an inspiring alternative to restore cardiac function after myocardial infarction. A large body of evidence has been obtained in this field but there is no conclusive data on the efficacy of these treatments. Preclinical studies and early reports in humans have been encouraging and have fostered a rapid clinical translation, but positive results have not been uniformly observed and when present, they have been modest. Several types of stem cells, manufacturing methods and delivery routes have been tested in different clinical settings but direct comparison between them is challenging and hinders further research. Despite enormous achievements, major barriers have been found and many fundamental issues remain to be resolved. A better knowledge of the molecular mechanisms implicated in cardiac development and myocardial regeneration is critically needed to overcome some of these hurdles. Genetic and pharmacological priming together with the discovery of new sources of cells have led to a "second generation" of cell products that holds an encouraging promise in cardiovascular regenerative medicine. In this report, we review recent advances in this field focusing on the new types of stem cells that are currently being tested in human beings and on the novel strategies employed to boost cell performance in order to improve cardiac function and outcomes after myocardial infarction.

Key words: Stem cells; Cardiac repair; Myocardial infarction; Heart failure; Second generation

Core tip: Myocardial infarction and heart failure represent two of the most prevalent and fatal diseases. Stem cell therapies represent a novel approach capable of restoring the cellular loss observed in these conditions. Data from initial human studies have been encouraging but inconclusive. However, refinements in cell populations as well as new stem cell sources are currently being tested in large phase III clinical trials after showing positive results in preclinical models and early clinical reports, thus holding a promise for the achievement of a true

Abstract

Over the last years, stem cell therapy has emerged as

myocardial regeneration after myocardial infarction. We review here recent developments in this field.

INTRODUCTION

Cardiac heart disease is a leading cause of mortality and morbidity worldwide. Coronary heart disease (CHD) is estimated to affect near 16 million people in the United States and accounts for about 1 of every 6 deaths^[1]. CHD and myocardial infarction (MI) are also a major cause of heart failure (HF), which is an important public health issue with an estimated prevalence of 5 million in the United States^[1] and 23 million worldwide^[2].

Risk factor modification, advances in medical, device-based therapies and interventional management have improved cardiovascular outcomes^[3], but even when mortality has shown a decline in most developed countries since mid 70s^[1,4-6], CHD is the leading cause of death in the United States^[7]. Its main consequence - HF - carries a poor prognosis, even worse than many cancers^[8]. Moreover, the decline in MI acute mortality achieved with primary percutaneous coronary interventions (PCI), has augmented the prevalence of HF among survivors^[9,10], because of the development of substantial scarring despite reperfusion strategies^[11].

Current treatment of systolic HF is mainly focused on counterweighting the neurohormonal activation cascade, improving contractile function and reducing the incidence of sudden cardiac death^[3]. None of these approaches is capable of restoring the cellular loss produced after MI, which is the cornerstone of the adverse ventricular remodeling process that leads to HF. Heart transplantation is a not viable alternative in most cases, and is hampered by limited donor hearts.

Since the beginning of the past decade, regenerative cardiac therapies have emerged as an option to satisfy these unmet needs^[12-14]. Until the end of the last century, the human heart was believed to be a terminally differentiated post mitotic organ, unable to be repaired after an injury such acute MI. This dogma was challenged in 2001 by the evidence of mitosis in cardiomyocytes after MI^[15]. Beyond that, and in contrast to some lower vertebrates^[16], cardiac self-repair ability is limited in human adults^[17], and unable to replace the massive cellular loss that occurs after MI, but its discovery opened up the possibility to be externally enhanced. In order to achieve this objective, two approaches can be adopted: (1) the addition of

progenitor cells for the repopulation of the damaged heart with contractile cells and vascular structures; and (2) the enhancement of cardiac self-repair ability. Most times both mechanisms are concomitant. The former, represented by stem cell therapy, has been the most extensively investigated, being tested in several studies enrolling thousands of patients worldwide and evaluating different cell types and delivery routes. Promising results were reported in preclinical studies, leading to a quick translation into clinical trials. Initial reports in human beings were encouraging and established the safety of these therapies. But their efficacy has been subject of continuous debate, since robust evidence is lacking due to inconsistency in benefits observed in clinical trials. Differences in methodologies have been invoked to explain these discrepancies. Notwithstanding, this initial preclinical and clinical data have provided important insights into the selection and manufacturing of cell products, their delivery and the mechanisms of action that drive myocardial regeneration. The initial concept of achieving cardiac repair by differentiation of stem cells into functional cardiomyocytes and vascular structures has shifted towards a paracrine paradigm, where stem cells exert their beneficial effects by promoting myocardial salvage and self-repair mechanisms.

So far, the optimal source for stem cell therapy as well as its processing, delivery route and dosage, remains unknown and many fundamental issues need to be addressed. Ideal stem cell therapy must accomplish with several requirements including: (1) the ability to regenerate damaged myocardium; (2) the ease of obtaining, storing and delivering; (3) no tumorigenesis, immunogenicity or ongoing ethical issues; and (4) cost-effectiveness. The heterogeneous cell products employed in the early years of regenerative cardiac medicine have been replaced by more purified stem cell populations with a greater reparative potential, and *in vitro* priming of stem cells to enhance their engraftment, survival, plasticity and paracrine activity, has also been extensively investigated. All of these advances have lead to a new generation of stem cells ("second-generation" stem cells) that should overcome the hurdles found with first-generation ones. In this review we summarize recent research and novel strategies in this field, focusing on priming of "first-generation" cells and on the new cell products that are being tested for cardiac regeneration after MI.

GENETICALLY ENGINEERED SKELETAL MYOBLASTS

The first type of stem cell thought to be useful for cardiac regenerative purposes were autologous skeletal myoblasts. Their muscular phenotype and many other advantageous features including ease of isolation through muscle biopsy, rapid expansion *in vitro* and lack of ethical or immunological issues made them

an attractive option^[18]. In fact, their use in animal models^[19-21] and phase I non-randomized human trials^[22-26] described their ability to form some cardiac structures and yielded promising results regarding improvement in cardiac performance after MI.

Nevertheless, subsequent studies documented that myoblasts differentiate into skeletal myocytes instead of cardiomyocytes^[27], and the first and larger randomized controlled trial in humans, the MAGIC trial, showed no benefits on cardiac function^[28].

More worrisome is the lack of electro-mechanical coupling of these cells, that made them prone to generate ventricular arrhythmias due to their inability to express certain cardiac-specific genes codifying important proteins of the gap junctions, as N-cadherin and connexin-4^[25,28,29]. Down-regulation of these genes is induced by the transdifferentiation process^[29]. However, improved electrical coupling as well as a reduction in the arrhythmogenic potential of the transplanted cells was demonstrated by the enhancement of connexin-43 expression *via* genetic manipulation^[30-32].

Another drawback of skeletal myoblasts in their application for cardiac repair is massive apoptosis and their low survival rate when applied to the ischemic myocardium^[33]. Pro-angiogenic factors, such as vascular endothelial growth factor (VEGF) or fibroblast growth factor (FGF), have showed their ability to induce angiogenesis^[34,35]. Indeed, transfected skeletal myoblasts with augmented VEGF and FGF expression exhibit increased survival, promoted by an anti-inflammatory and angiogenic effect^[36-38]. Cell survival after transplantation can also be improved using myoblasts lacking the *MyoD* gene. These myoblasts induce angiogenesis *via* secretion of stromal cell-derived factor-1 (SDF-1) and placental growth factor^[39], and are less sensitive to apoptosis by up-regulation of a number of anti-apoptotic genes (*Pax3*, *Bcl-2*, *Bcl-xl*)^[40].

Despite of these advances, skeletal myoblasts seem far from being the optimal cell source, with safer and more efficacious novel cell types displacing its role in cardiac regenerative medicine.

BONE MARROW DERIVED STEM CELLS

Bone marrow derived mononuclear stem cells

Bone marrow derived mononuclear stem cells (BMMNCs) are the most extensively used type of cells for cardiac regeneration. They represent a heterogeneous mixture of mononuclear stem cells including hematopoietic and endothelial progenitors and mesenchymal stem cells. The landmark study of Orlic *et al.*^[41] was the proof-of-concept that a population of Lin⁻/c-kit⁺ BMMNCs was capable of transdifferentiating into myocytes and vascular structures and restore a large amount of the damaged myocardium after MI in a mice model. This finding generated great interest in this type of cells, spurring

an intense research and rapid clinical translation.

The exact mechanisms by which BMMNCs are thought to work remain poorly understood. Different explanations have been advocated including paracrine effects, transdifferentiation into cardiomyocytes and activation of resident cardiac stem cells^[42-44].

Many studies have shown a positive effect of BMMNCs in cardiac function after MI, both in the acute and chronic phases^[45-51], although some other trials reported a less evident or even absent benefit^[52-62]. The different clinical settings where cells have been tested, as well as methodology differences in these trials may explain, at least in part, the contradictory observed results. Five systematic reviews and meta-analyses concluded that BMMNCs transplantation after MI resulted in a better left ventricular function and remodeling with a modest but significant improvement in left ventricular ejection fraction (LVEF), ranging from 2.55% to 3.96%. No safety concerns have been observed and what is more provocative, better clinical outcomes have been documented in treated patients, although these trials did not include hard clinical endpoints as primary objectives^[63-67].

BMMNCs-based therapies face many limitations: (1) homing, engraftment and maintenance of cells in the transplanted tissue^[68]; (2) limited plasticity when using adult stem cells^[69,70]; and (3) depletion and impairment of their functionality associated with advancing age and comorbidities^[71,72]. Many different strategies for cell enhancement have been studied in the last years in order to overcome these problems.

MicroRNA (miRs) are small non-coding RNAs controlling gene expression, either by inducing mRNA degradation or by blocking mRNA translation^[73]. They are involved in the maintenance of the pluripotent state of stem cells and its over-expression is able to induce such a state in somatic cells^[73,74]. They also participate in the differentiation and lineage commitment processes^[73,74]. Thus, miRNAs have been investigated as a target for stem cell enhancement. For instance, cardiovascular diseases and ageing promote up-regulation of the pro-apoptotic and anti-proliferative miR-34a in human BMMNCs. Its inhibition *in vitro* has shown to improve cell survival and their therapeutic benefit in a mice model of MI^[75]. Furthermore, BMMNCs seem to regulate the expression of miRs in cardiomyocytes *in vivo*. In a mice model, intramyocardial delivery of BMMNCs mediated a paracrine effect by releasing insulin-like growth factor 1 (IGF-1) which inhibited the expression of the pro-apoptotic miR-34, thereby exerting a cardioprotective effect^[76].

But as in the case of skeletal myoblasts, new and more refined cell products are supplanting BMMNCs. In the meanwhile, definitive conclusions about the efficacy of BMMNCs after MI are expected to be elicited by the ongoing BAMi trial (NCT01569178). This large scaled, multinational, multicenter randomized and controlled trial, will test for the first time, the effect of

intracoronary infusion of BMMNCs three to six days after acute MI with LVEF < 45% on all-cause mortality as its primary endpoint. Over 3000 patients in 11 European countries are planned to be enrolled. This trial will help to trace the future directions that should be followed with BMMNCs therapies, supporting its administration, warranting further investigations or definitively leaving apart their use to focus on new generations of cells.

Mesenchymal stem cells

Mesenchymal stem cells (MSCs), also known as multipotent stromal cells, represent a subset of BMMNCs discovered more than 40 years ago^[77]. They can be found within connective tissue in other organs, from which they can be easily isolated and cultured. They have awoken a big interest in recent years because they display a number of traits that made them an attractive cell product for cardiac repair^[78]. MSCs are multipotent and have the capability to transdifferentiate into lineages of mesodermal tissues^[79,80], including cardiomyocytes^[81]. *In vivo* studies have also proved the ability of human MSCs to differentiate into cardiomyocytes in adult mice hearts^[82]. They also display a great paracrine potential, secreting growth factors that promote endogenous healing^[83].

A number of preclinical studies have shown the benefit of these cells in cardiac function after MI^[84-86]. Clinical trials have also elicited promising results^[87,88] and a small and recent randomized phase I and II placebo-controlled trial suggested that transendocardial injection of MSCs is superior to BMMNCs and placebo in reducing scar size in chronic ischemic cardiomyopathy^[89].

But similarly to BMMNCs, autologous use of MSCs is hampered by their loss of functionality associated with ageing and comorbidities^[71,72], and their heterogeneous phenotype compromises their therapeutic effect^[90]. A variety of different strategies have been developed in order to improve MSCs regenerative potential. One of the most promising is the so-called "guided cardiopoiesis" of MSCs. This term defines the process by which a stem cell is engaged towards a cardiac differentiation program while its proliferative and self-renewal capacities remain intact^[91]. This can be achieved by mimicking the cardiogenic instructive signals that drive the embryonic development of the heart^[92]. The up-regulation of certain cardiac transcription factors such as Nkx-2.5, MEF2C, FOG-2, TBX5, MESP1 and GATA-4 is responsible of the adoption of a cardiogenic phenotype in MSCs, preserving their proliferative ability before the final differentiation step towards sarcomerogenesis begins^[92,93]. The up-regulation of these cardiac transcription factors is feasible when MSCs are cultured within a cardiogenic cocktail containing transforming growth factor beta (TGF- β), bone morphogenic protein (BMP)-4, activin A, FGF-2, IGF-1, interleukin (IL)-6, factor IIa (h-alpha-thrombin) and retinoic acid^[93]. Differentiation beyond this intermediate state is possible by exposing the cells to a 1% human

platelet lysate medium^[93]. In a murine model of ischemic cardiomyopathy, the priming of MSCs with these growth factors led to a cardiopoietic phenotype that improved their therapeutic benefit (by yielding sarcomere-containing myocytes with electromechanical response, and with mitochondrial structures closer to that seen in adult cardiomyocytes)^[93]. In another rat model of MI, transplantation of pretreated MSCs with IGF-1, BMP-2 and FGF-2 led to increased tolerance to hypoxic conditions of the MSCs and augmented expression of connexin-43 and gap junctions linking MSCs to cardiomyocytes. Indeed, MSCs exerted a protective effect over cardiomyocytes against hypoxia mediated by these gap junctions, showing a superior myocardial salvage of the infarcted heart and leading to an improvement in left ventricular function^[94]. Recently, the C-CURE clinical trial (Table 1) addressed the feasibility and the safety of cardiopoietic autologous MSCs in a randomized trial involving 48 patients with chronic ischemic HF^[95]. In this phase II study, the lineage-guided therapy with primed MSCs resulted in a total improvement in LVEF of 7% over baseline, compared to 0.2% in the standard of care group. Reductions in left ventricular volumes and increases in the 6-min walk distance were also observed. No adverse events related with the cells were documented^[95]. This study has supported the initiation of two ongoing large phase III trials, CHART-1 (NCT01768702) and CHART-2, where autologous cardiopoietic MSCs will be tested in patients with chronic HF secondary to IM.

A drawback of MSCs therapy is the poor survival and the low retention rate of transplanted cells that limit their regenerative potential. *Ex vivo* genetic modification may enhance viability of the transplanted cells by over-expression of anti-apoptotic genes. MSCs transduced with vectors encoding for genes such as heat shock protein (Hsp27)^[96], microRNA-1^[97], and protein kinase type 1 α ^[98] have shown increased survival and a more effective and efficient performance restoring cardiac function compared to conventional MSCs in rodent models of MI. Other pharmacological approaches to improve cell retention have also been evaluated. Thymosin β 4 is a protein implicated in cytoskeletal homeostasis that has been shown to protect MSCs against hypoxic injury and to increase cell retention in a rat model of MI^[99].

In summary, MSCs are among the most promising cells for cardiac reparative medicine. Novel approaches that prime cell functionality have shown encouraging results that have led to ongoing large-scaled randomized phase III clinical trials.

CARDIAC STEM CELLS

The classic concept stating that the adult mammalian heart is a post-mitotic organ without self-renewal capacity was challenged in the beginning of the past decade. The first evidence came out with the finding of mitosis among cardiomyocytes in human hearts after MI by Beltrami *et al.*^[15]. Shortly after, the same group

Table 1 Clinical trials evaluating new stem cells for cardiac repair following myocardial infarction

Study	n	Design	Type of cells	Delivery route	Clinical setting	Follow-up	Outcomes
Bartunek <i>et al</i> ^[95] (C-CURE)	47	Multicenter, randomized 2:1 (cells <i>vs</i> standard of care)	Autolo-gous bone marrow derived cardiopietic MSCs	Endo- myocardial injection	Chronic ischemic heart failure (LVEF 15%-40%)	Safety 2 yr Efficacy 6 mo	Feasible and safe ↑ LVEF ↓ LVESV ↑ 6-min walk distance and improvements in QoL and NYHA
Bolli <i>et al</i> ^[113] (SCIPIO)	23	Unicenter, randomized 2:1 (cells <i>vs</i> standard of care)	Autolo-gous c-kit+/lin- CSCs	Intra-coronary infusion	Chronic ischemic heart failure (LVEF ≤ 40% four months post CABG)	12 mo	Feasible and safe ↑ LVEF ↓ Infarct size
Malliaras <i>et al</i> ^[122] (CADUCEUS)	25	Two centers, randomized 2:1 (cells <i>vs</i> standard of care)	Autolo-gous CDCs	Intra-coronary infusion	Chronic ischemic heart failure (1.5-3 mo after MI)	12 mo	Feasible and safe ↓ Infarct size ↑ Viable myocardium and regional contractility ≈ LVEF and ventricular volumes
Hare <i>et al</i> ^[144] (POSEIDON)	30	Multicenter, randomized 1:1 (autologous <i>vs</i> allogeneic cells)	Three different doses of autologous or allogeneic bone marrow derived MSCs	Endo-myocardial injection	Chronic ischemic heart failure (LVEF ≤ 50%)	12 mo	Feasible and safe ≈ LVEF Autologous ↑ 6-min walk distance and QoL Allogeneic ↓ LVEDV

↑: Indicates increased; ↓: Indicates decreased; ≈: Indicates no change; MI: Myocardial infarction; MSCs: Mesenchymal stem cells; LVEF: Left ventricular ejection fraction; LVESV: Left ventricular end-systolic volume; QoL: Quality of life; CSCs: Cardiac stem cells; CABG: Coronary artery by-pass graft; CDCs: Cardiosphere-derived cells; LVEDV: Left ventricular end-systolic volume.

described the existence of a population of multipotent and clonogenic cells that expressed the tyrosine kinase receptor in their surface (c-kit⁺) and that were able to differentiate into the three cardiac lineages (cardiomyocytes, smooth muscle cells and endothelial cells)^[100]. Since then, strong evidence supported the concept that turnover in the adult cardiomyocyte population is provided by cardiac stem cells (CSCs)^[17,101], but the magnitude of this turnover and the exact underlying mechanisms remain unknown^[102]. CSCs are rapidly activated after myocardial injuries or physiological stimuli^[103-105]. Recently, Ellison *et al*^[106] have demonstrated in a murine model that some of the new cardiomyocytes generated after a myocardial injury are c-kit⁺ CSCs descendants. Nevertheless, this finding does not rule out other concomitant mechanisms that could be implicated in myocardial regeneration, and a recent report by van Berlo *et al*^[107] suggests that the new cardiomyocytes generated from CSCs are functionally insignificant. In fact, it is evident that self-renewal capacity of the adult human heart is unable to restore the large amount of cellular loss after MI.

Stem cell therapy with CSCs may offer some advantages over other extra-cardiac cells, because they are believed to be more prone to differentiate towards cardiac lineages. Most research has focused on transplanting CSCs in the infarcted area and various preclinical studies using this approach in different animal models have demonstrated the ability of CSCs to alleviate left ventricular dysfunction in both acute and chronic MI^[100,108-112].

These promising results warranted translation into

clinical research and led to the conduction of the first phase I clinical trial using c-kit⁺ CSCs, the SCIPIO trial^[113] (Table 1). This study reported that isolation and expansion of CSCs from cardiac tissue, harvested during coronary artery by-pass graft surgery, was feasible. Intracoronary injection of these cells in patients with left ventricular dysfunction (LVEF < 40%) after surgical revascularization improved LVEF by 12.3% compared with baseline, reduced scar size and was associated with improvements in quality of life and New York Heart Association functional class. These are preliminary data of the first eight patients enrolled in the study, which is still ongoing.

However the number of CSCs in adult hearts is small, and albeit their *ex vivo* isolation and expansion are feasible, their availability represents a major challenge. In 2004, Messina *et al*^[114] first described the *in vitro* formation of self-adherent multicellular spherical clusters from human surgical cardiac biopsies in culture, termed cardiospheres (CSs). These CSs were clonogenic and able to yield the three cardiac lineages *in vitro* and *in vivo* when transplanted in an animal model of MI, resulting in improvements in fractional shortening^[114]. CSs have a core of c-kit⁺ cells surrounded by progenitors in distinct stages of the differentiation process towards the three major cardiac lineages. They can also be obtained through percutaneous endomyocardial biopsy and used as source for cardiospheres-derived cells (CDCs), a mixed cell population that is clonogenic, express surface markers typical of stem cells (c-kit⁺, CD105⁺), negligible hematopoietic markers, and that can be expanded on fibronectin^[115]. This approach, described by Marbán *et al*^[115], has some advantages, *i.e.*,

the larger number of cells that can be obtained and the shorter time of manufacturing, in comparison to other methods to produce CSCs^[111,116,117]. In animal models of MI, human CDCs have been shown to promote cardiac regeneration and to improve LVEF^[115,118,119]. The same group conducted a direct comparison between CDCs and other extracardiac stem cells including BMMNCs, MSCs and adipose derived stem cells (ADSCs) in order to address their potency for myocardial repair. *In vitro*, CDCs showed a greater myogenic differentiation potency and higher angiogenic and paracrine potential. *In vivo*, injection of CDCs in infarcted mice provided the greatest functional benefit^[120].

This preclinical evidence led to the first phase I clinical trial using CDCs, the CADUCEUS trial (Table 1). This study randomized 25 patients with LVEF 25%-45%, two to four weeks after MI, to receive intracoronary autologous CDCs obtained from endomyocardial biopsies or standard of care. The primary safety endpoint was the proportion of patients who died due to ventricular tachycardia, ventricular fibrillation, or sudden unexpected death, or had MI after cell infusion, new cardiac tumor formation on MRI, or a major adverse cardiac event (MACE: Composite of death and hospital admission for HF or non-fatal recurrent MI). Preliminary efficacy endpoints on MRI parameters were also analyzed. Autologous CDCs treatment was safe and associated with reductions in scar size, increased viable myocardium and regional contractility. Nonetheless, ventricular volumes and LVEF did not differ between groups^[121,122], casting doubts about the true regenerative effect of CDCs.

Notwithstanding, both SCPIO and CADUCEUS trials included a small number of patients and there are some issues concerning their results, such as the low expression of cardiac markers in CSCs in the former, and the lack of benefit in terms of LVEF in the latter. Moreover, and although in both studies a true regeneration of damaged myocardium was invoked, the real underlying mechanism of action of these cells remains unproved.

Similarly to other extra-cardiac cell types, engraftment and retention rates of the transplanted CSCs and CDCs within the harsh environment of the infarcted myocardium are low, regardless of the administration route^[112,123]. Although direct differentiation of cardiac progenitor cells in cardiac lineages has been observed, this observation of low CSCs retention rates into the myocardium further supports the hypothesis of a paracrine effect, as another pathway responsible of the positive effect of the cells^[124].

In order to overcome the limited survival and retention of the transplanted cells, different strategies have been tested in animal models. Mohsin *et al.*^[125] used genetic manipulation to deliver the pro-survival gene Pim-1 kinase into human CSCs, resulting in a superior cellular engraftment and differentiation, that led to a superior reparative potential compared with conventional CSCs in an immuno-compromised

mice model of MI. Interestingly, no oncogenic issues were observed because telomere lengthening induced by Pim-1 overexpression was transitory^[126]. Another option for priming CSCs and make them less prone to apoptosis under hypoxic conditions is the preconditioning with cytoprotective pharmacological agents. For example, treatment of CSCs with cobalt protoporphyrin reduces oxidative stress-induced apoptosis, by up-regulation of heme oxygenase 1, COX-2, and anti-apoptotic proteins (BCL2, BCL2-A1, and MCL-1) and increased phosphorylation of NRF2^[127]. Hypoxic protection can also be achieved by means of β -O-linkage of N-acetylglucosamine to certain pathway proteins. Increases in this pro-survival signaling system by thiamet-G significantly improved CDCs survival after hypoxic injury^[128]. In addition, exposure of CSCs to H₂O₂ for 2 d before transplantation stimulates neoangiogenesis in the peri-infarct area following ischemic-reperfusion injury and could be a viable therapeutic option to prevent HF^[129]. CDCs engraftment and differentiation can also be enhanced by controlled release of FGF in ischemic myocardium in a pig model of MI, resulting in a significant functional improvement^[130].

Finally, previous reports suggest that one of the mechanisms by which MSCs promote cardiac repair is the stimulation of endogenous CSCs *via* paracrine effects^[131]. This finding raised the question whether combining both MSCs and CSCs could amplify the response to cell therapy. This hypothesis has been recently addressed by Williams *et al.*^[132], they found that intramyocardial delivery of human CSCs and bone marrow MSCs in a swine model of MI resulted in a 2-fold greater scar reduction and a 7-fold enhancement of engraftment of stem cells compared with each cell therapy alone, leading to improvements in hemodynamics and LVEF.

The discovery of CSC has revolutionized regenerative medicine. As they are derived from the target organ, they are supposed to be more committed with a cardiac fate, and the understanding of the molecular mechanisms that steer their mode of action is providing new insights that extend application of cell-based therapies. Early clinical experience with CSCs/CDCs warrants further investigation in larger phase II studies that will address the unresolved issues of SCPIO and CADUCEUS. At present, three clinical trials are evaluating the effect of CSCs and CSs in myocardial regeneration after MI: the RECONSTRUCT (NCT01496209), the ALLSTAR (NCT01458405) and the ALCADIA trials.

ALLOGENEIC STEM CELL THERAPY FOR CARDIAC REPAIR

Allogeneic stem cell therapy may offer many advantages in cardiac regenerative medicine. Firstly, allogeneic cells could be used as a scalable and reproducible cell product readily available "off-the-shelf"

that could be administered in the setting of primary PCI avoiding delays inherent to harvest and culture of autologous stem cells. Secondly, this type of cells can be obtained from young and healthy donors, thereby avoiding the aforementioned impairment in autologous stem cells functionality observed with advancing age and comorbidities.

Most research in allogeneic cardiac regeneration has been done with MSCs due to their immunoprivileged profile and immunosuppressive properties. MSCs lack expression of major histocompatibility class II antigens^[133], down-regulate T cells response through direct contact and secretion of anti-inflammatory cytokines^[134] and significantly affect the ability of dendritic cells to prime T-cell responses^[135]. These findings raised interest in MSCs for allogeneic stem cell transplantation. Nonetheless, recent data have challenged this assumption suggesting that under certain inflammatory environment and during their differentiation process, MSCs can switch their immune phenotype towards an immune-enhancing pattern, limiting their long term survival and benefits^[136,137]. However, and as pointed out before, autologous stem cell therapy faces the same problem, and if the advocated paracrine effect is responsible of stem cell regenerative capacity, survival and maintenance of cells in the transplanted heart could not be indispensable^[138].

There is a large body of preclinical work supporting the safety and the efficacy of allogeneic MSCs therapy^[84,139-142]. In a large animal model of MI in pigs, Amado *et al.*^[139] demonstrated that allogeneic MSCs injections in the necrotic area were feasible with no evidence of rejection and provided near-normalization of cardiac function and Quevedo *et al.*^[84] refrained these results in a swine model of chronic ischemic cardiomyopathy, where allogeneic MSCs showed to be able to differentiate in the three cardiac lineages and to improve LVEF. These findings supported the first-in-man clinical trial using allogeneic bone marrow-derived MSCs by Hare *et al.*^[143]. They conducted a randomized, double-blinded, placebo-controlled phase I trial in which 53 patients with reperfused MI were allocated to intravenous administration of allogeneic human MSCs or placebo. The study met its primary safety objective with no evidence of tumor formation or immunogenicity. It also suggested a greater benefit in cardiac function in larger MIs and improved outcomes regarding arrhythmias and pulmonary performance^[143]. The same group has recently conducted a head-to-head comparison between autologous and allogeneic MSCs in a phase I / II randomized pilot study involving 30 patients with chronic ischemic left ventricular dysfunction secondary to MI, the POSEIDON trial^[144] (Table 1). In this case, cell therapy was delivered by transendocardial injection. Both therapies were safe, with no or negligible allogeneic sensitization in the allogeneic group and no evidence of ectopic tissue formation. Both types of cells reduced infarct

size as measured by early enhancement defects in multidetector computed tomography, but no significant improvements in ejection fraction were documented. Intriguingly, allogeneic MSCs reduced LV end-diastolic volumes while autologous did not. Furthermore, improvements in quality of life, NYHA and 6-min walk test were more evident with autologous therapy. However, the small number of patients and the absence of a placebo group make these observations difficult to interpret. An interesting finding was the greater benefit regarding LV volumes and LVEF obtained with low-dose concentrations of MSCs vs high doses (20 million vs 200 million), which is consistent with preclinical data^[145] and warrants further investigation of the optimum dose before undertaking large clinical trials.

Mesenchymal precursor cells (MPCs) represent an immature subpopulation of bone marrow-derived cells that express the Stro3⁺ marker^[146]. MPCs are multipotent cells with an extensive proliferative and differentiation capacity as well as a great paracrine potential that outperforms the one of MSCs^[147,148]. They also display an immunoprivileged phenotype, appropriate for allogeneic transplantation. Previous animal studies have provided evidence on the positive effect of these cells in the setting of acute MI when delivered intramyocardially^[145,148,149] or by intracoronary infusion^[150]. Houtgraaf *et al.*^[150] have recently reported the benefit of the intracoronary infusion of different doses of allogeneic MPCs, when delivered few minutes after reperfusion in a sheep model of MI. The therapy was safe and provided reductions in infarct size *via* cardiomyocyte salvation and proliferation, and induced angiogenesis. It was also suggested that the smaller size of MPCs, compared to MSCs, prevents microvascular obstruction due to cellular aggregation observed in previous studies. Similarly to the findings of the POSEIDON trial, the benefit was more evident in the low-dose group (< 75 million vs 200 million), an observation which may be related to the better coronary flow observed after infusion with lower number of cells.

Recently, Penn *et al.*^[151] have tested a different bone marrow-derived cell product, named MultiStem, in 19 patients with acute MI in an allogeneic setting and using a novel delivery approach. Three different doses of cells were injected through a microneedle in the culprit vessel adventitia two to five days after primary PCI. The procedure was safe and LVEF was increased when compared to registry controls.

Another milestone in the field of allogeneic cell therapy is being carried out in the CAREMI clinical trial. This study represents the first-in-man experience with allogeneic CSCs in the acute setting of CHD. It is a phase I / II clinical trial that has been designed with a first dose-escalation phase and a second part with a randomized and controlled design. In this trial, 55 patients with acute reperfused MI and LVEF < 45% will be treated with intracoronary infusion of human

allogeneic CSCs, being the primary objective the rate of death from any cause at 30 d (dose-escalation phase) and MACE and magnetic resonance parameters at 12 mo (randomized phase).

In summary, allogeneic cell therapy represent a novel approach in cardiac regeneration that could overcome some of the strong barriers found by autologous cell products. Before large scaled trials are performed, some concerning issues as immunogenicity and rejection must be thoroughly examined.

OTHER SOURCES OF STEM CELLS

In contrast to adult stem cells, embryonic stem cells (ESCs) are pluripotent, *i.e.*, they are capable of differentiate into cells of the three germ layers. ESCs isolated from blastocysts demonstrate a great potential to generate functional cardiomyocytes and their transplantation into infarcted hearts in animal models have been evaluated showing improvements in LV function^[152,153]. Despite these findings, ESCs-based therapies face strong barriers that go beyond biological aspects, such as immune rejection or tumor formation. Ethical issues also remain a major limitation to the widespread use of these cells. So far, no clinical trial has tested ESCs in humans and is unlikely to be done.

Given these constraints, Takahashi and Yamanaka reported in 2006 the feasibility of generating induced pluripotent stem cells (iPSCs) from mouse adult fibroblasts by the transduction of four transcription factors that led to a phenotype similar to that of ESCs^[154]. This achievement could prevent the immunogenicity issues inherent to allogeneic ESCs application, but do not avoid oncogenic risks^[155]. On top of this, current reprogramming of somatic cells is a low efficient process that should be refined before translation to clinical trials. Therefore, nowadays, iPSCs represent a new source of cells that holds a great promise for reparative medicine but is not ready for their application in human beings yet.

ADSCs represent a population of stem cells located in the adipose tissue that are able to differentiate into multiple cell lineages including cardiomyocytes and vascular cells^[156]. They offer two major advantages over some previously mentioned types of cells: firstly, the easy and repeatable access that makes it possible to harvest large amounts of adipose tissue by a minimally invasive method and, secondly, their increased proliferative potential in culture^[157]. Preclinical reports have documented that administration of ADSCs after MI improves cardiac function^[158,159], in a range similar to BMMNCs^[159]. They have also been tested in 2 clinical trials, the APOLLO^[160] and the PRECISE trials^[161]. The APOLLO trial was a small randomized, double-blind, placebo controlled, phase I / II study designed to assess the safety and the feasibility of intracoronary infusion of ADSCs in patients with large ST-segment elevation acute MIs. The study proved the feasibility and the safety of both liposuction and ADSCs

intracoronary infusion after MI, and showed a trend towards improved cardiac function and reductions in scar formation^[160]. The PRECISE trial reported that intramyocardial injection of ADSCs in patients with refractory angina not amenable for revascularization ("no-option" patients) improved exercise capacity and myocardial perfusion, reduced scar size and preserved maximal oxygen consumption^[161]. However, the discovery of CSCs and new developments with MSCs and allogeneic therapies have somehow waned the initial interest in ADSCs.

