammation or postoperative asymptomatic and progressive allograft rejection^[23].

Regardless of the source of epithelial stem cells, amniotic membrane transplantation (AMT) has been widely used in an attempt to improve limbal grafts success^[24-26]. Nevertheless, a recent study interestingly showed no differences in the outcomes of chemically injured eyes treated with or without AMT as an adjunctive procedure to limbal transplantation^[27]. Amniotic membrane is a biologic, avascular tissue with anti-angiogenic, anti-scarring and anti-inflammatory characteristics^[28,29]. Since the process of

conjunctivalization in LSCD is invariably associated with destruction of the basement membrane^[10], amniotic membrane transplanted onto the corneal surface facilitates epithelial expansion *in vivo*. Amniotic membrane has a thick basement membrane that serves as a substrate upon which epithelial cells can migrate and regenerate to form new and healthy tissue^[28]. In cases of partial LSCD, AMT has been successfully used alone, without stem cell transplantation^[30]. Amniotic membrane can also be used as a biologic bandage in the acute phase of inflammatory disorders, such as ocular burns^[31,32] and Stevens-Johnson syndrome^[33-36], in order to prevent development of LSCD and other surface complications. Nevertheless, most of the studies are non-comparative, and a clinical trial that addressed the potential benefits of AMT did not find definite advantage of early AMT over conservative medical treatment in preventing scarring sequelae in eyes with chemical burns^[37].

With the development of cell therapy, amniotic membrane began to be employed in *ex vivo* expansion of limbal stem cells or their progeny^[38]. Pellegrini and colleagues published the first clinical report in the field of tissue engineering for the cornea in 1997^[39]. They reported an autologous cultivated epithelial cell transplantation that successfully restored the ocular surface in 2 cases of LSCD due to chemical burns. Other series of cultivated epithelial limbal transplantation (CLET) have followed^[38,40-46] and efforts to culture corneal cells *in vitro* are currently being made in different centers worldwide. Protocols use either an explant or cell suspension for culturing progenitor cells. The benefits of using explants are that they are easy to prepare and there is no danger of damaging the donor's corneal epithelium through enzyme exposure^[40]. However, limbal stem cells may poorly migrate from the limbal explants onto the carrier^[40,47]. Some protocols include co-cultivation with murine 3T3 feeder layers^[48], which are believed to promote niche regulation of limbal stem cells and thus delay epithelial differentiation^[49]. The use of animal-derived products carries a theoretical risk of infection, rejection or acquisition of prion diseases^[50]. By using autologous human serum instead of fetal bovine serum^[51] and eliminating feeder cells, complete xeno-free cultivation for CLET is possible^[52].

A novel possibility for delivering limbal stem cells on the corneal surface is to use contact lens as a carrier and as a substrate for cell expansion. Two studies with animal models of LSCD reported promising results with contact lens delivery, as stem cells retained their phenotype and mitotic activity after being transferred to the ocular surface^[53,54]. Furthermore, the seeded contact lenses were easy to manipulate and its material is nonimmunogenic^[54].

We perform transplantation of other cell lineages onto the ocular surface for LSCD when total LSCD occurs bilaterally and therefore no autologous tissue for CLET is available. Conjunctival epithelial cells are

the most akin biologically to corneal epithelial ones in the human body and our group has successfully cultivated and transplanted them for ocular surface reconstruction^[55]. Use of non-ocular surface epithelial cells was first made with cultivated oral mucosal epithelial transplantation in rabbits^[56] and application of this technique in humans has followed thereafter^[57-65]. Both conjunctival and oral mucosal epithelial cells are not expected to differentiate into corneal epithelial cells, like stem cells would. However, most studies show adequate functionality of the grafts, giving them clinical relevance in tissue engineering.

A promising source of stem cells for ocular therapy is the human deciduous teeth. These undifferentiated cells exhibit all characteristics of pluripotent adult stem cells and continuously express markers of limbal stem cells^[66]. Tissue-engineered sheets of dental-pulp stem cells were effective for cornea reconstruction in a rabbit model of chemical burn^[67]. Other recently proposed sources of stem cells for cornea epithelium are hair follicle^[68], bone marrow^[69,70] and umbilical cord^[71]. It has been demonstrated that adult tissue-specific stem cells have the ability to differentiate into lineages other than the tissue of origin^[72].

CORNEAL STROMA

One of the most challenging steps in engineering human corneal tissue is to produce the corneal stroma, given the difficulty in reproducing its highly ordered hierarchical ultrastructure, which relates to its exceptional biomechanical properties and optical transparency^[73]. Keratocytes are native resident cells of the corneal stroma and are responsible for maintaining the extracellular matrix (ECM)^[1]. The bulk of the stroma comprises approximately 200 orthogonally oriented lamellae, and each of them is made up of long uniform collagen fibrils lying parallel one to another with regular inter-fibril spacing^[74,75]. Under *in vitro* expansion in serum containing media, keratocytes lose their phenotype and soon become fibroblastic. Unlike keratocytes, fibroblasts secrete a disorganized ECM typically found in opaque corneal scars^[76-78]. Even in serum-free conditions, primary keratocytes maintain an *in vivo* phenotype through some population doublings, but lose their morphology, gene expression, and the ability to organize a cornea-like ECM after greater expansion^[79]. A more recent study, however, demonstrated that corneal fibroblasts respond to a specific pattern of topographical cues from the substratum and regain differentiation potential, thus being able to secrete highly organized ECM typical of corneal stroma^[79].

Recently, Du and coworkers identified the first human cells with keratocyte progenitor potential in the corneal stroma^[80]. This small population of cells exhibited properties of stem cells, such as clonal growth *in vitro*, extended lifespan, and the ability to differentiate into several different cells types, including

keratocytes of the cornea. When cultured as floating pellets in the absence of rigid scaffolding or substratum, in a serum-free medium, the human corneal stromal stem cells (hCSCs) differentiate into cells expressing a gene profile similar to that of human keratocytes and deposit tissue-like ECM with a composition and structure similar to that of the corneal stroma^[81]. A comparative study showed that, under the same culture conditions, human corneal fibroblasts tended to differentiate into myofibroblasts and deposited a less-organized collagen-fibrillar construct, while hCSCs successfully differentiated into keratocytes and secreted multilayered lamellae with orthogonally-oriented collagen fibrils, in a pattern mimicking human corneal stromal tissue^[73]. This *in vitro* secretion of stromal-like connective tissue points to a potential use of hCSCs in tissue bioengineering. An interesting finding is that hCSC may exhibit immune privilege: injected into mice corneas with scars, these cells did not elicit immune T-cell response^[82], as it would be expected in a xenotransplantation model. As a matter of fact, a successful restoration of corneal organization and transparency was achieved after the injection^[82]. Therefore, besides the utility in bioengineering stromal tissue, hCSC may have the potential to provide a direct cell-based therapeutic approach^[83].

Other engineering strategies for the corneal stroma include animal sources as a substitute of native tissue. Once rejection is a major obstacle to widespread use of xenotransplantation, fully acellular corneas have been proposed to overcome immune rejection. A decellularized animal tissue provides a three-dimensional ECM structure, favorable biocompatibility, adequate biomechanical tension and high transparency that mimics the native cornea and can be applied with or without the addition of a cellular component^[13]. Most studies use porcine corneas^[84-87], but other sources such as cow^[88] and cat^[89] are amenable for xenotransplantation. Since decellularized corneal stroma retains basement membrane components, it was used as a matrix scaffold for limbal stem cell expansion *in vitro*, and as a carrier for epithelial transplantation in animal models, with good results^[90,91]. Decellularization may be applied not only to xenogeneic, but also to allogeneic cornea tissues for transplantation. Theoretically, this would reduce the complications associated with allogeneic corneal transplants and improve the clinical outcomes.

CORNEAL ENDOTHELIUM

Corneal endothelium is a monolayer of cells that maintains a nonproliferative state, with cell density decreasing steadily under normal circumstances throughout life^[92,93]. It has been for long believed that they do not replace themselves once they are lost in aging or diseases. On the contrary of corneal epithelial cells, which readily and continuously divide from limbal stem cells, corneal endothelial cells fail to expand *in*

vivo, and expand slowly *in vitro*^[94,95]. Accumulating evidence, however, points to the existence of a dormant progenitor cell population located in the posterior limbus, the transitional area from the periphery of the endothelium and Schwalbe's line to the anterior portion of the trabecular meshwork. These putative progenitor cells are likely to be capable of producing both endothelial and trabecular cells^[96]. Identification of a circumferential and discontinuous cord of cells with unusual ultrastructural features along the Schwalbe's line in monkeys dates from 1982^[97]. Attention to these cells was drawn later, when repopulation of trabecular cells after argon laser trabeculoplasty was reported^[98,99]. Possibly, these cells are invigorated and proliferate after laser trabeculoplasty through the release of growth factors and cytokines^[96].

There is substantial evidence that the human corneal endothelium cells hold different characteristics according to their position in the cornea. Stained corneas revealed that cell density at the peripheral inner cornea, up to 1.6 mm from Schwalbe line, is about 30% higher than in the central cornea^[100]. Additionally, specular microscopy documented the uneven cell distribution from center to periphery *in vivo*^[101]. The reason for this difference is not known, albeit it has been suggested that the peripheral cornea may provide a physiologic reserve and storage region of endothelial cells for continuous, lifetime cellular supply for the central cornea^[101]. Bednarz *et al.*^[102] showed that cells isolated from the central part are densely packed and exhibit no mitogenic activity, while cells derived from the peripheral part of the cornea are characterized by mitogenic activity but their cell-to-cell attachment seems to be less tight than *in vivo*. Konomi *et al.*^[103] studied human donor corneas with different donor ages and found that cells from both the central and peripheral areas retain potential proliferative capacity, although the doubling time tended to be higher for cells from the central cornea and from older donors.

Data from molecular marker studies provide support for the existence of a stem-like cell niche at the corneal endothelium. Dissected endothelial tissues from human and rabbits exhibited positive telomerase activity in the peripheral and intermediate sections, but no activity was observed in the central endothelial tissues or the limbus between the trabecular meshwork and Schwalbe's line^[104]. Telomerase activity is a characteristic marker for transient amplifying cells. The same study also tested endothelial cells for alkaline phosphatase-catalyzed bromodeoxyuridine (BrdU) labeling, which demonstrates cell division. In the case of rabbit corneal endothelium, which is known to divide with regularity, BrdU staining was always seen following a mechanical wound, but in the human corneal endothelium, staining only occurred at the wound site in 10% of the corneas tested^[104]. Such results corroborate a typical lack of propensity toward cell division in wounding response in the human

endothelium. Another cellular marker for proliferation is Ki67, which is detected in the nucleus of proliferating cells. Ki67 antibody staining produces characteristic patterns depending on cell position within the cycle, so it makes possible to quantify cell cycle entry and completion *in vitro*^[105]. Stem cell markers that were also identified in the posterior limbus cells are nestin and alkaline phosphatase^[106]. Human corneal endothelial cell precursors have been isolated using the sphere-forming assay and expressed markers of the mesenchymal (α -smooth muscle actin) and neural (β 3-tubulin, glial fibrillary acidic protein) lineages, although none of these are specific markers of endothelial cells or their progenitors^[107]. More recently, two monoclonal antibodies taken together, anti-GPC4 and anti-CD200, were found to stain HCECs with specificity^[108]. The finding is useful for purification of cultures that may be contaminated by stromal fibroblasts. Since the endothelial cells are not expected to proliferate *in vivo*, isolation and stimulation of cell division *in vitro* is an important step towards cell replacement therapy^[109].

Human corneal endothelial cells proliferate and replicate under special conditions. In medium containing fetal bovine serum and fibroblast growth factor, cells from older donors proliferated but responded more slowly and to a lesser extent than cells from younger donors. When epidermal growth factor added to the medium, cells from older donors were stimulated to enter the cell cycle faster and the amount of actively cycling cells and mitotic figures increased^[105]. An important factor to activate endothelial cell cycle is the disruption of cell-cell contact. Zhu and colleagues demonstrated that maturation of intercellular adherent junctions correlates with a rapid decline of the proliferative potential in endothelial cell monolayers during cultivation^[110]. To overcome that, EDTA solution was used in an organ culture model once it has the ability to release endothelial cells from cell-cell contact. After treatment of the intact endothelial monolayer with EDTA, approximately 17% of the cell population entered the cell cycle^[111]. The use of EDTA alone, rather than a trypsin/EDTA solution to digest cells, may afford a greater cell survival rate^[112]. Also, the presence of L-ascorbic acid 2-phosphate (Asc-2P) in the culture was found to increase the proliferation of endothelial cells. Asc-2P is an antioxidant derivative of Asc that upregulates hepatocyte growth factor production *in vitro*^[113].

Further advance is required for the delivering method. Different cell carriers have been tested in animal models, and the main challenges are to achieve biomaterial transparency, structural strength and integration with native tissues^[113,114]. One approach to deliver cultured endothelial cells through direct injection employed magnetic attraction to attach cells to the Descemet's membrane, thus preventing them to disperse in the anterior chamber^[115]. Mimura *et al.*^[115,116] incorporated iron powder spheres in rabbit corneal endothelial cells and a neodymium magnet

was placed anterior to the eyelid to attract the particles after cell suspension injection. They demonstrated that the use of 5-10 micromoles of iron powder solution was associated with good cell survival rate and 12 mo later no noticeable toxicity was present. Since rabbit's endothelial cells are able to regenerate spontaneously, a control group that had been submitted to the same corneal injury did not receive the cell injection. The control group showed signs of endothelial failure. Magnetic field was later used in a human *ex vivo* model. Superpara-magnetic microspheres were incorporated into the cytoplasm of human corneal endothelial cells and facilitated cell migration and attachment without affecting cell viability or light transmittance^[117]. Toxicity to cells and other ocular tissues from magnetite oxide particles is a concern though, and safety remains to be demonstrated. Such compounds are used as magnetic resonance imaging contrast agents, on which safety and efficacy studies have been conducted, but the toxicity profile of this agent is likely to be different when delivered to the anterior segment of the eye.

The literature to date supports that the putative endothelial cells progenitors are precursors, not stem cells *per se*. Common features of precursors and adult stem cells are that both have self-renewal capacity and the ability to differentiate into mature effector cells, but stem cells can renew themselves indefinitely and produce one or more progenies through symmetric and asymmetric division, whereas progenitor cells have limited self-renewal capacity and more restricted differentiation abilities^[96,107].

CONCLUSION

Progress in corneal stem cell research provides an optimistic prospect on their use in regenerative medicine and tissue engineering. In this paper, we presented different limbal transplantation techniques, using either autologous or heterologous source of limbal stem cells, and the epithelial cells cultivated *in vitro* that are being successfully transplanted to the ocular surface. Future perspectives include the use of pluripotent stem cells or other adult stem cells to restore the corneal epithelium. However, a measured scientific approach is required to guarantee safety before transplantation can be done in patients. We discussed the growing data on human stromal stem cells, their immune privilege, and their potential to secrete organized collagen lamella that may eventually be useful in tissue engineering. We also summarized the accumulating evidence for the presence of putative stem cells in the corneal endothelium. These cells require specific conditions to show proliferative activity *in vitro* and researchers have already addressed that. Cell therapies for each corneal layer will target a specific disorder, instead of a full or partial thickness corneal transplant, which is the current treatment. Furthermore, one donor cornea will potentially treat multiple patients if the cells are successfully cultivated,

and certainly this would have a positive impact on the shortage of donor corneas worldwide.

Abstract

New stem cell based therapies are undergoing intense research and are widely investigated in clinical fields including the urinary system. The urinary bladder performs critical complex functions that rely on its highly coordinated anatomical composition and multiplex of regulatory mechanisms. Bladder pathologies resulting in severe dysfunction are common clinical encounter and often cause significant impairment of patient's quality of life. Current surgical and medical interventions to correct urinary dysfunction or to replace an absent or defective bladder are sub-optimal and are associated with notable complications. As a result, stem cell based therapies for the urinary bladder are hoped to offer new venues that could make up for limitations of existing therapies. In this article, we review research efforts that describe the use of different types of stem cells in bladder reconstruction, urinary incontinence and retention disorders. In particular, stress urinary incontinence has been a popular target for stem cell based therapies in reported clinical trials. Furthermore, we discuss the relevance of the cancer stem cell hypothesis to the development of bladder cancer. A key subject that should not be overlooked is the safety and quality of stem cell based therapies introduced to human subjects either in a research or a clinical context.

Key words: Stem cells; Urinary bladder; Urethra; Bladder reconstruction; Incontinence; Cancer stem cells; Safety

Core tip: This article reviews the current status of the stem cell based therapies in the field of treating urinary tract pathologies. We provide a particular focus on bladder reconstruction models that were based on stem cellular therapies. Stress incontinence and voiding dysfunction represent common clinical problems that could benefit from advancing the stem cell field. A

brief highlight is given to bladder cancer stem cells and therapeutic value that could arise from controlling their behavior. We also note the pressing need for more robust regulations and quality guidelines to prevent the transfer of research findings prematurely into routine clinical practice.

Mousa NA, Abou-Taleb HA, Orabi H. Stem cell applications for pathologies of the urinary bladder. *World J Stem Cells* 2015; 7(5): 815-822 Available from: URL: <http://www.wjgnet.com/1948-0210/full/v7/i5/815.htm> DOI: <http://dx.doi.org/10.4252/wjsc.v7.i5.815>

INTRODUCTION

The bladder and urethra compose the lower urinary tract. Pathologies of this part of the urinary system are common and clinically significant. Due to the bladder role as a versatile and dynamic reservoir of urine, it has unique structural and regulatory mechanisms that need to be thoroughly considered when cell and tissues engineering based therapies are thought of. Its complex mucosal-muscular-neural elements work together efficiently to produce a synchronized effortless urinary filling and emptying process. For instance, the bladder mucosa hosts a particular type of epithelium, "the transitional epithelium or urothelium", with cellular, intercellular and architectural features that make it expansible, durable, and resilient to life long persistent irritation by urine^[1]. Additionally, the detrusor muscle that surrounds the mucosa has a peculiar pattern of fibre arrangement to enable instant and complete emptying of the bladder once it is contracted. It can adjust to chronic outflow obstruction by hypertrophy and hyperplasia^[2]. The neurological control of the bladder and its urethral sphincter is compounded by autonomic, sensory and motor neural interaction^[3]. Multiple other hormonal and metabolic factors contribute to the integrity of the bladder function. Disturbance in one or more of these elements results in dysfunction in the vital process of urination which could significantly impair a patient's quality of life and may, in severe cases, cause disability or even death. Surgical removal of the bladder due to cancer or end stage benign disease necessitates the replacement of its function using alternative mechanisms, of which, stem cell based engineered tissue is proposed as a possible future strategy.

CONSIDERATIONS IN THE APPLICABILITY OF STEM CELL THERAPY

Stem cells are classically defined by their self-renewal based long-term survival and their flexible fate, being able to differentiate into other cell types. However, as simple as the concept seems to be, the accurate

identification, isolation and transplantation of stem cells could be more intricate than originally thought. For example, the functional distinction between stem cells and their progenitor cells remains ambiguous^[4,5]. This should be taken in consideration when planning stem cell therapies; a successful therapy may require other progenitor cells to turn on differentiation and proliferation signals of the parent stem cell. As well, the transition of the stem cell between quiescent and active stages is a dynamic process that challenges the accurate prediction of stem cell behaviour in different environments^[6]. The control of stem cell niche and microenvironment appears to be fundamental in the long-term success of stem cell therapy. Therefore, studying the stem cell niche could identify important biochemical and mechanical cues that need to be provided in addition to the cellular component to bridge the variability gap between the donor and host stem cells' niche and allow their effective engraftment and proper function *in vivo*^[7].

BLADDER ADULT STEM CELLS

The ability to use someone's cells to repair another area of one's own body could indeed reduce risks of infectivity and immunogenicity. For that, adult stem cells maintained its key position among other stem cell types^[8]. Tumorigenicity is also of much less concern. However, adult stem cells could be of less potential for long term survival due to inherent cell aging concerns^[9]. Various adult stem cell types have been used in treating bladder dysfunction including muscle; bone marrow and adipose tissue derived stem cells^[10]. In addition, urine stem cells have been isolated and differentiated into specialized cells to offer a readily accessible stem cell source for various applications^[11]. Although a general depot of adult stem cells exists in fat and bone marrow, however, lineage specific stem cells are believed to dominate in specific organs such as skin and cornea^[12,13].

The urothelial adult stem cells are thought to be slow cycling *in vivo* (3-6 mo), clonogenic, highly proliferative and located in protected sites. These cells are commonly identified by their localization in the basal layer of the urothelium, and by being label-retaining cells with high expression of β -4 integrin^[14,15]. The identification and isolation of these cells are important for tissue engineering of urothelium-lined organs including bladder, urethra and ureters.

CLINICAL APPLICATIONS OF STEM CELLS IN BLADDER PATHOLOGIES

Stem cells for urinary bladder replacement

Following cystectomy for benign or malignant bladder pathologies, bladder replacement or reconstruction is a critical step for maintaining patient's life. Whether ureterosigmoidostomy, ileal conduit or orthotopic

neobladder are used for reconstructing a new urinary reservoir, significant morbidity and mortality often occur due to the incorporation of intestinal segment into the urinary tract. This could result in recurrent urinary tract infection, metabolic and electrolyte disturbance, mucous retention and anastomotic site cancer. Moreover, the patient is left to deal with either an external draining bag through an opening on the skin called stoma or self catheterization with no external bag, both of which could interfere with body image and daily activities. Current *in situ* surgical bladder constructs are also unable to contract and squeeze the urine through the urethra since it lacks the muscle layer and the patient needs to adapt to techniques to push urine out such as contracting the abdominal muscles^[16-18]. Therefore, seeking new therapies to provide optimal bladder reconstruction is of utmost clinical importance.

Ideally, a perfect bladder reconstruct should be made of low immunogenic or autologous tissue that contains all anatomical layers of the bladder wall (mucosa, submucosa and muscle layer). It should be designed to mimic the detrusor muscle mechanics and to provide significant dispensability. It has also to provide similar urothelial mucosal barrier and ultimately should be incorporating functioning neuronal elements. Accordingly, advanced and complex tissue engineering and regenerative models are required. Thus far, there has been no such comprehensive efficient model; however preliminary studies are ongoing worldwide to achieve such goals.

Recently, tissue engineering using cell seeded scaffolds has been investigated in urinary bladder bioengineering studies^[19]. This method includes the seeding of a scaffold with autologous bladder muscle and epithelial cells. The use of autologous cells, however, may not be available as in cases of cancer^[20] or benign end-stage bladder diseases^[21]. Alternatively, stem cells can be derived from other sources including adipose tissue, bone marrow or amniotic fluid cells. They can be seeded on scaffolds and transplanted for *in vivo* differentiation. However, current data shows that such differentiation occurs only in a small percentage of the delivered cells^[22]. Another method is to differentiate stem cells into urothelial and smooth muscle cells *in vitro*. Stem cells have shown a good potential for urothelial differentiation. This was achieved by using either conditioned medium^[23,24] with or without growth factors such as all-transretinoic acid^[25]. Both direct culture (seeding stem cells with urothelial cells) and indirect co-culture (using trans-well system) have been attempted with variable outcome, though cell-to-cell contact in direct culture appears to be an enhancing factor for stem cell differentiation^[26,27]. Stem cell differentiation into smooth muscle cells is more feasible and can be achieved either by chemical induction^[28] or co-culture with smooth muscle cells^[22].

Induced pluripotent stem cells (iPS) reprogrammed

from adult tissue such as skin fibroblasts, urinary tract stromal cells and urine-derived cells have been also used and were subsequently differentiated into urothelial and smooth muscle cells^[29-31]. However, urinary tract-derived iPS cells are believed to be of superior differentiation properties to other sources, which should emphasize the epigenetic differences between individual iPS cell lines and stress on the importance of organ-specific iPS cells for tissue-specific studies^[29-31].

Stem cells for voiding dysfunction

Voiding dysfunction (VD) can affect the patient's quality of life and interfere with social activities. It can be manifested clinically as various disorders of urine storage or emptying. Current therapies of VD are generally inadequate and often fail to target the actual pathophysiology of the disease. Stem cell therapies have been also investigated in this field and were shown to cause some positive response either due to differentiation or more likely due to indirect paracrine effect associated with the release of growth factors and cytokines. The later mechanism could lead to modulation of local and systemic inflammatory responses and mobilization, stimulation and differentiation of native stem cells in addition to the enhancement of vascularization of regenerating tissues and reduction of fibrosis^[32]. A variety of stem cell types have been explored for the treatment of VD, including bone marrow, skeletal muscle and adipose derived stem cells^[33-35]. Adipose stem cells was most popular due to their easy harvest, high yield of stem cells and easier smooth muscle differentiation compared to other types^[35]. They could improve VD in animal models of bladder overactivity or hypoactivity associated with different etiologies such as diabetes mellitus, post radiation and hyperlipidemia^[32,35]. Nevertheless, more studies are needed to determine the efficiency of such therapy, the form of transplanted cells (unmodified or differentiated cells), the method of cell delivery (systemic or local injection into the bladder) and the appropriate cellular dose (number of cells per injection and frequency of treatment).

Stem cells for stress incontinence

Stress urinary incontinence (SUI) is a widespread disorder, particularly in women^[36], due to inherent predisposing anatomical and physiological factors specific to the female urethra. In addition, SUI is commonly initiated or aggravated by female specific physiological stages such as pregnancy, vaginal birth and menopause or pathological conditions such as uterine fibroid tumors^[37]. The current treatment of SUI relies on pelvic floor exercises in mild cases and surgical interventions in severe cases. The surgical methods aim to provide support to the urethra using various artificial tapes or autologous tissue slings. Each one of these methods has its adverse effects and post-operative complications^[38,39]. More recently,

Table 1 Examples of clinical studies of stem cell therapy used in the treatment of stress urinary incontinence showing a comparison of stem cell source, the duration of *in vitro* expansion and the follow up of patients post treatment

Origin of stem cells and duration of <i>in vitro</i> expansion	Number of women and route of injection	Follow up (yr)	Success rate (improvement and cure)	Ref.
Autologous muscle derived stem cells (SC), expanded 8-10 d	16 female patients, transurethral approach	2	Up to 75%	[76]
Muscle derived SC	222 male patients, transurethral injection	1	Up to 54%	[77]
Minced autologous muscle cells, no <i>in vitro</i> expansion	35 female patients	1	Up to 63%. Improvement (clinical, diary, and ICIQ-SF scores)	[78]
Muscle derived SC, expansion duration NA	8 female patients, transurethral injection	1	Significant improvement in 5 women (pad-weight, bladder diary and QOL assessment)	[79]
Muscle derived SC, expanded <i>in vitro</i> for 7 wk	20 female patients	2	Significant improvement (clinical, QOL and cystometry). Therapy based on this method is now licensed in Europe	[80]
ASCs combined with bovine collagen	5 female patients	1	2 out of 5 patients were satisfied with treatment with negative cough test	[81]
Autologous ASCs with and without fat	11 male patients with post-prostatectomy incontinence	1	60% improvement in urine leakage, frequency and amount of incontinence in 8 patients with one patient achieved total continence	[82]

the injection of bulking agents around or through the urethra to treat SUI has gained some popularity. Many agents have been used with variable success rates and complications were reported. Collagen, fat, Teflon, silicon or carbon coated beads are common examples of various agents employed^[40]. A recent systematic review in the Cochrane database showed that current data is insufficient to prove benefit of these therapies especially that saline injection was of similar effectiveness to bulking agents, with some reports of serious side effects associated with some of these agents^[41]. Consequently, stem cell therapies appeared as the next generation of therapies in SUI, which gained recent attention. Animal studies showed potential benefit in treating SUI. The animal model of SUI is usually induced by cutting the pudendal nerves. Muscle derived stem cells have been the most widely applied source and are believed to provide stem cells that are able to differentiate into committed striated muscle cells more than other stem cell sources. However, many other sources have been attempted with comparable success. To evaluate the success of stem cell therapy in SUI animal models, multiple outcome measures were used including leak point pressure, intra-bladder pressure, maximum bladder volume, urethral functional length, maximum urethral closure pressure, morphological examination of sphincter muscle and matrix^[42].

Adipose derived stem cells have been injected in rat models of stress incontinence using intravenous or trans-urethral routes, and showed significant improvement in terms of increased elastin content and voiding function measured by cystometry^[43]. Adding nerve growth factor and poly (lactic-co-glycolic) acid to the adipose stem cells when injected in the rat urethral sphincter improved stem cell proliferation *in vivo* and that was increasing in a dose dependant pattern. Such factors appear to improve stem cell survival and

functional performance of the urethra compared to using adipose stem cells alone^[44]. Furthermore, human amniotic fluid stem cells seem to be of potential benefit and favourable safety profile in restoring normal urethral function in the animal models of SUI due to their low immunogenicity and tumorigenicity^[45]. A triple stem cell therapy approach used human amniotic stem cells that were processed to the stage of early differentiation into three lineages *in vitro* (myogenic, neurogenic and endothelial). This approach was able to improve SUI signs in the animal model compared to using only one or two types of differentiated cells^[46]. A combination of gene therapy strategy by inducing urine derived stem cells to over express VEGF showed improvement of the sphincter composition especially the nerve fibres, muscle cells and vascularisation^[47].

The reconstruction of stem cell tissue engineered based slings to support the urethra was also investigated. A silk scaffold covered with bone marrow derived mesenchymal stem cell sheet has been implanted as a sling to support the rat urethra showing a better matrix deposition compared to using a silk sling alone^[48]. Likewise, adipose tissue derived stem cells and silk fibroin microspheres were combined together and they were able to retain improvement in SUI for longer duration than the silk fibroin microspheres alone^[49]. Following animal studies, a number of clinical trials have been attempted; examples are shown in Table 1.

Urinary sources and applications of iPS

iPS can be generated from somatic cells by inducing the expression of different transcription factors, originally Oct4, Sox2, Klf4 and Myc (OSKM). The induced pluripotent stem (iPS) cells have been considered as the stem cell that could offer several advantages over the adult stem cells while maintaining the plasticity of embryonic stem cells^[50]. However,

close examination of their possible adverse outcomes, such as the reported immunogenicity, should be undertaken prior to wide application^[51]. The urinary bladder and prostate cells were also reprogrammed successfully to iPS cells, offering a new method of the urinary system disease modeling^[29]. Likewise, urine cells were reprogrammed into iPS cells that were differentiated successfully into cardiac cells *in vitro*^[52]. Moreover, a model of personalized medicine was introduced by reprogramming urine cells of a haemophilia A patient into liver cells that express the traits of the disease^[53]. Conversely, the urinary bladder cells were obtained from iPS cells *in vitro*^[54]. Therefore, theoretically, the use of urine cells to produce urinary bladder wall cells for bladder reconstruction purposes would be attractive as they are originating in the same system^[55].

Bladder cancer stem cells

On the other end of the stem cell paradigm, adult cancer stem cells (CSC) are implicated in cancer development, progression and recurrence after conventional therapy. CSC are practically identified and confirmed by their ability to initiate tumours in immunocompromised mice and by their *in vitro* clonogenicity. The cancer stem cell theory was a build up on older clinical observations that related cancer to stemness^[56]. Starting with blood cancers that showed strong representation of the cancer stem cell model^[57], most solid cancers were studied for their CSC population^[58-62]. Several groups were able to isolate cells with CSC features from urinary bladder cancers. These cells were identified by several markers as being CD44+, negative for EMA, high expression of 67LR, low expression of CD66C, strong association with ALDH1A1 expression or as a side population based on the efflux of the Hoechst dye^[63,64]. It appears that CD44+ is one of the reproducible markers and its expression on bladder CSC was commonly supported by several groups^[65].

The value of such findings is to tailor specific target based therapies. Unlike traditional bladder cancer therapies, a cancer stem cell targeted therapy is postulated to be able to eradicate the resistant cancer initiating cells and minimize risk of recurrence. It is also important to understand bladder carcinogenesis and recognize how risk factors initiate cancer. For instance, activation of the transcription factor stat3 led to transformation of CK14+ urothelial stem cells into invasive cancer cells in a stat3 transgenic mouse model^[66]. Also, arsenic could transform normal prostate stem cells into cancer stem cells; this may explain its known detrimental effect on the urogenital system^[67].

One of the promising molecular targets include the CD47 which is an integrin associated protein known for its "do not eat me" effect on the cancer cell, leading to less recognition by cell mediated immunity especially

macrophages. The CD47 was found to be significantly more expressed in CSC compared to normal cells^[68]. A CD47 antibody labeled with fluorescence was used to distinguish human bladder cancer cells from normal cells with a specificity of more than 90%^[69]. A number of clinical trials have started to use the antibody against CD47 as a model of immunotherapy in leukemia and solid tumors^[70]. The bladder CSC niche and the microenvironment are also believed to significantly protect CSC from immunity and therapeutic factors and to maintain its carcinogenic behavior. Therefore, understanding the composition of this niche could highlight other potential targets for new therapies^[71].

Safety and quality

It is obvious that the use of stem cells in clinical investigations and therapeutics of bladder and urethral pathologies will be of potential importance in the near future. Nonetheless, the rapidly gained popularity of these interventions should be cautiously perceived and publicized in scientific and non-scientific media. Premature application of such therapies in human subjects without matching scientific evidence as off label treatment in research studies or their unregulated use in clinical practice should be truly concerning. In underdeveloped settings, such unregulated practices are quite common. Stem cell therapy tourism is also expanding and could expose patients to considerable health hazards^[72]. Factors such as sterility and viral screening of the introduced cell therapy, the lack of contaminants and toxic molecules, cell viability and cell karyotyping should be all included in stem cell clinical studies and should be reported clearly by researchers before being accepted in formal scientific publications^[73]. Tumorigenicity of stem cell therapies is another factor that should not be overlooked and available tumorigenicity assays should be routinely used^[74]. Awareness about current good manufacturing practices in stem cell therapy should be widely raised^[75]. Nonetheless, this would not be adequate in the absence of strict regulations enforced on using such therapies in human especially in underdeveloped settings where baseline research ethics and quality control are not well developed or monitored. Wide international collaboration is, therefore, strongly needed to come up with a global consensus and standards that allow the safe use of stem cell therapies in human subjects without ignoring the cost and training involved to implement these standards in poor settings.

CONCLUSION

Stem cell therapies will be in the clinical setting in the near future. At present, their use in bladder dysfunction and bladder reconstruction is under intense investigation. Various sources of stem cells

have been attempted with comparable success. More complex tissue engineered models that mimic the original bladder anatomy are awaited. Bladder cancer stem cells are investigated as a potential target for cancer therapies.

Abstract

Pathogenic mutations involving DNA repeat expansions are responsible for over 20 different neuronal and neuromuscular diseases. All result from expanded tracts of repetitive DNA sequences (mostly microsatellites) that become unstable beyond a critical length when

transmitted across generations. Nearly all are inherited as autosomal dominant conditions and are typically associated with anticipation. Pathologic unstable repeat expansions can be classified according to their length, repeat sequence, gene location and underlying pathologic mechanisms. This review summarizes the current contribution of mutant pluripotent stem cells (diseased human embryonic stem cells and patient-derived induced pluripotent stem cells) to the research of unstable repeat pathologies by focusing on particularly large unstable noncoding expansions. Among this class of disorders are Fragile X syndrome and Fragile X-associated tremor/ataxia syndrome, myotonic dystrophy type 1 and myotonic dystrophy type 2, Friedreich ataxia and C9 related amyotrophic lateral sclerosis and/or frontotemporal dementia, Facioscapulohumeral Muscular Dystrophy and potentially more. Common features that are typical to this subclass of conditions are RNA toxic gain-of-function, epigenetic loss-of-function, toxic repeat-associated non-ATG translation and somatic instability. For each mechanism we summarize the currently available stem cell based models, highlight how they contributed to better understanding of the related mechanism, and discuss how they may be utilized in future investigations.

Key words: Unstable repeat associated disorders; Human embryonic stem cells; Patient-derived induced pluripotent stem cells; Disease modeling; Epigenetics; repeat-associated non-ATG translation; RNA toxicity; Repeat somatic instability

Core tip: This review summarizes the current contribution of mutant pluripotent stem cells (diseased HESCs and patient-derived induced pluripotent stem cells) to the research of unstable repeat pathologies by focusing on particularly large unstable noncoding expansions. It demonstrates their importance as an unlimited cell source for generating rarely available impaired cells in culture, and as a model system for

exploring the mechanisms that are involved with this class of mutations. For each mechanism we describe the currently available stem cell based models, highlight how they contributed to better understanding of the related mechanism, and discuss how they may be utilized in future investigations.

INTRODUCTION

Unstable repeat expansions, termed also dynamic mutations, are the cause of over 20 different neurodevelopmental, neurodegenerative and neuromuscular heritable conditions that result from a change in the number of repeat units in coding genes when ordered in tandem (for comprehensive review see^[1]). Repeat instabilities change across generations, and may vary between cells within affected individuals. Nearly all are inherited as autosomal dominant conditions and are typically associated with anticipation, meaning that the disease symptoms tend to be more severe and occur earlier in age with successive generations. Most unstable repeat associated disorders are caused by the addition of repeat units (mostly tri-nucleotides) that, above a certain threshold, lead to misregulation of genes and/or to their RNA/protein products. Disease associated unstable repeat expansions can be classified into two groups according to the length and gene location of the expansion. One class of disorders results from small repeat copy changes (few to tens of units) that usually reside in exon coding regions of genes. Among them are the ployglutamine CAG expansion disorders like Huntington disease, Huntington's disease like 2 (HDL2), Dentatorubral-pallidoluysian atrophy (DRPLA), Spinal and bulbar muscular atrophy (SBMA) and spinocerebellar ataxia (SCA) 1, 2, 3, 6, 7 and 17, which lead to protein gain-of-function alterations. A second class of unstable repeat expansion disorders results from large expansions, ranging from hundreds to thousands of copies. Large pathogenic repeat expansions are typically located in noncoding regions including promoters, introns and untranslated regions (UTRs) of genes^[2]. Among disorders in this class are Fragile X syndrome (FXS) and [Fragile X-associated tremor/ataxia syndrome (FXTAS)]; both FXS and FXTAS are caused by large expansion of a CGG repeat in the 5'-UTR of the *FMR1* gene^[3-5], [myotonic dystrophy type 1 (DM1); caused by a CTG expansion in the 3' UTR of the *DMPK* gene^[6-8] and type 2 (DM2; caused by a CCTG expansion in intron 1 of the *ZNF9* gene^[9]), [Friedreich ataxia (FRDA); caused by a GAA expansion in intron 1 of the *Frataxin* gene^[10]], C9 related

[amyotrophic lateral sclerosis and/or frontotemporal dementia (ALS-FTD); caused by a GGGGCC^[11] expansion in intron 1 of the *C9orf72* gene^[12]], and [Facioscapulohumeral Muscular Dystrophy (FSHD); caused by a contraction of the D4Z4 macrosatellite repeat in sub-telomeres of chromosome 4q35].

The outcome of the expansion mutation may be different depending on its gene location and length. Unlike small expansions, which commonly result in alterations in protein function, large noncoding expansions introduce further complexity because they can lead to either loss-of-function, RNA gain-of-function, toxic protein gain-of-function, or to a combination of all these pathogenic mechanisms in unison^[13]. In addition and in contrast to small expansions, large noncoding expansions frequently coincide with marked changes in repeat tract length between and within tissues of affected individuals^[8,14,15]. This phenomenon, termed somatic repeat instability, results in mosaicism for expansion size and occasionally correlates with disease age of onset and severity. Modeling dynamic mutations, specifically large expansions, in mice can be particularly challenging due to the difficulty in artificially inducing and stably maintaining very large repeat expansions (especially CG-rich) *in vitro* and *in vivo*. In addition, despite the similarities between mouse and human, there are still major differences between the two species, leading to dissimilarities in biochemical pathways and phenotypes. These crucial discrepancies emphasize the need for complement model systems that will reproducibly copy the underlying mechanisms and clinical phenotypes in human.

Mutant human pluripotent stem cells, embryonic [human embryonic stem cells (HESCs)] or artificially induced [induced pluripotent stem cells (iPS cells)], may provide a great opportunity to study unstable repeat expansions by complementing existing models^[16]. They are expected to be especially useful in the study of heritable conditions where the animal model fails to fully recapitulate the phenotype of the disease in human, or when disease relevant cell cultures from patients are unavailable. The many advantages to the utilization of these cells for biomedical research include the fact that they are human derived, untransformed cells with an unlimited self-renewing capacity. In addition, they have the potential to differentiate into a wide range of cell types in culture, and recapitulate early human embryo development while they differentiate *in vitro*. Moreover, as mutant pluripotent stem cells can be derived directly from genetically affected embryos that are obtained through preimplantation genetic diagnosis (PGD) procedures (HESC)^[17], or by reprogramming somatic cells obtained from patients (iPS)^[18], they can reproduce disease cellular phenotypes as they occur *in vivo* without the need to artificially intervene with their genome through genetic manipulation. In addition, they are human derived and potentially be used to generate large amounts of impaired disease relevant cells in culture. This is particularly beneficial in the

Figure 1 Modeling pathogenic noncoding repeat expansions by the use of mutant pluripotent stem cells. Unstable noncoding repeat expansions have several features in common. They typically display somatic instability, and can lead to either epigenetic loss-of-function, toxic RNA gain-of-function, toxic RAN translation, or to a combination of all these pathogenic mechanisms. Future research might discover more similarities in the pathogenesis of these and additional repeat associated disorders. Disease modeling through the use of mutant HESCs and iPS cells is anticipated to be particularly useful considering their potential to generate impaired cells, and their ability to recapitulate developmentally regulated events upon differentiation. Indeed, using this model system, new mechanistic insights have thus far been gained for diseases marked in bold. FSHD: Facioscapulohumeral Muscular Dystrophy; FXS: Fragile X syndrome; ALS: Amyotrophic lateral sclerosis; FRDA: Friedreich ataxia; FXTAS: Fragile X-associated tremor/ataxia syndrome; DM1: Myotonic dystrophy type 1.

case of unstable repeat pathologies, where studies are frequently limited to postmortem brain samples or to unsuitable cell types obtained from patients such as peripheral blood cells or skin fibroblasts. Furthermore, as these cells can recapitulate early stage embryo development, they may be particularly valuable in modeling disease associated mechanisms that are developmentally regulated such as those that are elicited by differentiation. In terms of applied research, mutant pluripotent stem cells provide a powerful cell culture based system for gene correction. For instance, they may facilitate the efficient induction of irreversible changes in DNA that will correct the disease causing mutation by shortening the repeat tract through genome editing or other gene manipulation approaches^[19]. They can also provide a platform for drug screening and development, conditioned by the accessibility of efficient differentiation protocols and the availability of reliable biomarkers.

In this review we summarize the current contribution of mutant pluripotent stem cells to the research of unstable repeat pathologies by focusing on common mechanisms that are associated with large unstable noncoding expansions (Figure 1). A complete survey of the data regarding the use of mutant pluripotent stem cells for modeling phenotypes of coding unstable repeat

expansions, and the use of these cells as a platform for gene therapy, are beyond the scope of this review and can be found elsewhere^[20-22]. The discussion here will thus be limited to only pathological noncoding repeat expansions. For each mechanism we highlight the currently available pluripotent stem cell models by describing their exclusive utility for investigation of the mechanism, how they contributed to better understanding of the related mechanism, and we raise potential routes for future investigation.

TOXIC RNA GAIN-OF-FUNCTION

Over the past decade it has become evident that RNAs containing abnormally large microsatellite repeat expansions underlie the pathogenesis of at least 9 dominantly inherited human diseases. These are mostly neurological and neuromuscular diseases, including DM1^[23], DM2^[24], FXTAS^[25], C9/ALS-FTD^[26], SCA3^[27], SCA8^[28], SCA10^[29], SCA31^[30] and HDL2^[31]. These diseases arise when the repeat-containing RNA disrupts the function of specific RNA binding proteins (RBPs) *in trans*. The paradigm for such toxic RNA gain-of-function pathology is DM1, where a CUG repeat expansion located in the 3'-UTR of the *DMPK* gene interferes with the cellular function of specific CUG-binding splice-regulating proteins termed MBNL1 and CUG-BP1 (CLEF protein family)^[32,33]. The altered function of these splice regulators hinders the normal processing of transcripts encoding over twenty different muscle genes, resulting in inappropriate expression of embryonic rather than adult splice variants in adult disease manifesting tissues^[34,35]. The general hallmarks of unstable repeat disorders with RNA-mediated toxicity are the accumulation of repeat-containing RNAs in intra-nuclear inclusions along with the sequestration of common RBPs (mainly proteins involved with RNA metabolism) and alternative splicing misregulation^[36]. Co-localization of the large ribonucleoprotein (RNP) aggregates with ubiquitin and proteasome subunits is a common feature^[37]. These striking parallels have led to the identification of the most common (currently known) mechanisms underlying noncoding unstable microsatellite disorders. This subclass of disorders is caused not due to the loss of function of the mutant transcripts and haploinsufficiency, but rather from the loss of function of RBPs that aggregate with the lengthy RNAs, and possibly from the toxic effect of the aggregates themselves. As the RNA seeds accumulation of the proteins it interacts with, it alters their biological function by changing their abundance and/or localization in the cell. Furthermore, since most of these expansions are bi-directionally transcribed, multiple repeat-containing toxic RNAs seem to be involved^[38-40]. The susceptibility of neurons to this process is a common feature, most likely related to the ageing course of this specific cell type. Considering the reversibility of the process^[41-44], it may be possible to develop effective therapeutic strategies to ameliorate

the symptoms of these diseases.

Taking advantage of two DM1 affected pluripotent stem cell lines derived from embryos identified through PGD, Denis *et al.*^[45] produced impaired early progenitor neural cells in culture. To validate the pathological relevance of their differentiated cells, they show that DM1-neural stem cells (NSCs) and derived neurons harbored intranuclear RNP foci, contain the mutant RNA and co-localize with the splice factor MBNL1. Interestingly, functional characterization of DM1 HESC-derived neurons revealed reduced proliferative capacity and increased autophagy linked to the mTOR signaling pathway. In addition, the researchers were able to demonstrate that the loss of function of MBNL1 in wild type (WT) HESCs results in alteration of the mTOR signaling pathway, whereas gain-of-function experiments rescued the phenotype. Collectively, their findings provided a mechanism by which the DM1 mutation might affect a major signaling pathway, and highlighted the pertinence of using pluripotent stem cells to study neuronal defects in general. A complement model system to support the formation of intranuclear RNA foci by *in vitro* derived neurons was developed in iPS cells, validating the potential of pluripotent stem cells to offer an unlimited cell resource for CNS mechanistic studies^[46].

A different disease for which pluripotent stem cells have been employed to further understand the toxic RNA-mediated mechanism underlying unstable repeat expansions is in C9/ALS-FTD. Amyotrophic lateral sclerosis (ALS) and/or frontotemporal dementia (FTD) is an autosomal dominant neurodegenerative disorder characterized by adult onset of one or both of these conditions in an affected individual^[47-49]. The leading cause for ALS-FTD is a G₄C₂ repeat expansion in the first intron of the *C9orf72* gene, between noncoding exons 1a and 1b. Expansion of G₄C₂ repeat tract beyond a certain threshold, results in RNA gain-of-function resulting from bi-directional transcription^[40,50]. Its low incidence (1:100000) and mainly sporadic occurrence (90%), late onset, and accelerated progression, have thus far facilitated the preparation of iPS cells, but not HESC lines. By establishing multiple iPS clones from skin biopsies of patients' fibroblasts with over 1000 G₄C₂ repeats, researchers were able to generate motor neurons in culture that recapitulate key neuropathological features of ALS-FTD including RNA foci reminiscent of those observed in postmortem brain autopsies from patients^[51]. Interestingly, the RNA foci containing G₄C₂ repeats were present in all iPSC-derived human neurons as well as in undifferentiated iPSCs and primary fibroblasts. This suggests that these foci are not restricted to a specific cell type or developmental stage, as one would predict if functionally significant. Moreover, transcription of the repeat containing *C9orf72* transcripts, led to accumulation of G₄C₂ repeat-containing RNA foci selectively in various C9-ALS iPSC-derived neural cell types^[52]. It was also shown that the pathologic RNA foci co-localize with

the major known RBPs like hnRNP A1, Pur- α ^[52] and ADARB2^[53], suggesting that they may be able to disrupt RNA metabolism. Furthermore, it was found that the *in vitro* derived C9-ALS motor neurons present altered expression of genes involved in membrane excitability, and demonstrated a diminished capacity to fire continuous spikes upon depolarization compared to a WT motor neuron control^[52]. By targeting the RNA foci through antisense oligonucleotide (ASO), either through knockdown (KD) of the full length *C9orf72* transcripts or by differentially targeting the repeat containing mRNA isoforms (V1 and V3), researchers were able to suppress RNA foci formation and reverse gene expression defects in C9-ALS neuronal cells^[52,53], as well as, rescue to some extent disease phenotype (Glutamate toxicity^[53]). These data show that patient-derived motor neurons can be used to elucidate the pathogenic role of the toxic RNA in C9/ALS-FTD. More generally, they neatly illustrate the power of mutant pluripotent cells as a translational platform for therapeutic development.

Many questions regarding this repeat-associated mechanism remain to be addressed. For example, what dictates the cell-type specificity of this process? How is it age related? What is the protein composition of the aggregates in each disorder and, what is the nature of the inclusions? Are they toxic or do they simply represent clearance of toxic RNA? In addition, although animal models have provided firm evidence for RNA gain-of-function as a major contributing mechanism^[54,55], clinical and pathophysiological differences between human and available animals (mouse and *Drosophila*) limit their usefulness in delineating specific mechanisms underlying these toxic RNA-mediated pathologies^[56-61]. Therefore, a complement human-based model system is needed to enable molecular characterization of the onset and course of this class of conditions.

REPEAT-MEDIATED EPIGENETIC MODIFICATIONS

Among the disease associated expansions there are several, counting FXS, FRDA, DM1, and C9/ALS-FTD, that results from particularly large noncoding expansions (hundreds to thousands of copies) that reside within CpG islands (CGIs). CGIs typically remains free of DNA methylation and are rich in histone modifications associated with transcriptionally active chromatin. Yet, expansion of repeat copy number beyond a certain threshold leads to local acquirement of abnormal CpG methylation in addition to loss of active histone modifications and concomitant gain of repressive histone modifications that are typical to densely packed chromatin (like H3K4 demethylation and H3K9 and H3K27 tri-methylation, respectively). These aberrant epigenetic modifications can change local gene transcription. Their effect may vary from one locus to another, depending on the location of

the expansion in the gene. While in some genes it abolishes the activity of a promoter (as in FXS and C9orf72)^[62,63] or an enhancer (as in DM1)^[64], in other genes it interferes with RNA transcription elongation (as in FRDA)^[65] or termination (as in FSHD^[66]). Furthermore, even when hypermethylation leads to the loss of promoter activity, the outcome may be very different. For example, while in FXS transcriptional silencing results in FMRP protein deficiency (loss-of-protein function)^[67], in C9/ALS-FTD epigenetic silencing may potentially lead to increased use of an alternative promoter (RNA gain-of-function)^[39]. In addition, in some disorders hypermethylation seems to be acquired in a developmentally regulated process (FXS)^[17] whereas in others it is more of a tissue or an age-dependent phenomenon (DM1)^[68]. Therefore, it is essential to first understand when, where and how hypermethylation affects local gene expression, in order to examine whether and by what mechanism this contributes to disease pathogenesis. More generally, by unraveling how repeat expansions lead to the loss of CGI identity, we may gain new insights on how CpG islands are normally protected from *de novo* methylation throughout the genome.

The availability of mutant pluripotent stem cell lines carrying pathologic repeat expansions may provide a great model system to address the questions of when, where and how hypermethylation is aberrantly acquired. In particular, such cell lines can be utilized to better determine the timing, intervene with the mechanism, and monitor the effect of epigenetic modifications. In addition, they may provide an exceptional opportunity to rescue the mutant phenotype by resetting the undesired epigenetic modifications that are coupled with the expansion through cell reprogramming.

To date, pluripotent stem cell-based studies related to the epigenetic aspects of unstable repeat expansions have been mainly limited to FXS. In FXS, when the CGGs reach the full mutation range, they lead to the spread of abnormal CpG methylation and repressive histone modifications at the 5' regulatory region, resulting in epigenetic gene silencing and consequently to FMRP protein deficiency in patients^[62]. Initially, when the first FXS XY HESC line was established, it was found to express FMR1 at comparable levels with WT HESCs and to be completely FMR1 unmethylated^[17]. These findings validated a commonly accepted view that FMR1 epigenetic silencing is a developmentally regulated process that is triggered by differentiation. Moreover, it encouraged investigators to propose that since epigenetic FMR1 inactivation is differentiation-dependent (rather than being maternally transmitted in the gamete), it may be possible to rescue the cellular phenotype of FXS neurons simply by removing the epigenetic marks that are erroneously gained, through cell de-differentiation in culture. However, as more FXS HESC lines were available, it became apparent that FMR1 hypermethylation commonly occurs in the undifferentiated state. Taking advantage

of a large set of FXS HESCs (9 cell lines, including the former), Avitzour and colleagues found that FMR1 hypermethylation frequently occurs in these cell lines (six of nine lines, ranging from 24% to 65%)^[69]. This suggests that the wide variability in methylation levels between and within the different FXS HESC lines reflects a widespread event within mutant FMR1 embryos, where methylation state is initially set. It should be interesting to determine whether FXS preimplantation embryos are already FMR1 methylated, and whether methylation at this stage is incomplete. Mechanistically, the researchers tried to address the question of how the CGG expansion at the FMR1 locus leads to *de novo* methylation of the CpG island at the 5'-UTR of FMR1^[69]. They aimed to associate FMR1 hypermethylation with CTCF binding next to the repeats, taking in to consideration the well-known role of CTCF as an insulator binding protein that counteracts heterochromatin spreading^[70,71] and taking in to account previous reports demonstrating CTCF occupancy next to the CGG repeats at the FMR1 locus in differentiated cells. However, since no enrichment for CTCF could be detected, in both WT and affected HESC lines, this study ruled out the possibility that hypermethylation may be attributed by the binding loss of CTCF, as formerly suggested^[38,72]. Employing two other XY FXS HESC lines, Colak and colleagues uncovered an mRNA-mediated mechanism that drives epigenetic FMR1 inactivation in a way that relies on neuronal differentiation^[73]. In this study the researchers showed that the CGG-lengthy FMR1 mRNA hybridizes to the complementary CGG-repeat portion of the *FMR1* gene to form an RNA:DNA duplex. Upon differentiation the RNA:DNA hybrid elicits gene silencing on the protein and mRNA levels. According to their study, disrupting the interaction of the mRNA with the CGG-repeat portion of the *FMR1* gene at a critical time point during cell differentiation prevents promoter silencing. It remains to be determined whether silencing in undifferentiated cells is achieved by the same mechanism or by distinct one, and whether the loss of FMR1 mRNA and protein in the FXS HESC-derived neurons involves DNA hypermethylation.

In line with this study, it has been proposed that it may be possible to reverse the adverse effect of the modifications and correct the mutant phenotype by reprogramming terminally differentiated FXS cells. However, somatic cell reprogramming of FXS patients' fibroblasts by numerous independent studies failed to de-methylate and reactivate the gene simply by de-differentiation^[74], suggesting that once established, methylation is irreversible and/or is acquired prior to blastocyst formation^[75-77]. In line with this view, it should be feasible to obtain FXS-iPS clones that are FMR1 active from somatic cells with a full mutation provided that they carry an unmethylated full expansion at least in some of their cells. On the other hand, perhaps reprogramming may wrongly lead to hypermethylation of this mutation prone site, regardless of its initial

epigenetic state. Indeed, reprogramming fibroblasts from an unusual asymptomatic subject, bearing a full mutation that is entirely unmethylated, resulted in complete silencing, regardless of the reprogramming method used^[78]. Maybe the high levels of DNMT3b, that are induced as part of the reprogramming process^[79], led to this unexpected result. This suggests that FXS iPS cells, and potentially additional iPS models for epigenetically regulated disorders, may not serve as an ideal model for better understanding the mechanism by which hypermethylation is induced. Reprogramming of somatic cells from additional subjects with hypomethylated expansions will be required in order to establish whether this is a widespread event that is irrelevant to the disease. Regardless, it should be possible to use these disease affected iPS cells to explore the consequence of FMRP deficiency or reverse this effect in *in vitro* differentiated neurons, a disease relevant cell type. Indeed, re-activation of FMR1 by the treatment with the de-methylating agent 5-azaC has already been successfully practiced in neuron derived FXS-iPS cells^[80].

Apart from FXS HESCs, there is indirect evidence to suggest that hypermethylation is recapitulated in patient derived iPS cells for other unstable repeat related loci. One example is C9/ALS-FTD iPS cells that carry a G₄C₂ expansion at the *C9orf72* gene. In the *C9orf72* the G₄C₂ repetitive sequence is flanked by two CpG islands (CGIs) that span from the promoter sequence into intron 1 of *C9orf72*. Like many CGIs in the genome, this region typically remains unmethylated and is transcriptionally active. Yet, expansion to more than 90 repeats leads to the formation of one large CGI exclusively in patients, and to local acquirement of abnormal CpG methylation upstream^[11]. Hypermethylation is coupled with the local gain of repressive histone modifications, and is responsible for the inactivation of variant 2 of *C9orf72* that, unlike repeat-containing variants 1 and 3, initiates transcription from exon 1b and harbors the G₄C₂ sequence in its promoter^[26]. Overall, C9/ALS-FTD iPS cells demonstrate altered gene expression. While some reports demonstrate general reduction in the transcription of all variants, others show differential expression favoring variants 1 and 3 over variant 2^[26,52,81]. All together, this suggests that hypermethylation in fact exist in these cells. Nevertheless, the contribution of epigenetic gene silencing to disease pathogenesis is not fully clear. There is conflicting evidence regarding the correlation between hypermethylation and type of pathology (ALS vs FTD), age of onset or severity^[11,82,83]. Experimental evidence in animal models demonstrates inconsistent results^[84,85]. On the other hand, hypermethylation was suggested to have a protective role from the accumulation of pathogenic RNA/protein foci contributed by repeat-containing mRNA variants 1 and 3^[86]. These conflicting studies warrant further investigation regarding the contribution of DNA methylation to ALS-FTD pathogenesis, and may be

considerably advanced by the use of *in vitro* derived neurons from C9/ALS-FTD pluripotent cells.

Another elegant example for the power of pluripotent stem cells in resolving the contribution of epigenetics to disease pathogenesis is in FSHD. FSHD is caused by a contraction of a macrosatellite repeat (D4Z4 repeat, 3.3 kb unit) located in the sub-telomeres of chromosome 4q35. Non-affected individuals carry 11-100 repeat units, while FSHD patients have less than 10 repeats, but must have at least one unit to manifest the disease^[87-89]. Interestingly, the loss of DNA methylation and reduced H3K9me3 that coincide with repeat contraction have been found to be causally related to the up-regulation of a full transcript from the *DUX4* gene, a transcript which is exclusive to the most distal (telomeric) unit of the D4Z4 repeat containing region^[66,80-93]. Expression of the full length *DUX4* transcript, which is exclusive to FSHD myotubes, is responsible for the induction of nuclear foci, impaired myogenesis and ultimately to cell death by apoptosis^[94]. Immediately downstream to the most-telomeric unit there is a polymorphic site that acts as an alternative polyadenylation signal that controls the length and stability of the *DUX4* transcript. While normal alleles produce short transcripts and truncated proteins, contracted FSHD alleles utilize a cryptic splice donor to form a full length toxic protein. As alternative polyadenylation seemed to be a tissue-specific process, it was speculated to be a developmentally regulated event that is mediated by the loss of repressive epigenetic modifications due to D4Z4 repeat contraction. By comparing WT and FSHD iPS cell lines, Snider and colleagues^[94] found that both cell types equally express full length *DUX4*, independent of repeat number. However, upon differentiation, full length expression was switched off and converted back to short transcripts in WT controls while full length expression persisted in the diseased cells. Importantly, the researchers were able to correlate the switch in splice site usage with the enhancement of repressive chromatin modifications (H3K9me3) in the WT differentiated cells. Thus, it appears that H3K9me3 modification (and most likely CpG methylation) mediates the splicing for the truncated protein upon differentiation, and that the contraction of the D4Z4 repeats abolishes this developmentally regulated process. It remains to be determined how D4Z4 contraction interferes with the normal induction of heterochromatin. Nevertheless, the use of FSHD iPS in this particular study, neatly illustrates the power of mutant pluripotent stem cells in resolving the molecular mechanisms contributing to disease pathogenesis.

RAN TRANSLATION

During the past years it has become apparent that a third potential mechanism may act in the context of pathogenic repeat expansions. A novel form of

translation was found by Ranum's group, which results from translation in the absence of an initiating AUG codon next to disease causing unstable microsatellite repeats^[95]. They found that the CAG repeat tract at the DMPK (DM1) and ATXN8 (SCA8) loci undergo noncanonical translation in disease relevant tissues of patients, resulting in the production of homopolymeric proteins in all three frames (CAG, AGC, and GCA). This newly discovered phenomenon was termed RAN translation, abbreviated for Repeat Associated Non-ATG translation.

To date, RAN translation has been shown to occur across four different types of repeat motifs: CAG, CTG, CGG and GGGGCC, in a growing number of conditions, including DM1, SCA8^[95], FXTAS^[96] and C9/ALS-FTD^[39,40,50,97,98]. Among its effects, RAN translation leads to ubiquitin-positive intracellular protein inclusions, which may be toxic to cells^[96]. Furthermore, researchers have shown that when repeats are bi-directionally transcribed to form sense and anti-sense transcripts, six potential homopolymeric proteins can be produced^[48] as each transcript can be RAN translated in three different reading frames. Importantly, they provided evidence that long repeat tracts can express multiple RAN-translated products, simultaneously, in a single cell and suggested that RAN translation may contribute to disease pathogenesis by a protein gain-of-function mechanism^[95]. In addition, as longer expansions are more liable to the accumulation of RAN translated products, it was speculated to be involved with disease anticipation^[99]. Nonetheless, evidence for a role of RAN translation, if any, in disease pathogenesis still awaits further exploration.

Thus far, RAN translation has been documented in pluripotent stem cells only for C9/ALS-FTD. Indeed, postmitotic neurons derived from C9/ALS-FTD iPS cells have already been established, and were shown to present disease-relevant phenotypes that include RAN translation products in the form of cytoplasmic TDP-43 negative/p62 positive protein inclusions^[51]. Immunofluorescent staining of the C9/ALS-FTD iPSNs (induced pluripotent stem cells derived neurons) revealed cytoplasmic poly-(Gly-Pro) inclusions similar to those observed in C9orf72 expansion carriers postmortem affected brains^[53]. In addition, as the appearance of RAN peptide foci was coupled with increased sensitivity to cellular stress induced by autophagy inhibitors^[51,53], it raised the possibility that this mechanism may contribute (directly or indirectly) to impaired autophagy function in ALS-FTD and possibly additional conditions associated with RAN translation^[53].

There is by now enough evidence to indicate that mutant differentiated iPS cells can authentically recapitulate the late onset and tissue-specific cellular phenotypes that are typically seen in human C9orf72 postmortem brain samples. It should be interesting to explore whether similar cellular phenotypes can be reproduced in iPS cells derived from younger, yet

asymptomatic, C9 mutation carriers. In addition, it would be useful to establish additional C9/ALS-FTD iPS cells from patients who carry small, intermediate and large expansions to correlate inclusions with repeat tract size, C9orf72 transcription and disease severity. Such associations are not yet fully understood. Nevertheless, it should be kept in mind that mitigation of RNA foci and RBP aggregation by antisense oligonucleotide (ASO) treatment in affected iPSNs had no effect on the formation of RAN-translation inclusions^[53]. This would suggest that the detected homopolymeric inclusions may not have a major role in disease pathology. However, as only one type of di-peptide repeat was monitored [poly-(Gly-Pro)], it may be possible that in fact the other RAN peptides (such as the ones that are produced by antisense transcription) are crucial for the manifestation of the abovementioned cellular phenotypes. In any case, even if the RAN-translated products observed in iPS derived neurons will be proved to be irrelevant to disease pathology, they may be useful as a biomarker, providing an opportunity to develop a platform to test therapeutic agents for their effect on brain features of the disease. Compounds that will reverse the formation of the inclusions in the diseased cells are expected to offer a starting point for therapeutic development.

Many questions regarding RAN translation arise. For example, what is the clinical significance of RNA translation? Does RAN translation occur across all unstable microsatellite disorders? Is it age dependent? When and what determines its tissue specificity? In addition, it is still not yet clear which RNA structures and flanking sequences are required to facilitate RAN translation? Intrastrand RNA repeat associated hairpins and G-quadruplex structures have been suggested as candidates for RAN translation involvement^[95,99-101]. When more stem cell based disease models (HESC and/or iPS) will become available, it is anticipated that human pluripotent stem cells will be important in clarifying at least some of these fundamental questions.

REPEAT INSTABILITY

Repeat instability is a form of dynamic mutation that results from a change in the number of repeat units when ordered in tandem. Unlike static mutations, which involve permanent change in the DNA, repeat instabilities change across generations, and may vary between and within tissues of affected individuals (for comprehensive reviews see^[102,103]). We refer to germ-line instability when the change in repeat number occurs during transmission from parent to offspring, and somatic instability when the change takes place in the somatic cells of the patient. Germ-line instability, which is frequently biased towards maternal or paternal transmissions, is typically associated with anticipation (reviewed in^[103]). This is because the longer the repeat tract the more likely it will undergo expansion

in the next generation. As a result, disease symptoms worsen from one generation to the next. However, in some pathologies repeat instability extends beyond the germ-line, leading to a high degree of variation in repeat tract length in affected individuals^[14,104,105]. Unlike in germ-line repeat instability, the contribution of somatic instability to disease pathogenesis is not at all times clear. In some conditions there is an obvious correlation between expansion size and cell dysfunction^[106,107], whereas in others this association is not noticeable^[108,109]. Nevertheless, it is imperative to understand the molecular details of this mutation-associated phenomenon, considering that in some cases expansion size is clinically significant and may be used as a prognostic marker^[110].

It is important to note that not all expansions are alike in range and location. While expansions residing in coding regions are usually restricted in length (tens of copies) and limited to germ-line mutations, noncoding expansions are frequently large (hundreds-thousands of copies) and typically coincide with somatic instability. Furthermore, in some disorders somatic instability can be restricted to early embryonic development or to highly replicating cells, whereas in others it may be tissue-specific or age-dependent, and may be limited to particular post-mitotic cell types. Therefore, while the type of mutation is common to all of these heritable and devastating conditions, the marked variation in the pattern and distribution of expansion size among them may stem from assorted mechanisms.

It is generally accepted that repeat instability results from local disruption of DNA replication, repair or recombination (for comprehensive review see^[111]). Regardless of the mechanism, all proposed models for instability are based on the formation of unusual structures in the DNA (like hairpins and G-quadruplexes) that are eventually resolved by the addition (expansions) or deletion (contractions) of repetitive units^[112-120]. It remains to be determined when and how these changes occur. In that sense, expansion carrying pluripotent stem cells provide an exceptional opportunity to gain more insights on the mechanisms that are involved with repeat instability. This is because they recapitulate early molecular events as they happen *in vivo*. They can be induced to differentiate into a wide range of cell types, allowing the monitoring of repeat instability in diseased relevant cells that are otherwise inaccessible for research like heart muscle cells or post-mitotic neurons. In addition, there is no evidence for further repeat amplification beyond the range observed in somatic cell of patients. Thus far, only a limited number of reports dealing with repeat instability in pluripotent cells have been published. All are descriptive in nature. For example, by following CTG expansion size at the *DMPK* gene of DM1-affected HESC lines, it was possible to demonstrate a change in repeat tract heterogeneity along with time in culture^[121,122].

Furthermore, by inducing the cells to differentiate *in vitro*, instability was lost^[122], apparently contradicting observations *in vivo*^[123,124]. Nevertheless, it should be emphasized that tract-length heterogeneity within cell lines does not necessarily indicate that instability in fact exists, but rather proves that instability has occurred sometime before or during cell line growth in culture. This equally holds for CGG expansions at the *FMR1* locus, where repeat length heterogeneity is clearly observed in a large cohort of FXS HESC lines^[17,69]. Interestingly, in this case variations seem to be inversely correlated with CpG hypermethylation, a cis element that was formerly identified to constrain instability in FXS-affected fibroblasts^[125]. Indeed, CGG somatic instability has been shown to be largely restricted to early fetal development and to cease with epigenetic gene silencing of *FMR1*^[15]. In addition, as these cell lines are widely heterogeneous for expansion size and *FMR1* hypermethylation, it may indicate that differentiation by itself is irrelevant to the repression of repeat instability in FXS, as formerly suggested^[17]. It will be essential to generate single cell lineages from those FXS HESCs and monitor them for CGG repeat instability during growth *in vitro*, to unambiguously show that instability is, in fact, active in these cell cultures. Alternatively, it may be particularly useful to use patient iPS cells for these types of studies, considering the clonal origin of iPS cells. Two relevant examples for this application are C9/ALS-FTD iPS cells, where G₄C₂ tract size heterogeneity is evident both in undifferentiated and in *in vitro*-derived neurons^[51], and the GAA expansion at the frataxin gene in FRDA^[126,127]. On the other hand, the iPS based complimentary system should be cautiously tested before being adopted, as reprogramming may incorrectly enhance instability at repetitive loci as reported in FRDA iPS cells^[128].

Apart from monitoring repeat instability along with time or as a consequence of reprogramming/differentiation in culture, diseased pluripotent stem cells (HESCs or iPS cells) may provide an unusual opportunity to gain new insights into the mechanisms underlying this mutational event. For example, it was shown that when the mismatch repair proteins, including MSH2 and MSH6, are downregulated upon differentiation repeat instability is dramatically enhanced in DM1 (CTG), HD (CAG)^[122] and FRDA (GAA)^[126,128] pluripotent stem cells, suggesting that repeat instability is assigned to difficulties in DNA repair at these particular loci. This is in contrast to CGG somatic instability in FXS, where perturbations in DNA replication are assumed to be the underlying mechanism. In line with this perception is the study of Gerhardt and colleagues^[129], who employed the DNA combing methodology to associate CGG expansion with alterations in origin of replication (ORI) usage and rate of progression in undifferentiated FXS HESCs. Using a pair of FXS HESC lines, these researchers reported a difference in ORI usage ex-

clusive to undifferentiated FXS cells, proposing a switch in replication direction relative to the CGG repeats. According to their study, unlike in WT HESCs, replication proceeds predominantly from a downstream ORI in FXS HESCs, resulted in the replication of the CGGs by lagging strand synthesis (rather than by the leading strand) which favors expansions to occur. It remains to be determined whether the change in ORI usage in FXS HESCs is a cause or effect of the expansion, and whether it is mechanistically related to CGG somatic instability. The availability of a large cohort of FXS HESC lines that are diverse in their epigenetic state and CGG instability should help to address the aforementioned questions.

Lastly, it should be mentioned that while all of the aforementioned studies relate to the issue of somatic instability using mutant pluripotent stem cells, it should be most attractive to utilize the same systems in order to recapitulate germ-line instability and better understand why such disease associated repetitive sequences become increasingly unstable during germ-line transmission. This can be accomplished once efficient protocols for inducing HESC/iPS to differentiate into primordial germ cells and fully matured gametes will be available. Indeed, differentiation of ES cells into fully matured oocytes^[130] and the generation of viable offspring from these cells^[131] have already been accomplished in mice, paving the way for such studies to be carried out in human cells in the near future.

CONCLUDING REMARKS

HESCs are undifferentiated pluripotent cell lines with the potential for unrestricted self-renewal as well as the ability to differentiate into a wide range of cell types^[132-134]. They are established from *in vitro* fertilization (IVF)-derived embryos, and can be obtained from genetically affected embryos following PGD procedures. The derivation of HESCs directly from diseased embryos provides a powerful tool for disease modeling^[135,136] by affording the exploration of disease relevant tissues^[137,138] and/or developmental stages^[139] that are otherwise inaccessible for research. The main limitation of this approach is that it relies on the availability of genetically affected embryos, a valuable resource that is accessible to only a small number of stem cell deriving centers worldwide. In such cases, a complement model system may be employed which relies on the derivation of patient-derived iPS cells; ES-like cells that are established by somatic cell reprogramming of patients' cells in culture^[140]. The primary advantage of this alternative system is that it facilitates the establishment of pluripotent cell lines that share many features with HESCs and harbor the disease causing mutation/s without the need for affected embryos. As such, and although artificially induced, it has become the most common alternative for modeling human diseases in culture by many researchers^[16,141-146]. Nevertheless, iPS cells can be

useful only if the disease is not embryonic lethal, and if complete erasure of the epigenetic modifications that are normally gained with cell differentiation do not interfere with investigation of disease pathogenesis. It should be mentioned that both HESC and iPS cells have been reported to carry typical chromosomal aberrations resulting from culture adaptation^[147,148]. For this reason it is very important to perform routine characterization for chromosomal abnormalities in HESC and iPS cells lines.

The main benefits of both mutant HESC- and iPS-based model systems include the fact that they: (1) are human derived; (2) naturally carry disease causing mutations; (3) have the potential to differentiate into a wide range of cell types; (4) can self-renew without limitation while maintaining their undifferentiated and pluripotent potential; and (5) they mimic, to some extent, early embryo developmental stages as they spontaneously differentiate *in vitro* and *in vivo*. For all these reasons, they have become a commonly used model system for studying various disease associated mechanisms, particularly in cases where animal models do not authentically reproduce the affected human phenotype, or when the disease relevant cell types are unavailable for research.

In the context of disease causing unstable noncoding repeat expansions, which account for approximately half a dozen heritable conditions, the availability of mutant pluripotent stem cells is of particular importance. This is because most of these diseases are neuron-associated, restricting human-based research to a limited number of postmortem brain samples or to the use of disease irrelevant cell types. In addition, since noncoding expansions are hard to clone, it has been extremely difficult to artificially produce them in culture or to generate appropriate animal models^[149-153]. In general, pluripotent stem cells seem to reproduce many of the pathological features that are observed in noncoding repeat expansion disorder patient cells^[52,53,127,154-157]. Some of these features include nuclear RNA-protein foci, di-peptide cytoplasmic inclusions and hypermethylation. Therefore, stem cells are useful for basic research studies related to the different mechanisms that are involved with this group of disorders. By enlarging the number and repeat expansion heterogeneity of mutant stem cells cohort, we may gain new insights related to the underlying mechanisms that are associated with these pathologies early during embryo development. Once efficient differentiation protocols will be established, it will also be possible to generate large amounts of cells from affected tissues in culture. Studying cell types that are particularly vulnerable in these diseases will improve our understanding regarding the tissue specificity seen in patients. Moreover, such cells can be utilized for drug screening and development studies. Stem cells provide a convenient platform to genetically intervene with the molecular defect that is inherently found in the cells. Considering the recent advancements in the

Table 1 Modeling unstable noncoding repeat expansions repeat pathologies using pluripotent stem cells

Disease	Molecular mechanism	Ref.
DM1	Toxic RNA gain-of-function	[45,46]
C9/ALS-FTD		[47-49,51-53]
FXS	Reaped-mediated epigenetic modifications	[17,62,69,71-76,78]
C9/ALS-FTD		[52]
FSHD		[92]
C9/ALS-FTD	RAN translation	[51,53]
FXS	Repeat instability	[17,69,127]
C9/ALS-FTD		[51]
FDRA		[124-126]
DM1		[119,120]

DM1: Myotonic dystrophy 1; C9/ALS-FTD: C9 related amyotrophic lateral sclerosis and/or frontotemporal dementia; FXS: Fragile X-syndrome; FSHD: Facioscapulohumeral muscular dystrophy; FDRA: Friedreich ataxia.

field of artificially engineered nucleases (particularly the CRISPR/Cas9 system), it may be possible in the near future to insert, replace or remove repetitive DNA sequences from the genome of HESCs/iPS cells in a fairly uncomplicated procedure. This may hold a great promise for the development of new therapeutic approaches and hopefully will allow the ease, or even cure, pathologies resulting from unstable repeat expansions.

At present, mutant pluripotent stem cell lines are available for FXS, FXTAS, DM1, FRDA, C9/ALS-FTD, FSHD, and FRDA (Table 1). Most of these cell lines have been utilized for generating disease relevant cell types in order to validate the feasibility of the stem cell model system. In a few cases, where disease pathology is developmentally regulated, they have been particularly informative. For example, in FSHD stem cell lines facilitated the discovery of alternative polyadenylation signals responsible for the generation of toxic protein in a differentiation-dependent fashion^[94]. In the case of FXS, an mRNA-mediated mechanism that drives epigenetic *FMR1* gene silencing in affected neurons was uncovered in stem cells as well^[73]. In other cases, particular cellular phenotypes in differentiated stem cell-derived cultures have been monitored by effect of therapeutic agents or by defining proteins that are associated with pathological protein inclusions, as reported in C9/ALS iPS-derived neuronal cells^[52,53].

As a note of caution, it should be understood that the development of efficient stem cell differentiation protocols is not that straightforward. In particular, it can be quite challenging to use stem cells for the derivation of homogeneous cell populations that are functionally impaired. Moreover, molecular phenotypes in mutant pluripotent cells must be validated to see if they reproduce molecular events that are observed in diseased individuals. For example, despite all the benefits of iPS cells, investigators are becoming increasingly more aware of epigenetic instability in these cell types^[158-161]

as many iPSs wrongly acquire hypermethylation as a consequence of reprogramming^[78,162-164]. Accordingly, a comparison between mutant HESCs and patient-derived iPS cells will be essential in future investigations of the epigenetic aspects of repeat expansion diseases especially because many mechanistic questions still remain to be addressed in this area. Unanswered questions in the field include what molecular events lead to hypermethylation of repeat expansions? What pathogenic role do nuclear riboprotein or cytoplasmic di-peptide inclusions have, and what are the proteins that are sequestered into these structures? What are the mechanisms that are responsible for germ-line and somatic repeat instability, and why does somatic instability differ according to patient age and by tissue-specificity among differing genomic loci? Given proper experimental conditions, the answers to these riveting questions may be waiting to be uncovered by stem cell-based model systems.

Abstract

Stem cells are pluripotent cells, having a property of differentiating into various types of cells of human body. Several studies have developed mesenchymal stem cells (MSCs) from various human tissues,

peripheral blood and body fluids. These cells are then characterized by cellular and molecular markers to understand their specific phenotypes. Dental pulp stem cells (DPSCs) are having a MSCs phenotype and they are differentiated into neuron, cardiomyocytes, chondrocytes, osteoblasts, liver cells and β cells of islet of pancreas. Thus, DPSCs have shown great potentiality to use in regenerative medicine for treatment of various human diseases including dental related problems. These cells can also be developed into induced pluripotent stem cells by incorporation of pluripotency markers and use for regenerative therapies of various diseases. The DPSCs are derived from various dental tissues such as human exfoliated deciduous teeth, apical papilla, periodontal ligament and dental follicle tissue. This review will overview the information about isolation, cellular and molecular characterization and differentiation of DPSCs into various types of human cells and thus these cells have important applications in regenerative therapies for various diseases. This review will be most useful for postgraduate dental students as well as scientists working in the field of oral pathology and oral medicine.

Key words: Human dental pulp stem cells; Mesenchymal stem cells; Dentin; Pluripotency; Stem cell therapy; Molecular markers

INTRODUCTION

Stem cells are unspecialized cells having a property of self renewal and further differentiate into various types of specialized cells^[1]. Stem Cells are identified in a number of adult tissues including skin, adipose tissues^[2], peripheral blood^[3,4], bone marrow, pancreas, intestine, brain, hair follicles, as well as in the dental pulp cells^[5-7]. Stem cell research has expanded well due to their usefulness in regenerative therapies for improving the life of patients suffering from various genetical and neurological diseases. Studies have shown that the dental pulp tissue can also be used to derive mesenchymal stem cells (MSCs) when tissue is grown in culture^[7]. These MSCs can differentiate into several cell types as shown in Table 1. In year 2012, Shinya Yamanaka and John Gurdon have won Noble prize award for their excellent work on induced pluripotent stem cells (iPSCs) derived from adult somatic cells. This work has resulted into development of innovated technology to make an iPSCs from individual patient who needs treatment for specific disease. It is proposed that dental pulp stem cells (DPSCs) can develop iPSCs which can be used for therapies of various diseases^[8]. This review is mainly highlighting the importance of DPSCs, their isolation, characterization by cellular and molecular markers, differentiation and their applications in treatment of various diseases.