STEMLESS APPROACHES

To conclude, stemless therapies to restore cardiac function after MI haven also been proposed. As outlined above, if stem cell benefits are mediated by a paracrine effect and by activation of self-repair mechanisms, exogenous administration of the cytokines and growth factors implicated in the regeneration process could theoretically replace cell transplantation with a readily and "off-the-self" available product, similarly to other current biological treatments. Nadal-Ginard *et al.*^[102] advocate this cell-free therapies. They have reported that intracoronary administration of IGF-1 and hepatocyte growth factor after coronary reperfusion reduced cardiac remodeling, induced myocardial regeneration and improved ventricular function in a pig model of MI. This was achieved by activation of c-kit⁺ endogenous CSCs, which expanded and generated new cardiomyocytes and microvessels^[162,163]. Other acellular approaches have tried to promote stem cell recruitment by the infarcted myocardium. Modulation of the CXC-chemokine receptor 4 and SDF-1 axis *via* gene therapy has shown to exert beneficial effects in preclinical studies and in human phase I trials^[164,165].

In spite of that, molecular, cellular and myocardial tissue regeneration mechanisms are highly complex and driven by the interplay of several factors, not yet completely understood. Therefore, it seems unlikely that the simple administration of one or two growth factors could be capable of inducing a full cardiac regeneration. Nevertheless, further research in this field is warranted in order to shed light on these mechanisms and to elucidate if stemless approaches are a feasible option in the future.

CONCLUSION

Regenerative therapies represent a novel paradigm in cardiovascular medicine, and have grown up over infancy and into adolescence. Translation of basic research and animal studies into the clinical scenario has never been so quick, driven by the enormous enthusiasm raised by the possibility of achieving heart regeneration. This initial euphoria has been dampened by some contradictory results and by the modest benefits observed in cardiac function, leading

to skepticism in a part of the scientific community. But these pioneering results should not be interpreted as the definite evidence in favor or against cell-based reparative therapies. Instead, they have established their safety and have shown the strong barriers that should be overcome, providing important insights about the source of cells to be used as well as about manufacturing processes and delivery routes. With all this background, the state-of-the-art in the field of stem cell therapy can be summarized as follows: (1) The molecular mechanisms that rule myocardial repair are highly intricate and still remain poorly understood. It is unlikely that the simple administration of "first-generation" stem cells or growth factors to the failing heart will be able to achieve a complete restoration of cardiac function; (2) As a result of a better knowledge of the molecular and genetic mechanisms that induce progenitor cell proliferation and differentiation into cardiac structures, a new generation of cell products ("second-generation" stem cells) are now being evaluated in large clinical trials after promising and encouraging results in phase I and II studies; and (3) Combining cellular, molecular and genetic basic research with preclinical studies and well-designed clinical trials, together with more collaborative research networks and with the definitive help of bioengineering, will be the keys for the definitive development of cardiac regenerative medicine.

Keeping all this in mind, the future of stem cell-based therapies is more promising than ever, and the goal of a true regeneration or repair of the damaged myocardium stands awaiting in the years to come.

targeting components of the derailed host response have failed. Therefore, there is a dramatic need for new and mechanistically alternative therapies to treat this syndrome. Based on their immunomodulatory properties, adult mesenchymal stem or stromal cells (MSCs) can be a novel therapeutic tool to treat sepsis. Indeed, MSCs reduce mortality in experimental models of sepsis by modulating the deregulated inflammatory response against bacteria through the regulation of multiple inflammatory networks, the reprogramming of macrophages and neutrophils towards a more anti-inflammatory phenotype and the release of anti-microbial peptides. This report will review the current knowledge on the effects of MSC treatment in preclinical experimental small animal models of sepsis.

Key words: Adult mesenchymal stem cells; Therapy; Sepsis

Core tip: Sepsis remains as the most frequent cause of death in hospitalized patients and, therefore, new therapeutic alternatives are needed. Adult mesenchymal stem cells reduce mortality in experimental models of sepsis by modulating the deregulated inflammatory response against bacteria through the regulation of multiple inflammatory networks, the reprogramming of macrophages and neutrophils towards a more anti-inflammatory phenotype and the release of anti-microbial peptides. In this report we aim to provide a comprehensive snapshot of the potential clinical use of cell therapy with mesenchymal stem cells for sepsis.

Abstract

Sepsis is a clinical syndrome caused by a deregulated host response to an infection. Sepsis is the most frequent cause of death in hospitalized patients. Although knowledge of the pathogenesis of sepsis has increased substantially during the last decades, attempts to design effective and specific therapies

INTRODUCTION

Sepsis is a clinical syndrome caused by a deregulated host response to an infection. Sepsis is the most frequent cause of death in hospitalized patients. Although knowledge of the pathogenesis of sepsis has increased substantially during the last decades, attempts to design effective and specific therapies targeting components of the derailed host response have failed. Sepsis will remain an important clinical problem in the future, especially in light of the ageing population and emerging antibiotic resistance. Therefore, there is a dramatic need for new and mechanistically alternative therapies to treat this syndrome. Based on their immunomodulatory properties, adult mesenchymal stem or stromal cells (MSCs) can be a novel therapeutic tool to treat sepsis. This report will review the current knowledge on the effects of MSC treatment in preclinical experimental small animal models of sepsis.

SEPSIS

Epidemiology

The incidence of sepsis varies between different reports, largely due to the use of different case definitions and diagnosis codes^[1,2]. Nevertheless, sepsis clearly is a leading cause of death, and the most frequent cause of death in non-coronary intensive care units (ICUs) in the developed world^[2]. In the United States the yearly incidence of severe sepsis is estimated at 300 cases per 100000 person-years population, which accounts for 10% of all ICU admissions^[3]. The incidence of severe sepsis was recently reported to increase^[4], although it is uncertain whether this signifies a true increase or altered coding and registration practices^[2,5]. Mayr *et al.*^[2] have recently reported that the mortality of severe sepsis and septic shock lies between 25%-50%, with the extent and number of organ failures as the strongest predictors of an adverse outcome. Notably, the case fatality rate for sepsis has declined in the past decade, most likely due to improved general care in the ICU^[6].

The most common sources of sepsis are in descending order pneumonia, intra-abdominal-, urinary tract- and soft tissue infections^[5]. Blood cultures are positive in only one third of cases, and up to a third of cases are culture negative from all body sites. The most commonly isolated Gram-positive bacterial pathogens are *Staphylococcus aureus* and *Streptococcus pneumoniae*, and the most common Gram-negative pathogens are *Escherichia coli*, *Klebsiella spp.*, and *Pseudomonas aeruginosa*^[7]. While Gram-positive infections had been reported as surpassing Gram-negative infections in recent years^[8], a recent study encompassing 14000 ICU patients in 75 countries found that 62% of positive isolates were Gram-negative bacteria, vs 47% Gram-positive and 19% fungal^[9].

Pathophysiology and host response

Sepsis occurs when the body's response to infection

injures the host's tissues and organs. The deregulated host response during sepsis entails both excessive proinflammatory and immune suppressive anti-inflammatory components^[7,10].

Immune cells can sense pathogens *via* so-called pattern-recognition receptors (PRRs), which recognize conserved motifs expressed by microorganisms called pathogen-associated molecular patterns or PAMPs^[7,11]. Four classes of PRRs have been identified: Toll-like receptors (TLRs), C-type lectin receptors, RIG-I-like receptors and NOD-like receptors^[11]. Activation of PRRs by PAMPs causes upregulation of inflammatory gene transcription and initiation of innate immunity, a response aimed at eliminating the invading pathogen. However, when bacteria overcome the ability of the innate immune system to clear the infection, resulting in progression to sepsis, the interactions between pathogens and PRRs advances into a deregulated response that no longer benefits the host. During such injurious host response inflammation can be perpetuated by stimulation of PRRs by so-called danger-associated molecular patterns (DAMPs or alarmins), which are endogenous molecules released by injured or dying cells^[12]. Alarmins are also released during sterile injury such as after trauma or severe pancreatitis, which contributes to the concept that the pathogenesis of multiple organ failure in sepsis and non-infectious critical illness is not fundamentally different^[5,13].

Cytokines are an important component of the "hyperinflammatory" response to severe infection. Experimental sepsis induced by systemic challenge with high bacterial doses is associated with enhanced release of multiple cytokines, and elimination or inhibition of several of these proinflammatory mediators [including tumor necrosis factor (TNF)- α , interleukin (IL)-1 β , IL-12, IL-17, IL-18, interferon- γ , and macrophage migration inhibitory factor] improves survival in these models^[14]. However and importantly, these systemic challenge models do not adequately mimic the clinical syndrome of sepsis. Many trials evaluating the efficacy of proinflammatory cytokine inhibition, especially targeting TNF- α and IL-1, or other anti-inflammatory strategies have failed^[15]. Other proinflammatory mediators implicated in sepsis pathogenesis include high mobility group box 1 (HMGB1) and S100 proteins.

Activation of the complement systems forms a fundamental part of the innate immune response to infection^[16]. Sepsis is associated with systemic activation of the complement system, which can be harmful in the setting of fulminant sepsis. Indeed, neutralization or genetic absence of complement factor C5a and its receptors results in increased survival during abdominal sepsis or endotoxemia in mice. Other hallmark features of the sepsis host response include activation of the coagulation system and vascular dysfunction. The most severe manifestation of coagulopathy is the syndrome of disseminated intravascular coagulation, with an

estimated incidence between 30%-50% in severe sepsis, caused by tissue factor-driven activation of coagulation with concurrent impairment of anticoagulant and fibrinolytic mechanisms^[17]. Organ dysfunction in sepsis is at least in part caused by tissue hypoperfusion, secondary to hypotension, microvascular thrombosis and/or dysfunction of the vascular endothelium with loss of barrier function^[5]. Mitochondrial dysfunction and altered cellular bioenergetics have been implicated in sepsis-induced organ dysfunction, although further research is warranted to establish a causal relationship^[18].

While proinflammatory responses definitely contribute to sepsis pathogenesis, immune suppression is also a common feature in patients with sepsis^[7,10]. Autopsy studies have revealed strong deficiencies of splenocytes harvested from patients who had died of sepsis to produce cytokines upon stimulation^[19]. The mechanisms that underlie this phenomenon have not been fully elucidated, although likely anti-inflammatory cytokines, particularly IL-10 and transforming growth factor (TGF)- β , and inhibition of signalling by PRRs, partially due to epigenetic modifications of essential promoter regions, are involved. Moreover, apoptosis of immune cells has been implicated in immune dysfunction and mortality in sepsis^[10]. Most cells that undergo enhanced apoptosis in sepsis are of lymphoid origin (B cells, CD4 T cells), but also dendritic cells are affected. Preclinical studies have suggested that enhanced apoptosis of lymphocytes contributes to sepsis lethality^[10].

MSC

MSCs have emerged in recent years as therapeutic tools based on four important features: (1) differentiation potential; (2) capacity to modulate immune responses; (3) pro-angiogenic and repair promoting capacities; and (4) low immunogenicity; the latter feature may allow allogeneic treatments. MSCs have been found in a variety of adult tissues of mesodermal origin, such as bone marrow, adipose tissue, placenta, umbilical cord, dental pulp or synovium^[20-25]. Although sharing the main characteristics, differences between MSCs from different sources can be found, for instance at the RNA and protein expression profiles levels^[26-28]. MSCs are considered a promising tool for cell therapy, in particular for inflammatory diseases, based on their immunomodulatory properties and paracrine effects through trophic factors with anti-fibrotic, anti-apoptotic or pro-angiogenic properties^[29,30]. MSCs regulate the function of a broad range of immune cells^[30-37], and are activated by inflammatory mediators released from activated immune cells (*i.e.*, IFN γ , IL1 β and TNF α)^[38,39]. The mechanisms involved in the immunoregulatory activity of MSCs are still under investigation but rely on both cell contact-dependent mechanisms (*i.e.*, Jagged1-Notch1 interaction, Fas-Fas-L interaction)^[40,41] and

paracrine effects through the release of soluble factors including hepatocyte growth factor, prostaglandin-E2 (PGE2), TGF- β 1, nitric oxide (NO), IL-10, IL-6, heme oxygenase-1 (HO-1), HLA-G5 or the enzymatic activity of indoleamine 2,3-dioxygenase^[42]. In addition to the direct effect of these soluble factors, MSCs may also modulate immune responses through the generation of immune cells with regulatory phenotype, including regulatory T cells or anti-inflammatory macrophages^[43-45].

MSCs have also been reported to show antimicrobial activities against different pathogens upon activation with inflammatory cytokines^[46]. Noteworthy in the context of sepsis, the functionality of MSCs can also be modulated by activators of TLRs^[47]. It has been described that MSCs can be polarized *in vitro* towards either anti-inflammatory or pro-inflammatory phenotypes, depending on the TLR ligand time/concentration used for activation^[48]. Furthermore, it has been recently described that interaction of gastrointestinal bacteria (*Salmonella typhimurium* or *Lactobacillus acidophilus*) with MSCs increased their capacity to inhibit T lymphocyte proliferation *in vitro* through a PGE2-dependent mechanism, indicating that bacteria may also enhance the immunomodulating properties of MSCs^[49].

MSCs can sense inflammatory signals through the expression of cytokine/chemokine receptors and integrins, and subsequently migrate to sites of inflammation^[50]. Moreover, homing of systemically administered MSCs to lymphoid organs (draining lymph nodes and spleen) and the subsequent generation of functional Tregs have also been reported^[51-53]. MSCs do not long-term engraft at the inflammation site and cells seem to be cleared shortly after administration. This suggests that transient effects through soluble factors and cell-to-cell contacts play a main role in MSC-mediated initial controlling and balancing of local inflammation.

Allogeneic MSCs are regarded as a preferred source for treatment as they would allow treatment with a ready to use, off-the-shelf product, available for a large number of patients, specially, in acute life threatening indications like sepsis in which isolation and expansion of autologous MSCs is not an option. In that context, MSCs are considered immune privileged as they express constitutively only low levels of cell-surface HLA class I molecules and lack expression of HLA class II, CD40, CD80 and CD86 which would lead to reduced activation of the innate and adaptive immune responses^[54]. This immune privilege of MSCs therefore supports the feasibility of allogeneic treatments without the requirement of suppression of host immunity^[55,56]. However the immunogenic features of MSCs are currently under review as there is some evidence of immunogenicity in experimental animal models that coincides with immunomodulatory effects by MSCs^[57].

MSC IN EXPERIMENTAL MODELS OF SEPSIS

Sepsis being a disease that results as a consequence of deregulated inflammatory and immune responses against an infection can lead to tissue damage, multiorgan failure and death. Interest in investigating the therapeutic effect of MSCs on experimental models of sepsis emerged recently, and is based on their immunomodulatory properties^[58]. A description of the therapeutic effects of MSCs in experimental small animal models of sepsis and the mechanisms involved are described in the following sections. A summary of the data is provided in Table 1.

Experimental models of sepsis

In order to study sepsis pathophysiology, animal models of sepsis have been established. These models are normally used to preliminarily test potential therapeutic treatments prior to human clinical trials. On the basis of the initiating agent, sepsis models can be divided into three categories: toxemia models (exogenous administration of a bacterial toxin, such as lipopolysaccharide), bacterial infection models (exogenous administration of a bacteria) and host barrier disruption models (alteration of the animal's endogenous colonic protective barrier allowing bacterial leakage)^[59]. These experimental models have in common high inflammatory responses against endotoxins or bacteria, subsequent organ injury and failure and, as a consequence, high mortality rates within few hours or days. All models have contributed significantly to our understanding of sepsis pathophysiology, although no single one fully mimics the course of human disease. Two limitations of sepsis models compared to human disease are the timing of disease progression (the progression to multiorgan failure and death occurs in hours to days in most animal models, whereas in human sepsis this occurs in days to weeks) and lack of supportive therapeutic intervention (*i.e.*, intubation and mechanical ventilation, fluid therapy), in particular in small animal models. Therefore, extrapolation of efficacy results obtained in small sepsis animal models to the human disease has to be made with caution^[58,59].

The toxemia models involve the administration by intraperitoneal or intravenous injection of a bacterial toxin. Thus, a single injection of high dose LPS (normally 10-20 mg/kg) is the most commonly used toxemia model (LPS model). LPS administration induces a very rapid and transient increase in systemic cytokine levels, hypodynamic cardiovascular activity and a shock-like state. The injection of LPS may result within hours in high mortality rates that may vary with the dose, type of LPS, age and strain of animal. The bacterial infection models consist on an exogenous bacterial infection and the severity of the model may vary depending on the bacterial strain (*i.e.*, *Escherichia coli*, *Pseudomonas aeruginosa*) and route of infection

(intravenous, intraperitoneal, intratracheal) used. The clinical progression of the disease is rapid with hypodynamic cardiovascular state, high cytokine levels and progression towards death within hours. The host-barrier disruption models require the surgical disruption of the shielding barrier that protects sterile compartments from pathogens, allowing bacteria to spread. These models have become the most relevant sepsis models because they create a focus of infection that can disseminate throughout the body, mimicking the human situation. The caecal ligation and puncture model (CLP) is considered to be one of the most clinically relevant models for sepsis research. The model involves surgical ligation of the distal cecum with suture followed by one or two small punctures distal to the ligation. This allows the leakage of intestinal content into the peritoneal cavity, which results in polymicrobial sepsis (several bacterial species can be found in the blood and other organs of CLP animals). Technical variations (needle size and number of punctures) can influence the severity of the CLP model (mortality within hours or several days)^[59,60].

Effect of MSC treatment on mortality and organ injury induced by sepsis

The therapeutic effect of MSC treatment has been tested using different sepsis animal models, MSC types, dosing, timing and routes of administration. These studies have consistently reported improvement on survival rates of animals treated with MSCs (Table 1). In mice, one single dose of between 3×10^5 and 10^6 MSCs administered by intraperitoneal, intravenous or intratracheal route was able to significantly reduce sepsis-related mortality in LPS, CLP, *P. aeruginosa* peritonitis and *E.coli* pneumonia mouse models^[52,61-68]. Similar therapeutic effects have been observed using autologous, allogeneic or xenogeneic MSCs^[52,61]. Noteworthy, treatment with fibroblasts has not been reported to increase survival of septic mice, despite the shared immunomodulating properties of fibroblasts with MSCs^[61,63,64].

The effects on survival might depend on the dose (low/high, one/multiple) and the timing of administration (early/late after insult). Gonzalez-Rey *et al.*^[52] reported that one dose of 10^6 human ASCs administered intraperitoneally 30 min after LPS injection in mice had a higher protective effect on mortality than one dose of 3×10^5 cells. Mei *et al.*^[62] found that intravenous administration of one dose of 2.5×10^5 mouse BM-MSCs after 6 h of CLP did not significantly protect mice, unless MSCs were administered concomitantly with antibiotics. These results might be related to different experimental settings because, compared to other studies carried out in CLP mouse models, Mei *et al.*^[62] administered a lower dose of MSCs (2.5×10^5 vs 10^6 cells) and at a later time point (6 h after CLP vs a range between 24 h before and 4 h after CLP)^[52,61,66,68]. On the other hand, Hall *et al.* reported that three intravenous

LPS: Lipopolysaccharide; CLP: Caecal ligation and puncture; h: Human; r: Rat; m: Mouse; ASCs: Adipose mesenchymal stem cells; BM-MSCs: Bone marrow mesenchymal stem cells; UC-MSCs: Umbilical cord mesenchymal stem cells; Mphi: Macrophages; I.P: Intraperitoneal; I.V: Intravenous; I.T: Intratracheal; I.M: Intramuscular; ND: Not determined; CM: Conditioned medium.

administrations of 5×10^5 , 2.5×10^5 and 2.5×10^5 mouse BM-MSCs at 2, 24 and 48 h after CLP, respectively, also reduced mortality rates on mice, although they did not compare with the effects of one single dose^[64]. Unfortunately, so far, different timing of administration have only been compared in the same study by Németh *et al*^[61] who reported that a prophylactic intravenous treatment with mouse BM-MSCs 24 h prior to CLP had similar therapeutic effects than a therapeutic treatment after 1 h of CLP. However, due to the urgent and acute condition of sepsis, a prophylactic treatment is clinically not feasible and comparing in the same study single vs multiple dosing and different time regimens (early or late after the induction of sepsis) might be very important in order to understand if there is a time window in which MSC

treatment is most efficacious and, therefore, maximize the therapeutic benefit of MSC therapy.

In addition to the dose and time, the “fitness” of the cells at the time of administration might also affect the therapeutic effect of MSCs. Thus, Sepúlveda *et al*^[67] found that while intraperitoneal administration of normal human BM-MSCs 30 min after LPS injection reduced mortality in an LPS sepsis model in mice, senescent human BM-MSCs failed to protect them, despite the fact they conserved the capacity to modulate the function of lymphocytes and macrophages *in vitro*. However, in contrast to these positive results, Chang *et al*^[69] reported that three intraperitoneal administrations of 1.2×10^6 living rat ASCs (at 0.5, 6 and 18 h) did not reduce, but moderately increased, mortality in a rat model of CLP, whereas the administration of apoptotic rat ASCs protected rats from death. Further studies will be needed to better understand these results.

The effects of MSC treatment on survival are a consequence of the reduction of inflammation-associated organ injury and the improvement in organ function. MSC treatment has been reported to reduce damage in kidney (*i.e.*, reduced levels of apoptotic cells, serum creatinine and tubular injury score), liver (*i.e.*, reduced levels of apoptotic cells, serum liver enzymes and blood urea nitrogen), pancreatic (*i.e.*, reduced levels of serum amylase), spleen (*i.e.*, reduced levels of apoptotic cells), lung (*i.e.*, reduced levels of apoptotic cells and vascular leakage) and heart function (*i.e.*, improved cardiac depression) in a variety of sepsis models and experimental settings^[61,62,64-66,68-75]. Improvement in organ damage correlates with reduction on neutrophil infiltration and myeloperoxidase (MPO) activity in target organs^[52,61]. Notably, these effects can also be obtained by intraperitoneal administration of conditioned medium from BM-MSCs or ASCs in a LPS mouse model, suggesting that the therapeutic effects of MSCs might be mediated, at least in part, by soluble factors^[65]. Of note, Manukyan *et al*^[71] observed that female mouse BM-MSCs injected intraperitoneally had a better improvement of cardiac function of LPS septic rats than male mouse BM-MSCs. This effect correlated with a higher expression of the anti-apoptotic protein Bcl-XL in the myocardium of female MSC treated rats.

No specific side effects of MSC treatment have been reported in sepsis models (only Chang *et al*^[69] reported increased mortality when using living rat ASCs compared to the untreated group in a rat model of CLP). The fate of MSCs in sepsis models have been also investigated in some studies. When MSCs were administered intravenously, cells were always detected in the lungs and eventually, to a lesser extent, in spleen, liver, kidney or lymph nodes^[61,66,74]. When MSCs were administered

intramuscularly, cells were only detected in the muscle up to 24 h after administration^[76].

Effects of MSCs on inflammation induced by sepsis

The pathogenesis of sepsis is characterized by massive infiltration of immune cells in target organs and high pro-inflammatory cytokine levels systemically and locally, that can lead to tissue damage, multiple organ failure and death. Treatment with MSCs reduces the infiltration of neutrophils and monocyte/macrophages to target organs, including liver, lung, intestine and kidney^[52,61,62,64-66,68,70,76]. Furthermore, MSC treatment has also been reported to reduce the levels of proinflammatory cytokines (*i.e.*, IFN γ , TNF α , IL1 β or IL6) in several organs including serum, liver, lung, intestine and myocardium^[52,61,66-68,70-72,74,76]. These anti-inflammatory effects can be enhanced by preactivation of UC-MSCs with Poly I:C which results in the inhibition of miR-143 expression by MSCs^[68]. The reduction on the levels of anti-inflammatory cytokines was accompanied by the increase on the levels of the anti-inflammatory cytokine IL10^[52,61,66-68,70-72,74,76], although other authors have reported either no effect on IL10 levels or even a reduction^[62,63,67,75]. These differences might be related to differences in the experimental settings, such as the use of different animal models, MSCs, dosing and time of sample collection. Nevertheless, there is evidence that IL10 plays an important role in the therapeutic effects of MSCs in sepsis. Thus, injection of a neutralizing antibody against IL10 or IL10 receptor prior to CLP abrogated the therapeutic effects of mouse BM-MSCs^[61]. *In vitro* studies showed that IL10 was not directly produced by MSC, but by macrophages through a mechanism that required MSC-secretion of PGE2^[61,77]. Moreover, a role of IL10 in inhibiting the migration of neutrophils into the infected tissues has also been suggested^[61]. In addition to IL10, other mediators of the therapeutic effect of MSCs have been identified. Thus, Yagi *et al.*^[73] observed that blockade of sTNFR1, which is released by MSCs in response to inflammation, partially impaired the anti-inflammatory effects of MSC treatment.

The MSC-mediated reprogramming of macrophages towards a regulatory and anti-inflammatory M2 phenotype has also been reported in sepsis models by other authors. Krasnodemskaya *et al.*^[63] observed a larger population of monocytes expressing CD206 (a marker of alternative activated M2 macrophages) in the spleen of MSC-treated mice and a higher phagocytic capacity of blood monocytes. Furthermore, Anderson *et al.*^[77] provided strong evidence of the important role that MSC-induced regulatory macrophages play in the therapeutic effects of ASCs in sepsis. The authors generated "ASC-mediated regulatory macrophages" (ASC-Mph) by *in vitro* culture of mouse bone marrow macrophages and ASCs (either mouse or human) and injected 10⁶ ASC-Mph intraperitoneally in septic mice

at different time points after CLP. These treatments resulted in reduced mortality rates when ASC-Mph were administered between 4 h and 12 h (but not at 24 h) after CLP by a mechanism that required the production of IL10 by ASC-Mph^[77]. Moreover, these regulatory ASC-Mph also reduced levels of pro-inflammatory cytokines in serum and infiltration of inflammatory cells in the peritoneum, lung, liver and intestine. Finally, the relevance of monocytes/macrophages, but also neutrophils, in mediating the therapeutic effects of MSCs is highlighted by the fact that depletion of monocyte/macrophages (by using clodronate-filled liposomes) or neutrophils (by using anti-Ly6G antibody) completely abrogated the protective effects of MSCs *in vivo*^[61,64].

The effects of MSC treatment on transcriptional inflammatory pathways in target organs of CLP septic mice treated with MSCs have been investigated by microarray analysis of total RNA expression. The results show that MSC treatment affects an ample range of transcriptional networks (it was estimated that up to a 13% of total murine genome was transcriptionally reprogrammed after MSC treatment compared to control septic mice including: (1) downregulation of TLR, NF- κ B or IL6 signaling pathways; (2) upregulation of NF-AT-related genes; (3) upregulation of genes involved in phagocytosis, antigen presentation, bacterial killing, coagulation, complement regulation and platelet activation; and (4) upregulation of genes involved in cell-to-cell interaction and endothelial/vascular integrity^[62,78].

Effect of MSCs on bacterial burden in sepsis

The mechanism by which MSCs protect from sepsis is not only limited to reducing the production of inflammatory cytokines and migration of inflammatory cells to infected organs, but also includes direct anti-microbial properties, as well as the improvement of the phagocytic properties of monocyte/macrophages and neutrophils. Gonzalez-Rey *et al.*^[52] and Németh *et al.*^[61] first reported a reduction on bacterial load in target organs (*i.e.*, peritoneal cavity, blood, spleen or liver) in MSC-treated septic mice, despite the MSC-mediated reduction of the inflammatory response. Krasnodemskaya *et al.*^[70] determined that MSC have intrinsic anti-microbial activity because they secrete the anti-microbial peptide LL-37 in response to the stimulation with *Escherichia coli* or *Pseudomonas aeruginosa*. Intratracheal administration of human BM-MSCs in a mouse pneumonia model highly reduced bacterial counts in bronchoalveolar lavage (BAL). However, when a LL-37 neutralizing antibody was also administered to mice, the anti-microbial effects of MSCs were only partially lost, suggesting that additional anti-microbial mechanisms might be involved. This potential direct killing of bacteria by MSCs needs to be further confirmed as Gonzalez-Rey *et al.*^[52] did not observe direct killing of *Escherichia coli* by MSCs *in vitro* in the absence of other cells.

In addition, the enhancement of the phagocytic properties of monocyte/macrophages and neutrophils have also been reported to improve bacterial clearance by MSCs. Noteworthy, MSCs seem not to have the capacity to phagocyte bacteria *in vitro*^[62,64]. Mei *et al*^[62] found that MSC treatment in a mouse CLP model increased the phagocytic capacity of peritoneal and spleen CD11b positive cells (mainly monocyte/macrophages and neutrophils) in MSC treated mice. Krasnodembskaya *et al*^[63] observed a reduction on bacterial counts in several organs, but more significantly in peripheral blood of MSC treated mice infected with *Pseudomonas aeruginosa*, which was also associated to an increased capacity of peripheral blood monocytes to phagocyte bacteria. Hall *et al*^[64] determined that MSCs, but not fibroblasts, also enhanced the phagocytic properties of neutrophils *in vitro* and in a CLP mouse model. In fact, depletion of neutrophils *in vivo* abrogated the ability of MSCs to promote bacterial clearance^[64]. Notably, Németh *et al*^[61] noticed that while infiltration of neutrophils to target organs was inhibited in MSC treated mice, their presence in circulation was concomitantly increased and suggested that this mechanism might help to clear bacteria from circulation and minimize organ injury due to leukocyte infiltration. Interestingly, preactivation with Poly I:C increased the *in vivo* anti-microbial effects of UC-MSCs in a CLP mouse model through a mechanism that requires the inhibition of the expression of miR-143^[68].

CONCLUSION

Sepsis is a leading cause of death and the most frequent cause of death in non-coronary ICUs in the developed world and, despite improvement in treatments, the mortality of severe sepsis and septic shock remains very high, showing that current treatments are not sufficient to combat this syndrome. The use of MSCs in experimental animal models of sepsis has reported strong evidence of the therapeutic potential of MSC therapy in this indication. These studies have been mainly focused on the effects of MSCs on the pro-inflammatory phase of sepsis, while the effects of MSCs on the subsequent anti-inflammatory/immune exhaustion phase of the disease has not been elucidated so far and will need further investigation. The mechanisms by which MSCs improve survival in sepsis models rely on the collective effects of their immunomodulatory and anti-microbial properties: MSC treatment modulates inflammation in septic mice by a mechanism that requires the reprogramming of macrophages towards a more anti-inflammatory phenotype (release of anti-inflammatory IL10), resulting in reduced levels of pro-inflammatory cytokines in blood and organs and attenuated infiltration of immune cells in infected tissues (monocytes and neutrophils). Moreover, MSCs show direct (release of LL-37 peptide) and indirect (increase of phagocytic properties of

monocyte/macrophages and neutrophils) anti-microbial effects. The combined effect of reducing both the inflammatory response and the bacterial burden results in an improvement of organ function and higher survival rates. The promising results obtained in these, small animal, preclinical efficacy studies are encouraging and suggest that MSCs might be a therapeutic option to treat sepsis in patients. Importantly, efficacy of MSCs in large animal models that better replicate the inflammatory response, organ failure and disease in humans (e.g., sheep models) will be additionally relevant to support further testing of the therapeutic potential of allogeneic MSC treatment in humans. Such clinical trials should be prospective, controlled, and randomized so to guarantee a clear outcome of the MSC treatment effect. Moreover, taking into consideration the complexity and heterogeneity of sepsis and the poor results up to now in sepsis clinical trials, we believe that such trials should first be done in well defined and homogeneous sepsis patient populations.

Abstract

Neglected for years, astrocytes are now recognized to fulfill and support many, if not all, homeostatic functions

of the healthy central nervous system (CNS). During neurodegenerative diseases such as amyotrophic lateral sclerosis (ALS) and spinal cord injury (SCI), astrocytes in the vicinity of degenerating areas undergo both morphological and functional changes that might compromise their intrinsic properties. Evidence from human and animal studies show that deficient astrocyte functions or loss-of-astrocytes largely contribute to increased susceptibility to cell death for neurons, oligodendrocytes and axons during ALS and SCI disease progression. Despite exciting advances in experimental CNS repair, most of current approaches that are translated into clinical trials focus on the replacement or support of spinal neurons through stem cell transplantation, while none focus on the specific replacement of astroglial populations. Knowing the important functions carried out by astrocytes in the CNS, astrocyte replacement-based therapies might be a promising approach to alleviate overall astrocyte dysfunction, deliver neurotrophic support to degenerating spinal tissue and stimulate endogenous CNS repair abilities. Enclosed in this review, we gathered experimental evidence that argue in favor of astrocyte transplantation during ALS and SCI. Based on their intrinsic properties and according to the cell type transplanted, astrocyte precursors or stem cell-derived astrocytes promote axonal growth, support mechanisms and cells involved in myelination, are able to modulate the host immune response, deliver neurotrophic factors and provide protective molecules against oxidative or excitotoxic insults, amongst many possible benefits. Embryonic or adult stem cells can even be genetically engineered in order to deliver missing gene products and therefore maximize the chance of neuroprotection and functional recovery. However, before broad clinical translation, further preclinical data on safety, reliability and therapeutic efficiency should be collected. Although several technical challenges need to be overcome, we discuss the major hurdles that have already been met or solved by targeting the astrocyte population

in experimental ALS and SCI models and we discuss avenues for future directions based on latest molecular findings regarding astrocyte biology.

Core tip: Amyotrophic lateral sclerosis (ALS) and spinal cord injury (SCI) result in incurable neurological dysfunction due to loss of spinal motor neurons and axonal degeneration, amongst other mechanisms. Astrocytes are increasingly recognized as being necessary for neuroprotection and regeneration in the central nervous system as they promote axonal growth and deliver essential neurotrophic factors under both physiological and pathophysiological conditions. Given the central role played by astrocytes, we gathered convincing results from ALS and SCI literature that argue in favor of stem cell-based astrocyte replacement therapies and stress the scientific community to investigate more deeply the molecular understanding of astrocyte biology.

MULTIPLE FACETS OF ASTROCYTES IN THE CENTRAL NERVOUS SYSTEM

Astrocyte functions

Astrocytes are the most abundant cells in the central nervous system (CNS), outnumbering neuronal cells by several fold in some CNS regions. They have long been relegated to a secondary position, behind neurons or oligodendrocytes, as many thought that astrocytes were barely by-standers of the CNS. Accounting for a large fraction of the brain volume, their particular shape and tissue distribution are known to elaborate an extensive network of fine interconnected processes. Their star-shaped morphology projecting long branched processes provides a large coverage of CNS structures and the ensheathment of the brain or spinal cord in the pia matter. They draw the whole brain microanatomy by secreting astrocyte-derived extracellular matrix proteins (*e.g.*, chondroitin sulfate proteoglycans, hyaluronan, tenascin proteins family, thrombospondin), thereby providing structural support for nervous system cells. Beside their structural role, astrocytes are recognized to fulfill and support many, if

not all, functions of the healthy CNS^[1]. Astrocyte end-feet cover more than 90% of the CNS vasculature and come in contact with endothelial cells. Expressing key glucose transporter-1, astrocytes convey glucose from blood vessels to nervous system cells, most of them being devoid of direct access to this high-end source of energy. Hence, astrocytes synthesize *via* specific metabolic pathways glycogen and lactate, main energy fuels for neurons or distant synapses. Through humoral factors released at the perivascular space, astrocytes control local cerebral blood flow and blood-brain barrier (BBB) integrity. Transforming growth factor-beta, glial-derived neurotrophic factor (GDNF), fibroblast growth factor 2 (FGF2) and angiopoietin 1 (binding the endothelium-specific receptor TIE2), all secreted at the vascular end-feet, act on endothelial cells in order to induce or maintain an operational BBB^[2,3]. Astrocytes-released growth factors [*e.g.*, brain-derived neurotrophic factor, BDNF; ciliary neurotrophic factor (CNTF)] exert beneficial effects far beyond the perivascular space and act as neurotrophic factors on all CNS cells^[4,5]. The perivascular end-feet of astrocytes show other specialized features characteristic of this location, including a high density of orthogonal arrays containing the water channel aquaporin 4 (AQP4) and the Kir4.1 K⁺ channel^[6,7]. Those proteins closely interact with endothelial basal lamina and regulate ions/water fluxes through the BBB^[7-10]. Astrocytes finely tune the dynamics of cerebral blood flow in order to increase the availability of oxygen and glucose locally to highly active brain areas; this process is mediated via secreted vasoactive compounds (*i.e.*, endothelin-1, arachidonic acid, prostaglandins, nitric oxide) and intercellular Ca²⁺ signaling^[11-13]. As a member of the tripartite synapse, astrocytes are responsible for proper neurotransmission. Astrocyte end-feet express Kir4.1 channel, which is responsible for the rapid uptake of K⁺ released in the interstitial CNS fluid and thus for spatial extracellular potassium siphoning *needed* during high-frequency firing of neurons^[14-16]. Astrocytes also express membrane-bound transporters and receptors involved in the re-uptake and the response to neurotransmitters (*i.e.*, glutamate, GABA, glycine), whose synaptic concentrations must be tightly controlled in the synaptic cleft. In the case of glutamate homeostasis, two major CNS glutamate transporters, GLT1/EAAT2 and GLAST/EAAT1, are expressed almost exclusively by astrocytes in the adult mammals. GLT1 accounts for upward of 90% of glutamate uptake in most CNS regions^[17]. By regulating extracellular glutamate homeostasis, GLT1 assures proper synaptic function and prevents excitotoxic insult to susceptible neurons, axons and oligodendrocytes. In addition, astrocytes form a gap junction-coupled network of very narrow overlapping domains throughout the CNS^[18,19]. Each domain covers a CNS area encompassing from 20000 neuronal synapses in rodents up to 2000000 in humans and connects neighboring astrocytes by

junctional complexes made of connexin (Cx) family proteins. On a functional point-of-view, the astrocyte syncytium supports ATP-mediated long-distance propagation of Ca^{2+} waves^[20,21], which is involved in the control of local cerebral blood flow and the fine tuning of electrical neuronal activity^[22]. Cx channels allow the intercellular passage of monovalent ions (Na^+ , K^+) or small molecules up to 1.5 kDa (e.g., ATP, glutamate, d-serine), contributing to signaling, metabolic cooperation and ionic spatial buffering^[23,24]. Astrocytes express Cx26, Cx30 and Cx43 that interact with homologous connexins in astrocyte-to-astrocyte (A/A) gap junctions and that can also bind in a heterologous fashion Cx29, Cx32 and Cx47 on oligodendrocytes partners^[24-26]. In mammals at least, the presence of these 6 connexins suggests a high level of complexity in coupling partners within the glial cell populations and reveals close cellular interactions between astrocytes and oligodendrocytes. Astrocyte-oligodendrocyte (A/O) coupling via connexins is necessary to sustain myelin formation and maintenance throughout life. In humans, mutations in Cx29, Cx32 and Cx47 genes lead to myelin formation abnormalities and are linked to Charcot-Marie-Tooth disease and several forms of leukodystrophies^[27]. Beyond mutations targeting oligodendroglial connexins, the effect of loss-of-function of astrocyte connexins has been experimentally investigated using knockout mice. Double Cx30^{-/-} and Cx43^{-/-} knockout mice showed white matter pathology comprising vacuolated oligodendrocytes and intramyelinic edema^[28]. Histopathological changes were accompanied by significant sensorimotor and cognitive deficits. Similar findings were shown when double-deleting Cx43 and Cx32 in mice^[29]. All of these findings suggest an essential role of A/A and A/O coupling in maintaining overall CNS functions^[30] and pave the way for developing integrated therapies targeting the astrocyte syncytium and its dysfunction(s) during neurodegenerative conditions.

Wealth through diversity

A rapid look at the morphology of white matter astrocytes compared to gray matter astrocytes reveals the complexity and heterogeneity of this class of cells. Their different morphologies are most likely to be related with their wide range of functions, their neuroanatomical sites and the stem cells from which they derive (reviewed by^[31]). During development, astrocytes mainly arise from radial glial cells located in the brain and spinal cord. During adulthood, astrocytes are still generated from differentiating progenitors in stem cell niches^[32] or from dividing mature astrocytes in specific brain regions^[33]. Historically, two classes of astrocytes were described: "type I" fibrous astrocytes mostly found in white matter tracts and "type II" protoplasmic astrocytes found in the grey matter^[34,35]. Nowadays, the scientific community agrees that astrocyte complexity, in particular within

the protoplasmic subfamily, has increased along with phylogenetic evolution. As far as we know, this complexity culminates in the human CNS. Compared to rodents^[19], human astrocytes have a greater size, a more complex morphology, a large pleiomorphism^[36] and are able to propagate calcium waves five times more rapidly^[31,37,38]. Although mice represent a useful tool to study astrocytes and their *in vivo* functions through genetic manipulation, one limitation of rodent-to-human extrapolations is the wider diversity of human counterparts. For instance, primate brain contains two types of astrocytes not found in rodent brain: interlaminar and varicose astrocytes, whose functions are as of yet undetermined but seem to be related to the higher complexity of neuronal layers inside the human cortex^[37]. Despite this heterogeneity, astrocytes share similarities such as the expression of several common proteins. Intermediate filament proteins are very abundant in the cytoplasmic compartment among all astrocytes types: glial fibrillary acidic protein (GFAP), vimentin, desmin and synemin. Recently, the cell surface marker CD44, the receptor of extracellular matrix hyaluronan, has been described to distinguish, more accurately than GFAP, protoplasmic astrocytes from fibrous-like astrocytes^[36]. Resting astrocytes also display specific immunoreactivity for aldehyde dehydrogenase 1 family member L1, AQP4, S100, GLT1, GLAST and glutamine synthetase. Under pathological conditions affecting CNS [e.g., Alzheimer's disease, multiple sclerosis, stroke, amyotrophic lateral sclerosis (ALS), spinal cord injury (SCI)], astrocytes can switch to an activated phenotype. Activated astrocytes, which can in some case include a population of proliferating astrocytes, are commonly observed around focal CNS lesions, in areas of neuronal loss/damage, in demyelinating areas, during neuroinflammation or during CNS repair. Astrocyte hypertrophy and upregulation of GFAP, vimentin, nestin or S100 are hallmarks of activated astrocytes. For instance, new protein markers may also be expressed. Expression of S100A6, a calcium binding protein, is drastically increased in astrocytes from ALS spinal cord^[39,40], after traumatic CNS injury^[41] or in Alzheimer brain tissue^[42]. Given that ALS and SCI affect either diffuse or discrete areas, respectively within the CNS (*i.e.*, in ALS from motor cortex to bulbar respiratory nuclei to the lumbar spinal motor neurons; in SCI, both gray and white matter astrocytes are lost over a distance of several millimeters), therapeutically-targeting astrocytes would undoubtedly take into account their diversity of shape and function, with respect to their location. Our knowledge about astrocyte heterogeneity now allows for generating *in vitro* subpopulations of stem cell-derived astrocytes endowed with specific fates or defined functional abilities. These cells, isolated and expanded *in vitro*, can be further used in transplantation paradigms aiming at providing neuroprotection or replacing astrocyte-deficient

functions observed during neurodegenerative and traumatic diseases of the spinal cord such as ALS or SCI.

SOURCES OF STEM CELL-DERIVED ASTROCYTES

Glial-restricted precursor cells

Use of lineage-restricted progenitors as a source for deriving astrocytes has gained wide popularity in recent years due to their ability to generate specific glial types following transplantation. Glial-restricted progenitors are present in the embryonic spinal cord and through their ability to self-renew and differentiate give rise to oligodendrocytes and astrocyte populations. The first type of glial restricted progenitor that was originally characterized was the A2B5⁺ O-2A progenitor cell. This was isolated from optic nerve of embryonic and post-natal rats and through *in vitro* differentiation was shown to be able to differentiate into oligodendrocytes and a particular type of astrocyte called the type-2 astrocyte^[43-45]. More recently, a different type of progenitor cell was characterized that is able to differentiate into oligodendrocytes and two different populations of astrocytes. This cell type was isolated from E13.5 rat spinal cord and is also positive for the A2B5 antigen. *In vitro* conditions that supported their above mentioned differentiation included culture medium supplemented with fetal calf serum or platelet-derived growth factor (PDGF) and T3 thyroid hormone. Clonal analysis confirmed that these individual GRPs are tripotent. Furthermore, these cells are capable of extensive self-renewal in the presence of PDGF and FGF2. These GRPs differed from the original A2B5⁺ O-2A progenitor cell in several aspects such as absence of mitogen requirements, responsiveness to PDGF and morphologies^[46].

Neural stem cells or radial glia

Using cell genesis and fate specifying processes, neural tube-derived neural stem cells give rise to 10¹¹ neurons and at least 10¹² glial cells of many different phenotypes in the adult brain^[47-49]. Neural stem cells (NSCs) are an attractive source for generating astroglial cells through their multipotency and high potential of self-renewal. NSCs represent an endogenous population existing during brain development and to a lesser extent in adult brain niches. In adult CNS, they are found around the sub-ventricular zone, the sub-granular layer of the hippocampus and spinal ependymal canal. Their phenotype is characterized by an astrocyte-like morphology and GFAP expression^[50,51] together with other markers of an undifferentiated state (e.g., nestin, SOX2). The most common sources for NSC isolation include embryonic brain cortex and adult sub-ventricular zones. One of the basic features of NSCs is that they can easily divide *in vitro* either as

spherical aggregates called “neurospheres” or adherent layers of cells when supplemented with epidermal growth factor and fibroblast growth factor 2. Culture conditions involving growth factor withdrawal and serum exposure elicit a differentiation program into either neurons, oligodendrocytes or GFAP⁺ astrocytes, with various yields^[52-54]. Transplantation of NSCs into the CNS results in the generation of multiple cell types, including astrocytes^[53] and oligodendrocytes^[55]. Another source of astrocytes in the adult CNS is radial glial cells^[56,57]. Several lines of evidence support the existence of a small pool of such cells expressing classic radial glial markers (*i.e.*, NG2, RC1, 3CB2, brain lipid-binding protein)^[58] and located in limited regions of ongoing neurogenesis in the adult CNS^[59-61].

Embryonic or Induced-pluripotent stem cells

Embryonic stem cells (ESCs) and induced-pluripotent stem cells (iPSCs) represent an ideal pluripotent source for deriving human astrocytes. Even though early reports demonstrated differentiation of astrocytes from human iPSCs or ESCs, there was a great diversity in terms of reported methods and the total yields of neural cells were not high. Furthermore, astrocytes generated by these protocols were not defined in terms of their subtype identity. On the other hand, specific protocols to generate astrocytes with regional or subtype identity were not reported^[62-68]. This gap was fulfilled by a recently reported protocol, which allows directed differentiation of astrocytes *via* a prior differentiation of human stem cell derived neuroepithelial cells into glial progenitor cells by repression of neurogenesis. Astrocytes generated by this protocol were characterized by specific gene expression profiles, neurotransmitter and ionic uptake, support of neuronal maturation, and importantly expression of specific sets of homeodomain transcription factors that specify functional identity^[69]. On the basis of this, another protocol was recently reported for an efficient generation of immature astrocytes from human pluripotent stem cells (hPSCs)^[70]. The protocol consists of three steps. In the first stage, hPSCs were differentiated into neuroepithelial cells either by co-culturing with mouse embryonic fibroblasts or by differentiation in feeder free conditions. These appeared in the form of columnar epithelia that organized into neural tube-like rosettes at about day 10-15 of differentiation. Addition of morphogens at days 8 to 15 allows differentiation of specific astrocyte subtypes. In the second stage, floating neural progenitor aggregates were expanded with epidermal growth factor, FGF2 and mitogenic factors. Neuronal differentiation was repressed and potential for gliogenic progenitor was enhanced by weekly mechanical trituration. By around 90 d, most of the progenitors expressed markers for astrocyte progenitors or astrocytes such as CD44 and S100. Thus at this stage, they are referred to as “astrospheres”. In the third and

final stage, astroglial progenitors were differentiated into functional astrocytes by removal of mitogens. Addition of CNTF for 6 d stimulated gliogenic gene expression. If neuroepithelial cells were patterned in stage 1, terminally differentiated astrocytes expressed specific markers such as Hoxb4 for posterior identity or Nkx2.1 for ventral identity.

In vivo or in vitro transdifferentiation

Some cases of *in vivo* transdifferentiation into astrocytes have been described in the literature following transplantation of bone marrow-derived stem cells or mesenchymal stem cells into rodent CNS. It is not yet clear whether transdifferentiation normally occurs in healthy CNS and, if so, whether it requires a de-differentiation step. Several criteria must be filled to truly establish transdifferentiation into astrocytes: original cells must lose their committed-lineage differentiation markers; they have to adopt a astrocyte-like morphology and express astrocyte markers (*e.g.*, GFAP, S100). Several reports showed that GFP reporter-expressing bone marrow stem cells transplanted into adult rodent CNS gave rise to GFP⁺ GFAP⁺ astrocytes^[71-73]. Similarly, mesenchymal stem cells (MSCs) isolated from bone marrow, when grafted into neonatal mouse brain, have been shown to migrate extensively and differentiate into olfactory bulb granule cells and astrocytes^[74]. In an original experimental approach, Boucherie and colleagues intrathecally grafted MSCs in ALS-affected rodent spinal cord and observed that MSCs were able to extensively migrate while differentiating mostly into astrocytes at the sites of neurodegeneration^[75]. In recent years, *in vitro* transdifferentiation, starting from single skin fibroblasts, has also made possible the modeling of CNS diseases in a dish, bypassing invasive neurosurgical procedures to get human diseased tissue. Recent cell reprogramming protocols describe the direct conversion of human fibroblasts to "induced" neural stem cells, able to further differentiate into the three CNS lineages (neurons, astrocytes and oligodendrocytes) following appropriate culture conditions. Artificial and temporal expression of specific transcription factors such as Oct-3/4, Sox2, Klf4, Brn4 and c-myc seems to govern the cell conversion towards a neural fate^[76-78]. Molecular pathways and key transcription factors making transdifferentiation possible are currently under investigation for different cell types^[79].

RATIONALE FOR ASTROCYTE REPLACEMENT IN ALS AND SCI

What is amyotrophic lateral sclerosis?

Amyotrophic lateral sclerosis (ALS) is a common adult-onset neurodegenerative disease of the motor system, with a prevalence of 2-5/100000 people. It is characterized by a rapidly progressing neurode-

generation selectively affecting cortical, brainstem and spinal motor neurons. ALS remains an incurable disease, leading to fatal respiratory failure usually within 5 years following diagnosis^[80]. Pathophysiology of ALS is poorly understood and likely multifactorial. Proposed starting points for this complex disease targeting the motor neuron population include mitochondrial dysfunction, intracellular protein aggregation, disturbances of RNA metabolism, extracellular toxic environment, impairment at the level of axonal transport and at the neuromuscular synapse (reviewed by^[81]), together with extrinsic events: blood-brain barrier breakdown, glial cell reaction/dysfunction and neuroinflammation^[82-88]. It is known that dying motor neurons influence surrounding cells, of which astrocytes are most commonly investigated. Astrocytes shift from an anti-inflammatory and neuroprotective role to one that is pro-inflammatory and neurotoxic, thus adding to complexity of this fatal cascade^[80]. In 5%-10% of patients, ALS is inherited (familial ALS). In those cases, every fifth patient carries a detected mutation in superoxide dismutase 1 (SOD1), which is at present the most reliable and most widely used genetic animal model for ALS^[89]. Among others, the most commonly described mutations include genes encoding the DNA/RNA-binding proteins FUS, TDP43^[90], the ubiquitin-like protein Ubiquilin 2^[91] and optineurin^[92]. On the other hand, an intronic hexanucleotide repeat in the C9ORF72 gene was discovered in both familial and sporadic cases of ALS^[93].

What are spinal cord injuries?

SCI are devastating and diverse set of conditions that result from damage to spinal cord grey matter and white matter, as well as corresponding spinal nerves. The National Statistics for SCI estimates approximately 12000 new cases each year in the United States alone, most of which result from preventable causes (*e.g.*, motor vehicle accidents, falls, sports or violence). Some common outcomes of SCI include dysfunctions in the musculoskeletal, respiratory, uro-genital and gastrointestinal systems. The diversity of this condition results from differences in the location, type and severity of trauma, as well as on the consequent types and degree of functional impairment. Despite this diversity, all forms of SCI are linked to specific phenotypic changes in populations of spinal cord astrocytes. Some examples of these changes are: (1) acquisition of specific protective functions such as glial scar formation to constrain the secondary expansion of the lesion; (2) loss of certain crucial homeostatic functions such as the astrocyte glutamate transporter system that are key to normal CNS physiology; and (3) gain of toxic functions such as the generation of pro-inflammatory signaling molecules that contribute to degeneration, neuronal hyperexcitability and other detrimental effects. The response of astrocytes is a graded response such that there is diversity in these changes that vary with the type and severity of trauma and with proximity

to the lesion. Furthermore, even within a population of astrocytes within the spinal cord, the response of individual astrocytes to the same injury can vary, likely reflecting the normal heterogeneity amongst astrocytes that is now becoming increasingly appreciated.

Defective astrocyte glutamate handling: one rationale among others

ALS and SCI are both spinal cord disorders involving all CNS cells: neurons, oligodendrocytes, microglial cells, endothelial cells and astrocytes. In both cases, there is significant motor, as well as sensory, dysfunction, although sensory involvement is still a matter of debate in ALS. To some extent, they share histopathological features in the spinal cord tissue: death of spinal motor neurons, axonal damage in white matter tracts, anterograde axonal degeneration, BBB dysfunction, impaired astrocyte function and neuroinflammation. In the case where neurodegeneration reaches the cervical level of the spinal cord, the loss of phrenic motor neurons that control contraction of the diaphragm leads to severe respiratory deficits and represents a life-threatening condition. ALS, historically characterized by the loss of upper and lower motor neurons, is more and more recognized as endowed with a non-cell-autonomous component, in which microglia and astrocytes act as significant contributors to overall spinal cord dysfunction. It has been shown that microglia carrying ALS-linked mutant SOD1 drive ALS disease progression by fostering neuroinflammation and a toxic environment for spinal motor neurons^[81,94]. With respect to astrocytes in ALS, independent groups demonstrated that astrocytes bearing mutant SOD1 are key determinants of disease progression^[95-97]. In the absence of any pathology, normal astrocytes uptake glutamate, released at the synaptic cleft, through their glutamate transporters (GLT1/EAAT2 and GLAST/EAAT1). Furthermore, normal astrocytes protect motor neurons from glutamate excitotoxicity by stimulating the neuronal expression of AMPA-GluR2, which is less permeable to calcium making motor neurons less sensitive to excitotoxicity^[98]. During ALS disease course, it is known from human and animal model samples that astrocyte-based glutamate uptake is compromised due to an early loss of astrocyte GLT1. Drastic GLT1 downregulation is most likely to be linked with deleterious extrasynaptic glutamate accumulation, which gave rise to the theory of glutamate-induced excitotoxic motor neuron death and to the unique FDA-approved drug that slows ALS: Riluzole, based on its anti-glutamatergic action.

Following SCI, the entire architecture of the spinal cord is disrupted at the lesion site; the trauma produces both immediate and delayed cell death affecting all nervous system populations: neurons, astrocytes and oligodendrocytes. Shortly after injury, it has been demonstrated that glutamate starts to accumulate in

the extracellular space^[99], and can persist for over a week, depending on injury severity^[100]. Overload of CNS extracellular glutamate may cause excitotoxic damage to neurons, axons and oligodendrocytes *via* overactivation of both AMPA and NMDA receptors^[101,102]. Failure of long-term extrasynaptic glutamate clearance is suspected to be one major cause of secondary cell loss following SCI. Noteworthy, we and others demonstrated that astrocyte GLT1 was chronically lost at the injury epicenter following SCI but also downregulated in spinal cord regions distant from the lesion core^[103-106]. Furthermore, experimental data showed that the newly-generated astrocytes arising during the SCI repair phase lacked GLT1 expression, possibly compromising long-term astrocyte glutamate homeostasis^[107]. Other consequences of astrocyte dysfunction or loss should be considered in ALS and SCI: shortage of neurotrophic factors important for neuronal survival, overwhelming of anti-oxidative defenses, lack of support to maintain endothelial BBB integrity, impaired water, ionic and metabolic transport, release of harmful proinflammatory cytokines and synthesis of glial scar-related ECM proteins that block axonal regrowth^[1]. Regardless of whether astrocyte dysfunction is a cause of disease or a consequence of neuronal loss, altered physiology of pathologic astrocytes likely results in further susceptibility to CNS tissue loss, justifying the rationale for transplantation-based astrocyte replacement^[108]. Numerous studies indicate that transplantation of stem cell-derived astrocytes has exhibited beneficial effects on histological/functional outcomes in ALS and SCI animal models. In this review, we summarize the data from recent literature regarding transplantation of stem cell-derived astrocytes targeting the replacement of deficient or lost astrocytes during ALS and SCI.

METHODOLOGICAL CONSIDERATIONS

Feasibility of astrocyte transplantation in healthy spinal cord

Pilot studies were done on spinal GRPs isolated and characterized from the human aborted embryos^[46,109,110]. Upon transplantation into neonatal and adult rodent brain, human GRPs survived, migrated and differentiated into (im)mature oligodendrocytes and into GFAP-expressing astrocytes^[111]. These results were later confirmed by another group who analyzed the fate of GRPs harvested from alkaline phosphatase-expressing transgenic rats injected into intact and injured spinal cord. In the first set of experiments, GRPs survived at least 6 wk^[112] and in the second experiment up to 15 mo post-transplantation^[113], demonstrating their long-term integration. Cells showed morphological maturation and differentiated along astrocyte and oligodendrocyte lineages and not into neuronal lineages. Interestingly, cells grafted into the intact spinal cord showed a particular tropism for white matter tracts and robust migration capacities

since they were found more than 15 mm away from the injection sites^[112,113]. Transplantation of GRP-derived astrocytes seems to be a safe procedure, at least experimentally, since no tumor formation or pronounced immune response were observed at the graft sites. Isolated human GRPs express *in vitro* functional glutamate transporters EAAT1, EAAT3 and EAAT4 but not GLT1/EAAT2^[114]. According to the nature of *in vitro* pre-differentiation signals, GRPs do not give rise to homogenous astrocyte populations upon transplantation^[115,116]. Following bone morphogenic protein 4 (BMP4) driven differentiation, GRPs start to express EAAT2/GLT1 together with AQP4, AKAP12, Cx43 as markers of mature astrocytes^[116]. On the contrary, *in vitro* GRP exposure to CNTF give rise to mature astrocytes expressing FGF receptor-3 and several axon growth inhibitory proteoglycans, such as neurocan, brevican and phosphacan, suggestive of a phenotype of reactive astrocytes.

Routes of administration

Considering the route of administration for a stem cell therapy product is a significant factor when targeting the CNS and the spinal cord in particular. Stem cell transplantation into the spinal cord was successfully reported, in terms of homing and long-term engraftment, using different cell populations and different route of administration. Intraparenchymal injections of MSCs and NSCs into the thoracolumbar region^[117-123] and of GRPs into the cervical region^[104,124] have been successfully reported in animal models of ALS. Although direct targeting of the spinal cord is technically challenging and an invasive application, this route promises to be the most versatile and accurate method of targeted CNS therapeutic delivery, and therefore has been chosen for clinical translation of stem cell-based therapies in ALS patients. As both ALS and SCI affect long segments of spinal cord (several millimeters long and sometimes independent regions within the cord), a need for multiple injections adds to the complexity of the procedure. Aware of this issue, neurosurgeons are developing new surgical techniques or tools (e.g., radially-branched cannulae) able to deliver therapeutic agents to large CNS areas in a single shot^[125]. Other attempts to find the optimal delivery route used intranasal^[126], intrathecal^[127-129], intraperitoneal^[130], intramuscular^[131], intravenous^[132-135] and intra-bone marrow cell^[136] transplantation. Major shortcomings are poor CNS homing of the therapeutic product compared to the initial dose given (dilution of cells in unwanted organs/sites) and adverse effects such as blockade of intravenously-injected stem cells in lung capillaries or spleen (reviewed by^[137]). In many cases, researchers reported beneficial effects of peripherally-delivered stem cells associated with improved histological and functional outcomes in ALS animal models. While various routes of stem cell

delivery have been investigated in ALS therapy (Table 1), experimental SCI pathology was mainly targeted by focal stem cell injections in and around the lesion core, regardless of the spinal level affected (Table 2). Although the most efficient delivery method is still a matter of debate, the dose of transplanted cells, the timing, the location, the type of cells for particular needs, and their migratory abilities are additional parameters to take into account in designing CNS stem cell-based therapies. Numerous preclinical studies using animal transplantation paradigms will still be required to assess biodistribution, viability, integration into host tissue, differentiation into functional cells, lack of tumorigenicity and safety of delivery before broad clinical application^[138-140].

LESSONS FROM TRANSPLANTATION PARADIGMS IN ALS MODELS

Taking into account that neurons represent only a portion of the various nervous system cell types, it is not surprising that during onset and especially during progression of disease non-neuronal cells contribute significantly to neuronal dysfunction and death. For example, it has been shown that wild-type motor neurons in close proximity to mutant SOD1-containing non-neuronal cells became affected by pathological chain reactions specific for ALS and eventually die with many features of this disease^[141]. In the same way, wild type non-neuronal cells extend survival of SOD1 mutant motor neurons^[142]. It has been clearly shown that reduction of mutant SOD1 selectively in astrocytes results in a prolongation of disease duration, but has no effects on disease onset. At least a part of this process is modulated by dysfunction and decrease in levels of the primary astrocyte glutamate transporter, GLT1, in areas of motor neuron loss^[143]. Taken together, these results suggest a particular role for astrocytes in later progression of disease^[81,97]. Main studies that have assessed replacement of astrocytes based on transplantation in ALS animal models have been gathered in Table 1.

Transplantation of wild-type astrocytes or their precursors into CNS tissue affected by ALS represents a promising experimental approach. With the aim to rescue motor neurons responsible for breathing, which is the primary cause of death in human ALS, GRPs were transplanted into the cervical spinal cord of the SOD1^{G93A} rat model. GRPs survived in diseased tissue (32.2% ± 4.6% of transplanted cells survived at least 80 d post-transplantation), differentiated efficiently into astrocytes, and reduced microgliosis in the cervical spinal cord. Most notably, GRPs extended survival and disease duration, attenuated motor neuron loss, and slowed declines in forelimb motor and respiratory function. Since GRPs that did not express the glutamate transporter GLT1 did not have similar effects on behavioral measures or

Table 1 Transplantation-based astrocyte replacement in amyotrophic lateral sclerosis animal models

Animal	Type of cells	Delivery	Effect on disease	Main outcomes	Ref.
SOD1 ^{G93A} ALS rats (80 d-old)	GRPs from rat E13.5 spinal cord, wild-type and overexpressing GLT1	Injections into C4-C6 cervical spinal cord, 6 sites, bilateral 1.5×10^5 cells/site	Delayed decline in motor function and survival extension	Differentiation into functional astrocytes. Prevented motor neurons loss independently from growth factors secretion, sustained GLT1 levels, alleviated microgliosis	[104]
SOD1 ^{G93A} ALS mice (75 d-old)	Human neural precursors (hNPs) overexpressing BDNF, IGF-1, VEGF, NT-3, or GDNF	Injection in cisterna magna and cerebral ventricles	No effect on motor function or animal survival	Differentiation in GFAP ⁺ GLT1 ⁺ expressing and growth factors-secreting astrocytes. Prevented motor neurons loss	[147]
SOD1 ^{G93A} ALS rats (90 d-old)	Rat adult MSCs	Intrathecal delivery in lumbar cisterna magna, 1.95×10^6 cells	Preserved motor function and survival extension	Differentiation into astroglial cells. Decreased neuroinflammation	[75]
SOD1 ^{G93A} ALS mice (24-26 wk-old)	Human umbilical cord blood cells overexpressing VEGF and FGF2	Intravenous delivery, 1×10^6 cells	Not investigated	Differentiation in S100 ⁺ astrocytes	[146]
SOD1 ^{G93A} ALS rats (14-26 wk-old)	NSCs from rat E16 brain cortex	Intravenous delivery, 1×10^7 cells	Not investigated	Preferential homing to late symptomatic ALS brain and spinal cord. Differentiation into neurons and astrocytes	[135]
SOD1 ^{G93A} ALS mice (50-60 d-old)	hGRPs from fetal cadaver brain tissue (week 17-24 of gestational)	Injections into C4-C5 cervical spinal cord, 4 sites, bilateral 1.2×10^5 cells/site	No effect on histological or functional outcomes	Poor cell survival	[124]

ALS: Amyotrophic lateral sclerosis; BDNF: Brain-derived neurotrophic factor; C: Cervical; E: Embryonic; FGF2: Fibroblast growth factor 2; GDNF: Glial cell-derived neurotrophic factor; GFAP: Glial fibrillary acidic protein; GLT1: Glutamate transporter 1; GRP: Glial-restricted precursor; IGF-1: Insulin-like growth factor 1; MSC: Mesenchymal stem cell; NP: Neural precursor; NSC: Neural stem cell; NT-3: Neutrophin-3; SOD1: Superoxide dismutase 1; VEGF: Vascular endothelial growth factor.

animal survival, this highly suggested that glutamate-relevant pathways contribute to the cascade of events leading to cell death in this model and that the focal beneficial effects of GRP transplantation could be explained, at least in part, by increases in glutamate transporter expression^[104].

With the aim to translate astrocyte-based transplantation towards treatment of patients, human GRPs have been transplanted into SOD1^{G93A} mice. At disease end-stage, 10% of initial hGRP transplants survived and distributed throughout of the cervical spinal cord and up to 80% of all human derived cells co-expressed the astrocyte marker GFAP. Unlike the results obtained with rodent-derived GRPs, this xenograft transplantation paradigm using human GRPs did not provide a phenotypic preservation of motor function^[124].

In another study, Boucherie and colleagues tested a different approach: they injected MSCs into the cerebrospinal fluid of symptomatic SOD1^{G93A} rats. They successfully penetrated the CNS parenchyma and accumulated at sites of motor neuron degeneration. They differentiated into astrocytes and, most notably, decreased motor neuron loss in the lumbar spinal cord, preserving hindlimb motor function and extending the survival of SOD1^{G93A} rats. This neuroprotection correlated with decreased inflammation, as shown by a decrease in the proliferation of microglial cells and reduced expression of inflammatory-related genes, COX-2 and NOX-2^[75]. Recent publications confirmed that transplantation of stem cells indeed reduces neuroinflammation and suggests that alleviating

astrocytosis or microgliosis is an important parameter leading to both histological and functional improvement in ALS animal models^[144,145].