MSCs

MSCs are derived from any part of human body tissues or cells. They have a property of self-renew and differentiation into specific functional cell types as described before^[9]. MSCs are useful cells due to their therapeutic potentiality^[9,10]. Even though they are not immortal, they grow very well in culture and maintain their pluripotency property. MSCs are identified by their positive expression of *CD105* (SH2) and *CD13* (SH3/4) and *CD73* genes and are negative for the hematopoietic markers such as CD34 and CD45. Animal experimentation has shown that MSCs has migratory property and can reach to the site of injury. Light or phase contrast microscopy studies have shown that MSCs are elongated cells and look like fibroblast cells as shown in Figure 1. After subculture, MSCs exhibit a high expansion potential without loosing their normal karyotype and telomerase activity^[10-12].

As MSCs are derived from adult tissues, there is no

ethical concern required to use these cells for human therapies. Similarly, they have low immunogenicity and therefore they are promising candidates for regenerative therapies. *In vitro* differentiation of MSCs is mainly dependent on presence of growth factors and cytokines in growth medium. Bone marrow (BM) has been considered as the main source of MSCs, however, collection of BM from patient is a painful and invasive procedure. Therefore, there is a need to find out other sources of tissues which are non invasive and can give similar types of MSCs. Several investigators are presently testing adipose tissue derived stem cells and DPSCs for this purpose. Now it is already established that both these cells have same renewal and differentiating properties of BM cells and thus, these cells can be used for future regenerative therapies of various diseases^[12].

DPSCs

Dental Pulp tissue is extracted from the teeth recovered during routine dental procedure throughout the life and these teeth are the most convenient and valuable source of DPSCs which are well characterized as a MSCs as shown in Figure 1.

It is a non invasive process of extraction of MSCs from dental pulp tissue. DPSCs can be cryopreserved and revived whenever; they are needed for future regenerative therapies^[13]. Some of the diseases which are being cured by DPSCs include type 1 diabetes, neurological diseases, Immunodeficiency diseases and diseases of bone and cartilages^[14-16].

During the development of teeth, there is an interaction between epithelial cells of dental pulp which lead to the differentiation of ameloblasts and odontoblasts, resulting into deposition of specialized mineralized matrices, *i.e.*, enamel and dentin respectively^[17]. The inner area of dental pulp chamber contains a highly proliferative stem/progenitor cells possessing a self-renewal and differentiation properties^[17]. It has been shown that after teeth eruption, there is an induction of reparative dentin formation which protects dental pulp from further degradation^[17]. MSCs constitutes a heterogeneous population of cells which are found first in BM and later in multiple tissues like adipose tissue^[2,12], skin^[18], cartilage, umbilical cord^[19], placenta^[20,21], and now in dental pulp^[13,16]. As DPSCs have comparable therapeutic potential similar to BMMSCs, DPSCs is another alternative noninvasive source to be used for future regenerative therapies^[22].

DPSCs or stem cells from human exfoliated deciduous teeth (SHED) cells require a longer time for initial colony formation than other somatic cells^[23]. Third molar teeth derived cells differentiate into odontoblasts and secrete 3 D like crystal structure *in vitro*. Figure 2 shows calcium phosphate crystals secreted from DPSCs cells in culture experiment from my laboratory.

Table 1 Normal differentiation pathways of adult stem cells from various tissues and cells

Stem cell	Source	Types of cells produced
Hematopoietic	All types of blood cells	Red blood cells, B lymphocytes, T lymphocytes, natural killer cells, neutrophils, basophils, eosinophils, monocytes, macrophages and platelets
Bone marrow Stromal cells (mesenchymal)	Connective tissues	Tendons, osteocytes (bone cells), adipocytes (fat cells), chondrocytes (cartilage cells)
Neural	Parts of the nervous system	Neurons, astrocytes and oligodendrocytes
Epithelial	Lining of the digestive tract	Absorptive cells, goblet cells, paneth cells and endocrine cells
Epidermal	Basal layer of epidermis	Keratinocytes and dermal cells

It has been shown that DPSCs can be differentiated by modulation with growth factors, transcriptional factors, extracellular matrix proteins and receptor molecules into different cell types include odontoblast, osteoblast, chondrocyte, cardiomyocytes, neuron cells, adipocyte, corneal epithelial cell, melanoma cell and insulin secreting Beta cells^[24].

DPSCs usually remain quiescent when they are within the dental pulps, but respond quickly after injury. These DPSCs have a high proliferative capacity and immediately differentiate into odontoblasts, osteoblasts, and chondrocytes to produce dentin, bone, and cartilage tissues respectively for this repair process. It has been shown that the potentiality of

DPSCs differentiation into odontoblasts reduced after passage 9 and they can only differentiate into osteoblast cells^[24,25]. DPSCs are mostly derived from cranial neural crest cells because they expressed GFAP, HNK-1, Nestin, P75 and S-100 which are neural crest-stem cell markers^[26]. Our recent studies on DPSCs have shown the differentiation of DPSCs into neuron like cells, cardiomyocytes, adipocytes and insulin secreting beta cells as shown in Figures 3 and 4.

Almushayt *et al.*^[26] have confirmed the expression of odontoblast specific markers and presence of collagenous matrix and calcified deposits in DPSCs to show that these cells differentiate into odontoblast and form dentin material. Mokry *et al.*^[27] have

Figure 3 Differentiation of Dental pulp stem cells into neuron like cells and cardiomyocytes (Dr. Potdar's Laboratory). DPSCs: Dental pulp stem cells.

Figure 4 Differentiation of Dental pulp stem cells into adipocytes and insulin secreting beta cells. DPSCs: Dental pulp stem cells.

shown that due to telomere attrition, human DPSCs have shown extensive cell proliferation *in vitro* but progressive shortening of telomere length diminishes transplantation capacity of DPSCs and therefore these cells are less suitable for therapeutic applications. They have further proposed that the determination of telomere length and age of these stem cells are as important biomarkers to be assessed before utilization of these cells for regenerative therapies^[27]. Smith *et al.*^[28] have further shown that molecular signaling is responsible for the differentiation of DPSCs into odontoblast-like cells for reparative dentinogenesis. Therefore, determination of the molecules, responsible for signaling their DPSCs differentiation, may provide a powerful tool for the clinicians to evaluate a regenerative response of these cells appropriately for their application in regenerative therapies^[28]. d' Aquino *et al.*^[29] have shown that human DPSCs can co-differentiate into osteoblasts and endotheliocytes and form adult bone tissue after transplantation *in vivo*. This suggests an interesting area for development of three-dimensional tissue scaffold for reconstructing bone tissue engineering using DPSCs in dental disorder^[29]. Further it has shown that DPSCs and SHEDs are differentiated into neuron like cells and also shown expression of Nestin as a confirmation of this differentiation. These cells also have constitutive expression of Nestin^[30]. Thus, DPSCs have high potential to serve as a good resource for treatment in

neurodegenerative diseases^[31].

Human DPSCs which are grown by explant culture method have better proliferative capacity and also differentiate into various cell types *in vitro*^[32]. Recent study by Paino *et al.*^[33] have shown that DPSCs spontaneously differentiate *in vitro* toward the melanocytic lineage too. However, SHEDs differ from DPSCs with respect to their growth rate and their property to differentiate *in vivo*^[34]. Similarly, DPSCs have shown the greatest potential to produce a high volume of mineralized matrix suggesting that these cells also show promise for use in regenerative dental therapies^[35].

Stem cells from human exfoliated deciduous teeth

Stem cells can be isolated from the pulp of human exfoliated deciduous teeth. These cells induce bone formation and differentiate into other non-dental mesenchymal cells *in vitro*. SHED have higher proliferation rates, form a sphere-like clusters and differentiate into osteoblasts but they are not able to regenerate complete dentin and pulp-like complexes *in vivo*. These cells can repair calvarial defects in mice due to their ability to differentiate into osteoblasts. SHED secretes neurotrophic factor for repair of motor neurons following dental injury and therefore it has proposed that SHED can be useful for the treatment of neurodegenerative diseases^[23]. Jeon *et al.*^[36] have shown differences in *in vitro* and *in vivo* characteristics

of SHED isolated *via* enzymatic disaggregation (SHED) and outgrowth (o-SHED) by primary culture method. SHEDs have stemness characteristics, but o-SHEDs are mainly suitable for bone tissue regeneration therapy.

Stem cells from apical papilla

Stem cells from apical papilla (SCAP) are the cells which are found at the tooth root apex. They have higher proliferation rates as well as have a differentiation property *in vitro* similar to DPSCs. They are capable of differentiating into odontoblast cells and produce dentin *in vivo*^[23]. Due to their higher proliferative potential, SCAPs are also suitable for cell-based therapy for formation of apex roots. White Mineral Trioxide Aggregate (WMTA) is a capping material has a property to differentiate SCAPs into osteoblast cells and thus SCAPs are involved in this regenerative process. WMTA significantly increase the proliferation of SCAPs within 1-5 d whereas, calcium-enriched medium take 7 d to proliferate these cells. SCAPs migrate and proliferate steadily in the presence of 2% and 10% FBS. Thus, this data suggests that WMTA induces early migration and proliferation of SCAPs as compared with late induction by calcium chloride or fetal bovine serum (FBS)^[37].

Periodontal ligament stem cells

Human periodontal ligament stem cells (PDLSCs) can differentiate into cementoblast-like cells. They also have a capacity to form connective tissue which is riched in collagen I fiber. Human PDLSCs when seeded on 3D scaffolds such as fibrin sponge, generate bone *in vivo* and retain stem cell properties and tissue regeneration capacity^[23]. It has further been shown that Proteasome inhibitor, Bortezomib has a property of inducing differentiation of PDLSCs into osteoblasts. The main mechanism involved behind this is the mineralization of PDLSCs cells by accumulation of β catenin and significant expression of *BMP2* gene. Thus, it is clear that the Bortezomib plays important role in periodontal regenerative therapy^[38].

Dental follicle precursor cells

Dental follicle precursor cells (DFPCs) are derived from dental follicle tissue which is a loose connective tissue that surrounds the developing tooth. These cells have an ability to produce bone and cementum. Therefore, these stem cells have great potentiality to use in periodontal and bone regeneration therapies. DFPCs derived from human third molars teeth are rapidly attached to the culture plates and form a calcified nodules. They also exhibits a better plasticity than other dental stem cells^[39]. Dental pulp and dental follicle stem cells have similar mesenchymal stem cell characteristics, but DFPCs are easily accessible for cell culture and have a higher proliferation capacity

than DPSCs. Therefore it appears that DFPCs might have more advantages as a stem cell resource for regenerative therapies in dental abnormalities^[40].

ISOLATION OF DPSCs

Several investigators have described various methods for isolation of stem cells from human dental pulp. Raoof *et al*^[41] have used three different methods for isolation of DPSCs from dental pulp tissue: (1) Dental pulp tissue is digested with collagenase or dispase enzyme and isolated trypsinised cells are plated in culture dishes; (2) They have explanted undigested dental pulp small tissue pieces directly to petridishes; and (3) Dental pulp tissues are initially trypsinised and then small tissue pieces are explanted to petridishes for their outgrowth. They have grown these cultures in Minimum Essential Medium (MEM) supplemented with 20% FBS at 37 °C with 5% CO₂ and 90% humidity in CO₂ incubator. They have recommended the third method for isolation of DPSCs from dental pulp. This method gives better cell outgrowth with achieving confluency at 60% within 2 d of culture. They have further checked the pluripotency of these cells by studying the expression of Nanog, OCT-4, and Nucleotoxin markers by RT/PCR analysis. Thus, this study proposes the third method for obtaining better DPSCs with high efficacy in a short time^[41].

Lindemann *et al*^[42] have evaluated the effect of cryopreservation on DPSCs characteristics. They have isolated dental pulp cells from 7-d old non-cryopreserved and cryopreserved human deciduous teeth and culture them simultaneously. They found that there is no change in differentiating and immunophenotype properties of both these cells. There is a change in the morphology, proliferative capacity of cryopreserved cells than non- cryopreserved cells^[42].

Successful and efficient cryopreservation of living cells and organs is a key clinical application of regenerative medicine. Recently, Lin *et al*^[43] 2014 have reported magnetic cryopreservation for intact tooth banking and dental tissue. Human DPSCs isolated from extracted teeth are frozen and then stored at -196 °C for 24 h. During freezing, the cells are suspended in freezing media containing 10% DMSO. The results have shown that when the freezing medium is DMSO-free, the survival rates of revived DPSCs increase by 2 to 2.5-folds^[43]. Gioventù *et al*^[44] have developed a new method of cryopreservation of whole dental pulp by using laser beam. They have studied 4 human deciduous whole teeth, cryopreserved by making micro-channels into the tooth with the help of laser beam and then preserve these cells at -80 °C. This method saves a time in isolating DPSCs before cryopreservation and thus reduces the initial costs and workload of tooth banking. The DPSCs cells isolated by this method have shown normal morphology, cell

Figure 5 Mesenchymal stem cell markers in dental pulp stem cells.

viability and proliferation rate as well as maintain normal mesenchymal phenotype, similar to those of cells isolated from fresh non-cryopreserved teeth. They have further shown that DPSCs isolated without laser piercing have significant loss of cell viability and proliferation rate as compared to teeth cryopreserved by leaser piercing. Thus, this data has suggested the use of Gioventù *et al.*^[44] method for whole tooth banking.

MOLECULAR MARKERS FOR DPSCs

Stem cell markers

Since completion of human genome project in year 2003, several molecular markers are established to identify specific cell type. Several investigators have already established many markers but there are few markers which tell us their phenotypes, pluripotency status and differentiating characteristics. Dental pulp cells also should be characterized by such types of markers, some of which are explained in next paragraph of this review.

Mesenchymal stem cell markers

The mesenchymal phenotypes of stem cells can be confirmed by using 3 major genes, CD105 is termed as Endoglin (ENG). This protein is a component of the Transforming Growth Factor β Receptor Complex having high affinity in binding to TGF β 1 and TGF β 3. Figure 5 shows the expression of CD105 in DPSCs suggesting it mesenchymal phenotype.

It has been reported that there is a significant decrease in expression of *CD105* gene in differentiated osteoblasts, chondrocytes, adipocytes. Therefore there is a need to check for expression of *CD105* gene before use of these stem cells for stem-cell therapy^[45,46]. CD13 is another marker which is termed as alanyl (membrane) aminopeptidase (ANPEP). This gene plays very important role in a causation of various types of leukemia or lymphoma^[15]. CD73 (Cluster of Differentiation 73) also known as ecto-5'-nucleotidase

or 5'-nucleotidase (5'-NT). This is an enzyme, which encodes *NT5E* gene^[27,36]. This enzyme is used as a marker of lymphocyte differentiation. Barry *et al.*^[47] (2001) have reported expression of CD73 on MSCs. In our study, we have shown that all three markers such as CD105, CD13 and CD73 are expressed in human dental pulp cells as shown in Figure 5.

Hematopoietic stem cell markers

Blood cells mainly expressed two important hematopoietic markers, *i.e.*, CD45 and CD34^[48,49]. CD45 is also called as a Protein Tyrosine Phosphatase, Receptor Type C (*PTPRC*) gene. CD34 is other marker specifically expressed on human hematopoietic progenitor cells. It is also termed as a *RP11-328D5.2* gene. It is a cell surface glycoprotein and functions as a cell-cell adhesive factor. It has function in attaching stem cells to extracellular matrix of bone marrow as well as it can attach directly to stromal cells also^[49].

Pluripotency markers

Stem cells are pluripotent cells and express 3 major genes such as OCT4, NANOG and SOX2. The official symbol of *OCT4* gene is POU5F1B. OCT4 is a transcriptional factor involved in early embryogenesis and very much essential for maintenance of pluripotency of stem cells. It is well established marker for confirming undifferentiated status of stem cells and always involved in self-renewal capability of undifferentiated stem cells^[50]. Study has already shown that gene knockdown of OCT 4 brings about differentiation of undifferentiated stem cells^[51]. NANOG is termed as NANOG homoeobox. It is a transcription factor and well involved in self-renewal capacity of undifferentiated stem cells. It maintains pluripotency property of stem cells. The cells with NANOG protein have an ability to form any cell type of three germ layers of human body^[52,53]. The third pluripotency gene is Sex determining region Ybox 2 (*SOX2*). It is also a transcription factor and maintains self-renew capacity of undifferentiated stem cells. This is a intronless gene and is involved in the regulation of

embryonic development^[54].

Differentiation markers

LIF gene is called as Leukemia Inhibitory Factor and involved in the induction of hematopoietic differentiation in normal and myeloid leukemia cells. It plays a role in immune tolerance at the maternal-fetal interface. LIF derives its name from its ability to induce the terminal differentiation of myeloid leukemic cells^[55]. The other differentiating marker is a Keratin18. It is a KAP protein which forms a matrix of keratin intermediate filaments of cell cytoskeleton structure. Keratin 8, Keratin 18, and keratin 19 are used as a marker for epithelial cells and differentiate from hematopoietic cells^[56].

Specific markers for DPSCs

Specific markers for Dental pulp cells have been well described by researchers^[57,58] 2013.

Dentin sialophosphoprotein (DSPP) and dentin matrix protein 1 (DMP1) are the markers of odontoblast differentiation^[58]. DSPP is a major non-collagenous dentin specific protein expressed and secreted by odontoblasts. It is an essential protein for normal tooth development^[58]. DMP1 is an another extracellular matrix protein which is involved in differentiation of DPSCs into odontoblasts. It is a member of the small integrin-binding ligand N-linked glycoprotein family and has a critical role for proper mineralization of bone and dentin. It plays a role in regulating expression of osteoblast-specific genes during osteoblast cell differentiation^[58]. Telomerase is another dental pulp marker, which is known to play key roles in understanding the differentiating status of DPSCs. It has been reported that undifferentiated DPSCs express high telomerase activity, whereas, it is gradually decreased in differentiated cells^[59]. This is an important marker to be taken into consideration while therapy of patients to know undifferentiated status of DPSCs for transplantation^[59]. Alkaline Phosphatase (ALP) is also one of the markers of differentiation of DPSCs and plays important role in formation of calcified tissue and extracellular matrix^[60]. Similarly, Osteopontin (OPN) is an earlier marker of osteogenic differentiation^[61] and Bone Sialoprotein (BSP) is one of the late markers of mineralized tissue differentiation^[62]. Recent studies by Yu *et al*^[24] has shown that STRO-1⁺ DPSCs can differentiate into odontoblasts to form dentin, osteoblasts to form bone and chondrocytes to form a cartilage tissue respectively. This suggests that STRO 1 can be used as a marker for understanding the differentiating potentiality of isolated DPSCs^[24].

DIFFERENTIATION OF DPSCs

Biodentine is a bioactive dentine substitute which is used in direct contact with pulp tissue. Luo *et al*^[63] have investigated the response of DPSCs to

Biodentine and shown that this material acts *via* 3 major signaling pathways to induce odontoblast differentiation in DPSCs. They have also shown that Biodentine significantly increases alkaline phosphates activity, OCN, DSPP, DMP1, and *BSP* gene expression and mineralized nodule formation. Hence they have concluded that Biodentine is a bioactive and biocompatible material capable of inducing odontoblast differentiation of DPSCs^[63].

Studies have shown that optimal mechanical compression brings about the induction of cell differentiation^[64]. Miyashita *et al*^[64] have shown that the optimal mechanical compression significantly increases expression of the odontoblast-specific markers, *i.e.*, DSPP in dental pulp cells *via* MAPK signaling pathways. This also results into the expression of the *BMP7* and *Wnt10a* genes^[64]. These transcription factors have been implicated in regulating the differentiation of odontoblasts from DPSCs but their regulatory role is not completely understood. New transcriptional factors involved in odontoblast differentiation of DPSCs are analyzed by using a Microarray analysis^[65]. Choi *et al*^[65] have also shown that DPSCs strongly express Bobby sox homolog (*BBX*) gene during odontoblast differentiation. This gene is also expressed by adult molar odontoblasts cells and other tissues of our body. So overall, it is suggested that *BBX* plays an important role during the odontoblast differentiation of human DPSCs.

Kim *et al*^[66] have cultured dental pulp cells on a conventional surface and nano-patterned surface. It has been shown that cell plated on nano-patterned surface are in linear arrangement as compared to cells plated on a conventional surface. Gene expression analysis also has shown that there is a significantly higher expression of *LPL* in the nano-patterned group than in the conventional group. Whereas, there is a higher expression of *RUNX2* gene in the conventional group than in the nano-patterned group. This study overall suggests that nano-patterned surface enhances adipogenic differentiation of hDPSCs, whereas, normal surface may inhibits osteogenic differentiation of these cells^[66,67].

APPLICATIONS OF DPSCs IN REGENERATIVE MEDICINE

Presently therapies for dental pulp degradation are done by conventional methods such as dental pulp capping or by root canal therapy. However, advancement in dental research, dental scientists are focusing on using some of the medical devices in dental tissue engineering and also can use potential dental cells, extracted from dental pulp of patient. They can use biocompatible material as direct capping agents that can supply growth factors or molecules to stimulate reparative dentin formation. As DPSCs cells

have property to differentiate into odontoblasts, these cells can be used directly for dental therapy as well as very well used as *in vitro* model system to evaluate or optimize newly developed bioactive materials for future dental therapy^[17]. Regenerative property of the pulp-dentin complex is mainly depending on formation of tertiary dentin, reactionary dentin and reparative dentin. There are two different approaches implemented in regeneration of dentin by the use of tissue engineering techniques^[17]. The first approach includes a device which can use as a filling material into a deep cavity of tooth with partial layer of dentin on top of the pulp. In this process, they used some growth factors or molecules that can form reparative dentin. The second approach is to put scaffold on open pulp along with odontoblast-like cells to grow on it. These cells will synthesis reparative dentin. This is somewhat difficult and challenging approach and is being studied extensively for curing dental disorders. It is a mandatory that the scaffold used for clinical application should have capacity to adhere the cells to the surface of this scaffold and should proliferate and differentiate these dental pulp cells into dentin forming odontoblasts. It is also essential to have a good mobility of these cells on this scaffold^[17]. Similarly after implantation, the scaffold should be replaced by regenerated tissue without alteration of volume and size of this scaffold material^[17].

DPSCs and Deciduous teeth stem cells (DTSCs) are being used as stem cells for regenerative therapies for bone related diseases and orthopedics surgeries^[68] because DPSCs and DTSCs can be differentiated into multiple cell types including bone cells such as osteoblast and chondrocytes^[68] as well as we can make iPSCs cells for these treatment. Similarly DPSCs can express neural markers and differentiate into functionally active neurons suggesting, the use of DPSCs in cell based therapy for neuronal disorders and in many cases of accidental brain injury^[23].

MSCs show different pluripotency *in vitro* depending on their source of origin, which suggests that they could behave differently *in vivo*. DPSCs constitute an alternative to BMSCs in the armamentarium for cardiac repair because DPSCs are able to repair infarcted myocardium, due to their ability to secrete proangiogenic factor. It has also been reported that cardiac repair seen with DPSCs is similar to repair seen by using BMSCs. Therefore, DPSCs is considered as a good source of stem cells for regenerative therapies of ischemic heart diseases^[69].

The clinical studies by d'Aquino *et al.*^[70] have shown the use of DPSCs cells in oro-maxillo-facial (OMF) bone repair. They have used DPSCs on collagen sponge's scaffolds which produces an effective bio-complex which can give an optimal support for regeneration of DPSCs cells for OMF bone repair. Thus autologous transplantation of DPSCs can be used in a low-risk and effective therapeutic strategy for the

repair of bone defects^[70].

Vasculogenesis is a potential treatment for ischemic heart disease and it is an exciting area of research in regenerative medicine. Iohara *et al.*^[71] has shown that side population (SP) of dental pulp cells has a property of Vasculogenesis. They have isolated a highly vasculogenic subfraction of SP cells from dental pulp which are positive for *CD31* and *CD146* genes. Thus they have further suggested that these SP cells are a new source of stem cells which stimulate angiogenesis/vasculogenesis in tissue and can be used in cell based treatment of ischemic heart diseases^[71]. Under steady condition, EphB/ephrin-B molecule restricts DPSCs cells for their attachment, migration and to maintain within their stem cell niche and thus Eph/ephrin interactions may contribute to the localization and maintenance of DPSCs within adult human teeth. Following injury, the mobilization of DPSCs to the dentine surfaces may be mediated by EphB/ephrin-B interactions within in the adult dental pulp tissue. Therefore this result suggests a role of EphB/ephrin-B molecule in dental pulp development and regeneration^[72].

In dentistry, replacement of damaged tooth by functional and living tooth is one of the most promising areas of research in dental therapy. Recent advances in biotechnology have encouraged researchers to explore the possibility of regenerating living teeth with functional properties by use of scaffold and DPSCs cells. It has been seen that dental implants require high-quality bone structures for their support and reconstruction of teeth in these patients without adequate bone support would be a major problem. Thus, Stem cell-mediated root regeneration technology along with clinical crown technology may be a promising approach for functional tooth restoration in these patients^[73].

TGPCs cells from the human third molar have high proliferation activity than MSCs isolated from bone marrow. These cells can be frozen and use as per need for auto graft in the process of regenerative medicine. Studies have shown that TGPCs cells can help to stop malignant progression to HCC in hepatitis patients receiving antiviral treatment^[74]. Fibroblastic Growth Factor (FGF) helps in enrichment of DPSCs cells in culture and may be useful for regenerative medicine. It has been shown that bFGF signaling is unconditionally required for maintenance of self-renewal and pluripotency of hESCs^[75,76]. The DPSCs cultured in the presence of bFGF may obtain more undifferentiated characteristics than those cultured in its absence^[75,76].

CLINICAL STATUS OF USES OF DPSCs IN CLINICAL STUDIES

DPSCs have been extensively used in clinical studies by various investigators. Nakashima *et al.*^[77] have examined the effect of growth/differentiation factor 11

(GDF11) on differentiation of dental pulp cells in animal model and shown that GDF11 can differentiate DPSCs into odontoblasts. The odontoblasts differentiation is further confirmed by studying the expression of *DSPP* gene. *GDF11* gene is a morphogen and has property of enhancing process of wound healing in dental pulp tissue. They have further shown that *in vivo* transfer of GDF11 stimulates reparative dentin formation during dental pulp wound healing. Therefore they have suggested that GDF11 can be used for gene therapy for endodontic treatments in dental pulp disorder^[77]. Recently Yang *et al.*^[78] have studied TGF- β signaling pathways in mesenchymal and epithelial dental stem cells and shown that TGF- β signaling in homeostasis of mesenchymal types dental cells is *via* Wnt signaling^[78]. In regenerative endodontic, it is believed that EDTA induces odontoblast differentiation by releasing growth factors from the dentin matrix. After 3 d of culture, both the cell density and fibronectin expression level are shown to be significantly higher in the EDTA-treated Dental pulp cells. However, after three weeks, EDTA treated DPSCs have shown higher expression of DSPP and DMP1 indicating role of EDTA in inducing cell attachment and differentiation of DPSCs into odontoblasts or osteoblasts. Thus, it suggests an importance role of EDTA in achieving successful outcomes in regenerative endodontics^[79].

Estrela *et al.*^[8] have shown that DPSCs are differentiated into active neuron like cells in culture condition as well as these cells have expressed neural marker Nestin. This clearly indicates that there is a great use of DPSCs in regenerative therapies in neurological disorder especially, when there is a brain injury^[23]. Periodontitis is a chronic inflammatory disease leading to alveolar bone destruction resulting into tooth loss due to infection with periodontopathogenic bacteria as well as some genetic or environmental factors. DPSCs are known to be potent immunomodulators and they can be very well suitable for tissue regeneration^[80]. Thus, DPSCs can improve treatment outcome by promoting bone regeneration in these patients when used in combination with conventional treatment modalities for this disorder^[80].

Last few decades, the management of facial defects has rapidly changed. This defect is mainly caused due to Loss of vertical alveolar bone height which gives a stability of dental implants in adult patients. At present, there is no cure for the loss of vertical alveolar bone height and scientists are trying to achieve optimal pre-implantological bone regeneration before placement of dental implant in these patients. Recently, it has been shown that stem cells isolated from the dental pulp, dental follicle, and periodontal ligament can be used to treat alveolar bone defects in humans^[81].

Amir *et al.*^[82] have shown that the Chitosan added in the growth medium significantly increase DPSCs metabolism within 7 to 14 d in culture. Chitosan is responsible to increase in the release of ALP hydrolytic

enzyme activity into the medium during the first week of culture resulting into proliferation and early osteogenic differentiation of DPSCs. However, it has been shown that mineralization remains unaffected by Chitosan treatment. Chitosan also has its role as a 3D scaffold for estrogenic cells differentiation *in vivo* and acts similarly as in *in vitro* condition^[82].

Regenerative endodontic is a replacement of diseased or missing tooth and traumatized dental pulp by new dental tissue or cells. Recently new protocol for management of these cases has been introduced. Shieh-zadeh *et al.*^[83] 2013 have studied 3 cases of necrotic or immature teeth with periradicular periodontitis with dental MSCs and they are successful in bone healing within 3-4 wk after treatment. They have also discussed the mechanism of bone healing process and development of formation of root end in this paper. The regenerative endodontic techniques involve combination of disinfection or debridement of infected root canal systems along with use of stem cells, scaffolds, and growth factors. The new protocol is possibly involved in combination of disinfection or debridement of infected root canal systems along with the use of stem cells, scaffolds, and growth factors to permit the revascularization of this pulp. Therefore they have suggested that dental stem cells can be used successfully for this type of regenerative endodontic^[83].

Human PDLSCs can differentiate into cementoblast-like cells. They also have a capacity to form connective tissue which is richer in collagen I fiber. Human PDLSCs when seeded on 3D scaffolds such as fibrin sponge, generate bone *in vivo* and retain stem cells differentiating properties^[23]. Recent study by Bright *et al.*^[84] have shown the use of PDLSCs for periodontal regenerative therapy. This evidence is proved with their latest experimentation of injecting PDLSCs into animal model system. They are successful in periodontal regeneration therapy and shown the formation of bone, cementum and connective tissue fibers in the animals treated with PDLSCs^[84]. They have further postulated that this regeneration process is not depending on any type of periodontal ligament defect. Exiting results of this study encourages scientists to go further with transplantation of PDLSCs for periodontal regeneration therapy in human after examining its efficacy, safety, feasibility in clinical trials.

FUTURE DIRECTIONS

The stem-cell-based tissue-engineering approaches are widely applied in establishing functional organs and tissues. Rapid progress in advancement in technology such as development of iPSCs has provided great hopes in regenerative therapies for various diseases. Liu *et al.*^[85] have previously reported that iPS could be an appealing stem cells source contributing to tooth regeneration. The application of iPS technology in

dental bioengineering for whole tooth regeneration is an interesting area for future work^[85]. Advancement in stem cell and scaffold technology, damaged or lost teeth can be replaced by the use of regenerative therapies. Similarly, discovery of iPSCs technology has revolutionized complete treatment protocols in the field of dentistry by using a concept of autologous transplantation^[86].

Now day, dentist can very well manage periodontal diseases by using stem cell and scaffold technology^[87,88]. However, making whole artificial tooth and periodontal frame work by this technology is a challenge for scientists working in the field dental regenerative therapies. It is now well established that most of the dental related problems can be treated by using DPSCs alone or in combination with scaffold technology^[88]. Similar to periodontal disorder, advancement in use of DPSCs have added advantage in the field of Endodontic where, we can develop human dental pulp in the laboratory. These outcomes provide evidence suggesting that it might be feasible to restore viability in a necrotic young permanent tooth by engineering a new dental pulp. The potential impact of such therapies is immense and may allow for the completion and reinforcement of the tooth structure by biological regeneration in near future^[89].

ACKNOWLEDGEMENTS

Authors are thankful to the management of Jaslok Hospital and Research Centre for providing the facilities for development of stem cell research laboratory and carrying out stem research in the field of DPSCs and other related disorders. I am also thankful to our staff and students of our laboratory for their technical support.

Abstract

Cardiovascular diseases (CVDs), which include all

diseases of the heart and circulation system, are the leading cause of deaths on the globally. During the development of CVDs, choric inflammatory, lipid metabolism disorder and endothelial dysfunction are widely recognized risk factors. Recently, the new treatment for CVDs that designed to regenerate the damaged myocardium and injured vascular endothelium and improve recovery by the use of stem cells, attracts more and more public attention. Histone deacetylases (HDACs) are a family of enzymes that remove acetyl groups from lysine residues of histone proteins allowing the histones to wrap the DNA more tightly and commonly known as epigenetic regulators of gene transcription. HDACs play indispensable roles in nearly all biological processes, such as transcriptional regulation, cell cycle progression and developmental events, and have originally shown to be involved in cancer and neurological diseases. HDACs are also found to play crucial roles in cardiovascular diseases by modulating vascular cell homeostasis (*e.g.*, proliferation, migration, and apoptosis of both ECs and SMCs). This review focuses on the roles of different members of HDACs and HDAC inhibitor on stem cell/ progenitor cell differentiation toward vascular cell lineages (endothelial cells, smooth muscle cells and Cardiomyocytes) and its potential therapeutics.

Key words: Histone deacetylases; Stem cell; Endothelial cell; Smooth muscle cell; Cardiovascular diseases

Core tip: Stem cell differentiation toward vascular cell lineages is an area of important active research at present. Histone deacetylases (HDACs) are found to play important roles in cardiovascular diseases. Through modulating the homeostasis of acetylation status in histone and non-histone proteins and regulating grow factor activities, HDACs participate in stem cell differentiation and vascular cell homeostasis. In this review we provide an update on the roles of HDACs

and HDAC inhibitors on stem cell differentiation toward vascular cell lineages.

INTRODUCTION

Cardiovascular diseases (CVDs) are the number one killer of human beings globally, which is a class of disorders of the heart and blood vessels. CVDs include all diseases of the heart and circulation system, including coronary heart disease, angina, heart attack, congenital heart disease and stroke. Coronary heart disease (angina and heart attack) and stroke may be caused by the same problem - atherosclerosis^[1].

Atherosclerosis is a chronic inflammation process marked with thickened artery wall as a result of invasion and accumulation of fatty material (called atheroma) inside arteries. During this process, the endothelium, as the major regulator of vascular homeostasis, shows a number of vasoprotective effects, such as vasodilation, suppression of smooth muscle cell growth, and inhibition of inflammatory responses^[2]. Accumulating evidence suggests that endothelial dysfunction is an early marker for atherosclerosis and can be detected and repaired prior to structural changes within the vessel wall^[3].

Normally the repairing treatments for injured vascular endothelium include physical exercise and drug treatments aimed at reducing cardiovascular risk factors, such as lowering cholesterol, antihypertensive therapy, smoking cessation and some regulator replacement strategies such as angiotensin-converting enzyme 2 inhibitor therapy, estrogen replacement therapy in postmenopausal women, supplementation with folic acid^[4]. Recently, a new therapeutic strategy, that designed to regenerate the damaged myocardium and injured vascular endothelium and improve recovery by the use of stem cells, attracts more and more public attention^[5]. Till now, there has not established a specific cell type to serve best the treatment of CVDs. Many stem cell types such as embryonic stem cells (ESCs), adult stem cells and induced pluripotent stem cells have the ability to differentiate into vascular cell lineages *in vitro*.

Stem cell therapy is based on the stem cell characters, the potential to differentiate into specific cell types under different stimulation and proliferate to replace damaged cells with healthy functional ones^[6]. Like any biological process, the differentiation of stem cell involves gene expression reprogramming *via* histone acetylation homeostasis mediated chromatin

remodelling. Histone deacetylases (HDACs) are key components of the regulating system that controls histone acetylation homeostasis. HDACs play an essential role in multiple biology processes regulating cell survival, proliferation and apoptosis *via* histone and non-histone protein modification. Accumulating evidence showed that HDACs play an important role in vascular remodelling^[7].

HDACS

Histone acetylation is a reversible process characterized by histone and non-histone protein acetyl-transferase transferring the acetyl moiety from acetyl co-enzyme A to lysine residues. HDACs are a family of enzymes that remove acetyl groups from the N-acetylated lysine residues on histones^[8] and non-histone proteins. Histone acetylation/ deacetylation alters chromosome structure and affects transcription factors access to DNA^[9]. Accumulating evidence indicates that HDACs play a fundamental role in transcriptional regulation, cell cycle progression, and contribute to developmental events.

Mammalian genome encodes 18 HDACs, which can be grouped into four classes based on the homology with yeast histone deacetylases^[10]. All members share a highly conserved deacetylase domain but differ in structure, subcellular localization and expression pattern, which results in different cellular functions^[11]. Class I HDACs (homologous to yeast Rpd3) comprise of HDAC1, -2, -3 and -8, which are widely expressed in many human tissues and cell lines. Among them both HDAC3 and HDAC8 can shuttle between the cytosol and the nucleus, while HDAC1 and HDAC2 are exclusively located in nucleus^[12,13]. The deacetylation of histones to repress gene transcription is the main function of class I HDACs. Class I HDACs form large multi-subunit complex that associates with transcription factors and other chromatin modifiers, except HDAC8 whose function is not clearly clarified^[14]. In mammals, HDAC1 and -2 can bind to each other forming the catalytic core of three different complexes: Sin3, nucleosome remodelling deacetylase and corepressor of RE1-silencing transcription factor. HDAC3 can form two different multi-protein complexes, nuclear receptor corepressor and silencing mediator of retinoic acid and thyroid hormone receptors. Class I HDACs are mainly found in such nuclear complexes. Furthermore, the association with several different proteins show an essential role in regulating their activity, which is highly pronounced in developmental processes that requires a global modulation of transcriptional programmes. With the exception of HDAC8, knockout of class I HDACs in mice have indeed resulted in embryonic lethality^[15].

Class II HDACs can be divided into two sub-class groups. Class II a members include HDAC4, -5, -7, -9, while class II b comprises of HDAC6 and -10. Class II HDACs differ from Class I mainly for their tissue-

specific expression pattern and the considerable lower deacetylase activity. Besides, their length (almost the double of Class I HDACs) and cellular localization are all different. Class II HDACs can shuttle between nucleus and cytoplasm. Class IIa HDACs have conserved binding sites for the transcription factor myocyte enhancer factor 2 and the chaperone protein 14-3-3, which help HDACs shuttle from the nucleus to the cytoplasm. The nuclear-cytoplasm shuttling and occurrence of post-translational modification such as phosphorylation, indicates their primary role as signal transducers in numerous tissues during development and disease^[16].

Class IIb family includes HDAC6 and HDAC10. HDAC10 presents a leucine-rich domain at the C-terminal. Recent reports showed HDAC10 might be upregulated on human myeloma cell lines^[17]. HDAC6 is different from all other HDACs, as it harbours two deacetylase domains and a C-terminal zinc finger, being the important cytoplasmic deacetylase in mammalian cells^[18]. Cytoskeletal proteins such as α -tubulin and cortactin, transmembrane proteins such as the interferon- α receptor, and chaperones are all targets of HDAC6^[19,20].

Class III HDACs comprises a group of protein called Sirtuins (SIRT1-7). Although they possess a deacetylase domain, they diverge from classical HDACs as their enzymatic activity requires the cofactor NAD⁺. This feature suggests their involvement in metabolic functions^[21]. HDAC11 is the last discovered and the only member of Class IV HDACs^[22]. This review will focus on the classical HDACs, class I and II HDACs. The protein length, cellular location and potential cellular functions of these HDACs can be referred to references^[11,23].

HDACS AND ENDOTHELIAL CELL DIFFERENTIATION

In response to vascular injury, endothelial cell (EC) migration and proliferation contribute to the repairing of the damaged EC or denuded endothelium. Recent reports show that circulating or local resident stem/progenitor cell differentiation is also involved in this process^[24]. Through modulating chromatin structures and non-histone transcription factors, HDACs are involved in the gene expression reprogramming in multiple biological processes such as cell-cycle, cell differentiation and survival^[25]. Therefore, the involvement of HDACs in EC differentiation is expected.

The first evidence came from studies with HDAC inhibitors (HDACi). HDACi decreases endothelial lineage commitment of endothelial progenitor cells^[26,27]. Rössig *et al.*^[27] found that the suppressive effect of HDACi on EC differentiation was mediated by the down-regulation of homeobox transcription factor HoxA9, which directs the transcription of EC markers such as eNOS, VEGFR2 and VE-cadherin, suggesting that the

HDAC-dependent activation of Hox-A9 is essential for EC differentiation^[27].

There is no direct evidence that HDAC1, 2 and 8 are involved in EC differentiation, although indirect evidence indicates that HDAC1 may suppress EC differentiation. Rajasingh *et al.*^[28] showed that HDACs inhibitor, trichostatin A, improved AceH3K9 and reduced HDAC1 expression in bone marrow progenitor cells, leading to differentiation into myocytes and ECs, which suggests that HDAC1 plays a suppressive role in bone marrow progenitor cell differentiation toward EC lineage^[28]. Different from other members within class I HDACs, accumulating evidence suggests that HDAC3 possesses a pivotal function in stem cells differentiation into ECs, which is capable of repairing the damaged endothelium. VEGF is a well-known EC differentiation inducer. Xiao *et al.*^[29] reported that VEGF up-regulated HDAC3 in ESC-derived Sca1⁺ cells. Over-expression of HDAC3 *via* adenoviral gene transfer increased, while trichostatin A or HDAC3 siRNA abolished VEGF-induced EC marker expression in Sca1⁺ cells, suggesting HDAC3 may function downstream of VEGF signal pathway^[29]. Our study^[29] and reports from Illi B^[30] demonstrated that laminar flow enhanced ESC-derived progenitor cell differentiation into EC lineage in an HDAC dependent manner. We found that laminar flow stabilized and activated HDAC3 through the Flk-1-PI3K-Akt pathway in a ligand independent manner, which in turn deacetylated p53, leading to p21 activation, contributing to EC differentiation^[31]. Similar mechanism is involved in VEGF-induced EC differentiation, in which HDAC3 modulates differentiation process *via* regulating non-histone proteins. Our recent study found that unconventional splicing of HDAC3 might change HDAC3 function, inducing endothelial-to-mesenchymal transition^[32]. These reports suggest a critical role of HDAC3 in EC fate determination.

Class II HDACs seem not directly involved in EC differentiation. Several groups tried to link class II HDACs with EC differentiation, but no solid evidence has been obtained. In Spallotta *et al.*^[33,34]'s reports, nitric oxide induced a cross-talk between class I HDACs (HDAC3) and class II HDACs (HDAC4 and 7), which might contribute to the neovascularization in ischemic tissue and skin repairing^[33,34]. However, the effect of nitric oxide on EC differentiation may be largely derived from HDACs-mediated global hypoacetylation on pluripotency maintaining genes like Oct4, Nanog, KLF4, *etc.* Considering class II HDACs have only weak deacetylase activity, the histone hypoacetylation might be mainly caused by HDAC3 in the complex. Reports from other groups indicate that HDAC7 may participate in EC proliferation and cell-to-cell contact but is not involved in EC differentiation^[35,36]. A recent report from Song *et al.*^[37] showed that AMPK activation participated in endothelial colony forming cells differentiation. During this process, HDAC5 could be phosphorylated by AMPK. However, there is no direct evidence on the involvement of HDAC5.

HDACS AND SMOOTH MUSCLE CELL DIFFERENTIATION

Smooth muscle cells (SMCs) are the major cellular components within vessel wall, located in the tunica media controlling the calibre of the vessel. It is widely believed that in response to vascular injury SMCs in the tunica media undergo from contractile to synthetic phenotype change, followed by the migration into the intima and proliferation, contributing to the neointima formation. However, recent reports show that stem/progenitor cell-derived SMCs play an important role in neointima formation and atherosclerosis, but the origin of the progenitor cells is controversial. Reports from Shimizu *et al.*^[38], Han *et al.*^[39] and Li *et al.*^[40] support the notion that the circulating bone-marrow-derived progenitor cells contribute to SMC differentiation and neointima formation, but reports from Hu *et al.*^[41] and Tang *et al.*^[42] exclude the involvement of bone marrow-derived progenitor cells. They demonstrated that SMCs in the lesion area were mainly derived from local resident progenitor cells.

HDACs play diverse roles in SMC differentiation depending on the HDAC species, stem cell source and stimulus, exerting promoting or suppressive effects. Except HDAC1, all other three members of class I HDACs are reported to be involved in SMC differentiation. In response to oxidized lipids or PDGF, HDAC2 forms a complex with Class II HDACs (HDAC4/5) to deacetylate histone H4 in SMC marker gene promoter region, thereby suppressing SMC differentiation^[43,44]. Recently, Liu *et al.*^[45] reported that HDAC2 exerted suppressive effect on bone marrow mesenchymal stem cells to SMCs differentiation^[45]. In contrast, HDAC3 and 8 may play a positive role in SMC differentiation. Loss of HDAC3 in neural crest caused deficiency of aortic arch artery SMCs in midgestation during embryonic development *via* down-regulation of Notch signalling, suggesting a positive regulatory role of HDAC3 in the neural crest-derived smooth muscle lineage^[46]. Several reports demonstrate that HDAC8 is critical for SMC differentiation, therefore HDAC8 is even regarded as a novel SMC differentiation marker^[13,47,48]. The involvement of class II HDACs in SMC differentiation seems restricted to HDAC4, 5 and 7. Different from the suppressive role of HDAC4 and 5 from the reports by Yoshida *et al.*^[43,44], studies from Glenisson *et al.*^[49] revealed that HDAC4 is necessary for SMC marker expression in TGFβ1-induced myofibroblast differentiation^[49]. Our group found that different isoforms of HDAC7 might play opposite function in SMC differentiation. During ESC differentiation toward SMC lineage, HDAC7 mRNA underwent further splicing, which was enhanced by PDGF. The full spliced HDAC7 increased SMC marker expression through modulating the SRF-myocardin complex while the partially spliced HDAC7 decreased SMC marker expression by degrading myocyte enhancer factor 2C^[50].

HDACS AND CARDIOMYOCYTES DIFFERENTIATION

Cardiomyocytes (CMs) build the atria and ventricles of the heart, which are critical to the proper form during the beating of the heart. So the differentiation towards CMs is a prerequisite and an essential part of heart development^[51].

The effect of class I HDACs on CM differentiation seems a bit controversial, especially on HDAC1. Opposite effect of HDAC1 on CM differentiation has been reported by different groups. Dovey *et al.*^[52] reported that HDAC1 deficiency in ESCs increases CM marker expression in the embryoid bodies, suggesting a suppressive role of HDAC1 in CM differentiation. Lu *et al.*^[53,54] also reported that HDAC1 exerted negative effect on cardiac cell differentiation from mesenchymal stem cells under a myocardial microenvironment. The suppressive role of HDAC1 was further supported by Liu *et al.*^[55] as down-regulation of HDAC1 promoted cardiac cell differentiation. However, Hoxha *et al.*^[56,57] reported that HDAC1 knockdown decreased CMs marker expression in ES and induced pluripotent stem cells, suggesting a supportive role in CMs differentiation. HDAC1 favours stem cell differentiation *via* turning off pluripotency genes by modulating histone acetylation and DNA methylation. HDAC2 may play a positive role in CM differentiation, contributing to angiotensin II-induced cardiac hypertrophy^[58]. In contrast, HDAC3 suppresses CM differentiation through modulating transcription factor Tbx5, preventing the pre-maturation of cardiac progenitor cells^[59].

Current reports revealed that Class II HDACs mainly played a suppressive role in CMs differentiation. The inhibition of HDAC4 facilitates c-kit(+) cardiac stem cells to differentiate into cardiac lineage, leading to cardiogenesis and the restoration of cardiac function in myocardial infarction mouse model^[60]. Ha *et al.*^[61] reported that retention of HDAC5 in nucleus suppressed cardiac foetal gene expression and CMs hypertrophy. Gene disruption studies from Chang *et al.*^[62] revealed that HDAC5 or 9 deficiency induced cardiac hypertrophy in mice.

Depending on the stem cell source and stimulus, different HDACs may play different roles in stem cell differentiation toward different cell lineages. HDACs and their potential roles in cardiovascular lineage commitment are summarized in Table 1. Different HDACs (HDAC1, 2, 3, 4, 5, 7, 8) play different roles in stem cell differentiation toward different cell lineages, HDACs and their potential roles in cardiovascular lineage (ECs, SMCs, CSCs) commitment are summarized in Table 1.

HDACS INHIBITORS

The role of HDACs in injured vessel repairing and stem/progenitor cell differentiation derived originally from

Table 1 Summary of histone deacetylases' effect on endothelial cell, smooth muscle cell and cardiomyocyte differentiation

Commitment	HDACs	Characterization	Ref.

investigations on HDACi, which are a large number of natural and synthetic compounds. Generally, HDACi can be divided into 4 classes according to their chemical structure: hydroxamic acids, short chain fatty acids, cyclic tetra-peptides, and benzamides^[63]. These HDACi share the presence of an active group targeting a three-part structure consisting of a zinc-binding group of HDACs and inhibits their enzymatic activity. Some HDACi are able to discriminate HDACs among different classes and a few of them can even inhibit a single member^[64,65]. In addition to suppress the deacetylase activity of HDACs, HDACi may exert functions in HDAC-independent way, like through SP1^[66]. HDACi has been shown to regulate multiple cellular processes, including cell apoptosis and survival, proliferation and growth arrest, senescence, differentiation, immunogenicity, *etc.* Some kinds of HDACi are used in clinical trials as therapeutic drug against cancers. Detailed information on this aspect won't be discussed in this review.

SUMMARY AND PERSPECTIVES

CVDs characterized by vascular injury are one of the greatest health challenges we have been facing for decades. During the development of CVDs,

HDACs play a critical role in various signal pathways by modulating vascular cell homeostasis (*e.g.*, proliferation, migration, and apoptosis of both ECs and SMCs) and stem cell differentiation towards vascular cells. HDAC3 and HDAC7 have been proved to be capable of directing stem cell differentiation towards ECs and SMCs respectively. Through modulating the homeostasis of acetylation status in histone and non-histone proteins and regulating grow factor activities, HDACs participate in stem cell differentiation and vascular cell homeostasis. Targeting HDACs activities and their inhibitors' effect on injured vessel and heart will undoubtedly provide new therapeutic strategies for the treatment of CVDs.

Abstract

Liver cirrhosis is characterized by distortion of liver architecture, necrosis of hepatocytes and regenerative nodules formation leading to cirrhosis. Various types of cell sources have been used for the management and treatment of decompensated liver cirrhosis.

Knowledge of stem cells has offered a new dimension for regenerative therapy and has been considered as one of the potential adjuvant treatment modality in patients with end stage liver diseases (ESLD). Human fetal hepatic progenitor cells are less immunogenic than adult ones. They are highly propagative and challenging to cryopreservation. In our earlier studies we have demonstrated that fetuses at 10-18 wk of gestation age contain a large number of actively dividing hepatic stem and progenitor cells which possess bi-potent nature having potential to differentiate into bile duct cells and mature hepatocytes. Hepatic stem cell therapy for the treatment of ESLD is in their early stage of the translation. The emerging technology of decellularization and recellularization might offer a significant platform for developing bioengineered personalized livers to come over the scarcity of desired number of donor organs for the treatment of ESLD. Despite these significant advancements long-term tracking of stem cells in human is the most important subject nowadays in order to answer several unsettles issues regarding the route of delivery, the choice of stem cell type(s), the cell number and the time-point of cell delivery for the treatment in a chronic setting. Answering to these questions will further contribute to the development of safer, noninvasive, and repeatable imaging modalities that could discover better cell therapeutic approaches from bench to bedside. Combinatorial approach of decellularization and nanotechnology could pave a way towards the better understanding in determination of cell fate post-transplantation.

Key words: Hepatic stem cells; Bioengineering; Liver cirrhosis; Labeling and tracking

© **The Author(s) 2015.** Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: Liver cirrhosis is characterized by distortion of liver architecture, necrosis of hepatocytes and regenerative nodules formation leading to cirrhosis. The

available treatment modalities are not very effective against liver cirrhosis. Stem cells are considered one of the potential adjuvant treatment modality in liver cirrhosis patients. Fetal hepatic stem cells transplantation in liver cirrhosis has emerged as an alternative to organ transplantation. However long-term stem cells labeling and tracking is needed for cell fate determination after transplantation. Decellularization technology provides a novel tool to develop bioengineered personalized livers to accomplish the shortage of donor livers.

INTRODUCTION

The liver is a central metabolic and highly specialized detoxifying organ. Approximate 70%-75% of liver functions are being carried out by the hepatocytes which together with cholangiocytes (5%-10% of hepatic cells) constitute the liver parenchyma. Liver regeneration is a very rapid and well synchronized phenomenon. Liver responds to initial injury compensating the loss of parenchymal mass. If damage perseveres commencement of petite terminal peri-portal oval cells activates which engross mobilization of several vital factors.

EVOLUTION OF CELL THERAPY AND PRECLINICAL INVESTIGATION

Various strategies have been explored to provide functional support to the fading liver. Hepatic cell transplantation has emerged as one of the alternative modality. The experimental data of hepatocyte transplantation in different animal models has proved its efficacy. In early 1980s hepatocyte transplantation in D-galactosamine induced acute liver failure (ALF) model showed survival rate of more than 60%^[1-4]. Different routes were used for delivery of cells like intraportal, intrasplenic and intraperitoneal. Intra-peritoneal cell transplantation was found to be more appropriate site for transplantation as large number of cells can be delivered and also provides better engraftment of infused cells^[5]. In view of larger number of cells required, Habibullah *et al*^[5], infused 6×10^6 hepatocytes according to body weight (per kg) in ALF animal model and observed > 60% survival post-transplantation.

CLINICAL INVESTIGATION OF HEPATOCYTES TRANSPLANTATION

After preclinical investigations in animal models, first

attempt of hepatocytes transplantation in human with liver cirrhosis was carried out by Mito *et al*^[6] which provided proof for functional benefits post-transplantation. This was a landmark study proving a new paradigm for shifting hepatocytes transplantation towards the clinical perception and further followed by studies from our centre. In our preliminary clinical study, human fetal hepatocytes were infused intra-peritoneally into seven ALF patients^[7]. The study have demonstrated beneficial effects in ALF patients with grade III and grade IV hepatic encephalopathy because transplanted hepatocytes by virtue of their synthetic, metabolic and detoxifying functions causes clinical and functional improvements. Several other studies have also provided evidence for active bridging of orthotropic liver transplantation in patients though post-transplantation of human hepatocytes^[8]. Besides this various other studies have also demonstrated the functional benefits using different other routes of cell transplantation^[1,3,5]. We performed a pioneer study by intra-peritoneal hepatocytes transplantation in a 26 year old pregnant patient having acute fatty liver to investigate the functional benefit after transplantation^[9]. This study demonstrated significant improvements after 2 d of hepatocytes transplantation and provided an alternative option of liver transplantation and new hope for the patients suffering with end stage liver failure. After this several other studies have been reported from various centers for hepatocytes transplantation in different types of metabolic disorders^[10,11]. However, transplantation of large number of human hepatocytes for adequate liver function remains a challenge before its wide clinical applications.

CHRONIC LIVER DISEASE (LIVER CIRRHOSIS)

This category has produced a large burden on the society and has been considered as more appropriate type for cell therapeutic approaches. Liver cirrhosis is being characterized by distortion of liver architecture, necrosis of hepatocytes and regenerative nodules formation leading to cirrhosis. Various types of cell sources have been applied for the management and treatment of decompensated liver cirrhosis.

HEPATIC STEM CELLS AND LIVER CIRRHOSIS

Discovery of stem cells has provided a new dimension for regenerative therapy and are considered one of the potential adjuvant treatment modality in patients with ESLD. With the knowledge of embryonic stem cells, the area of cell biology has revolutionized for its potential in regenerative medicine. It gave a new hope and opened a new area of cellular therapy. However, a variety of stem cell types have been identified from various sources, hepatic stem cells (HSCs) has been

potential therapeutic option for the treatment of liver cirrhosis. HSCs are able to give rise mature progenies and have self-renewing capacity. Several studies have demonstrated isolation of HSCs from adult tissues followed by *in vitro* proliferation and differentiation into functional hepatocytes^[12-14]. However, regeneration of diseased liver by human HSCs is still awaited.

Hepatic progenitor cells (HPCs) isolated from human fetal liver is less immunogenic, highly propagative and more challenging for cryopreservation than the adult ones. In our previous study we have demonstrated that fetuses at 10-18 wk of gestation age contain a large amount of dynamic HPCs which possess bi-potent nature giving rise to both hepatocytes and bile duct cells^[15]. Fetal liver stem cells has been identified as transition between embryonic cells and adult ones which is mostly non-teratogenic^[16]. During third trimester of fetal development, plasticity to form liver parenchyma cells makes fetal HSCs an excellent resource for cellular therapeutic approaches.

SOURCES OF STEM CELLS IN LIVER DISEASES

There are two major sources of stem cells (1) embryonic; and (2) adult which have been considered to have potential in the treatment of various types of diseases. However, fetal liver derived stem cells are the transition between embryonic and adult sources and have several advantages on these two sources. Fetal liver derived cells are also termed as hepatoblasts which appears after the specialization of liver endoderm and growing liver bud. Various types of adult stem cell sources have been investigated for their application in liver regeneration such as mesenchymal stem cells (MSCs) derived from umbilical cord blood/tissue and bone marrow, induced pluripotent cells derived from somatic cells. These extra-hepatic sources have been reported to provide trophic support in injured liver. They also induce the endogenous cell proliferation and survival under diseased environment. But the control of their lineage specificity and plasticity needs more investigation in order to apply them in clinical settings. In this regard, MSCs from bone marrow has already been recognized as major player in clinical regeneration and resolution of liver cirrhosis due to its immunomodulation and regenerative potential.

ISOLATION AND DEPICTION OF HUMAN HEPATIC PROGENITORS FROM FETAL LIVER

After obtaining a human fetus in better clinical form, isolation of cells is performed by two step collagenase digestion method as earlier described by Habibullah *et al.*^[7]. Cells within the fetal liver are generally well connected with intercellular links rooted in extracellular matrix (ECM) which is required to be destroyed

for single cell isolation either by mechanical or enzymatic dissociation. The human fetal liver cells thus isolated can be enriched further for specific progenitor cells using magnetic activated cell sorting (MACS) or fluorescence activated cell sorting (FACS). Enrichment can be done either based on cell size and density or based on cell surface/functional markers. Enriched human HPCs further need to be distinguished from biliary and mature hepatocytes^[17]. In our earlier studies human HPCs were first enriched with epithelial cell adhesion molecule (EpCAM) and further identified for the expression of cytokeratin-18; a marker for liver epithelium, cytokeratin-19; a biliary marker and finally albumin and alfa-feto protein for mature hepatocytes using Real-Time quantitative polymerase chain reaction and immunocytochemical (ICC) staining. These explanations were further supported by FACS results indicating positivity for above markers including CD49f, CD29, CD90 and CD34 and negative for CD45 and HLA class II.

IN VIVO DELIVERY OF CELLS WITHIN LIVER

Portal vein

Portal vein is the most often used route for the stem cell transplantation due to multiple vascular accesses. It is admitted either by trans-jugular or trans-hepatic percutaneous approach. However accessing this route by above approaches is difficult in the presence of ascites and has major risk of bleeding, diathesis and coagulopathy.

Accessing through hepatic artery

In our knowledge this is a more suitable route for cellular transplantation as compared to the portal vein^[17]. It is accessed through trans-radial, trans-femoral and trans-branchial approaches.

Splenic infusion

Intrasplenic approach has been suggested as better approach compared to the splenic arterial infusion of hepatocytes transplantation^[18]. A recent study has proved this concept where the fetal hepatocytes were transplanted via intrasplenic infusion through the splenic artery in a patient with end stage liver cirrhosis leading to the improvement in clinical conditions^[19]. The translocation of infused cells through intrasplenic injection has also been demonstrated where cells after infusion first reaches to the splenic veins and then to hepatic sinusoids^[20].

CLINICAL STUDIES OF HUMAN HEPATIC STEM/PROGENITOR CELL THERAPY

HSCs-based therapies for the treatment of ESLD are in their early stages of translation. We have done the pioneering studies using HSCs transplantation

Figure 1 Hepatic artery characterization using angiograph of patients post transplantation after 6 mo (A) and after 12 mo (B).

in the treatment of patients with inborn metabolic errors, liver cirrhosis, hepatitis B/C, and other liver disorders^[17,20]. We used EpCAM+ve enriched human HSCs from human fetal livers following the approach described by Schmelzer *et al.*^[14]. Remarkably no immune suppressant was required and recipient was not matched for histocompatibility antigens. All the patients with decompensated liver cirrhosis receiving HSCs transplantation through hepatic artery showed significant decrease ($P < 0.01$) in the mean Mayo-End stage Liver Disease (MELD) score and improvement in multiple diagnostics and biochemical parameters after six-months follow-up^[17]. After 6 mo to one year of HSCs post-transplantation angiogram analysis of the patients showed significant improvement in branching of hepatic arteries and veins (Figure 1).

Recently we accessed cellular immune response in 5 patients with decompensated liver cirrhosis after transplantation of human HPCs. The study showed marked clinical recovery with decline in the MELD score and there was no significant variation found in T-cell subpopulation (CD3, CD4, CD8 and CD4/CD8 ratio), natural killer cells and in serum cytokine levels between pre and post transplantation demonstrating the safety of EpCAM+ve HPCs transplantation for liver cirrhosis (Unpublished).

Future efforts to use human HSCs/HPCs clinically will be facilitated by production of cells at large-scale. The sourcing of donor cells may be fetal tissue in those countries that permits their use. The cells may be utilized as directly isolated, or after *in vitro* expansion.

IN VIVO TRACKING AND MONITORING OF TRANSPLANTED HEPATIC STEM/PROGENITOR CELLS

Since last few decades' vast developments have been made for the management of liver disease. However more investigations are desired to direct the better tissue imaging approaches to identify the fate of grafted cells. It is essential for better understanding of cell infusion routes, migration and efficacy of

desired cells post-transplantation. Currently various magnetic, fluorescence or radio imaging methods have been used to evaluate efficacy of transplanted cells. However, few of them have proved their prospective in clinical settings but majority of them are still in their preclinical phases of investigations.

Tracking the fate of transplanted cells is vital to monitor the delivery and viability of the grafts over extended time. It could be achieved by merging optimal molecular imaging methods with stem cells. Through advancements in experimental and molecular imaging technologies, it would provide heavy motivation to improvise the molecular imaging approaches for better understanding of the regenerative mechanisms involved in stem cells transplantation.

Molecular imaging

Stem cells labeling and tracking in human tissues/organs is the most important subject nowadays in order to answer several unsettled issues regarding the cell delivery routes, stem cell choice, number of cells to be infused and the time-point of cell delivery for the treatment in a chronic setting. Answering to these questions will further contribute to the development of safer, non-invasive, and repeatable imaging modalities that could discover better cell therapeutic approaches from bench to bed-side. Long-term monitoring of transplanted stem cells continuously with high temporal resolution and good biocompatibility will allow us to better understand the precise regeneration mechanisms in different organs. Nanobiotechnology has emerged as the most immense area for labeling and tracking of cells both *in vitro* and *in vivo*.

HM-PAO based tracking of transplanted HSCs:

Our initial effort was made to monitor transplanted HSCs *in vivo* by using HM-PAO (lipid-binding dye). However, existence of short life-span of HM-PAO within the cells, we were able to identify transplanted cells only till 24 h of post-transplantation^[18]. However, other methods such as hepatic scintigraphy demonstrated that infused human HPCs homes evenly in both liver lobes with elevated engraftment, thus yet again

recalling the efficiency of cell delivery route through hepatic artery. During and after 6 mo of follow-up no other clinical complications were observed^[17].

Di-D labeling and tracking of transplanted cells:

Due to short life of HM-PAO, it was quite difficult to monitor transplanted cells in long-term. Hence, further we used live cell imaging dye (*i.e.*, Di-D) for labeling and long-term tracking of human HSCs post-transplantation. DiD-labeled EpCAM+ve human HPCs were infused in liver of nude mice to identify its engraftment and survival rate. Post-transplantation labeled cells were tracked and located at different time points by using an animal imaging system (KODAK Fx-PRO). Post-transplantation persistence DiD-labeled cells were observed up to 110 d. X-ray images of animals receiving cells were also captured and overlaid on fluorescence imaging to investigate better consignment (Unpublished). However, additional studies are required with regard to safety and efficacy of such dyes before applying into the medical conditions.

Magnetic resonance imaging of transplanted cells using high contrast nanoparticles: Magnetic resonance imaging (MRI) is widely used technique in preclinical and clinical studies. Particular type of stem cells are enriched with a contrast agent or directly labeled with super paramagnetic iron oxide (SPIO) to track them in damaged tissues post-transplantation. Non-invasive *in vivo* monitoring can be achieved by MRI using SPIO-labeled cells due to its significant temporal and spatial contrast^[21-24]. We have synthesized such high contrast nanoparticles by combining SPIO with Gadolinium which is also detectable in 1.5 T MRI machine. This approach represents one such tool that can provide insight into cell survival and proliferation following transplantation into the tissues.

LIVER BIOENGINEERING: A POTENTIAL APPROACH TO UNDERSTAND THE REGENERATIVE MECHANISMS OF HSCS POST-TRANSPLANTATION

Liver bioengineering is one of the most exciting areas in regenerative medicine. In last few decades various strategies have been attempted to support the liver tissue regeneration either by using artificial devices or two-dimensional culture system. However, three-dimensional architecture, vascular network and dense cellular masses are required to support the functional damage of liver. Hepatocytes are known to be attachment-dependent cells and loss very quickly in absence of suitable medium composition, ECM and cell-cell contacts. Cellular proliferation and differentiation is also influenced by three-dimensional organ architecture^[25-27]. Employment of naturally derived

matrices have proved their potential in hepatocyte culture^[26]. Several studies have demonstrated long-term heterotopic hepatocytes transplantation in a variety of matrices^[27,28]. Nonetheless, initial engraftment rates are suboptimal. Hence development of a whole tissue engineered liver construct is in urgent need for orthotopic transplantation.

Repopulation of human HSCs in whole decellularized liver scaffold to generate humanized organ

Decellularization is defined as the technology used to remove all parenchyma cells, endothelial cells, myofilaments and other cellular components from the organ while retaining its three dimension architecture and vascular tree. The use of naturally vasculature and rapid separation of debris and waste fluid from organ or tissue significantly improves the quality of organ scaffolds for reconstitution of new organ/tissue. Because of the above facts decellularization technology has been considered an ideal tool for regeneration of whole organ/tissues. Different types of stem cells from a variety of sources either alone or in combination with other cells have been tried to develop the whole functional organ architecture to provide a considerable approach for organ bioengineering.

Recellularization is a process of generating functional cells within the decellularized organ scaffold in order to get fully functional bio-artificial organ. Seeding of specific type of cells with high proliferation and controlled differentiation potential is necessary to repopulate the decellularized organ scaffold. Despite using various types of organs for decellularization and recellularization, none of them have proved their absolute potential to replace the damaged organ/tissue.

Since last two decades' most of the tissue engineering approaches have involved in reconstruction of thin masses of cells, for instance skin, arteries and bladder^[29-31]. Whereas construction of thick masses of cells/tissues such as muscles, liver and kidney, etc. has been proved difficult to mimic due to fractional distribution of oxygen and nutrients inside the engineered scaffold^[32]. Several recent studies have proved decellularization and recellularization technologies as a most significant tool for the creation of fully humanized functional organs^[33-37].

In our view, these decellularized liver bio-scaffolds have a great potential to ensure an advanced *in vitro* natural liver cell culture system for toxicology, pharmacology and drug discovery. This may also establish an excellent tool to cram the normal development of organs and diseased tissues. The technology of decellularization and recellularization passes much potential to reach the significant aim of engineering bio-artificial personalized livers for the treatment of acute and chronic liver diseases. Therefore lead has been taken by our centre to utilize the technology of decellularization and repopulation further to improvise the research quality and to reach the goal

for generating personalized whole functional liver for patients suffering with end stage liver failure.

CONCLUSION

Human HSCs-based therapies for the treatment of ESLD are in their early stage of the translation. Long-term stem cells labeling and tracking *in vivo* is the most important subject nowadays. High contrast and paramagnetic nanoparticles with high biocompatibility have emerged a better option in order to answer several unsettled issues regarding the cell delivery routes, better stem cell choice, number of cells to be infused and the time-point of cell delivery for the treatment in a chronic setting. The technology of decellularization and recellularization might offer a significant platform for developing bioengineered personalized livers to come over scarcity of desired number of donor organs for the treatment of ESLD. Combinatorial approach of decellularization and nanotechnology could pave a way towards the better understanding in determination of cell fate post-transplantation.

Abstract

Hair follicle stem cells (HFSCs) normally give rise to keratinocytes, sebocytes, and transient amplifying progenitor cells. Along with the capacity to proliferate rapidly, HFSCs provide the basis for establishing a putative source of stem cells for cell therapy. HFSCs are multipotent stem cells originating from the bulge area. The importance of these cells arises from two important characteristics, distinguishing them from all other adult stem cells. First, they are accessible and proliferate for long periods. Second, they are multipotent, possessing the ability to differentiate into mesodermal and ectodermal cell types. In addition to a developmental capacity *in vitro*, HFSCs display an ability to form differentiated cells *in vivo*. During the last two decades, numerous studies have led to the development of an appropriate culture condition for producing various cell lineages from HFSCs. Therefore, these stem cells are considered as a novel source for cell therapy of a broad spectrum of neurodegenerative disorders. This review presents the current status of human, rat, and mouse HFSCs from both the cellular and molecular biology and cell therapy perspectives. The first section of this review highlights the importance of HFSCs and *in vitro* differentiation, while the final section emphasizes the significance of cell differentiation *in vivo*.

Key words: Hair follicle; Stem cells; Bulge area; Neuron; Differentiation

Core tip: Hair follicle stem cells (HFSCs) can proliferate *in vitro* and retain the label for a long time. Various types of stem cells, including epidermal-neural crest stem cells, nestin-positive, keratin 15-negative cells, and CD34-positive cells have been demonstrated in

hair follicles. HFSCs normally give rise to keratinocytes, sebocytes, and transient amplifying cells *in vivo*. In addition, these cells differentiate into ectodermal lineages including oligodendrocytes, astrocytes, and neurons. Neural cells derived from HFSCs can replace lost cells in neurodegenerative diseases. Their easy accessibility along with their potential for neural differentiation makes HFSCs an ideal stem cell source for treatment of neurodegenerative disorders.

INTRODUCTION

Skin stem cells reside in the stratum basale of the epidermis, sebaceous glands, and bulge area of the hair follicles. A promising start to derive hair follicle stem cells (HFSCs) was made in the early 1990s, when it was found that label-retaining cells were located in the upper portion of the hair follicle (bulge area). Subsequently, it was clarified that during the early anagen phase, the bulge cells grew downward in response to the stimulating factors of the dermal papilla cells and formed half of a hair follicle, which was degenerated during the catagen phase. Studies on hair follicles suggest that mouse HFSCs occupy a relatively fixed location in the hair follicle called the bulge area, which is important for hair follicle cycling^[1]. HFSCs continuously supply new cells to the bulb during the anagen phase^[2], and have the ability to differentiate into most of the ectodermal lineages^[3]. These characteristics make them a promising cell source for grafting in various skin and nervous system diseases^[4].

Kobayashi *et al.*^[5] has shown that the bulge area of rat whisker follicles contains colony-forming stem cells that can be expanded continuously on the feeder cell layer and form 95% of the total colonies. Moreover, the bulge cells form larger colonies than the non-bulge keratinocytes^[6]. HFSCs have been seen to be able to differentiate either *in vitro* or *in vivo* upon grafting into a spinal cord injury (SCI)^[7,8] and Alzheimer disease (AD)^[9] animal models. The isolation of human HFSCs has generated tremendous interest, because the information gained from the study of human HFSCs, particularly those regarding cell differentiation, is of particular importance^[10].

The neural potential of HFSCs was first reported by Sieber-Blum *et al.*^[11] and Amoh *et al.*^[12] who demonstrated that the population of HFSCs could be converted into Schwann cells after pretreatment with neuregulin-1 or upon transplantation into a severed

sciatic nerve and SCI. Since then, many studies used inducers for neural differentiation of HFSCs, including neurotrophin-3 (NT-3)^[13], a glial cell line-derived neurotrophic factor (GDNF), a brain-derived neurotrophic factor (BDNF)^[14], a serum-free medium, *all trans* retinoic acid (RA), and other chemical neural inducers^[15].

In this review, we have summarized the progress achieved in both the proliferation and neural lineage differentiation of HFSCs. Research on the application of stem cells for the treatment of neurodegenerative diseases such as peripheral nerve lesions, SCI, and AD has created a growing interest in the field of biology. Ultimately, a good knowledge of the wide variety of cell differentiation will provide the therapeutic application of HFSCs in degenerative nervous system diseases and skin pathologies.

MAINTAINING HFSCS

HFSCs were initially identified in the bulge area of rat hair follicles^[5]. In 1990, Cotsarelis *et al.*^[1] suggested that follicular stem cells retain the label and are slow cycling. Similarly, Morris *et al.*^[16] demonstrated that bulge cells are quiescent and maintain a label for a long time following induction of anagen. The label-retaining cells divide asymmetrically into both identical copies of themselves and transient amplifying cells^[1,17]. The initial HFSCs culture is established and maintained by a co-culture, with a feeder layer of 3T3-J2 fibroblasts^[5]. Subsequent studies have revealed that the epidermal growth factor (EGF) and a basic fibroblast growth factor (b-FGF) are the feeder molecules that play a significant role in the maintenance and proliferation of these cells^[18,19]. HFSCs can also be grown in a medium supplemented with EGF, cholera toxin, insulin, and hydrocortisone^[13]. Sieber-Blum *et al.*^[11] suggests that epidermal neural crest stem cells (Epi-NCSCs) are pluripotent stem cells residing in the bulge area and can also be expanded continuously in the presence of an alpha-modified MEM medium, 5% chick embryo extract, and 10% of fetal calf serum. With these new culture conditions, it is now possible to grow HFSCs with defined factors in the absence of a feeder cell layer.

CELL SURFACE MARKERS

HFSCs can be routinely isolated from hair follicles and expanded *in vitro* to cell populations that are similar to the adult stem cells in respect to morphology and cell surface markers. In fact, numerous subsets of stem cells with varying differentiation potentials have been demonstrated in hair follicles, such as, Epi-NCSCs^[9,11], nestin-positive, and keratin 15-negative cells^[20], CD34-positive cells^[15,21], and CD200 -positive cells^[22].

Mouse bulges cells express specific markers including CD34 and K19, as well as CD200 and

K15^[23]. Expression of CD200 protects the bulge area from inflammation and hair loss in alopecia areata^[24] and these cell surface protein is the best positive marker for the human bulge stem cells^[22]. A central problem is the lack of a specific and reliable marker for the identification of HFSCs. Among the different markers, CD34 is possibly the most promising marker for HFSCs^[25]. Previously, bulge cells were isolated from mouse, rat, and human cells by manual dissection, but the purity of the isolated cells was unclear. Several years ago, Ohyama *et al.*^[22] used laser capture microdissection for precise bulge cell isolation. Now different isolation methods for bulge stem cells are accessible using CD34 as a hair follicle stem cell surface marker, by fluorescence-activated cell sorting (FACS)^[26] and magnetic activated cell sorting (MACS)^[8,27]. Therefore, the precise isolation of HFSCs having the ability to differentiate into many different cell types has generated a promising field for therapeutic application.

Some bulge stem cells are K15-positive and nestin-negative and differentiate into keratinocytes^[28]. More recently, Snippert *et al.*^[29], reported Lgr6 expression in HFSCs, which differs from Lgr5/CD34⁺ HFSCs. Lgr6⁺ HFSCs particularly express Sca-1, $\alpha 6$ -integrin, $\beta 1$ -integrin, sox9, and Lhx2, and contribute to wound repair. Sieber-Blum *et al.*^[7], showed that the other type of HFSCs express neural crest genes as well as neural stem cell markers, indicating a neural crest origin and neural differentiation potential. The other types of HFSCs in mouse hair follicles are called nestin-positive stem cells. These cells express some stem cell markers such as CD34, and can differentiate into non-follicular cell types, such as, neural cells^[30], which are maintained in the presence of FGF2 and a low concentration of B27^[20]. Nestin-positive cells exhibit a colony forming potential *in vitro* and are small oval or round shaped, with a dendrite-like structure. At the anagen stage, nestin-expressing cells form the lower part of the hair follicle^[30].

MULTIPOTENCY OR PLURIPOTENCY

This is an open question of whether bulge stem cells isolated from the hair follicle are pluripotent or multipotent cells and whether truly pluripotent cells can be isolated from the hair follicle by expansion, *in vitro*. HFSCs are considered to be multipotent cells because they differentiate into ectodermal derivatives such as neural cells, astrocytes, oligodendrocytes, and Schwann cells^[14], as well as mesodermal lineages, including chondrocytes^[11], myocytes^[31], adipocytes, and osteocytes^[17]. However, the expression of differentiation markers is often insufficient to conclude whether a cell has converted to a new state of differentiation^[32]. Bulge cells can proliferate and differentiate into the bulb keratinocytes at the onset of the anagen phase^[2,33]. In addition it is shown that these

stem cells can also emigrate and continuously provide progenitors, regenerating the epidermis and sebaceous gland^[34-36].

EP-NCSCs derived from the mouse vibrissae hair follicle express neural stem cell markers, such as Nanog and Oct4^[37]. The neural crest transcription factors such as nestin, Slug, Snail, Twist, Sox9, Sox10, Wnt-1 and BMP4 play essential roles in maintaining the undifferentiated state of bulge cells^[11,31]. The role of these transcription factors in neural crest stem cell renewal has been recently reviewed^[38,39] and we are not going to discuss further. Together, HFSCs has an extensive developmental potential, however, it is necessary to evaluate the multipotency of HFSCs by differencing, *in vivo*, after cell grafting. For this purpose, HFSCs are transplanted into the skin^[40], SCI^[8], peripheral nerve injury and AD^[9] models. The results suggest that HFSCs have extensive developmental potential. Further studies are required to determine whether the population of HFSCs can give rise to endodermal derivatives. Finally, the pluripotency of all subpopulations of HFSCs remains an unproven concept, but it seems that only Epi-NCSCs express two pluripotency factors, such as, Oct-4 and nanog^[11].

IN VITRO NEURAL DIFFERENTIATION OF HFSCS

HFSCs attract attention not only in dermatology, but also in the treatment of nervous system diseases. It has been shown that HFSCs retain the ability to generate differentiated progeny *in vitro*. Many differentiation approaches have been optimized using growth factors and other inducing factors. These protocols can also successfully generate certain lineages. HFSCs can be induced to produce an enriched population of glial and neuronal lineages following incubation in exogenous growth factors^[14]. On account of the diversity of HFSCs, differentiation and the proliferative potential of HFSCs is strongly dependent on the exogenous growth factors. Neuroregulin-1 has been found to be required for differentiation of HFSCs to Schwann cell and β -III tubulin positive neural cells. The Epi-NCSCs can also differentiate into smooth muscle cells in response to bone morphogenetic protein-2 (BMP-2)^[11].

Of late, Ghoroghi *et al.*^[13], isolated rat HFSCs and cultured them on a poly-L-lactic acid (PLLA) scaffold to provide a suitable microenvironment for neural differentiation, and then used NT-3 to induce neural differentiation in the HFSCs.

New protocols have been developed to generate neural cells from HFSCs. Of late, we have isolated CD34⁺ cells from the mouse hair follicle, using MACS, and then we applied RA, serum-free medium, and chemical treatments such as β -mercaptoethanol (BME), butylated hydroxyanisole (BHA), and dimethyl sulfoxide

(DMSO), for the neural differentiation in these cells. We have found that the serum-free condition and 1 $\mu\text{mol/L}$ RA appropriately triggered neurogenesis in HFSCs^[15]. In addition, it seems that prolonged serum deprivation induces formation of the ectodermal derivatives^[41]. However, chemical treatments with DMSO, BME, BHA, and potassium chloride (KCL) induced rapid changes in cell morphology, which led to the CD34⁺ cells dying within seven days of treatment^[15]. It will be important to determine whether the neural cells derived from HFSCs possess the functional characteristics of neurons.