Another approach was tested by Mitrećić *et al.*^[135]. They transplanted NSCs into the rat model of ALS using the intravascular route. It was clearly shown that in animals affected by disease cells did cross the blood-brain barrier and accumulated in the regions affected by disease (motor cortex, ventral horns of the spinal cord) more than in healthy non-diseased animals. In the diseased CNS tissue, although only 6% of the initial stem cell dose was found at 7 d post-infusion, the transplanted cells differentiated into neurons and astrocytes^[135]. Transplantation of genetically-engineered cells is another strategy to provide additional support or growth factors to ALS-affected cells and could also unexpectedly influence (stem) cell differentiation. This is what happened in a study from Rizvanov *et al.*^[146] who showed that wild-type human umbilical cord blood cells differentiated into endothelial and microglial lineages after transplantation into SOD1^{G93A} mice, while the same cells genetically modified to overexpress vascular endothelial growth factor (VEGF) and FGF2 exhibited preferentially an astrocytic differentiation^[146]. In the same vein, human neural precursors were also genetically engineered to express insulin-like growth factor-1, neurotrophin-3, BDNF, VEGF or GDNF. These cells were then transplanted into the spinal cord or brain of SOD1^{G93A} mice where they migrated and differentiated into neurons, oligodendrocytes or GLT1-expressing astrocytes. Unfortunately, although cells of interest

Table 2 Transplantation-based astrocyte replacement in spinal cord injury animal models

Animal and type of SCI	Type of cells	Delivery	Effects on disease	Main outcomes	Ref.
Rat, aspiration of C3 fasciculus gracilis	E14 rat spinal cord astrocytes	Intraparenchymal graft at lesion site	Worsened hindlimb function compared to controls	Migration of grafted GFAP ⁺ astrocytes toward the nucleus gracilis of the host medulla	[184]
Rat, L3 hemisection	Neonatal rat cortical astrocytes	Intraparenchymal injection at lesion site, 2.5 × 10 ⁵ cells, in suspension or in gelfoam	Not investigated	Migration more than 4 mm away from the injection site, reduced glial scarring	[185]
Rat, photochemically-induced infarction of dorsal funiculus	Neonatal rat mixed glial cells (close to type-1 astrocytes) Neonatal kitten mixed glial cells (giving rise to type-2 astrocytes) CG4-mixed glial cells (differentiated into type-2 astrocytes)	Intraparenchymal injection at lesion site	Not investigated	Produced dense clusters of astrocytes surrounded by meningeal cells within the cyst Produced cells that filled the cyst with a loose network devoid of meningeal cell infiltration at the lesion Filled the cyst with a loose network and increased the density of blood vessels in the lesion core	[186]
Rat, T9/T10 contusion	GRPs from rat E13.5 spinal cord	Intraparenchymal injection at lesion site, 5 × 10 ⁵ cells	Not investigated	Differentiated into oligodendrocytes and astrocytes. Reducing glial scar and proteoglycans synthesis. Supported axonal regrowth in the lesion but not on long-distance	[155]
Rat, T8 dorsal hemisection	P3 rat neonatal cortical astrocytes (mainly type 1 astrocytes)	Intraparenchymal injection at lesion site, 2.5 × 10 ⁵ astrocytes in a collagen I scaffold	Modest temporary improvements of locomotor function	No migration of astroglial cells out of the implant. Significant increase in the number of ingrowing axonal fibres	[152]
Rat, T8/T9 contusion	Mixed NRPs and GRPs (ratio 1:3) from rat E13.5 spinal cord	Intraparenchymal injections at and around lesion site, 3 sites, 1 × 10 ⁶ cells	Improvement of bladder, sensory and motor functions	Differentiation into neurons and glia. Volume of spinal cord spared was increased and local lumbosacral circuitry was modified	[187]
Rat, T8 complete transection	Adult rat cortical astrocytes	Intraparenchymal injection below lesion site (T11), 1.5 × 10 ⁵ cells	Not investigated	Massive rostral migration (8 mm)	[188]
Rat, C1/2 or C3/4 dorsal hemisection	GDAs ^{BM/IN} from rat E13.5 spinal cord	Intraparenchymal injections at and around lesion site, 6 sites, 2-3 × 10 ⁴ cells/site	Functional locomotor recovery	Significant axonal regrowth, decreased synthesis of inhibitory proteoglycans, suppression of axotomized neurons atrophy	[156]
Rat, C1/2 or C3/4 dorsal hemisection	GDAs ^{BM/IN} from rat E13.5 spinal cord GDAs ^{CNTF} from rat E13.5 spinal cord GRPs	Intraparenchymal injections at and around lesion site, 6 sites, 3 × 10 ⁴ cells/site	Same for GDAs ^{BM/IN} as in [156], GRPs and GDAs ^{CNTF} caused mechanical allodynia and thermal hyperalgesia	Same results for GDAs ^{BM/IN} as in [156], GRPs and GDAs ^{CNTF} failed to support axonal regrowth	[115]
Rat, C3/4 dorsal hemisection	GDAs ^{BM/IN} and GDAs ^{CNTF} from human embryonic spinal cord tissue (week 9 of gestation)	Intraparenchymal injections at and around lesion site, 6 sites, 3 × 10 ⁴ cells/site	GDAs ^{BM/IN} promoted locomotor recovery	GDAs ^{BM/IN} supported axonal regrowth, neuronal survival more efficiently than GDAs ^{CNTF}	[116]
Mouse, T9/10 contusion	Mouse iPSC-derived astrocytes	Intraparenchymal injection at lesion site, 1 × 10 ⁵ cells	No improvement of locomotor or sensory functions	No tumor formation. Long GFAP ⁺ processes from transplanted cells. No interaction with host cells.	[189]
Athymic rats, T10 contusion	hGRPs from fetal cadaver brain tissue (week 18-24 of gestational)	Intraparenchymal injections at and around lesion site, 3 sites, 1 × 10 ⁶ cells	No significant improvements in motor function recovery. hGRP grafts attenuated hyperactive bladder reflexes	Differentiation for 80% of grafted cells into GFAP ⁺ astrocytes	[159]
Athymic rat, C4/5 dorsal hemisection	GRPs, GDAs ^{BM/IN} and GDAs ^{CNTF} from human and rat embryonic tissue	Intraparenchymal injection at lesion site, 1 site, 6 × 10 ⁵ cells	Not investigated	In all 3 groups differentiation into astrocytes generating a permissive environment for axonal regrowth, but not out of the lesion	[157]
Rat, T9 contusion	GDAs ^{BM/IN} from rat E14 spinal cord and overexpressing D15A	Intraparenchymal injections around lesion site, 4 sites, 4 × 10 ⁵ cells	Improved locomotor function. No changes in neuropathic pain	Differentiation into GFAP ⁺ astrocytes not secreting CSFG and allowing robust axonal regeneration. Increased spared white matter and decreased injury size compared to controls	[181]
Athymic rat, C4/5 dorsal hemisection	GRPs, GDAs ^{BM/IN} and GDAs ^{CNTF} from fetal cadaver brain tissue (week 20-21 of gestation)	Intraparenchymal injection at lesion site, 1 site, 6 × 10 ⁵ cells	Not investigated	Differentiated astrocytes from all 3 groups generated a permissive environment for axonal regrowth	[160]
Rat, T8 contusion	GDAs ^{BM/IN} from rat E13.5 spinal cord	Intraparenchymal injection at and around lesion site, 12 sites, 1.5 × 10 ⁴ cells/site	Improved hindlimb motor function	Promoted axonal regrowth, reduced glial scarring, inhibited neuroinflammation	[190]

BM/IN: Bone morphogenic protein 4; CNTF: Ciliary neurotrophic factor; E: Embryonic; CSFG: Chondroitin sulfate proteoglycans; GDA: GRP-derived astrocyte; GFAP: Glial fibrillary acidic protein; GRP: Glial-restricted precursor; h: Human; iPSC: Induced-pluripotent stem cells; L: Lumbar; NRP: Neural-restricted precursor; P: Post-natal; SCI: Spinal cord injury; T: Thoracic.

were generated and produced substantial amount of growth factors, they were unable to modify ALS disease onset or progression^[147].

In the last few years, we have been witnessing translation of the basic research into clinical trials for ALS. Maybe too prematurely, clinical trials have been launched around the world, without consensus on the cell types used, the delivery methods, or targeted outcome measurements. The majority of the these studies have focused on safety measurements, and all of them have reported transplantation of stem cells as a safe procedure (reviewed by^[148]). As we are approaching the stage when some of these trials are moving from phase 1/2 to phase 2/3, the field is eagerly awaiting detailed reports of the clinical benefits of these cellular interventions. Currently, there are approximately 15 ongoing clinical trials in the EU and United States. Most of them are focused on intraspinal delivery of fetal/mesenchymal/neural stem cells (United States, Italy, Spain) and some used intrathecal delivery of autologous bone marrow-derived cells; so far, none of them is specifically addressing the replacement of ALS-affected astrocytes.

LESSONS FROM TRANSPLANTATION PARADIGMS IN SCI MODELS

Some of the major experimental studies addressing the replacement of astrocytes based on transplantation paradigm in SCI animal models are summarized in Table 2. Historical studies conducted in the laboratories of George Smith and Jerry Silver tested the therapeutic potential of rodent neonatal astrocytes by transplantation following CNS insults. In this paradigm, cerebral midline was lesioned causing severing of callosal axons. A nitrocellulose bridge was introduced at the site of injury. When conducted at postnatal day 8 or younger ages, no necrosis was observed within 24 h. Furthermore, glial cells migrated and integrated into the graft, which provided a substrate for axon growth. However, when conducted later, there was extensive tissue degeneration and the implant was covered with a scar like mixture of fibroblasts and astrocytes. This glial scar failed to promote axon regeneration. Interestingly, when this paradigm was modified such that glial cells from younger pups were grafted into lesions of the older pups, they retained their ability to promote axon outgrowth. These pioneering studies demonstrated an age dependent decrease in the ability of endogenous and transplanted astrocytes to promote axon regeneration^[149].

Successive *in vitro* studies conducted by these researchers confirmed age dependent changes in intrinsic properties and molecular basis for supporting axon growth in astrocytes. The rate and extent of chick, as well as rodent, axon outgrowth was consistently greater over the surface of immature compared to mature astrocytes. In terms of molecular properties,

NCAM and G4/L1 antibodies reduced the rate of outgrowth over immature but not mature astrocytes, whereas integrin B1 receptor antibody reduced outgrowth on immature, and to a lesser extent, over mature astrocytes^[150].

Furthermore, there are differences in the motile properties of the two cell populations such that following transplantation into adult brain immature astrocytes demonstrate extensive migration and interaction with host blood vessels, unlike mature astrocytes. This ability may be linked to their potential to limit glial scar formation and support axon outgrowth^[151]. Transplantation of neonatal astrocytes at the site of thoracic SCI resulted in outgrowth of axons along the transplants, as well as some motor recovery^[152].

Even though these early studies produced promising results, because of the difficulty in harvesting these beneficial immature astrocytes from human tissues, further studies explored more practically relevant cell types such as multipotent NSCs as a viable source to generate transplantable astrocyte populations. In studies conducted by the Whittemore lab, NSCs isolated from E14 rat cortex were transplanted into intact and injured spinal cord, without prior differentiation. In the intact spinal cord, over a 2-mo period, a 50% of multipotent stem cells differentiated into GFAP positive astrocytes and a small percentage differentiated into oligodendrocytes and neurons. Following injury to the spinal cord, astrocyte differentiation dropped to 35% and neuronal differentiation was not observed at all^[153], demonstrating an effect of the micro-environment on the differentiation pattern of the transplanted stem cells. To overcome this, in a separate study, NSCs were transfected with Ngn-2, followed by transplantation into injured spinal cord. This resulted in a significant reduction in astrocyte differentiation and an increase in differentiation into oligodendrocytes and neurons. Furthermore, Ngn-2-NSC treated rats showed improved motor function. These studies also showed that transplantation of control NSCs enhanced neuropathic pain associated with SCI, whereas this unexpected side effect was not observed in Ngn-2-NSC transplanted rats^[154].

While NSCs provide the benefit of being able to give rise to neurons as well as glia, the use of GRPs harvested from fetal CNS has gained wide popularity in recent years for targeting astrocytes. Early studies documented extensive migration of transplanted GRPs in injured and intact spinal cord and differentiation into cells of the glial lineage, predominantly into astrocytes^[112]. Transplantation of these cells into thoracic SCI reduced scar formation and expression of growth-inhibiting proteoglycans; however, no axon outgrowth was observed^[155]. This obstacle was overcome by pre-differentiating GRPs into astrocytes (GDAs) by treatment with BMP-4. These GDAs were able to promote axon outgrowth when transplanted into lesioned spinal cord without causing neuropathic

pain^[156]. These investigators also differentiated GRPs into astrocytes by treatment with a different estrogenic signaling molecule, CNTF. This type of GDA however failed to promote axon regeneration and promoted thermal hyperalgesia and mechanical allodynia following transplantation into lesioned spinal cord^[115]. These studies highlighted that heterogeneous astrocyte populations may have distinct therapeutic potentials. Contrasting results from the Fischer lab indicated that, although heterogeneous, both BMP-4 and CNTF GDAs promoted axon outgrowth to a similar extent^[157]. Although it is not possible to compare in detail the precursor populations used by the two labs, the properties of specific glial precursor populations, differences in the culture conditions, and different transplantation and tracing protocols may have led to these contrasting results. Advantages derived from the graft are manifold. For example, a recent report from the Proschel lab illustrated an underlying mechanism through which BMP4-GDAs promote axon regeneration involving secretion of periostin^[158].

While the above-mentioned studies involving rodent GRPs provided an understanding of their properties and therapeutic potential, further studies involving more clinically relevant human GRPs were designed based on these previous studies. hGRPs harvested from fetal human brain were pre-differentiated into astrocytes (hGDAs) by treatment with BMP-4 and transplanted into injured spinal cords of athymic rats. Graft expansion was seen over an 8 wk time period, and in both hGRP and hGDA transplant groups, cyst and glial scar formation was reduced. Although there was no significant motor recovery, lack of neuropathic pain and permissive properties of these cells make them promising therapeutic candidates after SCI^[159]. Based on their rodent GRP work, the Fischer group generated GDAs by treatment with either CNTF or BMP-4 and showed that these cells have similar therapeutic potential in terms of promotion of axon generation^[160], whereas the Davies and Proschel groups again reported contrasting results^[116]. These differences may be related to the age, region and technique of isolation of hGRPs, as well as differences in the culture conditions used by the two labs.

In recent years, the discovery of induced pluripotent stem cells (iPSC) cells has generated great excitement as large quantities of clinically relevant mature cell types can be generated from these pluripotent cells, without facing the ethical concerns presented by pluripotent embryonic stem cells (ESCs). However, this field is in its infancy, especially in the context of astrocytes. Recently, the Zhang laboratory developed a protocol for producing large quantities of regionally specific astrocytes from ES and iPSC cells^[69]. A shortcoming of this study however is that it required 6 mo of culturing. Shorter duration protocols were subsequently reported, but these produced mainly populations of immature astrocytes^[161,162]. Astrocyte maturation takes place in

two distinct phases and marker expression for these phases has been characterized, which led to the development of protocols that generate astrocytes with mature phenotypes. While the treatment of immature astrocytes with FGF1 or FGF2 promoted up-regulation of maturation markers such as glutamate transporters and downregulation of GFAP, treatment with tumor necrosis factor- pushed cells toward a reactive astrocyte phenotype. These cells can be used to model human pathological processes *in vitro* and *in vivo* as well as for therapeutic transplantation^[163]. More recently the Zhang laboratory reported another shorter duration protocol for generating astrocytes from iPSCs by differentiation of these cells into neuroepithelial cells, followed by removal of mitogen and treatment with CNTF to induce differentiation into astrocytes^[70]. Recently, the Maragakis lab conducted transplantation of iPSC- and ESC-derived immature astrocytes into rodent spinal cord. Although limited, the grafts showed long-term survival, with less than 5% of the transplanted cells surviving at 12 wk post-transplantation. Furthermore, graft derived astrocytes expressed markers of mature, quiescent astrocytes such as AQP4, EAAT1, EAAT2, as assessed by immunostaining analysis and gene expression profiling, suggesting that these cells are a promising resource for transplantation therapies^[164]. Additional reports suggest that it is important to evaluate the *in vivo* safety of these cells, especially in terms of their tumor formation tendency, prior to their use for clinical transplantation^[165,166]. Recent work from the Lepore lab, conducted as an extension of their work related to rodent GRPs, generated glial progenitors from human iPSCs, followed by further differentiation into astrocytes. Following transplantation into injured spinal cord, these cells showed long-term survival, no tumor formation, and efficient differentiation into GFAP expressing cells. These cells could even be engineered to express GLT1, suggesting that hiPSCs could be used as a safe source for transplantation therapies for targeted replacement of astrocytes in SCI and other CNS diseases (unpublished data).

Until recently, the SCI field primarily focused on the role of astrocytes with regard to scar formation and their inhibitory effects on axon re-growth. Recent studies however have elucidated their heterogeneity and the changes exhibited by these cells following SCI, thereby underscoring the need to preserve their normal physiological functions. Studies mentioned above, as well as other studies that are not detailed here, are indicative of the growing appreciation of cell transplantation therapies for therapeutically targeting astrocytes in SCI.

With a special focus on chronic SCI conditions, many clinical trials based on the transplantation of unmodified mesenchymal, neural or bone-marrow stem cells have been launched around the world^[167-171]. Among phase 1 studies, most of them have focused on safety measurements and graft survival according to different routes of administration (mostly intrathecal

or focal intraparenchymal delivery). All of these studies have reported transplantation of stem cells as a risk-free procedure. To our best knowledge, none of the current human trials are specifically addressing the replacement of lost astrocytes following SCI.

CONCLUDING REMARKS AND FUTURE DIRECTIONS

We must admit that, despite numerous preclinical animal studies demonstrating improvement in a variety of functional outcomes following astrocyte transplantation, the variability and the poor reproducibility of the results still hinder full clinical translation. The variability might be partly explained by the limited survival of transplanted cells in diseased spinal cord tissue. In published preclinical ALS and SCI studies, cell graft survival was found to be usually between 5% and 32% of the initial dose and was often assessed at early time points post-transplantation. Inter-laboratory discrepancies might also be due to the source or type of astrocytes (or precursors) used in the transplantation paradigms. Indeed, astrocytes, in rodents and even more in humans, are a broad class of CNS cells endowed with specific functions according to their location, their morphology, their degree of maturity and their activation state. Finally, lack of standardization, different type of cells, different animal species and single targeting strategies of multifactorial diseases may also be part of the failures. Therefore, future protocols should aim at standardizing the culture conditions, verifying the astrocyte population homogeneity, the cell purity and, above all, at enhancing cell survival after *in vivo* transplantation. Researchers are also encouraged to provide preclinical data about long-term follow-up of engrafted cells, including survival time, differentiation pattern and CNS integration several months post-transplantation.

During this last decade, detailed molecular dissection of astroglial populations has shown that astrocytes are active players in CNS homeostasis and far more than basic fibroblast-like cells of the CNS. Understanding the molecular mechanisms underlying the normal biology of astrocytes as well as their behavior during pathological conditions will provide us with undoubtedly novel astrocyte-specific therapeutic targets. Especially regarding ALS and SCI that share several common pathophysiology mechanisms, targeting astrocytes, whose dysfunction is now well established from animal and human studies, might be a promising therapeutic strategy. As far as we know, oxidative stress, neuroinflammation and glutamate excitotoxicity are all pathological events in which astrocytes are actively involved. Therapeutics that address each separately or all-in-one these specific pathological events are of great relevance to ALS and SCI.

Stem cell based therapy for ALS and SCI includes three main aims: (1) replacement of lost nervous cells for restoring homeostatic functions of the CNS;

(2) neuroprotection of unaffected surrounding tissue *i.e.*, by secretion of neurotrophic factors or anti-inflammatory molecules; and (3) enhancement of the endogenous repair process. Based on the biology and the known functions of astrocytes, here are a few examples of neuroprotection-based mechanisms that are under investigation and might deserve particular attention in future transplantation paradigms targeting astrocytes.

Increased oxidative stress has been implicated in the pathogenesis of ALS and SCI, leading to the testing of different antioxidants in affected patients. Several studies have demonstrated that astrocyte-secreted glutathione greatly contributes to neuroprotection against oxidative stress. One of the main regulators of glutathione production and release is the transcription factor Nrf2. ALS mice with astrocyte driven Nrf2 overexpression showed increased lifespan, better functional outcomes and lower glial reactivity in spinal cord tissue^[172]. Accordingly, it would be interesting to investigate the effect of transplantation of Nrf2-overexpressing astrocytes. Stat3 is another transcription factor regulating GSH synthesis^[173], as well as a "master-switch" that mediates transition from quiescent to reactive astrocyte. Following SCI, transgenic mice ablated for Stat3 in the astroglial population showed less reactive astrocytes in the spinal cord, resulting in more widespread neuroinflammation, motor neuron loss and axonal damage and thus worsened motor deficits compared to wild-type counterparts. This study and others demonstrates that Stat3 is a key transcription factor controlling astrocyte reactivity during neurodegenerative processes, providing a potential target for intervention^[174,175].

Far from being science fiction, researchers can genetically modify (stem) cells to make them produce more growth factors or proteins of interest, as Trojan horses to deliver molecules to specific CNS locations. For instance, NSCs engineered to overexpress CNTF exert neuroprotection by *in situ* differentiation into supportive astrocytes in a mouse model of photoreceptor degeneration^[176]. Similarly, NSCs overexpressing nerve growth factor showed beneficial effects on cognitive functions after CNS transplantation and astrocyte differentiation in a learning deficit mouse model^[177]. Another example is illustrated in a recent report from Gowing^[178]. This group engineered GDNF-secreting human neural progenitors that were able to survive up to 7.5 mo after intraspinal transplantation, differentiate mainly into astrocytes and still maintain locally high levels of GDNF. More specifically, intranigral transplantation of astrocytes transduced with a lentiviral vector expressing GDNF resulted in sustained local production of growth factor and provided neuroprotection in a rat model of Parkinson^[179]. Lastly, genetically-modified astrocytes designed to secrete BDNF promoted retinal ganglion cell survival^[180], and transplantation of neurotrophin-releasing GRPs improved functional and histological outcomes after

SCI^[181]. Growth factors released from transplanted cells act in a paracrine manner on surrounding host tissue but are likely to also act in an autocrine manner on grafted cells to promote survival and/or a specific differentiation pattern. All aforementioned examples should encourage us to investigate more deeply the therapeutic potential of grafted exogenous astrocytes or stem cell-derived astrocytes in neurodegenerative and traumatic CNS diseases, as well as to think about novel genetically-modified cells that specifically target pathogenic events occurring during ALS or SCI.

Inspired from encouraging results obtained following transplantation of GLT1-overexpressing GRPs in the rat model of ALS^[104], the Lepore lab is studying their applicability and evaluating their efficacy in clinically-relevant SCI models^[182,183]. The rationale behind such an approach is based on the findings that, following SCI, astrocyte GLT1 expression and function are compromised, resulting in excitotoxicity-induced cell death during the delayed secondary injury phase^[105]. Unpublished data from our group show that transplantation of astrocytes engineered to overexpress GLT1 can prevent excitotoxicity and protect respiratory phrenic motor neurons following cervical SCI. While unmodified transplants showed robust survival, they expressed relatively low levels of GLT1 in injured spinal cord. Excitingly, GLT1 overexpressing transplant-derived astrocytes continued to express high levels of GLT1 protein following transplantation into the injured spinal cord and promoted survival of these important phrenic motor neurons and preservation of diaphragm function (unpublished work).

Finally, although ALS and SCI share many similarities including the death of spinal motor neurons, it must be emphasized that important differences between two diseases exist. ALS is a progressive neurodegenerative condition starting with discrete and asymptomatic loss of motor neurons in remote specific regions of the CNS (upper and lower motor neurons), whose symptomatology becomes apparent at approximately 50% of motor neuron loss and fatally progresses when disease affects bulbar and/or spinal respiratory centers. Therefore, therapeutic strategies in ALS, once diagnosed, should focus on astrocyte-mediated neuroprotection that prevent further motor neuron loss, worsening of functional outcomes and delayed fatal respiratory failure. Unlike ALS, SCI is characterized by different temporal sequence of events. First, acute and sub-acute phases following the initial trauma in the first hours-by-days post-injury result in a hostile environment in the spinal cord around the lesion epicenter, including inflammation, excitotoxicity and oxidative stress that lead to more cell loss and thus extension of initial lesion. This narrow time window would be appropriate for interventional strategies targeting astrocytes that favor neuroprotection or compensate for lost astrocyte-specific functions. At later time points, during the chronic stage of SCI, characterized by the resolution of subacute events, glial scarring and reorganization of spinal tissue architecture, one can imagine designing astrocyte transplants to make

scar tissue permeable to axonal regrowth, to promote invasion by remyelinating oligodendroglial precursors, or to facilitate overall rewiring of ascending/descending tracts in the spinal cord.

Abstract

Tissue engineering is an emerging field of science that focuses on creating suitable conditions for the regeneration of tissues. The basic components for tissue engineering involve an interactive triad of scaffolds, signaling molecules, and cells. In this context,

stem cells (SCs) present the characteristics of self-renewal and differentiation capacity, which make them promising candidates for tissue engineering. Although they present some common markers, such as cluster of differentiation (CD)105, CD146 and STRO-1, SCs derived from various tissues have different patterns in relation to proliferation, clonogenicity, and differentiation abilities *in vitro* and *in vivo*. Tooth-derived tissues have been proposed as an accessible source to obtain SCs with limited morbidity, and various tooth-derived SCs (TDSCs) have been isolated and characterized, such as dental pulp SCs, SCs from human exfoliated deciduous teeth, periodontal ligament SCs, dental follicle progenitor cells, SCs from apical papilla, and periodontal ligament of deciduous teeth SCs. However, heterogeneity among these populations has been observed, and the best method to select the most appropriate TDSCs for regeneration approaches has not yet been established. The objective of this review is to outline the current knowledge concerning the various types of TDSCs, and discuss the perspectives for their use in regenerative approaches.

Key words: Cell-based therapy; Mesenchymal stem cells; Dental stem cells; Differentiation; Tissue engineering

INTRODUCTION

Stem cells (SCs) are cells that present two distinctive characteristics: they are able to continuously self-renew, and they can be induced to differentiate into multiple specialized cell types^[1]. SCs have therefore been a subject of interest to researchers and the general public, as a way to regenerate damaged tissues and improve the resolution of some illnesses, such as Parkinson's disease^[2] and diabetes^[3], that current approaches in the medical field have not yet achieved. In this context, many studies have been conducted to identify and isolate SCs and to understand their biologic aspects.

SCs can be isolated in the earliest stages of embryogenesis (embryonic SCs)^[4-9] or in various postnatal tissues (adult SCs)^[2,10,11] (Table 1). Although embryonic SCs present interesting properties, such as the ability to differentiate into hundreds of other cell types, the bioethical aspects involved in the study of these cells, especially for human embryos, have hindered advances in this field and research has thus been focused on adult SCs^[1,10-12]. Adult SCs can be obtained from adult specialized tissues, such as bone marrow^[13-16], skin^[17,18] and fat^[19-23], where they likely act to renew cell populations and maintain tissue homeostasis, or help to repair the tissue in case of injury^[18,24,25]. Even though adult SCs can be obtained from less ethically concerning sources, they have some limitations compared to embryonic SCs, such as more limited lifespan and differentiation potential^[1,11,24,26]. In order to overcome these drawbacks, adult SCs can be reprogrammed by the insertion of SC-associated genes, forming induced pluripotent SCs (iPSCs)^[3,27-31].

Within the medical field, mesenchymal SCs (MSCs) have been widely studied to understand their role in skeletal tissue development, physiology and repair^[14], and because of their promising therapeutic potential^[2]. MSCs are characterized by the capacity to differentiate into multiple types of skeletal tissues^[14,32-36]. They were first described as adherent, clonogenic, self-renewing, fibroblast-like cells (colony-forming unit fibroblasts) obtained from bone marrow^[35,37,38]. Subsequently, several studies were performed to identify other sources and to understand how these cells can give rise to distinct cell types, for the purpose of using these cells in regenerative procedures^[39-43].

In this context, dental tissues have also been investigated as niches of MSCs, and many tooth-derived SCs (TDSCs) have been identified and characterized, including dental pulp SCs (DPSCs)^[44-48], SCs from human exfoliated deciduous teeth (SHED)^[49-53],

periodontal ligament SCs (PDLSCs), dental follicle progenitor cells (DFPCs)^[54-56], SCs from apical papilla (SCAP)^[19,56-59], and periodontal ligament of deciduous teeth SCs (DePDL)^[50,51,60-62] (Figure 1). Dental tissues are an accessible source of MSCs that can be obtained with limited morbidity and without additional risks to the donor, as extracted/exfoliated teeth represent a waste product of dental procedures^[13,63-65]. However, the properties of these TDSCs and their feasibility for regenerating tissues still need to be investigated in greater detail. Thus, the aim of the present review is to describe the current knowledge concerning TDSCs, and to consider the perspectives for their use in regenerative approaches.

ISOLATION, CHARACTERIZATION, AND DIFFERENTIATION POTENTIAL OF TDSCs

Because of the variety of methodologies used to isolate and characterize MSCs, the Mesenchymal and Tissue Stem Cell Committee of the International Society for Cellular Therapy proposed minimal criteria to define human bone marrow SCs (BMSCs) and other types of MSCs *in vitro*^[32]. Briefly, MSCs must adhere to plastic under standard culture conditions, express cluster of differentiation (CD)105, CD73 and CD90, but not CD45, CD34, CD14, CD11b, CD79a, CD19, or human leukocyte antigen-DR surface molecules, and have the potential to differentiate along osteogenic, chondrogenic and adipogenic lineages^[32]. Therefore, studies characterizing TDSCs usually evaluate these criteria, as well as clonogenicity (capacity to form adherent colonies derived from one single cell) and differentiation potency, in order to compare them to each other and to BMSCs^[66,67] (Table 2).

DPSCs

DPSCs were the first TDSCs isolated and characterized in 2000^[44]. Obtained from permanent third molars, these cells were found to be more proliferative than BMSCs, and had the capacity to form mineral deposits *in vitro*, though in reduced amounts compared to BMSCs^[44]. DPSCs also failed to form lipid-laden adipocytes *in vitro*, whereas BMSCs are capable of differentiating into adipocytes^[44]. However, more recent studies demonstrate that DPSCs can differentiate into adipocyte cells when other supplements are added to the adipogenic induction medium^[46,65].

When transplanted *in vivo*, some DPSC clones differentiate into aligned odontoblast-like cells, with prolonged processes oriented into newly formed dentin-like structures^[44,46], whereas BMSCs form distinct lamellae of bone^[44]. DPSCs can also form reparative dentin-like tissue on the surface of human dentin *in vivo*^[68].

SHED

In 2003, progenitor cells were isolated from the remnant pulp of exfoliated deciduous teeth^[49]. SHED

Table 1 Classification of stem cells according to their plasticity^[1,2,41,66]

Stem cell type	Description
Totipotent	Stem cells able to differentiate into cells of all three germ layers (ectoderm, mesoderm and endoderm) and extra-embryonic tissues (<i>e.g.</i> , zygote)
Pluripotent	Stem cells able to differentiate into all cells of the body, but that cannot form extra-embryonic tissues (<i>e.g.</i> , embryonic stem cells and induced pluripotent stem cells)
Multipotent	Stem cells that have differentiation abilities restricted to some cell types, usually from the germ layer they are derived from (<i>e.g.</i> , mesenchymal stem cells)

Table 2 Characterization of tooth-derived stem cells

TDSCs	Ref.	Location	Expression markers		Differentiation capacity	
			Positive	Negative	<i>In vitro</i>	<i>In vivo</i>
DPSCs	[13,44,46,51,65]	Permanent tooth pulp	CD29, CD44, CD73, CD90, CD105, CD146, STRO-1, Oct-3/4, Sox-2, nanog	CD14, CD34, CD45	Osteoblast, adipocyte, chondrocyte, hepatocyte, neuron	Dentin-like structures
SHED	[49,51,53,69,70]	Deciduous tooth pulp	CD29, CD105, CD146, STRO-1	CD31, CD34	Osteoblast, odontoblast, adipocyte, neural cell	Dentin formation, induce bone formation by murine host cells
SCAP	[13,56,57,65]	Apical papilla of developing tooth	CD24, CD29, CD31, CD44, CD73, CD90, CD105, CD106, CD146, CD166, STRO-1, Oct-3/4, Sox-2, nanog, survivin	CD14, CD18, CD34, CD45, CD150	Osteoblast, adipocyte, chondrocyte, hepatocyte, neuron	Dentin-like tissue
DFPCs	[13,54,56,65,72]	Dental follicle of developing tooth	CD29, CD44, CD73, CD90, CD105, nestin	CD14, CD31, CD34, CD45, CD117	Osteoblast, adipocyte, chondrocyte, hepatocyte, neuron	Bone/cementum-like tissue
PDLSCs	[13,57,60,73]	Permanent tooth periodontal ligament	CD44, CD90, CD105, CD166, CD146, STRO-1, Oct-3/4, Sox2, nanog, nestin	CD14, CD34, CD34, CD45	Osteoblast/ cementoblast, adipocyte, neuron	Periodontal ligament/ cementum-like tissue
DePDL	[60]	Deciduous tooth periodontal ligament	CD105, CD166, STRO-Oct-4	CD34, CD45	Osteoblast, adipocyte	

CD: Cluster of differentiation; DePDL: Periodontal ligament of deciduous teeth stem cells; DFPCs: Dental follicle progenitor cells; DPSCs: Dental pulp stem cells; Oct: Octamer; PDLSCs: Periodontal ligament stem cells; SCAP: Stem cells from apical papilla; SHED: Stem cells from human exfoliated deciduous teeth; Sox2: SRY-box containing gene 2.

were found to be more proliferative than BMSCs and DPSCs^[49,51], and showed higher capability for osteogenic and adipogenic differentiation than DPSCs *in vitro*^[51]. SHED can also differentiate into neural cells^[69]. When 12 single-colony-derived SHED clones were transplanted into immunocompromised mice, only three clones demonstrated the potential to generate ectopic dentin-like tissue on the hydroxyapatite/tricalcium phosphate (HA/TCP) carrier equivalent to that generated by multiclonal-derived SHED^[49]. When SHED were seeded into human tooth slices and transplanted into immunodeficient mice, they were also able to form a dentin-like structure^[70]. Although some researchers claim that SHED have the ability to differentiate into osteoblasts *in vivo*^[51], Miura *et al.*^[49] reported that, in fact, SHED act as an osteoinductive factor, inducing the host cells to form bone.

SCAP

The apical papilla is the tissue located at the apex of the root of developing teeth^[66], and is distinct from the pulp^[71]. As this tissue is associated with root formation, it potentially provides a source of MSCs for

this purpose. SCAP are the cells isolated from this tissue that present characteristics of MSCs, and can give rise to odontoblastic, osteoblastic and adipocyte-like cells when cultured under appropriate conditions^[57]. SCAP also have the capability to form a dentin-like structure when transplanted into immunocompromised mice, using HA/TCP as a scaffold^[57]. Sonoyama *et al.*^[57] evaluated whether SCAP and DPSCs are the same or distinct MSC populations based on their cDNA microarray profile, and observed that many genes were differentially expressed by these MSC populations. In particular, CD24 and survivin were highly expressed in the SCAP population. Additionally, SCAP also showed other favorable characteristics, such as higher proliferative rate and telomerase activity, and improved migration capacity^[57].