Therapeutic application of HFSCs

HFSCs have advantages and disadvantages regarding the potential use of cell-based regenerative therapies. The main potential advantage of the HFSCs is that they are easily accessible adult stem cells, which have ectodermal differentiation potential^[15]. Moreover, HFSCs are attractive tools for future burn and neurodegenerative disease treatments.

HFSCs are similar to embryonic stem cells and have a high proliferative potential *in vitro*. Similar to other types of adult stem cells, they do not form tumors. Without a doubt, autologous transplantation and avoiding immune rejection has been demonstrated in HFSC-treated animal studies^[7,12,42].

HFSCs have the properties to differentiate into various neural cell types including neurons, astrocytes, oligodendrocytes, and Schwann cells. Among them some specific cell types can be produced in high purity, such as, Schwann cells, motor neurons, and oligodendrocytes, which are the main cells that degenerate in SCI, peripheral nerve lesions, and AD. One of the goals of the researchers in this field is to generate neural cells from stem cells, with the aim of replacing lost tissue in degenerative disorders. Therefore, we have used HFSCs as an alternative cell source for cell therapy in nervous system diseases. AD is one of the most common neurodegenerative disorders affecting about four million people throughout the world each year. AD brains have been characterized by amyloid β peptide plaque and neurofibrillary tangle formation, which leads to axonal transport defects and synaptic loss responsible for cholinergic neuron degeneration^[43].

HFSCs have the potential to constitute an anatomical nervous system structure. Thus, in the case of an AD model, these cells are capable of replacing the degenerated neurons. In a recent study, researchers transplanted a subtype of HFSCs (Epi-NCSCs) to differentiate into cholinergic neurons in the AD rat model. These stem cell-derived cholinergic neurons improved learning and memory deficits in the AD model. In spite of rare studies on the therapeutic effects of Epi-NCSCs in an AD model^[9], it will be possible to modify HFSCs to deliver neurotropic factors that modify the course of the disease, in the future.

It is well known that SCI induces paralysis in

about 2.5 million people, affecting the patients and society. Unfortunately, no effective treatment has been discovered for SCI to date^[44]. However, some studies are under way to promote regeneration and neural repair in patients with SCI^[45]. Cell therapy plays a major role in axonal regeneration and neuronal replacement in AD^[9], SCI, and other nervous system diseases. Potential strategies to repair neurodegenerative diseases include neuronal and glial replacement, axonal regeneration and remyelination, and increased production of neurotrophins by grafted cells^[46,47]. Various cell types have been assessed to repair central and peripheral nervous system disorders, such as, fetal tissue, olfactory ensheathing glia, Schwann cells, skin derived precursors, mesenchymal stem cells, and HFSCs^[48]. To this end, in this part of the review, we have focused on the transplantation of HFSCs in SCI.

Preclinical studies have shown a novel type of HFSCs known as Epi-NCSCs, which survive and differentiate into β III-tubulin, glutamic acid decarboxylase (GAD67), RIP positive, and myelin basic protein-positive neural cells, but not Schwann cells, when transplanted into the contusion model of the SCI; the cells can be even integrated with host neurites in the contused spinal cord. However, the transplanted cells do not form tumors^[7]. In another study, extensive Schwann cell differentiation of nestin-positive HFSCs has been reported after transplantation into a severed spinal cord. They have found that the differentiated cells facilitated the repair of SCI and promoted hind limb function recovery^[49]. Likewise, when rat HFSCs are transplanted into a compression model of SCI, they generate oligodendrocytes and neuron-like cells expressing RIP and β -III tubulin, respectively. Walking scale, limb coordination, and plantar stepping improved following HFSC transplantation^[8]. Consistent with this study, Hu *et al.*^[50], also demonstrated that unilateral bulge-derived Epi-NCSC transplantation into a contused spinal cord promoted a 24% recovery in sensory connectivity and touch perception. Moreover, some grafted Epi-NCSCs differentiated into functional motor neurons. *In vivo* studies using Epi-NCSCs isolated from the mouse hair follicle showed similar results^[7]. Briefly, these studies showed the safety of HFSC transplantation and enhanced recovery in animal models of SCI.

Damage to the peripheral nerve interrupts the axonal pathways and causes partial or total loss of motor, sensory, and autonomic functions. An important aim for the ongoing research is the development of therapeutic strategies that enhance axonal regeneration and replace lost neural cells, to bridge the gap of the lesion^[51].

HFSCs possess a self-renewal ability and neural differentiation potential. Amoh *et al.*^[12,52] transplanted HFSCs in the severed sciatic nerves of mice. Eight weeks after grafting, many spindle cells grew in the severed sciatic nerve rather than in the control, differ-

entiated extensively into Schwann cells, and promoted motor function.

In another study, extensive neuronal differentiation of the nestin-expressing cells was reported after transplantation of RA-pretreated cells into the transected distal sciatic nerve. In this study, the nestin-positive bulge cells grew in the distal sciatic nerve stump and caused locomotor recovery owing to the presence of many Tuj1, Is1^{1/2}, and EN1-positive cells and nerve fibers. Muscle atrophy was also reduced after grafting, and re-innervation was promoted^[53]. HFSCs transplanted to the subcutis and severed sciatic nerve also differentiated into blood vessels^[40] and Schwann cells^[12], respectively. It seemed that the differentiation of HFSCs supported neural regeneration and motor function of the lower extremity muscles, such as, the gastrocnemius^[12].

There are still many problems that need to be resolved before HFSCs can be widely used clinically. The main problem is that approximately only a few neural cells derive from these stem cells *in vivo* and further studies are required to determine whether the differentiated neurons are functionally integrated into the AD brain, SCI, and peripheral nerve lesion tissues. Some other forms of cell differentiation, such as keratinocytes, myocytes, and melanocytes are the other disadvantages of HFSC transplantation in neurodegenerative disorders. The successful directed differentiation of HFSCs into specific neurons with the help of different neural induction methods may make neural transplantation widely available for neurodegenerative disorders at some point in the future.

Collectively, these results indicate that HFSCs can promote the recovery of peripheral nerve injury, SCI, and AD. Thus, these cells have the desirable properties of neural replacement and remyelination.

CONCLUSION

In summary, we have explained that the hair follicle contains various multipotent stem cells. The ability of HFSCs to proliferate *in vitro* and the directed differentiation toward ectodermal and mesodermal lineage cell types render them potential for clinical application. These include the modeling of SCI, sciatic nerve injury, and AD, studies of cell therapy on progression, and amelioration of symptoms.

At present, HFSC transplantation provides the best chance of cure for many diseases. Future studies seek to characterize the signaling genes that regulate stem cell behavior.

Abstract

AIM: To determine the effects of transplanting osteogenic matrix cell sheets and beta-tricalcium phosphate (TCP) constructs on bone formation in bone defects.

METHODS: Osteogenic matrix cell sheets were prepared from bone marrow stromal cells (BMSCs), and a porous TCP ceramic was used as a scaffold. Three experimental groups were prepared, comprised of TCP scaffolds (1) seeded with BMSCs; (2) wrapped with osteogenic matrix cell sheets; or (3) both. Constructs were implanted into a femoral defect model in rats and bone growth was evaluated by radiography, histology, biochemistry, and mechanical testing after 8 wk.

RESULTS: In bone defects, constructs implanted with cell sheets showed callus formation with segmental

or continuous bone formation at 8 wk, in contrast to TCP seeded with BMSCs, which resulted in bone non-union. Wrapping TCP constructs with osteogenic matrix cell sheets increased their osteogenic potential and resulting bone formation, compared with conventional bone tissue engineering TCP scaffolds seeded with BMSCs. The compressive stiffness (mean $\pm$ SD) values were 225.0 ± 95.7 , 30.0 ± 11.5 , and 26.3 ± 10.6 MPa for BMSC/TCP/Sheet constructs with continuous bone formation, BMSC/TCP/Sheet constructs with segmental bone formation, and BMSC/TCP constructs, respectively. The compressive stiffness of BMSC/TCP/Sheet constructs with continuous bone formation was significantly higher than those with segmental bone formation and BMSC/TCP constructs.

CONCLUSION: This technique is an improvement over current methods, such as TCP substitution, and is useful for hard tissue reconstruction and inducing earlier bone union in defects.

Core tip: The treatment of bone defects is a common clinical problem for orthopedic surgeons. Artificial bone combined with cultured bone marrow stromal cells (BMSCs) has been examined and applied for the treatment of clinical cases such as small bone defects. In the present study, we developed constructs of BMSCs and beta-tricalcium phosphate (TCP) combined with osteogenic matrix cell sheets (BMSC/TCP/Sheet constructs), which showed a vigorous osteogenic potential compared with conventionally engineered bone tissue structures consisting of BMSC/TCP constructs. The BMSC/TCP/Sheet constructs will be useful for reconstruction of hard tissues, such as bone defects, as new tissue-engineered bone.

INTRODUCTION

The treatment of bone defects is a common clinical problem for orthopedic surgeons. Autologous bone grafts including vascularized bone grafts are performed for treatment of osteonecrosis and bone defects in clinical practice^[1,2]. However, it is necessary to sacrifice intact bone such as the pelvis or fibula. Moreover, there is limited bone available for autologous transplantation.

Artificial bone such as hydroxyapatite (HA) and beta-tricalcium phosphate (TCP) can be applied as a scaffold for the treatment of small bone defects. Although these biomaterials provide a physical matrix for deposition of new bone and may guide the extension of bone, they do not induce ectopic bone formation^[3]. To achieve osteogenesis in artificial bone, constructs of artificial bone combined with cultured bone marrow stromal cells (BMSCs), which are designated as engineered bone tissue structures^[4-6], have been examined and applied for the treatment of clinical cases such as avascular necrosis of the femoral head and benign tumors^[7-9]. However, some cases require a long period of time to replace autologous bone, which subsequently delays bone union.

Previously, we developed a mechanical retrieval method to fabricate cell sheets of cultured BMSCs with osteogenic potential, designated osteogenic matrix cell sheets, that could be transplanted without a scaffold, and resulted in bone formation at subcutaneous sites^[9-12]. The utility of transplantation of engineered bone tissue structures for hard tissue reconstruction will increase if such treatment can achieve sufficient bone formation for early bone union after transplantation. In our previous study, we reported that a construct of osteogenic matrix cell sheets and artificial bone results in extensive bone formation compared with a construct containing a BMSC suspension. A construct with osteogenic matrix cell sheets allows bone formation inside of the pores as well as outside of the artificial bone. Outside bone formation can unite two artificial bones by bridging bone formation^[11]. These results suggested that transplanting a combination of osteogenic matrix cell sheets and engineered bone tissue structures may advance bone formation for reconstruction of bone defects. Marcacci *et al*^[9] reported the clinical outcomes of long bone repair using macroporous bioceramics with BMSCs. However, they used a BMSC suspension to prepare BMSC/bioceramic composites. Therefore, in the present study, we prepared TCP constructs with or without osteogenic matrix cell sheets and assessed their osteogenic potential after transplantation subcutaneously and at bone defect sites. We compared the bone formation patterns between TCP constructs with or without osteogenic matrix cell sheets.

MATERIALS AND METHODS

Preparation of bone marrow cells

The experimental procedures were approved by the Animal Experimental Review Board of Nara Medical University. Male Fisher 344 (F344) rats were purchased from Japan SLC (Shizuoka, Japan) for use as donors and recipients. The method for bone marrow cell preparation has been reported previously^[12-14]. Briefly, bone marrow cells were obtained from the femoral shafts of 7-wk-old F344 rats by flushing with 10 mL of

culture medium. The cells were collected in two T-75 flasks (Costar, Cambridge, MA, United States) containing 15 mL of minimal essential medium (MEM; Nacalai Tesque, Kyoto, Japan) supplemented with 15% fetal bovine serum (FBS; Gibco Life Technologies, Carlsbad, CA, United States) and antibiotics (100 U/mL penicillin and 100 µg/mL streptomycin; Nacalai Tesque), and incubated at 37 °C in a humidified atmosphere with 5% CO₂. At confluency (approximately day 14), the primary cultured cells were harvested using a 0.25% trypsin/EDTA solution (Nacalai Tesque) to obtain in a cell suspension.

Cell sheet preparation

To prepare an osteogenic matrix cell sheet, a cell suspension was seeded at a density of 1×10^4 cells/cm² in a 100-mm cell culture dish (100 × 20 mm; BD Falcon, NJ, United States) and cultured with medium containing 10 nmol/L dexamethasone (Dex; Sigma, MO, United States) and 82 µg/mL ascorbic acid phosphate (AsCP; L-ascorbic acid phosphate magnesium salt n-hydrate; Wako Pure Chemical Industries, Kyoto, Japan) until confluency (approximately 2 wk)^[10,13]. The cells were then rinsed twice with phosphate-buffered saline (PBS; Gibco), and the sheet was lifted by a mechanical retrieval method using a scraper. Because the osteogenic matrix cell sheet was sufficiently robust to handle with a scraper and forceps, handling procedures for the cell sheet were performed easily, such as combination of the cell sheet with TCP. Although β-glycerophosphate (β-GP) was added to create osteogenic matrix cell sheets in our initial study^[10], recent investigations have revealed that osteogenic matrix cell sheets with high osteogenic potential can be prepared without β-GP^[15,16]. Therefore, the osteogenic matrix cell sheets in the present study were created without β-GP.

Construction of TCP containing BMSCs

Sterilized porous TCP ceramics (Osferion; disks: 5 mm diameter and 2 mm thick; cylinders: 5 mm outer diameter, 1 mm inner diameter, 5 mm in length, and 60% porosity) were provided by Olympus Terumo Biomaterials (Tokyo, Japan). After immersion in MEM, the air bubbles in the TCP were aspirated and each ceramic was soaked in a cell suspension (1×10^6 cells/mL) for 2 h in a CO₂ incubator at 37 °C^[13]. The constructs were then cultured with osteoinductive supplements including Dex, AsCP, and 10 mmol/L β-GP (Sigma) for 2 wk in a CO₂ incubator at 37 °C to obtain BMSC/TCP constructs.

Experimental groups

We prepared three experimental groups according to the type of implant received. The C group received BMSC/TCP constructs, the S group received TCP combined with an osteogenic matrix cell sheet (Sheet/TCP constructs), and the SC group received BMSC/

TCP constructs combined with an osteogenic matrix cell sheet (BMSC/TCP/Sheet constructs). Constructs with an osteogenic matrix cell sheet were prepared by simply wrapping the sheet around the constructs just prior to transplantation. The TCP ceramics used for subcutaneous transplantation and bone defect model experiments were the disk and cylinder types, respectively.

Subcutaneous implantation of constructs

Constructs with a TCP disk were implanted subcutaneously onto the back of syngeneic 7-wk-old male rats using a previously described procedure^[10,17]. Each group included six disks for one recipient rat as the subcutaneous implantation model. After 4 wk, the implanted constructs were harvested and evaluated radiographically, histologically, and biochemically. For radiographic and histological evaluations, the harvested disks were fixed in buffered formalin (Wako Pure Chemical Industries). After obtaining X-ray images, each disk was decalcified with a KCl solution (K-CX solution; Falma, Tokyo, Japan), embedded in paraffin, cut at the middle of the disk parallel to the base, and then stained with hematoxylin and eosin (HE) for histological evaluation.

Biochemical analysis

The alkaline phosphatase (ALP) activities and osteocalcin contents of harvested constructs were measured as described previously^[17,18]. Briefly, each disk was crushed and homogenized using a microhomogenizer in 1 mL of 0.2% Nonidet P-40 (NP-40), and then centrifuged at 12000 rpm for 10 min at 4 °C. A 10-µL aliquot of the supernatant was combined with 56 mmol/L 2-amino-2-methylpropanediol buffer containing 10 mmol/L p-nitrophenylphosphate and 1 mmol/L MgCl₂. After incubation for 30 min at 37 °C, 2 mL of 0.2 N NaOH was added to stop the reaction and the ALP activity was calculated by measuring the absorbance of p-nitrophenol released at 410 nm using a spectrophotometer.

After extraction with 0.2% NP-40 in 4 mL of 20% formic acid for 2 wk at 4 °C, osteocalcin was extracted from the sediment. A 0.5-mL aliquot of the formic acid extract was applied to a prepacked Sephadex G-25 column (NAP-5 column; Amersham Pharmacia Biotech AB, Uppsala, Sweden) and eluted with 10% formic acid. The protein fractions were pooled and dried. After dissolution in 0.5 mL of ELISA sample buffer, the osteocalcin content was assayed using a Rat Osteocalcin ELISA Kit (DS Pharma Biomedical, Osaka, Japan)^[18].

Implantation of constructs into the bone defect model

Bone defects of the femur were created in F344 rats (300–350 g body weight) under anesthesia. Briefly, a lateral incision was made on the hind limb and the vastus muscle was divided longitudinally to expose the femur. The femoral shaft was removed from

Figure 1 X-ray images and hematoxylin and eosin-stained sections at 4 wk post-implantation. A: BMSC/TCP constructs (C group); B: Sheet/TCP constructs (S group); C: BMSC/TCP/Sheet constructs (SC group). The S and SC groups showed abundant calcification around the TCP disk. Arrowheads indicate the area of calcification. Bone formation was observed histologically in the pores of the TCP disk in all groups. The S and SC groups showed bone formation on the surface of the disk. Higher magnification images of the boxed areas are shown at the right side of each panel. Asterisks indicate bone tissue. HE: Hematoxylin and eosin.

the distal lesser trochanter to a length of 10 mm to create a bone defect that was filled with a TCP-cylinder construct. The cylinder was fixed with an 18 G needle inserted into the intramedullary femoral shaft to achieve ridged fixation. A BMSC/TCP cylinder (BMSC/TCP construct) was transplanted into the bone defect of the left femur, while a BMSC/TCP cylinder with an osteogenic matrix cell sheet (BMSC/TCP/Sheet construct) was transplanted into the defect of the right femur. To evaluate bridging bone formation, X-ray images were taken under anesthesia at 2, 4, and 8 wk postoperatively.

Evaluation of bone formation in the bone defect model

At 8 wk post-transplantation, the rats were euthanized and both hind limbs were harvested. After removal of the intramedullary pins, micro-CT images were taken using a Microfocus X-ray CT system (SMX-160CTS; Shimadzu, Kyoto, Japan). Five of the harvested femurs were then dissected from the surrounding muscle, fixed in 10% formalin, decalcified with K-CX solution, and embedded in paraffin. For histology, the femurs were cut longitudinally and stained with HE. Eight of the harvested femurs were applied to compression testing using a universal testing machine (5566; Instron, Canton, MA, United States) equipped with a computer for data acquisition. The harvested femur was compressed longitudinally and the primary

yield point for fracture of the TCP was calculated. The crosshead speed was 10 mm/min. Compressive stiffness was calculated by dividing the compressive stress by the compressive strain in the linear portion to the primary yield point of the stress-strain curve.

Statistical analysis

The values for ALP activity, osteocalcin content, and compressive stiffness were calculated as the mean and SD. Statistical significance was determined by one-way ANOVA with post-hoc multiple comparisons using Tukey's test. A value of $P < 0.05$ was considered statistically significant.

RESULTS

Subcutaneous implantation

Figure 1 shows the radiographic images and histology (HE staining) at 4 wk after subcutaneous implantation. Abundant calcification around the disks was observed in the radiographic images of the S and SC groups, whereas no calcification was observed in the C group. Histology showed bone formation in all harvested disks. Although the C group showed bone formation only in the pores of the ceramics, the S and SC groups showed bone formation in the pores and around the disks. Less bone formation appeared to be in the central area of the disks in the S group compared with

Figure 2 ALP activity (A) and osteocalcin content (B) of harvested constructs. The C, S, and SC groups indicate BMSC/TCP (black column), Sheet/TCP (gray column), and BMSC/TCP/Sheet (white column) constructs, respectively. Values are means $\pm$ SD ($n = 6$). ^a $P < 0.05$. BMSCs: Bone marrow stromal cells; TCP: Tricalcium phosphate.

Figure 3 X-ray images of constructs implanted into femurs. The femoral shaft was removed and replaced with BMSC/TCP constructs with or without cell sheets. Callus formation appeared around the BMSC/TCP constructs with cell sheets (BMSC/TCP/Sheet) at 2 wk post-implantation, was extended at 4 wk, and continued to the host bone at 8 wk. In contrast, the BMSC/TCP constructs showed non-union at 8 wk. Arrowheads indicate continuous bone formation. Bar = 2 mm. BMSCs: Bone marrow stromal cells; TCP: Tricalcium phosphate.

the SC group.

The ALP activities (Figure 2A) and osteocalcin contents (Figure 2B) in the SC group were significantly higher than those in the other groups at 4 wk post-implantation. In the S group, these values were significantly higher than those in the C group.

Bone defect model

Radiographic images were taken at 2, 4, and 8 wk

post-implantation (Figure 3). At 2 wk, obvious callus formation was observed around the implanted constructs with osteogenic matrix cell sheets. At 8 wk post-implantation, callus formation had developed and bridging callus formation between host bones resulted in bone union. In contrast, no bridging callus formation was observed around constructs without osteogenic matrix cell sheets at 8 wk post-implantation.

Figure 4 shows the micro-CT images and histology of each construct implanted into femurs at 8 wk. Implanted BMSC/TCP/Sheet constructs showed bone formation around the TCP cylinder ($n = 8$). However, micro-CT revealed two patterns of bone formation, continuous bone formation to host bones (Figure 4A, $n = 4$) and segmental bone formation over the cylinder (Figure 4B, $n = 4$). The ratio of segmental and continuous bone formation among the samples was 1:1. We defined BMSC/TCP/Sheet constructs showing bridging bone formation between host bones across the TCP by micro-CT as continuous bone formation. Bone formation observed around the constructs, but not continuing to the host bones, was defined as segmental bone formation. Bone formation was not observed around implanted BMSC/TCP constructs ($n = 8$) in which soft tissue interposition between the cylinder and the host bone resulted in non-union (Figure 4C). Micro-CT also revealed that BMSC/TCP/Sheet constructs with either continuous or segmental bone formation were intact, whereas broken TCP cylinders were found in BMSC/TCP constructs (Figure 4C).

Figure 5 shows the results of biomechanical compression testing. The compressive stiffness (mean $\pm$ SD) values were 225.0 ± 95.7 , 30.0 ± 11.5 , and 26.3 ± 10.6 MPa for BMSC/TCP/Sheet constructs with continuous bone formation, BMSC/TCP/Sheet constructs with segmental bone formation, and BMSC/TCP constructs, respectively. The compressive stiffness of BMSC/TCP/Sheet constructs with continuous bone formation was significantly higher than those with segmental bone formation. The stiffness of constructs with segmental bone formation was similar to that of constructs without osteogenic matrix cell sheets (BMSC/TCP constructs).

Figure 4 Micro-computed tomography images and hematoxylin and eosin-stained sections at 8 wk post-implantation. A: BMSC/TCP/Sheet constructs with continuous bone formation to host bone. Both micro-computed tomography (CT) and histology showed bridging bone formation over the TCP to host bone (arrows); B: BMSC/TCP/Sheet constructs with segmental bone formation over the TCP. Soft tissue interposition was observed between the TCP and the callus (arrowheads); C: BMSC/TCP constructs implanted into femurs. The TCP cylinders of the BMSC/TCP constructs were broken. Arrowheads indicate soft tissue interposition between the TCP and the autologous femur. BMSCs: Bone marrow stromal cells; TCP: Tricalcium phosphate.

DISCUSSION

The present study clearly demonstrated that the osteogenic potential of the BMSC/TCP/Sheet construct was significantly higher than that of the BMSC/TCP construct, namely a conventional engineered bone tissue structure. When the conventional engineered bone tissue structures were combined with an osteogenic matrix cell sheet, the newly formed bone area spread from the center to the surface of the TCP. We observed bridging bone formation over the TCP cylinder implanted between both ends of autologous bones. Moreover, biomechanical examination showed significantly higher strength against compressive stress in the BMSC/TCP/sheet construct with continuous bone formation to host bones, indicating that the BMSC/TCP/sheet construct may be useful for hard tissue reconstruction.

Some scaffolds such as TCP can be replaced with

autologous bone by bone remodeling after implantation into bone defects^[19]. Although osteogenesis does not occur in artificial bone itself, HA and TCP are common scaffolds for artificial bone in hard tissue reconstruction^[20]. Ohgushi *et al.*^[21] and Akahane *et al.*^[22] reported a transplantation technique using artificial bone combined with cells. The cells combined with artificial bone can be freshly prepared bone marrow cells or cultured mesenchymal stem cells (MSCs). In clinical cases, differentiated osteoblasts have been used in combination with scaffolds for the treatment of patients with osteoarthritis and osteonecrosis^[8,9,23]. When a BMSC suspension is combined with such scaffolds, bone formation is observed but only in the pores of the artificial bone. Therefore, when artificial bone is combined with BMSCs for transplantation into a bone defect, soft tissue interposition between the construct and the host bone might occur and result in non-union.

Figure 5 Results of biomechanical compression testing. The stiffness was highest in the BMSC/TCP/Sheet constructs with continuous bone formation (black column), while the stiffness of the BMSC/TCP/Sheet constructs with segmental bone formation (gray column) was similar to that of the BMSC/TCP constructs (white column). Values are means $\pm$ SD. ^a $P < 0.05$. BMSCs: Bone marrow stromal cells; TCP: Tricalcium phosphate.

Several studies have reported tissue-engineered bone combined with BMSCs for reconstruction of bone defects^[24-26]. Kadiyala *et al.*^[26] showed that a critical-size segmental defect of the femur in a canine model can be healed by transplantation of culture-expanded cell-loaded artificial bone. However, defects that received no implant, cell-free artificial bone, or artificial bone loaded with fresh marrow failed to heal at 8 wk. Dallari *et al.*^[25] reported critical-size defect reconstruction using BMSCs, platelet-rich plasma (PRP), and freeze-dried bone allografts alone and in combination. They concluded that the combination of freeze-dried bone allografts, BMSCs, and PRP accelerates bone healing and remodeling processes. However, the bone healing was evaluated by radiology, histology, and histomorphometry in these previous studies. In contrast, we evaluated bone reconstruction by mechanical testing (compression testing) as well as micro-CT, radiology, and histology because the mechanical strength of the reconstructed site is an important clinical outcome.

The starting cell numbers were different for the three groups in this study. It would be very difficult to control the cell numbers because of the different modalities used for construct preparation. Considering clinical cases of bone defect reconstruction, tissue-engineered bone with a vigorous osteogenic potential should be used for better clinical outcomes. Therefore, we first evaluated the osteogenesis of the three types of constructs, BMSC/TCP, Sheet/TCP, and BMSC/TCP/Sheet, using the subcutaneous implantation model to determine the highest osteogenic construct, and found that the BMSC/Sheet/TCP construct had the most vigorous osteogenic potential. The number of cells that can be combined with artificial bone materials like TCP is limited because suspended cells remain in the pores of the TCP. In contrast, cell sheets can be wrapped around TCP, resulting in a large amount of loaded cells on the TCP. Moreover, the Sheet/TCP

constructs showed bone formation on the surface of the construct, which is greatly advantageous for bridging bone formation.

The bone union of conventionally engineered bone tissue structures was improved by combining the construct with an osteogenic matrix cell sheet. The BMSC/TCP construct with an osteogenic matrix cell sheet (BMSC/TCP/Sheet construct) had an excellent ability to form bone, as indicated by bone formation on the TCP surface as well as in the pores of the central area. Bone formation around the TCP was continuous with the host bone when BMSC/TCP constructs with osteogenic matrix cell sheets were implanted into bone defects of the femur. This finding may have occurred because the BMSC suspension entered the pores of the central area and the osteogenic matrix cell sheet was located on the surface of the TCP ceramic. The subsequent combination of osteogenesis by the BMSC suspension and osteogenic matrix cell sheet resulted in vigorous bone formation in the subcutaneous and bone defect sites. Prevention of soft tissue invasion and achieving early bone formation at the bone defect site is clinically important for reconstruction of bone tissue. Accordingly, our transplantation technique using constructs with osteogenic matrix cell sheets is useful because the defect is filled with the osteogenic matrix cell sheet to prevent the invasion of soft tissue, resulting in early bone formation.

MSCs have the potential to replace or regenerate damaged and diseased tissue by multipotent differentiation into osteogenic, chondrogenic, and adipogenic cells among others^[4,7,27]. Recently, although the detailed molecular mechanisms remain unclear, it was reported that MSCs, including BMSCs, can interact with cells of the immune system and modulate immune responses *in vitro* and *in vivo*^[28,29]. MSCs can drive immune responses toward immunosuppression and anti-inflammation. In the present study, we used TCP constructs to repair bone defects in the femur. Scaffolds such as TCP might cause inflammatory responses when they are transplanted *in vivo*^[30]. However, the transplantation model in the present study used a combination of TCP ceramics and cell sheets created from BMSCs, and therefore inflammatory responses could be reduced by the anti-inflammatory function of BMSCs. Further studies are necessary to clarify this point.

We used an osteogenic matrix cell sheet created in a 100-mm cell culture dish to prepare BMSC/TCP/Sheet constructs. When BMSC/TCP/Sheet constructs were transplanted into bone defects of the femur, half of the constructs (four of eight constructs) formed a segmental callus. Similar to the TCP cylinders, the mechanical properties of constructs with segmental bone were still fragile. This result indicates that coverage of the entire TCP cylinder with an osteogenic matrix cell sheet is important for continuous bone formation around the TCP cylinder. Two or more sheets

or a larger sheet can be used to cover the TCP surface and increase the compressive stiffness. Further studies will establish the numbers of sheets needed to cover certain sizes of TCP cylinders.

A thermosensitive cell culture plate is commonly used to fabricate cell sheets^[31]. Memon *et al.*^[32] used culture dishes coated with thermosensitive polymers to fabricate cell sheets for implantation into a heart disease model and for clinical treatment of corneal surface dysfunction^[33]. However, other methods have been reported, such as those using magnetite nanoparticles and magnetic force^[34]. Anil Kumar *et al.*^[35] reported a method for preparation of cell sheet/HA constructs. In their study, they showed rapid and complete cellularization of HA by wrapping it with a cell sheet. Gao *et al.*^[36] reported the results of osteogenic cell sheet transplantation using rabbit MSCs. They used osteogenic cell sheets to generate bone grafts, but did not find any bone formation on the outer HA surface in their model. We^[10,13] and others^[24,37] reported a method to prepare osteogenic cell sheets cultured in osteogenic medium. Our mechanical retrieval method only requires the use of regular cell culture equipment, including a cell scraper, to fabricate the osteogenic matrix cell sheet, in which cells form the sheet during culture with Dex and AscP. On the other hand, the methods of Anil Kumar *et al.*^[35] and Gao *et al.*^[36] require specialized culture dishes coated with thermosensitive polymers. The osteogenic matrix cell sheets used in this study were sufficiently robust to handle with forceps. The cell sheet could be easily handled for processes such as combination with artificial bone, and has osteogenic potential for osteoblastic differentiation induced by Dex and AscP. Therefore, we propose that this technique can be applied to bone defects that occur because of tumor resection or wounding.

In our study, there are a few limitations to be acknowledged. First, we only used TCP cylinders of 5 mm in length. We need to conduct further studies with longer TCP cylinders to assess their bone formation ability for cell sheet transplantation. Second, the experimental period in the present study was relatively short. Therefore, a further follow-up study is needed to determine whether the implanted TCP is replaced by autologous bone. Third, the TCP was transplanted into a bone defect site that was created by bone resection. We need to assess whether the cell sheet can form bone tissue when it is applied to a bone defect in a region with a poor blood supply, such as a large bone defect with soft tissue injury after severe trauma. Finally, we need to show the osteogenic ability using human BMSCs for future clinical application.

In conclusion, the present study clearly demonstrates that constructs of BMSCs and TCP combined with osteogenic matrix cell sheets show a vigorous osteogenic potential compared with conventionally engineered bone tissue structures consisting of a BMSC/TCP construct. Because bridging bone formation over the

implanted TCP can unite the ends of the cylindrical TCP to autologous bone, the construct will be useful for hard tissue reconstruction as new tissue-engineered bone.

ACKNOWLEDGMENTS

We thank F Kunda and M Matsumura (Nara Medical University) for their technical assistance. The TCP disks were kindly provided by Olympus Terumo Biomaterials Corp., Tokyo, Japan. We did not receive any monetary compensation or financial support from the company.

COMMENTS

Background

Bone defects are difficult to treat. Effective treatment options for bone defects have been reported that include tissue engineering of bone tissue structures using bone marrow stromal cells (BMSCs). Recently, many researchers have reported methods for creating cell sheets, such as thermo-responsive polymer-grafted culture dishes and mechanical retrieval.

Research frontiers

Tissue engineering for regenerative medicine using cell sheets are becoming much more common. The transplantation of cell sheets created from BMSCs will most likely be incorporated into clinical cases in the near future. Osteogenic matrix cell sheets have the potential to greatly advance the treatment of critical size bone defects.

Innovations and breakthroughs

Constructs comprised of BMSCs, tricalcium phosphate (TCP) and osteogenic matrix cell sheets show an increased osteogenic potential compared with conventionally engineered bone tissue structures consisting of a BMSC/TCP construct. Bridging bone formation by placing osteogenic matrix cell sheets over the implanted TCP can unite the ends of the cylindrical TCP to autologous bone.

Applications

The construct will be useful for hard tissue reconstruction, such as critical bone defects after tumor resection or traumatic injuries and avascular necrosis of femoral head, by acting as new tissue-engineered bone.

Terminology

Osteogenic matrix cell sheets are cell sheet created from BMSCs. The cell sheet is lifted by a mechanical retrieval method using a scraper. Beta-TCP is one of the most commonly used artificial bone in clinical treatments.

Peer-review

The article describes about the application of tricalcium phosphate and osteogenic matrix cell sheet for bone defect reconstruction. The efficacy of bone formation with matrix cell sheets, BMSC, and beta-tricalcium phosphate has been examined. Although the result section should be described more in detail, this study provides helpful insights for understating overall regenerative medicine technique.

Abstract

AIM: To facilitate close contacts between transplanted cardiomyocytes and host skeletal muscle using cell fusion mediated by hemagglutinating virus of Japan envelope (HVJ-E) and tissue maceration.

METHODS: Cardiomyocytes (1.5×10^6) from fetal rats were first cultured. After proliferation, some cells were used for fusion with adult muscle fibers using HVJ-E. Other cells were used to create cardiomyocyte sheets (area: about 3.5 cm^2 including 2.1×10^6 cells), which were then treated with Nile blue, separated, and transplanted between the latissimus dorsi and intercostal muscles of adult rats with four combinations of HVJ-E and/or NaOH maceration: G1: HVJ-E(+), NaOH(+), Cardiomyocytes(+); G2: HVJ-E(-), NaOH(+), Cardiomyocytes(+); G3: HVJ-E(+),

NaOH(-), Cardiomyocytes(+); G4: HVJ-E(-), NaOH(-), Cardiomyocytes(-). At 1 and 2 wk after transplantation, the four groups were compared by detection of beating domains, motion images using moving target analysis software, action potentials, gene expression of *MLC-2v* and *Mesp1* by reverse transcription-polymerase chain reaction, hematoxylin-eosin staining, and immunostaining for cardiac troponin and skeletal myosin.

RESULTS: *In vitro* cardiomyocytes were fused with skeletal muscle fibers using HVJ-E. Cardiomyocyte sheets remained in the primary transplanted sites for 2 wk. Although beating domains were detected in G1, G2, and G3 rats, G1 rats prevailed in the number, size, motion image amplitudes, and action potential compared with G2 and G3 rats. Close contacts were only found in G1 rats. At 1 wk after transplantation, the cardiomyocyte sheets showed adhesion at various points to the myoblast layer in the latissimus dorsi muscle. At 2 wk after transplantation, close contacts were seen over a broad area. Part of the skeletal muscle sarcoplasm seemed to project into the myocardiocyte plasma and some nuclei appeared to share both sarcoplasmas.

CONCLUSION: The present results show that close contacts were acquired and facilitated the beating function, thereby providing a new cellular transplantation method using HVJ-E and NaOH maceration.

Core tip: It is very important to produce close contacts between transplanted cell sheets and host cells without fibrous invasion for tissue reconstruction and function. Unfortunately, cellular transplantation research has not focused on this problem and convenient methods have not yet been developed. In this study using hemagglutinating virus of Japan envelope, transplanted cardiomyocyte sheets were placed in direct contact with host skeletal muscles. By adding NaOH maceration of connective tissues, rich, largely-movable, beating domains were observed. Histological observations revealed successful formation of close contacts between the two cell types. This paper proposes a new idea of introducing artificial cell fusion into cellular transplantation methods.

INTRODUCTION

Advances in regenerative medicine have realized clinical applications of pluripotent stem cell-derived differentiated cells^[1], and have simultaneously allowed recognition of the importance and potential of cellular transplantation and the necessity for its further improvement.

One of the issues is how to establish and maintain morphological, functional junctions or dense contacts without fibrous invasion between the transplanted and host cells. Regarding cardiomyocyte transplantation into the heart in particular, if direct electrical coupling through gap junctions is not established between the transplanted and host cells, the transplanted area becomes a source of arrhythmia and/or disordered contractions^[2,3].

Simple cellular injection does not always lead to the formation of electrical coupling between the transplanted and host cells. Instead, it can produce scarring, granulation, or connective tissue formation through tissue reactions such as phagocytosis of necrotic host cells, ingrowth of fibroblasts and capillaries^[4], and interposition of a layer of non-cardiomyocyte cells between the graft and host cardiomyocytes^[5], which may interrupt direct cell-cell interactions, electrical coupling, and integration. To overcome these disadvantages, there are two requirements: removal of the matrix and connective tissues surrounding the host tissue cells before transplantation to facilitate direct contacts between the transplanted and host cells, and close cellular contacts or fusion at the interface between the transplanted and host cells.

Another issue is how to obtain sufficiently large numbers of purified differentiated cardiomyocytes. Many methods using pluripotent stem cells have proposed improvements for maintaining cellular function for transplantation^[6]. However, if a method can be established that allows the production of more effective systolic function with fewer pluripotent stem cell-derived cardiomyocytes, it will be preferable and more ideal.

The notion, trialing, and practice of using skeletal muscles or myoblasts instead cardiac muscles have repeated vicissitudes. The latissimus dorsi muscle has been used as a cardiac bioassist in clinical settings, but requires continuous external stimulation^[7]. Some difficulties may remain in harmonizing the contraction of the muscle with the host heart. Skeletal myoblast transplantation has also been focused upon^[8,9] and clinically applied^[10]. However, other papers reported that myoblast transplantation caused arrhythmogenicity compared with human stem cell-derived cardiomyocytes (SC-CMs) because of the lack of gap junctions and presence of islet-like localized cell-clusters resulting in disturbance of the electrical conduction^[11], leading to questions regarding its value. Recently, a new therapy involving epicardial placement of generated

myoblast sheets in temperature-responsive dishes was developed and prevented arrhythmogenic substrate production through paracrine effects without islet-like cell-cluster formation causing electrical conduction disturbances^[12,13]. However, it remains unknown how long its effectiveness continues or whether it continues to function until complete recovery.

If cardiomyocytes can fuse directly with skeletal muscles, integrated systolic forces may be retained and produce tough contractions without requiring large numbers of differentiated cells from pluripotent stem cells. A previous report *in vitro* showed the potential of spontaneous fusion between mouse neonatal cardiomyocytes and primary neonatal skeletal myoblasts^[14]. Furthermore, mouse fetal cardiomyocytes and mouse embryonic stem cells were fused using polyethylene glycol, and survived to become chimeric cells^[15].

On the basis of the above descriptions, we planned to establish a new transplantation model using a safe virus-cell fusion technique of cardiomyocytes with the latissimus dorsi muscle in addition to maceration of the cellular matrix and connective tissue of the host tissues.

MATERIALS AND METHODS

Animals

Pregnant ICR mice (SLC, Hamamatsu, Japan) at embryonic day 14 and 6-wk-old ICR mice were used for *in vitro* experiments. In addition, 6-wk-old BALB/cSLC-nu/nu (SLC) were used as recipients for *in vivo* experiments. This study was approved by the Animal Care Committee of Shinshu University.

In vitro experiments

Preparation of fetal cardiomyocytes: Pregnant female mice were euthanized by cervical dislocation. After opening the abdomen under sterile conditions, the uterus was removed and washed three times with PBS containing 50 U/mL penicillin (Wako Pure Chemical Industries Ltd., Osaka, Japan) and 50 µg/mL streptomycin (Wako Pure Chemical Industries Ltd.). Fetuses were removed from the uterus and transferred to D-Hanks solution. After opening the thorax, the fetal heart was removed under a SZ-ST stereo microscope (Olympus, Tokyo, Japan), cut into small pieces, and centrifuged at 1200 rpm for 3 min. The supernatant was aspirated, and the pellet was resuspended with PBS and centrifuged again. This process was repeated three times. Subsequently, the pellet in a 15-mL tube was immersed in 5 mL of 0.05% trypsin/0.01% EDTA and shaken in a thermostatic bath at 37 °C for 10 min. The digested tissue was diluted with 5 mL of DMEM containing 10% FBS (Equitech-Bio Inc., Kerrville, TX, United States) and centrifuged as described above. After aspiration of the supernatant, the pellet was resuspended with the medium and filtered through a 70-µm Nylon Cell Strainer (BD, Franklin Lakes, NJ,

United States). The cells were adjusted to 1.5×10^6 cells/mL and transferred into 60-mm gelatin-coated dishes.

Preparation of skeletal muscle fibers: Six-week-old ICR mice were euthanized by cervical dislocation. After disinfection with 70% ethanol, the skin of the leg was cut and separated. The muscles surrounding the legs were removed *en bloc*, almost completely cleared of connective tissue and fat tissue in D-Hanks solution under a stereo-microscope, cut into small pieces, and centrifuged at 1200 rpm for 3 min. The supernatant was aspirated, and the pellet was resuspended with PBS and centrifuged again. This process was repeated three times. Subsequently, 10 g of the pellet was immersed in 0.6 g/L collagenase type 1 (Wako Pure Chemical Industries Ltd.) including 0.05% trypsin/0.01% EDTA in 30 mL, divided into 5-mL aliquots in 15-mL tubes, and shaken in a thermostatic bath for 10 min at 37 °C. The digested tissues were diluted with 5 mL of DMEM containing 10% FBS and centrifuged under the same conditions. After aspiration of the supernatant, the pellet was resuspended with 10 mL of the medium, filtered through a 70-µm Nylon Cell Strainer, transferred into a 100-mm gelatin-coated dish, and preincubated at 37 °C under 5% CO₂ for 3 h. After pipetting, the supernatant was transferred into another dish and preincubated for 2 h. This process was repeated twice. The final cell numbers were adjusted to 70 cells/mm², transferred into 60-mm dishes, and incubated. The medium was exchanged for fresh DMEM containing 10% FBS every day.

Fusion of the two types of muscle cells using an HVJ envelope cell fusion kit: Cultured skeletal muscle fibers were washed three times with PBS, resuspended in Vybrant DiI Cell-labeling Solution (5 µL/mL) (Molecular Probes, Eugene, OR, United States), and incubated for 15 min. After aspiration, the solution was exchanged for DMEM containing 10% FBS. Cultured cardiomyocytes were treated with Vybrant DiO Cell-labeling Solution (Molecular Probes) using the same process.

The treated cardiomyocytes were separated as a sheet using a TPP Cell Spatula (TPP-US, St. Louis, MO, United States) and transferred into 60-mm dishes containing cultured skeletal muscle fibers. Subsequently, 5 µL/mL of the fusogen (HVJ Envelope Cell Fusion Kit GenomONE-CF: Ishihara Sangyo Kaisha Ltd., Osaka, Japan) was added to them. After then, the dishes were incubated for 15 min. The medium was then changed and the dishes were observed at 6, 12, 24, 36, and 48 h using an Axio Observer Z1 (Carl Zeiss, Oberkochen, Germany). For negative controls, the fusogen was omitted.

In vivo experiments

Preparation of transplanted cardiomyocytes: At 2 d before transplantation, cardiomyocytes were

Table 1 Four experimental groups

cultured in medium containing $2.5 \times 10^{-5}\%$ Nile blue (Wako Pure Chemical Industries Ltd.) for staining. Alternatively, they were stained with DiO at 1 d before transplantation as described in *in vitro* experiments.

Transplantation: Depending on the treatments, the animals were divided into four groups as shown in Table 1. After peritoneal anesthesia (0.25 mL of 1% Nembutal Solution; Dainihon Sumitomo Pharma Co. Ltd., Osaka, Japan), the animals were fixed in a propped position. The dorsal skin was cut along the spine and separated to expose the latissimus dorsi muscle. After confirming the internal edge, the muscle was separated from the deeper intercostal muscle and its abdominal aspect was placed in contact with cotton wool immersed in 5 mol/L NaOH for a few seconds until the color of the muscle changed slightly. To inhibit any NaOH-associated damage to the intercostal muscle, a nylon film was inserted between the two muscles before maceration. The area was washed immediately with saline after the maceration. In control animals, no NaOH maceration was performed.

Nile blue-stained cardiomyocytes were separated from dishes with a scraper. A cell sheet was inserted between the latissimus dorsi muscle and intercostal muscle and expanded as extensively as possible with or without addition of HVJ-E (Figure 1). The incised skin was closed. At 1 and 2 wk after transplantation, the rats were deeply anesthetized, and the transplanted domains were analyzed by the following cell biological methods. As controls, the domains on the opposite side were evaluated.

Cell biological analyses

Observation with a fluorescence stereo-microscope:

To confirm that the cardiomyocytes survived and remained in the transplanted domain, cardiomyocytes were treated with DiO, transplanted under the latissimus dorsi muscle, and observed under a fluorescence stereo-microscope SZX12 after 2 wk.

Motion image analysis: To compare the beating strengths among groups, the variation distances followed by contraction seen on the latissimus dorsi muscle were estimated and computationally analyzed. After anesthesia, the dorsal skin was longitudinally cut and separated toward both sides to expose the latissimus dorsi muscle. A motion image of the transplanted domain was photographed

with an AE-AF Digital Camera including a P-TTL stroboscope (Ricoh Imaging Company Ltd., Tokyo, Japan). Motion image analyses were performed using the moving target analysis software VW-H1MA (Keyence, Osaka, Japan).

Electrophysiological analysis: To assess whether each motion was caused by an action potential, electrophysiological analyses were performed. Two probes were separately placed at each end of the motional domain of the latissimus dorsi muscle, but not directly over the transplanted cardiomyocytes. The action potentials were recorded with a PowerLab SP (AD Instruments Japan Inc., Nagoya, Japan).

Reverse transcription-polymerase chain reaction:

To confirm that the transplanted cardiomyocytes survived and did not lose their features, the gene expression in samples removed from the transplanted areas was confirmed by reverse transcription-polymerase chain reaction (RT-PCR) for cardiomyocyte markers (*MLC-2v*, marker of the ventricle; *Mesp1*, early marker of cardiac development). The primer sets, annealing temperatures, and predicted product sizes were as follows: *MLC-2v*: 5'-cctcgaactctccagaggtg-3' and 5'-cttcctgtttatttgccgac-3', 53 °C, 612 bp; *Mesp1*: 5'-cctgggatgctgtttctgacg-3' and 5'-acctgaccaagatcgagacg-3', 60 °C, 291 bp; *β-actin*: 5'-ttccttcttggtatggaat-3' and 5'-gagcaatgatcttgatcttc-3', 55 °C, 200 bp. Total RNA was extracted using TRIzol reagent (Invitrogen Japan, Tokyo, Japan). DNase-treated total RNA was used to prepare the first-strand cDNA with SuperScript II (Invitrogen Japan), following the manufacturer's protocol. The cDNA samples were subjected to PCR amplification with the specific primer sets under linear conditions to approximate the original amounts of the specific transcripts. The amplification conditions included denaturation at 94 °C for 1 min, annealing at the temperature specified for each primer for 30 s, and elongation at 72 °C for 30 s. A total of 30 cycles were performed. The PCR products were size-fractionated by 1.5% agarose gel electrophoresis and visualized by ethidium bromide staining.

Hematoxylin-eosin staining: *En bloc* removed samples from the beating domains were fixed with 4% PFA in 0.1 mol/L phosphate buffer (pH 7.4) overnight. After dehydration through a graded ethanol series, the samples were prepared for hematoxylin-eosin (HE) staining using standard methods.

Immunohistochemical double-staining for skeletal myosin and cardiac troponin

PFA-fixed tissue sections on slides were deparaffinized, rehydrated, washed three times with 0.02 mol/L PBS (pH 7.4), and treated with 20 µg/mL Proteinase K solution (Wako Pure Chemical Industries Ltd.) for 25 min at 37 °C. After three washes with PBS, the sections were

immersed in 0.1% Triton X-100 (Nakalai Chemical Ltd., Kyoto, Japan) at room temperature for 1 h. After another three washes with PBS, the sections were immersed in blocking solution I (5% goat normal serum in 0.02 mol/L PBS) at room temperature for 1 h. The treated cells were stained with a mixture of primary antibodies comprising mouse anti-cardiac troponin (1:100; Chemicon, Billerica, MA, United States) and rabbit anti-skeletal myosin (1:500; Sigma-Aldrich Japan, Tokyo, Japan) at 4 °C for 12 h. After washing, the sections were reacted with one secondary antibody (1:1000; Alexa Fluor 568-conjugated goat anti-rabbit IgG; Molecular Probes) in 0.02 mol/L PBS containing 5% goat normal serum at room temperature for 1 h. After washing, the sections were immersed in blocking solution II (5% rabbit normal serum in 0.02 mol/L PBS) at room temperature for 1 h and then reacted with another secondary antibody (1:1000; Alexa Fluor 488-conjugated rabbit anti-mouse IgG; Molecular Probes) at room temperature for 1 h. After washing with PBS and reaction with Prolong Gold antifade reagent containing 4,6-diamidino-2-phenylindole dihydrochloride (DAPI; Invitrogen Japan), the sections were observed under an Axio Observer Z1 fluorescence microscope (Carl Zeiss).

RESULTS

In vitro experiments

Cell fusion: To confirm the effectiveness of HVJ-E, DiO-stained cardiomyocytes were transferred onto DiI-stained muscle fibers in dishes, and HVJ-E was added. After 24 h, merged areas of DiO and DiI appeared (Figure 2A). In control dishes, no merged areas were observed (Figure 2B).

In vivo analyses

Before transplantation, the prepared cardiomyocyte sheets were peeled directly from the dishes using a scraper. The sheets were 50-100 μm in thickness and included rich dotted nuclei and eosinophilic cytoplasm. The nucleus had a spindle-type shape and showed a strong basophilic appearance with heterochromatin (Figure 3A). Immunostaining revealed cardiac troponin-positive cells (Figure 3B).

DiO-treated cardiomyocytes occupied the same position under the latissimus dorsi muscle as the first transplanted domain at 2 wk after transplantation, and did not extend or move into other areas around the muscle (Figure 3C and D).

Figure 3 Representative cardiomyocyte sheets. A: HE staining of a cardiomyocyte sheet separated from the dish; B: The sheets contain cardiac troponin-positive cells (red); C: At 2 wk after transplantation, the DiO-stained sheet (green) occupies the same position as the primary transplanted site (green arrow); D: Schematic diagram showing the transplanted area under the latissimus dorsi muscle.

Under four different experimental conditions (Table 1), cardiomyocyte sheets were inserted between the latissimus dorsi and intercostal muscles, and examined by motion image, action potential, RT-PCR, fluorescent dye, HE staining, and immunostaining analyses at 1 and 2 wk after transplantation.

Motion image and action potential analyses

After confirming arrest of the host heart beats, the motion variation seen in the transplanted domains was analyzed computationally. The effectiveness of NaOH maceration and HVJ-E addition was compared in different conditions (Table 1). The G1 [HVJ-E(+), NaOH(+), Cardiomyocytes(+)], G2 [HVJ-E(-), NaOH(+), Cardiomyocytes(+)], and G3 [HVJ-E(+), NaOH(-), Cardiomyocytes(+)] rats all showed a beating-like motion (Figure 4A-C). However, the G1 rats showed the most numerous motion areas (Figure 4A), with a larger amplitude ($2.5 \pm 1.80 \mu\text{m}$) compared with the other groups of rats. In G3 rats, the small amplitudes were seen more frequently (Figure 4B). The motion had a particular feature, in that some amplitudes did not return the basal line. The mean amplitude was $0.73 \pm 0.55 \mu\text{m}$. In G2 rats, no motion was found in the transplanted area at 1 wk after transplantation, while a few small motion areas were found at 2 wk after transplantation (Figure 4C). The amplitude was small (0.62 ± 0.36).

The action potentials were compared between G1 and G3 rats at 2 wk after transplantation. Consistent

with the low fluttering motion amplitudes in G3 rats, their action potentials were also disordered (Figure 5A). On the other hand, the action potentials in G1 rats were relatively ordered and larger, but contained varied patterns (Figure 5B).

RT-PCR

After transplantation, the motion samples under the latissimus dorsi muscle clearly expressed *MLC-2v* in G1 and G3 rats (Figure 6). *Mesp1* showed weak expression at 2 wk after transplantation compared with 1 wk after transplantation.

Histology of the interrelationship between the transplanted and host skeletal cells in vivo

The interfaces between the NaOH-macerated skeletal muscle fibers and transplanted cardiomyocyte sheets showed marked differences. In the case of HVJ-E addition in particular, the inserted sheet showed close contacts with the myoblast areas. NaOH maceration destroyed the skeletal muscle fibers and brought about marked myoblast differentiation (Figure 7A). Myoblasts were observed as small round cells with a round clear nucleus, typical nucleolus, and paler cytoplasm than skeletal muscle fibers. The transplanted cells closely adhered to this active zone at several points. At 2 wk after transplantation, myoblasts were rarely found, but the sheet extended among the skeletal muscle fibers. Without NaOH maceration, the inserted cardiomyocyte sheet still survived, but the interface area was quiet

Figure 4 Motion image analysis of transplanted domains. A: Rich motion areas (arrows) in G1 NaOH(+), HVJ-E(+), Cardiomyocytes(+). Length: μm ; width: time (s); A1: The amplitudes are ordered. Large amplitudes rarely appear (arrow); A2: The amplitudes are more frequent, and their width is mostly ordered, but their amplitudes are both high and low. Low amplitudes (arrows) are fewer than high amplitudes; A3: The amplitude width is disordered. The amplitudes consist of three kinds: high, middle (arrows), and low. The frequency of each size is as follows: low > middle > high; B: Poor beating areas in G3 NaOH(-), HVJ-E(+), Cardiomyocytes(+); B1: The width between the amplitudes is irregular. High and low amplitudes are mixed. In particular, some amplitudes do not return to the baseline, and stop on the way for a short time (arrows); C: Poor motion areas in G2 NaOH(+), HVJ-E(-), Cardiomyocytes(+); C1: The amplitude width is long. The amplitudes maintain the same height. HVJ-E: Hemagglutinating virus of Japan envelope.

Figure 5 Action potentials of transplanted domains. A: Definite action potentials are scarcely detected in G3 NaOH(-), HVJ-E(+), Cardiomyocytes(+) (arrows), but the few action potentials observed are varied in waveforms and sizes; B: In G1 NaOH(+), HVJ-E(+), Cardiomyocytes(+), the waveforms are definite and mostly the same (arrows), although there are a few different waveforms. HVJ-E: Hemagglutinating virus of Japan envelope.

Figure 6 Gene expression in transplanted sheets. *MLC-2v* expression is maintained at 2 wk after transplantation, but *Mesp1* expression decreases at 2 wk compared with 1 wk after transplantation. A: G3 at 1 wk; B: G1 at 1 wk; C: G3 at 2 wk; D: G1 at 2 wk.

without myoblast differentiation and showed definite separation (Figure 7B).

At 2 wk after transplantation, HE staining showed close contacts between the inserted cardiomyocyte sheet and the skeletal muscle fibers, in which collagenous fibers and fibroblasts were not found (Figure 8A). Immunostaining of the same area revealed that, although the interface was extremely close, cardiac troponin and skeletal muscle actinin did not merge (Figure 8B).

DISCUSSION

Cell transplantation is different from organ transplantation in that the transplanted cells interact with the surrounding host tissues and need to restructure themselves. The environments encircling transplanted cells are not always preferable for this restructuring. Transplanted cells are always close to cell death, because they cannot rapidly achieve a blood supply. If such cells are not in a sheet-like form, they need to conjugate with one another through a junctional apparatus, while fibroblasts or other free cells can

invade the cells and inhibit their interactions. Meanwhile, it is even more difficult for transplanted cells to create new structures with host tissue cells, because basement membranes demarcate both the host and transplanted cells or tissues as the first barrier, and fibroblasts, collagenous fibers, elastic fibers, fat cells, and other free immunopotent cells can invade the interface easily as a second barrier. Although injected neonatal or pluripotent stem cell-derived cardiomyocytes conjugate with host heart cardiomyocytes^[11], it remains uncertain whether these findings hold true, because extremely small domains were demonstrated by immunostaining.

In this study, cardiomyocytes were transplanted as sheets to avoid the cardiomyocyte restructuring process. Tough cardiomyocyte sheets can easily be acquired, because cardiomyocytes conjugate strongly with one another through intercalated disks and the sheets are easily peeled off using a scraper without requiring enzymatic digestion or other new techniques such as sheet engineering^[13]. The peeled sheets do not become broken and the cells remain alive.

In addition, NaOH was used to remove the connective tissues and basement membranes. This procedure was derived from a method based on the morphology, which involved maceration of basement membranes, collagenous fibers, and elastic fibers applied to fixed specimens^[16,17]. The myoblasts in the NaOH-macerated skeletal muscle fibers showed marked differentiation. The scrub of muscles alone did not produce as much reaction (data not shown). Myoblasts originate from satellite cells, which are self-renewing stem cells that become activated by products such as growth factors produced by crushed muscles to migrate to the injured areas, differentiate into myoblasts, and fuse with each other and the damaged cells to restore skeletal muscle cells^[18]. Although it is well known clinically that NaOH devastates the tissue, penetrates easily followed by an acute necrotic phase, coagulation of intracellular proteins, and intense inflammatory reactions, and causes serious complications^[19], no definite invasion of immunopotent cells and no fibroblasts, at least, were observed in this

Figure 7 Histology of transplanted domains at 1 wk after transplantation. A: In G1 NaOH(+), HVJ-E(+), Cardiomyocytes(+), myoblasts (dotted long arrows) are marked in the latissimus dorsi muscle (LD). The cardiomyocyte sheet (asterisk) adheres to the myoblast layer at various points (short arrows); B: There are no myoblasts, and no adhesion of the cardiomyocyte sheet (asterisk) to the skeletal muscles in G3 NaOH(-), HVJ-E(+), Cardiomyocytes(+). The interspace between the cardiomyocyte sheet and the skeletal muscle fibers is wider. ICM: Intercostal muscle.

Figure 8 HE staining and immunostaining of cellular close contacts in G1. A: The myofibrils of cardiomyocytes (asterisk) are looser than those of skeletal muscle fibers (MF). The boundary is not differentiated between the cardiomyocytes and skeletal muscle fibers. A part of the myoblast sarcoplasm seems to project into the cardiomyocyte plasma (arrows); B: Immunostaining for cardiac troponin (red), skeletal myosin (green), and nuclei (blue). Small projections of skeletal myosin produce invaginations of cardiac troponin (short arrows). Cardiac troponin and skeletal myosin sandwich some nuclei (dotted long arrows) from each side.

study for 2 wk after transplantation. While the marked myoblast recruitment and few invading cells created a better environment for cardiomyocyte transplantation, they were not sufficient because, although the cardiomyocyte sheets showed beating, their domains were smaller and they did not adhere closely to the latissimus dorsi muscle.

The procedure for cardiomyocyte sheet transplantation also required some improvements in this study. First, when the sheet was overlaid on the latissimus dorsi muscle under the skin, *i.e.*, between the skin and the muscle, the procedure failed, in that no beating was observed with or without NaOH maceration (data not shown). This site under the skin, as opposed to under the muscle, may not be as good probably because of the poor vessel supply. Therefore, for subsequent survival, use of cardiomyocyte sheets necessitates some suitable conditions. Although the sheets constantly showed beating in NaOH maceration, when they were inserted between the latissimus dorsi and intercostal muscles, the beating sites were smaller and less frequent, the motion amplitude was smaller, and the action potentials were disordered. Moreover,

close contacts between the transplanted sheets and the host muscular tissues were not formed despite the fact that the sheets were packed like a sandwich between the two muscular tissues. Thus, the space between the two muscles is good for transplantation, but not sufficient for close contact formation.

To obtain close contacts between a sheet and the latissimus dorsi muscle, artificial fusion of the membranes of cardiomyocytes and skeletal muscle fibers by HVJ-E was investigated. HVJ-E is composed of the envelope of Sendai virus and causes high fusion potency between cellular membranes^[20]. It is easier and safer to handle compared with other viruses. After its effectiveness was confirmed *in vitro*, the fusogen was applied to transplantation *in vivo*. Its addition alone was not effective, as the motion amplitude was smaller, and the interspaces were histologically wider. This result was within our expectation, because the lack of removal of fibroblasts, collagenous fibers, and other connective tissues would have interrupted any close contact formation between the transplanted and host cells.

The combination of HVJ-E and NaOH maceration

brought about dramatic changes, *i.e.*, increased beating sites, larger amplitudes, albeit varied, and ordered action potentials. Although there were areas where the interfaces were separated, close contacts between cardiomyocytes and skeletal muscle cells were often found at various points, in which collagenous fibers and fibroblasts were not observed. This morphological feature, *i.e.*, close contacts between skeletal muscle fibers and cardiomyocytes, may bring about complicated motion variance.

Cell fusion produces chimeric cells that include features of both cell types, as seen in hybridomas^[15,21]. Intracellular organelles, including the nucleus, pass back and forth between both cell types after the formation of weak cytoplasmic bridges^[22]. Although the close contact areas observed in this study seemed to be maintained as fused membranes, because both the cytoplasm shared one nucleus and seemed to be partially mingled with each other, while both cytoskeletal systems maintained independent forms from one another and did not undergo reconstruction. However, to prove the interrelationship between the membrane fusion and the cytoskeleton, other cellular morphological methods, such as transmission electron microscopy and deep-etching, may be required. This complicated cell biological theme exceeds the present study and needs to be further examined in future studies.

In conclusion, the combined method involving NaOH and HVJ-E treatments is effective for cellular transplantation as a new technique.

COMMENTS

Background

Advances in regenerative medicine requires further improvements of a cellular transplanted technique to realized clinical applications, because it is important to establish and maintain functional junctions or dense contacts without fibrous invasion between the transplanted and host cells.

Research frontiers

In particular regarding cardiomyocyte transplantation into the heart, if direct electrical coupling is not established between the transplanted and host cells, the transplanted area becomes a source of arrhythmia and/or disordered contractions. It is challenging to overcome this issue, which has been performed in this research.

Innovations and breakthroughs

The most important innovations of the research propose a new invention of myocardiocyte sheet transplantation, which is to fuse face-to-face areas between two tissues, after NaOH maceration, using virus envelopes and not to intervene connective tissues between them. This method will protect a host heart from conduction disturbance.

Applications

This transplantation method using cell fusion will be applied clinically as a new one to establish cell biological function between host and donor tissues without intervention of connective tissues.

Terminology

HVJ-E is a simplified form of hemagglutinating virus of Japan envelope. This virus is usually murine parainfluenza virus type 1 and is known as Sendai virus. The most novel feature is that it has an ability to fuse cells, which is a useful tool in the scientific world to produce hybridoma. In this experiment, its envelope is used, which guarantees safety as well as effectiveness.

Peer-review

The current study provided the evidence that a new method using HVJ-E and NaOH may facilitate the cell transplantation into the tissues.

ABOUT COVER

Editorial Board Member of *World Journal of Stem Cells*, Zong-Jin Li, MD, PhD, Professor, Department of Pathophysiology, Nankai University School of Medicine, Tianjin 300071, China

AIM AND SCOPE

World Journal of Stem Cells (*World J Stem Cells*, *WJSC*, online ISSN 1948-0210, DOI: 10.4252), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJSC covers topics concerning all aspects of stem cells: embryonic, neural, hematopoietic, mesenchymal, tissue-specific, and cancer stem cells; the stem cell niche, stem cell genomics and proteomics, and stem cell techniques and their application in clinical trials.

We encourage authors to submit their manuscripts to *WJSC*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

INDEXING/ ABSTRACTING

World Journal of Stem Cells is now indexed in PubMed Central, PubMed, Digital Object Identifier, and Directory of Open Access Journals.

Core tip: Circulating endothelial progenitor cells (EPCs) have important potential for use in the treatment of ischemic diseases. However, their clinical application is limited by the lack of unambiguous and consistent definitions. This article reviews the definition of EPCs, their status in subjects with cardiovascular disease and discusses strategies to enhance EPCs for treatment of ischemic diseases. In patients with cardiovascular conditions who may require EPC administration, EPC numbers are low and EPCs are dysfunctional. Augmenting these cells may eventually improve their clinical efficacy.

Abstract

Circulating endothelial progenitor cells (EPCs) have been demonstrated to correlate negatively with vascular

INTRODUCTION

Circulating endothelial progenitor cells (EPCs) are bone marrow - derived mononuclear cells that have the capacity to migrate, proliferate, and differentiate into mature endothelial cells (ECs)^[1]. Asahara *et al*^[2],

reported that CD34⁺ hematopoietic progenitor cells from adults can differentiate *ex vivo* to an endothelial phenotype, expressing EC markers and incorporating into neovessels. Since then, many publications have demonstrated the phenotype and function of these cells and use them in animal models and clinical studies^[3-7].

HETEROGENEITY OF EPC

The translation of basic research into the clinical practice of EPCs has been limited, in part, by the lack of unambiguous and consistent definitions of EPCs. In general, two methods have been used to isolate EPCs: (1) cell selection based on surface markers; and (2) cell culture and then selection. Besides CD34, a variety of cell surface markers have been shown to be associated with EPCs.

Both CD14⁺ monocytic and CD14⁻ non-monocytic mononuclear cells have been used as the starting population for cultivation of EPCs^[6]. Fernandez Pujol *et al.*^[8], demonstrated that CD14⁺ monocytic cells underwent a morphological transformation to oval cells and showed a clear expression of EC markers after 1 wk. These markers include von Willebrand factor (vWF), VE-cadherin, CD105, acetylated low-density lipoprotein (ac-LDL)-receptor, CD36, vascular endothelial cell growth factor receptor-1 (VEGFR-1, Flt-1), and VEGF receptor-2 (VEGFR-2 or KDR). However, Urbich *et al.*^[6], showed that CD14⁻ non-monocytic mononuclear cells also expressed endothelial marker proteins and were able to form colonies. CD14⁻ cells were found to incorporate into vascular structures of nude mice after hind-limb ischemia and significantly improved neovascularization.

Kalka *et al.*^[9], cultured human peripheral blood mononuclear cells and characterized adherent EPCs. EPCs were able to up-take ac-LDL and expressed endothelial surface markers such as vWF, VEGFR-2, VE-cadherin, CD146, and CD31. In a similar approach, Hill *et al.*^[10], found that colonial formation EPCs expressed KDR, CD31, and Tie2.

Interestingly, Hur *et al.*^[3], identified two types of EPCs from the same source and labelled them as early EPC and late EPC. They expressed different level of VE-cadherin, Flt-1, KDR, and CD45 markers. Late EPC produced more nitric oxide, incorporated more into human umbilical vein ECs monolayer, and are able to better form capillary tube than early EPC^[3]. However, early EPC secreted more angiogenic cytokines (VEGF and interleukin-8) than late EPC at culture^[3]. These suggest that two types of EPC might have different roles in neovascularogenesis.

More recently, besides CD34, CD133, KDR and Ac-LDL up-take have been used more frequently as EPC markers for selection^[11-14]. CD34 is a stem cell marker, CD133 an early EPC marker, KDR a marker for ECs, and Ac-LDL up-take, an endothelial function. Controversy remains on what are the most suitable makers for selecting EPC and what type of EPCs are most optimal for clinical application of cell therapy. Regardless of their

cell surface markers, EPCs shall have the capacity to form tubular structure on Matrigel^[3,4], take up Ac-LDL^[3,4], form colonies^[4-6] and have the capacity to form vessels *in vitro*^[2,9,15,16].

EPC NUMBER AND FUNCTION IN CARDIOVASCULAR DISEASES

Clinical studies documented a decreased number of circulating EPCs in coronary artery disease (CAD) patients, suggesting that levels of circulating EPCs might be associated with vascular endothelial function and cardiovascular risk factors^[17-21]. Hill *et al.*^[10] measured colony-forming units of EPCs from patients with different degrees of cardiovascular risk but without history of cardiovascular disease. A strong correlation was found between the number of circulating EPCs and the subjects' Framingham risk factor score and between the endothelial function and the number of EPCs. It was also found that EPCs from subjects at high risk for cardiovascular events had higher rates of *in vitro* senescence than cells from subjects at low risk.

Subsequently, it was demonstrated that reduced level of circulating EPCs independently predicts atherosclerotic disease progression and development of cardiovascular events^[17-19]. Sen *et al.*^[17], suggested that EPC determines the quality of the coronary collateral circulation. Georgescu *et al.*^[18] found that hypertension with hypercholesterolemia is accompanied by the alteration of vascular tone, the expression of pro-inflammatory molecules by the vessel wall, and reduced circulating EPC number.

However, contrasting results were reported, by Güven *et al.*^[22] and Werner *et al.*^[23], on the association between the level of circulating EPCs and severity of CAD. Similarly, contrasting reports were also published in patients with peripheral arterial disease (PAD)^[13,24-26]. This difference might be explained by different sampling time during the studies at different part of the disease process^[27]. Higher circulating EPC may indicate early stage of CAD and PAD, while lower circulating EPC indicates more severe and late stage of disease, and is associated with poorer outcome of these patients. It become clear that EPC cell number and function are reduced in subjects with cardiovascular risk factors and more severe cardiovascular disease^[28-32]. These are also subjects whom may benefit from EPC harvest for autologous transplantation. Thus it is important to enhance EPC cell number and function for clinical use.

STRATEGIES TO ENHANCE EPC POTENCY

Though animal studies of autologous EPC transplantation is feasible in both coronary and peripheral artery diseases, clinical application of these therapies are limited. Asai *et al.*^[33] demonstrated that topical Sonic hedgehog (*Shh*) gene therapy enhanced wound healing

by promoting recruitment of bone marrow derived EPCs. Besides migration, Shh also enhances EPC proliferation, adhesion, and tubule formation. In contrast, Jujo *et al.*^[34], showed that AMD3100, a CXCR4 antagonist, enhanced neovascularization and functional recovery after myocardial infarction through enhanced mobilization of EPC. Interestingly, the combinational therapy of Shh gene transfer with AMD3100 improved cardiac functional recovery by enhanced progenitor cell mobilization^[35].

Yao *et al.*^[12], modified EPCs with tissue kallikrein (TK) and found that TK protected EPCs from oxidative stress-induced apoptosis *via* inhibition of activation of caspase-3 and -9, induction of Akt phosphorylation, and secretion of vascular endothelial growth factor^[12]. Moreover, Fu *et al.*^[36], demonstrated that TK can enhance EPC migration and adhesion by up-regulating the expression of integrin- α 3. Thus, TK-modified EPCs may be another strategy to enhance therapeutic potency of EPC for tissue repair.

Other agents such as statin, adiponectin, thymosin β 4 (T β 4), losartan, aliskiren, hydrogen sulfide, GTP cyclohydrolase I, and ephrin-B2/Fc have been used to enhance EPC^[37-42]. Among these, statin, losartan, aliskiren, and T β 4 have good potential to improve quality and quantity of EPCs in patients with diabetes. Statins, a commonly used class of drugs to lower cholesterol levels by inhibiting the enzyme HMG-CoA reductase, have pleiotropic beneficial effect on EPC^[37,43], atorvastatin increased circulating EPC after just 4 wk of administration in patients with ischemic heart failure^[37]. Rosuvastatin mobilized EPC which is shown to be Akt/endothelial nitric oxide synthase dependent^[43].

Besides statins, losartan, an angiotensin II receptor antagonist drug, commonly used in hypertension, significantly improved impaired EPC function in hypertensive patients^[42]. T β 4, an actin sequestering protein, is found to possess angiogenic activity^[44,45] and anti-diabetic property^[46]. T β 4 is angiogenic and can promote EC migration and adhesion, tubule formation, aortic ring sprouting, and angiogenesis^[44,45]. T β 4 ameliorates hyperglycemia and improves insulin resistance in mouse model of type 2 diabetes^[46]. We showed that EPCs derived from Zucker diabetic fatty rat have reduced angiogenic potential. Treatment with T β 4 *in vitro* improved EPC function and survival. It also appears to be beneficial *in vivo* (unpublished results). T β 4 is a potential drug that can improve function of diabetic EPCs for cell therapy.

Clinically, EPC has been used in clinical trials^[7,21,47]. In early phase clinical trials using EPCs for intramyocardial transplantation in subjects with refractory angina, Losordo *et al.*^[7,48] used G-CSF to mobilize bone marrow cells and selected CD34⁺ cells using magnetic beads post-apheresis. Subsequently these are injected into the ischemic myocardium without enhancing the cells^[7,48]. Feasibility and safety appears to be established. However, efficacy remains to be demonstrated in sizeable clinical trials, preferably in a randomized and blinded manner. As subjects who need EPC therapy has lower EPC numbers and more dysfunctional EPC, these cells may need to be

augmented prior to autologous transplantation. There are already several agents discussed above, which can enhance mobilization (*e.g.*, AMD3100) and function of these cells. For the latter, post-processing after harvesting, may be employed. However, it will be important to make sure the cells improve and no adverse effect on these cells as a result. *In vitro* assays and animal experiments appear to show enhancement. Whether these strategies can be translated into clinical use remain to be demonstrated. It is also important to define relevant clinical end-points and surrogate parameters. Beyond statistical significance in improving markers, these need to be clinical significance. Thus, EPC migration may increase by a few millimeter *in vitro* in a dish or the left ventricular longitudinal strain may increase by a couple of percent, it is important to show clinical relevance in translation. Besides autologous strategies, allogeneic transplantation, which has been used in animal models, may also be considered for clinical use^[45,49].

Abstract

Functional synaptogenesis and network emergence are signature endpoints of neurogenesis. These behaviors provide higher-order confirmation that biochemical and cellular processes necessary for neurotransmitter release, post-synaptic detection and network propagation

of neuronal activity have been properly expressed and coordinated among cells. The development of synaptic neurotransmission can therefore be considered a defining property of neurons. Although dissociated primary neuron cultures readily form functioning synapses and network behaviors *in vitro*, continuously cultured neurogenic cell lines have historically failed to meet these criteria. Therefore, *in vitro*-derived neuron models that develop synaptic transmission are critically needed for a wide array of studies, including molecular neuroscience, developmental neurogenesis, disease research and neurotoxicology. Over the last decade, neurons derived from various stem cell lines have shown varying ability to develop into functionally mature neurons. In this review, we will discuss the neurogenic potential of various stem cells populations, addressing strengths and weaknesses of each, with particular attention to the emergence of functional behaviors. We will propose methods to functionally characterize new stem cell-derived neuron (SCN) platforms to improve their reliability as physiological relevant models. Finally, we will review how synaptically active SCNs can be applied to accelerate research in a variety of areas. Ultimately, emphasizing the critical importance of synaptic activity and network responses as a marker of neuronal maturation is anticipated to result in *in vitro* findings that better translate to efficacious clinical treatments.

Core tip: During stem cell neuronal differentiation, functional synaptogenesis and the emergence of coordinated, networked activity are critical behaviors in confirming that cells have developed into a relevant neuronal population. As the number of stem cell-derived neuron (SCN) models continues to proliferate, the use

of specific functional readouts to evaluate SCN maturity will become increasingly important compared to morphological or proteomic characterization of neuronal maturation. The review provides diverse options for reliably assaying the development of synaptic neurotransmission in derived neurons and describes the strengths, weaknesses and potential applications of several stem cell-based neuron models.

INTRODUCTION

Over the last few decades a large variety of *in vitro* models have been developed for use in basic and applied neuroscience. These neurogenic models originate from diverse sources, including dissociated primary neurons, immortalized cell lines derived from neuronal and non-neuronal tissues and, most recently, stem cells. The predictive value of these models is critically dependent on their ability to recapitulate fundamental neuronal behaviors exhibited by primary neurons. This is particularly important given the profound effects that subtle changes in neuron development or maturation can have on emergent network properties.

In vivo, the differentiation of neural precursors into synaptically active, post-mitotic neurons involves a complex developmental cascade of gene expression and morphological changes^[1-3]. These changes ultimately orchestrate synaptic, neuronal and network behaviors to produce the emergent properties responsible for sustained central nervous system (CNS) function. Given the complex cellular behaviors involved in producing synaptically active neurons, it is not surprising that synaptogenesis and maintenance of synaptic activity are highly sensitive to genetic and environmental perturbation^[4,5]. While many dissociated primary neuron cultures reliably form functioning networks that exhibit physiological behaviors, their use is limited by several factors, including the difficulty of dissection, variability among cultures, poor viability for longer-term studies and the regulatory, administrative and ethical burdens imposed by animal studies. In contrast, while immortalized cells have been extensively used as a replacement for primary neurons, they uniformly fail to recapitulate many neurotypic properties^[6].

The advent of neurons derived from stem cells offers the potential for a unique experimental platform that combines the relevance of primary neurons with the flexibility and scalability of immortalized cells^[6]. Stem cell-derived neuron (SCN) models that produce functionally mature neurons have multiple characteristics that render them exceedingly well-suited to the study

of neural development, neuron function and human disease. For example, SCNs can recapitulate functional behaviors that are characteristic of primary neurons, such as synaptic neurotransmission and network emergence. Many stem cell lines can be maintained in culture for prolonged periods prior to differentiation, enabling scalable expansion to accommodate the demands of high-throughput approaches and endowing differentiated neurons with reduced inter-experimental phenotypic and genetic variability. The ability to convert primary cells to patient-specific induced pluripotent stem cells (iPSCs) has kindled the extraordinary potential of personalized medicine, in which iPSC-derived neurons (i-neurons) expressing cellular correlates of particular neurological pathologies can be studied *in vitro* in the context of the patient's genome^[7]. Finally, SCNs have also been proposed to have a direct application in cell-based therapies, whereby partially differentiated neural progenitor cells or post-mitotic immature neurons can be directly injected into the CNS to integrate into existing architecture, supplement endogenous neurogenic processes and promote the repair of damaged neural tissues^[8,9]. However, SCN models must be shown to be competent to form context-appropriate, functioning neurons before these approaches can be used as intended.

The signature characteristic of CNS neurons is action potential (AP)-induced synaptic neurotransmission that synchronizes neuron firing to give rise to emergent circuit behaviors. Since synaptic activity is a principal endpoint of neurogenesis, detection of synaptic events and/or synaptically driven network behaviors serves as a higher-order readout that confirms the proper elaboration of the full range of biochemical, proteomic and morphological properties that are required for neuron function. However, in many cases the rigor and specificity of techniques used to characterize the physiological relevance of SCNs have been highly variable^[10,11]. Frequently, characterizations have been limited to expression of small sets of neurotypic genes or electrophysiological assessment of intrinsic electrical excitability, without evaluation of functional synaptogenesis or network formation^[12,13]. SCNs are frequently described as physiologically relevant based on insufficient or incomplete characterizations, therefore producing data of uncertain value. These inconsistencies illuminate a critical need for the identification of appropriate assays to evaluate the functional maturity and physiological relevance of derived neuron models.

In this review we will discuss methods to characterize the progression of *in vitro* neurogenesis and propose specific functional assays to confirm the physiological relevance of SCNs. We will focus on SCNs derived from four sources (summarized in Figure 1): embryonic stem cells (ESCs); restricted-potency neural stem cells (NSCs); iPSCs; and direct conversion of post-mitotic cells into induced neurons (iNs). Note that although iNs do not explicitly incorporate a pluripotent phase, the derivation of iNs uses principles and techniques involved

Figure 1 Illustration of the sources of derived neurons. Embryonic stem cells (ESCs) are derived from the inner cell mass of blastocysts, whereas neural stem cells (NSCs) are derived from several defined niches in the developing or adult brain. Both ESCs and NSCs are capable of neurogenesis without the forced expression of induction factors. Induced pluripotent stem cells (iPSCs) and induced neurons (iNs) can be derived from various tissues, and proceed to neuronal states via either reprogramming to a stem cell phenotype (iPSCs) or direct conversion using neuronal induction factors (iNs).

in production of other SCN models and therefore will be addressed in this review. We will also describe the current status of existing SCN models, and elaborate on reasons why synapse and network formations are critically important to SCN applications, even in cases where applications may not directly rely on neuronal function.