DFPCs

The dental follicle is a condensation of ectomesenchymal cells that surrounds the tooth germ in early stages of tooth formation and contains cells that form the three tissues that constitute the periodontium: periodontal ligament, cementum and alveolar bone^[54,72]. When the

Figure 1 Sources of tooth-derived stem cells. DePDL: Periodontal ligament of deciduous teeth stem cells; DFPCs: Dental follicle progenitor cells; DPSCs: Dental pulp stem cells; PDLSCs: Periodontal ligament stem cells; SCAP: Stem cells from apical papilla; SHED: Stem cells from human exfoliated deciduous teeth.

heterogeneity of DPFCs was analyzed, it was observed that, although all cloned cell lines were positive for MSC-related surface markers (CD105, CD44, CD29) and negative for hematopoietic markers (CD34, CD117), they were different in terms of proliferation and mineralization patterns, indicating that they could be committed to distinct lineages^[72].

In order to avoid donor variability, TDSCs from follicle, pulp and papilla were isolated from a single donor tooth and the morphology, proliferation rate, expression of MSC-specific and pluripotency markers, and *in vitro* differentiation into osteoblasts, adipocytes, chondrocytes and hepatocyte-like cells were compared^[65]. Adherent, fibroblast-like morphology was observed in all TDSCs cultured under the same standard conditions, and DFPCs were more proliferative than DPSCs and SCAP^[65]. Although all three cell types were able to differentiate into the osteoblast lineage, DFPCs and DPSCs showed higher potentials than SCAP to form mineralized nodules *in vitro*^[65]. Additionally, when cultivated under chondrogenic-inducing conditions, DFPCs expressed all three chondrogenic-specific markers (aggrecan, and type I and type III collagen), whereas DPSCs and SCAP only expressed aggrecan^[65].

PDLSCs

The periodontal ligament harbors a heterogeneous cell population, with subsets of cells in various stages of commitment to fibroblastic and osteoblastic/cementoblastic lineages^[34,73,74]. Within these subsets,

it was supposed that putative MSCs would be present in the periodontal ligament, which was confirmed in 2004^[73]. PDLSCs show expression of STRO-1 and CD146, SC markers previously reported to be expressed in BMSCs and DPSCs, and also express scleraxis, a tendon-specific transcription factor^[73].

PDLSCs are more proliferative and clonogenic than BMSCs^[34]. PDLSCs can also differentiate into adipocytes^[34,73] and chondrocytes^[34], as well as osteoblasts/cementoblasts^[34,60,73]. Although PDLSCs are able to form mineralized tissue *in vitro* when osteoblastic/cementoblastic differentiation is induced, they form fewer mineralized nodules than BMSCs^[34,73]. Additionally, when transplanted into immunocompromised mice, some clones of PDLSCs have been shown to form periodontal ligament-like structures *in vivo*^[73].

DePDL

As MSCs can be isolated from the pulp of deciduous teeth, it was thought that the periodontal ligament of deciduous teeth may also harbor MSCs^[60]. In 2010, DePDL were isolated and compared with their permanent counterparts and found to be more proliferative than PDLSCs^[60]. Moreover, it was observed that, although DePDL and PDLSCs have the ability to differentiate into both adipocyte-like and osteoblast-like cells *in vitro*, DePDL show a higher potential for adipogenic commitment, and PDLSCs have a higher potential for osteogenic commitment^[60].

iPSCs from TDSCs

Following reports of reprogramming of dermal fibroblasts to behave like embryonic SCs^[27,28], studies were conducted to evaluate if other cell types could also be reprogrammed, including TDSCs^[29,30]. It was reported that human gingival and periodontal ligament fibroblasts^[29], SHED, SCAP and DPSCs^[30] can be reprogrammed as iPSCs, with formation of teratomas after implantation in immunocompromised mice^[29,30].

PERSPECTIVES ON TDSCs IN REGENERATIVE APPROACHES

Tissue engineering is an emerging field based on basic science and engineering technology, designed to create suitable conditions to regenerate damaged tissues^[75-78]. The basic components for tissue engineering involve an interactive triad of scaffolds^[79-81], signaling molecules^[82-84] and cells^[24,33,41,85], which play a fundamental role in the regeneration process^[24,76,86,87]. Scaffolds serve as a three-dimensional template mimicking the extracellular matrix; signaling molecules enhance this cellular activity by stimulating cells to migrate, proliferate and differentiate; and cells provide the machinery synthesis of the extracellular matrix and tissue regeneration^[24,75,76,88,89]. Due to their interesting properties, including self-renewal and differentiation abilities, MSCs are considered important for tissue maintenance and renewal, and, therefore, a promising candidate for tissue engineering^[24,90-94].

Some studies demonstrated that cell-based therapies are able to regenerate dental tissues^[48,57,70,95-98]. In a study in dogs, complete pulp regeneration was achieved when CD105⁺ DPSCs with stromal cell-derived factor-1 were transplanted into pulp, and this was not observed when total pulp cells or CD105⁺ adipose-derived cells were used^[48]. Supplementation of guided tissue regeneration with periodontal ligament cells for the treatment of class II and III furcation defects in dogs enhances periodontal regeneration^[95,97]. Twelve weeks after PDLSCs with an HA/TCP scaffold were transplanted into periodontal defects in a minipig model, new bone, cementum and periodontal ligament formation was observed^[98]. Sonoyama *et al.*^[57] also explored the potential of human PDLSCs and SCAP to generate a root-periodontal ligament complex in minipigs. They were able to obtain engineered roots capable of supporting porcelain, though with lower compressive strength. Nakahara^[96] reported the formation of root and periodontal ligament in a new culture system using one tooth crown collected from a neonatal mouse, which was referred to as a "test-tube dental implant". The author stated that cell therapy will be the next generation of dental medicine, but further information regarding human SCs is necessary for safe and reliable clinical applications^[96].

In regard to human clinical trials, autologous progenitor cells obtained from periodontal ligament have been used to treat intrabony defects^[99]. These progenitor cells were of a later cell lineage with

decreased capacity for osteogenic and adipogenic differentiation compared to PDLSCs *in vitro*. Despite this, these progenitors were able to promote improvement in clinical and radiographic parameters. Another study reported the cultivation of periodontal ligament cells on titanium pins that were subsequently implanted in patients and in dogs^[91]. Clinical evaluation of the implants placed in the patients showed satisfactory mechanical function, and radiographs revealed bone filling and formation of a lamina-dura around the implants. Additionally, histologic evaluation of the implants placed in dogs revealed a ligament-like formation. Although these studies are not directly related to MSCs, they indicate that cell therapy can be a feasible clinical approach in the near future.

Despite these promising studies in cell-based tissue engineering, it is important to highlight that the best method to select the most appropriate MSC type for regenerating dental tissues is not yet clear. Although BMSCs, DPSCs, SHED, SCAP, DFPCs, PDLSCs, and DePDL present a common marker profile, they differ in their clonogenicity, proliferative ability, and differentiation potential *in vitro* and *in vivo*, suggesting that these properties are related to the microenvironments of origin of each cell lineage^[13,24,34,44,60,65,67,73]. Additionally, it has been noted that, even in the same population of MSCs, there are heterogeneous cell subpopulations with distinct differentiation potentials^[100]. This heterogeneity in relation to the ability to differentiate *in vitro* and to form dental tissues *in vivo* has also been reported in some TDSCs lineages, including DPSCs^[44,46,67], SHED^[49], DFPCs^[72], and PDLSCs^[34,73,74,101-104]. Therefore, it can be concluded that, although there are MSC-related surface markers, such as STRO-1, CD146 and CD105, specific surface markers associated with the hierarchical commitment to differentiation pathways of TDSCs are not yet well established. In this context, further advances in understanding the regulation of MSCs during differentiation and dental development are required in order to develop new approaches for dental tissue regeneration with predictable outcomes^[19,26,67,89].

CONCLUSION

The interest in organ regeneration using SCs has increased in the last decade. In this context, TDSCs are promising candidates, as they are readily available, highly proliferative, and present multi-differentiation abilities. Research on cell therapy for regenerating dental tissues has already been done, and shows promising results. Nevertheless, further research is needed to better characterize TDSCs and to understand their differentiation pathways in order to develop the most appropriate approaches for SC-based tissue engineering-therapies in dental practice.

article reviews the effect of MSCs on tumor establishment, growth and metastasis and also susceptibility to infection and its progression. Data published to date shows a paradoxical effect regarding MSCs, which seems to depend on isolation and expansion, cells source and dose and the route and timing of administration. Cancer and infection may thus be adverse or therapeutic effects arising from MSC administration.

Core tip: Mesenchymal stem cells (MSCs) derived from different origins have recently received much attention as potential therapeutic. However, such cells also appear to have essential functions in building and supporting tumor microenvironments. Here, we review the effect of MSCs on tumor establishment, as also susceptibility to infection and its progression. The literature reveals incongruity regarding the impact of MSCs on the development of cancer and infection; such paradoxical effect might be attributed to differences in isolation and expansion conditions, the source and dose of the cells, the administration route and its timing and host characteristics. MSCs immunomodulatory potential seems to be the leading mechanism responsible for such effects.

Abstract

Multipotent mesenchymal stromal cells [also referred to as mesenchymal stem cells (MSCs)] are a heterogeneous subset of stromal cells. They can be isolated from bone marrow and many other types of tissue. MSCs are currently being tested for therapeutic purposes (*i.e.*, improving hematopoietic stem cell engraftment, managing inflammatory diseases and regenerating damaged organs). Their tropism for tumors and inflamed sites and their context-dependent potential for producing trophic and immunomodulatory factors raises the question as to whether MSCs promote cancer and/or infection. This

INTRODUCTION

Multipotent mesenchymal stromal cells, also referred

to as mesenchymal stem cells (MSCs), were described for the first time half a century ago^[1]. Such cells are distributed throughout the stroma of several organs *in vivo* whilst MSCs adhere to plastic *in vitro* and proliferate when stimulated by fetal bovine serum^[1]. MSCs differentiate into mesodermal cells *in vitro* and *in vivo* (*i.e.*, adipocytes, chondrocytes, osteocytes and myocytes)^[2]. They can also cross the germ line barrier and produce cells from endo- and ectodermal lineages, such property being known as cell plasticity^[3].

MSCs are an ideal tool for cell therapy because they are easily procured from live donors^[4] and can be efficiently expanded *ex vivo*^[5]. The receptors do not need to have been conditioned before cell administration transplant^[6], as in total bone marrow or hematopoietic stem cell transplant. Once administered intravenously, they are able to home onto and engraft into damaged tissue where they could become differentiated into tissue-specific cells, release trophic factors, promote neovascularization, manage oxidative stress and fibrosis, or trigger an anti-inflammatory response^[7-11].

MSCs from the same individual (autologous) were administered into a human for the first time in 1995^[12]; MSCs were safely allogeneically transplanted seven years later^[13]. More than 350 clinical trials involving the use of MSCs are currently under way (www.clinicaltrials.gov) and no serious adverse events have been reported to date. Nevertheless, MSCs biosafety is still a major concern, particularly regarding the development of adverse event-related cancer and infection.

MSCs AND CANCER

MSCs might form tumors

Like any other cell, when MSCs are manipulated in the long-term they might have chromosomal aberrations and produce tumors in healthy animals^[14]; this has mainly been reported regarding mouse cells, which require extensive cultures for producing a significant number of hematopoietic-free MSCs^[14]. For instance, it has been shown that intravenously administered NOC/SCID bone marrow-derived MSCs embolize within the lung capillaries, expand and invade the lung parenchyma and form tumor nodules^[15]. These lesions rarely contain lung epithelial cells but they have the characteristics of cartilage and immature bone resembling well-differentiated osteosarcoma.

No transformation has been proven so far for human MSCs when expanded properly *ex vivo* (*i.e.*, non-exhausted and not forced to cell crisis)^[14]. The Canadian Critical Care Trials Group has recently published a meta-analysis of randomized, non-randomized, controlled and uncontrolled, phase I and phase II clinical trials^[16]; no association between autologous or allogeneic MSCs administration and tumor formation was reported in the 36 studies reviewed by them. Nonetheless, longer follow-up is required to draw a final conclusion regarding human

MSCs' tumorigenic potential.

MSCs may promote tumor growth

Human bone marrow-derived MSCs have increased the growth of ERA α positive breast cancer cell lines (T47D, BT474 and ZR-75-1) in an *in vitro* three-dimensional tumor environment, but have had no effect on an ERA α negative cell line (MDA-MB-231)^[17]; however, the growth rate of another ERA α negative cell line (MDA-MB-468) was high in the presence of human MSCs. Another study has shown that both human fetal MSCs and human adipose-derived MSCs transplanted subcutaneously into BALB/c-nu/nu mice alone or together with tumor cell lines F6 or SW480 (ratio 1:1 or 1:10), favored the growth of these tumor cell lines^[18].

Tumor cells obtained from primary breast cancer grown in the presence of human bone marrow-derived MSCs (ratio 1:1) and tested in secondary mice have been seen to have greater tumor-producing ability than cells obtained from primary tumors and grown in the absence of MSCs^[19]. Besides, tumor incidence and/or size^[18,20,21] as well as tumor vascularity^[22] have all increased when breast, lung, colon or prostate tumor cells have been co-injected with human adipose-derived or bone marrow-derived MSCs. The same has been proven for osteosarcoma, melanoma and glioma tumor cells^[23]. Another interesting observation concerned adipose tissue implant adjacent to lung cancer or Kaposi sarcoma xenografts resulting in a substantial increase in tumor size along with the appearance of stromal cells from the implant; adipose-derived MSCs can thus promote tumor growth^[24].

MSCs' innate tropism for established tumors has been widely reported^[24], yet the mechanism behind it still remains to be fully elucidated^[25]. The explanation advanced to date is that tumors behave as unresolved wounds as their stroma closely resemble healing granulation tissue and they produce cytokines, chemokines and other chemoattractants^[26] and MSCs chemotactic properties are similar to those of leukocytes^[27,28]. MSCs tropism for tumors has been successfully exploited for the delivery of antitumor agents in animal models of lung and breast cancer and melanoma and glioma^[25].

MSCs might promote metastasis

Breast cancer cells co-cultured with human bone marrow-derived MSCs (ratio 1:1) up-regulate the expression of oncogenes and proto-oncogenes associated with tissue invasion, angiogenesis and apoptosis (*i.e.*, N-cadherin, vimentin, Twist, Snail and E-cadherin)^[29]. Such molecular changes have been accompanied by morphological and growth alterations, these being features of a more metastatic phenotype. It has been seen that 0.5×10^5 breast cancer cells co-injected subcutaneously with 1.3×10^6 human bone marrow-derived MSCs have significantly increased lung metastasis rate in NOD/SCID mice. This effect was lost when bone marrow-derived MSCs were injected

separately from tumor cells^[20]. On the other hand, it has been shown that bone marrow-derived MSCs facilitate cancer cells [MCF-7, T47D low invasive cell lines and stromal cell-derived factor 1 (SDF-1)^{null} MDA-MB-231 highly aggressive ones] homing into bone marrow and have modified the metastatic niche through trophic factor secretion (SDF-1 and CXCR4) and improved neovascuogenesis in a xenogeneic mouse model^[30].

MSCs might inhibit tumor growth

It has been shown that human bone marrow-derived MSCs interfere *in vitro* with small cell lung cancer (A549), esophageal cancer (Eca-109), Kaposi's sarcoma and leukemic cell line proliferation kinetics^[31]. The foregoing was observed when 0.5×10^5 tumor cells were co-cultivated with 0.5×10^5 human bone marrow-derived MSCs but also when they were exposed to MSCs-conditioned medium; cells were arrested during the cell cycle G₁ phase in both cases by the downregulation of cyclin D2 and induction of apoptosis^[32,33]. MSCs from other sources, including human fetal skin-derived MSCs and adipose-derived MSCs, have also inhibited the growth of human liver cancer cell lines^[34], breast cancer (MCF-7)^[35] and primary leukemia cells by reducing their proliferation, colony formation and oncogene expression^[22]. The intravenous injection of 4×10^6 human bone marrow-derived MSCs into Kaposi's sarcoma-bearing nude mice has inhibited tumor cell growth^[36]. A similar effect has been observed in an animal model of hepatocellular carcinoma and pancreatic tumors as altering cell cycle progression has led to decreased cell proliferation^[22,37]; the same has happened with melanoma due to increased apoptosis of capillaries^[38] and rat colon carcinoma growth has been inhibited when rat MSCs (the MPC1cE cell line) were co-implanted with tumor cells in a 1:1 or 1:10 ratio^[39].

Human fetal skin-derived MSCs (Z3 cell line) have also delayed liver tumor growth and decreased tumor size when injected with the same number of cells from the H7402 cell line in SCID mice^[34]. Injecting human adipose-derived MSCs (1×10^3 cells/mm³) into established pancreatic cancer xenografts has led to apoptosis and the abrogation of tumor growth in female Swiss nude (athymic) mice^[37].

The role of MSCs in cancer thus remains paradoxical. Evidence to date has suggested that they are pro- as well as anti-tumorigenic^[40-42] such discrepancy seems to depend on isolation and expansion conditions, cell source and dose, the administration route and the tumor model used.

MSCs AND INFECTION

MSCs might increase infection

MSCs can be recruited into inflamed sites secondary to microbial infection where they promote potent immune-suppressive activity^[43,44]. For instance, it has

been shown that administering MSCs (1.25×10^5 cells/kg) to animals infected by *Trypanosoma cruzi* (*T. cruzi*, protozoa) or *Mycobacterium tuberculosis* (*Mtb*, bacteria) has worsened the natural course of infection. Activated macrophages play an essential role in host defense against *T. cruzi* as they can destroy intracellular parasites *via* interferon (INF)- γ - and tumor necrosis factor (TNF)- α -stimulated nitric oxide (NO) production^[45]. It has been shown that mice bone marrow-derived MSCs switch macrophages to an anti-inflammatory profile, thereby suppressing inflammatory cytokine production and enhancing interleukin (IL)-10 production^[46]. An immune response to *Mtb* depends on IFN- γ -producing T-lymphocytes activating macrophages to produce NO^[47,48]. Bone marrow-derived MSCs (2.5×10^5 /kg) infusion into animals, which are normally resistant to this infection [transforming growth factor β (TGF- β) RIIDN transgenic mice], has resulted in making them susceptible to disease. Furthermore, it has been observed that donor MSCs have been recruited to the periphery of live bacteria-containing granuloma and have induced regulatory T-cell differentiation, thus resulting in immunosuppression.

A recent study aimed to prove the safety and feasibility of autologous bone marrow-derived MSCs infusion (1×10^6 cells/kg, two doses) into kidney allograft recipients, showing that three out of six enrolled patients developed an opportunistic viral infection^[49].

MSCs might decrease infection

Regarding fungal infection, the intravenous administration of an IL-17-producing sub-population of bone marrow derived-MSCs (1×10^6 cells) significantly reduced the fungal burden of kidneys in immunocompetent mice, which had suffered invasive candidiasis^[50].

Both un-stimulated and IFN- γ stimulated human MSCs can inhibit the growth of Gram-negative bacteria such as *Escherichia coli* and *Pseudomonas aeruginosa*, as well as the growth of Gram-positive pathogens such as *Staphylococcus aureus*, *Staphylococcus epidermidis*, group B *Streptococci* and *Enterococcus faecium*^[46,51]. MSCs' antimicrobial effect depends on whether they have been stimulated^[51]; while cathelicidin LL-37 antimicrobial peptide is critical to un-stimulated human MSCs, tryptophan-catabolizing enzyme heme oxygenase-1 and indoleamine-2,3-dioxygenase (IDO) are needed in IFN- γ -stimulated human MSCs. Tryptophan depletion and toxic kynurenine accumulation leads to the inhibition of bacterial growth in the latter case. Differences between human and murine MSCs antibacterial activity have also been reported; murine MSCs do not produce cathelicidin LL-37 and cannot express IDO, even after stimulation with a combination of cytokines, but they do produce lipocalin 2 (an antimicrobial molecule)^[52].

Little data has been published concerning the

impact of MSCs on viral pathogens. One study has reported that IFN- γ -stimulated human MSCs have reduced intracellular replication of cytomegalovirus and herpes simplex virus type 1 *in vitro*^[46], such effect being attributed to IDO activity^[46].

Together with MSCs' direct antimicrobial effect, it has been shown that they play an important role in the complex network of host immune response against pathogens, particularly regarding the dynamic coordination of the immune system's pro- and anti-inflammatory components^[53].

MSCs' antimicrobial activity observed *in vitro* has been clearly supported by animal models of experimental infection, such as polymicrobial sepsis^[42], lipopolysaccharide (LPS) administration^[54] and pulmonary respiratory distress syndrome^[55]. Regardless of MSCs source, administration route (intravenously *cf* intraperitoneally) or strategy (prophylaxis *cf* therapy), their administration leads to reduced pathogen burden and significantly improved survival rate^[41,42,53,56].

It has been shown that administering 2.5×10^5 mouse bone marrow-derived MSCs led to decreased mortality, controlled multi-organ dysfunction/injury and reduced pulmonary and systemic inflammation in a clinically relevant model of polymicrobial sepsis where infection was settled after the inoculation of Gram-negative and Gram-positive organisms^[42]. An endotoxemic rat model (involving intravenous LPS injection) has been used to demonstrate that administering 2.5×10^5 human adipose-derived MSCs decreased inflammatory cytokine level in serum and the lungs, reduced inflammatory changes in the lungs, prevented apoptosis in the kidneys and reduced multi-organ injury^[54]. A pulmonary respiratory distress syndrome model (induced by intratracheal endotoxin administration) has been used to show that the intrapulmonary delivery of mouse bone marrow-derived MSCs has down-regulated an LPS-induced inflammatory response and reduced lung injury, while direct lung injury by toxins or pneumonitis led to severe pulmonary edema and inflammation^[57,58].

MSCs' antimicrobial effect has also been demonstrated in the blood, peritoneum, liver and spleen, using a Gram-negative pneumonia model involving immunocompetent mice^[42,44,56].

As MSCs might lessen the development of infection, they have been used recently in a clinical study aimed at treating patients suffering acute respiratory distress syndrome (NCT01902082); one intravenous dose of 1×10^6 cells/kg allogeneic adipose-derived MSCs proved to represent a safe and feasible therapeutic tool for this infection^[59].

MSCs have been seen as an innovative therapeutic tool for preventing or treating graft-versus-host disease (GvHD) following allogeneic hematopoietic stem cell transplant (HSCT)^[60,61] owing to their immunosuppressive properties, such as not eliciting immunological responses from alloreactive T-lymphocytes and/or other immunological effector cells. However, it is not

known whether using immunosuppressive MSCs may inadvertently inhibit antimicrobial immune responses and ultimately result in an increased risk of infection in allogeneic HSCT recipients^[62], considering that infection is one of the major complications following an HSCT contributing to high morbidity and mortality indexes^[63,64]. One open randomized clinical trial has demonstrated that acute grade II-IV and chronic GVHD incidence in 10 patients receiving a median 3.4×10^5 /kg MSCs dose from a human leukocyte antigen-identical sibling donor was lower than in 15 patients who did not receive MSCs (11% *cf* 53% and 14% *cf* 29%, respectively)^[65]. Unfortunately, this did not mean a lower risk for infectious complications. Early and mid-phase severe infection incidence was even higher in patients who had received a co-transplant of hematopoietic stem cells and MSCs compared to a control group, which did not receive MSCs, although differences were not statistically significant [4/10 (40%) *cf* 5/15 (33%)]. Patients receiving MSCs suffered from cytomegalovirus (CMV) interstitial pneumonia and bacterial and/or fungal infection whereas this was only seen in two of the patients who did not receive MSCs^[65]; no patient treated with MSCs died because of infectious complications, whereas this happened in two control group patients who did not receive MSCs. This raises the question of whether infection severity is lower when MSCs are co-transplanted with a graft.

By contrast, another two non-randomized clinical trials, involving 20 patients^[66] and 14 pediatric patients^[67], showed that co-transplanting MSCs did not result in higher infection incidence and severity when compared to historical controls.

On the other hand, multivariate analysis regarding a retrospective cohort study of 691 HSCT patients showed that GVHD grade II-IV, CMV infection and having received human bone marrow-derived MSCs were factors which were associated with overall pneumonia-related deaths^[68].

Thus, the role of MSCs in infection is paradoxical. Evidence reported to date suggests that there may be pro- as well as anti-microbial effects^[40-42] and this seems to depend on isolation and expansion conditions, cell origin and dose and administration route and timing.

MECHANISMS BEHIND MSCs CANCER-INDUCING EFFECT

MSCs modify cancer cells

Although the cancer stem cell (CSC) concept was first introduced in hematological malignancies (chronic and acute leukemia)^[69], it has been identified during recent years in a variety of solid tumors such as glioblastomas, medulloblastomas and carcinomas^[70]. It has been demonstrated that MSCs interact with CSC in human cancer and regulate their own self-renewal through cytokine networks involving IL-6 and CXCL7^[19]. CSC-produced IL-6 interacts with IL6R/gp130 expressed on MSCs to produce CXCL7; this molecule

interacts with CSCs through the CXCR2 receptor where it induces the synthesis of others cytokines (*i.e.*, IL-8, IL-6, CXCL6, and CXCL5)^[19]. These cytokines trigger CSC self-renewal and enhance their invasive properties while IL-6 mediates chemotaxis, which may facilitate MSCs homing to primary tumor growth sites. It has been shown that MSCs administered subcutaneously in mice having had a breast tumor xenograft became recruited to the tumors and produced IL-6 and IL-8, which accelerated their growth by regulating the CSC population^[20].

MSCs might induce epithelial-to-mesenchymal transition

Most malignancies have an epithelial origin, and cancer progression is often associated with epithelial-to-mesenchymal transition (EMT)^[71]; this is a physiological process, which is recognized as being crucial for embryogenesis and wound healing. It involves epithelial cell conversion to mesenchymal cells through the disruption of cell-cell junctions and the reorganization of the actin cytoskeleton; EMT has gained much attention recently due to its role in converting benign lesions into invasive and metastatic tumors^[72]. It is governed by complex networks, which are influenced by signals from the neoplastic microenvironment, such as collagen, cytokines and TGF β , epidermal growth factor, fibroblast growth factor (FGF), hepatocyte growth factor (HGF) and platelet-derived growth factor^[71-73]. Interestingly, all the aforementioned factors are secreted by MSCs^[9].

MSCs modify vasculogenesis

Vasculogenesis plays a critical role in tumor growth^[74]; MSCs could contribute towards tumor vasculogenesis because they act as pericytes but may also differentiate into endothelial cells and secrete provasculogenic factors^[75-77], thereby allowing blood vessel formation^[75]. Vascular endothelial growth factor (VEGF) and FGF-2 are the two main MSCs-secreted vasculogenic factors involved in tumor neovascularization^[76]. VEGF is known to regulate MSCs mobilization and recruitment to neovascularization sites and directs MSCs differentiation to vascular cell^[78,79]. VEGF expression in MSCs can be enhanced by hypoxia, a common phenomenon in tumor tissue^[80] whilst FGF-2 is a potent mitogen which is produced and secreted by endothelial cells and MSCs^[81]. This factor has been implicated in cell proliferation and endothelial cell migration during tumor growth^[81]; conversely, MSCs appear to reduce vascular density due to endothelial cell cytotoxicity in certain conditions^[38].

MSCs modify anti-cancer immune response

MSCs suppress both innate and adaptive immune responses^[82,83]; they inhibit CD4⁺ and CD8⁺ T-cell proliferation^[84] by producing a wide range of mediators, including TGF β 1, HGF, insulin-like growth factor, prostaglandin E₂, NO, heme oxygenase-1 and IDO^[85-89]. MSCs also inhibit monocyte and hematopoietic progenitor proliferation and differentiation into mature dendritic

cells^[32,90]. Other MSCs-induced effects regarding dendritic cells would be a loss of their ability to stimulate allo-responses^[91], acquiring a regulatory phenotype due to the production of large amounts of IL-10^[91] and changing dendritic cells' cytokine secretion profile by MSCs-derived PGE₂^[91]. MSCs alter the natural killer (NK) cell phenotype besides suppressing their proliferation and cytokine secretion^[92]; this requires cell-to-cell contact and soluble factors (TGF β 1 and PGE₂). Hence, MSCs could promote an anti-inflammatory response within a tumor, thereby allowing its enlargement^[93]. Systemically administered MSCs have promoted immune-tolerance in damaged organs, irrespective of whether donor cells home into them^[7,8,94]. It is expected that MSCs would worsen the immune-destruction of tumor cells and thus facilitate tumor growth and metastasis. Conversely, increased macrophage and granulocyte infiltration in MSCs-injected tumors has been shown, suggesting that allogeneic MSCs immunogenicity might contribute towards their antitumor effect^[32,39].

Changes in MSCs microenvironment, together with changes in transformed cells, would also seem to contribute towards carcinogenesis^[95].

MECHANISMS BEHIND MSCs INFECTION ADVERSE EFFECTS

MSCs modify bacterial growth inhibition and clearance

MSCs can participate in host defense through the secretion of antimicrobial peptides (cathelicidin LL-37^[51] and lipocalin 2^[52]), which can directly inhibit bacterial growth or kill the pathogens. The secretion of these soluble peptides improves resident phagocyte ability to clear bacteria through the up-regulation of pathways associated with monocyte/macrophage, phagocytosis, NK cell activity and antigen presentation^[42] while MSCs antifungal activity means an increased amount of TH17 cells in the blood, thereby promoting TH1-type immune responses and restraining TH2-type ones^[50].

MSCs modify anti-microorganism immune response

MSCs induce a marked decrease in Toll-like receptor 2 expression, which plays a fundamental role in pathogen recognition and activation of innate immunity^[96]. MSCs induce a marked increase in macrophage susceptibility to infection by parasites and bacteria. The mechanisms so involved appear to be linked to the production of inflammatory cytokines TNF- α , IL-12p70 and IFN- γ which drive NO production^[43]. MSCs switch activated macrophages into regulatory ones producing low levels of pro-inflammatory cytokines. MSCs could modify an immune response against microorganisms by inducing apoptosis and cell-cycle arrest of T-cells by producing NO, TGF β or IDO^[91]. MSCs can inhibit cellular immune responses and promote regulatory T-lymphocyte production, thereby establishing T-cell tolerance for microorganisms^[97-100].

MSCs and cancer

MSCs and infections

Figure 1 Paradoxical effect of donor mesenchymal stem cells in cancer and infection development. MSCs: Mesenchymal stem cells; TLR2: Toll-like receptor.

ARE CANCER AND INFECTION ADVERSE EFFECTS ARISING FROM USING MSCs IN THERAPY?

In vitro and *in vivo* studies have demonstrated MSCs' pro- and anti-cancer and pro- and anti-infection effects nevertheless, most clinical trials have reported that MSCs-based therapy appears safe and has not been associated with severe adverse events. Together, due to MSCs' context-dependent potential to produce immune-modulatory factors they seem to be an ideal therapeutic tool for both cancer and infections.

CONCLUSION

The pertinent literature reveals incongruity regarding the impact of MSCs on the development of cancer and infection (Figure 1); such paradoxical effect might be attributed to differences in isolation and expansion conditions, the source and dose of the cells being used, the administration route and its timing and host characteristics. MSCs immunomodulatory potential seems to be the leading mechanism responsible for such effects. Until conclusive data becomes available, cancer and infection will still be seen as adverse effects and therapeutic targets for using MSCs-based therapy.

somatic stem cells and are responsible for tumor initiation, chemoresistance, and metastasis. Evidence for the CSCs existence has been reported for a number of human cancers. The CSC mitochondria have been shown recently to be an important target for cancer treatment, but clinical significance of CSCs and their mitochondria properties remain unclear. Mitochondria-targeted agents are considerably more effective compared to other agents in triggering apoptosis of CSCs, as well as general cancer cells, *via* mitochondrial dysfunction. Mitochondrial metabolism is altered in cancer cells because of their reliance on glycolytic intermediates, which are normally destined for oxidative phosphorylation. Therefore, inhibiting cancer-specific modifications in mitochondrial metabolism, increasing reactive oxygen species production, or stimulating mitochondrial permeabilization transition could be promising new therapeutic strategies to activate cell death in CSCs as well, as in general cancer cells. This review analyzed mitochondrial function and its potential as a therapeutic target to induce cell death in CSCs. Furthermore, combined treatment with mitochondria-targeted drugs will be a promising strategy for the treatment of relapsed and refractory cancer.

Core tip: This review is devoted to the analysis of mitochondrial function as a therapeutic target to induce cell death in cancer stem cells (CSCs). In particular, we focused on the differences in energy metabolism and features between CSC and non-CSC mitochondria, and between CSCs and normal stem cells. We described the roles of mitochondria that may make CSCs more susceptible to anti-cancer treatment and apoptosis, and how these may be useful to develop novel strategies for cancer treatment, such as through combined therapy

Abstract

Cancer stem cells (CSCs) are maintained by their

with specific mitochondrial-targeting drugs.

INTRODUCTION

Over the last decade, cancer therapies have improved the quality of life of cancer patients. However, although almost all developed anti-cancer drugs are apparently successful following initial therapy, secondary tumors development and disease relapse is common. The limitation of classical anti-cancer therapies has been attributed recently to the existence of cancer stem cells (CSCs), which are quiescent, have relatively small population, and highly drug-resistant cells. CSCs act like stem cells (SCs) and are responsible for cancer growth and metastasis^[1]. Through the continued effort of many researchers, CSCs features have been revealed, such as anti-cancer drug resistance, metastasis, proliferation, hypoxic tolerance, and the capacity for neovessel induction^[2,3].