METHODS TO CHARACTERIZE NEUROGENESIS AND NEURONAL MATURATION

Measuring the maturation and relevance of neurogenic models

Developmentally regulated changes in proteomic, transcriptomic, biochemical and functional properties during embryonic neurogenesis can be repurposed to evaluate developmental progression *in vitro*^[14]. The specific markers used may vary depending on the ultimate application, but at a minimum should include morphological characterization of neurotypic compartments; the development of electrical excitability; the detection of post-synaptic responses to pre-synaptic release of neurotransmitter; and, when appropriate, network-level behaviors (Figure 2). While functional confirmation of synaptic neurotransmission represents indisputable evidence of synaptogenesis, supplemental studies such as transcriptomic analysis, planar multi-electrode array (MEA) analysis or protein expression studies can also provide valuable contributions to the overall understanding of the maturity and nature of derived neuronal populations, as described below.

Although methods to validate the progression

of neuronal maturation have been well-described in dissociated cultures of primary neurons, it is important to recognize that the source tissues for these neurons are often comprised of functionally mature neurons that are dissociated and plated^[15]. In these cases, re-establishment of synaptic activity is primarily contingent on the temporal re-elaboration of appropriate morphological structures. In contrast, the differentiation of pluripotent stem cells into mature SCNs requires recapitulation of the full range of transcriptional, morphological and proteomic changes involved in functional neurogenesis. Neurogenic progression is an intricate process that is susceptible to misdirection *in vitro*, and unlike in dissociated primary neurons, there is a lower correlation between expression of intermediate developmental markers and the probability of functional maturation. Inappropriate differentiation conditions can cause neurogenic models to become developmentally arrested, expressing immature neurotypic properties but lacking the functional correlates of active synapses and network emergence^[16]. Dissociated primary neuron cultures can also undergo developmental arrest if not properly maintained, despite having been functionally mature prior to dissociation^[1]. Once neurons become functionally mature, their survival continues to depend on synaptic activity-induced neurotrophic signaling^[17-20], as demonstrated by neurotoxicity following impaired synaptic function in neurodegenerative diseases^[21-23]. Therefore, researchers characterizing SCN differentiation should be careful to avoid phenomenologically conflating the expression of intermediate developmental markers with the eventual likelihood of producing functionally mature neurons. For example, the ability to fire repeated APs with hyperpolarizing after shoots in response to

Figure 2 Neurotypic markers and passive membrane responses are not predictive of functional synaptogenesis. A: Representative fluorescent immunocytochemistry of i-neurons from several protocols (A1-A4) imaged at 43 d after plating (DAP). SCNs display neurotypic morphologies, including distinct dendrites (Map2) and axons (Tau) around cell nuclei [4',6-diamidino-2-phenylindole (DAPI)], with distributed and punctate synapsin (top panel) and PSD-95 or gephyrin (bottom panel) often expressed in close proximity to synapsin (insets); B: Although all four i-neuron models displayed intrinsic excitability, including voltage-gated currents, and produced action potentials following current injection, responses were smaller in amplitude and depolarization led to fewer repeated action potentials compared to responses displayed by mouse embryonic stem cell-derived neurons (mESNs, top row); C: Only one of four human i-neuron models displayed miniature synaptic activity on DAP35 or later as indicated by miniature post-synaptic currents in the presence of tetrodotoxin, and those currents were smaller in amplitude, less frequent and slower to return to baseline when compared to mESNs; D: Transmission electron microscopy of single synapses in mESN and i-neuron models (D1) indicates that pre-synaptic compartments of mESNs are densely loaded with vesicles, while i1 is not. This indicates that while the model is capable of producing the morphology, synaptic markers and intrinsic characteristics of synaptogenesis, it lacks the capacity to maintain spontaneous activity and therefore is unable to model physiological synaptic transmission or network activity.

current injection is often associated with neuronal maturity. This may be valid in many well-characterized primary neuron cultures. However, there is no causal requirement that SCNs with this intrinsic behavior will exhibit functional synapses with synaptically driven network responses.

As the number of SCN models continues to proliferate, the deliberate use of specific functional readouts to evaluate SCN maturity will become increasingly important. By precisely and accurately associating neurotypic behaviors with stage-specific markers, researchers will be able to better ascertain the degree of relevance and applicability of SCN populations. Efforts to develop techniques to reliably determine the neurogenic potential of SCN differentiation models are currently underway^[11,24]. However, in the absence of such functional validation, claims of neuronal maturation and therefore relevance should be reviewed with care.

Approaches for morphological and structural characterization of neurogenesis

Much of the current understanding of neuronal maturation comes from longitudinal studies of the formation of specialized neuronal structures in dissociated primary neurons^[25]. These studies established that the progressive establishment of functionally specialized compartments (e.g., axons, hillocks, dendrites, and pre- and post-synaptic compartments) provided the cellular substrates for polarized neurotransmission *in vitro*. Many of these morphological features can be distinguished by the localization expression of specific proteins and therefore immunocytochemistry (ICC) is often used to characterize developmental progression^[26,27]. Morphological characterization may start with general neuronal markers, such as NeuN (post-mitotic neuronal nuclei) or β III-tubulin (immature neuronal marker), and progress to more specialized markers of cellular compartments, such as synapsin (pre-synaptic), tau (axon), MAP2 (somatodendritic) and gephyrin or PSD-95 (inhibitory or excitatory post-synaptic markers, respectively). It can then extend to the use of well-described antibodies to distinguish among neuronal subtypes, such as markers of glutamatergic (vesicular glutamate transporter-1 or -2), cholinergic (choline acetyltransferase), GABAergic (glutamate decarboxylase 1), serotonergic (serotonin transporter), aminergic (vesicular monoamine transporters 1 or 2), or dopaminergic and/or adrenergic (tyrosine hydroxylase) neurons. Longitudinal studies using such markers are a regular feature of SCN differentiation studies and are an important aspect of verifying neuronal maturation, even though expression of specific markers are not indicative of functional behaviors^[28,29].

In addition to providing information on the establishment of synaptic compartments, the morphological apposition of pre- and post-synaptic proteins can provide clear evidence of synaptic assembly^[30]. Synaptic assembly begins with the contact of complementary cell adhesion molecules between potential pre- and post-synaptic compartments, which in turn requires

the previous elaboration of axons and dendrites (with the exception of axosomatic synapses^[31]). From this point, proteins necessary for synaptic architectures and function are recruited to the site of contact in both compartments^[32,33]. In mature neuron cultures and *in vivo*, the establishment of new synapses can occur very quickly, with synaptic activity apparent almost immediately^[34,35]. However, as demonstrated in Figure 2 and discussed above, SCNs can form synaptic structures but fail to develop synaptic function. Based on this positional apposition, ICC for synapsin and PSD-95 (for example) have been used to provide a low-resolution confirmation that pre- and post-synaptic compartments are in close proximity. More recently, the mammalian GFP reconstitution across synaptic partners (mGRASP) method has been used as a fluorescent indicator of the co-localization of synaptic adhesion proteins. mGRASP is based on functional complementation of split GFP separately expressed from pre- and post-synaptic membranes, and therefore is a highly specific marker of synaptic proximity^[36]. Ultrastructural imaging using transmission electron microscopy (TEM) can also be used for advanced morphological analysis of synaptogenesis. TEM enables a definitive visualization of pre- and post-synaptic compartments, allowing researchers to search for characteristic intra-synaptic structures, such as pre- and post-synaptic densities, the presence of synaptic vesicles in the pre-synaptic compartment and possibly even vesicles docked or fused with the pre-synaptic membrane, suggesting neurotransmitter release. It is important to emphasize that positive confirmation of synaptic architectures by any of these methods is not *prima facie* evidence of synaptic function. Synapse assembly precedes onset of synaptic activity and is not indicative of the current or future development of synaptic function^[37-39]. However, pairing these types of morphological studies with electrophysiology may allow the identification of benchmarks that can be used to correlate synaptic function with gene expression (e.g., the onset of synaptic activity cannot precede the localization of protein X, etc.). While structural characterizations have rarely been used in the study of SCN maturation, they have the potential to offer highly specific and detailed correlations between structural and functional synaptogenesis when combined with synaptic activity assays.

While morphological characterization provides researchers with a visual confirmation of protein expression and compartmentalization, some neuronal markers (e.g., β III-tubulin^[40], synapsin^[41] or NeuN^[42]) may also be expressed in non-neuronal or neoplastic cells. Morphological characterization of neurogenesis should therefore be used as a secondary method to confirm neurogenesis and be corroborated by more direct methods to measure the production of neurons. For example, we have found transcriptomic analysis to be invaluable in reconciling neuronal fate with expression of neurotypic markers and evaluating neurotypic responses, including: (1) longitudinal characterization

of neurogenic progression; (2) identification of neuronal subtypes; (3) determination of which neurotransmitter receptors subunits are expressed; and (4) measurement of activity-dependent responses to treatment with pharmacological regulators of network activity^[43].

Measurements of intrinsic excitability

Functional evaluation of neuron maturation begins with electrophysiological characterization of intrinsic excitability, which is the ability to undergo the rapid, defined changes in ion flux that are necessary to repeatedly fire APs. These include measurements such as quantitation of Na⁺ and K⁺ voltage-gated responses, the ability to fire evoked APs, membrane resistance, membrane capacitance, sag (or I_h) currents, hyperpolarization-activated currents and establishment of a stable resting membrane potential. Another intrinsic neuronal characteristic that can be used as a developmental marker of maturation is the γ -aminobutyric acid (GABA) reversal potential (E_{GABA}). Immature neurons have high intracellular Cl⁻ levels, such that GABA_A receptor activation triggers Cl⁻ efflux^[44]. This excitatory GABA current has been proposed to contribute to the developmental activation of nascent excitatory synapses^[45]. Neuron maturation is associated with increased expression of the potassium chloride co-transporter KCC2, which is an electroneutral Cl⁻ exporter that decreases intracellular Cl⁻ concentration, thereby shifting E_{GABA} to a value that is close to the mature resting membrane potential^[46]. The developmental shift in E_{GABA} potentiates a transition from excitatory post-synaptic GABA currents to inhibitory GABA currents^[47]. While the development of E_{GABA} is rarely used for neuronal characterization because of the relative difficulty in measuring Cl⁻ reversal potentials, the shift in E_{GABA} is an elegant marker of the developmental changes that are required for the establishment of network-level activities in many neuron subtypes.

Once neurons have been determined to exhibit mature characteristics of intrinsic excitability, analysis then expands to measuring cell behaviors under non-evoked conditions, such as spontaneous production of APs and miniature post-synaptic currents. It is important to note that the mere presence of spontaneous APs does not necessitate or signify synaptic function^[48]. For example, dissociated primary neurons exhibit mature-appearing intrinsic characteristics and spontaneously fire APs prior to formation of active synapses^[27]. In fact, spontaneous, non-evoked AP firing appears to be a developmental phenomenon involved in the maturation of ionic gradients^[49,50]. Furthermore, the detection of APs can reflect a neuron with a membrane potential that is near to the threshold potential and therefore fires APs in response to subtle changes in the conductance of membrane ion channels, independent of synaptic activity^[51,52]. Since APs may occur in the absence of synaptic function, pharmacological antagonists of neurotransmitter receptors must be used to experimentally confirm that APs originate from synaptically driven events as described below.

Synaptic activity is a functional signature of successful synaptogenesis

In some cases, SCNs produce morphological characteristics of synapse formation, exhibit evidence of intrinsic excitability and fire spontaneous APs, yet fail to develop synaptic activity^[29,53]. As discussed below, this is currently a particularly vexing problem with human iPSC-derived neurons, which exhibit a wide array of morphological markers of neurogenesis, but often appear to be developmentally delayed or even arrested prior to the onset of synaptic activity. Consequently, measurements of synaptic activity are critical to providing unimpeachable confirmation of functional synaptogenesis.

The production of excitatory and/or inhibitory post-synaptic currents is a higher-order representation of the spatiotemporally precise elaboration of a large number of developmental processes required for synaptic activity, such as juxtaposition of pre-synaptic and post-synaptic compartments; loading and docking of neurotransmitter vesicles; and the appropriate localization and function of voltage-dependent ion channels. The two dominant modes of synaptic neurotransmission are spontaneous release and AP-evoked release. Under physiological conditions stochastic Ca²⁺ currents trigger synapses to spontaneously release neurotransmitter at approximate rates of 10⁻³ quanta per second (Hz) per CNS synapse^[54,55] and 0.79 Hz per motor neuron synapse^[56]. In a typical central neuron, which has 10²-10⁴ synapses, monosynaptic release probabilities result in a post-synaptic current detection rate of 0.1-10 Hz^[57,58]. Similar rates have been reported in mouse SCNs^[59]. In contrast, AP-induced pre-synaptic depolarization increases instantaneous quantal release rates increase to 10³ Hz^[54,55]. While either spontaneous or AP-evoked neurotransmission can be used to identify the presence of synaptic neurotransmission, the large currents generated by AP propagation can complicate rigorous characterization of post-synaptic behaviors, as described below. Consequently, detection and characterization of spontaneous post-synaptic events often provides a more reliable and quantifiable indicator of synaptic function than detection of synchronized release from many synapses following an AP.

Detection of post-synaptic events using whole-cell patch-clamp electrophysiology can involve characterization of excitatory post-synaptic potentials (EPSPs) in current-clamp mode or spontaneous miniature post-synaptic currents in voltage-clamp mode. For a number of technical reasons related to quantitation and characterization that will not be addressed here, we recommend the latter approach. Spontaneous release is a salient feature of all synapses *in vivo* and *in vitro* and direct measurement of spontaneous monosynaptic activity *via* detection of miniature excitatory or inhibitory post-synaptic currents (mEPSC or mIPSC, respectively) in the presence of tetrodotoxin (TTX) is an unambiguous indicator of synaptic function in neuron subtypes that utilize ionotropic neurotransmitter receptors (Figure

2)^[54,60-62]. TTX blocks voltage-gated Na⁺ channels, eliminating the large whole-cell currents caused by AP firing and enabling the detection of small post-synaptic currents resulting from the spontaneous activation of individual synapses. The addition of pharmacological agonists or antagonists for specific neurotransmitter receptors allows the contributions of different neuron subtypes to post-synaptic responses to be precisely determined.

Characterization of miniature post-synaptic currents (aka, minis) should include analysis of event rates and kinetics; functional responses to the addition of pharmacological modulators of post-synaptic function; and current: voltage relationships for well-characterized receptors^[59]. Much is known about the functional mechanisms of synaptic neurotransmission in primary CNS and peripheral neurons and an extensive pharmacopeia is available to manipulate and characterize post-synaptic responses for most synapse subtypes. Thus, there is a wide array of resources to identify and develop electrophysiological approaches to evaluate synaptic function in SCNs.

While the kinetic analysis of minis can be used to unambiguously distinguish between synaptic and non-synaptic neurotransmission, in some instances (e.g., synaptic potentiation studies) it would be valuable to simultaneously evaluate both pre- and post-synaptic behaviors. Paired recordings offer one means to do so. In paired recordings, two synaptically connected neurons are simultaneously patched, such that stimulation of one neuron elicits post-synaptic responses in the other. While this is a highly rigorous and reliable indicator of connectivity, it is a technically difficult method. Paired recordings are relatively feasible under conditions in which neuronal connectivity is well defined and the polarization of synaptic connections are known, such as in hippocampal slices^[63]. In contrast, trans-synaptic connectivity and polarization are stochastic in dissociated neuron cultures, making it difficult to identify and record from synaptically coupled neurons, even when plated at very low densities^[64]. Thus, while paired recordings are an effective method to characterize evoked synaptic neurotransmission, it is technically challenging to accomplish in neuron cultures and should be anticipated to have a high failure rate. Alternatively, the use of bipolar stimulating electrodes allows for the repeated stimulation of specific local synapses *in vitro* without requiring multiple patches^[65]. However, this approach relies on the stimulation of multiple processes in proximity to a patched neuron and therefore may result in field stimulus-like artifacts and difficult to interpret post-synaptic responses.

The use of post-synaptic miniature currents to measure synaptic neurotransmission is not feasible in neuron subtypes that rely on metabotropic neurotransmitter receptors, such as dopaminergic or serotonergic neurons. While methods such as ultrafast voltammetry or the use of fluorescent false neurotransmitters can directly measure synaptic release of neurotransmitters^[65,66], they are not a confirmation of synaptic neurotransmission,

but rather are limited to providing information about the pre-synaptic release of neurotransmitter. Alternatively, indirect measurements of the activation of metabotropic synapses in cultures containing multiple neuron subtypes can be conducted based on changes in network behavior, as described in the next section.

Table 1 lists exemplar SCN models that have been evaluated for the existence of spontaneous post-synaptic currents in the absence of co-cultured primary neurons. The latter were excluded due to the difficulty in disambiguating neurotransmission and neuro-excitation between SCNs and primary neurons^[67]. Table 1 does not include references for putative SCNs that have only been characterized for morphological markers or for intrinsic excitability, since as described above these are poor surrogates for assaying functional synapses.

Network behaviors as higher-order signatures of neuron function

Similar to synaptic activity, emergence of network activity confirms successful elaboration of the developmental processes required for functional synaptogenesis. We define "network potential" as the ability of derived neurons to integrate post-synaptic events into APs (excitability), to transmit outgoing synaptic signals to other neurons (neurotransmission), and to elicit activity-dependent post-synaptic behaviors (adaptability). While the emergence of network activity is a function of the neuronal subtypes present, and therefore is not a required feature of mature neuron cultures, it does provide unambiguous confirmation of synaptic activity. Ideally, neuron cultures will incorporate both excitatory and inhibitory neuron subtypes whose activity is modulated by feedback mechanisms to produce an excitatory/inhibitory (E/I) balance. This condition is maintained by adaptation of pre- and post-synaptic properties and can be considered functional evidence of synaptic plasticity^[68]. Alternatively, monotypic cultures comprised of excitatory or inhibitory neurons will result in unbalanced signaling and network inactivity^[69] or seizurogenic bursting^[70], conditions in which long-term neuronal viability may be compromised^[71,72].

Mature network activity is typically observed in SCNs as synchronous AP propagation among multiple neurons, a phenomenon often referred to as network bursting. Since AP production is a stochastic process caused by the near-simultaneous occurrence of a sufficient number of excitatory EPSPs to exceed the firing threshold, *in vitro* quantitation of APs is influenced by a number of factors which determine neuron connectivity, such as the number, weight and type of functioning synapses. Several methods are available to quantify network activity. The most specific is the use of electrophysiological methods to directly measure AP production^[59,73,74]. This can occur *via* simultaneous, multiple patch-clamp experiments, where the synchronicity of spontaneous AP production is compared among patched neurons. Alternatively, the effects of network modulators (e.g., bicuculline, aminopyridine or CNQX, as described below) on the

Table 1 Stem cell-derived neurons characterized for synaptic activity

Cell type	Source	Technical approach	Post-synaptic measurement (days after differentiation)	Additional notes	Ref.
ESC	Human (BG01, BG03)	Stromal cell factors applied	mEPSCs (21)	Also dopaminergic Continued expression of NPC marker <i>Msx1</i>	[254]
	Human (WiCell H9, H1)	SHH application on ESCs or NPCs	mEPSCs, mIPSCs (30)	Also dopaminergic	[110]
	Human (H9 and SA121)	Dual SMAD inhibition, variable SHH, several additional neurotrophic factors	sEPSCs, sIPSCs (35)	SHH concentration-dependent GABAergic and glutamatergic, or dopaminergic fates	[240]
	Mouse (R1)	RA treatment, suspension culture	mEPSCs, mIPSCs (21)		[6,59,226]
	Mouse (J1)	FACS sorting for dopaminergic NPCs, SHH treatment	sEPSCs (22)	Also dopaminergic	[255]
NSC	Human (NSI-566RSC from fetal spinal cord)	9 component differentiation media	mEPSCs (12-48)		[256]
iPSC	Mouse (Adult C57/Bl6 SEZ)	BDNF treatment	mEPSCs, mIPSCs (11-28)	Perforated patch recording	[171]
	Human (normal and ALS fibroblasts)	Dual SMAD inhibition, RA and purmorphamine treatment	sEPSCs (21-42)	sEPSCs only detected with picrotoxin and 4-aminopyridine	[86]
iN	Human (normal and AD fibroblasts)	FACS sorting of NPCs, BDNF, GDNF and cAMP treatment	mIPSCs, mEPSCs (26)	Currents detected in approximately 40% of cells	[148]
	Human (postnatal and adult fibroblasts)	Two-stage Dox, bFGF, Noggin, GDNF, BDNF, forskolin treatments	mEPSCs (30)	Currents detected in 25%-43% of converted cells	[158]
	Mouse (perinatal tail tip fibroblasts)	Glial co-culture, FACS sorting	sEPSCs (15-27)		[156,157]
ESC + iPSC	Human (HES3, BioTime ESI, and WiCell H9 ESCs + melanocyte hiPSCs)	5 morphogenic factors, FACS sorting, glial co-culture	sIPSCs (42-84)	% of cells with currents increases over time	[28]
	Human (HUES9 ESCs + fibroblast hiPSCs)	Noggin and dorsomorphin treatment, recombinant human <i>Dkk1</i> treatment of hiPSC EBs, glial co-culture	mEPSCs (35)	Implanted neurons also received EPSCs Currents detected in 33% of differentiated ESCs and 46% of differentiated iPSCs tested	[111]
	Human (WiCell H9 and SHEF4 ESCs + fibroblast hiPSCs)	3% O ₂	mEPSCs (35)	Mature AMPA and GABA profiles	[47,116]

ESC: Embryonic stem cell; NSC: Neural stem cell; iPSC: Induced pluripotent stem cell; ALS: Amyotrophic lateral sclerosis; AD: Alzheimer's disease; SHH: Sonic hedgehog; NPC: Neural precursor cell; SMAD: Sma and Mad related proteins; RA: Retinoic acid; FACS: Fluorescence-activated cell sorting; BDNF: Brain-derived neurotrophic factor; GDNF: Glia-derived neurotrophic factor; iN: Induced neuron; cAMP: Cyclic adenosine monophosphate; bFGF: Basic fibroblast growth factor; mEPSC/mIPSC: Miniature excitatory/inhibitory post-synaptic current; sEPSC/sIPSC: Spontaneous excitatory/inhibitory post-synaptic current; GABA: Gamma aminobutyric acid; AMPA: Alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid.

frequency or nature of synaptically driven APs can be evaluated in a single neuron in current-clamp mode, providing indirect evidence of the contribution of synaptic activity to AP production. A relatively new approach is the use of MEAs to quantify synchronized bursting behavior in two- and three-dimensional cultures, which provides a unique method for characterizing the effects of neuromodulatory compounds on longitudinal network responses^[75,76]. A more limited alternative to MEAs is the use of live-imaging assays to quantify bursting behavior using fluorescence-based detection of neuronal activity reporters, such as fluorescent genetically encoded calcium indicators (GECIs) or voltage-gated dyes^[77-79]. Calcium imaging is particularly useful for studying network activity, as it is capable of simultaneously monitoring up to thousands of neurons and their associated processes^[80]. While the temporal resolution and sensitivity

of calcium imaging can be limited by fluorophore kinetics, level of gene expression or equipment, it is an excellent complement to electrophysiology^[81]. Recently described GECIs have been found to be able to detect individual APs^[82]; however, improved detection of the small potential differences driven by sub-threshold events is still needed before calcium imaging can approach the resolution offered by whole-cell patch-clamp electrophysiology. The development of optical electrophysiology techniques that offer the throughput of GECIs with the sensitive of whole-cell recordings would represent a transformative approach in large population analyses that would be immediately applicable to synaptically active SCN models.

In all cases the presence of network activity must be confirmed by treatment with pharmacological modulators that alter synaptic activity without directly activating

post-synaptic receptors. This is particularly important for MEAs and calcium imaging, in which it is currently impractical to directly measure synaptic function. Such treatments could include bicuculline, which disinhibits the network by blocking GABAergic inhibitory activity; aminopyridines, which prolong APs by blocking K⁺ efflux; or CNQX, which blocks AMPAR activation and therefore eliminates excitatory signaling in glutamatergic networks^[83-85]. Depending on neuron maturity and the relative proportions of neuron subtypes in SCN cultures, the use of network modulators may be the only possible means to reveal excitatory synaptic activity exceeding the threshold of AP detection^[86]. Thus, the inability to detect APs by methods such as fluorescent calcium imaging or MEAs should not be considered evidence of the absence of synaptic activity.

Activity-dependent responses as an indirect measure of synaptic function

A signature *in vivo* characteristic of network function is the elaboration of activity-induced changes in post-synaptic neurons. In healthy networks a variety of mechanisms are used to balance excitatory and inhibitory inputs, producing circuits that can respond to increases or decreases in input^[68,87]. The best-described of these is Hebbian plasticity, which allows for the constant formation and strengthening of synchronously active synapses and weakening of asynchronous synapses and is mediated by altered phosphoproteomic signaling, changes in receptor function and expression and differential gene expression^[88,89]. Functional Hebbian plasticity can be indirectly evaluated in cultured neurons by measuring changes in the biochemical correlates of plasticity under conditions that up- or down-regulate network activity. Molecular correlates of plasticity include the surface localization of glutamate-responsive AMPA receptors, which can be measured by surface biotinylation or antibody labeling of extracellular residues^[47,90], or the phosphorylation state of post-synaptic kinases such as CaMKII, Akt or CREB, which can be quantified using routine immunoblot methods^[91-93]. Activity-induced changes in the expression of plasticity-related immediate early genes (IEGs) can be monitored by transcriptomic and/or proteomic methods, including Arc, the EGR family, c-Fos, Jun and Homer-1a^[69,70,94-96]. However, it is important to note that many of these genes have multiple functions and are regulated during development and other neuromodulatory treatments^[97,98]. Thus, researchers should be careful to ensure they are evaluating IEG expression under conditions that precisely modulate network activity without inducing acute cytotoxicity or other forms of neuronal stress. Synaptic plasticity can be directly measured by whole-cell patch-clamp electrophysiology in neuron cultures using trans-synaptic patch clamping or bipolar stimulating electrode techniques^[65]. Plasticity- and activity-related assays have rarely been described in SCN models or in primary neuron cultures, but do represent relevant physiological

correlates of network function and they should be considered to be a valuable confirmatory tool when characterizing and validating activity in SCNs.

SCNS: TYPES AND CHARACTERISTICS

Approaches to SCN differentiation

The yield, neuronal subtype(s) and purity of SCNs are heavily influenced by an array of biochemical factors that affect the differentiation process by modulating progression through neurodevelopmental stages. In some cases these factors can be controlled very precisely, such as by the addition of small molecules to promote exit from the pluripotency state, whereas others are less amenable to rational control, such as longitudinal changes in neurogenic potential caused by the spontaneous emergence of mutated subpopulations during routine culturing of stem cell lines. Thus identifying confirmatory markers of neurogenic progression is critically important to validate that differentiation of specific stem cell lines successfully results in the desired neuronal products. Derivation of neurons from human and mouse stem cells lines has been shown to recapitulate many ontological markers described during *in vivo* neurogenesis^[43]. These include markers of the different stages of neurodevelopment, starting from a stem cell state and expressing characteristics of a NSCs stage, neural progenitor cell (NPC) stage and an immature neuron stage before ultimately developing into functional mature neurons.

Neuronal differentiation typically starts with the induction of a neuroepithelial NSC phenotype by withdrawal of pluripotency factors, such as LIF (mouse stem cells) or FGF-2 (human stem cells). The resulting NSCs may be expanded in culture for a limited number of passages to increase neuronal yield^[99-101]. Identifying compounds that sustain the neurogenic competency of NSCs in culture will be valuable for manufacturing purposes, since this will both streamline the differentiation process and increase the total yield. Methods of neural patterning vary wildly. Many protocols involve the use of retinoic acid (RA), which is an early developmental signal for rostral-caudal patterning of the embryonic brain^[102-104]. Differentiation can be further enhanced or directed by a variety of techniques, including supplementation with growth factors, such as brain-derived neurotrophic factor or glia-derived growth factor^[100,105-107]; forced expression of transcription factors that control neuronal fates^[108,109]; or addition of small molecules such as Noggin, Sonic Hedgehog or dorsomorphin^[74,110,111]. Neural patterning can also be influenced by secreted factors, such as the increased production of motor neurons by co-culture of NSCs with muscle cells^[112]. While neuronal maturation can proceed without the deliberate addition of conditioned media or the presence of support cells, some studies suggest that synaptogenesis is significantly enhanced by co-culture with astrocytes^[113,114].

ESCs

ESCs are derived from totipotent cells collected from the inner cell mass of embryos at the blastocyst stage^[115]. Mouse ESC are frequently differentiated to neurons *via* the 4/4 method, which involves neural induction by the withdrawal of LIF and neural patterning by the addition of RA^[116,117]. The resulting ESC-derived neurons (e-neurons) have been shown to produce highly active glutamatergic and GABAergic synapses with emergent network responses^[59] and activity-dependent gene expression^[74]. ESC differentiation protocols can be modified by the addition of exogenous growth factors to generate other neuronal phenotypes, ranging from a mixture of dopaminergic, glutamatergic, cholinergic and adrenergic neurons^[118] to a homogenous GABAergic neuron population with immature, excitatory GABA signaling^[119]. Mouse e-neurons have been found to reliably form functioning synapses and robust emergent networks within weeks, whereas methods to produce comparable levels of network activity in human e-neurons are still under investigation^[28]. It has recently been suggested that many extant human ESC lines exhibit epigenetic markers of partially differentiated epiblasts rather than naïve ESCs, which could provide a plausible mechanism for their relatively poor and inconsistent neurogenic potential^[120]. In contrast, neurons derived from monkey, canine, pig, chicken, worm or fly ESCs^[121-127] have been found to develop neurotypic morphologies, although characterization of the resulting neurons has not included functional measure of synaptic activity and network emergence to date.

NSCs

NSCs are proliferating stem cells that are restricted to neural lineages. NSCs are isolated from fetal and adult CNS, and therefore their availability and use is limited and subject to ethical concerns^[128-131]. One advantage of NSCs is that they appear to replicate *in vivo* mechanisms of adult neurogenesis and therefore may represent a more physiologically appealing model than neurons derived from pluripotent cell lines^[132]. In the brain, slow cycling NSCs in the sub-ventricular zones and in the subgranular zone of the dentate gyrus produce neurogenic progeny that pass through sequential developmental stages with structurally and functionally distinct cellular properties^[133]. For example, in the well-studied rodent hippocampal subgranular zone, GFAP⁺ NSCs progressively differentiate into Trb2⁺ transiently amplifying NPCs, DCX⁺ migratory neuroblasts and finally into post-mitotic NeuN⁺-neurons which functionally integrate into existing hippocampal circuits within 3 wk and adopt mature dentate gyrus characteristics within 6-8 wk^[134]. A similar developmental progression has been shown to occur in cultured NSCs based on morphological analysis^[132]. Some NSCs have been observed to be restricted to specific neural lineages *in vitro*, such as lines that only generate astrocytes and oligodendrocytes^[135,136]. The mechanisms underlying this limited potency are unknown, and whether this is a consequence of culture conditions or representative of

in situ behaviors is unclear. As with iPSC- or ESC-derived NSCs, primary NSCs have a limited ability to proliferate in culture before losing their neurogenic competence^[137,138]. Despite the potential value of NSC models, few functional assays have been performed on neurons differentiated from these sources, making it unclear whether they reliably produce active synapses. Furthermore, the collection of human NSCs is only possible under limited conditions, such as from aborted fetuses, during brain surgery or immediately post-mortem, and consequently their use is likely to have limited clinical utility^[139].

iPSCs

iPSCs are reprogrammed from differentiated tissues through the exogenous expression of pluripotency genes, such as the original Yamanaka reprogramming factors *Oct4*, *Sox2*, *Klf4* and *cMyc* or subsequently described variants^[140,141]. While neurogenic iPSCs have been generated from a wide variety of animals and tissues, this review will specifically focus on human iPSCs, predominantly derived from fibroblasts. For reasons that appear to be attributable to stochastic variability in epigenetic changes that occurs during reprogramming, even iPSC clones derived from the same tissue typically exhibit a range of neurogenic potentials, requiring neurogenesis to be characterized from each individual line^[142,143]. As with human ESCs, there has been a recent focus on converting human iPSCs to a naïve epigenetic state (aka, ground-state), with the objectives of establishing a truly pluripotent phenotype that exhibits greater reliability and reduced variability during differentiation^[144-146]. Despite their current technical limitations, two characteristics of iPSCs render iPSC-derived neurons (i-neurons) highly valuable for clinical research. First is the ability to generate patient-specific i-neurons that express the specific genotypic and phenotypic characteristics for a given disease in the context of the patient's own genome. Second, the decreased risk of immunoreactivity following engraftment of autologous cells back to the patient renders iPSCs a viable model for cell replacement therapies. The clinical implications of these characteristics are described further in next section.

The production of i-neurons is relatively new and protocols to reliably generate synaptically active i-neurons are not yet currently available^[147]. For example, neurons differentiated from both normal and Alzheimer's disease patient iPSCs display neurotypic intrinsic electrophysiological properties within a week after differentiation from NPC cultures, but derived neurons were unable to fire repetitive APs following current injection, so they were considered immature^[148]. Similarly, iPSCs differentiated for 10 wk with standard stem cell derivation and differentiation directed towards cortical neurons were found to express abundant synaptic markers, but electron micrographs indicated sparse vesicles in pre-synaptic compartments, and no activity was reported^[16]. In another example, the ability to fire repeated APs was not observed in differentiated iPSC neurons until

about 12 wk after plating^[28]. These findings suggest that i-neurons produced using current methods tend to be developmentally arrested or undergo functional synaptogenesis much less quickly than rodent SCNs. In contrast, there are reports suggesting the robust production of synaptically active i-neurons; however, reproducible protocols have not been published nor have other labs validated these findings, making it unclear exactly what element(s) of the differentiation protocols promoted functional synaptogenesis^[111,116].

Rationally designed improvements to the speed and efficiency of i-neuron differentiation would be exceedingly valuable for a wide variety of uses, including pharmaceutical screening and cell replacement strategies. The ideal approach would enable the reproducible yield of large quantities of synaptically active neurons of defined lineages in a relatively short period of time. Recent experiments have focused on the ability of transgenic transcription factors and/or small molecules to increase the speed and efficiency of differentiation. For example, overexpression of neurogenin (Ngn1 or 2) transcription factors accelerates maturation of intrinsic neuronal characteristics in i-neurons, but has mixed results on the appearance of post-synaptic currents, with one study finding such currents at 2-3 wk^[149] while another did not find any until 7 wk^[150]. The addition of small molecules to iPSCs during neuronal differentiation increases the efficiency of differentiation into intermediate neuronal precursors^[151]. Small molecules may also be used to influence neuronal patterning, but to date this approach has only been successful in directing cells towards dopaminergic populations, and the resulting neurons have not been assessed for network activity^[152,153]. While these approaches are still immature, the identification of methods that improve the speed and efficiency/specificity of neuronal differentiation has the potential to render i-neurons a transformative tool in basic and clinical sciences.

iNs

Recent work suggests that a neuronal phenotype can be differentiated directly from non-neuronal tissue by the expression of specific genes. Direct conversion, or trans-differentiation, works on many of the same principles as iPSCs, involving the forced expression of transcription factors associated with the target neurons or neuronal intermediates. As with iPSCs, a variety of transcriptional and biochemical factors have been used as neural induction factors for iNs. Initially, the transcription factors Ngn2, Ascl1 (Mash1), and Dlx2 were found to directly convert non-proliferative mouse astrocytes into populations of glutamatergic and GABAergic neurons^[154,155]. Ascl1, along with the factors Brn2 and Myt1l (collectively BAM), can convert mouse fibroblasts into active neuronal populations^[156,157]. Human postnatal and adult fibroblasts appear to require expression of Brn2, Myt1l and microRNA-124 to produce active glutamatergic synapses^[158]. Alternatively, Nurr1, Lmx1a, Ngn2, Sox2 and Pitx3 have been found to induce

fibroblasts to express dopaminergic markers^[159-161], while BAM plus Lhx3, Hb9, Isl1, and Ngn2 promotes expression of motor neuron markers^[162]. Like iPSC models, iNs can be used to replicate functional pathologies. For example, neuroligin-3 mutations associated with autism cause post-synaptic dysfunction in iNs when co-cultured with primary neurons^[163].

The iN field is still new, and many of the challenges facing iPSC-based neuronal differentiation are likely to affect iN approaches as well. Only a small percentage of cells are successfully converted to neurons and most iNs retain epigenetic features of their non-neuronal origins^[161]. Unlike differentiation of iPSCs which can be expanded during the stem cell stage iN conversion has frequently proven to have low efficiency, with only 1%-20% of starting cells successfully reprogrammed to become neurons, although some more recent work indicates conversion rates that exceed 200% (indicating a period of proliferation during the conversion process)^[162,164]. Low success rates may complicate functional neurogenesis, leading to a sparser neuron population, variable intrinsic properties and little to no network activity, as demonstrated in electrophysiological profiling of iN populations with as few as five neuron-like conversions per coverslip^[165]. Conversely, the limited scalability may also render iNs less likely to become tumorigenic following implantation or conversion *in vivo*. One potential way around limited scalability might be to induce differentiated cells into neuronal precursor cells rather than directly into neurons. While this approach has been used to produce presumptive precursors (based on gene expression studies and morphology), it remains to be seen if induced progenitors cells can differentiate into functionally mature neurons^[166,167].

APPLICATIONS OF SCNS FOR NEUROSCIENCE AND THERAPEUTICS

General properties of SCN models that facilitate research applications

In addition to the clinical potential, SCNs have extensive potential for basic and applied neuroscience studies. In many cases, stem cells are genetically tractable, typically clonal and amenable to culturing in large numbers, facilitating the production of scalable quantities of synchronized SCNs that are genetically homogenous and amenable to forward and reverse genetics approaches as well as functional engineering for biotechnological studies^[101,168,169]. While the stem cell stage of SCN differentiation is the most obvious target for genetic manipulation, allowing for isolation and expansion of genetically identical clones, post-mitotic neurons can also be modified using a variety of techniques that are well-described in primary neuron cultures^[170]. Genetic manipulations have been used for a variety of studies. For example, exogenous expression of developmentally regulated transcription factors has been used to explicate the genetic regulators that influence neuronal patterning

and neuron subtype specification^[171,172]. In addition to influencing cell type or development, functionality can be added to SCNs by the expression of transgenic proteins. These functional modifications enable a particular readout, such as fluorescent reporters of gene expression, synaptic assembly, synaptic activity, or metabolic function^[77,173-175]. Recent advances that provide control over neuron activity *via* biologically orthogonal inducers, such as biophotonic or chemogenetic approaches, make it possible to measure and control synaptic activity in networked neuron cultures^[176,177]. For example, expression of channelrhodopsin under the control of a dopaminergic promoter allows for the light-activated stimulation of grafted dopaminergic neurons^[67]. The effects of these controlled stimuli on *in vitro* network behavior could be measured by whole-cell patch clamp or in MEAs, providing an indirect electrophysiological measure of the function of metabotropic synapses. Genetic manipulation may also be used to improve the therapeutic potential of SCNs. Targets include repairing the mutated huntingtin protein in models of Huntington's disease^[178,179] or expressing factors enhancing neuron growth and repair in implanted SCNs^[180,181]. Despite the utility of genetic modulation of stem cells, care must be taken in characterizing the resultant lines. For example, genetic modifications may alter differentiation outcomes, potentially producing cells that are morphologically and structurally neuronal, but lack intrinsic or synaptic electrophysiological characteristics^[182]. Although below we will focus on applications that are not dependent on genetic modification, it is important to remember that in most applications the incorporation of genetically modified SCNs would complement basic and clinical studies.

Study of disease mechanisms in personalized SCN models

The *in vitro* analysis of i-neurons produced from patient-derived iPSCs is expected to be one of the early successes of personalized medicine. Autologous SCN models are already in use for applications such as population-wide phenotypic comparisons and drug screening studies^[183]. Shortly after protocols became widespread to generate iPSCs, laboratories rushed to establish cell banks of iPSCs derived from patients with a wide variety of neurodevelopmental and neurodegenerative disorders, with the goal of developing diagnostics and assessing treatment efficacies *in vitro*^[184-186]. This approach has the distinct advantage of studying the phenotypic disease in the native genetic environment and avoiding confounds that may influence disorder penetrance and prognosis. One example of a disease-specific approach is i-neurons derived from a patient with Dravet syndrome epilepsy, which is caused by a single protein mutation in the Nav1.1 sodium channel. Dravet SCNs exhibited altered excitability, with reductions in evoked AP amplitude and probability of firing^[187]. Autologous iPSCs also facilitate the study of neuropsychiatric diseases with complex polygenic or unknown genetic origins, something

difficult or impossible by the rational introduction of mutations^[188]. For example, i-neurons derived from schizophrenia (SZ) patients have fewer post-synaptic markers and less neurite growth than controls, despite similar intrinsic electrophysiological profiles^[189]. When maintained in an immature NPC-like state, SZ cells were also found to have abnormal cytoskeletal development, increased oxidative stress, and aberrant migration, indicative of developmental abnormalities^[190]. These discoveries would have been considerably more difficult without access to a developmental SCN model.

Many neurodegenerative disorders originate from multiple genetic loci, including Alzheimer's disease, Parkinson's disease and other dementias^[191]. They often exhibit variable penetrance, which is further compounded by a lifetime of unknown environmental interactions. Patient-derived iPSCs offer the potential to study the effects of complex and subtle genetic contributions to these variable disease phenotypes by replicating the genomic context from which the disease is expressed. In some cases, disorders have displayed relatively consistent pathophysiologies in SCN models, enabling high resolution characterization of the disease pathophysiology. For example, i-neurons derived from Parkinson's disease patients from diverse genetic backgrounds exhibit initial morphological characteristics of synaptogenesis, but subsequently degenerate *in vitro*, accumulating α -synuclein and other toxic intermediaries^[192,193]. Other disorders have shown inconsistent pathophysiology *in vitro*, including iPSCs derived from Huntington's disease patients^[194,195] and multiple sclerosis patients^[196]. However, while sometimes confounding, this inconsistent pathology may also contribute to an improved understanding of disease mechanisms. For example, iPSC-derived motor neurons from a subset of amyotrophic lateral sclerosis (ALS) patients exhibit pathophysiological characteristics, while others ALS patient-derived motor neurons appear normal^[186,197-199]. Derived ALS motor neurons cocultured with astrocytes have suggested that some ALS neuropathology is due to aberrant glial function^[200-202]. Together, these studies suggest that ALS may originate from the interactions of multiple cell types and genetic loci, with potentially tissue-specific diagnoses and treatment requirements.

Two potential caveats to the general appeal of iPSCs for disease modeling are the possibility of selecting a non-representative line during reprogramming and increased risk of genomic changes during maintenance of reprogrammed iPSCs. For example, cultured iPSCs have been found to exhibit increased copy number variation, which is associated with a wide range of neuropsychiatric diseases^[203]. Unfortunately, while a variety of assays have been used to characterize the phenotype of neuropsychiatric i-neuron models, few have emphasized differences in synaptic and network activity, in large part because reproducible protocols to generate synaptically active i-neurons are not widely available. In fact, recent reviews have noted that functional assays, such as calcium imaging or electrophysiology are infrequently

performed compared to gene expression studies^[192]. This lack of rigor in characterizing SCN models may further contribute to discrepancies in translational interpretation. While i-neurons are not likely to be viable models for all neuropsychiatric diseases, particularly those that rely on multi-tissue interactions, the pathophysiological relevance of patient-specific SCN models has extraordinary potential to explicate complex disease mechanisms.

Neuro-reparative studies

Unlike the comparatively robust reparative mechanisms of the peripheral nervous system, intrinsic regenerative processes in the CNS do not appear to be capable of repairing damaged nervous tissue and restoring normal brain function in cases of severe or large-scale neural disease or injury^[204]. Consequently, clinical management of traumatic brain injury or degenerative neurological diseases is predominantly limited to supportive or palliative care. One of the most promising treatment strategies for regeneration of neural function is targeted cell replacement (TCR), in which exogenously derived cells are administered to the CNS to ameliorate the disease or injury process, protect from further decline of function and possibly facilitate repair of lost capacity. In one aspect of TCR, *in vitro*-derived neural cells of defined maturity and fate are delivered to specific CNS locations, where in theory they will appropriately integrate into existing circuits. This approach is complicated by several factors, including the intricate and poorly understood physiology of the nervous system; the fact that ontogenic processes such as axonal pathfinding and circuit formation may not be appropriately recapitulated in adult brains; and the difficulty in specifying the character of the grafted cells. Nonetheless, in preliminary studies centrally administered SCNs have exhibited potential as a regenerative CNS therapy. Administration of human NSCs, such as the NSI-566RSC line, have proven safe and effective in animal models of ALS, spinal cord injury, and ischemia^[205], and are currently undergoing clinical trials^[206]. These NSCs appear to form functioning neurons that integrate into existing neuronal networks *in vivo*^[207]. Studies using more mature dopaminergic neurons derived from fetal NSCs have also found that long-term integration and transplanted neurons conferred resistance to PD in mouse models^[208].

TCR has been made more technically feasible by the recent development of autologous iPSCs, which are less likely to evoke undesired immune responses. The development of autologous SCN-based TCR therapies would be immensely valuable for traumatic CNS injury as well as for neurodegenerative diseases such as Parkinson's disease and ALS. However, despite the promise of SCN therapies, early studies suggest that implantation of stem cells and stem cell-derived tissue suffers from several complications, most notably cell survival and functional integration into target circuits^[209,210]. For example, inappropriately integrated cells may disrupt existing circuits while cell death may trigger counterproductive inflammatory responses that further degrade central

function^[211,212]. More severe complications may arise if mitotically active donor cells proliferate to form non-neuronal, neoplastic tissues^[213] or otherwise damage the engraftment site, provoking responses that impair the function of implants over time^[214,215]. Despite these complications, SCN therapies have transformative potential now, and as protocols are established for improved graft survival and integration with reduced adverse host responses, such therapeutic modalities will be realized.

In vitro neurotoxicology

One of the most attractive uses of SCNs is as a scalable, relevant cell model of neuronal responses in pharmacological and toxicological testing^[216]. For example, the physiological relevance imparted by SCNs for *in vitro* toxicology is anticipated to significantly reduce dependence on the use of animals to detect, diagnose or study lethal toxins, such as with the mouse lethality assay, or to conduct initial efficacy testing of candidate therapeutics^[217,218]. Neuron-like immortalized cell lines, such as neuroblastomas and pheochromocytomas, have historically been used in *in vitro* toxicity studies and countermeasure screening protocols for the Tier 1 select agents collectively known as botulinum toxins (BoNTs)^[219-222]. However, as described above, these cell lines have poor neurogenic competence and thus are not suitable to study neurotoxic substances whose modes of action are mediated by neurotypic behaviors, act in specific neuronal compartments or are evidenced through altered neurotransmission^[223,224]. The various BoNT serotypes are good examples of neuron specific agents, as they are internalized at the pre-synaptic compartment and then specifically target and cleave SNARE proteins responsible for neurotransmitter release^[225]. In the absence of a functioning pre-synaptic compartment, it is doubtful that non-neuronal models faithfully reflect the biochemistry and host interactions involved in intoxication. In contrast, mouse e-neurons differentiated into a synaptically active population of glutamatergic and GABAergic neurons with emergent network behavior undergo synaptic blockade within hours after intoxication with femtomolar concentrations of botulinum neurotoxins serotype A^[6,226,227]. This represents the first *in vitro*-derived, cell-based model to manifest the functional pathophysiology responsible for the clinical symptoms of botulism, enabling novel *in vitro* studies on host: toxin interactions. This e-neuron model has also been shown to be highly sensitive to other neurotoxins, such as glutamate and latrotoxin, with mechanisms of injury, toxin sensitivities and cellular responses that are identical to those of primary neurons^[59]. Similar glutamate excitotoxicity has been demonstrated in human e-neurons and i-neurons^[228]. As these models are shown to be increasingly relevant neurotoxicological models, they are anticipated to rapidly become the primary approach for target discovery, drug screening and detection/diagnosis of neurotoxins and neurotoxic effects.

Another valuable application of SCNs in neurotoxin

studies is the modeling of developmental neurotoxicity. While primary neuron cultures may not recapitulate developmental vulnerabilities that occur during early stages of differentiation, SCNs are well-suited for studying specific mechanisms of early developmental toxicity, such as the effects of reactive oxygen production and alterations to specific cell signaling pathways during early stages of neurogenesis^[229-232]. SCNs can also be used to evaluate toxicant-induced changes to relative neurogenic and gliogenic outcomes during neural differentiation, as well as to test for persistent changes in synaptic function, such as the chronic functional deficits resulting from developmental exposure to ethanol^[233-235]. Taking advantage of the scalability of SCN models and high throughput detection platforms such as MEAs or calcium imaging, multiple neurotoxic compounds can be screened and compared in SCN systems over multiple stages of development to assess vulnerable stages and mechanisms^[236-238]. In addition, the use of MEAs facilitates high-throughput monitoring of the development and interruption of network activity^[75,76,239]. Finally by combining scalability with transgene expression, moderate-to-high throughput assays can be developed to rapidly assess the efficacy of candidate therapeutics on injury or disease at various stages of neurogenesis.

Histogenic models: A step beyond networks

Relevance is a key goal of neuronal models. In addition to functional relevance of neuronal monolayers, a relevant histotypic model can be generated by simultaneously producing or combining multiple nervous tissue types in two- or three-dimensional cultures. Depending on the differentiation protocol, multiple neural types, including glia and oligodendrocytes, can be produced simultaneously with neurons^[137,138]. Multiple neuronal subtypes are generated in many SCN differentiation protocols^[43,110,171,240]. The introduction of physcobiological techniques to differentiation methods may further enable the defined production of diverse neural cell types, such as the three-dimensional culture of neocortical-like organoids^[241-245] and use of chemical or physical micro-patterning of plates, including microfluidics^[246,247].

Histogenic neuronal models are anticipated to produce more complex neuronal circuits by facilitating synaptic interactions among multiple neuron types. For instance, complex retinal tissue has been generated from iPSCs^[248-250], including the formation of three-dimensional superstructures that facilitate the development of photoreceptor cells, multiple neuron types and other cells in the retina. The cells themselves respond to incident light with electrochemical and biochemical responses that are similar to those produced *in vivo*. Further elaboration of this retinal model would require optic nerve tissue as well as visual cortex tissue to more comprehensively model the circuits involved in sight. It may be that in producing SCN models with multiple active neuronal and glial types, researchers have incidentally begun to form specific regional patterning and developmental forms of neuroectodermal tissue that essentially produce many

of the outcomes of a histogenic model. For example, the rosettes formed during neurogenesis *in vitro* may be patterned similar to neural tubes or cortical plates *in vivo*^[251]. Similarly, three-dimensional cultures of some ESCs allow for the formation of stratified structures similar to fetal cortex^[252], and even recapitulates the folding of neuroepithelium^[253]. The functional generation of complex tissues such as retina and multi-layered cortex and neuroepithelium solely from stem cells suggests that generation of other complex CNS tissues may soon be feasible.

CONCLUSION

With available stem cell derivation and SCN differentiation techniques growing rapidly, researchers must be able to critically analyze and compare these models to *in vivo* neurons and circuits. Many SCN models, particularly those derived from human origins, still require optimized protocols to reproducibly generate synaptically active neurons. It may be a challenge for some researchers to functionally validate SCN models, but validation is essential for physiological relevance and to increase the translatability of findings regarding neurological development, function and dysfunction. It is encouraging to see newer research in the literature recognizing that functional endpoints, such as the establishment of a neuronal network, are highly sensitive and powerful tools. This review presents some variations in the approaches used to establish synaptic and network activity, but for now it should be apparent to those pursuing electrophysiological approaches that post-synaptic activity must be measured alongside intrinsic characteristics, followed by assays for networked activity. It is hoped that as techniques improve, the means of proving functional synaptogenesis and networked activity in SCNs will also expand. With expanding collections of validated models available, researchers will have excellent options for both basic neuroscience and therapeutic applications.

Abstract

The best known cases of cell autotomy are the formation of erythrocytes and thrombocytes (platelets) from progenitor cells that reside in special niches. Recently, autotomy of stem cells and its enigmatic interaction with the niche has been reported from male germline stem cells (GSCs) in several insect species. First described in lepidopterans, the silkworm, followed by the gypsy moth and consecutively in hemipterans, foremost the milkweed bug. In both, moths and the milkweed bug, GSCs form finger-like projections toward the niche, the apical cells (homologs of the hub cells in *Drosophila*). Whereas in the milkweed bug the projection terminals remain at the surface of the niche cells, in the gypsy moth they protrude deeply into the singular niche cell. In both cases, the projections undergo serial retrograde fragmentation with progressing signs of autophagy. In the gypsy moth, the autotomized vesicles are phagocytized and digested by the niche cell. In the milkweed bug the autotomized vesicles accumulate at the niche surface and disintegrate. Autotomy and sprouting of new projections appears to occur continuously. The significance of the GSC-niche interactions, however, remains enigmatic. Our concept on the signaling relationship between stem cell-niche in general and GSC and niche (hub cells and cyst stem cells) in particular has been greatly shaped by *Drosophila melanogaster*. In comparing the interactions of GSCs with their niche in *Drosophila* with those in species exhibiting GSC autotomy it is obvious that additional or alternative modes of stem cell-niche communication exist. Thus, essential signaling pathways, including niche-stem cell adhesion (E-cadherin) and the direction of asymmetrical GSC division - as they were found in *Drosophila* - can hardly be translated into the systems where GSC autotomy

was reported. It is shown here that the serial autotomy of GSC projections shows remarkable similarities with Wallerian axonal destruction, developmental axon pruning and dying-back degeneration in neurodegenerative diseases. Especially the hypothesis of an existing evolutionary conserved "autodestruction program" in axons that might also be active in GSC projections appears attractive. Investigations on the underlying signaling pathways have to be carried out. There are two other well known cases of programmed cell autotomy: the enucleation of erythroblasts in the process of erythrocyte maturation and the segregation of thousands of thrombocytes (platelets) from one megakaryocyte. Both progenitor cell types - erythroblasts and megakaryocytes - are associated with a niche in the bone marrow, erythroblasts with a macrophage, which they surround, and the megakaryocytes with the endothelial cells of sinusoids and their extracellular matrix. Although the regulatory mechanisms may be specific in each case, there is one aspect that connects all described processes of programmed cell autotomy and neuronal autodestruction: apoptotic pathways play always a prominent role. Studies on the role of male GSC autotomy in stem cell-niche interaction have just started but are expected to reveal hitherto unknown ways of signal exchange. Spermatogenesis in mammals advance our understanding of insect spermatogenesis. Mammal and insect spermatogenesis share some broad principles, but a comparison of the signaling pathways is difficult. We have intimate knowledge from *Drosophila*, but of almost no other insect, and we have only limited knowledge from mammals. The discovery of stem cell autotomy as part of the interaction with the niche promises new general insights into the complicated stem cell-niche interdependence.

Key words: Stem cell-niche interaction; Male germline stem cells; Spermatogenesis; Erythropoiesis; Stem cell autotomy; Thrombopoiesis

Core tip: A new mode of stem cell-niche interaction has been observed in insects. Male germline stem cells (GSCs) undergo autotomy by serial segregation of vesicles from finger-like projections. These vesicles either accumulate at the niche surface or are phagocytized by the niche cells. Autotomized projections are apparently replaced by newly sprouting ones. It is suggested that the unprecedented dynamics of GSC autotomy are involved in a not yet known form of information exchange between GSCs and niche. Apoptotic pathways and autodestruction programs could be involved in GSC autotomy.

Dorn DC, Dorn A. Stem cell autotomy and niche interaction in different systems. *World J Stem Cells* 2015; 7(6): 922-944 Available from: URL: <http://www.wjgnet.com/1948-0210/full/v7/i6/922.htm> DOI: <http://dx.doi.org/10.4252/wjsc.v7.i6.922>

EARLY OBSERVATIONS ON STEM CELL-NICHE RELATIONSHIPS PRIOR TO THE ESTABLISHMENT OF THE STEM CELL-NICHE HYPOTHESIS

When, in 1978, Schofield^[1] put forward the hematopoietic stem cell (HSC)-"niche" hypothesis it was solely based on the assumed requirements the niche must fulfill, but he had no knowledge concerning the physical identity of the niche: "The location of the stem cell niche can, of course, only be a matter of speculation, although there are several items of data which suggest that they may well be in intimate association with the bone". It is astonishing how accurate some of his predictions turned out to be. However, up to date the HSC niche is not fully understood and is apparently composed of a variety of different cell types: osteogenic cells, endothelial cells, perivascular mesenchymal cells and adipocytes^[2,3]. Recently, Chasis *et al.*^[4] pointed out that the first description of a hematopoietic niche actually took place 20 years earlier when, in 1958, Bessis^[5] described erythroblastic islands. These represent microenvironmental niches for erythropoiesis. Erythroblasts, which represent oligopotent progenitors derived from a small population of HSCs, are arranged rosette-like around a reticular cell (macrophage) where they proliferate and differentiate (Figure 1A). Erythroblastic islands offer striking structural similarities with another significant model system for research on stem cell niche-interactions, the male germline stem cells (GSCs) and its niche in insects (Figure 1B).

Due to its anatomical simplicity and the advantageous genetic access, the male GSC-niche system of *Drosophila* proved as an invaluable tool to study stem cell-niche interactions on the molecular level^[6]. In insects the GSC niche is located in the apex of testicular follicles and consists of the somatic apical cells (ACs) (called hub cells in *Drosophila*) and the cyst stem cells (CySCs). As in the case of the erythroblastic islands, apical complexes were described long before *Drosophila* became the model system. Figure 2 demonstrates the testicular GSC-niche complex of butterflies published in 1889 by Verson^[7] and in 1911 by Zick^[8], respectively (The first record of apical complexes stems from Spichardt^[9] published in 1886 from studies on butterflies). The drawings in Figure 2, based on light microscopical observations, indicate intricate physical relationships between AC and GSCs which could not be clearly resolved with the techniques available at that time. It is remarkable that several of the early investigators already suggested that the ACs might regulate the fate of the GSCs: Zick^[8] in 1911 believed that the spermatogonial pathway could only be entered after detachment of the germ cells from the AC, and Buder^[10] and Schneider^[11] in 1915 postulated that ACs release an inhibitory factor which prevents the differentiation of GSCs into spermatogonia; Nelsen^[12] in 1931 considered the ACs as an activation center which controls the mitotic activity

Figure 1 Simple systems of the stem cell/progenitor-niche interaction: isolated erythroblastic island and isolated apical complex from an insect exhibit strong resemblances. A: Erythroblastic island from dissociated rat bone marrow. A corona of erythroblasts (EB) has extensive cell-cell contact with their niche, the central macrophage (MA) (from Bessis *et al.*^[93] with kind permission of Springer Verlag, Berlin, Heidelberg); B: Isolated testicular apical complex from *Locusta migratoria*. Germline stem cells (GSC) surround the apical cell (AC), which represents the niche (besides the peripheral cyst stem cells, which were removed) (From Dorn *et al.*^[64]).

of the GSCs. Thus, main characteristics of a niche were already hypothesized at the beginning of cell research. Since the early investigations on butterfly apical complexes developmental studies have ascertained the identity of GSCs and the role of ACs as their niche (together with CySCs). Electron microscopic studies revealed complex physical interactions between ACs and stem cells which points to a hitherto not elucidated communication between these cells. Figure 3D demonstrates the complicated structure of lepidopteran apical complexes. In fact, enigmatic physical relationships between male GSCs and their niche have been observed in a number of insect species. One of the most astonishing phenomena is the controlled autotomy of GSC projections which are directed toward the ACs. Examples of these cases are examined for their functional significance in this review. They are compared with other stem cell-niche systems where cell autotomy takes place, such as enucleation of erythroblasts and megakaryocyte fragmentation are discussed in respect to the suggested “autodestruction program” of neurons.

GSC-NICHE INTERACTION IN THE TESTIS OF THE MODEL INSECT *DROSOPHILA MELANOGASTER*

The testis of *Drosophila* has become one of the most successful models for the exploration of molecular stem cell-niche interaction. Comprehensive reviews on this matter have been published recently^[13,14]. A summary of the structural and molecular relationships within the apical complex of *Drosophila* is presented here and compared with observations in other insects.

Figure 3A shows the apex of a testicular follicle of *Drosophila*. A longitudinal section of the testicular follicle shows the three cell types that constitute the germinal

proliferation center. A small cluster of somatic cells, the hub cells (*i.e.*, ACs), is located in the follicular apex (the hub). Hub cells, together with CySCs, represent the niche for the row of bordering GSCs. Except for the region where hub cells and GSCs contact one another; each GSC is embraced by a pair of CySCs whose tips also contact the hub cells. CySCs are of somatic origin and, besides their niche function for GSCs, represent stem cells that generate the cyst cells by asymmetrical division. Hub cells only function as the CySC niche. Prior to an asymmetric division of a GSC (which produces a gonialblast that is directed toward the periphery of the apical complex and a daughter GSC that remains in contact with the niche) its two associated CySCs undergo a synchronized division resulting in a pair of daughter cells which encloses the forming gonialblast and becomes the cyst wall. The two cyst cells forming the wall no longer divide during subsequent spermatogenesis although the cysts enlarge considerably.

The fate of GSCs - maintenance, self-renewal (asymmetric and symmetric division), frequency of mitotic activity - is orchestrated by a multitude of factors and processes: (1) Short-range signaling between niche and GSCs. This was the first factor to be elucidated and proved to be exemplary for other stem cell-niche systems; (2) Niche-stem cell adhesion. Adherens junctions were found to play a crucial role in the regulation of signaling and asymmetric GSC division in addition to its physical adhesion function; (3) Cell intrinsic regulation. This has more recently come into focus; and (4) Systemic regulation. This may affect all aspects of niche-stem cell interaction, but is to date the least understood.

Short-range signaling

GSC maintenance and self-renewal are supported by a wide range of signals from the hub. The cytokine ligand unpaired (Upd), secreted by the hub cells activates Janus kinase-signal transducer and activator of transcription (JAK/STAT) signaling in GSCs and CySCs^[15,16]. Gonialblast differentiation is caused by lower levels of Upd. In aging flies the number of GSCs and their proliferation rate declines in correlation with declining Upd levels in the hub cells. Upd secreted by hub cells also activates the JAK/STAT signaling in CySCs. Whereas JAK/STAT activation is sufficient for CySC maintenance and self-renewal, GSC self-renewal requires additional signals. Hub cells and CySCs both secrete glass bottom boat (Gbb) and decapentaplegic (Dpp). Both ligands activate the bone morphogenetic protein (BMP) signaling pathway in GSCs. BMP represses the transcription of the differentiation factor bag of marbles (Bam). Thus inhibition of differentiation to gonialblasts contributes to GSC self-renewal^[17,18]. Hub cells also produce the ligand Hedgehog (Hh) that supports the self-renewal of CySCs in addition to JAK/STAT activation. GSC maintenance does not require Hh signaling^[19,20]. Gbb and Dpp produced from CySCs contribute to the activation of BMP

Figure 2 Early histological studies on testicular follicles in butterflies (Lepidoptera) that depict the complex structures of the apical complexes. A: Testicular follicle of the silkworm *Bombyx mori* which includes the apical complex (a, b, d). The limited light microscopical resolution caused some misinterpretation concerning the identity of cell types: the central apical cell (a) was considered to be a "germ cell" ("Keimzelle") with radial extensions. The germline stem cells were described as clumps of protoplasm with nuclei (b, d) (from Vernon^[7]); B: Testicular follicle of the cabbage white butterfly *Pieris brassicae*. The relationship between apical cell (Az) (also called Vernon cell) and germline stem cells (Ps) is correctly described: The germline stem cells send projections toward the apical cell and their tips penetrate the apical cell. A layer of cells surround the germline stem cells, the cyst stem cell which, however, were not identified as such (from Zick^[8]).

in GSCs (besides Gbb and Dpp signaling from the hub cells)^[18]. They are conceivably activated by STAT and/or zinc-finger homeodomain protein 1 which is targeted by STAT as is chinmo (chronologically inappropriate morphogenesis)^[21,22] (Figure 4).

Niche-stem cell adhesion, adherens junctions, E-cadherin

GSCs and CySCs are both connected with hub cells via adherens junctions^[23]. Hub cell-GSC connection plays a crucial role in GSC behavior. Tight contact of the GSCs with hub cells is correlated with high levels of E-cadherin and β -catenin at the interface (adherens junctions). Accumulation of both proteins at the interface is dependent upon guanine nucleotide exchange factor 26 (Gef26) for the Rap GTPase (Rap0-GEF)^[24]. The intracellular domains of the cadherin molecules interact with cytoskeleton-associated proteins. JAK/STAT signaling is required in GSCs to maintain E-cadherin expression, niche anchorage and self-renewal and in CySCs to control BMP expression^[25]. In addition, the leukocyte-antigen-related-like receptor tyrosine phosphatase has been proposed to regulate the attachment of GSCs to the hub cells^[26]. It is responsible for the proper localization of tumor suppressor Adenomatous polyposis coli 2 (Apc2) and E-cadherin and the proper orientation of centrosomes in GSCs^[23]. The BMP receptor complexes are localized to E-cadherin rich adherens junctions at the stem cell-niche junction, which might help restrict BMP signaling activity to the GSC niche interface^[27]. Localized BMP signaling might be also affected by BMP signaling modulators that accumulate in the extracellular matrix such as the protein Magu (known to be involved in life span extension and late age female fecundity) which is transcribed in hub cells^[28] and the heparin sulfate proteoglycans Dally (division abnormally delayed) and Dally-like^[29]. Recently it was demonstrated that the actin-binding protein profilin is required cell autonomously to maintain GSCs, possibly facilitating

localization or maintenance of E-cadherin to the GSC-hub cell interface^[30].

The age dependent loss of GSC is accompanied by a decline in E-cadherin expression. Increased E-cadherin expression slows down GSC loss^[31].

E-cadherin is also required in CySCs to maintain their adhesion to the hub. In addition, integrin-mediated adhesion exists between the hub and CySCs, and is limited by a negative regulator of STAT signaling^[32].

Integrins: In the *Drosophila* testis, competition exists between GSCs and CySCs and among CySCs themselves for occupancy of the hub^[33]. Interestingly, the CySCs with higher JAK/STAT signaling activity, which can be achieved experimentally by removing the function of the JAK/STAT negative regulator SOCS36E, can outcompete normal CySCs and can also push GSCs out of their niche. This JAK/STAT-regulated stem cell competition is dependent on the cell adhesion protein β PS integrin, but not E-cadherin. Integrin-mediated cell competition is thus thought to play a crucial role in balancing two stem cell populations in the same niche^[33]. Integrins are also required for positioning the hub in the apical testis tip, but are dispensable for GSC or CySC anchorage to the niche^[34]. The extracellular domains of integrins can bind directly to extracellular matrix (ECM) proteins, such as laminin, but there is no ECM between hub cells, GSCs and CySCs.

Gap junctions: The gap junction protein zero population growth is required for GSC maintenance and differentiation in *Drosophila* testes^[35]. But it remains to be seen whether the function of gap junctions in the regulation of stem cell maintenance derives from their adhesion role, intercellular molecular transfer or electrical communication.

Cell intrinsic factors, hub cells

Upd levels in hub cells are regulated by IGF-II mRNA

Figure 3 Schematized longitudinal sections through the apices of testicular follicles of four insect species. The order of the images from (A) to (D) is arranged according to increasing complexity of the structural relationships between germline stem cells (GSCs) and their niche. It should be noted that the order is not in congruence with the positions of the species in the natural insect system based on evolutionary progress. **A:** *Drosophila melanogaster*. The ACs (hub cells) are located in a small terminal appendix of the follicle, the hub (HUB), where many of them border the testicular wall (TW). (The testicular wall consists of an outer pigment layer resting on a basal lamina and a muscle cell layer sitting on an inner basal lamina.) The testicular wall does not provide a hemolymph-testis barrier. A spermatogonial is constituted by two CCs which protect the spermatogonia against hemolymph. Both GSCs and CySCs contact ACs (Adapted from Hardy *et al.*^[61]); **B:** *Locusta migratoria*. Depicted is the rosette-like arrangement of GSCs and CySCs with the single AC in the center. The AC of this example includes two phagocytized GSCs (see above). Besides GSCs also CySCs contact extensions of the star-like AC. A plug of CySC-like cells (CySC-L) is located below the apical rosette. The wall of the spermatogonial cysts is composed of numerous CCs (Adapted from Szöllösi *et al.*^[154] and Dorn *et al.*^[64]); **C:** *Oncopeltus fasciatus*. The cellular extensions of GSCs and segregated vesicles surround the surface of ACs. CySCs cover only the distal part of the apical rosette; they do not make contacts with the ACs. Proximal to the rosette, remnants of degraded GSCs and probably young cysts amass (RDC). Cysts form at the lateral parts of the rosette (Adapted from Schmidt *et al.*^[65]); **D:** *Lymantria dispar*. Note that the cellular extensions of GSCs protrude into the large singular AC. The extensions autotomize and the segregated vesicles are phagocytized by the AC. Each GSC is affiliated with one CySC. During early larval development the AC is attached to the TW [comparable to the situation in *Drosophila*, where ACs (i.e., hub cells) are lifelong attached to the TW], but separates with progressing development. The apical complex then adopts a spherical organization. (Adapted from Klein^[66]). AC: Apical cell (often called hub cell in *Drosophila*) (green); CC: Cyst cell (orange); CySC: Cyst stem cell (yellow); GB: Gonialblast (purple); GSC: Germline stem cell (red); SPG: Spermatogonia (purple); TW: Testicular wall (grey).

binding protein (Imp) that binds to upd mRNA and protects it from degradation caused by short interfering RNAs. Imp itself is repressed by let-7 microRNA (miRNA) that is expressed at higher levels in aging male GSCs^[36]. epidermal growth factor (EGF) signaling negatively regulates GSC division frequency in adults, but not in larvae, and promotes gonialblast differentiation and enclosure of germ cells by somatic cyst cells. Stg (string, a Cdc 25 homolog-phosphatase) is essential for activating cyclin-dependent kinases and promoting the cell cycle and is therefore required for proliferation and maintenance of GSCs and CySCs. The transcriptional regulator lola (longitudinals lacking) is cell autonomously required for GSC (and CySC) maintenance^[37]. MiRNAs control the stem cell differentiation pathway by re-

gulating Bam^[38]. Recently, the impact of epigenetic factors on male GSCs has been analyzed. Nucleosome remodeling factor promotes STAT expression while repressing Bam thus contributing to the maintenance of GSCs^[39]. Additionally chromatin-associated proteins, such as no child left behind and PHD finger protein 7 are necessary for GSC maintenance^[40,41]. CySCs. JAK/STAT signaling in CySCs is suppressed by suppressor of cytokine signaling at 36E (Socs36E) which may harmonize self-renewal of CySCs with that of GSCs^[33,42]. Ken (ken and barbie, a transcriptional repressor) also promotes CySC identity^[43]. Restriction of proliferation and maintenance of CySC identity are affected by polycomb repressive complex 1 genes posterior sex combs and suppressor of zeste two [Su(z)2]^[44].

Figure 4 Short range signalling between the germline stem cells and their niche, which consists of the hub cells and the cyst stem cells. The hub cells secrete the ligand Upd, which activates JAK/STAT signalling in GSCs and CySCs. Whereas JAK/STAT activation is sufficient for CySC maintenance and self-renewal, GSC self-renewal requires additional signals. Hub cells and CySCs secrete the ligands Gbb and Dpp, which activate BMP in GSCs. BMP suppresses the transcription of Bam that inhibits the differentiation of GSCs to gonialblasts. BMP activation in GSCs is also supported by Gbb and Dpp produced by the CySCs. Gbb and Dpp in CySCs are conceivably activated by STAT and/or Zfh1 and Chinmo. Hub cells also secrete the ligand Hh (hedgehog), which supports CySC self-renewal in addition to, but independently of, JAK/STAT activity. Hh binds to the transmembrane receptor PTC (patched) of CySC, which releases Smo (smoothened) from repression. This leads to the activation of the transcription factor Ci (cubitus interruptus), which activates the transcription of target genes that support maintenance and self-renewal of CySCs besides JAK/STAT activity. The Hh signalling pathway in CySCs may also affect Zfh1 and, via Gbb/Dpp, influence BMP signalling in GSCs. Thus, Hh signalling in the testis niche apparently has a dual role. CC: Cyst cell; GSCs: Germline stem cells; CySCs: Cyst stem cells.

The histone variant His2Av and the ATP-dependent chromatin-remodeling factor Domino are also required for GSC and CySC maintenance. Furthermore, in a recent review Zoller *et al.*^[45] listed about 50 genes that were found (or expected) to be involved in the direction of CySC specification, CySC self-renewing divisions, cyst cell differentiation, and soma-germline interactions.

Systemic factors

Numerous environmental factors, such as changing seasons or periods of drought and rain, nutritional conditions (irregular food availability or starvation), injury or illness all affect tissue homeostasis. As a consequence niche and stem cell activity must be adapted to these changing demands. This is primarily accomplished *via* systemic factors that may influence any of the regulatory entities of the stem cell-niche complex.

Best known is the support of GSCs maintenance by insulin signaling^[46,47]. The source of some insulin-like peptides is the brain others are synthesized in the fat body and other tissues probably including the GSCs themselves. Effects of the nutritional status on GSC maintenance are apparently exerted by insulin signaling pathway^[48]. In the *Drosophila* female it has been shown that the nutrient-sensing insulin/FOXO signaling directly controls Notch activation in the GSC niche which maintains the niche and GSC identity^[49]. In maintaining embryonic stem cell pluripotency and the modulation of

adult stem cell quiescence nutrient-sensing pathways play an important role. They maintain energy production by inhibition and stimulation of crucial processes like oxidative phosphorylation and glycolysis. "This interplay is key to the maintenance of stem-ness"^[50].

Recently it has been found that day-night cycles and alterations in sleep can influence the daily dynamics of GSC divisions in male *Drosophila*^[51]. The GSC division rate increases, when the sleep-promoting factor, Sleepless, is lacking. This is mediated, in part, by the GABAergic signaling pathway.

A systemic signal that presumably plays a decisive role in testis development and spermatogenesis is the steroid hormone ecdysone^[52]. It is synthesized in testicular tissue of many insects: *Heliothis virescens*^[53], *Lymantria dispar*^[54], *Ostrinia nubilalis*^[55], *Spodoptera littoralis*^[56], *Melanoplus sanguinipes*^[57]. However, its significance in the regulation of male GSC proliferation and self-renewal in *Drosophila* is not known.

Ecdysteroids play a role in female GSC regulation in *Drosophila*. Ecdysteroids are synthesized by developing follicles of ovarioles and regulate directly GSC maintenance, proliferation and self-renewal. Ecdysteroids interact with the intrinsic epigenetic factor ISWI, a chromatin remodeling factor^[58]. The survival of ecdysone-producing follicles of ovarioles depends on the availability of food which points to an interaction of the hormonal with the nutrient-sensing signaling pathways^[59].

INCREASING COMPLEXITY OF STRUCTURAL RELATIONSHIPS BETWEEN MALE GSCS AND THEIR NICHE IN DIFFERENT INSECT SPECIES: DROSOPHILA MELANOGASTER, LOCUSTA MIGRATORIA, ONCOPELTUS FASCIATUS, LYMANTRIA DISPAR, AND THE CASE OF LAMPYRIS NOCTILUCA

Insects with their long evolutionary history may be expected to present great variations on a theme, in this case the organization of GSCs and their niche. And in deed, the Figure 3 exhibits an increasing complication of the physical interactions of the cells of the apical complex. However, the complexity of the structures is not correlated with the systematic position of a given species. In fact, whereas the hemipteran *Oncopeltus fasciatus* (Figure 3C) shows an astonishingly irregular and dynamic anatomy of GSCs^[60], another hemipteran, *Corizus hyoscyami*, has a relatively "simple" apical complex which harbors only one small AC, sparsely equipped with cell organelles, surrounded by a corona of pear-shaped GSCs (Klein personal communication). Nonetheless, it appears self-evident that the enigmatic structures expressed especially in the GSCs of *Oncopeltus fasciatus* and the lepidopteran *Lymantria dispar* (Figure 2D) - as well as in many other lepidopterans (Figure 2) - have a

Figure 5 Fine structural organization (schematized) of the apical complexes (longitudinal sections) of four insect species. The order (A) to (D) is arranged according to the order in Figure 3. A: *Drosophila melanogaster*. ACs are "light" and interdigitate richly between themselves. Their organelle equipment is scarce. GSCs are "dark" due to many free ribosomes and characterized by "spongy bodies" which may represent nuage. Adherens junctions are expressed between ACs and GSCs (marked by a rectangle) and between ACs and CySCs (encircled). CySCs are "light" and include few cell organelles (Adapted from Hardy *et al.*^[61]); B: *Locusta migratoria*. The single apical cell of an apical complex is "light" and harbors a complex organelle equipment: in particular a ring of mitochondria (M) and lysosomes (L) around the nucleus, and stacks of sparsely granulated endoplasmic reticulum (SGER) at the cell periphery. Arrow marks a phagocytized and partly lysed GSC. ACs and GSCs are connected by gap-like junctions (encircled). The "dark" GSCs include extremely irregularly shaped nuclei and nuage-like material (NU). Extensions of the "light" CySCs reach to extensions of the star-shaped AC (marked by square) (Adapted from Dorn *et al.*^[64]); C: *Oncopeltus fasciatus*. The ACs are rather small and very "dark". Cell organelles are inconspicuous besides Golgi complexes (GC) that face bordering GSC vesicles. The "dark" GSCs form cytoplasmic projections toward the ACs that undergo progressing autotomy. In the course of vesicle segregation rough endoplasmic reticulum (RER) and mitochondria (M) increase. Later autophagic vacuoles (AV) and myelin-like bodies (MY) are formed. Arrow points to a presumably newly sprouting cell projection. The "light" CySCs are characterized by extensive Golgi complex-like structures (GCL) that are often associated with sparsely granulated endoplasmic reticulum (SGER) (Adapted from Dorn *et al.*^[60]); D: *Lymantria dispar*. The single AC of an apical complex is "light" and exhibits a spherical organization: mitochondria (M), lysosomes (L) and rough endoplasmic reticulum (RER) surround the nucleus. The cell periphery shows deep indentations caused by invading, autotomizing GSC projections (arrows). Segregated GSC vesicles are taken up by the AC, and phagosomes (PH) accumulate in the cytoplasm. The "dense" GSCs exhibit projection formation and projection autotomy that closely resembles that of *Oncopeltus* (see Figure 4C). GSC projections that indent the AC are often surrounded by extracellular granules (arrow heads). CySCs are "light", and thin extensions reach the surface of the GSCs (encircled) (Adapted from Klein^[66]). AC: Apical cell (green); CC: Cyst cell (orange); CySC: Cyst stem cell (yellow); GB: Gonialblast (purple); GSC: Germline stem cell (red); TW: Testicular wall (grey); AV: Autophagic vacuole; GC: Golgi complex; GCL: Golgi complex-like structure; L: Lysosomes; M: Mitochondrion; MY: Myelin-like body; NU: Nuage; PH: Phagosomes; RER: Rough endoplasmic reticulum; SGER: Sparsely granulated endoplasmic reticulum.

specific function (see below), in reverse to the principle: no function without structure. We will briefly describe the portrayed apical complexes and characterize the cell types.

Drosophila melanogaster

Figure 3A demonstrates the rather "ordinary" organization of the apical complex and Figure 5A the fine structural characteristics of its different components. The niche consists of 8-16 small hub cells, which richly interdigitate and are anchored to the testicular wall. They are characterized by a "light" appearance and scarcity of cell organelles. No mitoses were observed. The GSCs are, in contrast, rather "dark" due to many free ribosomes. They have a spheroidal shape but are flattened where they contact the hub cells. Their

cytoplasm includes "spongy bodies"^[61] which may represent nuage material that is typical for germ cells^[62]. Mitoses of GSCs were rarely observed by the above authors, *i.e.*, one mitotic GSC in 50 GSCs. E-cadherin-mediated adherens junctions (Figure 4A) attach GSCs to hub cells^[26]. The CySCs are rather "light" and have inconspicuous organelle equipment. They also form adherens junctions with GSCs (Figure 5A). Among the 76 CySCs observed by Hardy *et al.*^[61] only two were in mitosis.