Mitochondria-targeted drugs may overcome potentially the drug-resistance mechanisms that have progressed toward conventional chemo-therapeutics in cancer^[4-7]. Mitochondria produce ATP, but they also mediate cell death and produce reactive oxygen species (ROS). Although ROS are affected in the regulation of various cellular responses, excessive production may be harmful to the cell^[8]. Cancer cells also exhibit extensive metabolic rearrangement that makes them more susceptible to alteration of mitochondria than normal cells^[9,10]. However, mitochondrial properties of CSCs in tumors remain unknown.

This review analyzed the potential role of mitochondria as a therapeutic target for inducing cell death in CSCs. In particular, we focused on the differences in energy metabolism and mitochondrial features between CSCs and non-CSCs, as well as between CSCs and normal SCs, and how these unique features of CSCs may increase the susceptibility of CSCs to anti-cancer treatment and apoptosis induction. We described how CSC mitochondria may be useful targets for the development of novel cancer treatment strategies, such as targeting CSCs *via* combination therapy with specific mitochondrial-targeting drugs.

CURRENT STATUS OF CSCs

History

The concept of CSCs is many decades old^[11]. In the middle of 1800s, the embryonal rest theory of cancer introduced the idea that cancer arises from SCs, but

the existence of CSCs in tumors could not be verified due to a lack of techniques. Furth *et al.*^[12] first alluded to CSCs in 1937 when they showed that a single cell within a tumor initiates the generation of new tumor in a recipient mouse^[12]. This finding was defined in the 1960s and 1970s by the development of quantitative methods to measure the tumorigenic ability able to sustain tumor growth *in vivo*. In the middle of 1900s, Radiolabeling permitted the measurements of cellular phenotype such as cell proliferation, lifespan, and hierarchical organizations within normal tissues^[13]. Al-Hajj *et al.*^[14] and Singh *et al.*^[15] represented that a small subset of cells within breast and brain tumors can be isolated prospectively and can generate phenotypically heterogeneous tumor *in vivo*. Thus, these various evidences represent that diverse solid tumors are organized hierarchically and sustained by a distinct subpopulation of CSCs.

Identification of CSCs

CSCs are classified according to several properties such as the presence of cell surface markers and their occupancy in the Fluorescence Activated Cell Sorting (FACS) analysis. Flow cytometry with antibodies against cell surface antigens has been the preferred method for characterizing and sorting normal stem cells. However, differences between CSC and normal SC markers are not well defined, and CSCs and normal SCs share some surface markers.

Most of CSCs studies isolate CSCs marker or a combination of markers, which is expressed heterogeneously in a certain tumor type. Based on this marker heterogeneity, subpopulations including CSCs are isolated from original tumors and injected into immunodeficient mice, after which tumor growth is assessed several weeks or months later. Table 1 shows current CSC markers according to cancer types, as FACS markers allow for consistent sorting according to marker expression. For example, Al-Hajj *et al.*^[14] used a marker combination of the CD24 and CD44 as an indicator of breast CSC, and the CD133 marker has been shown to be both normal SC and CSC marker^[16-20].

Stem cells and CSCs

The first embryonic SC lines were developed from the inner cell mass of early embryos in 1998^[21]. In 1999 and 2000, it was discovered that it could produce different cell types through manipulating adult mouse tissues, indicating that stem cell differentiation and proliferation could be controlled externally. Both somatic SCs and CSCs generate numerous daughter cells, differentiate into a variety of cell types, actively express telomerase, activate anti-apoptotic pathways, increase active membrane transports, and metastasize^[22]. Moreover, SCs are induced to differentiate by niche signaling and outer environmental stimuli. Niche signaling keeps the undifferentiation of SCs until they are stimulated to

Table 1 Markers used to identify stem cells and cancer stem cells

Marker	Cancer origin	Marker properties	Ref.
ALDH1	Breast	Catalyzes the oxidation of aliphatic and aromatic aldehydes Converts retinol to retinoic acid	[81]
ABC135	Melanomas	AdSC ATP binding cassette family Involved in transport of sterol and other lipids	[82]
Bmi-1	Breast, prostate, leukemias, neuroblastomas	HSC, NSC, and AdSC marker	[83,84]
CD20	Metastatic melanomas	Hematopoietic marker	[85]
CD29	Breast, colon	AdSC marker	[86,87]
CD34	Leukemias, sarcomas	HSC, MSC marker	[88-91]
CD44	Breast, pancreas, colon, head and neck, prostate	Adhesion molecule related to metastasis HSC and pluripotent stem cell marker Normal prostate epithelial stem cell marker	[91-96]
CD49f	Prostate	Adhesion to extracellular matrix	[97]
CD90	Liver, breast, glioblastomas	Glycoprotein, role in stem cell differentiation MSC marker	[98-100]
CD113	Lung, pancreas, colon, glioblastoma, melanomas, etc.	HSC, NSC AdSC (colon) marker	[16-18,101-104]
CD117	Breast, ovarian, lung, glioblastoma	Progenitor cell marker	[105,106]
Oct4	Many carcinomas	Embryonic stem cell and induced pluripotent stem cell marker	[107,108]
Sca-1	Lung	Skin epithelial stem cell and HSC marker	[109]

AdSC: Adult stem cell marker; HSC: Hematopoietic stem cell; NSC: Neuronal stem cell; MSC: Mesenchymal stem cell.

generate new cells, suggesting a similarity with signaling pathways that govern normal SC proliferation. Local environment signaling can initiate CSC proliferation, and thus, trigger tumor initiation and growth^[23]. Therefore, SC markers and features may not be effective therapeutic targets for inhibiting CSC growth.

MITOCHONDRIA AND CANCER

Roles of mitochondria

As the main energy producers, mitochondria produce ATP using the tricarboxylic acid (TCA) cycle and oxidative phosphorylation (OXPHOS). However, they also generate ROS during this process, which are harmful to the cell if produced excessively. In addition, mitochondria play a crucial role for the regulation of cell death pathways and intracellular Ca²⁺ homeostasis. Mitochondria activate apoptosis by regulating the releasement of proapoptotic proteins space to the cytosol from the mitochondrial intermembrane^[7], and they also play a crucial role in non-apoptotic cell death^[24].

Key regulators related to cell death and other cellular processes in the mitochondria are frequently altered in cancer cells^[8], as cancer cell mitochondria differ functionally and structurally compare with that of normal cells^[25]. Fast growing tumors result in hypoxia because of an inadequate amount of oxygen from the local vasculature. In addition, cancer cells include the DNA mutation of mitochondria and nucleus, which affect the OXPHOS components and result in ROS overproduction, wasteful ATP production, and mitochondrial oxidative damage^[25]. Warburg^[26] pioneered research on the cancer-related alterations in mitochondrial respiration and suggested a mechanism to explain how they progress during the tumorigenesis.

The proposed mechanism differs from that in non-malignant cells utilizing OXPHOS. Although aerobic glycolysis has been corroborated in cancer cells, the function of mitochondria has been controversial^[27]. In cancer cells, the aerobic glycolysis generate glycolytic intermediates to the pentose phosphate pathway. Moreover, the glycolytic ATP generation is important for survival in hypoxic conditions^[28]. In OXPHOS, the ATP synthesis requires much oxygen, which leads to continuous the ROS production such as superoxide anion, organic peroxide, and hydrogen peroxide^[29]. If the generated ROS are not eliminated by redox regulating system, they may cause cellular damage.

Mitochondrial antioxidant system

Mitochondria have a multi-level network of redox-defense systems for the elimination of hydrogen peroxide (Figure 1). Glutathione and glutathione peroxidases require nicotinamide adenine dinucleotide phosphate (NADPH) for the reduction of H₂O₂ and other peroxides generated in the mitochondria. Mitochondrial redox balances are also regulated by the mitochondrial inner membrane electrochemical gradient, which mitochondrial Complex V (ATP synthase) uses to produce ATP from ADP and inorganic phosphate (Pi).

Moreover, the physiological significance of mitochondrial redox balance has been highlighted by the antioxidant genes-deletion and over-expression. As antioxidant defense system, Peroxiredoxin (Prx) 3, Prx5, superoxide dismutase 2, and thioredoxin 2 eliminates ROS produced in mitochondria^[30,31]. Knockout (KO) of Prx3 mice result in induction of oxidative damage^[32], KO of thioredoxin 2 mice showed an embryonic lethal phenotype^[33] and KO of superoxide dismutase 2 mice die within 3 wk of birth because of mitochondrial

Figure 1 Antioxidant and oxidative phosphorylation systems in mitochondria. Under normal conditions, normal cells rely primarily on oxidative phosphorylation for ATP synthesis, whereas cancer cells rely more on glycolysis. Pyruvate from glycolysis is converted to acetyl-CoA, CO₂, and NADH by pyruvate dehydrogenase (PDH). Acetyl-CoA enters the TCA cycle by the citrate synthase-mediated reaction with oxaloacetate to generate citrate. NADH is oxidized first by Complex I in the electron transport chain (OXPHOS). Electrons from Complex I and II are transferred to coenzyme Q10, then passed on to Complex III, cytochrome c, Complex IV, and finally to O₂ to generate H₂O. O₂ is converted to H₂O₂ through the action of SOD2 and/or spontaneous dismutation. H₂O₂ is eliminated by three mechanisms: (1) glutathione (GSH) peroxidase (GPx) coupled to GSH and GSH reductase (GR); (2) Prx3 coupled to Trx2 and Trx reductase (TrxR 2); and (3) non-enzymatic eliminating by redox compounds. The H₂O₂ selectively oxidized cysteine Cys-SH to Cys-SOH, which then reacts with the resolving cysteine Cys-SH of the other subunit in the homodimer to form an intermolecular disulfide bond. The disulfide bond is reduced by Trx2. Moreover, the generated Cys-SOH is oxidized to Cys-SO₂H. Reactivation of the enzyme is achieved by reduction of the Cys-SO₂H moiety and is catalyzed by sulfiredoxin (Srx). Nicotinamide adenine dinucleotide phosphate (NADPH) is utilized by the reductases in the peroxidase system (GR and TrxR) to reduce disulfide bonds formed in proteins during the elimination of H₂O₂. TCA: Tricarboxylic acid; ATP: Adenosine triphosphatase; ADP: Adenosine diphosphate.

oxidative damage and severe neurodegeneration^[34,35]. Therefore, the inhibition of antioxidant systems may provide a targeted therapy that leads to mitochondrial dysfunction and cell death.

Mitochondrial membrane potential

Mitochondria harbor a robust mitochondrial trans-membrane potential ($\Delta\Psi_m$), and the exchange of small metabolites between the mitochondrial matrix and the cytosol is induced by the low conductance of permeability transition pore complex (PTPC)^[36]. The rupture of mitochondrial membranes leading to functional impairment result in the release of toxic mitochondrial intermembrane space proteins, such as apoptosis-inducing factor and cytochrome *c*, into the cytosol^[37]. Under apoptotic conditions, including ROS and Ca²⁺ overload, the PTPC presumes a high conductance state allowing uncontrolled influx of small solutes

into the matrix of mitochondria. This mitochondrial permeability transition (MPT) leads to osmotic swelling of the mitochondrial matrix and dissipation of the $\Delta\Psi_m$ ^[38,39], and eventually cell death occurs due to mitochondrial outer membrane permeabilization^[40]. The MPT is triggered by reagents increasing ROS generation, cytosolic Ca²⁺ concentrations, or acting on the PTPC. Therefore, the induction of mitochondrial membrane permeabilization are attractive targets to develop drug for cancer therapy.

Mitochondria-targeted cancer therapy

As mentioned above, mitochondria play important role in apoptosis, but also trigger cell death through various mechanisms^[41-43]. Various mitochondria-targeted strategies for cancer treatment have been developed over the last decade^[6,44] that focused on the development of agents that regulate the MPT,

Bcl-2 family proteins, and ROS production in cancer^[6]. Numerous molecules, acting on mitochondria, are currently used or being tested in clinical trials^[45]. Several experimental anti-cancer drugs, such as ceramide^[46], CD437^[47], and MKT077^[48], and clinically approved anti-cancer drugs, such as etoposide^[49], paclitaxel^[50], and vinorelbine^[51], induce apoptosis *via* mitochondria dysfunction. Furthermore, determining of pathophysiological differences of mitochondria between cancer cells and normal cells, will improve the selectivity of mitochondria-targeted anti-cancer agents.

MITOCHONDRIA OF CSCs

Because mitochondria play a key role in the alteration of oxidative stress, energy status, and apoptotic stimuli, scientists have assumed that they are also involved in the regulation of stemness and differentiation in SCs. Researchers have attempted to employ mitochondrial properties in the selection of SCs^[52]. Lonergan *et al.*^[53] and Bavister^[54] suggested that functional mitochondrial characteristics, such as subcellular localization and metabolic activity could verify stemness, SC stability, and pluripotency. Mitochondria are localized in perinuclear sites in embryonic stem cells (ESCs) and have a more scattered distribution throughout the cytoplasm after differentiation and senescence^[55].

Mitochondrial metabolic activity is also related to cell differentiation, as early passages of an adult primate stromal cell line have a higher oxygen consumption rate (OCR) and a low ATP/ mitochondrial DNA content compared with long-term cultured cells^[53]. In CD34⁺ hematopoietic SCs, a low mitochondrial OCR and mitochondrial mass result in a predominantly perinuclear mitochondrial arrangement^[56].

Antioxidant enzyme expression also shows a dramatic change during differentiation^[57]. Moreover, ROS play an agonistic role in the differentiation of ESCs. Enhanced intracellular ROS as the differentiation stimulus may act on transplanted SCs into the cardiovascular lineage^[58], indicating that mitochondrial redox metabolism act as a crucial regulator in cardiac differentiation of SCs. Furthermore, Plotnikov *et al.*^[59] suggest a correlation of the mitochondrial function and the status of neural SCs.

SC mitochondria play important roles in maintaining stemness and differentiation. However, whether the roles of CSC mitochondria are similar to SC mitochondria or cancer cells in general is uncertain. Two hypotheses on the origin of CSCs, both of which contribute to acute myeloid leukemia^[1,60], have been proposed. One hypothesis of the origin of CSCs is that they are derivatives of SCs residing in various organs. Genetic mutations and epigenetic changes, which are crucial for initiation and progression of tumor growth, accumulate in long-lived stem cells, and the transformation of SCs into CSCs initiates carcinogenesis.

CSCs may also have a greater differentiation potential than other SCs. (SCs can be divided into the following groups based on differentiation potential: the totipotent, pluripotent, multipotent, and unipotent group). Another hypothesis assumes the existence of ESC-like cells that convert into CSCs when they are exposed to damaging environmental factors. Additional differentiation and mutation of these cells may also contribute to development of CSCs^[61]. Based on these reports, the CSCs may be more differentiated than normal SCs and likewise, the mitochondrial properties of CSCs are different from those of SCs or general cancer cells.

Recently, Ye *et al.*^[62] determined the mitochondrial features between lung CSCs and non-CSCs. As a results, it is showed a lower mtDNA contents, lower OCR, glucose consumption, intracellular ATP and ROS level in the lung CSCs compared to non-CSCs. Leukemia CSCs showed a low ROS level and reduced OXPHOS compared with that of non-CSCs^[63]. However, Pastò *et al.*^[64] reported that CSCs exhibited over-expressed genes related to glucose uptake, oxidative phosphorylation, and fatty acid β -oxidation, indicating higher ability to direct pyruvate towards the TCA cycle. As reported, ovarian CSCs showed higher mitochondrial ROS production and $\Delta\Psi_m$ than non-CSCs. In addition, targeting mitochondrial biogenetics induced caspase-independent cell death in ovarian CSCs^[65]. In glioma CSCs, a higher mitochondrial reserve capacity was measured as compared to the differentiated cells^[66]. Glioblastoma CSCs also depend on OXPHOS for their energy production and survival^[67]. Besides, breast CSCs have higher ATP content compared to their differentiated progeny^[68]. Based on these studies, CSCs mitochondria showed the different roles and features according to the cancer type. A summary of the mitochondrial features between CSCs and non-CSCs according to cancer origin is highlighted in Table 2. Although the mitochondrial features of CSCs in several cancers are not identical, CSCs mitochondria obviously differ from those of non-CSCs. Moreover, mitochondrial features of CSCs have not been clearly defined in other cancer types. Most importantly, little has been known about the mitochondrial features related to energy metabolism and the ROS/antioxidant enzyme system of CSCs in colon, stomach, liver, bone, and prostate cancer. Therefore, defining these features will be essential for developing a mitochondria-targeted therapeutic drug that induces death of CSCs, and therefore, reduces the risk of relapsed or refractory cancer.

CLINICAL IMPLICATION AND THERAPEUTIC TARGETS OF CSCs

Despite the recent surge of published studies on CSCs, the clinical significance of this population remains unclear and has been slow in progression of the development of clinical agents to eliminate CSCs. However, most experts agree that effective

Table 2 Mitochondrial features of cancer stem cells according to cancer origin

Cancer origin	Mitochondria features			Energy metabolism of CSC	Target/drug for CSCs	Ref.

CSC: Cancer stem cell; OCR: Oxygen consumption rate; ROS: Reactive oxygen species; OXPHOS: Oxidative phosphorylation; ABT263: Bcl-2 inhibitor; NV-128: Isoflavone derivative (play a role as inhibitor of mitochondrial function); IMP-2: Insulin-like growth factor 2 mRNA-binding protein 2.

anti-cancer drugs should be targeted toward CSCs in addition to non-CSCs. Current cancer treatments such as conventional chemotherapy and radiotherapy target rapidly proliferating cells that make up the bulk of the tumor, but do not specifically target CSCs. Thus, the hypotheses on the origin of CSCs may explain the development of relapsed and metastatic cancer. In cancer therapy, the new paradigm requires development of novel anti-cancer drug molecules and drug targets to assess drug responses of CSCs.

Altered expression of genes involved in apoptosis, survival, and DNA repair machinery are among the multiple mechanisms responsible for the chemoresistance of leukemia^[69], brain^[70], pancreatic^[71], breast^[72], melanoma^[73,74], and colon cancer^[75] CSCs. Liu *et al.*^[23] reports that CD133⁺ glioblastoma cells isolated from patients have a high expression of genes in the Bcl-2 and inhibitor of apoptosis (IAP) families. Moreover, several types of CSCs have upregulated ATP binding cassette (ABC) pumps that make them resistant to various chemotherapeutics^[73,74]. Therefore, finding targets that efficiently promote CSC cell death is important and a focus of intensive research. Dong and colleagues demonstrate that loss of fructose-1,6-bisphosphatase in breast CSCs induces glycolysis, as well as inhibiting oxygen consumption and ROS generation, through the suppression of mitochondrial Complex I activity^[76]. The report implies

that overproduction of ROS and reduction in glucose metabolism may be effective against breast CSCs. Hirsch *et al.*^[77] showed that metformin, an AMPK activator and Complex I inhibitor often used as the first-line drug for treating diabetes, and selectively kills CSCs in breast cancer cell lines. The novel isoflavone derivative NV-128 significantly decreased mitochondrial function, as shown by a decreases in ATP, Complex I, and Complex IV levels, and induced cell death in ovarian CSCs^[65]. These results demonstrate that specific mitochondrial targeted compounds can induce cell death in chemoresistant CSCs and may be a new venue for treating ovarian cancer patients with relapsed or metastatic cancer. The new-generation taxoid SB-T-1214 significantly inhibited stemness gene expression profiles and induced cell death in both CSCs and general cancer cells, indicating its promise in overcoming relapsed and refractory cancer due to CSCs^[78]. Finally, mitochondria-targeted vitamin E succinate (MitoVES), which includes the positively charged triphenylphosphonium group, may be the most well-characterized toxic agent in its ability to induce apoptosis in breast CSCs^[79]. Meanwhile, it was reported that a drug which inhibits the self-renewal of CSCs by targeting of Notch and Hedgehog pathway has been developed^[80]. It was also reported that has been developed a drugs, which can eliminate CSCs by targeting cell surface markers such as CD133 and EpCAM. However, the use of these drugs increases

the exposure to side effects due to the sharing of signaling pathway and cell surface marker with normal SCs. Thus, it is important to understand how CSCs differ from normal SCs and differentiated cells. Moreover, a full understanding of the mitochondrial function and energy metabolism in CSCs contributes to the development of the agents targeting mitochondrial functions (such as ROS overproduction, energy metabolism inhibition, and antioxidant protein inhibition), and presents a need to develop new strategies to target CSCs in the clinical field^[80].

CONCLUSION

In summary, the mitochondria are an important tool to investigate CSCs properties and to develop anti-cancer drugs. However, the properties and clinical significance of mitochondria in CSCs have not been verified. Because mitochondria-targeted therapy may open new strategies for the treatment of relapsed and refractory cancer, mitochondrial properties unique to CSCs need to be defined. Furthermore, combined treatment with mitochondrial-targeted and anti-cancer drugs may specifically induce the death of both CSCs and general cancer cells and promises to be a novel cancer therapy.

Tissue engineering was first defined in 1987 by the United States National Science Foundation which critically discussed the future targets of bioengineering research and its consequences. The principles of tissue engineering are to initiate cell cultures *in vitro*, grow them on scaffolds *in situ* and transplant the composite into a recipient *in vivo*. From the beginning, scaffolds have been necessary in tissue engineering applications. Regardless, the latest technology has redirected established approaches by omitting scaffolds. Currently, scientists from diverse research institutes are engineering skin without scaffolds. Due to their advantageous properties, stem cells have robustly transformed the tissue engineering field as part of an engineered bilayered skin substitute that will later be discussed in detail. Additionally, utilizing biomaterials or skin replacement products in skin tissue engineering as strategy to successfully direct cell proliferation and differentiation as well as to optimize the safety of handling during grafting is beneficial. This approach has also led to the cells' application in developing the novel skin substitute that will be briefly explained in this review.

Key words: Hair follicle stem cells; Skin repair; Tissue engineering; Chitosan; Collagen

Core tip: Biomaterials and epithelial stem cells, and especially hair follicle stem cells are vital components for successful skin tissue engineering. Ignoring one of these components will decrease the opportunity for skin tissue engineering to foster complete healing through skin repair and will increase the failure of skin grafting in the clinical setting. The latest technology, new raw biomaterials and information on the significant contribution of stem cells are likely to be of great benefit to skin tissue engineering.

Abstract

Tissue engineering essentially refers to technology for growing new human tissue and is distinct from regenerative medicine. Currently, pieces of skin are already being fabricated for clinical use and many other tissue types may be fabricated in the future.

INTRODUCTION

In classical bioengineered skin, the engineered epidermis is reconstructed from a skin autograft or allograft serving as a cellular dressing. The limitations addressed by this technique are pain and scar formation at the donor site, impaired wound healing and non-healing wounds, insufficient material to cover a large defect area and autoimmune rejection in the case of an allograft. The emergence of skin tissue engineering has led to robust innovation in skin substitutes and skin replacement products for burn and wound management. Diseased or injured skin may rule out a particular treatment because of wound depth. Superficial, partial and full-thickness wounds require diverse skin substitutes that simultaneously function as a primary dressing. Although various commercial skin substitutes are available, novel findings on fabrication techniques for biomaterials and on regulators of wound healing have highly encouraged scientists to develop new engineered skin substitutes that offer an effective remedy for wound care and wound management. The combination of stem cells or other cells with a specifically designed novel biomaterial has resulted in different impacts on engineered skin after wounding. An ideal biomaterial with multiple combinations of cultured cells and a collectively established broad knowledge of the healing process are the main criteria for the future development of skin substitutes. Eventually, skin substitutes that can be kept frozen, that are ready for use, inexpensive in cost, less labor intensive, and permanently adherent to the wound bed, that yield an impressive cosmetic outcome and that do not contain animal or human serum will definitely be in increased demand for skin tissue engineering purposes.

DEFINITION OF STEM CELLS

Stem cells have at least two advantageous properties. First, these cells are capable of dividing or renewing themselves for long periods of time with the identical morphology and phenotypic characteristics as their parent cells. This self-renewal mechanism is crucial for recovering degenerated and damaged cells, tissues or organs. Second, the differentiation of stem cells is a mechanism that can maintain the cellular and molecular integrity of adjacent or other cells. Stem cells differentiate into specialized cells to perform a specific function^[1] after receiving internal or external signals, which are signs of signalling pathway changes in the

cells' microenvironment. Differentiation starts when the cells discontinue renewal. Differentiation abilities are used to rank stem cells' potency (Figure 1). Stem cells that are able to differentiate into one cell type are known as unipotent stem cells, such as epidermal stem cells which regenerate differentiated epidermis^[2]. Hair follicle stem cells (HFSC) are able to differentiate into multiple types of structures with specialized functions in the body including hair follicles^[3], epidermis^[4], sebaceous glands^[5] and neurons^[6]. These stem cells are known as multipotent stem cells. Pluripotent stem cells are stem cells that have the ability to differentiate into ectoderm, mesoderm and endoderm germ layers as demonstrated by embryonic stem cells and induced pluripotent stem cells^[7]. Totipotent stem cells have the excellent ability to differentiate into whole tissues. This total potency can be observed in the fertilized eggs of humans or animals.

SKIN STEM CELLS

The skin is known as cutaneous or integumentary and its appendages constitute the integumentary system. The skin is the largest organ, contributing 15%-20% of body mass to form the external covering of the body. The skin has two main components: the epidermis and the dermis. The epidermis is derived from ectoderm, composed of a keratinized stratified squamous epithelium that grows continuously and simultaneously maintains its normal thickness by the process of desquamation^[8]. The dermis is derived from mesoderm, composed of a connective tissue that provides mechanical support, strength and thickness to the skin. The hypodermis is not a part of the skin but lies beneath the dermis and is equivalent to the subcutaneous fascia. This layer contains adipose tissue arranged into lobules that are separated by connective tissue septa. The epithelial skin appendages are composed of the hair follicles and hairs, sweat glands, sebaceous glands, nails and mammary glands. The skin forms an effective barrier against pathogen invasion, chemicals and ultraviolet light^[9]; participates in homeostasis^[10] by regulating the body temperature and water loss; conveys sensory information; and function in pigmentation^[11], physical appearance, wound repair and regeneration^[12]. The skin is considered as a stem cell zoo, as it accommodates a variety of stem cell niches. A niche is the microenvironment in which stem cells remain quiescent. The dermal papilla is a stem cell niche for mesenchymal stem cells (MSC) which initiate hair follicle growth^[13]. The superior bulge is a stem cell niche for HFSC^[14] and melanocyte stem cells (MeSC)^[15]. Multipotent HFSC not only function to maintain the hair growth cycle^[16], but also give rise to sebaceous glands^[17] and contribute to skin re-epithelialization^[18], which form neo-epidermis by differentiating into keratinocytes within the wound. MeSC supply melanin for hair and skin pigmentation^[19] and are concurrently involved in skin re-epithelialization^[20]. The abundant fat

Figure 1 The potency of stem cells. ESC: Embryonic stem cells; iPSC: Induced pluripotent stem cells; HFSC: Hair follicle stem cells; EpiSC: Epidermal stem cells.

in the subcutaneous layer contains adipose stem cells (ASC)^[21] which are efficient in promoting skin repair^[22]. Collectively, the evidence suggests that skin's distinct resident stem cell pools have a crucial function in skin repair and regeneration. Therefore, it is very important for scientists to develop a good understanding of this idea before skin substitutes can be engineered in the future.

SKIN TISSUE ENGINEERING

Skin tissue engineering is the first field within tissue engineering that successfully engineered tissue in the laboratory. As the largest organ, the skin has high potential risk of injuries and diseases. Skin damaged requires a skin replacement product from either a natural or an artificial source. Skin replacement products are in high demand for the treatment of burns and wounds, leading the industrial sector to highly invest in skin tissue engineering. Skin tissue engineering utilizes biomaterials, stem cells, connective tissues and an established broad knowledge of the mechanism of the acute and chronic healing processes. The main target of skin tissue engineering is to produce an excellent skin replacement product for application in wound repair, especially in the case of full-thickness skin loss, with the goal of less or no scar formation after wounding. However, skin replacement products are not able to replace damaged skin as completely as native skin can, leaving a scar. Consequently, the field of skin tissue engineering is challenging.

BIOMATERIALS

Collagen gel is the first biomaterial or skin replacement product that has been used in skin tissue engineering to replace the use of allografts and autografts. Essentially, to produce an excellent skin substitute, a biomaterial must be able to support cell growth and differentiation in a similar manner as in the

cells' original microenvironment. Most importantly, biomaterials with multiple graded pore sizes allow the acceleration of tissue reconstruction^[23]. For example, microscopic pores improve cell attachment, proliferation and responses^[24] and macroscopic pores that are at least 100 μm in diameter play a role in enhancing the ingrowth of cells and blood capillaries^[25]. To allow three-dimensional (3-D) tissue reconstruction *in vitro*, a biomaterial should support uniform cell spreading into interconnected pores for the engineering specific tissue^[26]. Biomaterials with a single pore size have certain limitations, only allowing one cell type to grow according to the pore size whereas, biomaterials with multiple graded pore sizes can reconstruct various types of tissues simultaneously^[27]. A previous study has suggested that a pore size 20-120 μm in diameter is suitable for skin tissue engineering^[28]. Biomaterials must have the ability to absorb the nutrients involved in wound healing and the exudate of the wound bed which are important factors in skin tissue engineering. The absorption ability is known as the water uptake ratio (WUR). Biomaterials with a high WUR are suitable for use in full-thickness wounds that contain excess exudates and inflammation that lead to impaired wound healing. Meanwhile, a lower WUR is suitable for partial thickness wounds^[29]. An appropriate WUR enhances the biological activity of skin equivalents and contributes to hydrophilicity and the maintenance of 3-D structure. A moist wound bed is required to enhance dermal regeneration and wound closure which can be achieved if a scaffold has suitable water vapor permeability (WVP). The WVP depends on the scaffold thickness and the ratio of the scaffold area to the water surface area^[30]. A suitable WVP is an important factor for wound dressing. If the WVP is too high, the wound bed will be dry and it may increase metabolic activity. In contrast, if the WVP is too low, the accumulation of exudates will trigger the onset of bacterial growth. Following the criteria mentioned above, a fabricated skin replacement product will retain the cell-cell and cell-biomaterial signaling, allowing the complete layer

Table 1 Current skin replacement products

Brand	Cell and biomaterial	Wound type
Apligraf®, United States	Human keratinocytes and fibroblasts cultured on collagen	Full thickness
Biobrane®, United Kingdom	Silicone membrane attached to a nylon mesh	Partial thickness
CellerateRX®, United States	Gel containing 65% collagen	Superficial
Cryoskin®, United Kingdom	Keratinocytes cultured on silicone	Superficial
Dermagraft®, United States	Cryopreserved human fibroblasts from foreskin cultured on a polyglactin mesh scaffold	Full thickness
EpiDex®, Switzerland	HFSC cultured on silicone	Full thickness
EpiFix®, United States	Human amniotic membrane	Full thickness
Integra®, United States	Semi-permeable silicone membrane composed of bovine tendon collagen	Full thickness
MyDerm™, Malaysia	Human fibroblasts and keratinocytes cultured on fibrin-silk	Full thickness
OASIS™, United States	Porcine small intestinal submucosa	Full thickness
OrCel™, United States	Human keratinocytes and fibroblasts cultured on bovine collagen	Full thickness
PriMatrix, United States	Collagen from fetal bovine dermis	Full thickness
Transcyte™, United States	Human newborn fibroblasts cultured on nylon mesh	Full thickness

HFSC: Hair follicle stem cells.

of skin to be engineered. Subsequently, the engineered skin substitute can be used for grafting purposes, this is how skin tissue engineering works. Most importantly, the engineered skin must be tolerated by the host, be retained permanently and later be able to degrade slowly over time. A permanent skin replacement product is a primary dressing that is ideal for application in great skin loss because it is used only once during treatment, until healing is completed. In contrast, a temporary skin replacement product must be changed many times during treatment which may increase the cost of wound management and wound care. Commercial skin replacement products are collagen, chitosan or fibrin-based and these products have been broadly used in clinical applications as shown in Table 1.

Apligraf is a permanent cellular based skin replacement product for the treatment of non-healing wounds including diabetic foot ulcer and venous leg ulcer. It was approved by the United States Food and Drug Administration's guidelines (FDA) for use in non-infected, partial and full-thickness skin ulcers.

Biobrane is a temporary acellular based skin replacement product. It originated from porcine dermal collagen which is bonded to a nylon mesh and nylon membrane to form a biosynthetic skin dressing for use in superficial wound, partial-thickness wound and donor site wound dressing.

CellerateRX is a patented form of Type I bovine collagen for the treatment of diabetic or other impaired healing wounds. It is provided in a powder and a gel form which can be used as alone or a powder-gel combination.

Cryoskin is a cell spray-based skin replacement product and is prepared upon request by clinicians. It is made from allogeneic donor cells which are originally isolated from a newborn foreskin biopsy. Cryoskin spray is suitable for the treatment of chronic wounds and burns.

Dermagraft is a permanent cryopreserved cellular based skin replacement product. It composed of collagen which is isolated from neonatal foreskin biopsy and cultured on biodegradable mesh. Dermagraft was

approved by the FDA for use in diabetic foot ulcers.

EpiDex is a permanent autologous epidermal skin replacement product that is isolated directly from epithelial stem cells of patients. The patient's own hair was plucking using non-surgical procedure and then grafted onto a chronic wound.

EpiFix is a dehydrated amniotic membrane allograft. It is provided in sheets form, does not require FDA approval as human amniotic membrane is considered not significantly changed from its original structure. EpiFix is used in the treatment of acute and chronic wounds.

Integra is a bilayer engineered skin replacement product. It composed of porous matrix derived from bovine tendon collagen, glycosaminoglycan and a semi-permeable polysiloxane. Integra is used in the treatment of chronic and traumatic wounds.

MyDerm is an autologous bilayer engineered skin replacement product. It contained the mixture of fibrin-keratinocytes that seeded onto a piece of medical grade of silk. The mixture of fibrin-fibroblasts is then seeded onto fibrin-keratinocyte skin equivalent. MyDerm is used for the treatment of wounds and burns.

OASIS is a xenogeneic porous collagen matrix which derived from porcine small intestinal submucosa. It was approved by the FDA for the management of pressure ulcers, venous ulcers, diabetic ulcers and chronic vascular ulcers.

OrCel is an allogeneic bilayered cellular based matrix. It is biodegradable, made of composite bovine collagen which contained skin cells. OrCel was approved by the FDA for use in patients with dystrophic epidermolysis bullosa.

PriMatrix is a xenogeneic acellular based dermal matrix. It is derived from fetal bovine dermis. PriMatrix is provided in meshed, fenestrated and solid form. It was approved by the FDA for pressure and venous stasis ulcers.

Transcyte is an allogeneic bilayer skin replacement product for the treatment of burn. It made of human fibroblasts grown on nylon mesh and then combined with a synthetic epidermal layer. Transcyte has been

approved by the FDA for temporary covering over burn wounds.

Collagen

Collagen is the main protein component in connective tissue and its most abundant sources are found in mammals and marine animals. Collagen is easily obtained from porcine and bovine sources which provide bone, skin, tendon and many other parts of the body as raw materials. Unfortunately, prion disease that may transfer to humans after these materials' use^[31] has led scientists to have seek an alternative source. Currently, fish skin, seaweed, jellyfish and other marine sources are in high demand for isolating collagen and are the ideal sources for skin tissue engineering because prion disease transmission to humans is eliminated if marine-based sources are used compared with mammalian-based sources. Collagen-based biomaterials encode antimicrobial activity^[32] and do not support colonization by bacteria in a full-thickness wound. The prevention of infection in wounds leads to minimized scar formation and promote wound healing^[33]. Due to their biocompatibility and biodegradability, collagen biomaterials have been established for use in skin repair in the clinical setting since last decade with various forms such as a gel^[34], sponge^[35], film^[36] and paste^[37].

Chitosan

Chitosan is a biopolymer obtained from deacetylated chitin and the second most abundant biopolymer sources after collagen. Crude chitin can be found in shellfish. Chitosan is naturally insoluble unless in acidic solutions, and possesses a positive charge and low cytotoxicity which broadly imply excellence as a DNA carrier^[38], protein nanocarrier^[39], drug delivery system^[40], siRNA nanovector^[41] and growth factor carrier^[42]. Based on its composition, the structure of chitosan is similar to that of glycosaminoglycans. Glycosaminoglycans are a component of the extracellular matrix and are an important substrate for tissue constructs^[43]. Chitosan arrests bleeding in major hepatic injuries and is effective for use in patients who suffer major injury with clotting dysfunction^[44]. Therefore, chitosan is preferable for tissue engineering and especially for engineered skin applications. The used of a novel technique to develop a chitosan sponge by electrospinning has produced a chitosan nanofiber that provides excellent substrate-cell adhesion, proliferation and differentiation^[45]. During skin repair and regeneration, nanofibers contribute to increased vascularization, re-epithelialization and enhanced granulation tissue formation. The major skin cells, particularly epithelial and epidermal cells and also fibroblasts grow well on this type of biomaterial.

Fibrin

Fibrin-based biomaterials are well-established biological

sealants for skin tissue engineering. However, the use of raw blood to isolate the fibrin has limited fibrin's use as a novel skin substitute. Commercial fibrin in kit form can successfully heal a wound but is relatively expensive for the majority of patients. Fibrin gel is continuously in demand in plastics and reconstructive surgery as it minimizes subcutaneous seroma formation and decreases wound morbidity^[46]. The combination of fibrin with bone marrow mesenchymal stem cells can improve the condition of scalded skin, providing strong self-repair capability and promising an acceptable cosmetic appearance with hair follicle formation. This application is more suitable for the treatment of patients with burns in emergency cases^[47]. Long-lasting fibrin biomaterials ensure stable and functional angiogenesis by highly tunable and sustained delivery of growth factors^[48].

MESENCHYMAL STEM CELLS

Mesenchymal stem cells also known as mesenchymal stromal cells, have broadly contributed to cellular therapy and skin tissue engineering. MSC are spindle-shaped, or similar to morphology to but phenotypically different from fibroblasts. Bone marrow derived-MSC were first isolated in 1981^[49] before MSC from other tissues were explored. Skin derived-MSC were first isolated from mice in 2001, and were initially named skin-derived precursors^[50]. In the skin, MSC are predominantly found in the dermal papilla, functioning in secreting diverse growth factors after wounding to promote fibroblast proliferation and collagen formation and to elicit intrinsic stem cell differentiation^[51], serving as a modulator to activate macrophages^[52], and directly affecting hair follicle morphogenesis^[53] and neo-dermis reconstruction^[54]. MSC elicit leukocyte migration for skin homeostasis and produce hepatocyte growth factor and basic fibroblast growth factor to inhibit scar formation at the wound site^[55]. The MSC-based skin substitute constructs have increased paracrine factor levels in promoting skin repair^[56].

FIBROBLASTS

Apart from stem cells, other components of the dermis such as fibroblasts are important in skin tissue engineering^[57]. Fibroblasts synthesize and deposit extracellular protein after wounding, producing growth and angiogenic factors that accelerate cell proliferation and angiogenesis^[58]. Fibroblasts are also transformed into myofibroblasts that express contractile fibers. As a myofibroblast contracts, forces are applied to the collagen fibers, thus reducing the size of the wound^[59]. Cultured fibroblasts in biomaterials have been reported to improve regeneration of the dermis^[60] and epidermis^[61] especially by re-epithelialization^[57]. This specific role of fibroblasts, especially in improving scarring and the contraction of skin wounds has encouraged researchers

Figure 2 The rapid proliferating of hair follicle stem cells. At hour 0, cells were separated (A) and then closely adhered to a plate (B) until one of the cells doubled (arrow head) at 12.59 h post-culture (C). Magnification 400 $\times$.

Figure 3 The vital role of hair follicle stem cells in skin tissue engineering. HFSC: Hair follicle stem cells; DAPI: 4', 6-diamidino-2-phenylindole.

to highly prioritize facilitating these cells' use in skin replacement therapies^[62]. Additionally, a previous study has demonstrated that fibroblasts from the dermis are the best source for skin tissue engineering applications compared with fibroblasts from other sources based on yields and reduced contraction of wounds^[63].

ADIPOSE STEM CELLS

Fat accommodates adipose tissue-derived stem cells usually known as adipose stem cells^[21]. ASC are actually MSC therefore, ASC express the same surface markers and highly contribute to skin repair as well. ASC improve neo epidermis formation and skin aging^[64] by accelerating angiogenesis^[65] and fibroblast proliferation^[66]. The use of ASC in skin repair increases the deposition of extra cellular matrix components such as collagen type-VI which has the potential to improve the protein deficiency^[67]. A mixture of fibroblasts and ASC can improve the epidermal morphogenesis of tissue-engineered skin^[68]. The ability of ASC to grow on porous biomaterial and to differentiate into fibrovascular, endothelial and epithelial tissues for skin repair^[69] has proven these cells' excellent capability as a cellular source for skin tissue engineering.

HFSCs

HFSC and their progenitors are directly involved in hair and skin regeneration during skin homeostasis^[70]. Based on their anatomical classification and function, HFSC have mainly been called epithelial stem cells^[71,72] and have been broadly known as epidermal stem cells^[73,74] as well as bulge stem cells^[75,76] in diverse studies. The critical role of HFSC in epidermal homeostasis^[77] has led to their application in fabricating neo epidermis in skin tissue engineering. Due to their vital characteristic, HFSC are capable of proliferating rapidly and this phenomenon is shown in Figure 2.

The use of HFSC in skin tissue engineering was successfully performed in chronic wounding in 2002, when Limat and Hunziker demonstrated that their HFSC-silicone constructs contributed to accelerated the healing of patients' leg ulcers^[78]. To date, the contribution of HFSC to ameliorating impaired healing due to radiation has stimulated the interest of tissue engineers in using epithelial stem cells for other tissue reconstruction. In Figure 3 shows that the chitosan based skin substitute which composed of HFSC-fibroblasts is an ideal source for skin tissue engineering. The chitosan composite was then used for transplanting into irradiated wound. Full-thickness wounds 1 cm by 1 cm in size were excised and treated using the novel skin substitute. As a result, a complete re-epithelialization occurred during skin repair after 3 wk post-wounding.

CONCLUSION

This review has summarized the fundamentals of

stem cells and especially the terminology for stem cell potency which has occasionally created confusion in certain experiments. Stem cell potency provides the necessary guideline for skin engineering experiments. The importance of fibroblast, HFSC, MSC, ASC, chitosan, collagen and fibrin in skin tissue engineering highlights their critical role in the repair process. The use of stem cells and biomaterials is especially important in the case of impaired wound healing and in cases involving major excisional skin defects.

particularly those associated with *in vitro* differentiation. The inducers and pathways explored include retinoic acid, Wnt/ β -catenin, transforming growth factor/bone morphogenetic protein, Notch, fibroblast growth factor, cytokine, Hedgehog, c-Jun N-terminal kinase/mitogen-activated protein kinase and others. Some other miscellaneous molecular factors that have been reported in the literature are also summarized and discussed. These include calcium, calcium receptor, calcineurin, estrogen receptor, Hox protein, ceramide, glycosaminoglycan, ginsenoside Rg1, opioids, two pore channel 2, nitric oxide, chemically defined medium, cell-cell interactions, and physical stimuli. The interaction or crosstalk between these signaling pathways and factors will be explored. Elucidating these signals in detail should make a significant contribution to future progress in stem cell biology and allow, for example, better comparisons to be made between differentiation *in vivo* and *in vitro*. Of equal importance, a comprehensive understanding of the pathways that are involved in the development of neurons from ESCs *in vitro* will also accelerate their application as part of translational medicine.

INTRODUCTION

Having been established from the inner cell mass of the blastocyst, embryonic stem cells (ESCs) possess pluripotency and can theoretically differentiate into all kinds of embryonic tissue. During the last decade, a number of studies have reported the differentiation of ESCs into a range of embryonic tissues. These compelling results were done either by stimulating the cells with particular molecules or by simulating the environmental cues of the early embryo. Importantly, these differentiated cells can then be used in regenerative medicine and for drug discovery. Hence, it is important to elucidate the detailed involvement of signals and signaling pathways in these processes before these cells are used for therapeutic purposes. Compared to development *in vivo*, neurons that differentiate from ESCs *in vitro* seem to develop *via* a similar pattern and thus have become a promising field in terms of the medical applications in stem cell research.

Basically, a default model for development *in vivo* is hypothesized as that induction of neural differentiation reflects the earliest fate in determining neurons in the ectoderm. The neural inducers involved in the process have been found to be bone morphogenetic protein (BMP)-binding molecule called noggin in *Xenopus*^[1] and FGF in chicken^[2]. Utilizing a serum-free and patterning factor-free condition to cultivate mouse ESCs (mESCs), Tropepe *et al.*^[3] found that neural progenitors differentiated specifically from these stem cells. Neural differentiation occurs spontaneously and does not require the presence of any extrinsic neural inducer in a special culture system named serum-free culture of embryoid body-like aggregates with quick reaggregation (SFEBq)^[4]. ESCs were found to selectively differentiate into neural progenitors efficiently (> 95% of total cells). The endogenous signals can also be minimized by adding the inhibitors of Wnt and/or Nodal such as dickkopf-1 and/or lefty-1, respectively. Furthermore, utilizing transforming growth factor β (TGF β) antagonists to abolish the SMAD signaling is shown to enhance neural differentiation, especially in induced pluripotent stem cells and human ESCs (hESCs)^[5]. All the results are in agreement with the "neural default

model" of embryonic development.

Neural cells were one of the first lineages to be developed from ESCs *in vitro*^[6,7]. Many studies have effectuated subsequently to differentiate ESCs into the creation of different cellular subtypes such as neurons and glial cells. These ESCs can be surgically transferred back into vertebrate embryos and are then participated in brain development^[8]. Work on ESCs over the last three decades has been concentrated on elucidating the characteristics of stem cells, particularly the differentiation approaches to obtain specific cell types such as neurons. Neural differentiation by ESCs is able to provide insights into the mechanisms involved in neural induction. In this review, we focus on obtaining an improving understanding of the overall signaling that underlies neural differentiation from ESCs *in vitro*. The inducers and pathways explored include retinoic acid (RA), Wnt/ β -catenin, TGF/BMP, Notch, FGF, cytokine, Hedgehog, JNK/mitogen-activated protein kinase (MAPK) and others (Figure 1). This should help researchers with exploring the various areas of stem cell biology and also help to enhance the application of ESCs differentiation in regenerative medicine.

THE RETINOIC ACID INDUCTION PATHWAY

RA typically is used at a range of concentrations from 5 μ mol/L to 5 mmol/L in order to facilitate the differentiation of ESCs into neural progenitor cells (NPCs). Shan *et al.*^[9] found that the active cyclic AMP response element-binding protein (CREB) protein was obviously increased after treatment with 5 μ mol/L RA treatment during the differentiation/formation of embryoid body (EB). Inhibition of CREB activity was found to result in EBs switching the differentiation to other germ layers fate, while enhanced expression of CREB was found to augment NPCs differentiation. RA promoted the expression of active CREB by increasing the activity of c-Jun N-terminal kinase (JNK). These results show that JNK/CREB is likely to be a crucial factor in the RA-induction of NPCs differentiation^[9]. In addition, Theus *et al.*^[10] found that neurons derived from ESCs after RA induction led to significant neurite growth. This event is associated with an spread expression pattern of Src kinase from the cell body to the neurite processes and an up-regulated expression of Src, Fyn and Lck^[10]. These neurons were characterized by the expression of neurofilament, synaptophysin and NMDA as well as the presence of kainate currents; they were found to have become vulnerable to excitotoxicity and went on to form functional excitatory synapses. Since these events were abolished when the cells were grown in the addition of the Src family kinase inhibitor PP2, it seems likely that the pathway induced by RA is

Figure 1 A simplified scheme outlining the signaling pathways described in the text. The inducers that induce embryonic stem cells to differentiate into neurons reported thus far including RA, Wnt/ β -catenin, TGF/ β /BMP, Notch, FGF, cytokine, Hedgehog, JNK/MAPK and others. The inducers in the middle part of figure mediate signaling molecules that bring about the differentiation into neurons. $\rightarrow$ means stimulation. Some miscellaneous molecules/factors mentioned at the end of this text are not included in this figure. RA: Retinoic acid; TGF: Transforming growth factor; BMP: Bone morphogenetic protein; CREB: cAMP response element-binding protein; Dkk-1: Dickkopf-related protein 1; Erk: Extracellular signal-regulated kinase; FGF: Fibroblast growth factor; Hh: Hedgehog; JAK: Janus kinase; JNK: C-Jun N-terminal kinase; MAPK: Mitogen-activated protein kinase.

mediated *via* Src^[10]. Furthermore, Tonge *et al.*^[11] demonstrated that neural differentiation of hESCs and embryonal carcinoma cells induced by RA needs both prolonged exposure of RA and cellular interaction that is done by the presence of a high cell density. These factors are required for the increase of the expression of various neural genes (*NeuroD1*, *PAX6* and *Sox2*) and the development of a neuronal appearance. They also found that inhibition of GSK3 β activity was able to block the RA-induced differentiation of neural lineage derived from ESCs. This finding suggests a role for properly modulated Wnt signaling in this process^[11]. After RA induction for 1-5 d, Li *et al.*^[12] found that there is a dramatic increase in extracellular signal related kinase 1/2 (Erk 1/2) phosphorylation (p-Erk 1/2) and that this can be attenuated by treatment of U0126, a p-Erk 1/2 inhibitor. Furthermore, both the expression of associated cytoskeletal proteins and the number of NeuN-positive cells are dramatically reduced after the inhibition of p-Erk 1/2. As a result there was an increase in the differentiating ESCs of the nuclear translocation of STAT3, together with a

decrease in the expression of NGF, BDNF and GDNF molecules. These results imply that phosphorylation/activation of Erk 1/2 is a key signaling that is essential for survival of ESCs and early neural differentiation^[12]. Recently, Glaser *et al.*^[13] found that when mESCs were initiated to progress into neural differentiation with RA, the expression of Oct-4 and the P2X7 receptor, an ATP-gated cation channel, were reduced. Utilizing KN-62, a specific P2X7 receptor inhibitor, they found an increased number of SSEA-1 and type III β -tubulin expressing double-positive cells. This confirms the appearance of neuroectodermal differentiation and it would seem that the neural fate determination of mESCs is dependent on suppression of P2X7 receptor activity^[13].

RA could also mediate crosstalk among other signaling pathways such as the Wnt/ β -catenin, FGF, and Erk pathways in order to induce neural differentiation. This is based on the finding that 4-d of RA treatment substantially increases the synthesis of the Dickkopf-related protein 1 (Dkk-1), a Wnt antagonist, and induces the expression of the Wnt/

Dkk-1 co-receptor LRP6^[14]. When recombinant Dkk-1 was utilized, the EBs presented in a similar manner to treatment with RA, namely there was an induction of two neural markers, the distal-less homeobox gene (*Dlx-2*) and nestin gene. Dkk-1 overexpression was found to be able to block the Wnt pathway, as evidenced by a decrease of β -catenin protein in the nucleus. These findings show that the prevention of the canonical Wnt pathway is a prerequisite for neural differentiation of ESCs when this is induced by RA treatment^[14]. Conversely, judging from the expression of neural marker *Hoxc4*, Otero *et al.*^[15] found that neural differentiation can be initiated by overexpressing β -catenin alone or combination with RA. Nevertheless, RA treatment was found to inhibit the β -catenin-induced production of tyrosine hydroxylase positive neurons, which suggests that the effects of RA are only partially dependent on β -catenin signaling. These results also suggest that β -catenin signaling enhances determination of neural lineage in ESCs. Moreover, β -catenin signaling could play a role of required co-factor in RA-induced pathway so as to permit the neural differentiation^[15]. Papadimou *et al.*^[16] reported that p66ShcA is increased during neural induction of ESCs *in vitro*. Overexpression of p66ShcA in ESCs ablates GSK-3 β kinase activation which in turn to stabilize β -catenin protein. In parallel, p66ShcA over-expression was found to result in both mESCs and hESCs undergoing neural induction as predicted and accelerated neural differentiation. Thus there seems to be a role for p66ShcA in the regulation of Wnt/ β -catenin pathway as well as in ESCs neutralization. Based on the above, p66ShcA would seem to also participate in a part of the RA-induction pathway^[16]. Furthermore, Engberg *et al.*^[17] monitor ESCs containing reporter genes that allowed the detection of markers associated with the early neural plate and the primitive streak and its progeny. When RA signaling is inhibited, they found that the change from neural to mesodermal fate develops. In addition, neural induction in ESCs needs RA to block Nodal signaling. Thus, the mechanism by which Wnt signaling pathway inhibits neural development could be interpreted as *via* facilitation of Nodal signaling pathway^[17]. Stavridis *et al.*^[18] shows that retinoid repression of fibroblast growth factor (FGF) signaling is able to promote the onset of neural differentiation. Induction of FGF8 by RA and subsequent Erk activity under early differentiation conditions could function to ascertain the loss of self-renewal. Nevertheless, a progressing inhibition of FGF4 by RA would seem to be associated with an overall decrease in Erk activity at the later stage. The admission of a neural or a non-neural fate is therefore decided by an inhibition of FGF signaling. Hence, inhibition of FGF/Erk activity would enhance ESCs self-renewal, but a subsequent abolishment of FGF signaling seems to have the opposite effect and act as a driver for differentiation^[18].

THE TGF β /BMP PATHWAY

It has been speculated that a default mechanism for neural differentiation might be involved in regulating the property of neural stem cell identity directly from ESCs. As above-mentioned, Tropepe *et al.*^[3] characterized that the neural lineage of differentiation from a nascent stem cell is modulated negatively by TGF β -related signaling. Moreover, differentiated mESCs *in vitro* with *Smad4* or *Cripto* genes knockout have been found to produce increased numbers of neurons^[19]. The profiles analysis of gene expression *in vitro* further demonstrates that cells bearing *Smad4* gene deletion were inclined to possess expressing patterns of mid-hindbrain and anterior hindbrain. However, the *Cripto* knockout cells tended to express gene markers of rostral central nervous system (CNS) in addition to other previous genes. Thus it would seem that *Smad4*^{-/-} ESCs exhibit differentiation of mesoderm while *Cripto*^{-/-} ESCs develop into epidermal/neuroectodermal cell types^[19]. To investigate the role of BMP-4 in the determination of either epidermal or neural fate, Gambaro *et al.*^[20] demonstrated that treatment of BMP-4 on murine ESCs results in the significant apoptosis of neural precursor cells which contain Sox-1 expression. Furthermore, counteraction of the SMAD pathway by overexpression of SMAD6, an inhibitor SMAD (I-SMAD), hinders the BMP4-induced apoptosis. Utilizing Noggin and SB431542, Chambers *et al.*^[5] shown that these two inhibitors of SMAD signaling are sufficient to allow the induction of neural differentiation derived from hESCs.

Genome-wide mapping was used to obtain plausible downstream candidates within the TGF β /BMP pathway that are involved in ESCs differentiation. Fei *et al.*^[21] mapped the gene promoters on a genome-wide scale to search for the target sequences bound with SMAD1, SMAD4, and SMAD5. They found that these molecules were associated with many developmental regulators and these were abundant in terms of H3K4 and H3K27 trimethylation bivalent markers. These promoters were found to be repressed when cells were in the self-renewing state, whereas these promoters underwent rapid induction upon differentiation. In the same context, the results from SMAD loss-of-function experiments further supported the hypothesis that BMP mediating signaling *via* SMAD does not directly affect self-renewal, whereas is necessary for various processes relevant to differentiation. Within the various SMAD-associated genes, they were able to identify two regulators which have been known to participate in the early neural differentiation regulated by BMP. These genes are *Dpysl2* (also known as *Crmp2*) and the H3K27 demethylase *Kdm6b* (also known as *Jmjd3*). Bertacchi *et al.*^[22] also adopted a global gene expression approach and were able to show that mESCs produce, secrete, and respond to BMPs during neural differentiation *in vitro*. Utilizing the analysis of

several markers of dorsoventral and anterior/posterior identity, they found that the gene expression pattern of differentiated ESCs reflects the midbrain identity. They also revealed that the endogenous BMPs during neural differentiation principally function to inhibit the expression of genes with a telencephalic profile. This phenomenon was evidenced by treating ESCs with a number of BMP inhibitors or Noggin.

THE NOTCH PATHWAY

Lowell *et al.*^[23] explored the role of Notch receptors and ligands in mESCs. They found that genetic manipulation that the constitutively activated Notch does not change the phenotype of stem cells. Nonetheless, these cells differentiate exclusively and promptly into the neural lineage upon abolishment of self-renewal stimuli. Conversely, genetic or pharmacological interference with Notch signaling inhibits the determination of neural fate. The neural commitment enhancing by Notch needs parallel signaling through the FGF receptor. Since expression of Notch ligand in stromal cells also induces the neural differentiation of hESCs, it indicates this pathway is conserved within pluripotent stem cells^[23]. Das *et al.*^[24] investigate the role of the Notch pathway by engineering a mESCs line such that there were short pulses of activated Notch. The alteration of Notch protein could be induced at the various stages of neural differentiation *in vitro*. The results show that activation of Notch signaling for 6 h specifically at day 3 during neural induction from ESCs was found to lead to dramatically increase cell proliferation. This outcome is associated with the cyclin D1 expression induced by Notch. In contrast, a decrease of cyclin D1 was observed during the development of the CNS in mouse embryos without Notch signaling. The ESCs containing a dominant negative form of cyclin D1 was found to abrogate the Notch-induced cell proliferation. These seem to indicate the presence of a special function for Notch in regard of temporal context. These findings also confirm that cyclin D1 is a crucial signaling molecule in Notch-induced differentiation/proliferation in ESCs^[24].

Downstream of the Notch pathway, the protein RBP was also show to play a key role. Main *et al.*^[25] obtained RBP^{+/-} mice using RBPJK^{loxP/loxP} mice^[26] bred with CMV-cre mice. After RBP^{-/-} mESCs had been obtained and cultured at low density, they were found to behave in the same way as wild-type cells in terms of the origin of apical specification and neural progenitors. When ESCs undergo development through the rosette formation, RBP was found to be required for the modulation of neuronal differentiation and for the appropriate preservation of rosette structure. Utilizing inhibitors of Notch and/or loss-of-function analysis of Notch signaling resulted in the disintegration of neural rosettes and an acceleration of neuronal differentiation. Rosette integrity was

also found to demand Rho kinase activity and actin polymerization in addition to requiring normal Notch signaling. However, it is worth noting that rosette maintenance is not required as a prior condition for regular neuronal differentiation. Various results demonstrate that Notch signaling also plays a role in the maintenance and organization of polarity during early nervous system development^[25]. Furthermore, it was also showed that Hes1-high ESCs are inclined to a mesodermal fate, whereas Hes1-low ESCs are inclined to a neural fate^[27]. Kobayashi *et al.*^[28] further showed that Hes1-low and Hes1-high ESCs are respectively correlated with cells that have undergone activation and inactivation of Notch signaling. Although Notch and Hes1 function in the same direction in most other cell types, the abovementioned results show that both signaling leads to opposite effect during ESCs differentiation. That is, Hes1 would seem to be not the downstream signaling molecule of Notch pathway during ESCs differentiation.

It was known that both activation of the Sonic Hedgehog (Shh) pathway and inhibition of the Notch pathway induce the neural differentiation during the neural tube development *in vivo*. To distinguish the effect of Shh and/or Notch signaling on ESCs-derived EBs, Crawford and Roelink used N-[N-(3,5-difluorophenacetyl)-L-alanyl]-S-phenylglycine t-butyl ester (DAPT), an inhibitor of Notch, to investigate how critical the Shh signaling is in the EBs formation and neural differentiation *in vitro*. It was found that DAPT led to promote neuronal differentiation. On the other hand, more interneurons were identified in the absence of Shh. They also found that the effect of DAPT on EBs with an activated Shh signaling is associated with the premature disappearance of markers involved in the ventral neuronal precursors^[29].

THE FGF PATHWAY

Chen *et al.*^[30] showed that FGF family includes FGF1, FGF2, and FGF4, but not FGF8b, are able to enhance the neurogenesis of mESCs during serum-free neural induction. They found that the enhanced neurogenesis by FGF is not mediated through a promotion of the proliferation of Sox1⁺ cells or *via* a rescue of apoptosis. It was found to involve the inactivation of JNK-1 and Erk-2, but did not involve p38 MAPK, which is known to inhibit neural formation by inhibiting ESCs differentiation. Furthermore, ESCs that lacked FGF4 or have been treated with a FGF receptor inhibitor were found to be resistant to neural and mesodermal induction^[30]. Kunath *et al.*^[31] found that activated Erk 1/2 induced by FGF4 is a stimulus by which naive ESCs are able to be released from the self-renewal program. FGF4 is capable of initiating differentiation activity. The important role of Erk downstream signaling was further explored by an examination of Erk2 deficient

ESCs, which fail to proceed to either mesodermal or neural differentiation and retain their pluripotency. On the other hand, FGF2 which functions for the maintenance of epiblast stem cells and hESCs was found to inhibit development of early neural cells by epiblast intermediates. Nevertheless, FGF2 alone is sufficient to enhance self-renewal of epiblast stem cells. Conversely, FGF8, the endogenous inducer for embryonic neural differentiation, promotes more homogenous neural induction that is accompanied by transient self-renewal of early neural cells. They also found that completely blocking of FGF signaling in epiblast cells enhances prompt neural induction as well as the succeeding neurogenesis. Therefore, FGF signaling pathway seems to play a variety of roles during the different stages of ESCs differentiation^[31].

Dang *et al.*^[32] investigated the downstream molecules involved in FGF signaling. Sox1, enhancing the colony formation of definitive neural stem cells, is regularly used as a marker of neural precursors. Under typically culture conditions of ESCs in which the medium contains leukemia inhibitory factor (LIF) and serum, overexpression of *Zfhx1b* in these cells is essential to initiate the expression of Sox1. When mESCs were initiated to the neural differentiation, a prompt increase of *Zfhx1b* gene expression is observed and can be further potentiated by FGF signaling^[32]. In the same content, utilizing siRNA to knockdown *Zfhx1b* in ESCs leads to decrease the developmental capability of these neural cells although the initial transition of ESCs to a neural cell fate is not affected. Taken together, these findings show that intercellular FGF signaling induces *Zfhx1b* and this is able to promote the development of definitive neural stem cells after an initial neural specification event has occurred.

THE CYTOKINE PATHWAY

Under culture conditions, LIF is used to prevent the differentiation of mESCs. However, He *et al.*^[33] found that utilizing inhibitors to abolish the STAT3 signaling which was activated by LIF could block the neuronal differentiation of ESCs. Furthermore, inhibition of the MEK signaling which was activated by LIF decreased the differentiation of ESCs into glial cells. During ESCs differentiation, LIF enhanced proliferation of cells and inhibited apoptosis of cells. In addition, LIF promoted the determination of neural progenitors although inhibited the differentiation of mesoderm and extraembryonic endoderm fates. Foshay *et al.*^[34] further examine the role of STAT3. The loss of STAT3, brought about by generating STAT3 dominant negative ESCs, led to the production of significantly fewer neural stem cells and this was associated with a decrease in the expression of the neural stem cell marker nestin. Further investigation revealed that the Sox2 promoter is directly regulated by STAT3. The decreased expression of Sox2 would induce the expression of

nestin and result in a commitment to a neural stem cells fate. Using mouse embryonal carcinoma P19 cells, Pacherník *et al.*^[35] demonstrated that the effects of LIF on inducing neural differentiation were inhibited by blocking the JAK2/STAT3 signaling pathway. This is also partially true for the pro-neural effects of RA. Conversely, inhibition of the MEK1/Erk signaling pathway was found not to show any such effect. These data suggest that the cooperation between LIF and other factors, such as RA, may eventually converge into the STAT3 signaling pathway.

THE HEDGEHOG PATHWAY

Maye *et al.*^[36] demonstrated that mutants in the signaling molecules of the Hedgehog pathway within ESCs could lead to defect in the generation of neuroectoderm-forming EBs. These mutant ESCs are incapable to produce nestin positive neural stem cells or differentiate into mature neurons in respond to RA treatment. Moreover, ESCs lacking *Odf1*, a gene that causes Oral-Facial-Digital 1 (OFD1) Syndrome when mutated, were found to show an increased tendency on neuronal differentiation. Furthermore, the OFD1 mutant ESCs-derived neurons are unable to differentiate into V3 interneurons, a cell type dependent on Hedgehog signaling^[37]. These findings show a role for Hedgehog signaling in producing the neuronal and glial progenitors derived from ESCs.

THE JNK/MAPK PATHWAY

Amura *et al.*^[38] showed that there is an essential role for the JNK pathway during ESCs neurogenesis. ESCs lines containing homozygous destruction of the *JNK1*, *JNK2*, or *JNK3* genes were introduced into differentiation protocol *via* the procedure at the EB formation. The outcome shows that neural differentiation was observed in wild-type EB cultures, *JNK2*^{-/-} EB cultures, and *JNK3*^{-/-} EB cultures except in *JNK1*^{-/-} EB cultures. The identified inhibitors of ESCs neurogenesis, Wnt-4 and Wnt-6, were found to be increased their expression in *JNK1*^{-/-} cultures as compared to wild-type, *JNK2*^{-/-}, and *JNK3*^{-/-} cultures. Furthermore, a genetic approach using JNK knockout ESCs has revealed a role for JNK1 in neural differentiation that involves repression of Wnt expression using a murine ESCs model^[38]. Na *et al.*^[39] reexamined the role of Erk 1/2 in hESCs by using a chemically defined culture system. The results demonstrate that when the activity of Erk 1/2 is inhibited, the differentiation of neurons and mesendoderm is inhibited. However, these cells are still able to differentiate after BMP stimulation.

OTHER MOLECULES/FACTORS

Calcium, calcium receptor, and calcineurin

A number of studies have shown that calcium

homeostasis is a crucial factor in determination of neural fate. This has been thoroughly discussed in a previous review^[40]. It is worth noting that utilizing proteomic analysis or gene screening during neural induction in mESCs, four Ca^{2+} -related proteins, namely neuronatin, translationally controlled tumor protein, pyruvate dehydrogenase E1/E2 subunits, and calreticulin, have been found to be altered in expression^[41,42]. When neuronal cells are differentiated from ESCs lacking the Ca^{2+} release channel type 2 ryanodine receptors ($\text{RyR2}^{-/-}$), Yu *et al.*^[43] found that the rate of neurogenesis was significantly blocked. Meanwhile, the expression of NeuroD, a neuronal transcription factor, and the activity of intracellular Ca^{2+} signaling were also inhibited in the $\text{RyR2}^{-/-}$ deficient mESCs. Moreover, neuronal differentiation in $\text{RyR2}^{+/+}$ cells enhanced by activation of L-type Ca^{2+} channels or of GABA receptors was inhibited by RyR inhibitors. Therefore it would seem that cooperation between RyR2 channels and L-type Ca^{2+} is important for activity-dependent neurogenesis. Recently, Cho *et al.*^[44] found that neural induction is dependent on a Ca^{2+} -activated phosphatase, calcineurin. They also have shown that calcium entry mediated by FGF stimulation activates calcineurin, which then directly and specifically dephosphorylates BMP-regulated Smad1/5 proteins.

Estrogen receptor

Utilizing an estrogen receptor (ER) agonist, Zhang *et al.*^[45] found that $\text{ER}\beta$, but not $\text{ER}\alpha$, stimulated calcium oscillations in neurons derived from ESCs. The increase of calcium oscillations and the phosphorylation of PKC, AKT and Erk1/2 induced by the $\text{ER}\beta$ agonist in ESCs derived neurons could be blocked by nifedipine, an inhibitor of L-type calcium channels. The result demonstrates that $\text{ER}\beta$ could modulate neuron activity via L-type voltage gated calcium channels.