Locusta migratoria

The longitudinal section through the follicular apex (Figure 3B) shows that the apical complex has the shape of a rosette with a singular AC in the center. The pear-shaped GSCs reach deeply into the large star-like AC.

The CySCs are irregularly arranged around the GSCs and it is not clear how many CySCs are affiliated with a GSC. The ACs touch the protrusions of the CySCs between the GSCs. Remarkably, a plug of CySC-like cells is located beneath the rosette formed by AC, GSCs and CySCs. The CySC-like cells presumably participate in the formation of the cyst wall which consists of a higher number of cyst cells, up to 7 were counted on serial sections^[63].

In contrast to the hub cells in *Drosophila* the large AC of *Locusta* (also "light") shows a complex organelle equipment (Figure 5B). Around the large centrally located nucleus there is a broad ring of mitochondria that also includes lysosomal bodies. The periphery of the AC shows an abundance of sparsely granulated endoplasmic reticulum, often arranged in stacks and whorls that are also found in the cellular extensions that reach deeply between the basal parts of GSCs. The AC includes regularly one or two engulfed and more or less lysed GSCs (Figures 3B and 5B). The GSCs, "darker" than the ACs, show a polar organization. The nuclei are located in broader peripheral parts of the cells and present extremely irregular outlines. In the direction to the AC, mitochondria aggregate and fibrous nuage-like material is discernible. Free ribosomes are abundant. AC and GSCs form gap-like junctions (Figure 5B) but adherens junctions are not apparent^[63]. No specific junctions seem to exist between CySCs and GSCs. CySCs and CySC-like cells have the same fine structural characteristics but only the CySCs contact the AC. Both cell types are rather "light". Their cytoplasm is scant and shows no specifications. In mature males, many dividing GSCs, CySCs and CySC-like cells can be observed^[64]. Both, asymmetrical and symmetrical divisions occur at the same time. Sometimes whole clusters of these cells are seen in mitosis.

Oncopeltus fasciatus

The longitudinal section through the follicular apex of *Oncopeltus* (Figure 3C) reveals an organization of the apical complex similar to that of *Locusta* (Figure 3B), however, with important cytological differences of the different cell types. The niche is represented by a small cluster of "dark" cells with a relatively thin cytoplasmic lining. Small areas of the cytoplasm include a Golgi complex in continuation with some strands of smooth endoplasmic reticulum which is directed toward the periphery where GSCs are bordering (Figure 5C). Specialized cell-cell contacts were not seen^[60]. The GSCs reveal an extraordinary structure and astonishing dynamics. The GSCs have a polar structure, with a lobular perikaryon oriented toward the CySCs and prominent cytoplasmic projections toward the ACs (Figure 5C), which are reminiscent of neurons. The projections exhibit trabecular or septum-like ingrowths that are most advanced at their tips, next to the ACs. The process results in the segregation of free vesicles that amass around the niche. During the autotomy of the projection terminals, the number of mitochondria

increases in these segments, lysosomal bodies and autophagic vacuole-like vesicles become abundant and rough endoplasmic reticulum is often arranged in whorls (Figure 5C). Degradation processes proceed, indicated by the presence of acid phosphatase and TPPase, resulting in myelin- and autophagosome-like bodies^[60]. Autotomized vesicles aggregate at the surface of the ACs (Figure 6A). They finally rupture and release their content in the vicinity of the ACs. None of the debris is taken up by the ACs. Remarkably, intact-looking cytoplasm contains free ribosomes grouped in clusters. These clusters break up in slightly advanced stages of autotomy and the ribosomes are then evenly distributed. It is suggested that they give rise to electron dense granules of about 25 nm in diameter. These grana are sometimes enclosed in projection terminals; grana of lesser diameter occur free in the extracellular space between projection terminals and ACs (Figure 6A). This is of special interest, since morphologically similar grana were reported to be present at the same location in a number of apical complexes of different insect species (see *Lymantria dispar*, below). It is not clear whether or not these grana are taken up by ACs. After advanced autotomy of GSC projections new projections sprout at the "neck" of GSCs, where the projections arise from the perikaryon (Figure 5C). In this "neck" area of the cell there is an accumulation of mitochondria. CySCs surround only the apical part of the apical complex (Figure 3C). The ratio CySCs:GSCs is roughly 1:1, and only one cyst cell grows around a gonialblast. The cyst cell does not divide any more after its generation by division of a CySC but becomes highly polyploid as it enlarges during spermatogenesis^[60]. Divisions of GSCs and CySCs are rarely observed. Asymmetrical divisions of GSCs, where the spindle axis is oriented perpendicularly to the niche, were never observed. During symmetrical GSC divisions, the cell projections are persistent. In the process of gonialblast formation one of the GSCs, that shows no structural difference to the remaining GSCs, moves away from the niche toward the periphery. It loses its projections as the cyst cell encloses it. The spermatogonial cysts now move proximally. Cyst cells, which are rather "light", like the CySCs, develop striking organelles, composed of multiple complexes consisting of a meshwork of branching and anastomosing tubules and budding off vesicles which partly enclose electron-dense material. The Golgi complex-like structures (about 2.8 µm long and 1.1 µm in diameter) are often associated with sparsely granulated endoplasmic reticulum. The mitochondria are exceptionally long and branched. Cyst cells take up apoptotic spermatogonia^[65]. Follicular apices include regularly extensive clusters of degenerating GSCs and spermatogonia (Figure 3C).

Lymantria dispar

The niche of the apical complex consists of only one large AC (Figure 3D). The shape of the apical complex changes during development. During the first three larval stages the AC is attached to the envelope of the follicular apex,

Figure 6 Structural relationships between apical cells and projections and autotomized vesicles of germline stem cells in *Oncopeltus fasciatus* and *Lymantria dispar*. A: Electron micrographs. *Oncopeltus fasciatus*. Vesicles that are segregated from GSC projections accumulate at the surface of ACs. The vesicles show signs of degeneration. Mitochondria are abundant and appear electron dense. (From Schmidt *et al.*^[65]). Upper inset: Intracellular granules in autotomizing GSC projections. Lower inset: Extracellular granules (arrow) between autotomizing GSC projections; B: Electron micrograph. *Lymantria dispar*. Numerous autotomized GSC projections protrude deeply into the AC (long arrows). Some of the segregated vesicles were apparently taken up by the AC and are being digested (arrow heads). Double arrow points to extracellular granules between GSC vesicles and the AC. Upper inset: Extracellular granules at higher magnification. Lower inset: Tubular indentations into the AC include electron dense material. (From Klein^[66]). GSCs: Germline stem cells; AC: Apical cell.

and only the distal part of it is contacted by GSCs^[66]. From third to fourth larval stage the AC detaches from the follicle envelope and moves somewhat distally. Then it adopts a concentric organization, and the GSCs attach from all sides (Figure 6A). Each GSC is accompanied by one CySC whose perikaryon covers the peripheral part of the GSC and sends delicate projections to the AC, separating neighboring GSCs. Whereas the symmetry of the apical complex changes during larval development (from bipolar to rotationally symmetrical), the intricate relationships between AC and GSCs are largely similar until the pupal stage when signs of senescence become apparent and cyst formation seizes^[66].

The large, "light" AC includes a centrally located nucleus around which the cell organelles are concentrically arranged (at progressed developmental stages) (Figure 5D). Mitochondria, rough endoplasmic reticulum and lysosomes are especially abundant. As a rule the cell contains phagosomes, exceedingly numerous during early larval stages, with cell fragments of variable degree of degradation (Figure 5D and 6B). The periphery of the AC shows many Golgi complexes. The pear-shaped GSCs are "darker" than the AC apparently due to the presence of many free ribosomes. Striking are the cell projections of GSCs that deeply invade the AC. Similar to the GSC projections in *Oncopeltus*, GSC projections of *Lymantria* autotomize. But, unlike to *Oncopeltus*, the separated vesicles are phagocytized by the AC (Figure 6B). The GSC projections contain whorls of rough endoplasmic reticulum, many free ribosomes, mitochondria and multivesicular bodies. Phagosomes of the AC include similar cell organelles before they are digested indicating their origin from GSC projections. The electron micrograph Figure 6B demonstrates the extremely complex interactions between GSCs and AC. Extracellular space between GSC projections and AC regularly contains electron dense granules of 25-38 nm in diameter (Figure 6B inset 1). Tubular invaginations of the AC also contain electron dense material which often

exhibits a fibrillar consistency (Figure 6B). A relationship with the dense granules is unclear. The large nucleus of the GSCs is located in the peripheral part of the cells. The organelles in the perinuclear cytoplasm are inconspicuous. Symmetrical as well as asymmetrical divisions have been observed (see below). CySCs are "light". They divide apparently prior to the associated GSC^[66].

Lampyrus noctiluca

The glowworm represents a special case in as far as no niche cells (ACs) for the GSCs could be identified^[67]. During early larval stages the gonadal follicles only include ("dark") GSCs but no ACs and no CySCs; male and female gonads can not be differentiated. The onset of testis differentiation is marked by the appearance of "light" cyst progenitor cells (CPCs) segregated from the apical part of the follicle wall^[67,68]. Whereas a cluster of these cells is located and multiplies in the apex of the follicle, a cluster of dividing GSCs is located at the basal part of the follicle. The ratio of GSCs/CPCs is about 1/1. At that stage of development there are no associations between individual GSCs and individual CPCs. ACs are never observed. In later larval development, CPCs form cell projections, move toward and between the germ cells, which now may represent gonialblasts, contact and ensheath them, thus forming spermatogonial cysts^[67]. During transformation from CPCs to cyst cells, the cells develop conspicuous stacks and whorls of smooth endoplasmic reticulum. It was speculated that the cyst cells may produce hormones, *i.e.*, juvenile hormone or ecdysone. Since all GSCs/gonialblasts and CPCs engage in cyst formation at approximately the same time, a precise temporal regulation of GSC division and gonialblast differentiation seems obsolete and the function of a niche therefore not necessary. The absence of ACs has also been reported from several other insect species^[69].

In summary primarily electron microscopic studies

Figure 7 Comparison of autotomizing germline stem cell projection with autodestruction of an injured axon. A: Sequence of vesicle formation of a GSC projection in *Oncopeltus fasciatus*. The area of projection formation is characterized by an accumulation of mitochondria (blue). At the base of the projection ribosomes form small clusters (yellow), mitochondria are infrequent. Rough endoplasmic reticulum (rER, orange) and lysosomes (brown) are scarce. With progressing vesicle segregation mitochondria become more frequent and swollen, ribosomes form no longer clusters, rER becomes more prominent and lysosomal bodies increase. Segregated vesicles show many autophagosomes and myelin bodies. They accumulate at the surface of the apical cells (green) and disintegrate. Arrows point to newly sprouting projections (adapted from Dorn *et al.*^[60]); B: Sequence of progressive axonal fragmentation after injury. First neurotubules and neurofilaments break down. Then mitochondria accumulate and lysosomes (brown) become more abundant. Finally vesicles which mainly include autophagosomes and myelin bodies are segregated and taken up by macrophages. Arrows points to newly sprouting axon (adapted from Lingor *et al.*^[155], Beirowski *et al.*^[156], Kerschensteiner *et al.*^[157]). GSC: Germline stem cell.

revealed the enigmatic relationship between GSCs and their niche in numerous insects. Identification of the different cell types and their interactions were facilitated by the profound differences in electron density between the components of the apical complex: GSCs, ACs and CySCs. In almost all species studied, the ACs and the CySCs were "light" and the GSCs "dark". *Oncopeltus* is an exception: here, ACs are "very dark" whereas GSCs are "dark" and the CySCs "light". But, whereas the "light" and "dark" marking facilitates identification of the cell types, the functional significance of these characteristics remains unclear. In contrast, the intriguing processes of GSC autotomy and the interaction of autotomized GSC vesicles with niche cells (ACs) point to a to date unknown form of communication between GSCs and their niche. Next we will examine the process of GSC autotomy and compare it with morphologically similar processes in other systems: axon autodestruction, erythropoiesis and thrombopoiesis.

THE AUTOTOMY OF GSC PROJECTIONS: ARE THERE COMPARABLE PROCESSES IN OTHER CELL TYPES?

Autotomy of GSC projections in *Oncopeltus fasciatus* and *Lymantria dispar*

In both species the autotomy process follows an apparently standardized pattern (see above). Figure 7A

gives a schematized view of the process in *Oncopeltus*. At the base of the cell projections the cytoplasm exhibits similar organelle equipment as the GSC perikaryon: scattered mitochondria, few strands of rough endoplasmic reticulum, many free ribosomes, often forming typical clusters and few lysosomes. The fractionation of the projections that leads to vesicle formation starts with the sequential ingrowth of the plasma membrane from the periphery (described by Schmidt *et al.*^[65] in *Oncopeltus*). With progressing vesiculation of a projection, mitochondria and rough endoplasmic reticulum that often form concentric whorls, become more abundant, clusters of ribosomes dissolve and the ribosomes are scattered evenly. Mitochondria and vacuoles accumulate. With progressing projection segregation mitochondria become swollen and show signs of degradation and the number of lysosomal bodies increase. Finally, autophagosomal activity becomes evident^[60] and secondary lysosomes and myelin-like become abundant. The terminal vesicles then completely segregate from the GSC projections.

In the case of *Oncopeltus* the separated vesicles amass at the surface of the ACs, where they eventually rupture and release their contents. In the case of *Lymantria* the GSC projections are embedded in the AC and the segregated vesicles are phagocytized and digested by the AC (Figure 6B).

The process of projection segregation of GSCs exhibits remarkable similarities with degenerative processes of axons that take place either after injury, in neurodegenerative diseases or during developmental axon pruning. In the following it will be discussed whether an autodestruction program that may underlie the axonal destruction processes could possibly also be active in the process of GSC autotomy.

INJURY-INDUCED AXON DESTRUCTION (WALLERIAN DESTRUCTION) AND THE HYPOTHESIS OF AN AUTODESTRUCTION PROGRAM

Programmed cell autotomy seems to be a rather rare process. It is best known in axon degeneration that occurs after nerve injury in vertebrates and invertebrates (Wallerian degeneration), developmental neuron pruning and as pathological symptoms of neurodegenerative diseases (multiple sclerosis, Parkinson's disease and others)^[70]. Other examples of programmed cell autotomy are the formation of blood platelets and erythrocytes in mammals which are discussed later. Wallerian degeneration (Figure 7B) shares morphological similarities with axon degeneration during normal brain development (axon pruning) and with the "dying back" degeneration in neurodegenerative diseases.

Recent studies on the degeneration of injured axons strongly suggest that an active autodestruction program exists akin to apoptosis, and that the autodestruction pathway may be conserved between fly and human^[71,72]. The sequence of progressing autodestruction of the

stumps of transected giant nerve fibers in the cockroach *Periplaneta americana*, for instance, follows closely the segregation of GSC projection terminals in *Oncopeltus* (Figure 7): swelling of mitochondria, accumulation of myelin bodies, accumulation of lysosomal vacuoles and sequential segregation of vesicles^[73]. Vesicle formation at the axon stump starts like in GSC projections with cell membrane ingrowths. Whereas the distal nerve stump degenerates, the proximal stump produces sprouts that have been interpreted as axonal regeneration. This resembles the expected outgrowth of new GSC projections after exhaustive vesicle segregation (Figures 5C and 7A).

Although still little is known concerning the signaling pathway directing the autodestruction program, some progress has been reported recently. The *Wlds* gene protects severed axons from degeneration. It encodes dNmnat (nicotinamide mononucleotide adenylyltransferase 1). Nmnat is a critical enzyme in the NAD⁺ biosynthesis pathway and is essential for many cellular processes^[74]. Nmnat is likely essential for normal axon maintenance. Down regulation of Nmnat in the wing nerve of *Drosophila* leads to robust dying back fragmentation that markedly resembles Wallerian degeneration, whereas upregulation of Nmnat protects axon degeneration. The function of WldS/Nmnat may involve its essential role in NAD⁺ biosynthesis. The question arises if the mitochondria are the site of Nmnat-mediated action and mechanism^[71]. Also the ubiquitin proteasome system (UPS) plays a crucial role in axon and dendrite maintenance and neuropathology, but the precise effects of WldS/Nmnat and the effect of the UPS vary depending upon the situation, an acute injury, developmental pruning or disease context (for review see Fang *et al.*^[71]).

The UPS is a potent regulatory mechanism used to control protein stability in numerous cellular processes, including neural development^[75]. Many neurodegenerative diseases are featured by the accumulation of UPS-associated proteins, suggesting the UPS dysfunction may be crucial for pathogenesis. Recent experiments have highlighted the UPS as a key player during synaptic development. Recent discoveries center on the role of UPS in synapse remodeling and draw attention to the potential link between synaptic UPS dysfunction and the pathology of neurodegenerative diseases: Parkinson, Alzheimer, Huntington's disease^[75]. In *Drosophila*, the E3 ubiquitin ligase RPM-1 (disease resistance protein) targets DLK1 (delta homolog 1) which acts in the mitogen activated protein kinase (MAPK) cascade consisting of the MAPK MKK4 and the p38 kinase pMK3 or the MAPK c-Jun N-terminal kinase. Thereby RPM-1 regulates the organization and stabilization of presynaptic terminals and axon termination in mechano-sensory and motor neurons^[76].

Regeneration of injured neurons can restore function, but most neurons regenerate poorly or not at all. The failure to regenerate in some cases is due to a lack of activation of cell-intrinsic regeneration pathways. These

pathways might be targeted for the development of therapies that can restore neuron function after injury or disease. Hammarlund *et al.*^[77] showed that the DLK-1 MAPK pathway is essential for regeneration in *Caenorhabditis elegans* motor neurons. Loss of this pathway eliminates regeneration, whereas activating it improves regeneration. Further, these proteins also regulate the later steps of growth.

Osterloh *et al.*^[78] demonstrated that the ortholog genes sterile alpha and TIR motif-containing protein 1 (Sarm 1) in mouse and dSarm (sterile alpha/Armadillo/Toll-Interleukin receptor homology domain protein) in *Drosophila* promote cell autonomous axon destruction. The genes otherwise involved in innate immune response, are also players in a highly conserved axon destruction pathway. dSarm and Sarm 1 exhibit a punctate localization in neuronal cell bodies and a broad localization in neuritis of *Drosophila* and mouse respectively. An early event in the axon self-destruction pathway is the increase of intra-axonal calcium levels followed by a calcium-dependent cytoskeletal breakdown^[72].

There is evidence that WldS enhances physiological functions of the mitochondria and that axonal mitochondria are required for WldS-dependent axon protection. WldS/Nmnat activity enhances mitochondrial motility and Ca²⁺ buffering and that the mitochondrion is an organelle necessary for WldS/Nmnat-mediated axonal protection^[79,80].

DEVELOPMENTAL AXON PRUNING, DYING-BACK DEGENERATION AND NEURODEGENERATIVE DISEASES

Developmental axon pruning occurs at a large scale during metamorphosis of holometabolous insects, including *Drosophila*, where the process was studied in detail. Metamorphosis and axon pruning are controlled by ecdysone. Interestingly, in the mushroom body of the fly brain glia cells participate actively in axon pruning. Ecdysone stimulated axons extrinsically activate glial cells to infiltrate the axon branches and eliminate varicosities actively. They induce the fragmentation of axons, and engulf the fragments^[81,82]. The process resembles the interaction of GSCs with the AC in *Lymantria* (Figure 6B). In both cases, the perikarya survive whereas the autotomy of cell projections/axons proceeds, and fragments are taken up by the AC and glia cells, respectively. In *Oncopeltus*, the GSC projections also autotomize but the severed and degrading vesicles are almost never phagocytized. It has been suggested that new projections sprout from the perikarya of *Oncopeltus* comparable to the sprouting of new neurites from pruned neurons. The neuron-glia interaction has an indispensable role in the pruning process of neurons in the mushroom body. The pruning proceeds in a neuron-autonomous manner. It resembles the interaction between phagocytes and apoptotic cells^[81,82]. It was shown that dendrite-

Figure 8 Symmetric and asymmetric germline stem cell division in *Lymantria dispar*. Both symmetric and asymmetric GSC divisions occur in this insect species. Both are preceded by the division of the single cyst stem cell that is associated with a GSC (A to C). Asymmetric division is depicted in D1a to D1d. One of the daughter cells is oriented toward the AC and still forms projections, whereas the other daughter cell has no contact with the AC and is devoid of projections (D1b). Then this daughter cell “swivels” round toward the AC (D1d) and adopts a similar position as daughter cells have after a symmetric GSC division (D2a to D2c). In each case, the daughter cell that doesn’t form projections becomes the gonialblast (E to H) (from Klein^[66]). GSCs: Germline stem cells; AC: Apical cell.

specific remodeling of *Drosophila* sensory neurons is controlled by two intracellular mechanisms: the ecdysone pathway and ubiquitin-proteasome system^[83]. It should be noted that components of the ubiquitin-proteasome pathway has been linked to apoptosis^[84].

A dying-back degeneration of axons can be induced in culture of mice neurons by removing nerve growth factor from the chamber. In the process, several distal ends of axons atrophy and undergo fragmentation while the neuronal somata survive. The controlling events are obviously confined to neurites and occur autonomously from the soma^[85]. Many neurological diseases are accompanied by neurodegeneration. Although different factors might contribute to axon pathology in each case, what is clear is that the end result is always the same, the axon degenerates in a process that resembles Wallerian degeneration^[86].

Wallerian degeneration is an evolutionary highly conserved process that is central to neurite autotomy occurring either regularly in developmental remodeling of neurons or pathologically in neurological diseases and experimental manipulations. The mechanism of serial autotomy of GSC projections in *Oncopeltus* and *Lymantria* (and probably butterflies in general) resembles closely axon autotomy described above. Molecular studies are necessary to uncover whether similar signaling pathways are involved.

CONSEQUENCES OF GSC AUTOTOMY ON SIGNAL EXCHANGE WITH THE NICHE AND GSC DIVISION (SYMMETRIC VS ASYMMETRIC DIVISION)

Until recently it was accepted that adult male GSCs in

Drosophila only undergo asymmetric divisions^[87]. GSCs attached to hub cells by adherens junctions provide a polarity cue that orients stem cells. The centrosome is oriented toward the hub cell-GSC interface throughout the cell cycle. The mother centrosome is always located close to the hub cells whereas the daughter centrosome moves to the opposite side. Consequently, GSC spindle orientation is predetermined during interphase^[88]. The correct centrosome orientation toward the hub cells requires the adherens junction which is composed of E-cadherin and β -catenin, centrosomin, and Apc2. Apc2 is believed to connect astral microtubules to the adherens junction/actin cytoskeleton network formed between hub cells and GSCs thereby anchoring the centrosome^[89]. Centrosome orientation prior to mitosis is accomplished by Par-1 (a serine/threonine kinase that regulates polarity in many systems) that regulates cyclin A localization^[90]. Recently “symmetric renewal” of male GSCs in *Drosophila* has been observed^[91]. In this process, GSC division starts like a typical asymmetric mitosis (the mitotic spindle is perpendicularly oriented toward the hub surface) but then the still interconnected pair of cells “swivel” such that both cells contact the hub. Studies on other insect testes revealed still different modes of GSC divisions and gonialblast differentiation.

Unique processes have been described in male GSCs of *Lymantria* (Figure 8). GSCs undergo either symmetrical divisions (the spindle is oriented parallel to the AC surface) or asymmetrical divisions (the spindle is oriented perpendicularly to the AC surface). Both types of mitosis can result in gonialblast formation but, surprisingly, after asymmetrical division GSC and daughter cell - interconnected by a fusome - “swivel”, comparable to the process in *Drosophila* described by Sheng *et al.*^[91] in 2011, and both contact the AC. Whereas the mother GSC maintains its intense interaction with the AC, the daughter and presumptive gonialblast does not form cell projections. Finally, the daughter cell moves further to the periphery and differentiates to a gonialblast. Alternatively, after symmetrical division the daughter cell is again characterized by the lack of cell projections, develops to a gonialblast in a similar fashion as in the case of asymmetric GSC division^[66]. Each GSC is associated with one CySC. CySC division precedes GSC division and the mitotic spindle is always oriented parallel to the AC surface. The mechanism destining the centrosome location is not known and adherens junctions between GSCs and AC have not been described - and are not likely to exist, given the complex relationship between GSCs and AC. Consequently, the regulation of spindle orientation must differ in *Lymantria* from *Drosophila*.

Also in *Oncopeltus* adherens junctions could not be identified in electron microscopic studies^[92]. In this species, only symmetrical divisions of GSCs have been observed. GSC projections persist during division. Gonialblasts are formed when GSCs migrate toward the periphery of the apical complex. Its projections elongate, become thin and gradually degenerate before one cyst

cell encloses the gonialblast^[92]. *Locusta* shows both symmetrical and asymmetrical divisions^[64]. But again, besides tight junction-like connections, no adherens junctions have been detected between GSCs and AC. It should be mentioned, however, that GSCs and AC are extremely difficult to separate, either enzymatically or mechanically, in *Locusta*^[64].

In summary, the mechanism for spindle orientation appears variable in insect male GSCs. But up to date, *Drosophila* is the main species studied in this respect in the evolutionary highly diversified group of insects.

Interactions between GSCs and ACs in the testes of various insects are diverse and it is evident that the mode of short range signaling between stem cell and niche differ in distinct species from that in *Drosophila*. In *Oncopeltus*, ACs are surrounded by vesicles segregated from GSC projections (Figure 6A). This poses the questions: how is the communication and information exchange organized between GSCs and AC? and how is the sequential projection autotomy, progressing degradation, and sprouting of new projections programmed? There are no studies on the molecular level concerning these questions. However, the ancient conserved axon destructing Wallerian pathway bears many similarities with GSC projection autotomy. Further, the outgrowth of new projections near the perikaryon of *Oncopeltus* GSCs parallels the outgrowth of new neuritis after Wallerian axon destruction. As described above, developmental axon pruning and neurite dying-back in neuronal diseases all appear to be governed by a related axon-autonomous program that carries characteristics of apoptotic processes. Extensive fragmentation of megakaryocyte projections takes place during platelet formation as described below. Also in this case apoptotic processes take place, *i.e.*, fragmentation of the nucleus. The segregation of platelets, however, appears to follow a different pattern than Wallerian axon fragmentation and GSC projection autotomy. In the latter cases, concentrically transverse ingrowing plasma membrane that finally fuses, cuts off vesicular fragments. Pinching off platelets apparently involves transverse microtubule arrangement and vesicle widening at the constriction zone (see below).

In *Lymantria*, segregation of GSC projection terminals resembles that in *Oncopeltus*. Thus, the underlying cell autotomy program is expected to be similar as in *Oncopeltus*. But in *Lymantria* and several other butterflies (see above) the AC embraces the GSC projections and engulfs and digests separated vesicles. In *Locusta*, ACs almost constantly include one or two phagocytized GSCs. The interactions of GSCs and ACs (their niche) are puzzling in *Oncopeltus* as well as in butterflies. We speculate that the AC sends signals that promote GSC autotomy and that in return the AC receives information concerning the surrounding GSC population. In response to that information the AC may regulate GSC self-renewal and maintenance. Unfortunately, none of these aspects have yet been tested. In about all insect apical complexes studied

by electron microscopy, "dark" granules have been described in the interface between AC and GSCs (Figure 6). In *Lymantria*, the AC shows tubular invaginations filled with "dark" material of unknown fate. Due to the phagocytic processes and material exchange early investigators suggested a trophic role of ACs^[92]. We believe that these processes are part of the information exchange and signaling pathways. In erythroblastic islands, after release of the reticulocyte, the pyrenocyte is phagocytized by the central macrophage. This is mandatory for continued erythropoiesis (see below). This indicates that the involvement of phagocytic processes in stem cell-niche interaction is existent but needs further investigation.

STEM CELL/PROGENITOR AUTOTOMY IN ERYTHROCYTE AND PLATELET FORMATION

Erythroblastic islands and enucleation of erythroblasts

In vivo, erythropoiesis occurs in specific units, the erythroblastic islands in the bone marrow of mammals^[93]. Erythroblastic islands were also described in the spleen, yolk sac and fetal liver. They harbor a central macrophage that arises from a resident monocyte precursor with a unique immunophenotypic signature^[94]. The central macrophage, representing the niche, is surrounded by one or more synchronously maturing cohorts of erythroid cells that undergo four or five divisions between proerythroblast and orthochromatic erythroblast stage. In their fine structural study Allen *et al*^[95] describe gap junction-like contacts between the macrophage and erythroblasts and possible reciprocal vesicular activity. Several molecules indicate adhesive interactions within the erythroblastic islands^[4]: (1) Erythroblast macrophage protein (Emp) forms macrophage/erythroblast attachments *via* hemophilic binding; (2) $\alpha 4\beta 1$ integrin in erythroblasts and vascular cell adhesion molecule-1 in the central macrophage mediate receptor/counter receptor cell-cell interactions; (3) Macrophage α integrin and erythroid intercellular adhesion molecule-4 are expected to contribute to the island integrity; and (4) Other macrophage adhesion glycoproteins, *i.e.*, CD69 and CD 163, have been detected^[96] although their erythroid binding partners are unknown. It is expected that adhesive connections between erythroblasts and macrophages play a crucial role in signaling pathways as they do in *Drosophila* testes. The central macrophage secretes soluble factors, cytokines, that promote proliferation and maturation of erythroblasts (insulin-like growth factor-1 and others) and also negative regulatory factors [transforming growth factor- $\beta 1$ (TGF- β), TNF- α , ILG and others]^[4] (Figure 9).

The most striking event in mammalian erythrocyte maturation is the enucleation of orthochromatic erythroblasts at the last stage of erythroblast differentiation. It results in multilobulated non-nuclear reticulocytes and

Figure 9 Erythropoiesis in mammal bone marrow (schematized). The erythroblastic island consists of a central macrophage (MA) that functions as the niche, and the peripheral erythroblasts (EB), that represent stem/progenitor cells. Erythroblasts undergo an enucleation process (arrow) that results in the pyrenocyte (PC) that mainly consists of the erythroblast nucleus, and the nucleus-free reticulocyte (RC). The pyrenocyte is phagocytized by the macrophage (PH, phagosome), whereas the reticulocyte develops to the erythrocyte (EC) (adapted from Chasis *et al.*^[4]; Keerthivasan *et al.*^[96]).

pyrenocytes which mainly consist of the nucleus and the enwrapping plasma membrane. Enucleation is regulated by retinoblastoma protein (Rb) but other signaling molecules, *e.g.*, p38 MAPK (p38) and Rac-1 GTPase, have been found to be involved in the enucleation^[97]. Interestingly, sorting of protein and vesicle trafficking in the orthochromatic erythroblast in concert with nuclear positioning are essential for the enucleation process^[98]. The pyrenocytes express phosphatidylserine, a recognition signal similar to apoptotic cells, on their surface that signals macrophages to engulf and digest them. The taken up DNA is digested by DNase II from the macrophage^[99]. The lack of DNase II in DNase II knockout mice is lethal *in utero* due to embryonic anemia. Digestion of engulfed pyrenocyte nuclei is vital for continued erythropoiesis^[100].

Already in the 1990ties Hanspal *et al.*^[101,102] found that the interaction between erythroblasts and macrophages is needed for normal erythroblast proliferation and for enucleation. The authors showed that this interaction is mediated by Emp that prevents apoptosis of developing erythrocytes. Nonetheless, erythroblasts cultured *in vitro* in the absence of macrophages undergo complete differentiation including nuclear extrusion^[103,104]. Although erythropoietin was used to start erythroblast amplification (and other factors were eventually added) erythropoiesis proceeded apparently normal without macrophages, however, at a much lower pace as it does in erythroblastic islands^[93]. Thus the question arises: have macrophages merely a trophic function? As mentioned above, genetic manipulations of macrophage activity resulted in lethality due to anemia. It may be speculated that in these cases erythropoiesis was (only) insufficient (but not completely) suppressed. The "true" function of island macrophages is to optimize and accelerate erythrocyte production allowing effective erythrocyte supply and rapid adjustment to the actual need. Erythrocyte homeostasis might be largely

regulated by systemic factors that convey the need or surplus of erythrocytes and affect short-range signaling within the erythroblast island which determines the pace of erythrocyte production.

We suggest that spermatocyte production in insect testes is regulated in a similar way. The example of *Lampyrus* shows that no ACs are needed for GSC differentiation *per se*. The apparent reason: all GSCs differentiate at the same time and the process does not need any temporal regulation. Onset of GSC differentiation and production of CC progenitors occurs during larval development of *Lampyrus* and is expectedly put in motion by the release of morphogenetic hormones, *e.g.*, ecdysone and juvenile hormone, representing systemic signals^[67].

Another conspicuous interaction shared by the niche of erythroblastic islands and the niche of butterfly testes are spectacular phagocytic processes. In the case of erythroblastic islands, macrophages engulf the pyrenocytes; in the case of butterflies, ACs phagocytise large vesicles segregated from GSC projections. DNA taken up by macrophages plays a role in signaling, as described above. And there are also vesicle interactions with expected receptor exchange. In butterflies, the vivid autotomic activity of GSCs and the phagocytotic uptake of the autotomized vesicles are not understood. We propose that it represents an interaction/communication between niche and stem cell hitherto unknown. Noteworthy, whereas autotomy of GSC projections also takes place in *Oncopeltus* the segregated vesicles are not taken up by ACs, but degenerate in a distinct pattern as described above. We suggest that the degenerating vesicles provide specific signals that are recognized by the AC. Interestingly, the ACs of *Locusta* include, as a rule, one or two phagocytized GSCs (see above). Phagocytosis here may play a similar role as it does in *Lymantria*. The variations in stem cell-niche relation seem highly variable in insect testes, and the analysis of species beyond *Drosophila* might provide new insights.

Platelet formation by megakaryocyte fragmentation

The probably most spectacular case of programmed cell autotomy is the shedding of 5000-10000 platelets from one megakaryocyte. Platelets are characterized by the absence of a nucleus and by the accumulation of three types of granules: (1) Dense (or delta) granules, with a diameter of 150 nm, contain ADP or ATP, Ca and Serotonin. They are secreted to recruit other platelets; (2) Alpha-granules, with a diameter of 200-400 nm, contain P-selectin, platelet factor 4, TGF- β 1, platelet-derived growth factor, fibronectin, B-thromboglobulin, von Willebrand factor (VWF), fibrinogen, coagulation factors V and XIII. They are responsible for adhesion and healing processes; and (3) Lambda granules, with a diameter of 175-250 nm, resemble lysosomes. They contain several hydrolytic enzymes that are able to eliminate circulating platelet aggregates (for review see Rendu *et al.*^[105]) (Figure 10).

Megakaryocytes mature from megakaryoblasts

Figure 10 Thrombopoiesis (platelet formation) in mammal bone marrow (schematized). Platelets are produced by a most spectacular form of cell autotomy performed by the megakaryocyte (MK). Maturation and fragmentation of the megakaryocyte is orchestrated by the vascular niche which consists of the endothelial cells (EC) of sinusoids and the extracellular matrix (MA) of the endothelium. The megakaryocyte is located at the outer surface of the sinusoid epithelium and sends pseudopods through the pores of the endothelium into the lumen of the sinusoids (arrows). The pseudopods branch and form proplatelets (PPL). These are released into the sinusoids (rPPL) followed by the release of platelets (PL). Nu, polyploidy nucleus of the megakaryocyte (Adapted from Patel *et al*^[115]).

via promegakaryocytes in the bone marrow. Megakaryoblasts reside in the osteoblastic niche where osteoblasts secrete the cytokine thrombopoietin (TPO) that regulates megakaryopoiesis and thrombopoiesis, *i.e.*, platelet formation, as well^[106]. Stromal cell derived factor-1 from stromal fibroblasts and fibroblast growth factor-4 direct megakaryocyte interaction with the bone marrow stroma and regulate cytokine-independent megakaryocyte maturation^[107]. A number of cytokines [interleukin-3 (IL-3), IL-6, IL-11, IL-13, leukemia inhibiting factor (LIF), stem cell factor, and others] affect megakaryopoiesis which was mostly tested in *in vitro* systems^[108,109]. In the process of maturation, the precursors of the megakaryocytes migrate from the osteoblastic to the vascular niche along an oxygen gradient to the higher oxygen of the vascularized compartment of the bone marrow^[110]. During maturation megakaryocyte progenitors undergo endomitosis, up to 128 times. Reaching the endothelium of the marrow sinusoids the strongly enlarged megakaryocytes form cytoplasmic projections that protrude through endothelial pores into the lumina of the sinusoids. There, the projections presumably (as inferred from *in vitro* observations) branch repeatedly forming formidable trees of proplatelets which segregate and release the platelets into the lumina of the sinusoids. The vascular niche that promotes platelet formation and shedding consists of the endothelial cells and the extracellular matrix of the endothelium^[111].

The dynamic interactions of megakaryocytes with different extracellular matrix proteins seem to orchestrate their maturation in specific sites^[111]. In the vascular niche such proteins include collagen type IV, fibronectin, laminin, fibrinogen and VWF. (VWF is secreted by endo-

thelial cells and megakaryocytes into the blood and has a function in adhesion and aggregation of platelets.) In mice (*in vitro*) fibrinogen binding to the fibrinogen receptor $\alpha_{IIb}\beta_3$, which is expressed in megakaryocytes, is essential for proplatelet formation. However, the role of the interaction in humans is not fully understood^[112]. Astonishingly, *in vitro* studies have shown that the cytokine TPO alone is required for thrombopoiesis and that extracellular matrix and other cytokines are not essential, although they may have regulatory functions *in vivo* that accommodates platelet homeostasis^[113]. This is reminiscent of the niche function in erythroblastic islands and testes of insects where stem cell differentiation can proceed without niche but is adjusted to the actual need by niche interaction.

The process of proplatelet formation and platelet shedding is highly complicated and still not fully understood^[114,115]. Electron microscopic studies on cultured megakaryocytes demonstrated that prior to proplatelet formation mature megakaryocytes have already a well-developed demarcation membrane system^[116]. This elaborate membrane system is - as commonly believed - formed by invaginations of the plasma membrane, shows open cisternae and is at first randomly distributed throughout the cytoplasm. Randomly scattered α -granules and some dense granules are also present. Preparing for active platelet shedding, the peripheral demarcation membranes dilate and align at the cell periphery. Cytoplasmic sheets unfold and cell projections extend. The extensions display a beaded appearance with constriction points separating discrete platelet-like territories. A bundle of longitudinal microtubules runs through the center of the extensions. At the constriction zone transverse microtubules are observed near the longitudinal microtubules. Also, a vacuole of increasing size is formed at the constriction zone which may lead to the detachment of the platelet fragment. These observations of Cramer *et al*^[116] suggest that vesiculation and microtubule force attribute to autotomy. Other studies emphasize even more the role of microtubules in platelet segregation^[115,117]. Before proplatelet formation, microtubules align into bundles beneath the surface of megakaryocytes and, at projection formation, fill the cortex of outgrowing cones. Cell organelles are in direct contact with microtubules and are transported along these elements. Microtubules coil at the end of the projections, but their exact role in platelet segregation remains unresolved.

It should be mentioned that in an opposing view the membrane boundaries of platelets are not provided by involutions of the megakaryocyte plasma membrane but by vesicles from Golgi complexes. So-called proplatelets constitute within the megakaryocyte whose plasma membrane finally ruptures and releases the platelets. Extensions of the megakaryocyte with proplatelets and segregation of terminal platelets are considered as artifacts by some authors^[114,118,119].

It is, however, the prevailing view that platelets segregate from ends of the megakaryocytes extensions that

offer a beaded structure, in as much platelet-sized and platelet-structured proplatelets are connected by string-like connections with longitudinally running microtubules (Figure 10). Interestingly, the process of platelet assembly is accompanied by some characteristics associated with apoptosis: cytoskeletal reorganization, membrane condensation and chromatin condensation. Microtubules and F-actin play supposedly a major role in proplatelet formation and fragmentation. The kinetics of platelet release *in vitro* corresponds to the onset of apoptosis in the megakaryocyte. Maximal platelet production and megakaryocyte apoptosis are closely related events^[115,120,121]. Molecular evidence of apoptotic processes in megakaryocytes provided the detection of caspase 3. Before the platelet formation caspase 3 shows a punctuate cytoplasmic distribution (in a presumably inactive state) and a diffuse staining pattern (in a presumably active state) in senescent megakaryocytes. It was concluded, that proplatelet formation is regulated by caspase activation limited to only cellular compartments^[122]. Further evidence for an involvement of apoptotic processes in platelet formation comes from the presence of the antiapoptotic protein BclxL which is upregulated during megakaryocyte differentiation but absent during late megakaryopoiesis. BclxL overexpression causes a strong decrease in proplatelet formation^[123]. Other apoptotic-related genes such as TGF- β 1 and SMAD proteins are expressed during thrombopoiesis which supports the significance of apoptotic signaling in the process^[124]. Besides, NO in conjunction with TPO facilitates platelet production^[125]. Nagata *et al.*^[126] report that estradiol synthesized in megakaryocytes triggers proplatelet formation by autocrine action. Few transcription factors were reported to play major roles in thrombopoiesis. GATA-1, which interacts with friend of GATA-1 controls proliferation during megakaryopoiesis, and NF-E2 regulates platelet biosynthesis^[127-129].

Cell autotomy in the process of erythrocyte formation (*i.e.*, enucleation) and platelet generation (by megakaryocyte fragmentation) appear to follow quite different strategies. However, in both cases apoptotic processes play a prominent role. This offers parallels to the autodestructive processes in neurons (see above). Concerning GSC autotomy, no attempts have been made to demonstrate apoptotic processes in GSC projections. Schmidt *et al.*^[92] described apoptosis of GSCs and spermatogonia in *Oncopeltus* but its significance - apart from removal of surplus spermatogonia - remains obscure. Dying germ cells in *Drosophila* revealed mixed morphologies of apoptosis and necrosis that may indicate an alternative developmental cell death pathway^[130]. The role of the cytoskeleton in cell autotomy is little understood although it may play a major role in all cases. Concerning megakaryocyte fragmentation, the cytoskeleton is obviously decisively involved in platelet segregation. Neurofilaments and microtubules are the first cell organelles that break down in axonal autodestruction following intracellular calcium

increase after nerve injury. The role of the cytoskeleton in GSC autotomy is not known but is conceivably important and should be analyzed.

COMPARISON OF THE INSECT AND MAMMAL SPERMATOGENESIS

Testes of insects offer a rather simple architecture. One testis is composed of one to many testicular follicles, blind ending tubules that join into a common seminal duct. GSCs and niche exhibit a globular arrangement, mostly in the form of a rosette at the apex of a testicular follicle, representing the apical complex. Spermatogonial cysts move distally during spermatogenesis. The follicular epithelium that envelopes the apical complex and cysts is mostly thin and has, so far, not been considered as part of the niche for GSCs. However, as pointed out above, in a number of species, the envelope synthesizes and releases the steroid ecdysone at some point of development^[53]. Although effects of ecdysone on spermatogenesis have been reported, a specific function or signaling pathway has not been elucidated. Nonetheless, it parallels the production of steroids, androgens, in Leydig cells of the testes of mammals.

Mammalian testes exhibit a complex epithelial organization (for review see Yoshida^[131]). The long seminiferous tubules are convoluted and both ends open into the rete testis. Figure 11 shows the organization of a seminiferous tubule. The high epithelium of the tubules consists of the larger Sertoli cells, and the smaller spermatogonia and spermatocytes. The epithelium rests on a basement membrane, and below it stretches peritubular myoid cells. Located in the interstitial between the seminiferous tubules are Leydig cells, macrophages, lymphoid epithelial cells and connective tissue. Blood vessels form a network around the tubules and run in the interstitial spaces. Besides the germ cells all mentioned cell types and structures may be part of the GSC niche. The complexity of the niche, which doesn't offer spatial specifications, is reflected by the difficulty to define GSCs. They represent obviously a small population of spermatogonia. According to de Rooij *et al.*^[132] and Russell *et al.*^[132,133], spermatogenesis progresses uniformly all over the inner surface of the seminiferous epithelium, and stem cells are scattered all over. But how are GSCs identified? First, they are located in the basal compartment of the epithelium. All neighboring Sertoli cells form tight junctions at a distinct height separating a basal compartment which has contact with blood vessels and an adluminal compartment without blood contact. Thus, a blood-testis-barrier is installed at the level of tight junctions. Located in the basal compartment are "undifferentiated spermatogonia" (A_{undiff}), comprising singly located spermatogonia (A_s) and such that have undergone up to four mitotic divisions. The mitotic spermatogonia form syncytia due to incomplete cytokinesis. A_s have contact with the basement membrane and a subpopulation of them might represent yet-to-

Figure 11 Organization of the mammalian testicular germline stem cell niche (adapted from Yoshida^[131]). The seminiferous tubules exist of large sertoli cells (SC) and spermatocytes (SPC). The putative germline stem cell (GSC) is located at the basement membrane (BM) at an interstitium. It is in close vicinity of a blood vessel (BV) and leydig cells (LC). Myoid cells (MC) that line the BM are thought to be "specialized" MC (sMC) below the GSC. The basal part of the SC that surrounds the GSC presumably performs a specialized "domain" acting as (the main) part of the complex niche. The niche allegedly consists of several additional entities besides the specialized SC domain: the BM, the sMC, the BV, the LC and probably others (see text). Tight junctions (arrow) between SCs establish a blood-testis barrier: GSCs and spermatogonia are exposed to the vascular system, whereas primary spermatocytes (SPC) and the following stages of Spermatogenesis proceed behind the barrier. dSPT: Differentiating spermatid; SP: Spermatozoon; N: Nucleus of SC; Red: GSC; Light green: SC; Dark green: sSC domain surrounding the GSC; Purple: Spermatogonia and different stages of spermatogenesis; Dark blue: sMC; Light blue: MC; Light red: BV; Orange: LC; Grey: BM.

be-identified GSCs. At the transition from mitotic to meiotic divisions, spermatogonia move to the adluminal compartment and are now called spermatocytes. From there on spermatogenesis takes place behind the blood-testis-barrier. Round spermatids move to the luminal surface where they elongate. The accumulation of stags of spermatogonia and spermatocytes among the Sertoli cell epithelium results in a multilayered organization of the seminiferous tubules.

Since A_s are spread all over the tubules the question arises: which mechanisms provide uneven features within the basal compartment to specify the niche microenvironment for stem cells? Yoshida *et al.*^[100] demonstrated that A_{undiff} (and possibly GSCs) are preferentially localized to the area adjacent to the interstitium at branching points of blood vessels of medium thickness. Yoshida *et al.*^[131] suggests that Sertoli cells and myoid cells in this region might be "specialized". Theoretically, all parts of the niche could control stem cells directly by short-range signaling. Systemic signals could arrive *via* blood directly at the GSCs or indirectly by modulating the short-range signaling of other parts of the niche. The niche region might not be fixed.

Several signaling factors are known to have effects on spermatogenic cells (Figure 12). Most important is glial cell line-derived neurotrophic factor (GDNF), a member of the TGF- β superfamily^[134]. The ligand GDNF is expressed in Sertoli cells and its receptor c-Ret and co-receptor GFR α 1 is expressed in the least mature subsets of A_{undiff} , the putative GSC^[135,136]. Thus, *via* GDNF signaling Sertoli cells control self-renewal, survival, and maintenance of GSCs. Another receptor highly expressed in GSCs is colony stimulating factor 1 receptor. Its ligand is expressed in Leydig cells of the interstitium and a subset of myoid cells^[137]. It is suggested that CSF1 may cooperate with GDNF in supporting the self maintenance of GSCs. The tyrosine kinase receptor c-kit and its ligand KitL, which is expressed in Sertoli cells, have been recently shown to be involved in proliferation, survival and migration of spermatogonia. However, only KIT(-) spermatogonia have stem cell activity. Several factors have effects on GSCs *in vitro*: FGF, EGF and LIF, in the presence of GDNF, support the proliferation of GSCs^[138]. LIF is probably also involved in the maturation of gonocytes into spermatogonia^[139]. But a possible function *in vivo* is uncertain. The transcriptional regulator Ets related molecule has been detected in nuclei of Sertoli cells of adult testes. It is assumed that it regulates Sertoli cell function that mediates germ cell self-renewal^[140].

Stem cells and spermatogonial populations express α 6 and β 1-integrin^[136] which mediates the attachment to the basement membrane *via* binding of laminins, probably as a heterocomplex with α 6-integrin^[141]. Its significance in signaling *in vivo* is not known; GSCs lacking β 1-integrins fail to develop spermatogenic colonies after transplantation^[142]. E-cadherin is expressed in A_{undiff} but is dispensable for the normal functioning of stem cells^[143].

Despite the profound differences between the organization of the insect *Drosophila* and the mammal mouse testis, several important common principles can be observed. In both cases, the stem cell-niche complex is exposed to blood: in insects hemolymph freely surrounds the testicular follicles whose envelope allows the passage of larger molecules^[144]. In mammals blood vessels run through the niche of GSCs and release molecules in the vicinity of GSCs. In several adult stem cell-niche systems blood vessels and endothelial cells are an integral part of the niche: the HSC niche and the vascular niche of platelet producing megakaryocytes (see above), the neural stem cell (NSC) niche the B1 NSCs within the ventricular-subventricular zone send out a basal process ending in a specialized end-foot that contacts blood vessels; blood-borne factors and endothelial-derived factors may act on B1 cells in this domain^[145], intestinal stem cell and probably other niches^[146,147]. Recently, it has been reported that an important function of endothelial cells in glioblastoma multiforme is to create a niche that helps to promote self-renewal in cancer stem-like cells^[148]. In liver regeneration, endothelial cells establish an instructive vascular niche, which through elaboration of paracrine trophogenesis stimulates organ regeneration,

Figure 12 Short range signalling between germline stem cell and its niche. GDNF is the most important signal produced by the “specialized” basal compartment of SC. Its receptor - c-RET (transmembrane tyrosine kinase receptor) and co-receptor GFR α 1, which functions as a glycosylphosphatidylinositol-anchored docking receptor that is needed for GDNF to bind with c-RET - is expressed in GSC, and SFK and Akt pathway are initiated. They control self-renewal and maintenance of GSCs. GSCs also express CSF1R (colony stimulating factor 1 receptor). Its ligand CSF1 is synthesized in “specialized” MCs (sMC) and in leydig cells (LC). Thus, CSF1 may cooperate with GDNF in supporting self-maintenance. Integrins attach the GSCs to the BM and may also contribute to signalling. Red: GSC; Light green: SC; Dark green: sSC domain surrounding the GSC; Purple: Spermatozoon (SG); Dark blue: SMC; Light blue: MC; Light red: BV; Orange: LC; Grey: BM.

in a manner similar to endothelial-cell-derived angiocrine factors that support hematopoiesis^[149].

Meiotic divisions of spermatogonia in mammals and all mitotic and meiotic divisions after gonialblast formation in insects take place behind the blood-testis-barrier. Whereas tight junctions between neighboring Sertoli cells establish the barrier in mammals, it is the cyst cells that isolate the developing germ cells from the hemolymph in insects. There is little information on the necessity for a compartment in which spermatogenesis is protected from blood-borne factors.

Mouse and *Drosophila* differentiating germ cells share another astonishing potency: they can generate GSCs, *in vivo*. In mice “spermatogonial progenitors committed to differentiation” can generate functional GSCs that can repopulate germ cell-depleted testes when transplanted into adult males. GDNF and FGF2 are able to reprogram *in vitro* spermatogonial progenitors for reverse differentiation^[150,151]. Amazingly, posttransplantation homing GSCs have to perform multiple steps: attachment to the Sertoli cell surface, retrograde translocation to the basal compartment across tight junctions, migration to the presumptive stem cell niche, survival, proliferation, and self-renewal within the niche, expansion of the transient amplifying spermatogonia and differentiation into sperm^[131]. β 1-integrin, which is expressed in spermatogonial cells, plays an essential role in GSC homing^[142]. In *Drosophila* testes spermatogonia undergoing transit-amplifying divisions can be reverted to stem cell identity by conditionally manipulating Jak-STAT signaling^[152]. In the process, the spermatogonia, which

are enclosed in cysts and interconnected by fusomes, have to break up their connections, and the cyst wall has to disintegrate in order to release the dedifferentiating germ cells. These germ cells populate the orphaned niche and reestablish normal spermatogenesis. Spermatogonial dedifferentiation can be genetically induced by conditional loss of STAT or misexpression of the differentiation factor Bam within the testes. This causes the differentiation of all GSCs and free niche space. If normal signaling is restored differentiating spermatogonia revert to stem cells, as described above, adhere to hub cells and function normally^[14,152]. Remarkably, dedifferentiation of oögonia has also been shown in the *Drosophila* ovary^[153].

CONCLUSION

This review summarizes the current knowledge of a novel mode of interaction between GSCs and their niche, the ACs, in insects. In several insect species (*Oncopeltus*, *Lymantria* and other moths) male GSCs undergo autotomy of cell projections, which are directed toward the ACs. The segregated GSC vesicles degrade at the surface of the niche cells or are phagocytized by them. This unique stem cell-niche relationship has been compared with known examples of stem cell/progenitor autotomy (*i.e.*, erythrocyte and thrombocyte formation) and autotomy of neurons in developmental axon pruning or neurodegenerative processes. In all the cases described, apoptotic signalling is involved. Studies on injury-induced axon destruction (Wallerian degeneration) suggest that an active autodestruction program exists akin to apoptosis and that the autodestructive pathway maybe conserved between fly and human^[71,72]. We propose that this pathway also exists and is active in male GSCs of *Oncopeltus*, *Lymantria* and other species. The analysis of signal exchange between autotomized GSC vesicles and niche cells is expected to reveal a new mechanism of stem cell-niche interaction.

Abstract

Epigenetics finely tunes gene expression at a functional

level without modifying the DNA sequence, thereby contributing to the complexity of genomic regulation. Satellite cells (SCs) are adult muscle stem cells that are important for skeletal post-natal muscle growth, homeostasis and repair. The understanding of the epigenome of SCs at different stages and of the multiple layers of the post-transcriptional regulation of gene expression is constantly expanding. Dynamic interactions between different epigenetic mechanisms regulate the appropriate timing of muscle-specific gene expression and influence the lineage fate of SCs. In this review, we report and discuss the recent literature about the epigenetic control of SCs during the myogenic process from activation to proliferation and from their commitment to a muscle cell fate to their differentiation and fusion to myotubes. We describe how the coordinated activities of the histone methyltransferase families Polycomb group (PcG), which represses the expression of developmentally regulated genes, and Trithorax group, which antagonizes the repressive activity of the PcG, regulate myogenesis by restricting gene expression in a time-dependent manner during each step of the process. We discuss how histone acetylation and deacetylation occurs in specific loci throughout SC differentiation to enable the time-dependent transcription of specific genes. Moreover, we describe the multiple roles of microRNA, an additional epigenetic mechanism, in regulating gene expression in SCs, by repressing or enhancing gene transcription or translation during each step of myogenesis. The importance of these epigenetic pathways in modulating SC activation and differentiation renders them as promising targets for disease interventions. Understanding the most recent findings regarding the epigenetic mechanisms that regulate SC behavior is useful from the perspective of pharmacological manipulation for improving muscle regeneration and for promoting muscle homeostasis under pathological conditions.

Core tip: Skeletal muscle needs to efficiently respond to internal and external stimuli, and satellite cells (SCs), the stem cells of muscle, play key roles in the preservation of muscle mass under both physiological and pathological conditions. Epigenetic pathways participate in coordinating the precise time-dependent expression of different subsets of myogenic genes in SCs. Thus, these pathways represent promising targets for therapeutic interventions. In this review, we focus on the epigenetic changes mediated by histone modifications - methylation or acetylation - and by noncoding mRNAs throughout SC differentiation.

SATELLITE CELLS

The first report and ultrastructural description of satellite cells (SCs) was in 1961 when Mauro reported the presence of cells containing a scant cytoplasm that were "intimately associated with the muscle fiber wedged between the plasma membrane of the muscle fiber and the basement membrane"; Mauro termed them SCs^[1]. In the same report, despite the absence of direct functional evidence, Mauro proposed that SCs "might be pertinent to the vexing problem of skeletal muscle regeneration".

In subsequent decades, Mauro's hypothesis proved true, and a number of studies demonstrated that SCs are the key mediators of post-natal skeletal muscle growth, homeostasis and repair^[2-4]. The core functions of SCs are the repair of damaged muscle fibers and the maintenance of an adequate pool of stem cells. In fact, dividing SCs were shown by autoradiographic studies to supply both new nuclei within growing or regenerating muscle fibers and new SCs adjacent to the muscle fibers^[5,6].

Quiescent SCs express the transcription factor Pax7^[7]. However, quiescent SCs constitute a heterogeneous population: most SCs are committed to the myogenic lineage (Pax7⁺, Myf5⁺), whereas a small subpopulation of SCs (Pax7⁺, Myf5⁻) are interpreted as representing satellite stem cells, whose asymmetric division produces both Pax7⁺, Myf5⁻ stem cells and Pax7⁺, Myf5⁺ committed SCs. SCs are also capable of maintaining or expanding their number *via* symmetric division^[8,9]. The observation that SC proliferation contributes to both the growth or repair of the muscle fiber and the maintenance of the SC pool provided the basis for considering SCs as muscle stem cells^[10]. The equilibrium between asymmetric

and symmetric division is therefore relevant to the maintenance of a homeostatic population of stem cells. In SCs, this equilibrium is influenced by signaling that includes WNT7A and its receptor Frizzled 7 (Fzd7) *via* the -catenin-independent, non-canonical planar cell polarity pathway^[11]. Such signals dictate the polarity (parallel or perpendicular) of the orientation of mitotic division with respect to the fiber sarcolemma (and the basal lamina). WNT7A activity induces stem cells to divide in a planar orientation, parallel to the fiber sarcolemma, thereby favoring symmetric division, which produces two Pax7⁺, Myf5⁻ stem cells. Conversely, in the absence of WNT7A activity, the mitotic spindle is oriented perpendicular to the fiber sarcolemma, thereby favoring asymmetric division into two daughter cells; the daughter cell that contacts the basal lamina retains stem cell characteristics (Pax7⁺, Myf5⁻), whereas the other daughter cells, which contacts the fiber sarcolemma, becomes a Pax7⁺, Myf5⁺ committed SC.

SCs in muscle regeneration

Many stimuli, such as those present in injured or diseased muscle, induce SCs to activate, expand and contribute to new fiber formation. Importantly, SC activation is not restricted to the damaged area; rather, SC proliferation and migration to the regeneration site have been observed along entire fibers of injured muscles^[12]. Muscle regeneration is absolutely dependent upon muscle-resident Pax7⁺ cells^[13], which predominantly, although not exclusively, consist of SCs^[14]. The absolute requirement of Pax7⁺ SCs for muscle regeneration was demonstrated in different studies^[13,15,16]. In the absence of Pax7⁺ SCs, regeneration does not take place; instead, fibro-adipogenic cells invade the tissue. In keeping with the notion that SC-dependent muscle regeneration processes are similar to those of embryonic myogenesis, SC activation involves the upregulation of myogenic basic helix-loop-helix transcription factors and SC differentiation^[17]. In particular, at the molecular level, the activation of SCs is characterized by the rapid expression of *MyoD* and *Myf5*, which is triggered by Pax7 (and its paralog Pax3)^[18] and is modulated by epigenetic mechanisms^[19].

After the proliferation phase, the expression of the myogenesis regulatory factor (MRF) members myogenin and MRF4 is upregulated, leading to terminal SC differentiation^[20]. This event is concomitant with the activation of the cell cycle arrest protein p21 and permanent exit from the cell cycle. The completion of the SC differentiation program includes the activation of muscle-specific proteins, such as myosin heavy chains, and the fusion of SCs to each other or the repair of damaged muscle. SC fusion, which is a complex and tightly controlled process^[21], is regulated by numerous proteins involved in cell-cell adhesion and actin dynamics^[22-25], as well as muscle-specific membrane proteins^[26].

The depletion of SCs is a common occurrence in

chronic muscle degenerative diseases, and these cells cannot be replaced. Thus, the regulation of SC renewal is central to the promotion of muscle regeneration in muscle diseases, such as muscular dystrophies.

EPIGENETIC MECHANISMS OF GENE REGULATION

Epigenetics is responsible for the identity of distinct cell types despite the same genetic information by modulating gene expression without altering the genetic code. In other words, the ensemble of epigenetic characteristics, referred to as the epigenome, determines the gene expression pattern that defines the distinct characteristics and functions of each cell type^[27]. In fact, although their genomes are essentially identical, the cell types in a multicellular organism perform strikingly different behaviors over extended periods. Lineage commitment during development is the most extreme example of epigenetics. During embryogenesis, cells progress from totipotency to terminal differentiation, and each step of this progression involves the establishment of a stable state in which specific developmental commitments that can be transmitted to daughter cells are encoded. The understanding of the epigenome of different cell types and the complexity of the post-transcriptional control of gene expression is constantly expanding due to the development of new technologies and the continuous discovery of noncoding RNAs that participate in epigenetic regulation.

Histone methylation

The eukaryotic genome is packaged into chromatin, a chain of nucleosomes composed of four core histones - H2A, H2B, H3, and H4 - whose amino-terminal tails are exposed on the surface of nucleosomes and are subjected to a wide range of post-translational modifications^[28,29]. Gene activation and repression, as well as transcriptional initiation and elongation, are regulated by many such histone modifications. In the last decade, studies of human and mouse embryonic stem cells have delineated the role of the histone methyltransferase (HMT) families Polycomb group (PcG) and Trithorax group (TrxG) in modulating the pluripotency and lineage restriction of several cell types^[30]. For instance, numerous trimethylations of histone 3 lysine 4 (H3K4me3) mediated by the TrxG family surrounding the transcription start sites indicate transcriptional gene activation, and trimethylations of histone 3 lysine 36 (H3K36me3) in the gene body are generally associated with active gene transcription; alternatively, the trimethylation of histone 3 lysine 27 (H3K27me3) mediated by the PcG complex is associated with transcriptional repression^[28]. Although the repressive H3K27me3 mark is transmitted to daughter cells^[31] and is dominant over the permissive H3K4me3 mark^[32], transcriptional gene activation requires the demethylation of H3K27me3, which is mediated by the demethylase

families lysine-specific demethylase 6A (Kdm6a) and KDM1 lysine-specific demethylase 6B (Kdm6b)^[33-35]. Thus, whereas polycomb repressive complex 2 (PRC2) establishes gene silencing at developmentally regulated loci, the TrxG and Kdm6a/Kdm6b families work together to antagonize the repressive activity of PRC2 and to promote gene expression in specific cell types.

Histone acetylation

Histone acetylation modulates transcription *via* multiple mechanisms. The acetylation of lysine residues within histone tails neutralizes their positive charge, thereby facilitating chromatin relaxation and increasing the accessibility of transcription factors to their target genes^[36]. Acetylated histones are also recognized as binding sites for transcriptional activators. Conversely, histone deacetylation induces transcriptional repression by compacting the chromatin structure^[37]. The combined activities of two enzyme families, histone acetyltransferases (HATs) and deacetylases (HDACs), determine the overall levels of histone acetylation in the genome. Both HATs and HDACs act on chromatin by associating with a variety of DNA-binding transactivator proteins. In some cases, DNA targeting involves other chromatin-modifying activities, such as histone methylation. Thus, the effects of HATs and HDACs on gene regulation depend on the cell type and the spectrum of available partners^[38].

Noncoding RNAs

Advances in the field of gene regulation mediated by single-stranded noncoding RNA molecules have demonstrated their importance in gene regulatory networks. Until recently, small noncoding RNAs (miRNAs) were believed to solely negatively regulate target mRNAs^[39]. However, published studies are increasingly indicating that miRNAs can also stimulate gene expression in response to specific cellular conditions or cofactors^[40]. miRNAs are able to reduce gene expression *via* multiple mechanisms. At the transcriptional level, miRNAs repress gene expression by pairing nucleotides 2 to 8, termed the seed region, to the seed match site in the target mRNA, typically positioned at the 3' UTR or, less frequently, at the 5' UTR or the coding region^[41]. In addition to transcriptional effects, miRNAs can repress translation initiation *via* multiple mechanisms, such as promoting mRNA degradation or interfering with the formation of closed-loop mRNA or other translation initiation factors^[41]. Moreover, increasing evidence indicates that some miRNAs can upregulate gene expression in specific cell types and under certain conditions *via* the direct action of miRNAs or *via* the indirect inhibition of repressive miRNA activity^[42]. Another class of noncoding RNAs, long noncoding RNAs, has been shown to take part in many transcription regulatory processes^[43] and post-transcriptional events, such as mRNA stability and translational control^[44-46], and to function as competing endogenous RNA^[47-49] by acting as an miRNA sponge to participate with coding RNA in a regulatory circuit that controls the binding of RNA to

miRNA.

Reciprocal and dynamic interactions between different epigenetic mechanisms and transcription factors modulate gene expression. For instance, changes in histone modifications are caused by the recruitment of chromatin-modifying enzymes, such as HATs or HMTs, by transcription factors and the RNA polymerase II complex^[28]; at the same time, combinations of histone modifications in the proximity of consensus sequences may anticipate and direct the binding of the transcription factor, facilitating the transcriptional activation of a given gene^[50].

Numerous epigenetic mechanisms regulate the different phases of myogenesis, including chromatin remodeling and post-transcriptional gene regulation mediated by noncoding RNAs^[51-53]. Such orchestrated regulation permits the correct timing of muscle-specific gene expression and influences the fate of muscle progenitors into muscle or non-muscle cell lineages^[54,55]. In this review, we report and discuss the recent literature about the epigenetic regulation of the myogenic process from activation to proliferation and SC commitment. We focus on the epigenetic changes, specifically those mediated by chromatin methylation or acetylation and noncoding RNA function to regulate gene expression, that occur during the different steps of SC differentiation.

EPIGENETICS IN SCs

Epigenetics mediates most of the signaling integrating the regeneration cues released by interstitial cells and by the external environment within the SC niche. Our understanding of the highly coordinated layers of epigenetic regulation of SC maintenance, activation and differentiation and cross-talk of epigenetic regulatory mechanisms with muscle-specific transcriptional machinery has tremendously increased due to the recent results obtained *via* next-generation genome-wide sequencing^[56]. Using ChIP-Seq experiments, chipped chromatin can currently be entirely mapped across the genome to identify the regions that are over-represented among these sequences, revealing the interactions between chromatin-remodeling enzymes, transcription factors and DNA, thereby facilitating the production of chromatin-state maps.

Epigenetic control of SC quiescence

In quiescent SCs, while the *Pax7* gene must be expressed, modulators of cell cycle progression and transcription factors of the myogenic lineage need to remain silenced. Increasing studies have suggested that quiescent SCs are not in a dormant state but rather are primed for activation and differentiation in response to external stimuli^[57,58]. At the chromatin level, this primed state is maintained by the general lack of the repressive mark H3K27me3 across the genome and the concomitant presence of H3K4me3 at the transcription start sites of a large number of genes (nearly 50% of all annotated genes)^[59], including myogenic regulatory

factors such as MyoD, SRF and Myf5^[60], whose encoded proteins are the primary activators of the myogenic program. Consistent with the notion that H3K4me3 alone does not predict the transcriptional state of a gene but rather marks the gene for transcriptional activation^[61], neither the number nor the identity of genes marked by H3K4me3 is significantly different between activated and quiescent SCs. Indeed, SC activation is accompanied by the retention of H3K4me3 and the acquisition of H3K27me3 *via* PcG members^[62], often in association with the transcriptional repressors YY1 and HDAC1. Interestingly, low levels of H3K27me3 are associated with the pluripotency of embryonic stem cells^[56,63]. The current understanding is that the general lack of repressive H3K27me3 marks and the concomitant presence of H3K4me3 at the transcription start sites of a large number of genes may establish a permissive chromatin state that underlies and permits the pluripotency of stem cells. In addition, numerous transcription start sites across the genome of quiescent SCs contain bivalent chromatin domains^[59], which are characterized by the concomitant presence of both H3K4me3 and H3K27me3 marks. Consistent with the presence of H3K27me3 marks, these genes are either not transcribed or transcribed at very low levels. Interestingly, bivalent domains correspond to genes that are associated with the development of other organs and tissues aside from muscle, suggesting that SCs retain the potential to adopt a non-myogenic fate because of the presence of bivalent domains that contribute to the determination of cell lineage^[59].

miRNAs also contribute to the generation of an epigenetic state that enables the maintenance of the myogenic lineage in quiescent SCs and that facilitates the activation of muscle gene expression and the formation of differentiated myotubes in response to SC activation. An important role in the maintenance of muscle stem-cell quiescence has been demonstrated for microRNA-489, which is highly expressed in quiescent SCs, in which it suppresses the expression of the oncogene *DEK*, and which is rapidly downregulated upon SC differentiation^[57]. Additionally, miR-31 has been demonstrated to play an important role in quiescent SCs^[58]. In quiescent SCs, the *Myf5* gene has already been transcribed but cannot be expressed because miR-31 functionally inactivates *Myf5* mRNA by retaining it inside cytoplasmic mRNP granules, thereby preventing its translation and blocking myogenic differentiation^[58].

Epigenetic control of SC activation

In response to different stimuli, *e.g.*, muscle damage, SCs become activated, begin to express cell cycle markers, which are readily marked by the permissive H3K4me3^[64], and re-enter the cell cycle. SCs that divide in a parallel orientation to the myofibers, undergo a symmetrical cell division and give rise to two SCs that can return to the quiescent state^[8]. In contrast, cells that divide in the sagittal orientation undergo asymmetric cell division to produce one cell that returns to the

quiescent state and one proliferating myoblast^[8]. The latter cell expresses the *Myf5* and *MyoD* genes, as well as genes that regulate cell cycle progression, all of which are characterized by the enrichment of the transcriptionally permissive H3K4me3 mark within their associated chromatin^[19]; Pax7 is progressively silenced while transitioning from a transcriptionally permissive state of H3K4me3 to a repressive state of H3K27me3 throughout cell differentiation^[65]. Additional mechanisms that regulate SC proliferation include p38-gamma MAPK, which phosphorylates the MyoD protein to reinforce the interaction between MyoD and the HMT KMT1A, and the consequent inhibition of the premature expression of the myogenin gene. Consistently, in p38-gamma MAPK-null SCs, KMT1A cannot associate with the myogenin promoter; therefore, myogenin is expressed earlier, resulting in decreased SC proliferation and defective differentiation^[66].

During myoblast proliferation, distinct classes of HDACs are also involved in the repression of muscle gene transcription by countering the activities of HATs. Whereas local hyper-acetylation at consensus MyoD-binding sites in myoblasts likely predetermines the regions of chromatin accessibility, class I and II HDACs contribute to the hypo-acetylation of the *MyoD* gene and the inhibition of *MEF2* transcription and activation, respectively. In undifferentiated SCs, *MyoD* interacts with HDAC1, and this interaction is responsible for silencing the MyoD-dependent transcription of p21 and muscle-specific genes^[67,68]. Moreover, class II HDACs are localized to the nucleus during SC proliferation and are responsible for blocking the activity of the myogenic co-factor MEF2^[69]. A recent study of HDAC4 function and SC proliferation reported that the HDAC4 levels positively correlate with the expression of *Pax7* and *Lix1*, both of which are important for appropriate SC proliferation^[70]; however, the molecular mechanism underlying this phenomenon remains unclear.

SC proliferation is also promoted and maintained by miR-27a/b, which targets and downregulates myostatin mRNA^[71]. Consistently, SCs treated with antagomirs specific to miR-27a/b displayed increased myostatin expression and reduced proliferation. In activated SCs, miR-27b plays an important role in determining the appropriate timing of myogenic gene expression and regulates the Pax3 protein levels to control the entry of these cells into the myogenic differentiation program^[72]. SC proliferation is also promoted by miR-133a, which represses the expression of serum response factor^[73], and by miR-682, which is highly upregulated during myoblast proliferation both *in vitro* and *in vivo*; the inhibition of miR-682 results in reduced myoblast proliferation^[74]. Moreover, in activated SCs, tissue inhibitor of metalloproteinase 3 (TIMP3), an inhibitor of tumor necrosis factor (TNF)-alpha-converting enzyme, regulates TNF-alpha release and acts as a switch for myogenic differentiation. miR-206 promotes TIMP3 downregulation^[75] and suppresses Pax3 expression^[74], thereby promoting SC differentiation. Paradoxically,

quiescent SCs express high levels of both Pax3 and miR-206. An additional layer of gene regulation explains these contradictory data. In fact, it has been shown that in quiescent SCs, Pax3 transcripts are alternatively polyadenylated and are expressed as shorter 3' UTR transcripts, thereby resulting in the resistance of Pax3 expression to miR-206-mediated regulation^[76].

Epigenetic control of SC differentiation

As a general rule, genes no longer required for lineage progression are targeted for stable repression^[59,62]. Accordingly, during differentiation, SC chromatin converts to a more repressed state by accumulating H3K27me3 across the genome at both transcription start sites and intergenic regions. In fact, in contrast to the level of H3K4me3, the level of the repressive mark H3K27me3 is low in quiescent SCs and is dramatically increased in differentiating SCs. In particular, when SCs differentiate, PRC2 is released from muscle differentiation genes (*MyoD* and *SRF*) to translocate to loci that are typically repressed in differentiated myotubes, e.g., Pax7. By inducing a transition from the transcriptionally permissive mark H3K4me3 to the repressive mark H3K27me3 on the Pax7 gene, PRC2 contributes to the switching off of SC proliferation^[65]. Similarly, a switch from the permissive mark H3K4me3 to the repressive mark H3K27me3 on genes involved in the cell cycle is mediated by the E2F family of transcription factors and by the retinoblastoma protein as the SC exits the cell cycle to terminally differentiate^[64,77,78]. Moreover, Pax7 associates with the Wdr5-Ash2L-MLL2 HMT complex, which mediates H3K4me3^[19]. The binding of the Pax7-HMT complex to Myf5 results in the formation of H3K4me3 on the surrounding chromatin. Thus, Pax7 also participates in the induction of chromatin modifications that stimulate transcriptional activation of target genes to regulate the entry into the myogenic developmental program. Concomitantly, lysine-specific demethylase 4A, together with heterochromatin protein 1 alpha, promotes the demethylation of H3K9me3 at myogenic promoters, facilitating myoblast commitment^[79].

The Ezh2 subunit of PRC2 complex has been demonstrated to play a critical role in mediating SC differentiation into the skeletal muscle lineage by suppressing a subset of regulators of non-muscle cell fate. Indeed, Ezh2-mediated H3K27me3 marks are specifically present on genes associated with alternative lineage selection, although Ezh2 does not suppress terminal differentiation into skeletal muscle^[80]. In contrast to PRC2-Ezh2, PRC2-Ezh1 is required for the myogenic differentiation of SCs; specifically, PRC2-Ezh1 replaces PRC2-Ezh2 on the myogenin promoter to regulate the appropriate timing of the transcriptional activation of myogenin^[81].

When SCs differentiate, HDAC1 downregulation and pRb hypo-phosphorylation occurs, enabling the formation of the pRb-HDAC1 complex in differentiated myotubes. The pRb-HDAC1 interaction coincides with the disruption of the MyoD-HDAC1 complex, the

transcriptional activation of muscle-specific genes, and the differentiation of myoblasts^[68]. Muscle differentiation also induces the nuclear-to-cytoplasmic translocation of class II HDACs, thereby releasing the inhibitory constraints on MEF2 and consequently activating the expression of muscle-specific genes^[69].

Over the course of differentiation, p38 alpha/beta MAPK activity increases and is required for complete myoblast differentiation and fusion, which is partially due to its regulation of the epigenetic mechanisms controlling gene expression^[82]. In particular, p38alpha/beta MAPK, by selectively enabling the recruitment of SWI-SNF to the gene promoters of myogenin and creatine kinase, facilitates chromatin remodeling and the consequent expression of muscle genes. Indeed, p38-alpha-null SCs display increased Pax7 expression, persistent proliferation, and impaired differentiation and fusion^[83], highlighting the distinct role of different members of the p38 MAPK family in SC proliferation and differentiation. It appears likely that the relative abundance of p38-alpha and p38-gamma MAPK activity in activated SCs serves as a balance between SC proliferation and differentiation.

As SCs differentiate, the downregulation of the enzymatic subunit of PRC2-Ezh2 and its partner YY1 is mediated by the combined action of miR-214^[84], miR-26a^[85] and miR-29^[86], thereby relieving PRC2-mediated repression of muscle genes. Once SCs differentiate, miR-128a, miR-1 and miR-206 cooperate to block cell proliferation by inhibiting the expression of several targets in the insulin signaling pathway and Pax7 expression^[87,88]. Indeed, the loss of miR-1 and miR-206 increases Pax7 expression, enhances SC proliferation and significantly inhibits myoblast differentiation^[87,89]. The inhibition of cell proliferation is also achieved *via* the downregulation of the *Ccnd1* gene by both miR-26a and miR-1^[90]. In addition, miR-133a and miR-133b inhibit cell proliferation and promote myoblast differentiation by negatively regulating the FGFR1 and PP2AC proteins, which participate in ERK1/2-mediated signal transduction^[91]. In addition to inhibiting Pax7, miR-206 promotes SC differentiation and fusion to muscle fibers *via* the suppression of a collection of negative regulators of myogenesis, such as notch3, igfbp5, Meox2, RARB, Fzd7, MAP4K3, CLCN3, and NFAT5^[89,92]. An important role in determining SC lineage commitment has been attributed to miR-133^[93]. By targeting the mRNA of PRDM16, a master gene for brown fat determination, miR-133 modulates the choice between the myogenic and brown adipose lineages during SC differentiation. In SCs, HDAC4 expression correlates with that of miR-133, and HDAC4 inhibition induces SCs to partially differentiate into adipocytes^[70]; however, the link between HDAC4 and miR-133 has not been yet characterized. Moreover, by modulating the insulin-like growth factor (IGF)-1 pathway *via* the downregulation of the IGF-1 receptor, miR-133a promotes SC differentiation^[94] and sarcomeric actin organization^[95]. In differentiating myoblasts, the repression of tumor

growth factor-beta signaling, which is known to negatively affect SC differentiation, is ensured by the combined activity of miR-26a, which represses Smad1 and Smad4 expression^[96], miR-206 and miR-29, which are capable of inhibiting Smad3 expression^[97]. Together with myomiRs whose expression is upregulated during SC differentiation, the expression of other microRNAs needs to be down-regulated in order to achieve SC terminal differentiation. One such example is miR-23a, which directly regulates the expression of myosin heavy chain genes^[98].

CONCLUSION

The maintenance of skeletal muscle homeostasis is a key survival factor, considering that skeletal muscle accounts for approximately 40% of body mass. Skeletal muscle needs to efficiently respond to internal and external stimuli - such as changes in levels of blood sugar, circulating hormones, or growth factors or mechanical insults - or to pathological conditions to maintain homeostasis, particularly in muscle. Unequivocally, SCs play central roles in adult regenerative myogenesis and in the preservation of muscle mass. Different epigenetic marks contribute to the coordination of the precise time-dependent expression of different subsets of myogenic genes in SCs (Table 1 and Figure 1). For instance, the PcG catalytic subunit Ezh2 is specifically distributed on the regulatory regions of late but not early muscle genes^[60], whereas the methyltransferases PRMT5 and CARM1 are detected on promoters of early and late muscle genes, respectively^[99].

Despite the observation that most muscular diseases do not have an epigenetic cause *per se*, the importance of epigenetic pathways in modulating muscle-specific gene expression renders them as excellent candidate targets for disease interventions. For instance, an elegant study demonstrated that epigenetic commitment mediated by SMARCD3, a member of the SWI/SNF family of proteins, and MyoD is required for the efficient generation of skeletal muscle cells from human embryonic stem cells^[100]. Several drugs that target epigenetic mechanisms are currently undergoing clinical trials for many diseases. These drugs include HDAC inhibitors^[101] and HMT inhibitors alone^[102] or in combination^[103]. In amyotrophic lateral sclerosis, HDAC inhibitors have been proposed as potential drugs to ameliorate patient symptoms^[104,105]. In the case of muscular dystrophy, HDAC inhibitors have been extensively studied using the mdx mouse model^[106]; currently, these drugs are under review in a clinical trial for muscular dystrophy^[107]. Their effects are believed to be primarily due to the inhibition of class I HDACs^[108]. However, the prolonged treatment of patients with drugs that inhibit these ubiquitously required chromatin-modifying enzymes is a potential concern. An alternative approach ideally relies on the identification of small molecules that interfere with the epigenetic enzymes to specific loci within the genome. This approach may provide similar benefits

without exerting side effects caused by the modification of gene expression in other cell types. In the last few years, numerous studies involving RNA-seq or ChIP-seq have contributed to provide a picture of the epigenetic characteristics of muscle-specific gene promoters during the different stages of myogenesis. However, most of these studies were performed using muscle cell lines

and remain to be validated using *in vivo* models, for instance by analyzing mice in which individual epigenetic regulators are inactivated in a muscle-specific manner. The elucidation of the epigenetic mechanisms regulating SC function might reveal new targets for pharmacological manipulation to improve muscle regeneration and to promote muscle homeostasis under pathological

conditions.

Abstract

AIM: To study the therapeutic effect of three tube-guides with electrical conductivity associated to mesenchymal stem cells (MSCs) on neuro-muscular regeneration after neurotmesis.

METHODS: Rats with 10-mm gap nerve injury were tested using polyvinyl alcohol (PVA), PVA-carbon nanotubes (CNTs) and MSCs, and PVA-polypyrrole (PPy). The regenerated nerves and tibialis anterior muscles were processed for stereological studies after 20 wk. The functional recovery was assessed serially for gait biomechanical analysis, by extensor postural thrust, sciatic functional index and static sciatic functional

index (SSI), and by withdrawal reflex latency (WRL). *In vitro* studies included cytocompatibility, flow cytometry, reverse transcriptase polymerase chain reaction and karyotype analysis of the MSCs. Histopathology of lung, liver, kidneys, and regional lymph nodes ensured the biomaterials biocompatibility.

RESULTS: SSI remained negative throughout and independently from treatment. Differences between treated groups in the severity of changes in WRL existed, showing a faster regeneration for PVA-CNTs-MSCs ($P < 0.05$). At toe-off, less acute ankle joint angles were seen for PVA-CNTs-MSCs group ($P = 0.051$) suggesting improved ankle muscles function during the push off phase of the gait cycle. In PVA-PPy and PVA-CNTs groups, there was a 25% and 42% increase of average fiber area and a 13% and 21% increase of the "minimal Feret's diameter" respectively. Stereological analysis disclosed a significantly ($P < 0.05$) increased myelin thickness (M), ratio myelin thickness/axon diameter (M/d) and ratio axon diameter/fiber diameter (d/D; g-ratio) in PVA-CNT-MSCs group ($P < 0.05$).

CONCLUSION: Results revealed that treatment with MSCs and PVA-CNTs tube-guides induced better nerve fiber regeneration. Functional and kinematics analysis revealed positive synergistic effects brought by MSCs and PVA-CNTs. The PVA-CNTs and PVA-PPy are promising scaffolds with electric conductive properties, bio- and cytocompatible that might prevent the secondary neurogenic muscular atrophy by improving the reestablishment of the neuro-muscular junction.

Core tip: The rat sciatic injury neurotmesis injury model is an appropriate model to evaluate the nerve regeneration when electric conductive tube-guides of polyvinyl alcohol (PVA)-carbon nanotubes (CNTs) and PVA-polypyrrole (PPy) associated to mesenchymal stem cells (MSCs) are used as scaffolds. The results obtained revealed that treatment with MSCs associated to PVA-CNTs tube-guides induced an increased number of regenerated fibers and thickening of the myelin sheet. Functional and kinematics analysis revealed positive synergistic effects brought by MSCs and PVA-CNTs. The PVA-CNTs and PVA-PPy are promising scaffolds with electric conductive properties, bio- and cytocompatible that might prevent the secondary neurogenic muscular atrophy by improving the reestablishment of the neuro-muscular junction.

INTRODUCTION

Functional recovery is rarely satisfactory in patients where peripheral nerve repair is needed, remaining a challenging task in neurosurgery^[1,2]. Direct repair is the procedure of choice but only when a tension-free end-to-end suture is possible. However, for patients with loss of nerve tissue, resulting in a gap it is necessary to reconstruct the injured nerve using an autograft or a graft from a compatible donor^[1,3]. One of the disadvantages of grafting is the necessity of a second surgery for collecting the nerve sample and respective donor site morbidity. In addition, non-matching donor and recipient nerve diameters often occur, which might be the reason for an incomplete functional recovery^[4]. Entubulation offers advantages compared to graft implantation, including the potential to manipulate and to improve the regeneration environment within the tube-guide by adding to the lumen, growth factors and/or cellular systems^[5]. Consequently, guidance of regenerating axons is improved by a mechanical effect but also by cellular growth factors, a chemical^[6] and electrical cues^[7]. Natural and synthetic biomaterials have been used as tube-guides, being the later sub-divided into two major groups: biodegradable and non-biodegradable^[8,9]. The development of tube-guides is a consequence of the limitations inherent in the use of grafts, in terms of length, diameter and type of fiber, preventing damage to the sampling local, as it was previously referred^[10]. For a correct nerve regeneration some important physical properties of tube-guides have been listed and referred by several authors like: the tube-guides should be made of biodegradable biomaterials with appropriate porous dimensions; the ability to deliver growth factors and drugs and allow the incorporation of cellular systems; an internal geometry to support an organized cell migration or intraluminal structures similar to nerve fascicles; and with some electrical activity in order to promote axon regeneration^[11]. The use of electric conductive biomaterials to achieve nerve regeneration is a promising research area^[12]. The goal of this work was to evaluate the therapeutic effect (by morphological and functional analysis) of three previously developed tube-guides with electrical conductivity for nerve regeneration associated to mesenchymal stem cells (MSCs) isolated from the Wharton's jelly of umbilical cord (UC) on neuro-muscular regeneration after neurotmesis injury using the rat sciatic nerve model. The three tube-guides used *in vivo* where those made of polyvinyl alcohol (PVA), PVA loaded with MWCNTs [functionalized carbon nanotubes (CNTs), PVA-CNTs], and PVA loaded with polypyrrole (PVA-PPy). Such composites with electric conductivity can be used to

host cell therapies, and beneficial regenerative electrical stimulation can be applied directly to the cells through the composite^[13]. PVA is a polymer used as a biomaterial due to its biocompatibility, non-toxic, non-carcinogenic, swelling properties, and bio-adhesive characteristics. PVA can also be used as host material in order to increase the solubility as well as the mechanical strength of conductive materials, and it is approved by Food and Drug Administration^[14,15]. PPy and CNTs are two of the most studied conductive polymers for tissue engineering, especially for nerve tissue engineering^[16]. The authors previously to *in vivo* application, focused on tube-guides design and *in vitro* characterization. The PVA-CNTs and PVA-PPy tube-guides presented conductivity advantages, important for nerve regeneration. The developed electrical conductive nerve tube-guides was achieved by loading PVA with 0.05% of PPy or COOH-functionalized CNTs. The inclusion of CNTs and PPy brought a significant increase of electrical conductivity of the simple PVA tube-guide. The PVA-CNTs tube-guides showed the rougher topography. The DSC and X-ray diffraction (XRD) studies revealed that all materials have similar low crystallinity. The wettability studies indicated a hydrophilic behaviour of all nerve tube-guides, being the PVA-PPy slightly more hydrophobic. In terms of surface charge, the zeta potential measurements revealed that both COOH-functionalized CNTs and PPy loads turned the surface charge slightly more positive. Regarding the elastic behaviour, the COOH-functionalized CNTs load caused a slight decrease of the rigidity of PVA. PVA-CNTs and PVA-PPy might present a regenerative potential and were tested in the rat sciatic nerve neurotmesis injury model^[17]. Also, since the PVA-CNTs presented the rougher topography, which is important for the association and viability of the associated cellular systems^[9], where also tested associated to the MSCs-based therapy^[3,18].

Considering the peripheral nerve system (PNS), MSCs are promising cell-based therapies to be applied alone or associated to scaffolds. MSCs have a high plasticity, proliferative and differentiation capacity, and also have the advantage of presenting immunosuppressive properties^[3,19,20]. For these reasons, MSCs have been used in experimental trials as cell-based therapies, including pathologies of PNS and central nervous system (CNS). Furthermore, nowadays the characterization of MSCs is well defined by recommendations and standards stated by the international society for cellular therapy (ISCT)^[19]. The MSCs therapeutic effect resides on their capacity to replace original cells of damaged tissues, and also by the physiologic secretion of growth factors and cytokines that modify the microenvironment inducing the activity of endogenous progenitor cells within the injured tissue, and by modulating the inflammatory and immune responses. The inflammatory modulation includes the Wallerian degeneration, a crucial step for nerve regeneration after neurotmesis injury^[3]. Therefore, the use of cellular systems is a rational approach for promoting nerve

Figure 1 Synthetic biodegradable tubes of polyvinyl alcohol, polyvinyl alcohol loaded with COOH-functionalized multiwall carbon nanotubes MWCNTs (polyvinyl alcohol-carbon nanotubes, polyvinyl alcohol-carbon nanotubes tube-guides), and polyvinyl alcohol loaded with polypyrrole (polyvinyl alcohol-polypyrrole, polyvinyl alcohol-polypyrrole tube-guides).

regeneration by delivering growth-promoting factors and cytokines at the nerve lesion site^[9]. MSCs can be isolated from several tissues, including bone marrow (BM), umbilical cord blood (UCB) and umbilical cord tissue (UCT), dental pulp, and adipose tissue^[9]. BM collection has several disadvantages, since the BM include a high percentage of adipocytes and a heterogeneous cell population, there is the possibility of morbidity associated to donor collection, as well as it is observed a decreasing number of BM-MSCs along the adult life and available for therapeutic applications. The research concerning other sources of MSCs has been intensively performed for the past years for identifying tissues that will allow MSCs isolation, and safe and controlled *ex vivo* expansion of these cells for potential allogeneic and autologous application^[9]. MSCs isolated from the Wharton's jelly UCT have been tested for the clinical application in CNS and PNS, including neurodegenerative diseases^[21]. It has been reported that MSCs from the UCT are still viable 4 mo after transplantation and there is no need for immunological suppression of the patients and experimental animals^[22]. The reason for this advantage is the fact that these cells are negative for major histocompatibility complex (MHC), and have low expression of MHC class I^[19] with potential application for MSC-based therapies in allogeneic treatments. *In vivo* studies involving these MSCs are limited but encouraging, especially what concerns PNS. Also, there are an increasing number of high quality cryopreserved cord tissue units in Cord Blood Banks worldwide. In addition, these cells represent a non-controversial source of MSCs, without neither ethical nor religious issues that are routinely harvested after birth, cryogenically stored, thawed, and can be expanded for therapeutic uses^[9]. On the other hand, it was demonstrated in some studies, that grafted MSCs have a signalling role which initiates the recruitment and direction of endogenous cells by growth factors production, promoting the local regeneration and modulating the inflammatory process^[23]. Nowadays it is believed that factors secreted

by MSCs are primarily responsible for their therapeutic action, so it is particularly important to understand and fully characterize the MSCs secretome^[18,24,25]. Recent studies demonstrated that MSCs produce and secrete multiple paracrine factors like interleukine-2 (IL-2), IL-6, IL-8, IL-12, IL-15, monocyte chemoattractant protein-1, macrophage inflammatory protein-1 β , regulated on activation, normal T cell expressed and secreted, and platelet-derived growth factor-AA. The several secreted factors previously listed that are present in MSCs conditioned medium (CM) was already described by others^[26] and more recently, by our research group^[18]. These paracrine factors are important to promote the MSCs therapeutic effects identified by the scientific community, like immunomodulatory and chemoattractive, anti-apoptotic, anti-fibrotic, angiogenic, and anti-oxidants activities. The hypothesis that MSCs and the growth factors produced during expansion in culture (CM) is an appropriate therapeutic product for local application in severe peripheral lesions seemed to be a rational approach and was studied in the present experimental work.

MATERIALS AND METHODS

Tube-guide preparation

Synthetic biodegradable tubes of PVA (Aldrich, Mowiol 10-98), PVA loaded with COOH-functionalized multiwall carbon nanotubes MWCNTs (Nanothinx, NTX5, MWCNTs 97% - COOH) (PVA-CNTs tube-guides), and PVA loaded with PPy (Aldrich, 10-40 S/cm of conductivity) (PVA-PPy tube-guides) were prepared using a casting technique to a silicone mould. A 15% (%w/v) aqueous solution of PVA was prepared. Then the solution of PVA was mixed with 0.05% of COOH-functionalized MWCNTs and 0.05% of PPy. The tube-guides were produced by freezing/thawing process. The treatment consisted in three cycles of freezer (-30 °C)/ incubator (25 °C), and an annealing treatment started with a stage of 14 h on an incubator (25 °C) followed by a ramp rate of 0.1 °C /min until 80 °C, and then a stage of 20 h at 80 °C. The tube-guides were sterilized by gama-radiation and hydrated in a sterile saline solution during 2 h before microsurgical application in the rat neurotmesis injuries (Figure 1).

MSCs cell culture and in vitro characterization

MSCs culture and expansion: Human MSCs isolated from the Wharton jelly (WJ) of UCT from PromoCell GmbH (C-12971, lot-number: 8082606.7) were cultured and expanded in a humidified atmosphere with 5% CO₂ at 37 °C by replacing the mesenchymal stem cell medium, PromoCell (C-28010) every 48 h. At 80% confluence, normally obtained after 4 d in culture (Figure 2), MSCs were harvested with 0.25% trypsin with EDTA (GIBCO) for further expansion at an initial concentration of 1 × 10⁴ cells/cm². Immediately previously to *in vivo* application, a MSCs suspension was prepared in 1 mL syringes. Each syringe contained MSCs at a concentration

Figure 2 Mesenchymal stem cells culture and expansion. A: Isolated mesenchymal stem cells (MSCs) from the Wharton's jelly of umbilical cord presented a fusiform, fibroblast-like morphology in culture (magnification: 100 ×); B: Selected metaphases from MSCs in culture, showing normal number of chromosomes (46, XY) (magnification: 1000 ×).

of $1 \times 10^6/\mu\text{L}$ for posterior intra-operatively nerve injection.

The MSCs lot used in the present experimental study was characterized by flow cytometry analysis for a comprehensive panel of markers by PromoCell as previously reported^[18,25]. The MSCs exhibited a mesenchymal-like shape with a flat and polygonal morphology during cell culture expansion. Their phenotype was evaluated by flow cytometry for PE anti-human cluster of differentiation-105 (CD105); APC anti-human CD73; PE anti-human CD90; PerCP/Cy5.5 anti-human CD45; FITC anti-human CD34; PerCP/Cy5.5 anti-human CD14; Pacific Blue anti-human CD19 and pacific-blue anti-human Human Leukocyte Antigen-DR (HLA-DR) (antibodies and their respective isotypes from BioLegend).

MSCs karyotype by cytogenetic analysis: Cytogenetic analysis was carried out before *in vivo* application between passages 4 and 5 as previously reported^[18,25]. Chromosome analysis was performed by one scorer on 20 Giemsa-stained metaphases and each MSC cell was scored for chromosome number. For determination of the karyotype, a routine chromosome G-banding analysis was also carried out and no structural alterations were observed which demonstrates the chromosomal stability to the cell culture procedures and also that the *in vivo* applied MSCs are not neoplastic (Figure 2).

Cytocompatibility evaluation of biomaterials: Intracellular free Ca^{2+} concentration ($[\text{Ca}^{2+}]_i$) by using dual wavelength spectrofluorometry as previously described^[27] was measured in Fura-2-loaded MSCs cells. $[\text{Ca}^{2+}]_i$ from MSCs cultured without the presence of any biomaterial, sub-cultured over PVA discs, over PVA loaded with CNTs (PVA-CNTs) and PVA loaded with PPy (PVA-PPy) discs of 10 mm diameter are results obtained from epifluorescence technique confirming that the MSCs did not begin the apoptosis process.

Reverse transcriptase polymerase chain reaction to confirm that MSCs are undifferentiated: Reverse

transcriptase polymerase chain reaction (RT-PCR) and quantitative PCR (qPCR) targeting specific genes expressed by the MSCs that were *in vivo* applied was performed to certify that the MSCs used *in vivo* were not differentiated. For that, primers were designed targeting seven human genes based on the literature^[18]. DNA sequences from growth associated protein-43 (GAP-43), neurofilament-H (NF-H), Nestin, Glyceraldehyde-3-Phosphate Dehydrogenase (GAPDH), β -actin, neuronal nuclear (*NeuN*) and glial fibrillary acidic protein (*GFAP*) genes from mice (*Mus musculus*), rat (*Rattus norvegicus*) and human (*Homo sapiens*) were downloaded from GenBank (www.ncbi.nlm.nih.gov/genbank) and aligned using the Clustal Omega bioinformatic tool from EMBL-EBI (<http://www.ebi.ac.uk/Tools/msa/clustalo>). MSCs culture was harvested with 0.25% trypsin EDTA solution (Gibco) and centrifuged at 2000 rpm 4 °C during 5 min. Cell pellets were used for total RNA extraction using an adequate extraction kit, high pure RNA Isolation kit (Roche). Briefly, cell pellets were lysed with a lysis buffer, loaded into a High Pure Filter Tube, DNA was removed with DNase I enzyme, washed twice on column, and eluted with 100 μL of Elution Buffer. RNA was quantified and its quality assessed by using a Nanodrop ND-1000 Spectrophotometer and reads from 220 nm to 350 nm, and then stored at -80 °C until further use. In the following step, cDNA was synthesized from the purified RNA. To fulfill that issue, the kit Ready-To-Go You-Prime First-Strand Beads (GE Healthcare) was used following the manufacturer instructions. Briefly, 1.5 μg of total RNA was used and diluted in DEPC-treated water to a 30 μL final volume in a RNase-free microcentrifuge tube; then heated at 65 °C for 10 min and then chilled in ice; transfer the RNA solution to the kit tube containing the first-strand reaction mix beads; add 0.2 μg of Oligo(dT) primer and DEPC-treated water to a 33 μL final volume; mix the content and incubate at 37 °C for 60 min. cDNA was synthesized and stored at -20 °C until further use. Of referring that, due to the use of the Oligo(dT) primer, the synthesized cDNA corresponds to the mRNA present in the sample at the time of collection. cDNA synthesized from undifferentiated MSCs was used to

check the expression of seven genes, two housekeeping genes (β -actin and *GAPDH*) and five specific of neuronal cells (GFAP, NeuN, Nestin, NF-H and GAP-43). Primers were designed in house and then synthesized in an external laboratory (MWG Operon, Germany). The primers were rehydrated in DNase/RNase free water in a concentration of 100 pmol/ μ L. qPCR was performed in a iCycler[®] iQ5TM (BioRad) apparatus using the iQTM SYBR[®] Green Supermix (BioRad). Each pair of primers targeting a gene was used to analyze its expression in the MSCs cDNA, in triplicate, along with a negative control. The plates containing the mix targeting the seven genes for both types of cells were submitted to the following cycles of temperatures: 95 °C during 4 min, 35 cycles comprising 95 °C during 20 s, 55 °C during 20 s and 72 °C during 20 s ending with Real-Time acquisition, and final extension of 75 °C for 7 min. After cycling temperatures, the number of cycle threshold for each well was recorded. The plate containing the amplified genes or qPCR products was kept in ice and observed in a 2% agarose gel to check and reinforce the identity of the amplicons. Briefly, 2 g of NuSieve[®] 3:1 Agarose (Lonza) were mixed with 100 mL Tris-Acetate-EDTA buffer, melted, mixed with ethidium bromide in a final concentration of 0.2 μ g/mL, and loaded in a horizontal electrophoresis apparatus. After solidification, 15 μ L of the qPCR products were loaded in the agarose wells, and submitted to a 120 V potential difference during 40 min to separate the amplicons. Gel was then observed under UV light and pictures recorded using the GelDoc[®] 2000 (BioRad) and Quantity One[®] software (BioRad). In the MSCs, the molecular analysis showed a very small amplification of *GFAP* gene, absence of amplification of the *NF-H* and *GAP-43* genes, and reasonable amplification of *NeuN*, β -actin, *GAPDH* and *Nestin* genes. Amplification of a given gene is correlated with its expression seeing that the template DNA is the one generated from mRNA. The RT-PCR results confirmed that the MSCs used *in vivo* were not differentiated into neuro-glial cells.

Surgical procedure for the rat sciatic nerve model for neurotmesis

The article describes a basic research study involving animal subjects and was approved by the Veterinary Authorities of Portugal [Direcção Geral de Alimentação e Veterinária (DGAV)] in accordance with the European Communities Council Directive of November 1986 (86/609/EEC), and the National Institutes of Health (NIH) guidelines for the care and use of laboratory animals have been observed. Also all the authors involved in the *in vivo* tasks have a degree in Veterinary Medicine and are accredited by the Veterinary Authorities of Portugal (DGAV) and by Felasa - Category C for working with laboratory animals.

The OECD Guidance Document on the Recognition, Assessment and Use of Clinical Signs as Humane Endpoints for Experimental Animals Used in Safety Evaluation (2000) were always followed by the authors

by taking adequate measures to minimize pain and discomfort.

Polycarbonate cages type 3 were used for housing under standard laboratory conditions adult male Sasco Sprague Dawley rats with 300 g (Charles River Laboratories, Barcelona, Spain) always in a temperature and humidity controlled room with 12-12 h light/dark cycles. The rats were fed with standard chow and water *ad libitum* until the day of surgery. For surgery, the rats were anesthetized with ketamine 9 mg/100 g and xylazine 1.25 mg/100 g (body weight), by intraperitoneal administration. In lateral recumbence, the right sciatic nerve was exposed unilaterally and a transection injury was performed above the terminal nerve ramification using a straight microsurgical scissors, for creating a neurotmesis injury with 10 mm gap. Six experimental groups were studied: in groups 1, 2 and 3 after neurotmesis the proximal and distal nerve stumps were inserted 3 mm into PVA (group 1: PVA), PVA loaded with 0.05% (%w/v) of COOH-functionalized MWCNTs (group 2: PVA-CNTs), and PVA loaded with PPy 0.05% (%w/v) tube-guides (group 3: PVA-PPY), respectively, and tube-guides were sutured with two epineural sutures using 7/0 polypropylene monofilament, maintaining a nerve gap of 10 mm; in group 4 after neurotmesis, an autologous 180° inverted graft was sutured between both nerve stumps (group 4: Graft); in group 5 after neurotmesis, immediate coaptation with 7/0 monofilament polypropylene suture (group 5: End-to-End); in group 6 after neurotmesis the proximal and distal nerve stumps were inserted 3 mm in a PVA loaded with 0.05% (%w/v) of COOH-functionalized MWCNTs tube-guide kept in place with 2 epineural sutures using 7/0 monofilament polypropylene suture and the interior of the tube-guide was filled with 100 μ m of MSCs at a concentration of 1×10^6 cells/ μ L in culture medium, also 100 μ m of MSCs at a concentration of 1×10^6 cells/ μ L in culture medium were infiltrated in both nerve stumps inserted in the tube-guide (group 6: PVA-CNTs-MSCs) (Figure 3).

Functional assessment

After injury and sciatic nerve microsurgery reconstruction using the developed scaffolds in standardized neurotmesis injuries, a follow-up consisting in functional parameters measurements are important to evaluate the regeneration process and recovery. The animals were tested in an appropriate environment to minimize stress and handled by a single operator already trained for that purpose. Animals have been tested before the surgery at week 0, and after the surgery, at week 1, at week 2 and then every two weeks until the end of follow-up time of 20 wk.

Evaluation of motor performance and nociceptive function:

Motor performance was evaluated by measuring extensor postural thrust (EPT) and nociceptive function using the withdrawal reflex latency (WRL). The EPT included in the neurological recovery evaluation

Figure 3 Surgery of the rat sciatic nerve neurotmesis injury model. Under deep anesthesia the right sciatic nerve was exposed unilaterally through a skin incision extending from the greater trochanter to the mid-half distally followed by a muscle splitting incision (A). After nerve mobilization (B), a transection injury was performed (neurotmesis) using a straight microsurgical scissors (C). In group 5 (End-to-End) after neurotmesis, immediate coaptation with 7/0 monofilament polypropylene suture was performed (D). Implantation of the tube-guide in the 10 mm gap (E). Local application of the mesenchymal stem cells (MSCs), the MSCs suspension filled the polyvinyl alcohol (PVA)-carbon nanotubes (CNTs) tube-guide lumen (group 6: PVA-CNTs-MSCs) (F).

of the rat after sciatic nerve injury was first described by^[28]. EPT is induced by lowering the affected hind-limb towards the platform of a digital balance supporting the animal by the thorax. During the test, the rat extends the hind-limb and the distal metatarsus and digits contact with digital platform balance. The force in grams (g) applied is recorded individually and the results for both hind-limbs (affected and un-affected hind-limb) are taken for equation 1 calculation. The normal (unaffected limb) EPT (NEPT) and experimental EPT (EEPT) values considered for equation (1) and the percentage of functional deficit is calculated^[9,28-31].

$$\% \text{ Motor deficit} = [(NEPT - EEPT)/NEPT] \times 100 \quad (1)$$

To assess the nociceptive WRL, the hotplate test

described by Masters *et al.*^[32] was used with some modifications and previously described by the authors^[3,9,17,25,31,33]. Also, it is considered by the scientific bibliography that rats without sciatic nerve injury withdraw their paws from the hotplate within 4.3 s or less^[9,17,31,33]. If there was no paw withdrawal after 12 s, the animal was assigned the maximal WRL of 12 s and the heat stimulus was removed to prevent tissue damage^[34-36].

For sciatic functional index (SFI), a confined walkway measuring 42 cm long and 8.2 cm wide with a dark shelter at the end (own fabrication) that the rats cross was used. The footprints from the experimental (E) and normal (N) sides are measured: (1) distance from the heel to the third toe, the print length; (2) distance from the first to the fifth toe, the toe spread (TS); and (3) distance from the second to the fourth toe,

Figure 4 Kinematic plots in the sagittal plane for the ankle angle (°) as it moves through the stance phase, during the transection injury study. The mean of each group is plotted. PVA: Polyvinyl alcohol; CNTs: Carbon nanotubes; PPy: Polypyrrole; MSCs: Mesenchymal stem cells.

the intermediary toe spread (ITS). In the static sciatic functional index (SSI) is a simpler test where only the parameters TS and ITS are the measurements included in equation (6). Prints for measurements are chosen at the time of walking based on precise, clear and completeness of footprints^[9,36,37]. The mean distances of 3 measurements are used to calculate the following factors (dynamic and static):

$$\text{TSF} = (\text{ETS} - \text{NTS})/\text{NTS} \quad (2)$$

$$\text{ITSF} = (\text{EITS} - \text{NITS})/\text{NITS} \quad (3)$$

$$\text{PLF} = (\text{EPL} - \text{NPL})/\text{NPL} \quad (4)$$

TSF: Toe spread factor; ITSF: Intermediate toe spread factor; PLF: Print length factor; ETS: Experimental toe spread; NTS: Normal toe spread; NITS: Normal intermediary toe spread; EITS: Experimental Intermediary toe spread; NPL: Normal print length; EPL: Experimental print length.

SFI is calculated as described by Bain *et al.*^[38] according to the following equation:

$$\text{SFI} = -38.3 \times (\text{EPL} - \text{NPL})/\text{NPL} + 109.5 \times (\text{ETS} - \text{NTS})/\text{NTS} + 13.3 \times (\text{EITS} - \text{NITS})/\text{NITS} - 8.8 = (-38.3 \times \text{PLF}) + (109.5 \times \text{TSF}) + (13.3 \times \text{ITSF}) - 8.8 \quad (5)$$

Considering the SFI measurements, it was not possible to obtain values during the 20 wk follow-up after the surgery procedure, due to autotomy of the fingers. As a matter of fact, the rat sciatic nerve model for neurotmesis has this disadvantage; the autotomy observed in several experimental animals even when a repellent substance is applied routinely^[9]. SSI was calculated as described by^[39] according to the following equation (equation 6):

$$\text{SSI} = 108.4 \times \text{TSF} + 31.85 \times \text{ITF} - 5.49 \quad (6)$$

For SFI and SSI, when no footprints are measurable,

the index score of -100 is given considering total impairment, on the other hand, a score of 0 means that there is no alteration and the footprint is normal.

Kinematic analysis: Ankle kinematics was carried out at the end of the 20-wk follow-up time in the following experimental groups: PVA, PVA-CNTs, PVA-PPy, Graft, End-to-End, and PVA-CNTs-MSCs. A Perspex track with length, width (adjustable) and height of 120, 12, and 15 cm, respectively was used to record the rat locomotion in a straight line. The animals' gait was video recorded at a rate of 300 Hz images per second (Casio Exilim PRO EX-F1, Japan) by a camera with a visualization field of 14 cm wide, that was positioned at the track half-length, and 1 m distant from the track, where gait velocity was steady. The software APAS® (Ariel Performance Analysis System, Ariel Dynamics, San Diego, United States) was used for data analysis. The authors used a two-segment model of the ankle joint, adopted from the model firstly developed by^[40] (2D biomechanical analyses in sagittal plan), and the rat ankle angle was determined using the scalar product between a vector representing the foot and a vector representing the lower leg. Dorsiflexion and plantarflexion is considered for positive and negative values of position of the ankle joint (θ°). Initial contact (IC), opposite toe off (OT), and heel rise (HR) and toe-off (TO)^[33,40] were the time points analyzed for each step cycle, the values were time normalized for 100% of step cycle. The normalized temporal parameters were averaged over all recorded trials (Figure 4). Since the animal's normal walking velocity is 20-60 cm/sa^[33,40], stance phases lasting between 150 and 400 ms were considered for analysis.

Morphological analysis and histopathology: For histomorphometric analysis, nerve samples obtained from the 10-mm-long sciatic nerve segments distal to the neurotmesis site and from un-operated controls^[41-44]. The histological nerve preparation followed the previously reported protocol^[3,9,17,25,31,33,35] and a systematic random sampling and D-disector were adopted^[41-44].

At the end of the healing period tested (week 20), tibialis anterior (TA) muscles of all experimental (PVA, PVA-CNTs, PVA-PPy, Graft, End-to-End, and PVA-CNTs-MSCs) and Control (no lesion) groups were collected, and the tissue samples were fixed in 10% buffered formalin, routinely processed, dehydrated and embedded in paraffin wax. Consecutive 3 μm transverse sections from the mid-belly of each muscle were cut, stained with haematoxylin and eosin (HE) and used for morphometry evaluation and determination of the degree of atrophy. For the morphometric analysis, an unbiased sampling procedure was applied and the following measures were calculated: area, perimeter, "Feret's angle" and "minimal Feret's diameter" (which is the minimum distance of parallel tangents at opposing borders of the muscle fiber). These parameters were evaluated from the cross sections using the ImageJ® software (NIH) which allowed to apply this set of individual fiber measurements. A

Figure 5 Graphical representation of the mean of area (A) and "minimal Feret's diameter" (B) of control, regenerated tibialis anterior muscle fibers at week-20 after neurotmesis (Graft) and neurotmesis with the proximal and distal nerve stumps sutured to a polyvinyl alcohol (polyvinyl alcohol) tube and polyvinyl alcohol coated tubes (polyvinyl alcohol, polyvinyl alcohol polypyrrole and polyvinyl alcohol carbon nanotubes). Values are presented as mean $\pm$ SEM. ^a $P < 0.05$ vs Graft; ^c $P < 0.05$ vs Graft PVA CNTs MSCs; ^e $P < 0.05$ vs Graft PVA; ^g $P < 0.05$ vs Graft PVA PPy; ⁱ $P < 0.05$ vs Graft PVA CNTs. PVA: Polyvinyl alcohol; CNTs: Carbon nanotubes; PPy: Polypyrrole; MSCs: Mesenchymal stem cells.

minimum of 1000 skeletal muscle fibers was measured from each group. This assessment was performed by 2 independent operators. Each one of the operators measured, blindly and randomly, an average of 50 fibers in each section. Images were acquired using a Nikon® microscope connected to a Nikon® digital camera DXM1200, at low magnification (100 $\times$) under the same conditions that were used to acquire a reference ruler.

At the end of the study, all animals were subjected to a complete necropsy examination in order to evaluate the presence of possible internal anomalies and/or injuries. Lung, heart, kidneys, liver and spleen were collected and weighed and then submitted to histological analysis to check whether there were related microscopic changes such as inflammation, degeneration, or accumulation of biological material. The organs were fixed in 10% buffered formalin and processed for routine histology with HE stain. Microscopically, massive carbon deposits generally appear as well-recognized anthracotic black pigment, especially in the lung. A recent report described that some types of carbon nanotubes may appear as small punctuated accumulations inside Kupfer cells (liver) and in the intermediate zone of the spleen, when intravenously administered^[45]. Special stains, such as Von Kossa (method that demonstrates phosphates and carbonates) and Masson-Fontana (method used for distinguish carbon deposits from melanin) were also performed in consecutive sections.

Statistical analysis

The statistical review of the study was performed by a biomedical statistician [PAS Armada-da-Silva, CIPER-Faculdade de Motricidade Humana (FMH): Centro Interdisciplinar de Estudo de Performance Humana, FMH, Universidade de Lisboa, Estrada da Costa, 1499-002, Cruz Quebrada - Dafundo, Portugal].

A mixed model repeated measures ANOVA was used to test for differences across time and sciatic nerve treatment. Sphericity was assessed by Mauchly's test and Greenhouse-Geisser degrees of freedom correction was used in cases sphericity could not be assumed or when corrected P -values were below the accepted level of significance ($P < 0.05$). Tukey's HSD test was used for pairwise comparisons. All data is presented as mean

and standard deviation, unless otherwise stated. These statistical tests were carried out with IBM SPSS Statistics version 19. For stereology, statistical comparisons of quantitative data were subjected to one-way ANOVA test, followed by pairwise comparisons using Tukey's HSD test. Statistical significance was established as $P < 0.05$. Stereological data was analyzed using the software using the SPSS version 19.0 (SPSS, Chicago, IL). For muscle morphometry, statistical analysis was performed using the SPSS version 19.0 (SPSS, Chicago, IL). Results are presented as mean $\pm$ scanning electron microscope (SEM) in Figures 5 and 6. Multiple comparisons between groups were performed by one-way ANOVA supplemented with Tukey's HSD post hoc test. Differences were considered statistically significant at $P < 0.05$.

RESULTS

Development and characterization of MSCs isolated from UC WJ

MSCs are defined by the ISCT which includes the following characteristics: (1) their capacity to adhere to plastic surfaces during cell culture; (2) expression of the specific surface markers (positive for CD73, CD90, and CD105, and no expression of CD14, CD19, CD34, CD45 and HLA-DR); and (3) are able to undergo tri-lineage differentiation into adipocytes, chondrocytes and osteoblasts^[19]. MSCs isolated from the UCT were expanded to P5-P6 where the culture appeared homogeneous and cells presented their typical fusiform, fibroblast-like, morphology (Figure 1). Flow cytometry analysis performed previously to *in vivo* application to expanded MSCs showed that over 95% of the cells in the population were consistently positive for the cell surface markers CD44, CD73, CD90 and CD105 and less than 2% positive for CD14, CD19, CD31, CD34, CD45 and HLA-DR. Also, the phenotype of MSCs was assessed by PromoCell by flow cytometry analysis for an additional comprehensive panel of markers: PECAM (CD31), HECAM (CD44), CD45, and Endoglin (CD105). Overall, these results are the ones expected for MSC-type stem cells according to ISCT^[19].

Giemsa-stained cells of MSCs at P5 were analyzed

Figure 6 Macroscopic appearance of control tibialis anterior muscle and histological haematoxylin and eosin staining of a transverse section of tibialis anterior muscle. A: Macroscopic appearance of control tibialis anterior (TA) muscle (left) and 20 wk following neurotmesis and surgical treatment with PVA CNTs MSCs (right); B: Histological haematoxylin and eosin staining of a transverse section of TA muscle from PVA CNTs MSCs group. Magnification 40 ×. PVA: Polyvinyl alcohol; CNTs: Carbon nanotubes; MSCs: Mesenchymal stem cells.

for cytogenetic characterization. The karyotype of MSCs was determined previously to *in vivo* application to ensure that no neoplastic cells were used proving the cell therapy safety. The karyotype analysis demonstrated that no structural alterations were found, as well as chromosomal stability in terms of number and structure of the somatic and sexual chromosomes, to the cell culture procedures. The transplanted MSCs also presented normal morphology and flow cytometry markers for MSCs according to ISCT^[19].

Results obtained from epifluorescence technique confirmed that MSCs did not begin the apoptosis process, showing that the *in vivo* applied MSCs were viable even in the presence of the tube-guides biomaterials. The $[Ca^{2+}]$ measured was 47.9 ± 4.5 ($n = 25$), 46.2 ± 3.5 ($n = 25$) and 48.1 ± 3.9 ($n = 25$) for MSCs cultured in the presence of PVA, PVA-CNTs, and PVA-PPy discs after 7 d of culture, respectively. The MSCs cultured and expanded in the presence of the three tested biomaterials reached confluence and exhibited a normal star-like shape with a flat morphology in culture. According to these results, it is reasonable to conclude that the three biomaterials (PVA, PVA-CNTs, and PVA-PPy) are viable substrate for MSCs culture and survival and may be used in the pre-clinical trials.

The MSCs were harvested and its RNA purified and converted to cDNA using adequate procedures. Primers targeting markers, two housekeeping genes (β -actin and *GAPDH*) and five specific of neuronal cells (GFAP, NeuN, Nestin, NF-H and GAP-43) were used to support the fact that the MSCs used *in vivo* were not differentiated into neuro-glial cells. The molecular analysis showed a very small amplification of GFAP gene, absence of amplification of the NF-H and GAP-43 genes, and reasonable amplification of *NeuN*, β -actin, *GAPDH* and Nestin genes. Amplification of a given gene is correlated with its expression seeing that the template DNA is the one generated from mRNA. According to the results of RT-PCR, the molecular analysis showed a small expression of *GFAP* gene and absence of expression of the NF-H and *GAP-43* genes in the expanded MSCs.

Biomaterials characterization

The electrical conductivity achieved for the different tube-guides (PVA, PVA-CNTs and PVA-PPy) was the following: $1.5 \pm 0.5 \times 10^{-6}$ S/m, $579 \pm 0.6 \times 10^{-6}$ S/m, and $1837.5 \pm 0.7 \times 10^{-6}$ S/m, respectively. Therefore these three tube-guide [simple PVA, PVA loaded with 0.05% (%w/v) of COOH-functionalized CNTs and PPy] compositions were chosen for further characterization and for *in vivo* application in the rat sciatic nerve neurotmesis injury model. The thermal characteristics of simple PVA and loaded PVA materials was examined by differential scanning calorimetry and enthalpy of fusion (ΔH) was calculated, and the percentage of crystallinity was near 7.4% for all analyzed nerve guide tubes. Fourier transform infrared spectroscopy analysis the bands identified for PVA loaded with COOH-functionalized CNTs were similar of the bands detected for simple PVA. For PVA loaded with PPy new bands appeared at 1313/cm (C - N stretching vibration in the ring) and 1170/cm (C - H in-plane deformation). Compared with simple PVA the other nerve guide tubes showed a less intensity of the peaks, especially between 2237 and 2380/cm (unpublished data). Considering the XRD analysis previously performed, the broad peak observed at 20° corresponded to a typical diffraction peak of PVA, and it could be also observed in all tube-guides. Near 26° a broad scattering peak appeared for the tube loaded with PPy, and it was an indication of the presence of PPy as supported in literature^[46]; (unpublished data).

Both PVA and PVA loaded with PPy when analyzed by SEM exhibited similar surface appearance. On the other hand, the PVA loaded with COOH-functionalized CNTs showed a rougher surface as expected due to the presence of CNTs on PVA matrix, with oriented features. This characteristic was determinant to choose this biomaterial to be associated to the MSCs (PVA-CNTs-MSCs group). The Wettability analysis showed a hydrophilic behavior for the three biomaterials used for tube-guide tested, also the three materials showed negative zeta potential being the PVA the most negative

Static sciatic functional index (SSI) measured pre-operatively (week-0), and every week after the surgical procedure until week-20. An index score of 0 is considered normal and an index of 100 indicates total impairment. The measurements of the toe spread (TS), and the intermediary TS, were taken from the experimental (E) and normal (N) sides. Results are presented as mean and SD. *n* corresponds to the number of rats within the experimental group. PVA: Polyvinyl alcohol; CNTs: Carbon nanotubes; PPy: Polypyrrole; MSCs: Mesenchymal stem cells. ^b*P* < 0.01 *vs* Graft.

surface (-4.97 mV) (Figure 2).

Functional analysis during the healing period of 20 wk

SFI and SSI analysis: A few SSI data were missing due to inability to collect visible fingerprints as it was previously referred. As a result of the limited number of animals and the limitations of repeated measures analysis, missing SSI values were replaced using interpolation. Nine of a total of 275 SSI values were interpolated with only one animal having two missing values replace using the linear interpolation procedure. Also because of missing values, the 2-wk time point was not considered for statistical analysis. Sciatic nerve neurotmesis caused a steep decrease in SSI scores in every experimental group and therefore a significant effect of time could be found [$F(10, 200) = 20.445$; $P < 0.001$]. SSI scores remained negative and with little changes throughout the time following sciatic nerve neurotmesis and independently from sciatic nerve treatment, leading to a non-significant time *vs* treatment interaction effect [$F(40, 190) = 279.581$; $P < 0.651$]. However, there was significant differences in the extent of SSI scores' decrease between the experimental groups [$F(4, 20) = 5.848$; $P < 0.01$], with PVA-PPy tube-guides ($P < 0.01$) and PVA-CNTs-MSCs ($P < 0.01$) groups showing less severe SSI scores compared with Graft group (Table 1).

The motor performance by SFI was not possible to perform due to autotomy observed in all treated animals.

Evaluation of motor performance (EPT) and nociceptive function (WRL): In the weeks following sciatic nerve neurotmesis there was a large increase in the time latency to withdraw the paw in response to the thermal stimulus, with most animals reaching the cut-off time of 12 s and leading to a significant effect of time [$F(11, 341) = 17.944$; $P < 0.001$]. A mild improvement in latency times occurred over the weeks of recovery

at a rate that was similar between the experimental groups so that no significant interaction effect existed [$F(55, 341) = 5.727$; $P < 0.503$]. According to ANOVA results, differences between treated groups (PVA, PVA-CNTs, PVA-PPy, PVA-CNTs-MSCs, Graft and End-to-End) in the severity of changes in WRL times existed [$F(5, 31) = 2.942$; $P < 0.05$], but these differences were not large enough to be detected by the pairwise comparisons (Table 2).

The motor performance by EPT was not possible to perform due to autotomy observed in all treated animals.

Ankle joint kinematics: Measures of ankle joint angle at the four selected instants of the stance phase (IC, OT, HR and TO) were collected at the end of 20-wk recovery period. This analysis was carried out only for biomaterial (PVA, PVA-CNTs and PVA-PPy groups, *n* = 7) and biomaterial plus MSCs-treated animals (PVA-CNTs-MSCs group, *n* = 7). Ankle joint angle values were similar across the experimental groups at the times of IC, OT and HR (P = non-significant). However, at TO less acute ankle joint angles were seen for PVA-CNTs-MSCs group, compared with PVA-PPy group ($P < 0.01$) and with PVA-CNTs group showing similar trend also compared with PVA-PPy group ($P = 0.051$). Such less acute ankle joint angles might suggest improved ankle muscles function during the push off phase of the rat's gait cycle (Table 3 and Figure 4).

Morphological analysis

Muscle results: After the healing period of 20 wk, TA muscle of all treated rats from the experimental groups (PVA, PVA-CNTs, PVA-PPy, PVA-CNTs-MSCs, Graft and End-to-End) was collect for histological analysis and morphometry to evaluate the secondary neurogenic muscle atrophy associated to neurotmesis injury. It was also evaluated the muscle healing process that followed the sciatic nerve regeneration where the scaffold

	Group 3: PVA + PPy	36.46 ± 10.14
	Group 6: PVA-MSCs	34.07 ± 6.85
TO	Group 1: PVA	33.99 ± 9.57
	Group 2: PVA-CNTs	27.01 ± 10.99
	Group 3: PVA + PPy	43.90 ± 8.76
	Group 6: PVA-MSCs	20.56 ± 11.31

Values were obtained performing video analysis at 20-wk of the healing period. Results are presented as mean and standard deviation (SD) (*n* = 7). For each step cycle the following time points were identified: Initial contact (IC), opposite toe off (OT), heel rise (HR) and toe-off (TO). PVA: Polyvinyl alcohol; CNTs: Carbon nanotubes; PPy: Polypyrrole.

was applied. It was possible to observe by muscle morphometry that there was a significant difference (*P* < 0.05) in terms of the increase in mean fiber size between some of the treatment (PVA-PPy and PVA-CNTs) groups and the Graft group. In fact, in the PVA-PPy group there was a 25% increase in terms of average fiber area and a 13% increase in terms of the "minimal Feret's diameter", when compared to the Graft group. Whereas in the PVA-CNTs treatment group there was a 42% increase in terms of average fiber area and a 21% increase in term of the "minimal Feret's diameter", when compared to the Graft group. Although both these two treatment groups (PVA-PPy and PVA-CNTs) exhibited significant improvement in fiber size, approaching the values for normal muscles (collected from rats with no sciatic nerve neurotmesis lesion), both of them were

still significantly different (*P* < 0.05) from the control group (without lesion) at 20 wk after lesion. PVA treatment without any coating (PVA group) revealed no regeneration benefit since the mean fiber size was lower (with significant difference in terms of "minimal Feret's diameter"; *P* < 0.05) when compared to the Graft group (Figure 5). However, unexpected results were observed with PVA-CNTs-MSCs, which showed the worst results in terms of muscular atrophy after denervation, results not correlated with functional analysis (considering mostly kinematics gait analysis and SSI) (Figure 5). The decreased fiber size observed in these animals' TA muscles was coincident with the smaller sized muscles that were collected at 20 wk after surgery macroscopically evaluated during the collection for histological evaluation. Histologically it was also possible to detect a considerable amount of necrosis with delayed muscle regeneration in this group's muscles (Figure 6).

Histomorphometry of the regenerated sciatic nerve:

Histological analysis showed that nerve fiber regeneration occurred in all reconstructed nerves. In comparison to controls (sciatic nerve without neurotmesis injuries, data not shown)^[3], in all repaired nerves regenerated fibers showed small axons with thin myelin sheaths and microfasciculation (Figure 7). Microfasciculation was more evident in the PVA-CNTs-MSCs repaired group (Figure 7 and Table 4). Also, stereological analysis disclosed a significantly (*P* < 0.05) larger axon diameter, but not fiber diameter, in the regenerated nerves from PVA-PPy group compared with those from PVA-CNT-MSC group (Table 4). On the other hand, as it was previously reported^[3,25], the application of MSCs-based cell therapy to neurotmesis nerve injuries resulted in a significantly increased myelin thickness (M), ratio myelin thickness/axon diameter (M/d) and ratio axon diameter/fiber diameter (d/D; g-ratio) when compared to PVA, PVA-CNTs, PVA-PPy groups (*P* < 0.05). The results clearly demonstrate a

Table 4 Stereological quantitative assessment

Density, total number, axon diameter (d), fiber diameter (D), myelin thickness (M), ratio myelin thickness and axon diameter (M/d), ratio fiber diameter and axon diameter (D/d), ratio axon diameter and fiber diameter (d/D, g-ratio) of regenerated sciatic nerve fibers at week-20 after neurotmesis. Values are presented as mean ± SD. *n* corresponds to the number of animals within each experimental group. PVA: Polyvinyl alcohol; CNTs: Carbon nanotubes; PPy: Polypyrrole. ^a*P* < 0.05 vs PVA-CNT-MSC; ^c*P* > 0.05 vs End-to-End; ^e*P* > 0.05 vs Graft.

Figure 7 Histological appearance of regenerated nerve fiber in the different groups of neurotmesis. A: PVA; B: PVA-CNTs; C: PVA-PPy; D: PVA-CNTs-MSCs; E: Graft; F: End-to-end suture (magnification: 1000 ×). PVA: Polyvinyl alcohol; CNTs: Carbon nanotubes; PPy: Polypyrrole; MSCs: Mesenchymal stem cells.

synergistic positive effect on regenerated nerve fibers resulting from combined use of MSCs with the PVA-CNTs tube-guides. Also, in the PVA-CNTs-MSCs group these three stereological parameters (M, M/d, and g-ratio) were not significantly different from the values obtained from End-to-End and Graft groups (Table 4). The total number of nerve fibers and nerve fibers density were similar in all groups.

Histology of internal organs: At the microscopic exam, no alterations were observed. The histology sections of all organs confirmed the absence of inflammation, cell degeneration, necrosis and fibrosis. No signs of nanotubes, neither carbon deposits were detected in all organs.

DISCUSSION

An organ re-innervation and functional recovery after nerve injury has been intensively studied worldwide and regenerative medicine methods including cellular systems and new biomaterials concerning the peripheral nerve have been developed. The involved mechanisms in the regeneration process and the ideal scaffold have not been discovered yet. Peripheral nerve might regenerate after some types of injury like axonotmesis but it is difficult to achieve functional recovery after neurotmesis, especially when there is loss of nerve tissue and a gap is created. In the peripheral nervous system, nerves after axonotmesis injuries can regenerate, without any treatment but in most clinical cases a muscle regional neurogenic atrophy occurs. When neurotmesis injuries occur, the nerves must be surgically treated by direct end-to-end suture^[33,47,48], using appropriate microsurgery techniques and suturing material. Nowadays most tissue engineered nerve grafts are composed of a neural scaffold prepared with a variety of biomaterials, and surgically applied in neurotmesis injuries with loss of nervous tissue where the direct end-to-end suture is not possible creating tension in the suture line and compromising the nerve regeneration^[9]. The introduction of cell therapies should be delivered by appropriate vehicles promoting an important biochemical and physical cue. MSCs represent an appealing source of adult stem cells for cell therapy and tissue engineering including peripheral nerve. Because MSCs are present in low percentage in the adult BM and also because of some of the disadvantages previously listed, alternative sources have been studied, like the UCT (also called Wharton's jelly). MSCs were defined by the ISCT in 2006, and since that time it is considered that MSCs must adhere to plastic; have a specific profile for the specific surface markers (positive for CD73, CD90, and CD105, and negative for CD14, CD19, CD34, CD45 and HLA-DR). Other important characteristic is that MSCs are also able to undergo tri-lineage differentiation into adipocytes, chondrocytes and osteoblasts^[19]. *In vivo* and *in vitro* studies referred that MSCs have the capacity to induce the regeneration of cartilage, bone,

tendon, and meniscus^[18]. The MSCs are also able to differentiate into neuro-glial cells, which have been studied *in vitro* and *in vivo* using animal models, by our research group^[25]. Children and adult clinical trials have been performed where MSCs were used to treat a wide range of pathologies, including neurological disorders, PNS and CNS injuries (access www.clinicaltrials.gov). In fact, nowadays, the cryopreservation of UCB, and UCT is performed worldwide in private and public cord blood banks. Furthermore, the MSCs from the UCT and hematopoietic stem cells from the UCB have positive clinical outcomes not only in hematologic malignancy patients, where the MSCs work as a co-adjuvant for the hematopoietic transplant success, but also in PNS injuries and neurologic disorders. For that reason, the crucial role of MSCs in tissue renewal and regeneration has been well established for several limiting pathologies, not treated by the traditional therapeutic approaches^[49]. The *in vivo* application of MSCs performed by the authors was intended to improve the regeneration process in the rat sciatic nerve after a neurotmesis injury which was surgically reconstructed using electric conductive tube-guides of PVA-CNTs composition. At that moment there are several nerve tube-guides in the market, however they still have limitations and the functional outcome of the patients is still not complete. In this work the previously developed tube-guides with high electrical conductivity for nerve regeneration (unpublished data) were used *in vivo* using the rat sciatic nerve neurotmesis injury model. A matrix of PVA was used loaded with the following electrical conductive materials: COOH-functionalized multiwall carbon nanotubes (MWCNTs) and PPy PVA-CNTs and PVA-PPy tube, guides, respectively. The tubes production was carried out by a freezing/thawing process (physical cross-linking) and a final annealing treatment. After producing the tube-guides, the physicochemical characterization was performed. The most interesting results were achieved by loading PVA with 0.05% of PPy or COOH-functionalized CNTs, by combining the electrical conductivity of CNTs and PPy with the biocompatibility of PVA matrix, which seems to have potential to be used in peripheral nerve regeneration. For that reason, these two biomaterials were chosen to proceed for *in vivo* pre-clinical trials using the rat sciatic model. As a matter of fact, the microscopic exam performed to lung, heart, kidneys, liver and spleen collected after animal euthanasia, confirmed the absence of inflammation, cell degeneration, necrosis and fibrosis, and no signs of nanotubes, neither carbon deposits were detected in all organs, confirming the biocompatibility of these biomaterials loaded with CNTs. The evaluation of cytocompatibility was performed by measuring the $[Ca^{2+}]_i$ in Fura-2-loaded MSCs cells by using dual wavelength spectrofluorometry, sub-cultured over PVA discs, over PVA loaded with carbon nanotubes (PVA-CNTs) and PVA loaded with PPy (PVA-PPy) discs of 10 mm diameter, as previously described^[3,25,27]. Results correspond to $[Ca^{2+}]_i$ from viable MSCs that did not begin the apoptosis

process, confirming the MSCs ability to expand and viability when associated to PVA, PVA-PPy and PVA-CNTs tube-guides.

The MSCs isolated from the WJ used as cell-based therapy for promoting nerve regeneration when associated to electric conductive tube-guides was previously *in vitro* validated concerning flow cytometry profile, RT-PCR, and cytogenetic analysis. MSCs were expanded to P5-P6 where the culture appeared homogeneous and cells presented their typical fusiform, fibroblast-like, morphology (Figure 1). Also, the flow cytometry analysis confirmed their profile according to ISCT^[19] and the karyotype demonstrated that no structural alterations were present demonstrating absence of neoplastic characteristics in these cells, as well as chromosomal stability to the cell culture procedures. RT-PCR and qPCR targeting specific genes expressed by the MSCs *in vivo* applied was performed to certify that the MSCs used *in vivo* were not differentiated into neuro-glial cells. For the MSCs, the molecular analysis showed a very small amplification of *GFAP* gene, absence of amplification of the *NF-H* and *GAP-43* genes, and reasonable amplification of *NeuN*, β -actin, *GAPDH* and *Nestin* genes, confirming that MSCs used *in vivo* were undifferentiated and not neuro-glial differentiated. In fact, the small detection of the *GFAP* gene expression may be due to the high sensitivity of the molecular tests in comparison with immunocytochemistry tests previously performed using undifferentiated and neuro-glial type differentiated MSCs^[3,18]. Moreover, the expression of the remaining genes, *NeuN*, β -actin, *GAPDH* and *Nestin* was also observed in undifferentiated MSCs. The expression of the housekeeping genes, β -actin and *GAPDH*, is expected to occur. As per the *NeuN* and *Nestin* gene, the observation of its expression in undifferentiated MSCs is not new; Bertani *et al.*^[50] showed that naïve MSCs express at a constitutive level *NeuN* gene, which increases when these cells are chemically induced to differentiate to pre-neuronal cells. Furthermore, compared gene expression profiles before and after MSCs induction for a number of germ layers, and observed that even before neuronal induction, MSCs population and clonal lines expressed a mixture of mesodermal, germinal, endodermal and ectodermal genes, including several whose expression was thought to be restricted to neuronal cells^[51]. Molecular analysis previously performed^[18] on these same genetic markers over the differentiated MSCs showed an increase in the expression of *GFAP*, *NF-H* and *GAP-43* genes. These genes were not expressed, or expressed at very low levels, in the undifferentiated MSCs transcriptome. Overall, these results support the fact that the MSCs used *in vivo* were not differentiated but presented a neuro-glial potential for differentiation confirming previous results where the same MSCs undifferentiated and *in vitro* differentiated into neuro-glial cells were tested in axonotmesis and neurotmesis injuries associated to other biomaterials namely poly(DL-lactide- ϵ -caprolactone), hybrid chitosan and collagen^[3,25,31].

The rat sciatic nerve model has been widely used in experiments on peripheral nerve regeneration and it has been demonstrated that it is reliable and reproducible model, but research on peripheral nerve injury needs to include both functional and morphological analysis^[52]. Since it is not generally agreed which type of evaluation tool is the most useful for evaluation of functional recovery; our research group like others has been using different methods for an overall assessment of nerve function, which has been widely recommended^[53]. The sciatic nerve regeneration after neurotmesis studies described by the authors were followed during 20 wk after the surgical procedure based on the previous experimental work^[17,29,54,55]. The morphological evaluation together with functional data has been used to assess neural regeneration after induced neurotmesis injuries, but some subjective evaluation, depending on the operator/research analysis is observed^[9]. Some methods for evaluation of nerve recovery, like peroxidase and retrograde fluorescent labeling, histomorphometry, and retrograde transport of horseradish^[47,56] fail in assessing the functional recovery, which is essential to evaluate the success of a scaffold application^[57,58]. The present experimental work includes a variety of independent evaluation tools considering the morphologic and functional recovery, in order to understand and estimate the potential therapeutic benefit of a nerve repair strategy^[9]. EPT, WRL, SSI and SFI, have been proven to be valid methods and to give some information to determine functional recovery following sciatic nerve injury, including motor and nociceptive evaluation^[59]. The use of biomechanical techniques and rat's gait kinematic evaluation was a progress in documenting functional recovery, largely published by our research group^[3,9,17,31,33,35]. Indeed, the use of biomechanical parameters allows an accurate analysis of the sciatic denervation/reinnervation process, permitting to understand the integration of the neural control acting on the ankle and foot muscles, and thus allowing to evaluate the nerve and muscle regeneration after neurogenic muscle atrophy associated to neurotmesis injuries^[60,61]. At the end of the 20-wk healing period, it was performed kinematic gait analysis of rats from the groups where it was applied the biomaterial alone or associated to MSCs-based therapies (PVA, PVA-CNTs, PVA-PPy, and PVA-CNTs-MSCs groups) and measures of ankle joint angle at the four selected instants of the stance phase (IC, OT, HR and TO) were obtained (Table 3 and Figure 4). Considering the histological analysis, it was performed stereology of the regenerated sciatic nerves and morphometry analysis of the TA muscles, trying in this way, not only correlate the neurotmesis injury and the secondary neurogenic regional atrophy, but also consider and validate the morphometry of regional muscles (for instance, by biopsy of the injured muscle) as a method to assess functional recovery after peripheral nerve injuries^[18,25]. The restoration of locomotor activity following damage of the PNS has emerged as one of the most important and critical clinical problem in

neuroscience and neurosurgery fields. Regional muscle weakness and impairment of joint control and mobility occurs in many patients with peripheral nerve or spinal cord injuries which results in gait disorders only evaluated with accuracy by kinematics analysis. During the past 10-15 years, experimental work has been carried out on rat gait analysis which may significantly contribute in the future for a more precise peripheral nerve research. Indeed, the use of biomechanical parameters permits an integration of the neural control acting on the ankle and foot muscles, relevant for the analysis of the sciatic denervation/reinnervation effects. The biomechanical analysis is very useful and accurate to evaluate different therapeutic approaches, describing high number of kinematic variables including positions, velocities, and accelerations, often using high speed digital cameras^[35,40,62,63]. There is high variability between individual joint kinematics and between different animals from the same the same experimental group^[64]. The high level of variability observed in normal quadruped walking, affects significantly the precision of joint kinematic measures of functional recovery after nerve injury. It is important to reduce this variability in kinematics analysis to assess functional recovery after neurogenic muscle atrophy and neurotmesis/axonotmesis injuries. One evident advantage is that using a treadmill the operator reduces step-by-step variability in joint kinematics^[59] which has the disadvantage of being expensive equipment. Also the possibility of combining kinematic analysis with other data, such as ground reaction forces, should be consider for a more accurate evaluation of nerve regeneration^[59,64,65]. Our research group has recently analyzed hip, knee and ankle joint kinematics during recovery of rat sciatic nerve axonotmesis injury, using reflective markers attached to the rat hind-limb to track the motion with infra-red capture cameras, to better assess the rat sciatic nerve model hind-limb joint kinematics during walking. Due to physiological constraints and muscle actions it was observed that different joints have different motion patterns within motion planes, more evident when a 3D segmental kinematic analysis using a 3D reconstruction of the rat hind-limb was performed^[9]. This method allowed a more complete segmental kinematic analysis using both planar angles computation (2D) and a 3D reconstruction of the rat hind-limb but unfortunately, in the present experimental work it was only possible to perform a 2D gait analysis^[9]. In the present work, 2D biomechanical analysis (sagittal plan) was carried out applying a two-segment model of the ankle joint, adopted from the model firstly developed by Varejão *et al.*^[40]. For that reason, ankle joint angle values were similar across the experimental groups at the times of IC, OT and HR. However, less acute ankle joint angles observed in PVA-CNTs-MSCs group, compared with PVA-PPy and PVA-CNTs groups might suggest improved ankle muscles function during the push off phase of the rat's gait cycle (Figure 4 and Table 3). It is well known and demonstrated by the scientific bibliography that neuromuscular pathologies

are related to important clinical signs or motor deficits that should be observed, qualified, and quantified, only possible with a precise kinematic analysis^[65,66]. In the field of peripheral nerve research using the rat sciatic nerve model, an improved walking analysis might include several methods combination like joint kinematics, ground reaction forces and electromyographical data of muscle activity. These methods refinements might be important to differentiate the regenerative potential of different scaffolds used, that are not evident when using the traditional standardized methods previously referred^[9,66].

The recent published paper by di Summa *et al.*^[67] where collagen tube-guides (Neurogen®) were used *in vivo* to promote peripheral nerve regeneration, combined with schwann cells (SCs), it was possible to demonstrate an improved distal stump sprouting^[68]. This sprouting was more pronounced in the experimental group where the SCs were derived from BM-MSCs when compared to SCs derived from adipose tissue MSCs (AT-MSCs). On the other hand, no significant differences were observed in proximal regeneration among all the experimental groups. BM-MSCs and AT-MSCs -loaded conduits induced a diffuse sprouting pattern of the axons. On the other hand, the tube-guides loaded with SCs induced an enhanced cone pattern and a typical sprouting along the collagen type I conduits walls, showing improved regenerating results. This observation is important and should be related to results obtained from the innervated muscle morphometry analysis. It should be bear in mind that the sprouting is also evaluated and a constant observation in the histomorphometry analysis of the regenerated peripheral nerve after axonotmesis and neurotmesis lesions, where different reconstruction strategies were tested *in vivo* in the rat model by our research group for the past years^[3,25,31,68].

The morphometry and histological analysis of TA muscles collected from rats where the neurotmesis injury was reconstructed with PVA-CNTs-MSCs tube-guides is in fact somehow surprising since in the treatment groups presented in a previous published study (Gärtner *et al.*^[3], 2014), no adverse effect was noticed when MSCs isolated from UC WJ were used. The TA muscles from PVA-CNTs-MSCs group presented the worst results in terms of muscular atrophy after denervation, results not correlated with functional analysis (considering mostly kinematics gait analysis and SSI) (Figure 5). The decreased fiber size observed in these TA muscles was coincident with the smaller sized muscles that were collected at 20 wk, macroscopically evaluated during the collection for histological evaluation. Histologically it was also possible to detect a considerable amount of necrosis with delayed muscle regeneration in this group's TA muscles (Figure 6). Some toxic metabolite resulting from the interaction between the vehicle where the MSCs are suspended (PBS) which has calcium and magnesium, and PVA-CNTs tube-guide, could explain the histological results. These results may occur, not because there is a deleterious effect of the cellular

system, but because the vehicle is not appropriate to the cells microenvironment. As a matter of fact these MSCs were previously tested associated to Floseal® and some local nerve necrosis could be observed by histological analysis. On the other hand, the myelin sheath of the MSCs-treated regenerated nerves was thicker, suggesting that MSCs might exert their positive effects on SCs, the key element in Wallerian degeneration and consequent axonal regeneration^[3]. From the data obtained from the stereology analysis of PVA, PVA-CNTs, PVA-PPy, Graft, End-to-End and PVA-CNTs-MSCs groups, it was also demonstrated a synergistic positive effect on regenerated nerve fibers resulting from combined use of MSCs with the PVA-CNTs tube-guides, where PVA-CNTs-MSCs presented higher myelin thickness (M), ratio myelin thickness/axon diameter (M/d) and ratio axon diameter/fiber diameter (d/D; g-ratio) when compared to PVA, PVA-CNTs, PVA-PPy groups (Table 4). Also, these three stereologic parameters (M, M7d, and g-ratio) measured in PVA-CNTs-MSCs regenerated nerves, were not significantly different from the values obtained from End-to-End and Graft groups. In conclusion, as it was previously reported^[3,25], in the MSCs-based cell therapy applied to neurotmesis nerve injuries, it is observed a significantly higher myelin thickness, and similar to Graft and End-to-End regenerated nerves, which are considered the Gold Standards in nerve neurosurgery. These results clearly are consisted with functional data, from SSI and kinematic gait analysis. The PVA-CNTs and PVA-PPy groups presented significantly higher axon diameters (d) and fiber diameters (D), suggesting also the positive effect of these electric conductive materials on axon regeneration and reestablishment of the neuro-muscular junction in agreement with the TA muscle morphometry analysis.

In conclusion, the results revealed that treatment with MSCs associated to PVA-CNTs tube-guides induced an increased number of regenerated fibers and thickening of the myelin sheet. Functional and kinematics analysis has revealed positive synergistic effects brought by MSCs and PVA-CNTs. The PVA-CNTs and PVA-PPy are promising scaffolds with electric conductive properties, bio and cytocompatible, that might prevent in some degree the secondary neurogenic muscular atrophy by improving the reestablishment of the neuro-muscular junction. Since the present studies were carried out in rats with human MSCs, it is important to continue these studies to evaluate the therapeutic potential of these MSCs in human nerve injuries. However, the results discussed herein show a promising effect of MSCs and PVA-CNTs tube-guides in neurodegenerative diseases that are typified by demyelination since this scaffold induced myelin production in surgically reconstructed nerves after a neurotmesis injury.

COMMENTS

Background

The sought for effective new therapeutic strategies for improving peripheral

nerve regeneration represents one of the hot topics in biomedicine because of the high number of lesions affecting peripheral nerves (much higher than lesions to the spinal cord).

Research frontiers

In this study, the authors have tested *in vitro* and *in vivo* mesenchymal stem cells (MSCs) derived from the umbilical cord matrix [Wharton's jelly (WJ)] associated to electric conductive tube-guides developed by their research group, focusing on its effect in promoting nerve regeneration in the rat neurotmesis model. In particular, *in vivo* assessment of nerve regeneration and functional recovery was carried out using a comprehensive battery of complementary methods of analysis that the authors have developed along their previous experience in the study of nerve repair and regeneration and which include behavioral analysis of motor and nociceptive function, kinematic analysis using high speed cameras and histological analysis of nerve fiber regeneration.

Innovations and breakthroughs

The results of this study open interesting perspectives for the clinical application of biodegradable membranes in peripheral nerve reconstruction associated to MSCs isolated from the umbilical cord matrix. Interestingly, these cells, which are major histocompatibility complex class II negative, not only express both an immune-privileged and immune-modulatory phenotype, but their major histocompatibility complex class I expression levels can also be manipulated, making them a potential cell source for MSC-based therapies. In addition, these cells represent a non controversial source of primitive mesenchymal progenitor cells that can be harvested after birth, cryogenically stored, thawed, and expanded for therapeutic uses.

Applications

The results revealed that polyvinyl alcohol (PVA)-carbon nanotubes (CNTs) and PVA-polypyrrole (PPy) are promising scaffolds with electric conductive properties, bio and cytocompatible, that might prevent in some degree the secondary neurogenic muscular atrophy by improving the reestablishment of the neuro-muscular junction. Also, a promising effect of MSCs and PVA-CNTs tube-guides in promoting myelin production in surgically reconstructed nerves after a neurotmesis injury was demonstrated. A new gateway it therefore opened for using these cells in neurodegenerative diseases that are typified by demyelination.

Terminology

Neurotmesis (in Greek tmesis signifies "to cut") is part of Seddon's classification used to classify nerve damage. It is the most serious nerve injury. In this type of injury, both the nerve and the nerve sheath are disrupted. Nowadays, when a nerve is damaged and there is a neurotmesis injury with a gap, it can be repaired using a nerve tube-guide, whenever it is not possible to perform an end-to-end suture without tension or there isn't a graft available. This work focused on the development of electrical conductive nerve tube-guides, which was achieved by loading PVA with PPy or COOH-functionalized CNTs and their *in vivo* application in the rat sciatic nerve neurotmesis injury model. The inclusion of CNTs and PPy brought a significant increase of electrical conductivity of the simple PVA tube-guide. MSCs as defined by the international society for cellular therapy in 2006, are cells characterized by: (1) their capacity to adhere to plastic; and (2) expression of specific surface markers, namely, CD73, CD90, and CD105, and no expression of CD14, CD19, CD34, CD45 and human leukocyte antigen-DR. Additionally, MSCs are able to undergo tri-lineage differentiation into adipocytes, chondrocytes and osteoblasts.

Peer-review

The article is very interesting. The experimental part is very well designed.

Abstract

AIM: To investigate the effectiveness of mesenchymal stem cells (MSCs) in maxillary sinus augmentation (MSA), with various scaffold materials.

METHODS: MEDLINE, EMBASE and SCOPUS were searched using keywords such as sinus graft, MSA, maxillary sinus lift, sinus floor elevation, MSC and cell-based, in different combinations. The searches included full text articles written in English, published over a 10-year period (2004-2014). Inclusion criteria were clinical/radiographic and histologic/ histomorphometric studies in humans and animals, on the use of MSCs in MSA. Meta-analysis was performed only for experimental studies (randomized controlled trials and controlled trials) involving MSA, with an outcome measurement of histologic evaluation with histomorphometric analysis reported. Mean and standard deviation values of newly formed bone from each study were used, and weighted mean values were assessed to account for the difference in the number of subjects among the different studies. To compare the results between the test and the control groups, the differences of regenerated bone in mean and 95% confidence intervals were calculated.

RESULTS: Thirty-nine studies (18 animal studies and 21 human studies) published over a 10-year period (between 2004 and 2014) were considered to be eligible for inclusion in the present literature review. These studies demonstrated considerable variation with respect to study type, study design, follow-up, and results. Meta-analysis was performed on 9 studies (7 animal studies and 2 human studies). The weighted mean difference estimate from a random-effect model was 9.5% (95%CI: 3.6%-15.4%), suggesting a positive effect of stem cells on bone regeneration. Heterogeneity was measured by the I^2 index. The formal test confirmed the presence of substantial heterogeneity ($I^2 = 83\%$, $P < 0.0001$). In attempt to explain the substantial heterogeneity observed, we considered a meta-regression model with publication year, support type (animal vs humans) and

follow-up length (8 or 12 wk) as covariates. After adding publication year, support type and follow-up length to the meta-regression model, heterogeneity was no longer significant ($I^2 = 33\%$, $P = 0.25$).

CONCLUSION: Several studies have demonstrated the potential for cell-based approaches in MSA; further clinical trials are needed to confirm these results.

Key words: Mesenchymal stem cells; Maxillary sinus; Sinus floor augmentation; Scaffolds; Bone regeneration

Core tip: Cell-based approaches, utilizing adult mesenchymal stem cells, may overcome the limitations of conventional bone augmentation procedures. The present review of the current literature aims to systematically review the available evidence on the characteristics and clinical effectiveness of cell-based maxillary sinus augmentation, compared to current evidence-based methods.

Mangano FG, Colombo M, Veronesi G, Caprioglio A, Mangano C. Mesenchymal stem cells in maxillary sinus augmentation: A systematic review with meta-analysis. *World J Stem Cells* 2015; 7(6): 976-991 Available from: URL: <http://www.wjgnet.com/1948-0210/full/v7/i6/976.htm> DOI: <http://dx.doi.org/10.4252/wjsc.v7.i6.976>

INTRODUCTION

Implant dentistry is a successful treatment procedure, as demonstrated by more than 20 years of clinical evidence^[1-3].

However, the edentulous posterior maxilla is often characterized by a lack of bone because of severe post-extraction alveolar crest resorption coupled with age-linked sinus pneumatization^[4,5]. This anatomic limitation often dictates the need for reconstructive osseous surgery to re-establish adequate bone volume for implant positioning^[4,5].

Accordingly, different augmentation approaches have been introduced to obtain more maxillary bone volume, placing various grafting materials in the maxillary sinus^[6-9]. Nowadays maxillary sinus augmentation (MSA) has become a reliable, commonly used procedure to increase bone volume in the posterior maxilla^[4,5,9,10].

Autogenous bone (AB) is still the best grafting material in bone reconstructive surgery, and MSA has been originally carried out with it^[10,11]. In fact, AB exhibits osteogenic and osteoconductive potential, since it contains living cells and growth factors^[10-12]. However, additional surgical procedures are needed to harvest bone chips from other skeletal sites (intraorally or from the iliac crest); the available AB supply is limited, and morbidity at donor site is often a problem^[11,12]. In

addition, AB shows resorption patterns proportional to the quantity of harvested material, and this may result in a significant loss of grafted bone in large defect fillings over time^[11,12].

To overcome these limitations, several osteoconductive materials have been used in MSA, such as autogenous bone [allografts (AL)]^[13,14], xenografts [bovine bone mineral (BBM)]^[9,15,16], synthetic bone grafts [calcium phosphate ceramics (CPC)]^[4,17] or composite materials^[18]. However, these bone grafting substitutes don't contain living cells, so their healing times are longer than AB^[12,19].

Bone tissue engineering (BTE) procedures may help to overcome these limits^[20]. According to BTE, a bone substitute should have biological and morphological features as similar as possible to AB, and the fabrication of the ideal bone graft requires the manipulation of three essential components: osteogenic cells, growth factors and osteoconductive scaffolds^[20,21]. In particular, BTE aims to achieve bone augmentation without surgical AB harvesting from other donor sites, through the use of specific scaffolds seeded with osteogenic cells^[12,19,21].

The aim of the present review was to evaluate the effectiveness of cell-based approaches in MSA, associated with various scaffold materials, in animals and humans.

MATERIALS AND METHODS

Study design

The protocol of this review is in accordance with Preferred Reporting Items for Systematic Reviews and Meta-Analyses^[22], the Cochrane Collaboration^[23] and CheckReview^[24] checklists. It was developed a priori, covering rationale, design of the study, focused question, inclusion/exclusion criteria, search strategy, data synthesis. The protocol was examined and refereed by researchers with experience in systematic reviews. The focused questions was: "What is the effectiveness of cell-based approaches in MSA, with different materials?"

Inclusion and exclusion criteria

Most important study designs to address the focused question were randomized controlled trials (RCTs) and controlled trials. Although this, both experimental and observational studies (RCTs, controlled trials, case series, case reports and prospective cohort trials) were included in this review. Inclusion criteria were studies of BTE methods in MSA using different scaffolds, in animals and humans, with analysis using either radiographic or histologic/histomorphometric approaches. Exclusion criteria were studies where there was no information about the surgical team or the location (private practice/hospital/university) where MSA was performed.

Search strategy

Systematic searches were performed in MEDLINE, EMBASE and SCOPUS databases including full text articles published in English between October 2004 and October 2014, presenting either radiographic or

Figure 1 Flow chart of manuscripts screened through the review process.

histologic/histomorphometric evaluations.

Keywords such as sinus graft, MSA, maxillary sinus lift, sinus floor elevation, mesenchymal stem cell (MSC) and cell-based, in different combinations, were used. Titles and abstracts were examined and then expert reviewers (Mangano FG and Colombo M) evaluated full text of publications extrapolating relevant information. Data extraction procedures affected title, authors, year of publication, type of study, cells and scaffold used, design, randomization/blinding if present, number of procedures performed, treatment phase, follow-up, radiographic and/ or histologic/histomorphometric outcomes, statistical findings, conclusions. In addition, the reference lists of included studies were hand searched.

Statistical analysis

Experimental studies (RCTs/CTs) on MSA with an outcome measurement of histologic/histomorphometric evaluation were subjected to meta-analysis. Mean and standard deviation values of new bone formation were used; to overcome the differences of sample size between studies weighted mean was calculated. Test and the control groups values were compared by calculating the differences of bone gain in mean, and 95% CIs. Software package R version 2.14 (Package Metafor; Wolfgang Viechtbauer, Maastricht, The Netherlands) was used to perform all statistical analyses.

RESULTS

Result of search and included studies

Of the 325 eligible articles initially identified, 270 were excluded following assessment of the title and/or abstract. In total, 39 studies (18 animal studies and 21 human studies) were eligible for inclusion in the present literature review (Figure 1). All these publications were issued between 2004 and 2014, and were variable with respect to study type, design, follow-up, and results.

MSCs

A stem cell is an undifferentiated cell with the capability

to renew itself and to get a specific cell-phenotype if exposed to proper stimuli^[25-28]. The more relevant stem cells types in clinical researches are embryonic stem cells (ESCs), typical of embryonic blastocyst, and adult stem cells, also defined as pluripotent MSCs^[28-31].

ESCs have unlimited proliferation potential and are able, under appropriate inductive conditions, to produce all three germ layers cellular phenotypes^[28-31]. ESCs can be cultured indefinitely *in vitro* for more than two years, with approximately 400 doubling cycles, without the loss of differentiation potential. They can be re-implanted into a host embryo giving rise to progenies that differentiate into all kind of tissues^[29-31]. Although their clinical potentials several issues remain to be addressed with ESCs^[30,31]. The use of these cells, in fact, presents the potential risks of immunorejection or teratogenesis^[30]. Moreover, despite the pluripotency of ESCs, moral and legal controversies concerning their use for therapeutic and clinical application have encouraged to find the reservoirs of progenitor cells in adult tissues^[28,32,33].

Adult stem cells or pluripotent MSCs, derived from different adult tissues, have a wide self-renewal and proliferation capability, whereas if correctly stimulated have the ability to differentiate into specific cell-lines^[25-31]. Although MSCs display a finite life span and get into senescence faster than ESCs, current *in vitro* techniques allow to expand them in sufficient number for clinical uses maintaining the undifferentiated phenotype^[25-31]. MSCs lack immunogenic or tumorigenic features^[26-28]; moreover, there is no ethical or legal concern for the clinical use of MSCs^[32]. For all these reasons, these cells can be used in cell-based approaches in bone regeneration^[25-31,33].

MSCs can be extracted from different tissues such as bone marrow [bone marrow stem cells (BMSCs)]^[25-31,34], periosteum (periosteal derived stem cells)^[35], trabecular bone^[36], adipose tissue [adipose stem cells (ADSCs)]^[37] or skeletal muscle^[38], umbilical cord^[39], amniotic fluid [amniotic fluid stem cells (AFSCs), and amniotic epithelial stem cells (AESC)]^[40,41], skin [skin-derived stem cells (SDSCs)]^[42], dental pulp (dental pulp stem cells)^[43,44], deciduous teeth [deciduous tooth stem cells (DTSCs)]^[45] and periodontal ligament [periodontal ligament stem cells (PDLSCs)]^[46].

The bone marrow aspirates (BMA), from the iliac crest of the pelvis, has always been considered the first source for MSCs^[25-34]. The tibial and femoral marrow compartments are also available as alternative sources. Due to the morbidity and the operative difficulties of this procedure the possibility to harvest MSCs from other tissues, such as periosteum or maxillary tuberosity has become of interest^[35,36]. At present, MSCs can be also achieved from adipose tissue by liposuction^[37] or from the dental pulp^[43,44]. The latter represents a very interesting option in the field of oral surgery^[43,44].

As the number and the concentration of transplanted MSCs are critical to induce a significant clinical outcome, an adequate number of cells for cell culture/replication is

needed. BMA represent a heterogeneous cell population; the amount of MSC is very small compared to that of hematopoietic cells and averaging 0.001%-0.01% of the total nucleated cells^[47], thus requiring extensive *in vitro* separation steps and expansion. Moreover, the number of MSCs that can be collected is inversely correlated to patient age and to his/her systemic health state. Younger donors tend to provide higher yield of stem cells in the aspirate, and the age of the donor seems to be directly associated with detrimental effects in term of proliferation and differentiation, such as senescence^[47]. Cell density varies with different skeletal sites of the donor: on average, human BMA yield 400 to 500 cells/mL with an estimated total volume of 600 cc in the iliac crest^[48].

At present, using standard cell culture techniques, MSCs can be isolated and expanded with great efficiency, inducing to grow into multiple lineages if exposed to the appropriate culture conditions^[25]. For *in vitro* separation and expansion, cultured MSCs undergo successive passages. Cells are cultured in a medium supplemented with autogenous serum or fetal bovine serum and growth factors^[49]. MSCs have fibroblastic morphological features in a monolayer culture and tend to adhere to the tissue culture substrate^[49]; changing the medium, non-adherent hematopoietic cells are discharged^[28,50]. MSCs are identified by their adhesion to plastic and their expression of peculiar membrane epitopes (CD73, CD90, CD105), with a lack of expression of human leucocyte antigen-DR and the hematopoietic markers (CD14, CD34, CD38, CD45)^[49,50]. Unfortunately, MSCs display finite life spans. Recent studies have shown that extensive *in vitro* proliferation can affect MSCs replicative potential and differentiation capability: long-term culture and sequential passages affect the quality of MSCs in that their proliferation rate decreases and gradually lose their progenitor properties due to senescence and telomere shortening^[51]. Since MSCs undergo limited mitotic divisions *in vitro*, the number of passages in *in vitro* expansion should not exceed five^[51]. The addition of fibroblast growth factor-2 to the culture medium can stimulate the proliferation of MSCs maintaining their osteogenic potential, keeping the cells in a more immature state^[52].

Usually, the osteogenic differentiation is initiated by supplementing the medium with dexamethasone, ascorbic acid and beta-glycerolphosphate^[53]. In addition, soluble signals like bone morphogenetic proteins (BMPs) such as BMP-2, BMP-6 and BMP-9 can be used^[53,54].

Scaffold

Cells are usually seeded onto a three dimensional (3D) scaffold that guides their growth and proliferation^[55]. At present, there are at least 4 different strategies for the delivery of MSCs into the recipient site: MSCs can be replicated and differentiated in culture, then seeded on a 3D solid scaffold that can be implanted, after a stabilization time to obtain cell adhesion; MSCs can be replicated in culture and seeded into the 3D solid

scaffold, then the cell-scaffold composite is placed in differentiation medium to stimulate the shift into the osteoblastic phenotype, ready to be implanted into the site; MSCs can be replicated and differentiated directly in the 3D scaffold *in vitro*, and the cell-scaffold composite can be implanted after a maturation time; finally MSCs can be replicated and differentiated *in vitro*, and the cell-scaffold composite can be incubated for a short time to prepare an injectable bone preparation.

In all these strategies, the scaffold has a key role providing a substrate into which bone cells migrate, proliferate, differentiate and make new bone^[55,56]. The scaffold should be characterized by specific physical structure and chemical composition in order to mimic the hierarchical architecture and biological functions of native extracellular bone matrix^[55,56]. Native extracellular matrix offers a physical substrate for cells, but also a biological environment for cell adhesion and chemotaxis through specific ligands. Providing specific growth factor, bone matrix regulates cellular proliferation and function^[55,56]. First generation biomaterials were designed promoting mechanical resistance and stability over time, bioinertness or biocompatibility; nowadays new generation scaffold materials are developed with biologically-inspired approach; these new materials should incorporate signals into the scaffold, to modulate proliferation and differentiation^[55-57]. Architectural characteristics define the ultimate shape of the new tissue. Highly porous structures with many interconnection and with large surface areas related to volumes, can aid cell ingrowth and their diffusion throughout the scaffold as well as the passage of nutrients and waste products^[55,57].

Angiogenesis is a pre-requisite for osteogenesis^[57]. Accordingly, pore sizes in the range of 200-800 µm have good results in these situations: in fact, they stimulate osteoprogenitor and endothelial cells to migrate into the matrix. Endothelial cells produce the vascular vessels for new bone nourishment^[55-58]. Surface roughness, surface energy and the presence of cell attachment sites all influence specific proteins expression, quantity and structural conformation which adsorb onto materials surfaces, modulating cells behaviours^[55,57]. Finally, substrate degradation by matrix enzymes^[57] is critical. The ideal material should incorporate controlled resorption, and the regenerated tissue should assume function while the scaffold is slowly degraded^[55,57].

Scaffolds and stem cells: Animal studies

In total, 18 animal studies evaluating the histologic/histomorphometric results obtained with MSCs combined with different scaffold materials were found in the literature^[40-42,59-73]. Among these, one single study was on MSCs with allogeneic bone matrix (AL)^[42], 6 studies were on MSCs with xenografts (BBM)^[59-64], 10 studies were on MSCs with synthetic bone grafts (CPC)^[40,41,65-71], and 2 studies were on MSCs with platelet-rich-plasma (PRP)^[72,73].

AL (bone tissue from human cadavers), provides an osteoconductive scaffold which offers structural support

for vascular and perivascular tissues growth, and for osteoprogenitor cells migration from the adjacent environment^[13,14,42]. In a study on minipigs, Kang *et al.*^[42] evaluated *in vivo* osteogenesis of SDSCs with scaffolds composed by allogeneic demineralized bone (AL) and fibrin glue. The animals were allocated in two groups: in one group, MSA was performed with SDSCs + AL/fibrin glue (test), while in the other group the scaffold without cells was used^[42]. They observed better trabecular bone formation and osteocalcin expression with scaffolds seeded with SDSCs compared with controls^[42]. The authors found that autogenous SDSC grafting with a AL and fibrin glue scaffold can provide an adequate alternative to bone grafting in MSA procedures^[42].

BBM associated with bone marrow aspirate concentrate (BMAC) could provide a substitute for AB to stimulate new bone formation^[9,15,16,59-64]. Sununliganon *et al.*^[59] investigated the bone regeneration capacity of autologous BMAC mixed with BBM in MSA. Twenty-four white New Zealand rabbits were randomly subdivided into groups and when subjected to maxillary sinus floor elevation and augmentation with four different materials: saline solution, AB, BBM and BMAC + BBM^[59]. Four MSA procedures were performed per each material. The animals were sacrificed at 2, 4 and 8 wk, and rates of new bone apposition in augmented surgical sites were evaluated; bone histomorphometry was also examined. Significant increase in the quantity of nucleated cells and colony forming unit-fibroblasts were confirmed in BMAC. MSCs in BMAC retained their *in vitro* multi-differentiation capability. BMAC + BBM showed a similar benefit to AB in term of acceleration, since higher (though not significantly different) rates of mineral appositions in the early period were detected in BMAC + BBM and AB than BBM alone^[59]. Furthermore, graft volume/tissue volumes in BBM and BMAC + BBM resulted to be higher than in AB and saline solution. The results of this study suggest benefit in early bone formation *in vivo* using immediate autologous BMAC transplantation^[59]. In a similar study, Yu *et al.*^[60] compared the potential of tissue-engineered bone derived from different stem cell sources for canine MSA. Bilateral MSA were performed in six beagle dogs and were randomly repaired with three graft types: BBM granules alone ($n = 4$), a complex of osteoblasts derived from BMSCs + BBM ($n = 4$), and a complex of osteoblasts derived from PDLSCs and BBM ($n = 4$). After 12 wk, the animals were sacrificed and fluorescent labeling, maxillofacial computed tomography (CT), scanning electron microscopy, and histologic/histomorphometric analyses were used to evaluate new bone deposition, mineralization, and healing processes in the augmented area^[60]. At the end of the study, the osteogenic capacity was greater with BMSCs + BBM and PDLSCs + BBM than with BBM alone^[60]. The level tended to be higher with PDLSCs than with BMSCs; however, the difference was not statistically significant^[60]. Oshima *et al.*^[61] investigated the *in vivo* osteogenic potential of a novel gabapentin-lactam (GBP-L) in MSA. Bilateral MSA in 10 adult sheep were conducted. BBM and MSCs

combined with novel GBP-L were placed into the test sinus of each sheep; MSCs + BBM alone served as the control on the contralateral side^[61]. The animals were sacrificed after 8 and 16 wk, and the amount of newly formed bone was analysed using histology/histomorphometry. The histologic evaluation showed newly formed bone connected with the original bone in the control and test groups; however, the amount of newly formed bone was not significantly different between the test and control sites^[61]. The authors concluded that the application of GBP-L did not induce faster new bone formation. However, GBP-L did not alter the multipotency of the MSCs or impair bone formation^[61]. Jhin *et al.*^[62] evaluated the potential of BMP-2 gene-transduced BMSCs to facilitate osseous healing after MSA in rabbit. BMSCs derived from New Zealand white rabbits were cultured and some of these cells were transduced with BMP-2 (BMP-2/BMSCs) using an adenovirus vector. Then, BMSCs and BMP-2/BMSCs were seeded on a BBM scaffold. Twenty-seven animals were randomly allocated into three groups: MSA with BMSCs + BBM, MSA with BMP-2/BMSCs + BBM and MSA with BBM alone^[62]. During all these procedures, a mini-implant was placed in the floor of each sinus^[62]. Animals were sacrificed at 2, 4, and 8 wk after surgery, and new bone area and bone-to-implant contact (BIC) were evaluated histomorphometrically. The histomorphometric evaluation revealed that at 2 and 4 wk, the BMP-2/BMSC group showed more new bone and higher BIC than the other two groups; however, at 8 wk, there was no difference in new bone area or BIC among the three groups^[62]. The authors concluded that BMP-2 delivery using BMSCs may result in earlier and increased bone formation in MSA; nevertheless, limitations in the stimulatory effect of BMP-2/BMSCs were evidenced in later healing stages^[62]. Gutwald *et al.*^[63] compared the efficacy of mononuclear cells (MNCs, including MSCs) plus BBM with AB in MSA in sheep. Bilateral MSA were performed in 6 adult sheep. MNCs + BBM were mixed together and used into one sinus, AB in the other sinus^[63]. After 8 and 16 wk, animals were sacrificed. Sites of augmentation were evaluated through radiographic and histological methods. After 8 wk, no difference in new bone formation was noticed between the two groups, but after 16 wk, sites grafted with MNCs + BBM showed 29% of newly formed bone vs 16% in sites grafted with AB^[63]. The authors concluded that MNCs combined with BBM have the potential to stimulate new bone formation in MSA^[63]. Finally, in a similar study, bilateral MSA were performed in 6 adult sheep by the same group of authors^[64]. BBM and MSCs were used in test side and only BBM in the contra-lateral control side of each animal^[64]. Animals were sacrificed after 8 and 16 wk. The regenerated areas were evaluated by CT, histology and histomorphometry. They observed that the newly formed bone was closely connected to BBM particles; furthermore its apposition was significantly faster in the test sides^[64]. The authors concluded that mixture of BBM and MSCs could stimulate new bone

deposition in MSA^[64].

Synthetic CPC such as porous hydroxyapatite (HA), beta-tricalcium phosphate (beta-TCP) and biphasic combinations of these two are excellent bone alternatives^[40,41,65-71]. CPC are considered biocompatible, non-immunological, osteoconductive (they act as scaffolds which allow internal growth of vessels from neighbouring bone tissue)^[40,41,65-71]. Zhao *et al.*^[65] investigated the effect of MSA with engineered bone constructs from DTSCs and CPC in goats. Eighteen bilateral maxillary sinuses of nine goats were randomly assigned into three groups (6 sinuses per group). In the first group, MSA was performed with DTSCs + CPC, while in the second and in the third group MSA was performed with CPC alone and AB, respectively^[65]. All augmentation sites were analysed using CT, histology and histomorphometry. After 12 wk of healing, CT analysis evidenced that the volume of new bone with DTSCs + CPC was greater than that in the other two groups^[65]. In addition, the histological/histomorphometrical evaluation indicated that the DTSCs + CPC compound significantly stimulated new bone formation and mineralization, when compared with CPC and AB alone^[65]. The authors concluded that DTSCs can stimulate new bone formation and maturation in the maxillary sinus of goats, and that the engineered mixture of DTSCs and CPC should represent a possible substitute for MSA procedures^[65]. Zhang *et al.*^[66] compared the bone formation capacity of ADSCs and BMSCs in a canine MSA model. Bilateral MSA were performed in nine beagle dogs using randomly three graft material combinations: BMSCs + CPC ($n = 9$), ADSCs + CPC ($n = 9$) and CPC alone ($n = 9$)^[66]. After 6 wk, the animals were sacrificed and the histological/histomorphometric evaluation suggested that BMSCs might be more advantageous than ADSCs for fast bone regeneration in MSA^[66]. Barboni *et al.*^[41] evaluated the bone regenerative property of AESCs seeded on a CPC synthetic bone substitute (fabricated using rapid prototyping techniques) in MSA in sheep. Two blocks of CPC, engineered with ovine AESCs or alone, were grafted bilaterally into maxillary sinuses of six adult sheep^[41]. The sheep were randomly divided into two groups and sacrificed at 45 and 90 d after surgery. Micro-CT, morphological, biochemical and morphometric analyses were performed to evaluate tissue regeneration in the sinus explants. AESCs seem to influence positively scaffold integration and new bone deposition^[41]. Engineered scaffolds, derived from explanted sinuses grafted with AESCs, displayed an accelerated process of angiogenesis; moreover, AESCs significantly promoted osteogenesis^[41]. These results confirmed those of a previous study by the same group of authors^[40] in which bilateral MSA was performed on eight adult sheep, in order to evaluate the bone regeneration process at 6 and 12 wk after implantation of AFSCs combined with a magnesium-enriched HA/collagen-based scaffold (test) with the scaffold alone (control). In fact, the use of AFSCs increased bone apposition and promoted a faster angiogenesis^[40]. The authors concluded that AFSCs may be a new, easily accessible source of MSCs to develop

cell-based therapy for oral augmentation procedures: in fact, the osteoinduction of a biomimetic commercial scaffold may be significantly enhanced by these cells^[40].

Zeng *et al.*^[67] evaluated the efficacy of BMSCs seeded on CPC, magnesium phosphate cement (MPC), and a calcium-MPC (CMPC), in MSA in rabbit. In test groups augmentation procedures were performed using BMSCs in addition to CPC, MPC, and CMPC; the same materials (CPC, MPC and CMPC), without cells, were used for surgical procedures as control^[67]. In each group new bone formation was investigated histologically and by fluorochrome labeling at weeks 2 and 8 after MSA^[67]. The authors found that CMPC cement could better help new bone formation and mineralization than CPC or MPC cements, and that the addition of BMSCs could further promote its osteogenic capacity significantly^[67].

Zou *et al.*^[68] assessed the potential of BMSCs when combined with CPC in MSA in goats. They randomly allocated nine goats in three different groups: the first group received BMSCs + CPC, the second CPC alone and the third AB. Each animal underwent a bilateral MSA procedure. Implants were also placed in order to evaluate BIC^[68]. After 12 wk, the histological/histomorphometric evaluations showed that the BMSCs + CPC composite could foster earlier bone formation and mineralization, and could preserve more volume and height after MSA^[68]. In addition, BIC was significantly higher in the BMSCs + CPC group than in the other two groups. The authors concluded that BMSCs + CPC seems to be a good graft material for MSA, allowing faster healing in augmented sites and a better stability of implants^[68]. In a study by Xia *et al.*^[69] 36 rabbits were randomly allocated in 4 groups, to test CPC scaffolds associated with recombinant BMP-2 and BMSCs, in different combinations. Although the authors found no significant difference among groups for augmented height, histomorphometric analysis showed significantly less residual graft material and more new bone formation and mineralization in BMP-2/BMSCs + CPC than in other groups^[69]. Based on these outcomes, they suggested that combining BMP-2/BMSCs with CPC could enhance new bone formation and maturation as compared with BMP-2 + CPC or BMSCs + CPC^[69]. In two different studies, Sun *et al.*^[70,71] evaluated the outcome of MSA with CPC and BMSCs in rabbits. In the first study^[70] 16 MSA were performed bilaterally in 8 animals and randomly grafted by BMSCs + CPC, CPC alone, AB and blood clot (4 sites per group). The animals were sacrificed 2, 4 and 8 wk after the surgery and studied histologically and histomorphometrically^[70]. After 8 wk, the authors observed a significantly higher amount of new bone in the test groups (BMSCs + scaffold and scaffold alone) than in control groups (AB and blood clot). An increase in bone height along time was found for the test groups, while control groups showed a constant decrease of augmented height^[70]. Surgical sites augmented with BMSCs + CPC showed more bone than areas grafted with CPC alone, but this difference was not statistically significant. These results suggested that CPC could be used as a bone graft substitute in

bone augmentation procedures and that adding BMSCs to this material could successfully promote new bone formation in maxillary sinus elevation^[70]. In a second, similar study^[71] the same authors evaluated the effects of MSA by a tissue engineered bone composite with *BMP-2* and *EGFP* gene modified BMSCs and CPC. In this study, eight rabbits were allocated in two groups (four rabbits per group), and subjected to bilateral MSA with two different materials: *BMP-2*/BMSCs + CPC (test) and *EGFP*/BMSCs + CPC (control)^[71]. Histological/histomorphometric evaluation was performed 2 and 4 wk after surgery. The vertical bone gain was maintained, over all the experimental period, for both groups, while new bone volume increased over time for test group^[71]. Four weeks after surgery, bone area in test group was significantly more than that in control group^[71]. The authors concluded that BMSCs modified with *BMP-2* gene can stimulate new bone formation in MSA in rabbit animal model, and that CPC scaffold can be a valid vector for gene improved BTE^[71].

Finally, in a split-mouth controlled study on eight minipigs, Pieri *et al.*^[72] investigated whether BMSCs and PRP loaded on a HA substrate can influence bone formation and BIC in MSA, when compared to HA scaffold alone. Bilateral MSA procedures were performed in eight minipigs: each animal received BMSCs + PRP + HA in one sinus (test) and HA alone in the other (control)^[72]. In addition, distal to the augmented site, one endosseous implant was placed per sinus, to evaluate BIC. The animals were sacrificed 12 wk after surgical procedures. Block sections of the implant sites were extracted and prepared for histologic/histomorphometric analysis. The histomorphometric observations revealed statistically significant increase both in bone quantity and in the BIC for the test sites^[72]. This study showed that the use of BMSCs and PRP with a HA scaffold can significantly promote bone growth in MSA techniques, and can enhance the osseointegration of endosseous dental implants positioned in the augmented sites, in comparison with HA alone^[72]. In another, similar study, Ohya *et al.*^[73] evaluated the outcomes of BMSCs associated with PRP vs particulate cancellous bone and marrow (PCBM) with PRP. Bilateral MSA procedures were performed in 18 adult Japanese white rabbits. Each rabbit received BMSCs + PRP in one sinus (test) and PCBM + PRP in the other (control)^[73]. The animals were sacrificed at 2, 4, and 8 wk after surgery, and histological/histomorphometric evaluation was executed. Both test and control sites displayed newly formed bone and neovascularization at 2 and 4 wk in histological preparations; at 8 wk, authors observed large areas of fatty marrow inside lamellar bone in both sites. The analysis of bone volume and augmented height did not highlight any significant differences between BMSCs + PRP and PCBM + PRP groups. On the other hand, significant differences in bone volume and augmented height between 2 and 8 wk in PCBM + PRP or BMSCs + PRP groups were found, as well as in bone volume between 4 and 8 wk in the PCBM + PRP group^[73]. The

authors concluded that the use of a BMSCs + PRP compose could give good outcomes in osteogenesis and bone volume gain comparable to that achieved by particulate cancellous bone in MSA^[73].

The histologic/histomorphometric results of all these animal studies are reported in Table 1.

Scaffolds and stem cells: Human studies

In total, 21 human studies evaluating the histologic/histomorphometric results obtained in MSA with MSCs combined with different scaffold materials were found in the literature^[74-95]. Among these, 2 studies were on MSCs with allogeneic bone matrix (AL)^[74,75], 9 studies were on MSCs with xenografts (BBM)^[77-85], 2 were on MSCs with synthetic grafts (CPC)^[86,87], 6 were on MSCs with synthetic polymers [polylactid-co-glycolic acid, (PLGA)]^[88-93], and 2 were on MSCs with PRP^[94,95].

A commercially available AL containing native MSCs has been clinically used for MSA in 2 different studies^[74,75]. McAllister *et al.*^[74] evaluated the bone formation following MSA using an AL containing native stem cells. After a healing period of 4 mo, biopsy and histologic evaluation were performed. The histologic and histomorphometric evaluation for the five cases reported revealed a high percentage of vital bone content, after a relatively short healing period^[74]. A recent clinical study by Gonshor *et al.*^[75] evaluated bone formation in MSA sites using either an AL cellular bone matrix containing MSCs or a conventional AL. Statistically significant difference were found between the two groups, in terms of vital and residual bone content, using histomorphometric comparison^[75]. In AL, cryopreservation is used to maintain cell viability and multipotential characteristics^[75]. This might help the healing process stimulating bone formation directly from within the graft material, allowing earlier and larger quantity of available vital bone^[74,75]. However, there is a high level of uncertainty around the possibility of iatrogenic transmission of prion or viral infections with AL, due to a lack of evidence-based research on this problem^[76].

BBM has excellent osteoconductive properties^[9,15,16] and the encouraging results emerged from pre-clinical studies^[59-64] have led to the clinical use of this material in MSA, with the cell-based approach^[77-85]. Unfortunately, however, human studies^[77-85] on MSCs + BBM have not confirmed the excellent outcomes originally emerged from animal studies. In a recent clinical study on implant survival after MSA, Duttenhoefer *et al.*^[77] concentrated MSCs with either Ficoll (control group, $n = 6$ sinus) or BMAC (test group, $n = 12$ sinus) and transplanted in combination with BBM. 50 dental endosseous implants were positioned with other surgical procedures (17 Ficoll/33 BMAC) and loaded after 4 mo. At the end of the study, implant survival of the Ficoll group was 100% compared with 93.4% survival of the BMAC group; however, both cell isolation methods were found to be efficient because the difference between the groups was not statistically significant^[77]. In a randomized, controlled, split-mouth design study by Rickert *et al.*^[78], a

bilateral MSA procedure was executed in 12 edentulous patients. At random, one side was treated with BMSCs + BBM (test side) and the other with BBM mixed with AB (control side)^[78]. Three to four months after MSA, 66 implants were placed. Implant survival, plaque, gingival, and bleeding indices, probing depth, and peri-implant radiographic bone levels were assessed at baseline and 1 year after functional loading. During osseointegration, 3 implants failed on the test side and no implants failed on the control side, resulting in 3-mo survival rates of 91% and 100%, respectively. No other implants were lost after 1 year of functional loading^[78]. Even if the two reconstructive techniques were reliable in providing new bone for implant placement in the posterior maxilla, a higher implant failure rate was reported in MSA procedures with BMSCs + BBM^[78]. In a radiographic study, Kühl *et al*^[79] investigated BMA and BMAC influence on graft materials stability when added to BBM within the first 6 mo after MSA. Using a 3D reconstruction software, CT data of 13 patients undergoing bilateral MSA in a split-mouth study, were processed to evaluate graft volumes 2 wk after the sinus lift procedure and 6 mo later^[79]. The comparison between volumes at 2 wk and 6 mo showed a statistically significant decrease in all single groups between 15% and 21%. However, changes in volumes between the different groups were not statistically significant^[79]. Since an evident decrease in graft volume over the first 6 mo of healing has to be expected, over-augmentation of the sinus is recommended with this cell-based approach^[79]. In an interesting split-mouth design study, Wildburger *et al*^[80] evaluated early bone formation in BBM sinus

grafts using also BMSCs in test group, after 3 and 6 mo. Seven patients, with a posterior maxilla characterized by atrophic bone, were included in this study^[80]. In test side, augmentation procedures were performed with BMSCs mixed to BBM; control sides were grafted using pure BBM. At 3 and 6 mo, biopsies of augmented sites were taken^[80]. The histologic/histomorphometric evaluation found no significant difference in new bone formation between the test and control group^[80]. These results confirmed those of a previous multicentric, controlled study by Sauerbier *et al*^[81]; they found that BMAC + BBM or a mixture of AB + BBM, used in sinus augmentation, give similar new bone formation values, after 3-4 mo of healing. However, these outcomes are partially in contrast with those of a previous histologic/histomorphometric study^[82], where adding MSCs to BBM led to more new bone formation compared with BBM combined with AB. In this study, Rickert *et al*^[82], in fact, described how BMSCs seeded on BBM particles could bring sufficient volume of new bone to allow clinicians to place endosseous implants with a comparable timing regarding to the use of AB or a mixture of AB + BBM. The slow resorption rate of BBM permits an adequate bone integration before scaffold resorption^[81-83]; however, the rate of non-mineralized material is generally high, even 6 mo after augmentation procedure^[81-83]. Finally, Fuerst *et al*^[84] examined the 12-mo histologic/histomorphometric and radiologic outcomes after MSA with autogenous culture-expanded bone cells and BBM. In total, 22 sinuses of 12 patients were grafted with AB cells seeded on BBM. Six months after MSA, during endosseous implants ($n = 82$) placement procedures, a

biopsy was taken from each sinus^[84]. The percent newly formed bone was determined on undecalcified histologic preparations. Graft stability was estimated using dental CT scans after MSA (CT 1), after implant insertion (CT 2) and after implant uncover (CT 3)^[84]. Despite a considerable reduction of the graft volume along time, AB cells and BBM provided an adequate bone volume, which permitted implant placement and tolerated functional loading^[84].

Synthetic porous CPC ceramics can support new bone apposition by MSCs *in vivo*^[86,87]. Osteoconductive scaffolds such as HA and beta-TCP have the ability to attract fibronectin and vitronectin, which are ligands for the integrin family of cell adhesion receptors; these proteins mediate adhesion of MSCs and osteoblast precursors^[20,21,86,87]. In addition, HA/beta-TCP degradation products may favour an alkaline microenvironment and provide calcium and phosphate ions requested for the mineralization of extracellular matrix phases during ossification process^[20,21,86,87]. Finally, microporosity of synthetic CPC (given by pores with a controlled size, communicating through interconnections) supports angiogenesis^[20,21,86,87]. Blood vessels carry cells and soluble signals that promote new bone apposition^[86,87]. In a recent study by Shayesteh *et al.*^[86], CPC has been used in combination with BMSCs in MSA. Six patients underwent MSA with BMSCs + HA/beta-TCP. Three and twelve months after MSA, a radiographic evaluation was performed^[86]. In total, 30 fixtures were inserted and a biopsy was taken from each implant site. Prosthetic rehabilitation were delivered after 4 mo. Clinical successful implant rate was 93% (28 implants over 30)^[86]. Histologic evaluation showed several areas of osteoid and bone formation without any inflammatory cell infiltration. Mean bone regenerate was 41.34%. No complications were clinically observed. Mean bone height was 12.0 mm, 10.0 mm, 3 and 12 mo after MSA, respectively^[86]. The authors concluded that sinus grafting with HA/beta-TCP seeded with BMSCs can offer reliable results^[86]. A previous study by Smiler *et al.*^[87] evaluated the effect of bone marrow aspirate added to xenografts or alloplast graft matrix scaffold (beta-TCP) to enhance bone formation in MSA. Clinical procedures involved harvesting four cc of bone marrow aspirate from the anterior iliac crest; these materials were seeded on matrix scaffold before sinus augmentation operations. Seven graft sites were evaluated in five patients; various MSA techniques were performed such as particulate onlay graft of the maxilla *via* a tunneling procedure, and particulate onlay graft of the maxilla stabilized with titanium mesh. Biopsies at 4 mo showed, in beta-TCP scaffolds, 40% a newly formed bone completely vital^[87]; there was 57% of interstitial material and 3% of residual graft scaffold^[87]. With these histological preparations, the authors presented evidence that stem cells aspirated from bone marrow and seeded onto beta-TCP scaffolds can be a useful method to obtain new bone in augmentation procedures^[87].

Synthetic polymeric materials are an interesting

category of materials. PLGA copolymer and its homopolymer derivatives have been considered for potential use in bone reconstruction procedures. MSCs have been associated to PLGA in MSA^[88-93]. MSCs were isolated from periosteum, re-suspended and cultured; the suspension was soaked in polymer fleeces and the cell-polymer association were used in MSA^[88-93]. Under specific conditions, periosteum-derived, tissue engineered bone grafts showed typical osteogenic differentiation characteristics such as: expression of alkaline phosphatase activity, bone gene expression and mineralization^[93]. Trautvetter *et al.*^[88] performed MSA with simultaneous dental implant placement; they used an autologous tissue-engineered periosteal bone grafts based on bioresorbable PLGA scaffolds. Ten patients were radiologically assessed 5 years after MSA; in addition, histologic evaluation was performed^[88]. The authors reported excellent outcomes after only 4 mo from surgical procedure; they observed significantly greater bone height over the 5-years follow-up observation period. Furthermore histological preparation from bone biopsies of two patients six months after surgery showed trabecular bone with osteocytes and active osteoblasts^[88]. Accordingly, the authors concluded that the use of autologous periosteal bone grafts with simultaneous dental endosseous implants placement is a valid procedure, with excellent clinical, radiographic and histologic outcomes^[88]. Although this clinical study^[88] and those of previous researches^[89,93] have reported that the newly formed bone provided by augmentation procedures, using tissue engineered bone grafts, allowed proper initial stability for dental implant placement^[89,90], the degradation rate of the PLGA scaffold may be too fast to maintain an optimal substrate to support bone formation^[90-92]. This was evidenced by a recent MSA study, where AB transplants from the iliac crest were compared with tissue engineered grafts (BMSCs loaded on PLGA scaffolds): this research showed considerable graft resorption (approximately 90%, in a 3 mo observation period) and less mineralization density in the sites augmented with tissue engineered bone^[92]. Two other comparative studies revealed that coral-derived HA^[90] and AB^[91] show greater volume maintenance than PLGA scaffolds cultured with MSCs. These studies showed that the significant resorption of the PLGA grafts may be an important problem in the clinical scenario, with potential failure of augmentation particularly in large areas^[90,91]. The fast resorption rate of the PLGA, in fact, represents an unfavourable factor for bone regeneration, making it impossible to provide mechanical stability to MSCs transplanted in the augmentation site. Osteoblasts must adhere to a stable structure to produce a new bone matrix that will be interested by consequent mineralization and maturation processes. In this way, a too fast and extended degradation of the supporting scaffold determines an instability of augmented area and then the probably failure of bone regeneration because of the collapse of newly formed, immature bone matrix^[90,91]. Supply of oxygen and nutrients is essential

to cells embedded within large cell-polymer constructs, in order to sustain their survival and proliferation^[89-92]. In addition, PLGA resorption generates a low pH that is detrimental to osteoblasts^[89-92].

Finally, two different clinical studies used an injectable tissue engineered bone, composed by BMSCs and PRP, to conduct MSA^[94,95]. In a recent study, Yamada *et al*^[94] evaluated the effects of an injectable tissue engineered bone on osteotome technique with simultaneous implant placement. Injectable bone, composed of BMSCs and PRP, was used as bone graft in 23 cases of MSA^[94]. The osteotome technique was used^[7]: after dental implant sites were pre-prepared with pilot drills and/or using the osteotomes, the injectable bone was inserted and then endosseous implants were placed. The bone regeneration technique was effective, as the lift-up bone height by injectable bone using BMSCs showed an increase of 6.1 ± 1.5 mm; the authors concluded that the application of injectable bone using osteotome technique can stably predict the success of bone formation and dental implants, providing also minimally

invasive cell therapy^[94]. These results confirmed those of a previous study by Ueda *et al*^[95] in which the height of mineralized tissue after 2 years showed a mean gain of 8.8 mm compared to pre-operative values. However, more studies are needed to understand the efficacy of injectable bone as a graft for MSA: this material has poor compressive and tensile strength^[94].

The histologic/histomorphometric results of all these human studies are reported in Table 2.

In vivo experiment meta-analysis

A meta-analysis of 9 studies (7 animal and 2 human studies) was performed to give a quantitative estimate of the mean difference of the newly formed bone between the two groups (stem cells + scaffold vs scaffold alone). We considered the mean difference in % newly formed bone at 12 wk as it was the most frequently reported time period; the latest examination period was at 8 wk in 4 studies, all of them on animals. All the analyses were conducted using Package Metafor (R version 2.14). The weighted mean difference estimate from a

Figure 2 Differences in regenerated bone between test and control groups from meta-analysis. RE: Reference.

random-effect model was 9.5% (95%CI: 3.6%-15.4%), suggesting a positive effect of stem cells on the bone re-growth (Figure 2). Heterogeneity was measured by the I^2 index. The formal test confirmed the presence of substantial heterogeneity ($I^2 = 83\%$, $P < 0.0001$). In an attempt to explain the substantial heterogeneity observed, we considered a meta-regression model with publication year, support type (animals vs humans) and follow-up length (8 or 12 wk) as covariates. After adding publication year, support type and follow-up length to the meta-regression model, heterogeneity was no longer significant ($I^2 = 33\%$, $P = 0.25$).

DISCUSSION

The finding that adult MSCs can be manipulated *in vitro* and subsequently form bone *in vivo* provides new therapeutic strategies for bone regeneration in dentistry.

Several researches have demonstrated that MSCs can be used in MSA: controlled experimental and clinical studies showed higher bone regeneration applying MSCs compared with controls. However, further clinical trials, which clearly demonstrate benefits of cell-based approach compared to conventional treatments are still needed: these studies should evaluate patient-based outcomes, including the time and cost-effectiveness of cell-based approaches.

In the future, the use of stem cells seeded on appropriated scaffold materials will dictates advances in bone regeneration: as a consequence, improvements upon current therapeutic strategies will depend on innovations in material science. It will be mandatory to search for appropriate scaffolds for MSCs, with adequate resorption rate and osteoconductive surface, over which new bone formation can occur.

The merger between these two disciplines - stem cell research and scaffold engineering - will draw the future of regenerative medicine.

COMMENTS

Background

Adult mesenchymal stem cells (MSCs) that can be obtained from several tissues represents the new frontier for bone regeneration, due to their proven ability to differentiate into functional osteoblast, capable to produce new bone. Maxillary sinus augmentation (MSA) enables rehabilitation with oral implants in the posterior maxilla. Fresh autogenous bone (AB) has been always considered the gold-standard for MSA, but limited availability and donor-site morbidity reduce its application. Several osteoconductive scaffolds, such as allografts, bovine bone mineral and synthetic bone grafts (calcium phosphate ceramics) have been used in MSA with clinically successful results, but these materials do not have cells and require more time for healing. The science of bone tissue engineering (BTE) aims to overcome this problem, as it promises to obtain bone regeneration through the use of scaffolds seeded with osteogenic cells, without harvesting AB from other anatomical sites.

Research frontiers

According to BTE, a bone substitute should possess the same biological and structural properties as native bone, and the fabrication of the ideal bone graft requires the manipulation of three essential elements: scaffold, growth factors and osteogenic cells. BTE is a multidisciplinary science, based on harvesting of living cells that are expanded and differentiated in laboratory, then seeded on an appropriate scaffold, capable to mimic the structures and physiological behaviour of natural tissues. Ultimately, these "engineered scaffold" are implanted in patients. In this context, cells are the basic unit for the regeneration strategy. Several cell types have been investigated for their application in bone regeneration: MSCs can be a suitable for this aim. The authors' present review aimed to investigate the effectiveness of MSCs in MSA, with different scaffold materials, in animals and humans.

Innovations and breakthroughs

In total, 39 studies (18 animal studies, 21 human studies) published over a 10-year period (between 2004 and 2014) were included in our present review; these studies were variables with respect to type, study design, follow-up, and results. Meta-analysis was performed on 9 studies (7 animal studies and 2

human studies): the weighted mean difference estimate from a random-effect model was 9.5% (95%CI: 3.6%-15.4%), suggesting a positive effect of MSCs on bone regeneration. These results are similar to those of previous reviews of the literature on the same topic, where a positive influence of MSCs on bone regeneration was evidenced.

Applications

The use of scaffolds seeded with MSCs seems to represent a safe and successful treatment procedure to achieve bone regeneration in MSA. In the coming years there will be a further, huge flood of new studies on MSA with MSCs. Accordingly, dental professionals/surgeons need to change the way they think and work, to adapt to a new challenging scenario that is increasingly driven by the fascinating concepts of BTE. BTE will change the world of dentistry, changing patients' expectations towards dental treatments: waiting to adopt or integrate these new techniques would leave oral surgeons decades behind.

Terminology

MSA is a surgical procedure to increase the amount of bone in the posterior maxilla by sacrificing some of the volume of the maxillary sinus. In case of tooth/teeth loss (due to caries, periodontal disease or traumatic injury) the alveolar process undergoes remodelling, usually losing both height and width; in addition, the floor of the sinus gradually becomes lower. This represents a problem for the correct placement of dental implants, which rely on osseointegration. The aim of MSA is to graft extra bone into the maxillary sinus, in order to support dental implant. BTE is a new science that combines cells, materials and growth factors, with the aim to obtain bone regeneration in the clinical field. While most definitions of tissue engineering cover a broad range of applications, in practice the term is closely associated with applications that repair or replace portions of or whole tissues (*i.e.*, bone, BTE: science that aims to achieve bone regeneration, without harvesting AB from other anatomical sites, through the use in combination of scaffolds, osteogenic cells and soluble signals).

Peer-review

Several studies have reported the potential for cell-based approaches in MSA; however, most of these are animal studies. Accordingly, further clinical studies, which clearly demonstrate benefits of cell-based approach compared to conventional treatments are still needed.

ABOUT COVER

Editorial Board Member of *World Journal of Stem Cells*, Kumiko Saeki, MD, PhD, Director, Division of Stem Cell Therapy, Department of Disease Control, Research Institute, National Center for Global Health and Medicine, 1-21-1 Toyama Shinjuku-ku, Tokyo 162-8655, Japan

AIM AND SCOPE

World Journal of Stem Cells (*World J Stem Cells*, *WJSC*, online ISSN 1948-0210, DOI: 10.4252), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJSC covers topics concerning all aspects of stem cells: embryonic, neural, hematopoietic, mesenchymal, tissue-specific, and cancer stem cells; the stem cell niche, stem cell genomics and proteomics, and stem cell techniques and their application in clinical trials.

We encourage authors to submit their manuscripts to *WJSC*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

INDEXING/ ABSTRACTING

World Journal of Stem Cells is now indexed in PubMed Central, PubMed, Digital Object Identifier, and Directory of Open Access Journals.

Abstract

Stem cell differentiation is regulated by multiple signaling events. Recent technical advances have revealed that differentiated cells can be reprogrammed into stem cells. The signals involved in stem cell programming are of major interest in stem cell research. The signaling mechanisms involved in regulating stem cell reprogramming and differentiation are the subject of intense study in the field of life sciences. In this review,

the molecular interactions and signaling pathways related to stem cell differentiation are discussed.

Key words: Stem cell; Signaling; Differentiation; Gene; Genome; Reprogramming

© **The Author(s) 2015.** Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: Signals in stem cell are regulated both genetically and epigenetically by many molecules. The programming of stem cell signaling is an important aspect of understanding stem cell phenotype transitions and functions. The differentiation process as well as intra- and inter-cellular signaling of stem cells is described in this article. The epigenetic regulation of these cells is also discussed.

Tanabe S. Signaling involved in stem cell reprogramming and differentiation. *World J Stem Cells* 2015; 7(7): 992-998 Available from: URL: <http://www.wjgnet.com/1948-0210/full/v7/i7/992.htm> DOI: <http://dx.doi.org/10.4252/wjsc.v7.i7.992>

INTRODUCTION

Stem cells are the source of all other cells, and they have the potential to differentiate into many types of cells that contribute to the various organs, such as the heart, lungs, liver, and blood. There are many kinds of stem cells: totipotent embryonic stem cells (ESCs) found in the embryo; mesenchymal stem cells (MSCs) that give rise primarily to bone marrow stroma, adipocytes, and cord blood; epithelial stem cells that reside in the intestine; induced pluripotent stem cells that are artificially reprogrammed from differentiated cells; and cancer stem cells (CSCs). In this article, signaling in stem cells and the role of signaling molecules in the differentiation and reprogramming of stem cells are discussed.

STEM CELL DIFFERENTIATION

Stem cell differentiation is tightly regulated. Among the various pathways related to cellular differentiation, epigenetic regulation is the key mechanism that controls midbrain dopaminergic neuron differentiation^[1]. Urocortin, which is expressed in the developing ventral midbrain, mediates dopaminergic neuron differentiation *via* the up-regulation of acetylated histone H3 and the dopaminergic regulators *Nurr1*, *Foxa2* and *Pitx3*^[1]. Dimethyl sulfoxide down-regulates the pluripotency genes *OCT4* (also known as *POU5F1*) and *NANOG* in human embryonic stem (ES) cells during definitive endoderm differentiation and controls hepatic differentiation^[2].

A previous report indicated that *N*⁶-methyladenosine (*m*⁶A) transferase (*Mettl3*; methyl transferase-like 3) regulates murine naïve pluripotency^[3]. mRNA methylation is a key RNA modification and an essential factor in epigenomic regulation and cell fate determination^[3]. Pluripotent cells are affected by environmental factors such as culture conditions, and such factors can affect the spatial regulations of transplanted stem cells^[4]. Several signaling pathways are involved in the transformation of stem cells, such as fibroblast growth factor 2 (FGF2)/Activin-A signaling and histone 3 lysine 4 trimethylation alterations^[4]. Matrix-bound heparan sulfate (HS) proteoglycans are needed for the differentiation of stem cell-derived endodermal cells into airway epithelial cells^[5]. The three-dimensional extracellular matrix scaffold is essential for effective functional expression of lung epithelial cells^[5], and HS proteoglycans also appear to play an important role in this process. Human ES cells differentiate into osteogenic cells, which can be identified by *RUNX2* expression^[6]. Monitoring the osteogenic differentiation of human ES cells is useful for the therapeutic strategies used in bone regeneration^[6]. The three-dimensional poly(L-lactic acid) scaffold culture of human ES cells on a nano-fibrous matrix results in enhanced osteogenic differentiation^[7]. *RUNX2* expression in nano-fibrous matrix culture is significantly higher than in control cultures^[7]. Additionally, an efficient method for the osteogenic differentiation of human ES cells using primary bone-derived cells has been reported^[8]. Some cellular factors from bone-derived cells may be involved in human ES cell differentiation^[8]. Cell surface proteins play roles in stem cell culture differentiation^[9]. The use of functionalized hyaluronic acid surfaces with either fibronectin or collagen enhances the attachment of human ES cells^[9]. During the osteogenic differentiation of human ES cells, hyaluronic acid surfaces with collagen I and collagen IV have inductive effects on differentiation compared to fibronectin alone^[9]. Transcription factors are regulated dynamically during human ES cell differentiation^[10]. Transcription factor binding dynamics are classified into static, dynamic, enhanced, and suppressed states^[10]. Transforming growth factor (TGF)- β and WNT signals are involved in human ES

cell differentiation into mesendoderm and endoderm, whereas bone morphogenetic protein (BMP), vascular endothelial growth factor, and FGF2 are key regulators of the differentiation of ES cells into mesoderm. The inhibition of TGF- β , WNT or BMP signals result in ES cell differentiation into ectoderm^[10]. *RUNX2* is down-regulated in late-stage cultures of MSCs^[11,12]. The osteogenic differentiation capacity is decreased in late-stage cultures of MSCs compared to early-stage cultures; thus, gene expression levels can be used as an indicator of stem cell differentiation capacity^[11]. Neural differentiation is regulated by epigenetic mechanisms^[13]. Deep cortical layer neuronal markers such as *BCL11B* are expressed in differentiated neurons derived from neuroepithelial and early radial glia, and superficial layer neuronal markers such as *POU3F2/POU3F3* and *MEF2C* are expressed in differentiated progeny derived from mid radial glia^[13]. Transcription factor activity is modulated dynamically during each stage of the neural progenitor population^[13]. In addition to intracellular molecular network signaling, intercellular communication is also an important factor in stem cell signaling. Human neural stem/progenitor cells (hNSCs) and peripheral blood mononuclear cells (PBMCs) interact with each other when co-cultured under allogenic conditions. hNSCs increase the production of regulatory T cells, while PBMCs promote the differentiation of hNSCs^[14]. The effect of intercellular communication on stem cell differentiation is an interesting topic for investigation. Cartilaginous tissue can be generated from human induced pluripotent stem (iPS) cells^[15]. In severe combined immunodeficiency (SCID) mice transplanted with human iPS cell-derived differentiated cartilaginous cells, cartilage formation without tumor formation is observed^[15].

STEM CELL SIGNALING

Tools for bioinformatics

A wealth of "big data" in gene and genome information, which has been collected *via* integrative profiling and is publically available on the internet, combined with recent advances in bioinformatics, have enabled us to analyze gene and signaling information. These advances include a useful web-accessible tool called the Database for Annotation, Visualization and Integrated Discovery (DAVID) Bioinformatics Resource (<http://david.abcc.ncifcrf.gov/home.jsp>) and the cBioPortal for Cancer Genomics (<http://www.cbioportal.org/index.do>)^[16,17]. The open-source tool Cytoscape is a molecular network analysis tool for integrating the networks with annotation and gene expression profiles (http://cytoscape.org/what_is_cytoscape.html).

Hedgehog pathway

Hedgehog (Hh) signaling is an important player in epithelial and mesenchymal regulation during embryonic limb and bone development and cell fate determination^[18-20]. Sonic Hh signaling is involved in

vascular differentiation and regulates human CD34-positive cell function^[20]. Hh signaling also has an important role in hematological CSCs^[21]. Targets of the Hh signaling pathway include the Notch pathway, the epithelial-mesenchymal transition (EMT) pathway, the WNT signaling pathway, the TGF- β signaling pathway, and the regulation of cell cycle, adhesion, fate determination, and stem cell signaling^[21].

Ephrin pathway

Ephrin signaling is involved in inflammatory bowel diseases^[22]. Bone marrow stem cells and stem cell factors play important roles in mucosal regeneration. In the intestine of a rat model of inflammatory bowel disease, ephrin-B3 is up-regulated in bone marrow MSCs during mucosal regeneration^[22]. Ephrin type-B receptor 3 (*EPHB3*), a tumor suppressor gene, is important in cancer cell metastasis, which is regulated by Notch signaling in colorectal cancers^[23]. *EPHB3* down-regulation in tumorigenesis correlates with Wnt/ β -catenin, Notch and mitogen-activated protein kinase (MAPK) signaling^[23]. EphrinA1 expression decreases as β -catenin expression is inhibited in liver tumor cells^[24]. The treatment of hepatocellular cancer with cell-permeable, gamma guanidine-based peptide nucleic acid antisense oligonucleotides resulted in the inhibition of β -catenin and Wnt target gene expression^[23]. The EphrinA1 receptor has been reported to be an independent prognostic marker for different survival endpoints in clear cell renal cell carcinoma^[25]. The use of Ephrin and ephrin receptor signaling as either a prognostic marker or for revealing cancer progression mechanisms is an interesting topic for future study.

WNT pathway

The WNT pathways regulate stem cell differentiation and proliferation. WNT3-WNT9B signaling is involved in the regulation of neural differentiation^[26]. An increase in WNT9B is reported to control the switch between pluripotent and differentiated states *via* noncanonical Rho/JNK signaling, whereas canonical WNT3/ β -catenin signaling promotes proliferation^[26]. WNT5A is known to promote cancer cell invasion and proliferation^[27]. WNT5A activation of the Wnt/ β -catenin-independent pathway, including Src family kinases, induces the proliferation of certain cancer cell types, such as HeLa S3 cervical cancer cells and A549 lung cancer cells^[27]. Interestingly, WNT5A is not involved in the proliferation of KKLS gastric cancer cells, although cancer invasion is dependent on the WNT5A pathway^[27]. Wnt5A up-regulation is reported to induce EMT and metastasis by pancreatic cancer cells^[28]. In this case, β -catenin-dependent canonical Wnt signaling is involved in promotion of EMT^[28]. Graphene oxide is reported to target CSCs by inhibiting a number of signaling pathways including the WNT, Notch and STAT pathways^[29]. Graphene oxide selectively inhibits CSC proliferation but does not affect normal fibroblast viability^[29]. STAT3 signaling alters the tumor microenvironment and angiogenesis and

promotes KRAS-induced lung tumorigenesis^[30]. The Wnt signaling pathway is reported to be down-regulated in irradiated tumor cells^[31]. Wnt signaling may be involved in tumor repopulation after radiotherapy^[31]. Notch1 and Delta-like 4 signals are important factors for cell fate decisions^[32]. The Notch pathway is a therapeutic target in cancer treatment^[32]. Interleukin-27 (IL-27) down-regulates EMT- and stemness-related genes such as *SONIC HEDGEHOG* in adenocarcinoma and *OCT4A*, *SOX2*, *NOTCH1*, *KLF4*, *Nestin*, *SNAI1/SNAI1*, *SNAI2/SLUG* and *ZEB1* in squamous cell carcinoma^[33]. *SNAI2*, an EMT-related gene, and stemness genes are known to be down-regulated by IL-27^[33]. WNT signaling modulation also mediates the long-term expansion and chondrogenic differentiation of adult human MSCs^[34]. WNT3A and FGF2 maintain the phenotype and multipotency of MSCs^[34]. In ES cells, cyclin-dependent kinase 1 (CDK1) inhibition is reported to prevent teratoma formation^[35]. CDK1 signaling and its association with other cancer signaling pathways such as the WNT pathway would be interesting topics for future study of the mechanisms of tumor formation by stem cells.

MicroRNA signaling

MicroRNAs (miRNAs) are involved in cancer cell signaling^[36]. The tumor microenvironment that maintains cancer cells is regulated by microRNA-mediated gene expression^[36]. Anti-miRNAs, antisense oligomers that inhibit onco-miRNAs, can be used as anti-cancer drugs^[36]. The conserved, well-established promoter of the terminal differentiation *let-7a* miRNA induces mitochondrial reactive oxygen species production and up-regulates oxidative stress-responsive genes^[37]. The regulation of energy metabolism in cancer cells *via let-7a* is a potential target of anti-cancer therapy because *let-7a* miRNA plays a tumor-suppressive role^[37]. Human MSCs that support the tumor microenvironment deliver tumor regulatory miRNAs *via* extracellular vesicular trafficking^[38]. The extracellular vesicles of hMSCs contain proteins and lipids on the vesicle membrane, and miRNAs and metabolites inside the vesicles^[38]. The internalization of these vesicles by cancer cells may be one of the key mechanisms for cancer cell survival^[38]. During the hypoxia-induced myogenic differentiation of ES cells, miRNA-26a is up-regulated and inhibits the mRNA expression of histone deacetylase 6 (*HDAC6*) and of stemness genes such as *Oct4* (also known as *Pou5f1*) and *Nanog*^[39]. miRNA-26a-mediated signaling may be important for stem cell differentiation^[39]. Hypoxia contributes to the development and phenotype of CSCs *via* miRNA- and cytokine-mediated microenvironmental regulation^[40]. The vascular CSC niche is regulated by miRNAs, which may induce CSC generation and EMT *via* the NFkB, PI3K/Akt/mTOR, NOTCH, Wnt/ β -catenin and Hedgehog signaling pathways^[40].

In the murine cortex and hippocampus, subclasses of neurons and glial cells have been characterized by the expression of regulatory genes using large-scale

single-cell RNA sequencing^[41]. These cells exhibit differential gene expression and epigenetic regulation and miRNAs have recently become a focus of these processes as selective cell markers^[42]. Glioma cells expressing miR-302 are enriched by serum deprivation, and miR-302 may be a marker of CSCs^[42]. miRNA-30c plays a role in sphere formation, self-renewal and neural differentiation in C6 glioma cells^[43]. In these cells, the astrocyte marker glial fibrillary acidic protein (GFAP) is up-regulated during differentiation. However, GFAP expression decreases in miRNA-30c-overexpressing cells^[43]. The fate of neural stem cells is also regulated by miRNAs^[44]. The differentiation of neural stem cells into neurons is promoted by kuwanon V, a phytochemical isolated from mulberry tree (*Morus bombycis*) roots that may up-regulate the expression of miR-9, miR-29a and miR-181a^[44]. Cancer stem cell self-renewal, differentiation and tumorigenesis are regulated by the Notch pathway, in which miRNAs such as the miR-34 family, miR-200 family, and miR-199-5p, miR-146a, miR-1 and miR-143 play important roles^[45]. Notch signaling cross-talk with miRNAs may be involved in cancer cell proliferation, which suggests possible therapeutic approaches *via* miRNA re-expression in cancer^[45]. Moreover, genome-wide analysis has revealed that long noncoding RNAs (lncRNAs) are regulated by Notch signals in acute leukemia^[46]. lncRNAs are defined as transcripts of greater than 200 nucleotides that function by means other than coding for proteins, and regulate active and silent chromatin states^[47]. Pluripotent states are epigenetically regulated by lncRNAs^[47]. Epigenetic modifications in pluripotency are conducted *via* several steps such as histone modifications, DNA methylation and chromatin remodeling^[48]. miRNA expression is also regulated in atherosclerosis^[49]. Endothelial miRNA expression profiling *in silico* is one area for future study of miRNA signaling^[49].

CELLULAR REPROGRAMMING

Stem cells can be reprogrammed from differentiated cells^[50]. The abundant genes including *CDH1*, *RGS1*, and *NOTCH1* are related to the cell characteristics such as MSCs and gastric cancer cells^[51]. A recent study revealed that neural stem cells could be reprogrammed from adult fibroblasts, senescent somatic cells, and blood cells by HMGA2/let-7^[52]. These induced neural stem cells could be successfully differentiated into neurons, astrocytes, and oligodendrocytes *in vitro* and *in vivo*^[52]. The clinical application of reprogrammed iPS cells has also been attempted^[53]. The transplantation of reprogrammed cells efficiently overcame spinal cord injury in mice; however, the possibility of tumorigenesis is a concern during long-term therapy^[53]. One of the mechanisms of tumor development in transplanted iPS cells seems to be the acquisition of mesenchymal features such as either snail up-regulation or epithelial-mesenchymal transition^[53]. Careful investigation and gene expression analysis are needed before iPS cells can

be utilized in clinical settings^[53]. The selective targeting of human iPS cells to avoid tumorigenesis has been described using a stem cell-specific lectin probe and *Pseudomonas aeruginosa* exotoxin A fusion proteins^[54]. iPS cells are reprogrammed from cancer cells that are used as a carcinogenesis model^[55]. The expression of pluripotency associated genes such as either *Oct4* (also known as *Pou5f1*) or *Nanog* is regulated by the bromodomain and extraterminal domain family member BRD4^[56]. BRD4 regulates transcription by binding to acetylated histones^[56]. The induced differentiation of human iPS cells by interleukin-3/granulocyte colony-stimulating factor results in CD45⁺CD11b⁺CD14⁺CD163⁺CD68⁺ monocyte/macrophage-type cell formation^[57]. Mesenchymal-amoeboid transition is a suggested mechanism by which cancer cells might adopt a migration mode^[58]. The cell migration mode is characterized by three qualities: adhesion, confinement, and contractility^[58]. The change in cell phenotype that occurs during reprogramming may be related to migration parameters. *WNT5A* is reported to be up-regulated in MSCs compared to diffuse-type gastric cancer cells^[59]. Genes related to EMT such as *WNT5A* or *NOTCH2* may have roles in maintaining mesenchymal features^[59]. A genome-wide analysis of chromatin interactions in human ES cells, ES cell-derived mesendoderm, MSCs, neural progenitor cells and trophoblast-like cells revealed that 36% of active and inactive chromosomal compartment alterations occur during differentiation^[60]. An integrative analysis of 111 reference human epigenomes has been performed by the NIH Roadmap Epigenomics Consortium; this analysis profiled histone modification patterns and gene regulation in several cell types and found that each identified mechanism of genetic regulation targets different tissues and cell types in human biology and disease^[61].

The analysis of adipose-derived stem cell differentiation has revealed that keratinocyte progenitor cells are present in adipose tissue^[62]. The reprogramming of fibroblasts into iPS cells requires WNT signaling^[63]. The efficiency of cell reprogramming is regulated by WNT signaling in fibroblasts^[63]. Single-cell mass cytometry has revealed that iPS cell reprogramming is related to mesenchymal-epithelial transition (MET)^[64]. A time-resolved progression analysis of iPS cell reprogramming has revealed that the expression patterns are altered at each time point and that some similarities exist between Oct4-GFP, Nanog-Neo, and Nanog-GFP mouse embryonic fibroblast reprogramming systems^[64]. NANOG, which regulates the pluripotency and reprogramming of iPS cells, binds to the OCT4 promoter, and its mutation enhances ES cell self-renewal^[65].

In early-stage diabetic endothelial progenitor cells, the expression of anti-oxidative enzymes compensates for oxidative stress levels^[66]. The relationship between oxidative stress and progenitor cell function may be an interesting future topic for future study of the reprogramming process. The expansion of human

ES cells can be successfully maintained using MSC feeder layers^[67]. Considering that xenogeneic-free culture conditions are necessary for safe advances in regenerative medicine, the mechanisms that maintain pluripotent status and induce differentiation in the cellular microenvironment should be investigated.

CONCLUSION

In conclusion, stem cells have diverse internal signaling and communicate with surrounding cells. This communication among cells, such as immune cells and cancer cells, through signaling proteins and molecules leads to dramatic alterations in cell responses and pathological physiology. The intra- and inter-cellular signaling pathways in the cellular microenvironment must be elucidated to safely manipulate stem cells and program signaling cascades for therapeutic applications. Abundant data about cellular gene expression, genomics and epigenomics, which are “big-data”, and database analyses are publically available *via* the internet and will contribute to our understanding of cell phenotype transition and the mechanisms that regulate various cell populations in the context of disease and therapy.

Abstract

Stem cells offer great promise for the treatment of multiple disorders throughout the body. Critical to this premise is the ability to govern stem cell pluripotency, proliferation, and differentiation. The mechanistic target of rapamycin (mTOR), 289-kDa serine/threonine protein kinase, that is a vital component of mTOR Complex 1 and mTOR Complex 2 represents a critical pathway for the oversight of stem cell maintenance. mTOR can control the programmed cell death pathways of autophagy and

apoptosis that can yield variable outcomes in stem cell survival and be reliant upon proliferative pathways that include Wnt signaling, Wnt1 inducible signaling pathway protein 1 (WISP1), silent mating type information regulation 2 homolog 1 (*Saccharomyces cerevisiae*) (SIRT1), and trophic factors. mTOR also is a necessary component for the early development and establishment of stem cells as well as having a significant impact in the regulation of the maturation of specific cell phenotypes. Yet, as a proliferative agent, mTOR can not only foster cancer stem cell development and tumorigenesis, but also mediate cell senescence under certain conditions to limit invasive cancer growth. mTOR offers an exciting target for the oversight of stem cell therapies but requires careful consideration of the diverse clinical outcomes that can be fueled by mTOR signaling pathways.

Key words: Apoptosis; Autophagy; Cancer; Cardiovascular; Erythropoietin; Mechanistic target of rapamycin; Neurodegeneration; Progenitor stem cells; Silent mating type information regulation 2 homolog; Wnt1 inducible signaling pathway; Wnt

MECHANISTIC TARGET OF RAPAMYCIN SIGNALING

The mechanistic target of rapamycin (mTOR) is a

289-kDa serine/threonine protein kinase that is encoded by a single gene *FRAP1*^[1,2]. mTOR, also known as the mammalian target of rapamycin and the FK506-binding protein 12-rapamycin complex-associated protein 1, oversees a complex array of cellular functions that involve gene transcription, cellular proliferation, senescence, metabolism, survival, and cellular death. The target of rapamycin (TOR) was initially identified in *Saccharomyces cerevisiae* with the genes *TOR1* and *TOR2* that encode two isoforms in yeast Tor1 and Tor2 through the use of rapamycin-resistant TOR mutants^[3]. Rapamycin is a macrolide antibiotic derived from *Streptomyces hygroscopicus* that can inhibit TOR as well as mTOR activity.

mTOR is a vital component for the function of the protein complexes mTOR Complex 1 (mTORC1) and mTOR Complex 2 (mTORC2) (Figure 1)^[4-7]. Rapamycin primarily inhibits mTORC1 by blocking mTOR phosphorylation^[8]. However, mTORC2 activity can be limited during chronic administration of rapamycin. mTORC1 is composed of Raptor (Regulatory-Associated Protein of mTOR), the proline rich Akt substrate 40 kDa (PRAS40), Deptor (DEP domain-containing mTOR interacting protein), and mLST8/GβL (mammalian lethal with Sec13 protein 8, termed mLST8). Phosphorylation of Raptor through the protein Ras homologue enriched in brain (Rheb) leads to mTORC1 activation. PRAS40 is inhibitory to mTOR activity and can prevent the binding of mTORC1 to Raptor^[9]. Phosphorylation of PRAS40 by protein kinase B (Akt) frees PRAS40 from Raptor and allows PRAS40 to be sequestered by the cytoplasmic docking protein 14-3-3 to activate mTORC1^[4-7]. Similar to PRAS40, Deptor inhibits mTORC1 activity through the binding of the FAT domain of mTOR (for FKBP associated protein, Ataxia-telangiectasia, and Transactivation/transformation domain-associated protein). In contrast to PRAS40 and Deptor, mLST8 fosters mTOR kinase activity through p70 ribosomal S6 kinase (p70S6K) and the eukaryotic initiation factor 4E (eIF4E)-binding protein 1 (4EBP1) that bind to Raptor^[10]. PRAS40 can block mTORC1 activity by preventing p70S6K and 4EBP1 to associate with Raptor^[9,11].

mTOR activity also is controlled by Akt and AMP activated protein kinase (AMPK) through the hamartin (tuberous sclerosis 1)/tuberin (tuberous sclerosis 2) (TSC1/TSC2) complex (Figure 1)^[12,13]. TSC2 is considered to be a principal site to govern the activity of the TSC1/TSC2 complex that is an inhibitor of mTORC1. As a GTPase-activating protein (GAP) that can convert Ras homologue enriched in brain (Rheb-GTP) to the inactive GDP-bound form (Rheb-GDP), TSC2 prevents the activity of Rheb-GTP and blocks mTORC1 activity by limiting binding of 4EBP1 to mTORC1. Akt can phosphorylate TSC2 to disrupt the TSC1/TSC2 complex, force TSC2 to be sequestered by the cytoplasmic protein 14-3-3, and activate mTORC1^[14]. It should be noted that under some cellular protection scenarios, a limited activity of TSC2 as well as AMPK appears necessary since complete knockdown of TSC2 can prevent cellular

protection^[15].

AMPK also provides a mechanism to control the activity of the TSC1/TSC2 complex, but in contrast to Akt serves to promote TSC2 activity and block mTORC1 function. AMPK phosphorylates TSC2 to enhance GAP activity to process Rheb-GTP into Rheb-GDP that can then block mTORC1 activity. Interestingly, AMPK can influence sirtuin (silent mating type information regulation 2 homolog) 1 (*S. cerevisiae*) (SIRT1) activity that can be critical for stem cell survival and proliferation^[16]. AMPK increases the cellular NAD⁺/NADH ratio that results in the deacetylation of the SIRT1 targets peroxisome proliferator-activated receptor-γ coactivator 1 (PGC-1α) and forkhead transcription factors FoxO1^[17] and FoxO3a^[18]. AMPK also can increase nicotinamide phosphoribosyltransferase (NAMPT) activity that catalyzes the conversion of nicotinamide to nicotinamide mononucleotide^[19], increases nicotinamide adenine dinucleotide (NAD⁺) levels, decreases levels of the SIRT1 inhibitor nicotinamide, and promotes SIRT1 transcription^[20-22]. SIRT1 up-regulation in combination with AMPK activation promotes the induction of autophagy that can protect endothelial cells exposed to oxidized low-density lipoproteins^[23]. Similar to AMPK that is an inhibitor of mTOR, SIRT1 appears to exert its effects over cellular proliferation through blockade of mTOR^[24]. SIRT1 inhibits mTOR activity to preserve the integrity of embryonic stem cells during oxidant stress^[25]. SIRT1 also inhibits mTOR signaling to foster neuronal growth^[26] and assist with mesangial cell proliferation during high glucose exposure^[27].

In relation to mTORC2, this complex consists of Rictor (Rapamycin-Insensitive Companion of mTOR), mLST8, Deptor, the mammalian stress-activated protein kinase interacting protein (mSIN1), and the protein observed with Rictor-1 (Protor-1)^[28-33]. Rictor and mSIN1 through mTORC2 can activate Akt to promote cell survival^[11,29,34]. Protor-1 is a Rictor-binding subunit of mTORC2 and is believed to activate serum and glucocorticoid induced protein kinase 1 (SGK1), since loss of Protor-1 reduces the hydrophobic motif phosphorylation of SGK1 and the substrate N-Myc down-regulated gene 1 in the kidney (NRDG1)^[35]. mTORC2 is a member of the protein kinase A/protein kinase G/protein kinase C (AGC) family of protein kinases and is activated by growth factors to control ion transport. mTORC2 also controls cytoskeleton remodeling through protein kinase C-α (PKCα) and oversees cell migration through the Rac guanine nucleotide exchange factors P-Rex1 and P-Rex2 and through Rho signaling. In contrast to mTORC1, mTORC2 is activated by the TSC1/TSC2 complex through the N-terminal region of TSC2 and the C-terminal region of Rictor^[36].

MECHANISTIC TARGET OF RAPAMYCIN AND STEM CELL PROGRAMMED CELL DEATH

mTOR is an important component in the control of

Figure 1 The components of the mechanistic target of rapamycin regulatory pathways. The mechanistic target of rapamycin (mTOR) is an important component of mTOR Complex 1 (mTORC1) and mTOR Complex 2 (mTORC2). The function and activity of mTOR is controlled by multiple pathways that include protein kinase B (Akt), AMP activated protein kinase (AMPK), and the hamartin (tuberous sclerosis 1)/tuberin (tuberous sclerosis 2) (TSC1/TSC2) complex. mTORC1 is consists of Raptor (Regulatory-Associated Protein of mTOR), the proline rich Akt substrate 40 kDa (PRAS40), Deptor (DEP domain-containing mTOR interacting protein), and mLST8/GβL (mammalian lethal with Sec13 protein 8, termed mLST8). mTORC2 is composed of Rictor (Rapamycin-Insensitive Companion of mTOR), mLST8, Deptor, the mammalian stress-activated protein kinase interacting protein (mSIN1), and the protein observed with Rictor-1 (Protor-1).

programmed cell death that involves autophagy and apoptosis for stem cell proliferation and survival (Figure 2). The process of autophagy recycles cytoplasmic components to remove defective organelles that can no longer be used by the cell^[37]. Autophagy has three categories of chaperone-mediated autophagy, microautophagy, and macroautophagy^[38]. Chaperone-mediated autophagy uses cytosolic chaperones that transport cytoplasmic components across lysosomal membranes^[39]. Microautophagy sequesters components of the cytoplasm through invagination of the lysosomal membrane for digestion^[40]. The most prevalent of the three categories is macroautophagy that sequesters cytoplasmic proteins and organelles into autophagosomes. These autophagosomes then fuse with lysosomes for degradation and are recycled for future use^[24,41].

In yeast and mammals, TOR and mTOR are associated with genes that control autophagy^[4,6,42]. At least 33 autophagic related genes (*Atg*) have been identified in yeast that can affect multiple disorders including cancer, diabetes, vascular disease, and neurodegenerative disorders^[37,38,40,43-48]. In this group, Atg1 and Atg13 (also known as Apg13) are associated with phosphoinositide 3-kinase (PI 3-K), Akt, and the TOR pathways. When Atg13 is dephosphorylated such as during starvation, Atg1 is active to promote autophagy. Phosphorylation of Atg13 through a TOR dependent pathway releases it from Atg1 and lessens Atg1 activity. In mammals, the homologues of Atg1 are UNC-51 like kinase 1 (ULK1) and ULK2^[4]. Mammalian Atg13 binds to ULK1, ULK2, and FIP200 (focal adhesion kinase family interacting protein of 200 kDa) to activate

ULKs, promote phosphorylation of FIP200 by ULKs, and lead to the induction of autophagy^[49]. Activation of mTOR prevents the induction of autophagy by phosphorylating Atg13 and ULKs to inhibit the ULK-Atg13-FIP200 complex.

Autophagy can become a vital determinant for stem cell survival and proliferation. In some stem cell populations, activation of autophagy can lead to stem cell demise. Breast cancer stem cells have been shown to succumb to apoptosis during the activation of autophagy and the inhibition of Wnt signaling^[46]. Wnt proteins are cysteine-rich glycosylated proteins that oversee stem cell proliferation and tumor cell growth^[50-56]. Reduction in autophagy also may prevent the development of cellular senescence^[57]. Endothelial progenitor cells that lead to the regeneration of vascular endothelium become dysfunctional during exposure to elevated glucose as a result of autophagy activity^[58].

However, under other conditions, autophagy appears critical for stem cell survival. In endothelial progenitor cells, SIRT1 activity prevents apoptotic cell death during oxidative stress through the induction of autophagy^[59]. In human embryonic stem cells challenged with oxidative stress, autophagy was found to be protective and required SIRT1 activity with the down-regulation of mTOR^[25]. Furthermore, activation of SIRT1 is necessary to promote autophagy to maintain proteostasis, produce energy during nutrient deprivation, and maintain muscle stem cell activation^[60]. In such cases, SIRT1 may have an inverse relationship with mTOR to foster stem cell survival^[16,20].

The programmed cell death pathway of apoptosis also has an important role with mTOR signaling and

Figure 2 Mechanistic target of rapamycin governs stem cell development, pluripotency, survival, and differentiation. The mechanistic target of rapamycin (mTOR), mTOR Complex 1 (mTORC1), mTOR Complex 2 (mTORC2), protein kinase B (Akt), AMP activated protein kinase (AMPK), and the hamartin (tuberous sclerosis 1)/tuberin (tuberous sclerosis 2) (TSC1/TSC2) complex each play a role in stem cell development and proliferation with downstream pathways. Stem cell maintenance and survival is reliant upon mTOR signaling pathways that work in concert with Wnt signaling, Wnt1 inducible signaling pathway protein 1 (WISP1), silent mating type information regulation 2 homolog 1 (*S. cerevisiae*) (SIRT1), and trophic factors such as erythropoietin (EPO). Stem cell development is under the regulation of Wnt and WISP1. Regulation of mTOR can control stem cell differentiation and stem cell pluripotency. As a result, mTOR signaling pathways have oversight of stem cell development, pluripotency, survival, and differentiation.

stem cell survival^[61]. During the early stages of apoptotic cell injury, the loss of plasma membrane lipid phosphatidylserine (PS) asymmetry occurs^[62-64]. If membrane PS externalization is not reversed and allowed to remain, inflammatory cells are activated that seek out membrane PS positive cells to engulf and remove these cells. Under such circumstances, these membrane PS positive cells may remain functional but their ultimate loss leads to tissue injury^[65-71]. During the later phase of apoptotic cell injury, cellular DNA is destroyed which is usually not considered a reversible process^[72-75]. During most conditions, activation of mTOR and its related pathways of PI 3-K and Akt can block apoptotic cell death in stem cells. Inhibition of mTOR, such as with rapamycin, leads to endothelial progenitor cell apoptotic death that may be related to inhibition of growth factor signaling^[76]. Growth factors that include erythropoietin (EPO)^[77,78] are cytoprotective against apoptosis through mTOR activity against sepsis-associated encephalopathy^[79], oxidative stress^[80], cerebral microglial injury^[81], and beta-amyloid (A β) toxicity^[82]. EPO has been shown to protect retinal progenitor cells from apoptotic cell death during oxidative stress through activation of the PI 3-K, Akt, and mTOR pathways (Figure 2)^[83]. Interestingly, protection with EPO and mTOR may be lost with high exogenous EPO concentrations, since elevated concentrations of EPO result in decreased phosphorylation and activity of mTOR with subsequent increased apoptotic cell death^[84]. Similar to EPO, other growth factors rely upon mTOR to maintain stem cell

integrity (Figure 2). In murine experimental models, mTOR is used by the growth factors epidermal growth factor (EGF) and fibroblast growth factor (FGF) that are protective of stem cells and neurons^[85-89] to maintain the proliferation of neural stem and progenitor cells^[90]. EGF also uses the PI 3-K, Akt, and mTOR pathways to block cell injury such as during metabolic stress^[91] and prevent memory impairment^[92]. The growth factor brain derived neurotrophic factor (BDNF) relies upon mTOR activation for memory consolidation^[93]. However, in some experimental models with growth factors, mTOR blockade with the induction of autophagy may take precedent over the inhibition of apoptosis to prevent cellular injury. During oxygen deprivation, cortical neurons are protected by BDNF through the induction of autophagy and the inhibition of mTOR^[94].

MECHANISTIC TARGET OF RAPAMYCIN CONTROL OF STEM CELL PROLIFERATION AND MAINTENANCE

mTOR governs the proliferation and maintenance of stem cell in multiple systems of the body (Figure 2)^[4]. The loss of the *mTOR* gene leads to limited trophoblast growth, faulty implantation, and inability to establish embryonic stem cells^[95]. A decrease in proliferation of embryonic stem cells occurs during the deletion of the C-terminal six amino acids of mTOR that blocks the kinase activity of mTOR^[96]. mTOR can maintain long-term undifferentiated growth of human embryonic

stem cells. Inhibition of mTOR promotes pluripotency, cell proliferation, and blocks mesoderm and endoderm activities in embryonic stem cells^[97]. mTOR activity also leads to mesenchymal stem cell senescence^[98]. Yet, under some conditions, activation of mTOR signaling components can lead to cell differentiation. In embryonic stem cells, mTOR signaling with p70S6K is limited, but once this signaling is increased, differentiation ensues^[99].

In the nervous system, loss of mTORC1 activity in neural stem cells leads to reduced lineage expansion, prevention of differentiation, and blocked neuronal production^[100]. Loss of mTOR activity during aging may influence decreased neurogenesis. In the aged brain, mTOR signaling is reduced which leads to a reduction in the proliferation of active neural stem cells^[101]. mTOR activity appears important for the timing and control of neurogenesis. Inhibition of mTOR through the RTP801/REDD1 pathway delays neuronal differentiation. However, in newborn and mature neurons, levels of RTP801/REDD1 are diminished with increased mTOR activity to allow for the maturation of neurons^[102]. Expression of mTOR is necessary for the neuronal phenotype of post mortem neuronal precursors^[103]. Yet, the degree of mTOR activity may independently affect different populations of stem cells since in this model inhibition of mTOR activity leads to cell differentiation into astrocytic cells^[90]. Akt and mTORC1 inhibition also has been shown to result in reduced neuronal stem cell self-renewal and earlier neuronal and astroglial differentiation^[104]. Neighboring cells also may influence the growth of neuronal stem cells. Endothelial cells can promote mTOR activity and lead to the expansion of long-term glioblastoma stem-like cells^[105].

In the cardiovascular system, mTOR is one of several components necessary for the proliferation of human embryonic stem cell-derived cardiomyocytes^[106]. The activity of mTOR also controls the proliferation of hematopoietic stem and progenitor cells^[107]. Maintenance of hematopoietic stem cells and inhibiting differentiation is tied to mTOR signaling and the reduction in phosphorylation of p70S6K^[108]. Failure of endothelial progenitor cell development may be the result of decreased growth factor signaling and loss of mTOR activity^[76]. Growth factors such as EPO have been shown to require mTOR activation to regulate bone homeostasis with osteoblastogenesis and osteoclastogenesis^[109]. Differentiation of neural precursor cells that may be used for neurodegenerative disorders also is dependent upon EPO and mTOR^[103]. mTOR may be necessary to increase angiogenesis from endothelial progenitor cells that may provide neuroprotection during cerebral ischemia^[110]. The ability of human amniotic fluid stem cells to influence the differentiation of embryonic kidney cells is dependent upon mTOR activity^[111].

During tumorigenesis, mTOR activation may affect neural precursor and oligodendroglial precursor cells to promote high-grade glioma proliferation^[112]. Blockade of

mTOR can prevent the conversion of astrocytoma cells to oligodendroglioma cells that can lead to glioblastoma multiforme^[113]. Inhibition of mTOR signaling may reduce the population of cancer stem cells that can lead to disease recurrence and therapeutic resistance^[114].

Under some conditions, mTOR may be protective against tumor cell growth by inhibiting proliferative pathways of Wnt. Wnt signaling can lead to rapid cell proliferation and cancerous growth, but in epithelial stem cells this process is blocked by mTOR that maintains cell senescence and prevents tumor growth^[115]. Wnt may result in malignant melanoma^[116], metastatic disease^[117-120], and glioma proliferation^[121,122]. It should be recognized that Wnt signaling also leads to beneficial and cytoprotective effects^[52,54,123-125]. Loss of Wnt can result in human monocyte injury^[126], impairment in bone repair^[127], spinal cord injury^[125], loss of neurogenesis^[128], inhibition of wound healing^[129], loss of stem cell differentiation^[130], programmed cell death^[38,66,131], and defects in placental development^[132]. Wnt signaling activation can block inflammatory cell loss during neurodegenerative disorders^[66,70,82,133], prevent cerebral ischemia^[134,135], and protect cells during experimental diabetes^[136-138]. Furthermore, trophic factors employ cytoprotective pathways of Wnt to prevent cerebral endothelial cell injury^[137], preserve mesenchymal stem cells^[139], block apoptosis during forkhead transcription factor activation^[136,140], promote the maintenance of immune cells in the nervous system^[81], and prevent A β toxicity in cerebral microglia^[82]. However, prolonged exposure of growth factors such as EPO that rely upon Wnt signaling can have ill effects with the proliferation of cancer^[141-143], inflammation, and blood-brain barrier injury^[144].

In the Wnt signaling pathway, Wnt1 inducible signaling pathway protein 1 (WISP1), also known as CCN4, is a member of the six secreted extracellular matrix associated CCN family of proteins that are involved in cellular survival and stem cell proliferation^[145]. WISP1 can activate the components of the mTOR pathway that determine stem cell survival (Figure 2)^[21]. WISP1 increases mTOR activity by blocking the inhibitory actions of the mTOR component PRAS40^[146]. WISP1 controls the post-translational phosphorylation of AMP activated protein kinase (AMPK), a pathway involved in stem cell proliferation and cellular metabolism^[12,147]. WISP1 differentially decreases phosphorylation of TSC2 at Ser¹³⁸⁷, a target of AMPK, and increases phosphorylation of TSC2 at Thr¹⁴⁶², a target of Akt^[15].

As a tightly linked pathway to mTOR, WISP1 can significantly influence stem cell survival and proliferation. During stem cell migration, WISP1 expression is increased^[148]. WISP1 is differentially regulated during human embryonic stem cell and adipose-derived stem cell differentiation. WISP1 expression is increased during human adipocyte differentiation^[149] and is repressed in adipose-derived stem cells during hepatic differentiation^[51]. WISP1 can modulate induced pluripotent stem cell reprogramming^[150,151]. WISP1 is

one of several genes that are over-expressed during pancreatic regeneration^[152]. WISP1 also may support vascular regeneration during saphenous vein crush injury^[153]. WISP1 oversees cellular senescence^[154] and does not appear to foster excessive cellular proliferation under circumstances involving aging vascular cells^[155]. However, as a proliferative agent, WISP1 can lead to excessive cell growth. WISP1 may promote distant metastatic disease^[156] and WISP1 expression is increased in neurofibromatosis type 1 tumorigenesis^[157]. Variants of WISP1 can be extremely aggressive in promoting cell growth^[158] in comparison to non-variant WISP1 expression that may be protective under specific scenarios and block tumor cell invasion, motility, and metastases^[159].

FUTURE CONSIDERATIONS

Stem cells represent an important strategy as well as a vital experimental tool for the treatment of multiple disorders that can affect diverse systems of the body that include the brain, cardiovascular system, metabolism, and tumor cell growth. mTOR, a 289-kDa serine/threonine protein kinase and a critical component for the protein complexes of mTORC1 and mTORC2, oversees cellular development, proliferation, and senescence that can directly impact stem cell maintenance, proliferation, and differentiation.

Although mTOR is a highly attractive target to control stem cell maintenance and differentiation, the complexity of this system raises a number of considerations. How does mTOR interface with programmed cell death pathways that can directly affect stem cell populations? mTOR regulates the programmed cell death pathways of autophagy and apoptosis that have a complex outcome in stem cell survival. Through the modulation of Wnt signaling, activation of autophagy that necessitates inhibition of mTOR can block breast cancer stem cell growth. Yet, activation of autophagy that may work in concert with SIRT1 has been shown to play a vital role to maintain muscle stem cell activation and the protection of endothelial progenitor cells. Apoptosis that consists of both an early stage with membrane PS externalization and a late stage involving the destruction of genomic DNA usually relies upon activation of mTOR and its related pathways of PI 3-K, Akt, and growth factors such as EPO, EGF, FGF, and BDNF to block apoptotic cell death in stem cells. However, during some toxic environments, stem cells that become differentiated may require the induction of autophagy with mTOR inhibition to prevent apoptotic cell death.

Another consideration for mTOR is its variable role in the maintenance of stem cell populations and the eventual differentiation of cells into specific phenotypes. mTOR is necessary for trophoblast growth, implantation, the establishment of embryonic stem cells, and the maintenance of pluripotency. Loss of mTOR, such as in the aged brain, may be a factor that results in the

reduction of the proliferation of active neural stem cells. Yet, mTOR signaling that can involve p70S6K also affects the modulation of stem cell genesis and cellular differentiation. The activation of mTOR rather than its inhibition can be necessary for stem cell differentiation as well as the ability to selectively promote the maturation of specific cell phenotypes. The control of stem cell development, migration, and proliferation by mTOR can be dependent upon both Wnt and WISP1 signaling.

Ultimately, consideration also must be given for the role mTOR plays to block tumorigenesis and the ability of mTOR signaling to at times accelerate tumor cell growth. Given its proliferative role, mTOR can foster cancer stem cell development and the conversion of differentiated cells into cells that have invasive growth. The degree of mTOR activity may be critical during tumorigenesis, since mTOR in some cell populations can either maintain cell senescence and prevent tumor growth or conversely promote cancer stem cell development that can lead to disease recurrence and therapeutic resistance. By clearly addressing the challenges that lie ahead, targeting mTOR and its signaling pathways offer an exciting approach to translate the development and utilization of stem cells into new therapeutic strategies for multiple disease entities.

Abstract

Medical research in regenerative medicine and cell-based therapy has brought encouraging perspectives for the use of stem cells in clinical trials. Multiple types of stem cells, from progenitors to pluripotent stem cells, have been investigated. Among these, dental pulp stem cells (DPSCs) are mesenchymal multipotent cells coming from the dental pulp, which is the soft tissue within teeth. They represent an interesting adult stem cell source because they are recovered in large amount in dental pulps with non-invasive techniques compared to other adult stem cell sources. DPSCs can be obtained from discarded teeth, especially wisdom teeth extracted for orthodontic reasons. To shift from promising pre-clinical results to therapeutic applications to human, DPSCs must be prepared in clinical grade lots and transformed into advanced therapy medicinal products (ATMP). As the production of patient-specific stem cells is costly and time-consuming, allogenic biobanking of clinical grade human leukocyte antigen (HLA)-typed DPSC lines provides efficient innovative therapeutic products. DPSC biobanks represent industrial and therapeutic innovations by using discarded biological tissues (dental pulps) as a source of mesenchymal stem cells to produce and store, in good manufacturing practice (GMP) conditions, DPSC therapeutic batches. In this review, we discuss about the challenges to transfer biological samples from a donor to HLA-typed DPSC therapeutic lots, following regulations, GMP guidelines and ethical principles. We also present some clinical applications, for which there is no efficient therapeutics so far, but that DPSCs-based ATMP could potentially treat.

Key words: Adult stem cells; Multipotent stem cells; Cell-based therapy; Cell tissue bank

Core tip: To achieve clinical applications, stem cell-based therapy must shift from lab experimentation to clinical grade stem cells. We present here the development of advanced therapy medicinal products (ATMP) by the banking of dental pulp stem cells (DPSCs) for allogenic use. The dental pulp represents an efficient tool for industrial applications due to its accessibility after wisdom teeth extraction for orthodontic purpose. DPSC therapeutic batches can be produced in good manufacturing practice condition after human leukocyte antigen typing and stored in allogenic biobanks. We propose some clinical applications, for which there is no efficient therapeutics so far, but that DPSCs-based ATMP could potentially treat.

INTRODUCTION

Adult organisms contain postnatal somatic stem cells that are involved in symmetrical and asymmetrical cell divisions, allowing stem cell compartment maintenance and cell differentiation^[1]. Thus, adult stem cells provide replacement and repair cells for normal turnover or injured tissues^[2]. As these stem cells are able to renew particular tissues, they have motivated research on how to apply them in the clinic. Because of their self-renewal and ability to regenerate tissue, stem cells could provide long-lasting clinical benefits to recipients. Among these potentially beneficial cells, mesenchymal stromal cells are spindle-shaped, plastic-adherent cells isolated from bone marrow, adipose tissue, dental pulp and many other tissue sources^[3,4]. They are also called mesenchymal stem cells (MSCs) in reference to their significant self-renewing properties and ability to form skeletal and connective tissue, and are suggested to be responsible for the normal turnover and maintenance of adult mesenchymal tissues^[2,5]. MSCs are now the focus of intensive efforts in order to elucidate their nature and properties, and to develop cell-based therapies with real clinical applications^[6]. Moreover, MSCs provide promising therapeutic benefits as they primarily mediate positive effects through paracrine mechanisms independent of cell differentiation^[7]. Many preclinical and clinical trials have been completed and the major hurdles are now cell engraftment and survival, stem cell fate control, and donor-patient compatibility for allogenic applications. Several current efforts are directed at promoting the registration and banking of stem cell lines and providing associated data^[8,9]. Banking MSCs, with shared materials and data, is an important step for the efficient progress of stem cell research and clinical translation. Emphasis on clinical applications is increasing, with

an aim of establishing clinical grade, human leukocyte antigen (HLA)-matched banks for clinical translation^[10].

DENTAL PULP STEM CELLS

Teeth are formed of two main parts, the crown and the root, that can be defined by anatomic criteria. They are linked by the periodontal ligament to the supporting alveolar bone, which is composed of both compact and trabecular bone. The dental crown consists of enamel, dentin, and dental pulp tissue. During tooth growth and development, ameloblasts form enamel and odontoblasts generate primary dentin. After tooth eruption, ameloblasts disappear from the surface of the enamel; consequently, enamel formation ceases to occur naturally *in vivo*. In contrast, odontoblasts, along the inner surface of the dentin inside the pulp chamber, continue to deposit dentin matrix to form secondary dentin throughout life. In addition to secondary dentin, odontoblasts can form tertiary (reparative) dentin in response to several stimuli, such as mechanical, chemical, and/or bacterial stimulation. Even when odontoblasts have been damaged, the reparative dentin can be formed in the dental pulp to protect against further disruption of the pulp tissue. This reparative dentinogenesis has been thought to be mediated by newly generated odontoblasts arising from dental pulp tissue. These findings led to the speculation that odontogenic progenitor cells or stem cells may exist in dental pulp tissue^[11]. The first type of dental stem cell was subsequently isolated from the human pulp tissue and given the name dental pulp stem cells (DPSCs)^[12]. Dental pulp is a soft connective tissue entrapped within the dental crown, and divided into four layers. The external layer is made up of odontoblasts producing dentin; the second layer is poor in cells and rich in collagen fibers; and the third layer contains progenitor cells and undifferentiated cells, some of which are considered stem cells. From this layer, undifferentiated cells migrate to various districts where they can differentiate under different stimuli and make new differentiated cells and tissues. The innermost layer is the core of the pulp and comprises the vascular area and nerves^[13]. Dental pulp is an interesting source of adult stem cells because of the large amount of cells present and the non-invasiveness of the isolation methods compared to other adult tissue sources^[13-15]. MSCs defined as dental stem cells can be obtained from human permanent and primary teeth, human wisdom teeth^[12], human exfoliated deciduous teeth^[16], apical papilla^[17], the periodontal ligament^[18,19] and the dental follicle^[20,21].

Dental pulp tissue from human third molar, exfoliated deciduous or supernumerary teeth represent an easily accessible source for harvesting MSCs as these teeth are often discarded.

Stem cells that reside in dental pulp (DPSCs) have been described as a population of MSCs, as they match the definition given by the Mesenchymal and Tissue

Stem Cell Committee of the International Society for Cellular Therapy^[3]: DPSC are plastic-adherent when maintained in standard culture conditions; they express some specific surface molecules such as CD105, CD73, CD90 and lack expression of CD45, CD34, CD14, CD19 and HLA-DR surface molecules; and they have the ability to differentiate into osteoblasts, adipocytes and chondroblasts *in vitro*^[11,12,18,22-24]. Moreover, DPSCs can differentiate into a large array of cells and tissues^[25-28] and a comparison of their multipotency with Bone Marrow Stem Cells has demonstrated that proliferation, availability, and cell number of DPSCs were greater than for bone marrow MSCs^[24,29].

In addition, DPSCs were also found to undergo myogenic and neurogenic differentiation capacities *in vitro*, expressing respective gene markers and exhibiting neuron-like cell morphologies. The plasticity and multipotential capability of DPSCs can be explained by the fact that dental pulp is made of both ectodermic and mesenchymal components, and contains neural crest-derived cells^[13]. Concerning cell surface molecules, the persistence of negative results for CD45 demonstrates that these cells are not derived from a hematopoietic source, although they are of mesenchymal origin^[25]. Like all MSCs, DPSCs are also heterogeneous and the various markers may be expressed differently by subpopulations of these stem cells^[24]. A selected subpopulation of CD34⁺/CD45⁻ DPSCs, which represented roughly 10% of dental pulp cells, has also been described. These cells displayed an increased capacity of self-expanding and differentiating in pre-osteoblasts, and were able to self-maintain and renew for long time^[17]. Although MSCs were originally described as CD34 negative, it seems that this subpopulation of DPSCs expresses the CD34 cell surface antigen in the manner reserved for the most primitive stromal stem cells (other than hematopoietic) that was gradually lost after the differentiation of lineage committed progenitors^[30].

DPSCS BIOBANKING

The term "biobank" describes various facilities that store biological samples, from small tissue collections to wide repositories featuring a variety of tissues and biological sample types^[31,32].

Storage and collection of biological material might be accompanied by various medical and epidemiological data that are used for current research and for potential future works^[33]. Biobanking has been defined as a structured resource for genetic and medical research and their therapeutic applications. It includes human biological material and extensive associated information^[34,35].

Several types of biobanks can be distinguished, according to the purpose and target: case control, clinical trial, tissue, biomolecular resource center, stem cells^[36]. Stem cell biobanks have received much attention as a new biologic resource for both research

and clinical applications, leading to the development of stem cell banks around the world^[37]. Stem cells of dental origin represent a promising source of new stem cells as, in western countries, 80% of teenagers and/or young adults have their wisdom teeth extracted. Furthermore, dental pulp is naturally protected within the pulp chamber, the inner cavity of the tooth, in a sterile environment. Pulp from one wisdom tooth generally contains between 200000 and 300000 DPSCs^[38]. Studies have indicated that DPSC isolation was feasible for 5 d after tooth extraction^[39]. Efficient results were obtained by cryopreserving second-passage DPSC cultures, but could also be achieved by isolating and cryopreserving entire pulp tissues, with digestion and culture performed post-thaw^[40]. Such minimal processing may be of interest for the banking of samples for which there are no immediate plans for expansion and use. Furthermore, cell recovery could be achieved by mechanical disruption with a single-use device, in accordance with the GMP (European Good Manufacturing Practices) standard. Dental pulp and DPSC recovery is represented in Figure 1.

Immunologic considerations: Allogenic use and immunomodulation

Immune mechanisms confer immediate protection against foreign organisms (innate immunity) and specific immune responses to neutralize pathogens (adaptive immunity). The immune system recognizes tissue compatibility and can raise an effective immune response against pathogens or incompatible allogenic tissues. Tissue compatibility or incompatibility is determined from allelic similarities or disparities at genetic loci that encode the major histocompatibility complex (MHC) antigens, also called the HLA system. The HLA system encodes two major classes of highly polymorphic cell surface glycoproteins: HLA class I molecules are expressed on all nucleated cells and HLA class II molecules are expressed on antigen-presenting cells, thymic epithelial cells, and B lymphocytes. These immunological principles, which apply to organ or tissue transplantation, can be extended to transplantation of DPSCs or DPSC-derived tissue, especially for HLA class I molecules (HLA-A, HLA-B and HLA-C)^[41]. Thus, a major clinical challenge to DPSC banking will be to overcome the immunological barriers to the transplantation of DPSC-derived tissues in order to prevent rejection^[42,43]. Ensuring HLA compatibility is certainly the most interesting method of minimizing the risk of rejection. Embryonic stem cells have been shown to express very low levels of HLA class I proteins, with a moderate increase during differentiation^[44]. Regarding MSCs, HLA expression remains unclear, but they have been extensively studied for their immunomodulatory properties^[45-49]. Indeed, MSCs exert a profound inhibitory effect on T cell proliferation *in vitro* and *in vivo*, with similar effects on B cells, dendritic cells and natural killer cells^[50]. Moreover, T-cell inhibition is not restricted by HLA type, and immunosuppressive effects are

Figure 1 Dental Pulp tissue and dental pulp stem cell recovery. Wisdom teeth are extracted in aseptic conditions and transferred to the cell bank in a sterile transport tube. The teeth are then cracked opened and the pulps are mechanically disrupted in a tissue grinder/homogenizer. The cell suspensions obtained are screened for expression of stemness markers by flow cytometry, before storage in liquid nitrogen. DPSC: Dental pulp stem cell.

mediated through soluble factors and the generation of regulatory cells^[47,51]. These findings suggest that MSCs can induce peripheral tolerance, enhancing their potential for therapeutic applications^[45,48]. A higher immunosuppression of T-cell alloreactivity has also been demonstrated in DPSCs in comparison with bone marrow stem cells^[52]. These properties distinguish DPSCs as one of the most accessible cell sources for cell-based therapy in regenerative medicine and inflammation-related diseases^[46].

To overcome rejection and use DPSCs in transplantation medicine, the formation of a histocompatibility bank is an attractive option, where DPSCs are stored after HLA isotyping. Ideally, considering the large numbers of wisdom teeth extracted from genetically diverse populations, adequate levels of isotype matching with patients may be achieved. The establishment of an HLA-organized DPSC allogenic bank could be sufficient to provide stem cells for a large number of patients. The concept of haplobanking with HLA homozygous cell lines would also limit the number of HLA mismatches^[53]. Several studies have been conducted to determine the number of donors needed to cover the population of a country. These findings are dependent on ethnic disparities of the population and the type of stem cells considered. The creation of a bank containing highly selected homozygous lines is an attractive approach to HLA matching. Selected homozygous lines can provide

HLA matches for a wide percentage of populations. Estimates of the number of homozygous cell lines needed have mainly been established considering embryonic stem cells, for the main proteins HLA-A, HLA-B and HLA-DR. Data from cadaveric organ donors, cord blood bank or *in vitro* fertilization-derived embryos led to the estimate that approximately 150-190 human embryonic stem cell lines with various HLA genotypes, or a collection of 10-30 homozygous lines for the common HLA types, would be sufficient to provide HLA-matches for a wide part of the population in the United Kingdom^[54], Japan^[55,56], the United States^[57] or China^[58]. Because of the low incidence (1.5%) of HLA-homozygous individuals in the normal population^[54], a systematic collection of discarded wisdom teeth would be of prime interest. The determination of the HLA types of 100 DPSC lines from teeth collected in Japan revealed 2 homozygous lines for all the 3 considered HLA loci. These 2 homozygous lines therefore have the potential to cover approximately 20% of the Japanese population with a perfect match^[59].

Methods and good manufacturing practices

The production and marketing of stem cell-based therapy faces imperative steps, including product characterization, safety testing and clinical trials design. At both national and international levels, numerous standards and regulations must be followed in order

Figure 2 Process flowchart for current Good Manufacturing Practices manufacturing of dental pulp stem cell lots/therapeutic products. The chart is divided into 4 areas: Hospital for tooth recovery, Cell Bank, Research Institute and Hospital for clinical applications: (1) Hospital: direct contact between patients and authorized medical staff, such as Medical Doctor (MD) or Doctor of Dental Surgery (DDS). Clinical sample and donor's personal data are recovered; (2) Cell Bank: current Good Manufacturing Practices manufacturing of Advanced Therapy Medicinal Products (ATMP) from the biological samples (dental pulps). All data concerning the donors are anonymous; (3) Research Institute: dental pulp stem cell (DPSC) lots are used for animal experiments to develop new therapeutics; and (4) Hospital: clinical grade DPSC lots are used for therapeutics. Red arrows represent critical parameters related to each step of processing (informed consent, quality, safety, confidentiality). HLA: Human leukocyte antigen.

to translate DPSCs into clinical products. There are variations in these international and national guidelines, and in the regulations that are applied to the collection and storage of human tissue, personal data and medical records^[32]. The Food and Drug Administration, in the United States, and the European Medicines Agency (EMA), in Europe, are responsible for creating and enforcing these regulations. In Europe, stem cells for clinical therapies are classified under advanced therapy medicinal products (ATMP) unless they are minimally manipulated and intended for homologous use^[60]. A Committee for advanced therapies (CAT) has even been created to evaluate cell production marketing by assessing the quality, safety and efficacy of ATMPs, in accordance with the regulatory framework. EMA regulation defines the current Good Manufacturing Practices (cGMP) guidelines to manufacture ATMPs^[61]. Even though clinical grade production of DPSCs needs to be implemented, DPSCs can be isolated, stored, and eventually expanded by applying rational modifications to the commonly used methods^[15,62], in order to continue complying with good manufacturing prac-

tices^[63] from the donor (patient having his/her tooth extracted, in aseptic condition) to the storage tank. The critical step of enzymatic pulp tissue digestion can be replaced by mechanical disruption in single use devices, such as a tissue grinder/homogenizer. Fetal bovine serum usually required for *in vitro* expansion can be replaced by human serum supplements derived from peripheral blood serum, peripheral blood plasma, or platelet lysate^[64]. Moreover, genetic stability has been demonstrated for DPSCs for up to 9 cell passages^[65,66].

Legal and practical issues (consent, confidentiality, commercialization)

Translation of DPSC research into clinical applications relies on abundant *in vitro* and *in vivo* preclinical data. However, when it comes to potential therapeutic applications, some barriers can appear, due to restrictions specified in the consent document used for the collection of biological materials, questions about ownership of the collected DPSCs, and the confidentiality of the information associated with the cell lines^[10]. The constitution of an allogenic DPSC bank contains

procedures to ensure anonymity, although authorized parties can access some clinically relevant information.

The rights of donors and the interests of researchers are protected by incorporating relevant government legislation (ethical committee review) and procedures (e.g., anonymity and consent). It is crucial to explain the use and transfer of cells and data at the time of informed consent, especially highlighting features that distinguish collection for research from collection for a biobank^[67]. The whole process, from the patient coming for tooth extraction to storage of DPSC lots, is presented in Figure 2.

Allogenic DPSC biobanking brings together a multitude of data on individuals, including health and lifestyle. Thus, the way the informed consent is obtained should reflect the personal information used for medical research, taking into account that the patient was originally coming for a routine tooth extraction. As informed consent is derived from the standard that every donor has the right to self-determination, the patient must be informed about the nature of biobanking, the procedures in which the tooth he has donated might be involved, and the expected outcome of the research^[36,68]. The physical and intellectual property of biological samples collected must be clearly established and explained^[69].

INNOVATIVE THERAPEUTICS

Upon discovery of stem cells in the dental pulp, DPSCs demonstrated their ability to regenerate a complex consisting of a mineralized matrix of odontoblasts and connective tissue containing blood vessels similar to that observed in normal human tooth^[12]. Since then, the use range of potential medical applications based on DPSCs include the repair and regeneration of bone^[13,70], the central nervous system^[27,71,72], liver tissue^[73], heart tissue^[74], eyes^[75], muscles^[76,77], and salivary gland cells^[78,79]. Overall, it holds great potential in the field of regenerative medicine and tissue engineering^[13,23] alone or combined with various biomaterials^[80-84]. Some have proposed that DPSCs may have greater potential than the current MSC gold standard, the bone marrow-derived MSC^[29].

Allogenic banking of DPSCs could boost industrial and therapeutic innovations by providing tools for unsolved medical problems, including the production of advanced therapy medicinal products (ATMP). We present here some clinical applications, for which there is no efficient therapeutics so far, but that DPSCs-based ATMP could potentially treat.

Spinal cord injuries

Chronic medullary lesion, a result of spinal cord trauma, is characterized by neurologic deficiency without evolution. Six months after trauma, these lesions are considered chronic, with no chance of improvement. According to the Christopher Reeves foundation, these spinal cord lesions affect 1.2 million persons

in the United States and 300000 persons in Europe. Numerous preclinical studies have been conducted to graft stem cells of various origins into injured spinal cords, such as neural stem cells^[85], embryonic stem cells^[86-88], with encouraging results^[89]. DPSCs, due to their embryologic origin, express some markers of both mesenchymal and neuroectodermic origin^[12,16]. Indeed, DPSCs originate from migrating cranial neural crest cells. During embryonic development, these neural crest cells differentiate into a wide variety of cell types, including neurons of the peripheral nervous system^[27]. MSCs have been thought to be usable in the treatment of spinal cord injuries, and adult human DPSCs could provide an ideal source of stem cells for therapeutic applications in such neurological pathologies^[90]. The efficiency of DPSCs in improving neural regeneration has been shown *in vitro*^[72,73,91] and *in vivo* after spinal cord injury^[92-94]. These preclinical data enhance the therapeutic potential of intrathecally administrated HLA-typed DPSC lots in treatment of nerve tissue injuries.

Sjögren's syndrome

Sjögren's syndrome is an autoimmune pathology affecting 0.2% to 3% of the general population^[95]. It is a chronic inflammation of the salivary and lacrimal glands, characterized by lymphocytic infiltration of the exocrine glands with a polyclonal B cell activation^[96]. Although the pathogenesis of primary Sjögren's syndrome remains unclear, T cells and B cells have been shown to be involved. Pharmacological treatments have limited efficiency, with only the capacity to temporarily ameliorate symptoms, and with no modification of the overall course of the disease^[97]. Given the lack of disease-modifying drugs, treatment options are now focused on biotherapies^[98]. As detailed above, immunomodulatory properties of MSCs have been demonstrated *in vitro* and *in vivo*, suggesting a therapeutic potential for autoimmune disease treatments^[47], especially through anti-inflammatory cytokines production and T regulatory cells promotion^[99]. These immunomodulatory properties have also been demonstrated for DPSCs, identifying them as a cell source for cell-based therapy of immune and inflammation-related diseases^[47]. Intravenous injection and local injection of DPSC lots into salivary glands represents a potential novel immunotherapeutic tool for autoimmune Sjögren's syndrome.

Irradiated salivary glands

Cancers that originate from the aerodigestive epithelium, including carcinomas of the head and neck, are the leading causes of cancer-related mortality worldwide, accounting for about 2 million deaths and 500000 new cancers diagnosed annually^[100,101]. Treatment involves chemotherapy, radiotherapy, and surgery. Radiation-induced salivary hypofunction is one of the major developments that affect survivors. Even though radiotherapy is focused on the cancerous area, radiations often affect salivary glands, causing severe hyposialia and oral dryness after orofacial cancer

treatment; hyposalivation underlying xerostomia after radiotherapy is still a major problem in the treatment of head and neck cancer. To date, the only treatment for this oral dryness is the use of artificial saliva to supply salivary glands, a treatment with limited efficiency. Salivary stem cell (salisphere) transplantation has been shown to functionally restore salivary gland efficiency after radiation-induced impairment of salivary gland function and consequential xerostomia^[79]. Furthermore, it was demonstrated that DPSCs used as a cell source for the treatment of salivary gland hypofunction could partially revert this hypofunction^[80]. Thus, stem cell-based therapy has great potential in prevention or treatment of radiation-induced hyposalivation^[102]. New therapeutic strategies are now being considered using stem cells injected intravenously or directly into salivary glands to allow salivary gland cell reactivation^[103-106].

Acute periodontitis

Periodontal diseases are highly prevalent diseases that can affect up to 90% of the population worldwide. They have various forms, from gingivitis, the mildest form caused by dental plaque, to periodontitis, which induces the loss of connective tissue and bone support, and causes tooth loss in adults^[107]. Acute periodontitis is an inflammatory disease of the periodontium triggered by the host's immune response and resulting in the progressive loss of gingival tissue, periodontal ligament and supporting alveolar bone^[108]. Actual therapeutics consist of the control of bacterial infection and the stabilization of tissue loss. Regenerative treatment using bone grafts, gingiva grafts, and growth factors offer interesting possibilities, but only in specific indications^[109-111], and with unpredictable results^[112]. In this context, topical application of stem cells in periodontal lesions appeared to be a promising strategy to regenerate periodontium^[113]. *In vitro* studies demonstrated the ability of DPSCs to differentiate into osteoblast and cementoblast lineage, and to participate in periodontal ligament and cementum regeneration^[114,115]. *In vivo* experiments enhanced the therapeutic potential of dental stem cell grafting to regenerate periodontal tissues^[116-118]. Allogenic transplantation could enhance periodontal tissue repair and limit local inflammation through MSC immunomodulation^[108,119].

Endodontic regeneration

Dental pulp, the soft connective tissue described above, is the tissue entrapped within the teeth, in which are recovered DPSCs. In case of dental decay, this tissue can be infected and become necrotic, because it is encased in a thick dentin wall, and consists of a microcirculatory system originating from a very small opening at the apex of the root. This anatomical configuration limits the development vascular supply during pulp regeneration. Endodontic treatment, when needed, includes the removal of vital and necrotic tissues from the root canal system, along with infected

root dentine. It aims to prepare the canal space to facilitate disinfection by irrigants and medicaments. Prevention of reinfection is then achieved through the provision of a fluid-tight root canal filling and a coronal restoration^[120]. The potential possibility of regeneration of pulp tissue by cell therapy is a promising approach for the future treatment of pulpitis or peri-apical disease assuring longevity of teeth and improved quality of life. It has been demonstrated that transplantation of DPSC was capable of inducing complete pulp regeneration in a root canal after pulpectomy^[121]. Thus, the use of DPSC, combined with a supporting scaffold, could be used to treat and heal infected root canals, providing an interesting alternative to the actual inert fillings used in endodontics. Root canals anatomy limits the use of rigid scaffold systems in pulp regeneration: scaffolds for pulp regeneration should be injectable, with fibrous structures that ideally mimic the extracellular matrix of the pulp tissue and support stem cells growth.

Induced pluripotent stem generation from DPSC

Pluripotent stem cells can be induced from fibroblasts by retroviral introduction of Oct3/4, Sox2, c-Myc and Klf4^[122]. These induced pluripotent stem (iPS) cells are similar to embryonic stem cells in morphology, proliferation and differentiation capacities^[123]. They proliferate extensively and differentiate into virtually any desired cell type, providing an unlimited source of replacement cells for human therapy^[124]. It has been shown that DPSCs could be also reprogrammed into iPS cells, with a higher efficiency rate than dermal fibroblasts. DPSCs-derived iPS cells were indistinguishable from human embryonic stem cells, highlighting the potential of DPSCs as an alternative source for generating iPS cells^[125,126]. Many reprogrammed cell lines could easily be established from DPSCs obtained from young patients with a low risk of bacterial contamination and genetic modification, as extracted wisdom teeth are generally aseptically obtained from the mandible and are protected from ultraviolet and other damage by surrounding hard tissues. It was shown that iPS cells could be efficiently generated from DPSCs using the conventional 4 reprogramming factors (Oct3/4, Sox2, c-Myc and Klf4)^[59,125,126], as well as using only 3 factors (Oct3/4, Sox2 and Klf4)^[59], or even using only 2 non-oncogenic factors (Oct4 and Sox2)^[30]. Interestingly, the efficiency rate of reprogramming was related to the donor's age, with higher rate for younger patients with wisdom teeth still under maturation^[59].

With respect to safety, it would be ideal not to use retrovirus vectors for transient expression of the reprogramming genes. DPSCs are assumed to offer high efficiency of iPS cell generation even with the use of non-integrating vectors such as Sendai viruses or modified mRNA. Clinical use of iPS in regenerative medicine is very promising. However, time-efficiency and financial considerations argue in favor of the use of allogenic rather than autologous iPS lines. Similarly to DPSCs, biobanking of iPS lines would be a reasonable

strategy. In this setting, DPSC banking could be of great help to establish iPS cell banks with a sufficient repertoire of HLA types, since the establishment of clinical-grade iPS cell lines from individual patients would require much time and incur a high cost^[59].

From DPSC to successful therapy: Limitations and issues

The notion of stem cells as postnatal units of organ or tissue regeneration allows imagining therapies such as tissue engineering. A stem cell that could be expanded and modified *ex vivo*, and transplanted *in vivo* encourages attempts to treat severe or lethal diseases. However, even when the use of stem cells could replace the lost cells, it does not guarantee that the regenerated cells could circumvent the cell death caused by the disease. And replacing lost cells, even with cells expressing several specific cell markers, is far from a successful therapy with fully functional cells. Indeed, clinically successful translation of stem cell science into medicine has been conducted following a simple framework in which organ-specific stem cells were used for organ-specific diseases^[6]. The roles of DPSC, and MSCs in general, as niche cells, tissue organizers and skeletal or neural progenitors open opportunities and pose challenges. The molecular mechanisms by which stem cells become functional are still largely unknown. Its comprehension and identification may involve new methods that go far beyond the empirical injection of poorly characterized cultured cell strains^[6]. Such methods may involve modeling of disease mechanisms, identification of cell-derived bioactive factors and their use as drugs (including factors mediating the interactions with endothelial and hematopoietic cells), definition of targeted specific disease mechanisms and organ-specific strategies to deliver DPSC to a site of interest^[127].

CONCLUSION

DPSC-based therapy is now entering into a new stage of development, shifting from initial *in vitro* and *in vivo* studies to optimization of therapeutic products for clinical applications. As for other MSC, there are still many challenges concerning stem cell potency, age-related and disease-related tissue impairment, and production of clinical grade stem cells lots. The strategies presented in this review emphasize the potential of DPSC to be used for innovative clinical trials based on rational DPSC therapy, following GMP conditions.

Indeed, dental pulp is a remarkable site of stem cells, and the collection of stem cells from dental pulp is a non-invasive practice that can be performed after routine wisdom teeth extraction. DPSC can be recovered in GMP conditions and cryopreserved for long periods, after HLA typing. However, in the perspective of therapeutic use, optimization and better methods are still necessary for DPSC isolation, expansion and

banking.

Although producing and storing patient-specific stem cells could resolve immunological problems, this procedure would be costly, laborious, and time-consuming. Allogenic DPSC banking containing clinical grade stem cell lines offers an alternative and provides stem cell lines from which it will be possible to choose a HLA match for the patient to be treated. There are variations in national and international regulations for the collection and storage of human tissue, but ethical principles related to biobanks always include safety, informed consent and confidentiality. The recovery of DPSC doesn't involve any invasive procedure as they come from already extracted teeth. Thus, the main concerns are: (1) for the donor, clear explanations about the banking project and confidentiality of all personal and medical data; and (2) for the patient, safety of DPSC lots produced in accordance to guidelines. To date, despite promising preclinical data, clinical trials using DPSCs have not been widely reported. Allogenic biobanks represent a new strategy that aims to develop the clinical applications of the DPSC potential, involving both researchers and clinicians.

Abstract

Relapses remain a major concern in acute leukemia. It is well known that leukemia stem cells (LSCs) hide in hematopoietic niches and escape to the immune system surveillance through the outgrowth of poorly immunogenic tumor-cell variants and the suppression of the active immune response. Despite

the introduction of new reagents and new therapeutic approaches, no treatment strategies have been able to definitively eradicate LSCs. However, recent adoptive immunotherapy in cancer is expected to revolutionize our way to fight against this disease, by redirecting the immune system in order to eliminate relapse issues. Initially described at the onset of the 90's, chimeric antigen receptors (CARs) are recombinant receptors transferred in various T cell subsets, providing specific antigens binding in a non-major histocompatibility complex restricted manner, and effective on a large variety of human leukocyte antigen-divers cell populations. Once transferred, engineered T cells act like an expanding "living drug" specifically targeting the tumor-associated antigen, and ensure long-term anti-tumor memory. Over the last decades, substantial improvements have been made in CARs design. CAR T cells have finally reached the clinical practice and first clinical trials have shown promising results. In acute lymphoblastic leukemia, high rate of complete and prolonged clinical responses have been observed after anti-CD19 CAR T cell therapy, with specific but manageable adverse events. In this review, our goal was to describe CAR structures and functions, and to summarize recent data regarding pre-clinical studies and clinical trials in acute leukemia.

Key words: Chimeric antigen receptors; Adoptive immunotherapy; Acute leukemia; T cells; Immune surveillance

Core tip: Leukemia cells ultimately escape to the immune system, due to various mechanisms such as limited availability of tumor specific T cells or down-regulation in major histocompatibility complex expression. Chimeric antigen receptor (CAR) T cell technology redirects immune reactivity towards a broad variety of chosen antigens in a human leukocyte antigen-independent manner. Recent introduction of co-stimulatory domains

in the CAR construct enhances significantly *in vitro* and *in vivo* expansion and persistence of these genetically modified T cells. First clinical trials, especially with anti-CD19 CAR T cells, report promising results in acute lymphoblastic leukemia.

Adoptive immunotherapy for acute leukemia: New insights in chimeric antigen receptors. *World J Stem Cells* 2015; 7(7): 1022-1038 Available from: URL: <http://www.wjgnet.com/1948-0210/full/v7/i7/1022.htm> DOI: <http://dx.doi.org/10.4252/wjsc.v7.i7.1022>

INTRODUCTION

Despite recent advances in therapeutics over the last decades, relapses remain a major concern in acute leukemia (AL). Despite complete remission (CR) achievement, leukemia stem cells (LSCs) resist to therapeutic strategies, hiding into bone marrow hematopoietic niches or other unknown sanctuaries^[1]. More than evading apoptosis and self-sufficiency of growth signals, these leukemia cells are also characterized by their ability to evade the immune system. Malignant cells escape such immune surveillance through the outgrowth of poorly immunogenic tumor-cell variants, known as immune selection, and/or through disruption of the immune system^[2,3]. A robust innate immune system is mandatory to avoid relapses by targeting chemoresistant malignant cells, underlining that bone marrow should be preserved as many as possible from aggressive chemotherapy agents. Allogeneic stem cell transplantation (ASCT) is a potential way to restore the tumor cell immunogenicity by transferring a brand new immune system. However, ASCT is largely unspecific and the benefit of graft versus leukemia is offset by the potential complications related to graft versus host disease (GVHD)^[4].

In order to achieve long-term survival and good quality of life, other types of immunotherapy have been developed, such as treatments using tumor-associated antigen (TAA)-monoclonal antibodies (mAbs) and more recently adoptive cellular therapies. Adoptive transferred tumor reactive T cells compared favorably with mAbs. They display direct tumor lysis, enhanced bio-distribution and synergism with the immune system through release of cytokines, and long-term memory properties. Cytokine induced killer (CIK) cells are *in vitro* manufactured T lymphocytes with natural killer (NK) cell properties. They can be extracted from human peripheral blood, bone marrow or cord blood mononuclear cells^[5]. They showed a non-major histocompatibility complex (MHC)-restricted lysis function on a broad spectrum of tumor targets *in vitro*, which was confirmed *in vivo*^[6,7]. However, first clinical results were not convincing, probably due to a lack of specificity, with a limited basal anti-leukemia activity and a rapid exhaustion of these cells^[8,9]. Adoptive transfer of

autologous or allogeneic manipulated T cells has proven to be safe and extendable in clinical practice. In patients presenting prolonged lymphopenia, adoptive multi-virus specific T cell transfers have showed promising data in reconstituting anti-viral immunity after SCT or in patients infected by human immunodeficiency virus^[10,11]. Another approach is to genetically engineer lymphocyte subsets to redirect their natural immune response, correct impaired immunity, and improve T cell anti-tumor effector response.

First described in 1989, the concept of the genetic redirection of T cells is based on chimeric antigen receptors (CARs), which are recombinant receptor molecules genetically transferred, redirecting T cells against a specific TAA^[12]. CARs are composed of 3 distinct domains, each displaying their own functions. The extra-cellular domain is generally constituted by a single chain variable fragment (scFv). Its targeting moiety derived from the fused variable heavy and light chains of an antibody. The trans-membrane domain is connected to the scFv through a "spacer" to provide flexibility and stable expression of the extracellular moiety. The intra-cellular signaling domain, usually derived from the CD3 ζ -chain of the T cell receptor (TCR)-CD3 complex, mediates activation of CAR T cells. CAR T cells overcome some primordial limitations of TCR by targeting antigens in a non-MHC manner, and can recognize tumor independently of human leukocyte antigen (HLA) molecules^[13]. After years of investigations to implement gene transfer tools and codify good manufacturing practices, CARs have been considered for human application. The first clinical trials have shown promising results in hematological diseases^[14-17].

In this review, we focused on the CAR backbone technology and its application in the setting of human AL therapy.

CHIMERIC ANTIGEN RECEPTOR T CELLS: STRUCTURE AND FUNCTIONS

CAR is an artificial T cell surface receptor that simulates the physiological response of a T cell receptor and targets native cell surface antigens. However, CARs have the ability to target molecules that can be recognized without requiring peptide processing or HLA presentation. Unlike regular T cells, CAR T cells can restore immunogenicity of tumor cells. They recognize antigens in any HLA background, independently of the patient haplotype, and without any cross-reactive action toward endogenous antigens^[18,19]. With a capacity of binding to any cell surface antigens, including proteins, carbohydrates and glycolipids, CARs can respond to a broader range of targets than native TCR. However, antibody-mediated recognition by CARs is not restricted to peptide antigens and does not exclude targeting MHC presented peptides. Engineered NK cells harboring a scFv specific for HLA*A2 (MHC class I) carrying a peptide derived from the Epstein-Barr virus latent

Figure 1 Schema of the general structure of a chimeric antigen receptor. The antigen recognition moiety is composed of the variable domain of heavy (VH) and light (VL) chains of the antibody, specific for a native tumor-associated antigen expressed on the surface of malignant cells. This structure is connected to the cytoplasm by a spacer, generally derived from CD8 or CD28 subunits, and a transmembrane domain. First generation chimeric antigen receptor T cells were solely composed of a single intracellular domain generally derived from CD3 ζ subunit and its immunoreceptor tyrosine-based activation motifs (ITAMs), essential for Lck recruitment and full downstream T cell receptor-like signaling transduction. In order to improve engineered T cells proliferation and persistence, investigators introduced successively one (second generation) or ≥ 2 additional intracellular signaling domains (third generation). ICOS: Inducible costimulator.

protein EBNA3C have been recently developed^[20]. These CAR NK cells showed substantial cytolytic activity against peptide-pulsed HLA-A2⁺ antigen-presenting lymphoblastic B-cell line in a peptide-specific, HLA-restricted manner without cross reactivity with native HLA*A2, paving the way toward highly sensitive and specific target cell killing^[21].

CARs engage the target *via* their extra-cellular recognition subunits, usually a scFv, but other strategies are actually explored, such as antigen-binding domains derived from natural ligand receptors (*i.e.*, NKG2D)^[22,23]. These TAA extra-cellular moieties are either derived from murine or humanized Fab's (variable fragment of an antibody) or synthesized *via* phage display libraries (Figure 1). Because of their accessibility, murine scFvs are the most frequently used, but they are considered more immunogenic than those derived from human libraries. The major risk is to induce humoral and/or cell mediated immune responses as previously reported^[24]. There is currently broad evidence that distinct epitopes of a same antigen, as well as their distance to the cell membrane, have not the same potential upon T cell activation. Based on the kinetic segregation model (KSM) relating TCR activation and ligands size-sensitivity, several reports support that this also occurs in CAR T cells^[25]. The KSM implied that TCR engagement through distal epitopes binding creates larger TCR-MHC-peptide complexes and that close-contact zone displays the synapse to phosphatase action such as CD45 or CD148 repressing TCR signaling. Conversely, targeting more proximal epitopes favored more potent TCR-MHC

interaction and more efficient downstream signaling^[26]. In a study assessing the anti-leukemia effect of anti-CD22 CAR T cells, it was showed that proximal targets have superior anti-leukemia effects^[27]. This was confirmed by further published data^[28]. An increased affinity for the target was not necessarily associated with an increased cytotoxicity. CARs with high affinity for an antigen had a higher proliferation rate than CARs with lower affinity, although this increased affinity was not correlated with higher T cell effector functions^[29,30]. Similarly, the effects of antigen density are not well understood but it seems that CARs exert various cytolytic activities according to antigen expression. In a CD123 CAR T cells model, it was demonstrated that engineered T cells eliminated CD123^{high} cells, while CD123^{low} targets survived in co-culture^[31]. A high affinity and density regarding a specific antigen is not an absolute condition for an optimal anti-tumor activity, but this should be considered as an advantage in order to reduce the severity of the "on target/off tumor" effect. Despite technical considerations, identifying the perfect target remains a matter of debate, specifically in AL. The ideal antigen target should be homogeneously expressed on malignant cells without ubiquitous expression on healthy tissues, and should be critical for tumor cell survival. CD19 is currently the best candidate in B cell precursor acute lymphoblastic leukemia (ALL). The situation is more complex in acute myeloid leukemia (AML), for which the best target still remains to be defined.

A short spacer region, which is the least aspect

of CAR design under discuss, generally follows the scFv's moieties. With the trans-membrane domain, these structures contribute to flexibility, accessibility and synapse formation of the extra-cellular complex. They also seem to influence CARs specificity^[32,33]. The simplest form of spacer region is that derived from human immunoglobulin (Ig) Fc (constant fragment) (*i.e.*, IgG4) potentially linked with CH₂CH₃ molecule(s). However, constant regions from human CD8 α and CD28 have been until now the most frequently used in pre-clinical assays (Figure 1). Following scFv binding moiety interaction with its target, CAR T cells need an active signaling transfer through their intra-cellular domain for proliferation, cytokine production, and acquisition of effector functions. In order to enhance T cell persistence and anti-tumor functions *in vivo*, research in CAR T cells has been focused on co-stimulation over the last decade.

CO-STIMULATORY DOMAINS IN CAR T CELLS: FIRST TO THIRD GENERATION

First generation CARs were composed only of one signaling domain such as the CD3 ζ -chain of the TCR-CD3 complex or the γ -chain of the high affinity IgE Fc receptor (Fc ϵ RI) initially associated with antigen-specific scFv derived from a murine antibody (Figure 1). They were associated with the activation of the phosphatidylinositol and tyrosine kinase pathways. However, they failed to mediate persistent and robust anti-tumor activity^[15,34,35]. Clinical trials with first generation CAR T cells have been conducted in different settings. Some of them are still ongoing, but first results were rather disappointing (Table 1). In a study exploring CD20 CAR T cells in 7 patients with relapsed or refractory indolent lymphoma, only a clinical partial response was obtained in one patient. Moreover, after three infusions of autologous CD20 specific T cells, T cell persistence was less than 10 wk (15-65 d), even after interleukin (IL)-2 administrations^[36]. In a cohort of 4 patients with non-Hodgkin lymphoma (NHL) treated by CD19-CD20 CAR T cells, no objective response and a very limited persistence of T cells was observed. In other patients, cellular anti-transgene immune rejection responses (specific immune response against transfected T cells) have been observed, showing that the immunogenicity of the transgene used is of major importance^[37]. In ALL, there is no clinical data available with first generation CAR T cells. However, two clinical trials based on CD19 scFv-CD3 ζ (19z1) CARs with or without IL-2 supplementation are currently recruiting (Table 1). Nevertheless, CD3 ζ alone is able to induce a TCR-like signal through immunoreceptor tyrosine-kinase based activation motif (ITAM) phosphorylation and lymphocyte-specific protein tyrosine kinase (Lck) recruitment, which are indistinguishable from those generated by an intact TCR currently used to provide

signal one.

It is well known that TCR engagement (signal one) without co-stimulatory signal (signal 2) lead to T cell anergy and rapid activated induced cell death (AICD). Signal 2 is provided by engagement of co-stimulatory domains, mediated essentially by the CD28 superfamily, involving receptors for the agonistic CD80 (B7.1) and CD86 (B7.2) ligands. However, these ligands are generally missing in most cancer cells. This plays a major role in the immune surveillance escape. In this setting, second generation CAR T cells have been designed by adding an additional intra-cellular co-stimulatory domain such as CD28 (forming at the end one polypeptide single chain) to the CAR backbone (Figure 1)^[38,39]. CD28, a disulfide-linked homodimer of the immunoglobulin superfamily is activated by binding either B7.1 or B7.2, expressed on the surface of antigen presenting cells. This represents one of the most potent co-stimulatory pathways. It facilitates Lck recruitment to ITAMs and the formation of the linker activation (LAT) complex. This structure is necessary for signal transduction through phospholipase C gamma (PLC γ) leading to IL-2 promoter activation and full T cell activation. Other co-stimulatory domains have been tested, such as members of the tumor necrosis factor (TNF)-receptor family [4-1BB (CD137) or OX40 (CD134)], ICOS or DAP10^[28,40-42]. Second generation CAR T cells generally show sustained polyclonal proliferation without B7-CD28 engagement, enhanced IL-2, interferon-gamma (IFN γ), TNF-alpha (α), and granulocyte-macrophage colony-stimulating factor (GM-CSF) cytokine production and enabled resting primary T cells to survive^[43]. In two recent clinical studies, it was reported that CAR (scFv-4-1BB-CD3 ζ) T cells undergo 1000-fold amplifications *in vivo* compared to only 3.75-fold reported in first generation CAR clinical trials^[44,45]. This may be related directly on the co-stimulatory signal that seems to counteract the inhibition effect of tumor growth factor β 1 (TGF- β 1) secreted by regulator T cells (T_{reg}) on proliferating CAR T cells^[46]. Generally, TGF- β 1 represses IL-2-dependent T cell amplification, CD122 up-regulation (IL-2R- α), and IFN γ production. Dual signaling provided by second-generation CAR T cells enhanced engineered T cell persistence comparatively to their first generation counterparts. This was demonstrated in patients treated with either CD3 ζ or CD3 ζ -CD28 CARs^[47]. Besides overcoming PD1-mediated inhibition (an activation-induced inhibitory receptor expressed on T cells), co-stimulation through CD28 induces intrinsic survival signals independently of the exogenous survival signals mediated by IL-2. *In vitro*, CD28-B7 interaction leads to an up-regulation of Bcl_{xL}, an anti-apoptotic protein of the Bcl2 family, and to resistance to apoptosis by Fas (CD95, APO-1) cross-linking^[48]. This interaction enable protection from intrinsic and extrinsic cell death signals and promotes survival of the expanding lymphocyte population^[49]. Surprisingly, it seems that the adjunction

of a co-stimulatory domain (*i.e.*, CD28) do not modify the threshold of antigen-dependent MHC-independent T

cell activation^[50]. It seems therefore that incorporation of at least one co-stimulatory domain in a CAR cons-

tract is mandatory for complete T cell activation. However, a major remaining issue concerns the potential superiority of one endodomain comparatively to another. Because of their heterogeneity, some CD28 or 4-1BB-based second generation CARs have been compared, essentially in mice models, and showed contradictory results. Regarding cell proliferation and cytokine production, second generation CD28 transfected CAR T cells were superior to CD19z1 (first generation CAR T cells), but also to constructs with 4-1BB, OX40 or DAP10 endodomains^[51]. Conversely, it was showed that CD28⁺ and 4-1BB-based CAR T cells, directed against the same epitope (SS1 scFv-based chimeric receptor), have the same anti-tumor activity^[52]. Other pre-clinical studies, containing 4-1BB signal transduction endodomain, exhibited a greatest anti-leukemia activity and prolonged *in vivo* survival^[53]. In AL, most of the current clinical trials use indistinctly CD28 or 4-1BB endodomains. Comparisons between intra-cellular signaling domains should take into account all representatives of distinct antigen epitopes, their location, their density, and their affinity for the target in order to clarify their exact contribution in the anti-tumor activity.

More recently, third generation CAR T cells have been developed, including more complex structures with three or more signaling domains, enabling wider T cell effector function in a specific fashion (Figure 1). In mice models, the inclusion of multiple endodomains showed enhanced functionality and greater potency of tumor targeted T cells *in vivo* and *in vitro*. However, this was not confirmed in other models^[54-56]. In a study comparing the consequences of CD28, OX40 and 4-1BB co-stimulation, it was showed that third generation CD3 ζ -CD28-OX40 CARs prevent AICD in memory T cells, and substantially improve effector functions in both naive and memory CD4 and CD8 T cells. They also increase cytokine production comparatively to second generation CAR T cells combination^[57]. Considering these results and the substantial improvement in terms of efficacy, the addition of a third endomain should be associated with increased long-term persistence and should delay anergy. However, a pilot study, using CD28-4-1BB-based CARs in 4 NHL patients, reported one partial response, one disease progression, and 2 cases free of disease at 12 and 24 mo, respectively. In this study, engineered T cells were detectable up to 12 mo after infusions by quantitative polymerase chain reaction (PCR) at low levels (< 1%)^[58]. Because of discrepancies among pre-clinical and clinical results, further investigations are warranted to optimize our understanding regarding CAR T cell signaling. Because massive activation and uncontrolled proliferation of genetically modified T cells has been associated with serious adverse events, investigators should take into account these features and find the right balance between efficiency of these engineered T cells and an acceptable tolerance.

CARS MANUFACTURING: A PERSONALIZED ASSEMBLY-LINE WORK

Investigators developed distinct approaches to introduce efficiently CAR constructs into T cells. Actually, most of them utilized viral transduction systems (mostly γ -retroviral) leading to permanent sequence integration into T-cell DNA. However, this kind of vehicle presents disadvantages: (1) high costs related to the production process; (2) risks of CAR expression silencing due to terminal repeat alterations; (3) risks of insertional mutagenesis; and (4) production of replication competent virus. Alternatively, lentiviral vectors, which are theoretically less genotoxic, can permanently transduce T cells, but display inferior yields of transgene integration^[59,60]. However, no genotoxic-related events related to viral vectors have been reported until now in human clinical trials using manipulated T cells^[61]. Moreover, residual vector sequences present in the genome lead to immunogenic epitope expression and can increase anti-CAR mediated response. First clinical trials in B-cell lineage ALL using viral vectors reported very limited gene transfection efficiency (5%-15%), without impairing anti-leukemia effect^[62,63].

Non-viral based DNA transfection represents an interesting alternative because of its low cost and its theoretically limited insertional mutagenesis [insertion at thymidine-adenosine (TA) dinucleotide base pairs and non-preference of integration into transcriptional units]. DNA plasmids were the first non-viral vehicles that have been tested. They seemed less immunogenic and independent of the sequence size comparatively to viral vectors. However, because of low chromosomal intake and sustained transgene expression, long-term cultures are required to obtain a sufficient number of CAR-modified T cells, despite a potential negative effect on T cell activity and *in vivo* expansion. One major issue with plasmid vectors is represented by the genomic integration of multiple copies and transfected DNA hypermethylation, leading to transgene silencing^[64]. Originally described in 1996, "Sleeping Beauty (SB)" transposase/transposon, based on the concept of "jumping genes" discovered by McClintock, enabled to overcome these issues and to restart non-viral DNA vectors^[65]. Generally, one plasmid is loaded with a transgene, named transposon, surrounded by inverted repeats that contain short direct repeats (Figure 2). These sequences are recognized by an enzyme (transposase) transported in a second plasmid, which cut the transposon out of the plasmid. The genetic cargo is then delivered into the targeted cell cytoplasm by any of the established non-viral delivery techniques, and inserted randomly into TA dinucleotide base pairs of the recipient (Figure 2). Costly but safer, the SB platform displays attractive features for human gene therapy, to such an extent that many protocols for manufacturing clinical grade T cells recently came to light^[66]. At the last European Bone Marrow Transplantation (EBMT)

Figure 2 Schema of the transposon/transposase “sleeping beauty” system. A: The genetic cargo of a first plasmid (plasmid 1) is the chimeric antigen receptor (CAR) (anti-CD19 CD3 ζ -CD28) flanked by inverted/short direct repeats (IR/DR). The whole set composed the transposon. The enzyme transposase is loaded in a second plasmid, which is specific of the IR/DR sequence; B: Materials of the two plasmids are fused together by electroporation, an electric current opening pores or channels at the cell surface. Transposase binds to the IR/DR sequences; C: The enzyme cut out of the plasmid the flanked sequences (CAR transgene with its promoter) and transfect the genetic cargo into a random DNA sequence of the recipient (T cell).

meeting, promising results were reported about the production of third generation CD19/CD123 CIK CAR cells. With about 50% CAR transfection yields, investigators are now able to greatly expand CAR T cells and produce clinical grade within 3 wk (vs 90 d with retroviral vectors). To our knowledge, two human clinical trials using the SB system are currently ongoing at the MD Anderson Cancer Center (Table 1)^[67].

Clinical trials have reported serious adverse events during CAR T cells therapy in early clinical phase trials, which were related to uncontrolled T cells proliferation, cytokine storm, or “off tumor” effect^[68,69]. In this context, strategies to incorporate abortive mechanisms inside the genomic load have emerged. Based on *ex vivo* genetic modification of donor T lymphocytes, suicide gene therapy with the Herpes simplex thymidine kinase (Hsv-tk)/ganciclovir (GCV) suicide system in the context of ASCT has demonstrated its safety and efficacy^[70]. In order to facilitate its clinical development, this technology has been applied to CAR T cell development. Despite successes in the treatment of severe GVHD, Hsv-tk/GCV system showed some limitations: (1) the HSV-TK protein can be immunogenic in an immunocompetent situation; (2) the system can lead to unexpected elimination of modified T-cells in case of treatment with GCV; and (3) the system can show efficacy only on dividing cells^[71]. Other non-immunogenic suicide systems have been developed, especially through a modified caspase 9 (iCasp9) member of the intrinsic apoptosis

pathway^[72]. A modified FK506-binding protein (humanized FKBP12), belonging to a family of protein which display a propyl isomerase activity, has been combined with caspase 9. Infusion of a synthetic drug, AP1903, allows the dimerization of iCasp9 and activates the apoptosis cascade. Beside optimal bio-distribution of the dimerization inducer, iCasp9-based cell safety switch offers superior pharmacodynamical properties than the HSC-tk system, and leaves GCV available for antiviral therapy^[73]. The major issue of this suicide gene strategy is that anti-tumor T cells could be definitely eliminated, impairing the efficacy of cellular therapy. However, to date, no suicide gene therapy has been already used in human clinical trials with engineered CAR T cells. Although not as effective as CAR using integrating vectors technology, transient CAR expression is an interesting alternative approach currently under investigation. According to a recent study published by the University of Pennsylvania, CAR mRNA can be efficiently transduced into T cells by *in vitro* repeated electroporation procedure and administrated repeatedly safely, avoiding the risk of CAR T cells accumulation. This approach precludes transgene persistence for one week or two, and a rapid decrease of toxicity in case of adverse events after T cell discontinuation^[73]. The current stocks and production rates of adequate serum for good manufacturing procedure (GMP) are insufficient regarding the outgrowing demand, suggesting a further development of serum-free conditions for cell therapy cultures^[74].

CAR'S CULTURE: EXPANSION, PERSISTENCE AND TRAFFICKING

The technique and the duration of CAR T cell cultures prior CAR transfection and infusion of the product may be also critical in the setting of clinical activity. Autologous/allogeneic non modified-T cells are harvested from peripheral blood by leukapheresis, with heterogeneous threshold according to the underlying pathology. Then, naive T cells are expanded *ex vivo* generally with an artificial-antigen presenting cell system or anti-CD3/CD28 coated beads in combination with various cytokines (IL-2, IL-15, IL-17, IFN γ). As T cells are grown under GMP, expansion protocols and manufacturing input may vary among centers, depending on transduction efficiency yields, CD4/CD8 ratio, and final T cell phenotype. Most of culture protocols support the acquisition of a central memory phenotype (CD45RA⁺/CD122^{low}/CD62L^{low}/CCR7⁺), which is associated with self-renewal, high proliferation potential, and increased longevity. However, it was highlighted that proliferation, cytolytic activity, and persistence are markedly hampered by long-term *ex vivo* cultures, likely due to T cell exhaustion and telomere length shortening^[36,58]. In addition, the T cell subtype transduced with CARs seems to play a key role in the clinical efficacy of adoptive immunotherapy. Due to their well-known cytolytic activity through granzyme/perforine and Fas/FasL complexes, $\alpha\beta$ CD8⁺ CAR T cells have been considered as the effective component of CAR T cell-based therapy and have been the major T cell subset used in pre-clinical trials. However, recent data revealed that CD4⁺ T cell subset transduced with CARs showed cytolytic activity similar to that of CD8⁺ T cells toward their targeted antigen. They are also useful on CAR mediated activation^[75,76]. All T cell subsets play a key role in the anti-tumor immune response. The most powerful subset depends likely on tumor phenotype, its accessibility, and the tumor-cytokine microenvironment. In this setting, $\gamma\delta$, Th17, central memory, stem cell like memory, virus specific T cells and hematopoietic stem cells are also a part of CAR-based therapy^[77-80].

For a long-term disease control by adoptive immune surveillance, engineered T cell persistence is highly warranted. Preclinical studies indicate that tumor burden and the degree of lymphocyte depletion prior T cell infusion are likely to be critical requirements for proper T cell expansion and persistence. First clinical trials indicate that persistence and *in vivo* expansion of adoptively transferred T cells is strongly correlated with treatment outcome, as previously documented with tumor-infiltrating lymphocytes (TILs)^[45,69]. Conditioning chemotherapy is a way to enhance persistence and expansion of transferred CAR T cells. However, the optimal regimen is still a matter of debate. Although underlying mechanisms are not fully understood, this model probably involves homeostatic proliferation. Actually, T cell populations are tightly regulated by homeostatic mechanisms that maintain the T cell pool

at a near-constant level. These mechanisms mimic chronic T cell activation, depend upon TCR/MHC self-peptide interaction, and involve cytokines, such as IL-7 and IL-15. During the first clinical trials in chronic lymphoid leukemia (CLL) patients, anti-CD19 CAR T cell infusions without conditioning chemotherapy showed limited T cells persistence and disappointing results^[45]. Conversely, in a cohort of 5 relapsed ALL patients treated with 19-28z CAR T cells after lymphocyte depletion by cyclophosphamide, it was reported long-term CAR modified T cells persistence for 3 to 8 wk. Four of the five patients underwent ASCT and remained in minimal residual disease (MRD)-negative status. This study was the first to suggest an inverse relationship between CAR T cells clinical efficiency and initial tumor burden at the time of infusion. It was also shown that lymphocyte depletion prior CAR T cells infusion enhanced CAR T cells persistence^[62]. Lymphocyte depletion following chemotherapy (cyclophosphamide/fludarabine) or total body irradiation (TBI) suppresses repressive cell populations, such as T_{reg}, and cells competing for stimulatory cytokines (IL-2, IL-7, IL-15, IL-21), preventing rapid anergy of adoptively transferred T cells and transient "cytokine sink". "Cytokine sink" corresponds to the competition between transferred and host T cell subsets regarding homeostatic cytokines, and can decrease *in vivo* T cell expansion^[81]. IL-2, which has been widely used for adoptive T cell expansion *in vivo*, is essential for the maintenance of peripheral self-tolerance and is able to promote T cell effector functions. However, the administration of exogenous cytokines remains highly controversial. It has been shown that homeostasis and efficient suppressor functions of T_{reg} were essentially mediated by IL-2 receptor signaling. The infusion of anti-IL-2 plus IL-15 in tumor bearing mice increases effector functions of adoptively transferred T cells^[82]. Although IL-2 represents a key factor in the induction of terminal differentiation of effector T cells, its use for *in vivo* expansion may impair anti-tumor immunity. More recently, cyclophosphamide lymphocyte depletion has been shown to significantly reduce FoxP3 T_{reg} and to induce IL-12 and IFN γ secretion^[83]. IL-12 is a heterodimeric cytokine secreted by APCs, known to enhance T cell clonal expansion and T cell effector function in concert with TCR complex signaling (signal 1 and 2), serving as signal 3. This cytokine favors NK recruitment, but also avoid T cell anergy and T_{reg} action on effector T cells. This was illustrated by CAR targeted T cells (first generation 19z1) modified to produce autocrine IL-12 and to manage B lymphocyte depletion associated with tumor eradication^[84]. The exact schedule for infusing CAR T cells after lymphocyte depletion is still a matter of debate. Nevertheless, recent evidences support the superiority of a rapid transfer in term of T cell engraftment and immune reconstitution^[85,86].

AL is defined by an erratic clonal proliferation of immature hematopoietic stem cells, essentially localized in the bone marrow. Despite 60%-80% of CR

achievement after a first induction course of chemotherapy, most of AL patients will ultimately relapse, due to LSCs or persistence of resistant clones in unreachable reservoirs to standard chemotherapy. CAR T cells have to traffic in the entire body, after *ex-vivo/in vivo* activation, to clear central (bone marrow) and peripheral reservoirs. In solid tumors and lymphomas, preclinical studies and clinical trials have established that CAR T cells, specifically when using second generation CARs, can accumulate and persist over time at the site of disease^[47,62]. In a recent phase I study using anti-LeY CAR T cell therapy in AML, it was demonstrated by detection of a transgene derived PCR signal and by radio-labeled cells that CAR T cells have a systemic distribution and migrate to the bone marrow^[87]. Genetically engineered T cells seem to naturally traffic to the bone marrow, but also to the central nervous system (CNS), with however 5 to 10-folds less than what is observed in blood^[17,44]. The reasons why CAR T cells naturally cross the meningeal barrier remain intriguing. However, this is a major concern regarding B cell lineage-ALL, for which CNS involvement could have dramatic repercussions on treatment outcome. Lymphocyte depletion by cyclophosphamide or TBI stimulate the production of chemo-attractants by the microenvironment, and thus favor CAR T cells migration and engraftment in the bone marrow^[88]. Because chronic activation is associated with down-regulation of homing receptors such as CD62L, investigators are currently exploring genetic expression of chemokine/cytokine receptors (*i.e.*, CXCR2) and *ex vivo* cell surface glycan engineering (*i.e.*, modifications of fucosyltransferase, an enzyme involved in hematopoietic stem cell homing) in order to enhance bone marrow trafficking, which is critical for successful leukemia cell eradication^[89,90].

CARS IN ACUTE LEUKEMIA: A MATTER OF TARGET

Acute lymphoblastic leukemia

Historically, the first hematological malignancies treated with CAR T cells were CLL and lymphomas from the B cell lineage. As mentioned above, several issues have to be considered to select a target for CAR-mediated tumor cell recognition and unfortunately most of the TAA are self-antigens expressed on healthy tissues. In this setting, CD19 arise as a perfect target antigen, since it is expressed in almost all B cell malignancies (except 5% of undifferentiated immature B cell lineage-ALL) and long-term B cell depletion is generally well tolerated (*i.e.*, chimeric monoclonal antibody rituximab). CD19 is expressed on normal B lineage cells from pro-B-cells to mature B cells and plasma cells, but hematopoietic stem cells and other tissues lack this antigen expression. CD19 is thought to play a role in the balance between self-tolerance and antigen activation of the B cell receptor (BCR) complex in a specific and sensitive manner. Another hypothetical advantage of CD19 is

that CD19-positive cells are constantly produced in the bone marrow, thus providing an inexhaustible source of antigen stimulation. It was shown that CD19 was involved in Myc driven B cell oncogenesis in a BCR-independent manner, through paired box protein 5^[91]. Although they are sharing the same target, B cell lineage malignancies may respond differentially to adoptively transferred T cells. Based on promising pre-clinical data with first and second-generation CARs, first trials with anti-CD19 CARs were designed in patients with recurrent indolent NHL or CLL. They showed promising results with prolonged CR^[37,47,69]. However, the initial enthusiasm was hampered by further trials showing no CR achievement and very limited CAR T cells persistence^[47,62]. Discrepancies among studies could be attributed to the suppressor role of the tumor microenvironment, differences in treatment history, pretreatment tumor burden, potential tumor resistance to the lymphocyte depleting agent, and/or impaired T cell immunological function in lymphomas^[92,93]. CD-19-CAR T cells appeared as the best choice for the treatment of B-cell lineage-ALL with an overall CR rate of 80% (Table 2). The first case of treatment by CD19-CAR T cells in B cell lineage-ALL has been published by the Memorial Sloan Kettering Cancer Center. The patient was in early relapse and has been treated with second generation 1928z CAR T cells (second generation CAR T cells anti-CD19 scFv CD28-CD3 ζ). After CR achievement, the patient received cyclophosphamide (3.0 g/m²) followed after 2 d by a split dose of autologous 1928z T cells (1.8×10^8 cells/kg). He underwent ASCT 8 wk after T cell infusion. Prolonged B lymphocyte depletion was observed and related to 1928z CAR T cells persistence confirmed by immunohistochemistry on bone marrow aspirates through 6 to 8 wk post-infusion^[62]. This trial has been recently updated reporting about 13 patients (including the first one) with relapsed/refractory B cell lineage-ALL (of whom 3 patients with Philadelphia-positive B cell lineage-ALL). CR rate was 85% (10/13 patients) with complete molecular responses obtained 7 to 14 d after T cell infusion. Cytokine release syndrome (CRS) was observed in 6/13 patients and was controlled by corticosteroids or anti-IL-6R antibody therapy. Nine of the 13 patients underwent ASCT^[94]. Another phase 1 trial was reported in 5 adults with relapsed/refractory B cell lineage-ALL. They received one single dose of autologous 1928z-CAR T cells (1.5 to 3×10^6 cells/kg) after administration of high-dose cyclophosphamide. All patients became MRD-negative after CAR T cell infusion. Four of them underwent ASCT and were still MRD-negative at the time of the last report. The last patient, ineligible for ASCT and further CAR T cell infusion, relapsed 13 wk after T cell administration. Relapse was due to abrogation of CAR T cells persistence^[63]. Another phase 1 study, using virus-specific 1928z-CAR T cells (CD19 CAR-VSTs, cytotoxic T cells with a native receptor specificity directed to persistent human viruses) in patients relapsing after ASCT or with high-risk B cell malignancies, included 3 patients with B cell lineage-

Table 2 Completed chimeric antigen receptor T cells trials including acute leukemia patients

Indications	CAR construct	Vector	Cell dose	Pre-treatment	Patients	Responses	Relapses	CAR persistence (days median)	Toxicities	Ref.
Acute lymphoid malignancies										
Relapsed B-ALL ± post-ASCT	Anti-CD19 scFv 4-1BB-CD3ζ	Lentiviral	10 ⁶ -10 ⁷ cells/kg	Cy	30	90% CR (27/30)	6 relapses (one CD19)	145	CRS for all responding patients (fever, ARDS, MODS)	[17,97,98]
Relapsed B-ALL post-ASCT	Anti-CD19 scFv CD28-CD3ζ	γ-retroviral	10 ⁶ cells/kg	Cy + flu	2	100% CR (5/5)	1 transient CR	ND	Mild CRS, no GVHD	[117]
B-ALL relapsed	Anti-CD19 scFv CD28-CD3ζ	γ-retroviral	3 × 10 ⁶ cells/kg	Chemo	13 (3 Ph ⁺ B-ALL)	85% CR (10/13)	1 NR, 1 relapse	ND	6/13 CRS	[62,94]
B-ALL relapsed without prior ASCT	Anti-CD19 scFv CD28-CD3ζ	γ-retroviral	1.5-3 × 10 ⁶ cells/kg	Cy	5	100% CR (5/5)	1 relapse (no ASCT)	ND	3/5 mild CRS (MRD ⁺ or bulk)	[63]
Relapsed B-ALL/CLL post-ASCT	Anti-CD19 scFv CD28-CD3ζ VST (CMV, EBV, ADV)	γ-retroviral	1.5 × 10 ⁷ -1.2 × 10 ⁸ cells/m ²	No	4 (4/8)	75% CR (3/4), 25% PD (1/4)	1 relapse (no ASCT)	80	No CRS, No GVHD	[95]
Acute myeloid malignancies										
Relapsed AML	Anti-LeY scFv CD28-CD3ζ	γ-retroviral	1.3 × 10 ⁹ cells	Chemo	4	25% CR, 50% SD	4 relapses	14-120	Neutropenia, skin "flare" reaction, fever, rigors	[87]

CAR: Chimeric antigen receptor; ADV: Adenovirus; AML: Acute myeloid leukemia; ARDS: Acute respiratory distress syndrome; ASCT: Allogeneic stem cell transplantation; B-ALL: B-lineage acute lymphoblastic leukemia; Chemo: Chemotherapy prior CAR T cells infusion; CLL: Chronic lymphoid leukemia; CMV: Cytomegalovirus; CR: Complete remission; CRS: Cytokine release syndrome; Cy: Cyclophosphamide; EBV: Epstein Barr virus; GVHD: Graft versus host disease; MODS: Multi-organ dysfunction syndrome; ND: Not determined; NR: No response; PD: Progressive disease; SD: Stable disease; VST: Virus specific T lymphocytes.

ALL. No pre-conditioning regimen was administered. CD19 CAR-VSTs required several rounds of expansion (5-6 wk of cell culture) before infusion in order to reach clinical CAR T cell threshold. No GVHD was observed and all B ALL patients achieved CR, but relapsed between 2 to 8 mo after T cell infusion (Table 2)^[95]. The largest cohort was initially reported by the Children Hospital of Philadelphia in 2013 and updated at the 2014 EBMT meeting. The study included 30 patients (25 children and 5 adults) with chemo-refractory B cell lineage-ALL or ALL relapsing after ASCT. Patients received CTL019 CARs (second generation anti-CD19-scFv CAR T cells) coupled with 4-1BB endodomain and lentivirus transfected. The median dose of CTL019 was 3.7×10^6 cells/kg administered in 3 doses with 5×10^9 total cells as a target dose. Lymphocyte depletion regimens varied among patients, but were mostly based on cyclophosphamide administered during the week prior T cell infusion. Patients were at least in second relapse or were refractory to several lines of treatment. Overall, 90% of them achieved CR, and half of them underwent subsequently ASCT. With a median follow-up of 3.4 mo (range: 2-18 mo), only 6 patients relapsed. In one case, relapse occurred with emergence of CD19 negative blast cells. As previously reported with blinatumomab (a

bi-specific T-cell engager antibody designed to redirect CD3⁺ cytotoxic T cells to CD19⁺ malignant B cells), this relapse from CD19 negative leukemia cells illustrates the impact of such a targeted therapy on leukemia sub-clones^[96]. No such cases have been reported in CLL^[93]. CRs were observed independently of the level of tumor burden before T cell infusion. Among the 16 patients treated after ASCT, T cells were efficiently collected from recipient. No GVHD recurrence was observed after CAR T cell infusions. CTL019 cells expanded to levels that were more than 1000 to 10000 times as high as the initial levels. CAR T cell persistence was observed until 6 to 18 mo. This was concomitant of B lymphocyte depletion in responding patients, as previously reported in CLL patients treated with CTL019. Long-term persistence (≥ 145 d) was significantly associated with CR achievement. All responding patients developed some degree of delayed CRS, which was concomitant to T cell expansion and increased levels of IL-6. This seemed in relationship with the tumor burden prior CAR T cell infusion (Table 2)^[17,97,98]. Overall, these first results suggest that CD19 gene-modified T cell therapy is likely not enough efficient by itself, but it should be considered as a potentially life-saving bridge to ASCT. Recently, a multi-center clinical consortium was proposed in order

to harmonize practices and further export this new technology to academic institutions.

Alternative targets are likely to be developed. CD22, a type I trans-membrane sialo-glycoprotein expressed specifically on B lineage cells, is closely related to the BCR pathway. Moxetumomab pasudotox, an anti-CD22 covalently fused to a pseudomonas exotoxin, has shown promising results^[99], and could be considered as a suitable possible choice. On the other hand, in order to prevent antigen loss through selective clonal pressure and to improve tumor specificity, investigators are developing combinatorial antigen recognition strategy, and oncogene targeted CARs^[100,101].

Acute myeloid leukemia

Treatment of AML remains a great challenge. Whereas combined efforts in the field of intensified chemotherapy, SCT, and supportive care have yielded to improve survival, more than 50% of patients will relapse. Because 70% of AML patients are over 60 years, many of them are not eligible for ASCT^[102]. Recent preclinical reports demonstrated that CAR T cells have the potential to effectively and durably eradicate primitive myeloid blast cells^[103,104]. Although two trials are currently recruiting in China and in Australia, only one phase 1 trial, targeting Lewis Y (LeY) antigen coupled with cytoplasmic CD28 and CD3 ζ chain, has been reported so far in the literature regarding AML (Table 1). LeY antigen is a difucosylated carbohydrate antigen, part of the human blood system. It is widely expressed on AML cells, but has a limited expression in healthy tissues. However, its exact role and its functional significance for survival of the leukemia cells have to be elucidated. Four patients received 1.5 to 4.7 $\times 10^6$ cells/kg CAR T cells 6 wk after fludarabine-based chemotherapy regimen. A modest T cell expansion and persistence (1 to 10 mo) was observed and resulted in limited advantages. Only 2 out of four treated patients showed a reduction of leukemia cells. Beside these disappointing results, this study conveys major endpoints. Infusions were well tolerated with no CRS even in cases presenting with a high tumor burden. Second, it was demonstrated by SPECT imagery that anti-LeY CAR T cells can target bone marrow leukemia cells, but also peripheral lesions (leukemia cutis). The absence of down-regulation of LeY antigen after CAR T cell infusions suggests that this target is suitable for long-term immune control of the disease^[87]. However, the weak anti-leukemia activity of this antigen-based therapy should be balanced with combinatorial recognition strategy or loaded in more potent effectors such as CIK cells. Other antigens are also on the bench, such as CD33, CD123 or CD44v6, but only pre-clinical data are currently available, demonstrating a potential efficacy against AML blasts. CD33 is a member of the sialic acid-binding receptor family and is highly expressed on myeloid progenitor cells, and on the surface of 90% of AML blasts. Gemtuzumab ozogamicin (Mylotarg), an anti-CD33 humanized mAb conjugated

to calicheamicin, was the first agent of its class and one of the first targeted therapies in AML. However, initial enthusiasm was tempered by inadequate efficacy, severe hepatotoxicity (*i.e.*, veino-occlusive disease) related to accumulation of the drug acting like an intercalating agent, and prolonged neutropenia^[105]. Moreover, drug resistance rapidly may occur by active efflux from leukemia cells through the P-glycoprotein pump. Because of the very strong non HLA-restricted NK-like cytotoxicity and the lack of allogeneic activity in the ASCT setting, CIK have been largely used in pre-clinical studies of CAR redirected T cells in AML. Anti-CD33 CAR-T cells might have several potential advantages over gemtuzumab ozogamicin. First pre-clinical data using CIK and EBV-specific T cells endowed promising features^[104,106]. Beside the anti-leukemia activity and its expected myelotoxicity, *in vitro* colony forming unit (CFU) assays showed remnant clonogenic activity of hematopoietic progenitors suggesting that toxicity is reversible. Furthermore, it was shown that anti-CD33 CAR T cells with CD28-OX40 endodomains exert cytolytic activity on KG-1 cell line, known to be resistant to gemtuzumab ozogamicin^[106]. In order to avoid off-target toxic effect on hematopoietic stem cells (HSC), CD123, also known as IL-3 receptor α -subunit, appears as an attractive target. Its functional role in AML is still unknown. CD123 is widely over-expressed among AML blasts and LSCs, while its expression is lower on HSCs, monocytes, and endothelial cells. The expression of CD123 at the time of diagnosis has been associated with a poor prognosis and resistance to apoptosis. Preliminary *in vivo* data showed that one single administration of anti-CD123 CAR T cells led to an immunologic memory associated with a specific anti-tumor response, yielding to long-term survival in mice engrafted with AML cell lines or fresh AML cells^[107]. Results of CFUs, regarding distinct anti-CD123 CAR constructs, were heterogeneous. However, one study revealed a limited activity against normal CD123^{low} expression on endothelial cells and monocytes^[31,103,104]. It is therefore hypothesized that suboptimal affinity of the scFv for CD123 allows recognition of targeted cells by CAR T cells, according to their antigen density and their expression of co-stimulatory molecules^[108]. The hyaluronase receptor CD44, a ligand for E-selectin, is broadly expressed on malignant cells in hematological malignancies. It plays a crucial role in the bone marrow homing of initiating leukemia cells and in interactions with the microenvironment. It was recently showed that CD44 inhibition drives leukemia cells into differentiation and apoptosis by dislodging them from the osteogenic niche^[109]. The isoform variant 6 (CD44v6) recently emerged as one of the most promising TAA for AML. It is absent on normal HSCs, but is over-expressed in 80% of AML cells^[110,111]. It has been demonstrated that anti-CD44v6 redirect T cells were able to efficiently kill leukemia cells, while sparing HSCs and keratinocytes that expressed low levels of CD44v6^[72]. These findings suggest that "off tumor" target expression levels do

not accurately predict susceptibility to CAR T cells^[72]. All together, these results suggest that anti-CD123 and anti-CD44v6 CARs are safer than anti-CD33, but *in vitro* data have to be confirmed in clinical practice (Table 1).

TOXICITY: NEW INSIGHTS IN CYTOKINE RELEASE SYNDROME MANAGEMENT

With the development of new therapeutic reagents, physicians have to face previously unknown toxicities. Immunotherapy adverse events are mainly related to autoimmune direct toxicity, known as “on tumor/off target effect”, and to an indirect cytokine-associated toxicity, called CRS.

Indirect toxicity: Cytokine release syndrome

CRS has been initially described following mAb infusions (*i.e.*, anti-CD52 or anti-CD20) and more recently with bi-specific antibodies and CARs^[112,113]. This syndrome is characterized by a massive non-antigen specific inflammatory response. CRS shares features with macrophage activation syndrome, such as cytopenia, fever, hyperferritinemia and hypofibrinogenemia. Regardless the TAA target, it seems that T cell expansion activates other hematological effectors (B cells, neutrophils, macrophages), and favors release of inflammatory cytokines, such as TNF- α , IL-2, IL-6, IL-13 and IFN γ ^[44,98]. Symptom onset has been reported with a widely variable timing among clinical trials, ranging from 1 d to 3 wk for anti-CD19 CARs. All CRS reported with anti-CD19 in ALL trials were related to the tumor burden prior the first infusion and corresponded with maximal *in vivo* T cell expansion. Symptoms of CRS were drastically mild or even absent with anti-LeY in AML and with anti-CD19 CARs in CLL^[45,87]. The magnitude of immune activation after engineered T cell infusion is therefore dependent upon the underlying condition, the remaining lymphocyte pool, and CAR T cell features. Symptoms are not specific and confusion can be made with those of infections. Fever appears as the hallmark of CRS, and arises generally concomitantly to rigors, myalgia, and gut disorders. However, other life threatening complications can occur. Recently, IL-6, a pleiotropic cytokine with ambivalent functions, emerged as the gatekeeper in the pathophysiology of CRS. In this setting, tocilizumab, an anti-IL-6R mAb initially developed for rheumatologic autoimmune diseases, has proven its efficacy in severe CRS. This agent showed a safe profile with few side effects at the recommended dose (one injection at 8 mg/kg for children and 4 mg/kg for adults). It did not seem to alter anti-leukemia functions of the transferred T cells. Alternative therapy in non-responders could involve anti-TNF- α mAb (infliximab), soluble TNF- α receptor (etanercept), or corticosteroids especially in patients presenting neurological symptoms^[114]. Cardiac complications (similar to stress cardiomyopathies) are non frequent and generally reversible events, although

potentially fatal. Neurological symptoms include mainly headache, dysphasia, confusion, seizure. Magnetic resonance imaging has shown abnormalities consistent with a mild encephalopathy with reversible splenial lesion syndrome, as observed in severe viral infections. The exact pathophysiology of neurological features during CRS is not fully understood, but seems to be related to a direct neurotoxicity of IL-6^[115]. IL-6 levels in cerebrospinal fluid have been monitored during CRS and have shown high levels. It can be hypothesized that systemic inflammatory response after CAR T cells infusion could lead to permeable blood-brain barrier, yielding trafficking of IL-6 and activated immune cells to CNS. At least for CTL019, CAR T cells revealed to cross the blood-brain barrier and to be evolve in the neurological symptoms, which can be overcome by tocilizumab therapy. However, the occurrence of neurological symptoms can be enhanced by the IL-6R inhibitor. Tocilizumab may inhibit the IL-6 receptor mediated clearance and may allow transient increase of IL-6 levels. In patients with severe neurological symptoms, but without other life-threatening organ failure, it has been recommended to treat with corticosteroids (especially dexamethasone)^[116]. Acute respiratory distress syndrome, hepatic/renal failure, disseminated coagulopathy have also been reported.

Direct toxicity: “On tumor/off target effect”