Hox protein

In order to investigate the role of the *Hox* gene in neuronal differentiation, Bami *et al.*^[46] used a mESCs cellular model by combining efficient neural differentiation with inducible *Hoxb1* expression. The profile of gene expression indicates that *Hoxb1* could function as both activator and repressor in the short term, whereas as a repressor in the long term. Such a pattern of *Hoxb1* activity was observed in the regulation of mESCs after RA induction.

Ceramide

It has been previously showed that bioactive lipids are important regulators of stem cell survival and differentiation^[47]. It was found that the sphingolipid ceramide and its derivative, such as sphingosine-1-phosphate, are able to function synergistically during ESCs differentiation and the guided differentiation of mESCs toward neural and glial lineages^[48].

Glycosaminoglycan

mESCs that lack heparan sulfate (HS) cannot process into neural specification whereas this phenomenon can be recovered by adding a highly sulfated glycosaminoglycan, one kind of soluble heparin^[49]. Pickford *et al.*^[50] demonstrated that specific heparin polysaccharides or HS support the formation of Sox11 neural progenitor cells from wild-type ESCs. They also found that a number of receptor tyrosine kinases were affected by HS during the differentiation.

Ginsenoside Rg1

Ginsenoside Rg1, a saponin and major component in ginseng, has been shown to possess neuroprotective effects. Wu *et al.*^[51] explored the effect of Rg1 on the promotion of mESCs differentiation towards the neuronal lineage. They found Rg1 increased the phosphorylation of Akt and Erk 1/2 in a time dependent pattern through glucocorticoid receptor. Treatment with either LY294002, an inhibitor of PI3K, or U0126, an inhibitor of MEK, blocked the Rg1-induced neuronal differentiation.

Opioids

Kim *et al.*^[52] measured μ -opioid receptor and κ -opioid receptor expression in various cell types including ESCs and neural progenitors induced by RA. In the RA-induced ES cells, a biphasic profile of Erk activation after opioid stimulation was observed. Nevertheless, the proliferation of the neural progenitors was inhibited after opioid stimulation in which this phenomenon was Erk independent. The findings indicate that opioids could have opposite effects on ESCs self-renewal and ESCs differentiation.

Two pore channel 2

The nicotinic adenine acid dinucleotide phosphate (NAADP), located on membranes of lysosome, has a potent effect on mobilizing endogenous Ca^{2+} . Two pore channel 2 (TPC2), voltage-gated ion channels, is shown to be the receptor of NAADP. Zhang *et al.*^[53] found that expression of TPC2 was decreased dramatically when the ESCs entry differentiation towards neural progenitor cells. During the late stages of neurogenesis, the expression of TPC2 reoccurred. Analysis of loss-of-function mutants of TPC2 found that TPC2 knockdown in mice accelerated mESCs differentiation into neural progenitors. This contrasted with the situation where there was TPC2 gain-of-function in a mouse model; this revealed that gain-of-function inhibited mESCs from entering the early neural differentiation. These findings suggest that TPC2 signaling plays a vital role in regulating the differentiation of mESCs into the neural lineage.

Nitric oxide

Employing various approaches, including ESC-derived neural precursor cells, Arnhold *et al.*^[54] studied the

role of nitric oxide in initiating the differentiation of neurons. They found that specific blocking of the NOS- II isoform was able to bring about the inhibition of neurite outgrowth.

Chemically defined medium

When chemically defined medium (CDM) is used for growth, ESCs differentiation is highly neurogenic. Neural differentiation in CDM is shown to be dependent on endogenous FGF signaling. This process is able to be inhibited by BMP4 or LiCl in which they simulate Wnt pathway. The neural differentiation in CDM could be terminated by blocking Hedgehog activity endogenously. Therefore, a common developmental mechanism could be processing since the profile change of gene expression in stem cells cultivation in CDM and the ones in the early embryos are extremely similar^[55].

Cell-Cell interactions

Parekkadan *et al.*^[56] observed that the presence of a previously specified Sox1-GFP⁺ cell in contact with undifferentiated ESCs was able to initiate a similar specification. This induction relied on the age of previously specified cells before co-culture. Further search for the cell adhesion molecules, it was found that connexin (Cx)-43 expression was associated with the age-dependent effect of cell contact in the experiments of cell pair. Both aberrant neuroectodermal specification and lineage commitment were seen in ESCs in which Cx-43 was knockout. Such an observation highlights the important role of gap junction signaling in the neuronal development.

Physical stimuli

Interestingly, physical stimuli are also able to affect the differentiation of ESCs and these phenomena have gained some attention recently. Piacentini *et al.*^[57] reported that the percentages of cells expressing type III β -tubulin, microtubule-associated protein 2, and calcium channel proteins (Cav1) were dramatically increased when differentiating neural stem cells are exposed to extremely low-frequency electromagnetic fields (ELFEFs, 1 mT, 50 Hz). An obviously increase in spontaneous firing were also found in these ELFEF-exposed neurons. Furthermore, they found that stimulation of ELFEF during the early differentiation could induce an increase of cells expressing CREB phosphorylation by which it is calcium channel dependent^[57]. In another study, Maioli *et al.*^[58] created a Radio Electric Asymmetric Conveyer (REAC) that is able to deliver wireless fidelity radiofrequency (Wi-Fi RF) at 2.4 GHz. This radio wave is delivered by immersing the conveyer electrodes into the culture medium. Using such a device allows mESCs to be exposed to REAC and in such circumstances it was found that transcription of genes involved

in differentiation, such as neuronal commitment (neurogenin1), were upregulated, while other genes, such as *Sox2*, *Oct4*, and *Nanog*, were downregulated. These findings mean that the physical environment is also able to regulate the fate of stem cells.

CONCLUSION

Some canonical pathways involved in cell size such as Hippo/Yap pathways and/or growth such as PI3K/Akt pathways seem to have little relationship with the initiation of neuronal differentiation from ESCs *in vitro*. The PI3K/Akt pathway is viewed as important to the maintenance of neuronal survival, but not to the differentiation process. In this context, Watanabe *et al.*^[59] show that the membrane bound Akt through myristoylation (myr-Akt) could maintain mESCs at the undifferentiated status without supplement of LIF in the medium. Once the myr-Akt was deleted, the dependence of LIF and ability of differentiation were recovered. They found that the PI3K/Akt signaling could regulate "stemness" of many stem cell systems. Zhao *et al.*^[60] also found that insulin can rescue ESCs-derived neural progenitor cells from hypoxia-induced cell death. Such an effect is able to be inhibited by LY294002, an inhibitor of the phosphatidylinositol 3-kinase (PI3K). Nevertheless, Chuang *et al.*^[61] have recently reported that the mTOR pathway, a downstream pathway of PI3K, would seem to play a role in ESCs-derived neuronal differentiation. In order to reveal the role of raptor/mTOR in neurons differentiated from ESCs, we established raptor gene-trap mESCs and raptor knockdown mESCs using raptor RNAi infection followed by puromycin selection. Embryonic body growth in both cases was greatly reduced and the result was an unsuccessful differentiation of neurons. Furthermore, treatment with 1 μ mol/L rapamycin over 48 to 72 h of treatment starting at the point when neuronal precursors began to differentiate from mESCs was found to bring about a gradual loss of neuritis together with a shrinkage of the soma and a decreased ratio of neurite length to cell number. Knockdown of raptor during neuronal differentiation from mESCs also resulted in a gradual loss of neurites and cell body shrinkage. The loss of neurite density that results from rapamycin treatment is able to be reversed by overexpression of S6K T389E. Therefore, raptor/mTORC1/S6K would seem to play a critical role in the differentiation and survival of neurons derived from mESCs^[61]. Therefore, it seems likely that the mTOR pathway plays a pivotal role in neuronal differentiation of ES cells *in vitro*.

To comprehensive understand these pathways will definitely contribute greatly to stem cell biology and translational medicine. In conclusion, the pathways outlined here are simple and linear. However, it is still unclear how these pathways crosstalk with each other and/or what is the level of

interplay between the pathways both temporally and spatially. The integration of these pathways into a comprehensive network will probably require more incisive investigative approaches. Generating specific types of neurons from ESCs *in vitro* has created high expectations in terms of possible medical treatments and/or potential cures for neuronal pathological diseases. Knowledge obtained by the research related to ESCs derived neurons *in vitro* should also provide a technical basis for regenerative medicine, applied medical research, and drug discovery.

Abstract

Cell therapy is a promising treatment for diseases that are caused by cell degeneration or death. The cells for clinical transplantation are usually obtained by culturing healthy allogeneic or exogenous tissue *in*

vitro. However, for diseases of the eye, obtaining the adequate number of cells for clinical transplantation is difficult due to the small size of tissue donors and the frequent needs of long-term amplification of cells *in vitro*, which results in low cell viability after transplantation. In addition, the transplanted cells often develop fibrosis or degrade and have very low survival. Embryonic stem cells (ESCs) and induced pluripotent stem cells (iPS) are also promising candidates for cell therapy. Unfortunately, the differentiation of ESCs can bring immune rejection, tumorigenicity and undesired differentiated cells, limiting its clinical application. Although iPS cells can avoid the risk of immune rejection caused by ES cell differentiation post-transplantation, the low conversion rate, the risk of tumor formation and the potentially unpredictable biological changes that could occur through genetic manipulation hinder its clinical application. Thus, the desired clinical effect of cell therapy is impaired by these factors. Recent research findings recognize that the reason for low survival of the implanted cells not only depends on the seeded cells, but also on the cell microenvironment, which determines the cell survival, proliferation and even reverse differentiation. When used for cell therapy, the transplanted cells need a specific three-dimensional structure to anchor and specific extra cellular matrix components in addition to relevant cytokine signaling to transfer the required information to support their growth. These structures present in the matrix in which the stem cells reside are known as the stem cell microenvironment. The microenvironment interaction with the stem cells provides the necessary homeostasis for cell maintenance and growth. A large number of studies suggest that to explore how to reconstruct the stem cell microenvironment and strengthen its combination with the transplanted cells are key steps to successful cell therapy. In this review, we will describe the interactions of the stem cell microenvironment with the stem cells, discuss the importance of the stem cell microenvironment for cell-based therapy in ocular diseases, and introduce the progress of stem cell-based

therapy for ocular diseases.

INTRODUCTION

Limbal stem cell deficiency, corneal endothelial decompensation, corneal grafts endothelial decompensation, retinitis pigmentosa, age-related macular degeneration, Stargardt disease and other hereditary retinal diseases are all caused by cell degeneration or death. There is no effective clinical treatment currently available. Unlike traditional medicine or surgical therapy, cell therapy is a promising treatment and can treat the abnormal cells most directly and efficiently.

The road to cell therapy has been a long and tortuous process. In the early days, most of the efforts to obtain sufficient therapeutic seed cells were based on establishing cell lines or improving tissue culture methods with the expectation that they will provide therapeutic effects after the cell transplantation. The former long-term passaged cell lines were mainly obtained by transgenic or nuclear atypia. Because of biosecurity risks and allograft immune rejection, cells obtained by this method are mainly used for basic research^[1]. The cells for clinical transplantation are usually obtained by culturing healthy allogeneic or exogenous tissue *in vitro*. It is hard to get large tissue from the eye to obtain a sufficient amount of cells and the culture often needs to go through long-term amplification *in vitro*, resulting in low cell viability after transplantation. Cells often develop fibrosis or are absorbed and cannot survive long. Thus, the desired clinical effect of the cell therapy cannot be accessed

and so it was shelved for a while.

Considerable progress has been made in the induction and differentiation of embryonic stem cells (ESCs) since the last century and it brought new vitality to cell therapy. However, the differentiation of ESCs can bring immune rejection, tumorigenicity and differentiation of uncertainty, which limits its clinical application. Although induced pluripotent stem cells (iPS) can avoid the risk of immune rejection caused by ESC differentiation post-transplantation, the low conversion rate and the risk of tumor formation still exists and the potentially unpredictable biological danger achieved through genetic manipulation hinders its clinical application. Thus, cell therapy returns to the transplantation of the cultured autologous cells, especially the enriched stem cells and the methods and the results have been greatly improved.

With the development of research, it is increasingly recognized that the reason the implanted cells cannot survive long-term in cell therapy is not simply because of seed cells, but also because of the cell microenvironment which determines cell survival, proliferation and even reverse differentiation. The birth of Dolly the sheep is the best example. In a good embryo environment, mature breast cells can be re-developed into a new individual sheep. From a biological point of view, whether it is a cell or an organism, it must exist in its surroundings with exchange material, energy and information. In terms of cell therapy, the transplanted cells need a specific three-dimensional structure to anchor and specific extra cellular matrix (ECM) components and cytokine biological information transfer to support their growth. These structures are present in the matrix in which the stem cells located and are called the stem cell microenvironment. The microenvironment interacts with the stem cells and they are interdependent, mutually promote and complement each other, working together to maintain the stem cell homeostasis^[2-5]. A large number of studies suggest that exploring how to strengthen the organic combination of the transplanted cells and the stem cell niche and reconstructing the stem cell microenvironment is the key to successful cell therapy.

In this review, we will recount the interactions of the stem cell microenvironment with the stem cells, discuss the importance of the stem cell microenvironment for cell-based therapy in ocular diseases, and introduce the progress of stem cell treatment for ocular diseases.

THE ROLE OF THE STEM CELL MICROENVIRONMENT

Obtaining autologous cells for cell therapy aided by the stem cell microenvironment

In the process of inducing embryonic stem cells and iPS cell differentiation, it was discovered that the adult cells can induce embryonic stem cells to differentiate

and the embryonic stem cells can promote somatic cell proliferation, repair the defects of co-cultured cells, or even reverse the differentiation state of somatic cells^[6-9] by improving the microenvironment *via* secreting a variety of factors and cell interactions, *etc.*

We began to work on the induction and differentiation of embryonic stem cells and epidermal stem cells^[10-12] in 1997 and found that when the adult cells were treated with supernatant from cultured embryonic stem cells or co-cultured with the embryonic stem cells, the aging process of adult cells can be slowed down or even reversed into progenitor cells and their self-renewal and proliferation capacity can be increased significantly^[13-18], whereas the adult cells can also induce embryonic stem cells to differentiate. We found a phenomenon that the corneal epithelial cells maintain long-term proliferative capacity and tissue-specific cell phenotype by factors secreted from murine ESCs. Rabbit corneal epithelial cells, cat corneal endothelial cells, rabbit skin epithelial cells and rabbit conjunctiva epithelial cells grew very well in culture medium with addition of ESC conditioned medium. These corneal epithelial cells were serially subcultured for more than 20 passages and maintained high cell purity, cobblestone-like morphology, enhanced colony forming efficiency, normal diploid and capacity to regenerate a functional stratified corneal epithelial equivalent. The rabbit corneal epithelial cells cultured in the embryonic stem cell microenvironment can be continuously passaged over 55 generations in 22 wk, gradually restoring its precursor characteristics, such as: decreased corneal epithelial cell specific differentiation markers K3/K12 expression, increased corneal epithelial precursor cell markers *P63* and *ABCG2* expression, but the expression of *Oct-4* was not detected, indicating that the embryonic stem cell microenvironment treated cells obtained a strong proliferative capacity without the potential tumorigenicity and uncertain differentiation^[13-18]. Zhang *et al.*^[13] also found that the proliferation and maturation of the dendrite cells co-cultured with the bone marrow mesenchymal cells were able to be significantly promoted, with the enhanced precursor cell marker expression and reduced expression of differentiation markers, so that the mature dendritic cells were reversed to the original progenitor cell stage. Pearton *et al.*^[9] reported that mouse embryonic skin can induce the terminal rabbit central corneal epithelial cells to reverse to the limbal stem cells by gradually losing specific marker K12 and K3. These results strongly suggest that the stem cell microenvironment can significantly regulate adult cell proliferation. It has the potential to become a more effective and safe method to access autologous seed cells with high proliferative activity which are close to pluripotent stem cells or transient amplifying cells without uncertain differentiation direction or tumorigenicity and render them more

suitable for clinical use.

Repair of the stem cell microenvironment is the basis for long-term efficient cell-based therapy

Stem cell microenvironment is the general term of the three-dimensional structure and a variety of signaling molecules (growth factors and their receptors, hormones and signaling molecules) present in the stroma where the stem cells reside and it can regulate the fate (proliferation/differentiation) of the stem cells. Because of its specific three-dimensional structure, it is vividly called niches (niche), which consists of three components: the extracellular matrix (ECM), niche cells (supporting cells, stem cells) and soluble factors derived from the niche cells (Figure 1). The proliferation and differentiation of stem cells are pre-programmed by themselves and are also affected by the microenvironment where they are residing. The stem cell microenvironment can anchor stem cells *in vivo* and regulate the self-renewal and production of their progeny cells through cell-cell, cell-ECM and cytokine-cell interactions. The different macromolecules or properties of the cells and ECM interact with each other in a complex and dynamic network^[19,20]. Nowadays, there is increasing evidence showing that the ECM is not only the supportive scaffold but also plays a fundamental role in cell biology. It plays important roles in the development of the cells and can regulate their behavior^[21] by the production, degradation of its components and the remodeling of the structure^[22,23] and the direct and indirect signaling properties^[21]. The polarity, division and migration of the cells can be influenced by the physical properties of the ECM, such as rigidity, porosity, topography and insolubility^[24]. Cytokines play an important role in exchanging information from cell-cell and cell-ECM. The changes of the extracellular matrix components also affect the differentiation of the stem cells and the induced differentiation *in vitro* is accomplished by mimicking the cell microenvironment. So, it is difficult to obtain a long lasting therapeutic effect in cell-based therapy without the support of a good stem cell microenvironment, even when excellent cells are transplanted.

The importance of stem cell microenvironment in tissue engineering has also been verified. How to rebuild the stem cell microenvironment becomes the biggest challenge currently for constructing tissue engineered tissues and organs. In the past, because the scaffolds for tissue engineering of organs and tissues had no such sophisticated stem cell microenvironment, the desired therapeutic effect could not be achieved and the structure and function could not be completely recovered after transplantation. In 2009, we introduced phospholipase A2, which can specifically hydrolyze the phospholipids of the corneal stroma cell membrane, can destroy the cell structure and be used to prepare acellular porcine corneal stroma acellular porcine corneal stroma

(APCS) for biological tissue engineering cornea^[25]. The natural corneal collagen structure and 80% of the extracellular matrix components can be retained by this means. This APCS not only has good biocompatibility and biomechanical strength, but also keeps the limbal stem cells microenvironment necessary for their long-term proliferation. The grafts of APCS maintained good biomechanical strength and high transparency post-transplantation in animal experiments and it can help to rebuild the limbal stem cell microenvironment^[26-30]. Nakayama *et al.*^[31], Ott *et al.*^[32], Petersen *et al.*^[33], Uygun *et al.*^[34] and Conrad *et al.*^[35] have also reported the use of acellular matrix as a scaffold in tissue engineering in kidneys, lungs, heart, trachea and bladder. As Song *et al.*^[36] stated, using an acellular matrix scaffold with natural extracellular matrix to build tissue engineering products can mediate organ development, reparation and regeneration which cannot be accessed by synthetic materials. There are further experiments that proved that the acellular materials with extracellular matrix play an important role in the regulation of stem cells^[37]. These studies showed that a decellularized tissue with the natural ECM scaffold can induce the stem cells to differentiate into cell types present in certain tissue^[31] and thus the decellularized organ has already been used in tissue engineering and cell therapy^[31,36].

The microenvironment has a great effect on the fate of stem cells. In recombination experiments, hair follicle stem cells were induced to differentiate into corneal epithelial cells when they were cultured in a limbus-specific-like niche^[38]. These cells grow into stratified epithelium and express the cornea-specific markers K12 and Pax6 while the epidermal specific K10 obviously down-regulated^[38]. While in other studies the rabbit epithelial cells from the central cornea differentiated into epidermal keratinocytes when recombined with mouse embryonic dermis, it lost corneal-specific marker K3/K12 together with the down-regulation of Pax6 and expressed keratinocyte marker K5/K14^[9]. All of these changes showed that

the microenvironment has an important regulation role in the fate of the stem cells.

Stem cells can sustain and repair the structure and the function of the niche

On the other hand, evidence *in vivo* showed the relevance of the ECM and the stem cell behavior in that the altered properties or the aged niches' ability of maintaining stem cells' stemness can be reduced^[39] and it further affected stem cell proliferation and updated, which created a vicious cycle. Scientists from Harvard University attempted to study the relationship between human aging and microenvironmental changes between stem cells via the stem cell microenvironment (niche) and they found that altering the aged microenvironment with the young microenvironment can improve the ability of the proliferation and renewal of the stem cells. The study also found that adding "insulin-like growth factor-1" (IGF-1) can also improve the state of the aging stem cell microenvironment.

Cell receptors can directly mediate the interactions between the stem cells and the ECM where they are located. It was also found that integrins, a large family of heterodimeric transmembrane receptors, are important receptors for the ECM-stem cell interactions and can regulate cell survival, migration, proliferation and differentiation by connecting the ECM to the intracellular cytoskeleton^[40] as well as the adhesion, anchorage and homing of the stem cells. Different kinds of integrins bind to different ECM components or different cell surface adhesion molecules and receptors^[41-43]. Integrins can regulate the self-renewal and proliferation of the stem cells by directly activating focal adhesion kinase (FAK) and the phosphoinositide 3-kinase (PI3K) signaling pathway^[40,44,45]. The $\alpha\beta1$ integrin can bind to the ECM protein laminin and help the spermatogonial stem cells home in to the testicular niche^[46] and NSCs (neural stem cells) adhere to the vascular niche^[47]. The $\alpha9$ integrin is essential for the proliferation of the HSC^[48] and NSC microenvironment^[49] *via* binding protein tenascin-C in the ECM. The $\alpha4$, $\alpha6$, $\alpha9$ and $\beta1$ integrin chains are also important to the HSCs in their homing in to the bone marrow niche^[50-53]. HSC homing and proliferation are also regulated by $\alpha\nu\beta3$ integrin^[54-56]. Furthermore, $\beta1$ integrins can control the balance between symmetric and asymmetric divisions in skin and brain, as well as the differentiation and self-renewal of the stem cells^[57-60] by regulating the activity of the Notch pathway and EGF receptor^[61,62]. They are also important for the proliferation of intestinal stem cells (ISCs) *via* the Hedgehog signaling pathway^[63]. Signaling pathways of the growth factors and cytokines, such as IL-3 and TGF- β ^[43,64-67], can also be regulated by integrins and these signaling pathways can regulate the expression of integrins conversely^[46]. Therefore, the receptors

have specific activities in a certain kind of stem cell microenvironment.

Some ECM components can regulate their availability by setting a biochemical gradient and binding growth factors^[21]. On the one hand, the ECM can also make the growth factors insoluble, unavailable or not bioactive and serve as the reservoir for them, like proteoglycans, collagens, fibronectin and vitronectin, which bind VEGFs, FGFs, HGFs, TGF- β and BMPs. On the other hand, ECM proteins and proteoglycans can be induced to be soluble and remodeled to release and distribute growth factors under the action of enzymes, such as metalloproteinase^[21]. The function NSC can be favored by the ECM components in its niche by promoting growth factor activity *via* capturing FGF-2 from it^[68,69]. Similarly, in the procedure of the regulation of muscle satellite cells, all kinds of growth factors bind to the cell surface or the basal lamina proteoglycan and then they can be activated in a certain signaling pathway^[70].

The biophysical properties of the ECM can determine the behavior of stem cells. The balance of the internal forces generated by cell cytoskeleton tension and the external forces from the compression of the neighboring cells and the stiffness of the surrounding ECM maintains the shape of the cells and makes them stay in their anatomical localization^[71], which can regulate the cell behavior finally^[72-74]. Recently, the YAP/TAZ transcriptional factors were found to have key biological effects on the ECM elasticity, cell geometry and cytoskeletal modulation^[71,74,75] among the mechanotransduction pathways (Wnt/ β -catenin, PI3K/Akt, TGF- β , Ras/MAPK, and RhoA/ROCK pathways). In fact, ECM organization and composition can regulate tissue stiffness and then have an influence on the stem cell behavior^[72,76]. The human mesenchymal stem cells can express organ-specific transcription factors and differentiate into myoblasts, neurons and osteoblasts^[77] when they are cultured on ECMs with similar stiffness of the muscle, brain or bone respectively. Culture on hydrogel with the same elastic modulus as the bone marrow can increase the self-renewal ability and maintain multipotency of the hMSCs (human mesenchymal stem cells) compared to those cultured on stiffer substrates^[78]. NSCs cultured on hydrogel with similar stiffness to the brain tissue gain the neuronal differentiation potential, while the stiffer gels make them differentiate into glial cells^[79]. That the stiffness gradients of the hippocampus regulate NSC behavior *in vivo* confirmed that ECM and its biomechanical properties play important roles in the fate of the stem cell^[80]. This opens new insights in to the role of ECM mechanical properties in the stem cell microenvironment.

Stem cells in ocular tissues: Several studies showed the conjunctiva epithelial stem cell niche located in the fornix by growth potential assays, label-retention analyses and keratin expression detection^[81-84]. They have bipotential to differentiate

into both epithelial cells and goblet cells^[85].

Corneal epithelial stem cells resident at the basal limbal epithelium and called limbal stem cells were first applied to clinical use in ophthalmology. Tung-Tien Sun's group did immunostaining with monoclonal antibodies against the corneal-specific K3^[86] and showed the negative expression of K3/K12 in the limbal basal layer, which gave rise to a number of experiments that verified that the corneal stem cells were located in the limbus^[86-88]. These label-retaining limbal cells^[89] have a higher proliferative potential^[90] and colony-forming ability^[91] compared with central ones.

People made efforts to find specific molecules markers of the limbal stem cells. p63^[92], vimentin^[93-95], α -enolase^[96,97], α 9 β 1 integrin^[98], tenascin-C and EMILIN1^[99], ABCG2^[100-103] and ABCB5^[104] are all highly expressed in the basal layer of limbal epithelium but none of them are the specific markers of the limbal stem cells as expected. This is because the early differentiating cells^[105,106] still have the stem cell markers and show intermediate profiles between stem and differentiated cells until the stem cell markers are down-regulated with the expression of the differentiated phenotype^[107]. Thus, we can only enrich the stem cells while separating them with these molecules markers^[108].

Since it is complex and difficult to characterize the corneal stem cells, people try to identify them by analyzing their niches and the regulatory functions of the niche.

The limbus is a specific region which is characterized by the palisades of Vogt with the papillae-like projections and the vascular net in the peripheral cornea^[109]. It enables the epithelial cells to interact with ECM and chemical signals diffused from the vascular network^[110]. Some studies showed that the limbus has a specific anatomic structure such as the niche, the LEC (limbal epithelial crypt) or LC (limbal crypt), which consists of a cord or finger of cells that are located between the palisades of the limbal stroma and extends radically to the conjunctiva stroma^[92,93]. The high expression of K14^[111], ABCG2^[112] and p63^[92,93] in cells at the LEC^[112]/LC^[113] suggest that they are the microenvironment of the limbal stem cells but the LEC/LC structure has not been found in other species besides humans and pigs^[94].

This tissue with unique cellular properties can synthesize different kinds of ECM substrates. Several studies on the ECM components of the cornea were performed regarding the aspect of the biochemical and immunological characteristics. Corneal stroma comprises collagen type I-VI^[114-117], glycosaminoglycans (chondroitin, heparin, dermatan) and keratan sulfates^[118-122], fibronectin and laminin^[105,123] and hyaluronic acid^[124] and the limbal epithelial cells are more likely to adhere to a rougher surface than those in the central cornea^[125]. To further study the interaction between corneal stem cells and their

microenvironment and the different functions between the central cornea and the limbus, the corneal basement membrane components were analyzed by several studies. These studies found that the conjunctiva, limbal and central corneal epithelia have a heterogeneous composition of the basal membrane (BM)^[126]. Some studies reported that there was no collagen IV in the central cornea BM^[127], while others had the controversial results that collagen IV presented both in the limbal and the central corneal BM^[126]. Later, people found that collagen IV $\alpha 1$ (IV) and $\alpha 2$ (IV) chains show more intense staining at the corneal limbus and the $\alpha 3$ (IV) chain shows an abrupt decrease at the limbus^[128,129], while collagen types IV ($\alpha 3$ - $\alpha 4$ chains) and XII are only expressed in the central cornea^[128]. Then, other components of the limbal BM were studied further. Laminin $\alpha 2$ - $\alpha 5$, $\beta 1$ - $\beta 3$, $\gamma 1$ - $\gamma 3$, nidogen-1, -2, SPARC/BM-40, as well as agrin are preferentially expressed in the limbal BM^[128], which colocalized with the ABCG2/p63/K19-positive and K3/Cx43/desmoglein/integrin- $\alpha 2$ -negative stem cells and early progenitor cell clusters^[128,129]. The BM components, such as type XVI collagen, fibulin-2, tenascin-C/R, vitronectin, bamacan, chondroitin sulfate and versican, are colocalized with the putative vimentin-positive late progenitor cells^[128-130] at the limbus. On the contrary, type V collagen, fibrillin-1 and 2, and thrombospondin-1 were almost only found in the corneal BM^[128]; others, such as type IV collagen $\alpha 5$ and $\alpha 6$ chains, collagen types VII, XV, XVII and XVIII, laminin-111, laminin-332, laminin chains $\alpha 3$, $\beta 3$ and $\gamma 2$, fibronectin, matrilin-2 and 4, and perlecan, were expressed throughout the epithelial layer on the ocular surface^[129,130]. All these studies showed that the BM at the limbus has a specific ECM composition which is different from that in the peripheral or central cornea. This suggested that the EMC at the LEC/LC created a microenvironment that regulates stem cells and their progeny by supporting stemness while inhibiting the differentiation and preserving the proliferative abilities in limbal cells.

The stem cells of the corneal endothelium and the trabecular meshwork are believed to be located at the transition zone between the peripheral corneal endothelium and the anterior non-filtering portion of the trabecular meshwork^[131]. Corneal stroma stem cells are located in the limbal stroma, play roles in visualization and have corresponded to the limbal niche cells^[132].

At the early stage, the stem cells of the lens were assumed to be the label-retaining cells which are located at the anterior central region of the lens^[133]. Yamamoto *et al.*^[134] concluded that the germinative zone of the lens epithelium contains transient amplifying cells with the positive expression of proliferation markers, such as A1, B1, C and D1 cyclins and PCNA (proliferating cell nuclear antigen), and can be labeled by BrdU (5-bromo-2'-deoxyuridine). On the

other hand, other studies showed that they were probably located in the region anterior to the germinative zone. However, Remington *et al.*^[135] assumed that lens stem cells resided in the ciliary body because the lens is non-vascular, its epithelium does not have the morphology of other stem cells and no type of tumors are derived from the lens. Thus, the existence of the lens stem cells remains controversial and needs to be elucidated.

Previously, it was believed that there were no stem cells in the mammalian retina since it cannot regenerate^[136] but von Leithner *et al.*^[137] found retinal precursors in the peripheral retinal pigment epithelium later. However, the cells from the pigmented ciliary margin were later found to have the ability to form spherical colonies and produce various types of differentiated retinal cell^[138]. These results gave the evidence that retinal stem cells are located in the pigmented ciliary margin epithelium.

CELL-BASED THERAPY IN OCULAR DISEASES

Progress in the research of stem cell therapy for corneal diseases

Limbal stem cell deficiency can be caused by a myriad of insults that present with the following pathological states: damaged corneal barrier function, persistent corneal epithelium defects or recurrent corneal erosions, chronic inflammation associated with corneal stromal scarring, visualization, conjunctivalization and eventually blindness. Some researchers speculate that this occurs due to gradual deterioration of the limbal stromal niches^[139]. Thus, limbal epithelial stem cell transplantation and the reestablishment of the limbal stem cell microenvironment are necessary for ocular surface reconstruction in these diseases^[139].

Autologous or allogenic limbal transplantation has achieved good clinical efficiency in the treatment of limbal stem cell deficiency. However, in successful cases post limbal transplantation, there is a doubt as to whether there is a causal relationship between the survival of the donor limbal stem cells and the clinical effect. Shimazaki *et al.*^[140] detected the presence of donor-derived epithelial cells in 60% of cases (10 eyes/9 cases) post human limbal transplantation with fluorescence in situ hybridization assay, with 77.8% by RFLP analysis. At the same time, the authors stated that there was no difference in the postoperative clinical outcomes whether the presence of survived donor-derived cells was detected. Thus, more studies should be carried out to confirm the clinical significance of the survival of donor cells. Furthermore, it was reported that donor-derived cells were undetected in cases with objective clinical improvement after three to five years post limbal transplantation, even with DNA fingerprinting analysis^[141]. This suggested that the survival of

donor-derived cells is not essential for improvements of the clinical symptoms. These results indicated that limbal transplantation might simply serve as the corneal stroma transplantation. Presumably, limbal transplantation improves the residual stroma stem cell microenvironment, making residual stem cells in the patient regenerate on the ocular surface and allowing for improvement of the ocular surface^[142]. Therefore, some scholars believe that the essence of limbal transplantation may be the restoration of the limbal stroma resulting in increased stability of the limbal stem cell "niche"^[143]. So, limbal epithelial stem cell deficiency treatment lies in the application of various methods to restore the normal limbus matrix.

Although traditional corneal transplantation, limbal transplantation, has already achieved good results in ocular surface reconstruction for corneal diseases, there still several problems that have hindered clinical application, such as the shortage of donors, the immune rejection post-transplantation and other issues. Therefore, the construction of tissue engineering cornea *in vitro* with appropriate biomaterials and synthetic materials is the hope for solving these questions. How to get a sufficient amount of high activity seed cells for tissue engineering has been the challenge for tissue engineering product construction and cell therapy. The microenvironment plays an important role in the survival and development of cells and tissues. The microenvironment or simulated microenvironment can effectively induce ES and iPS differentiation in a certain direction and the embryonic microenvironment also has the effect of reverse differentiation of the adult cells. We have considered two aspects in our studies: (1) cellular microenvironment: embryonic stem cell microenvironment culture systems can make the differentiated corneal epithelial cells, conjunctiva epithelial cells^[15] and even human corneal endothelial cells^[17] obtain a strong proliferation ability and can be passaged long-term with de-differentiation cell marker expression, normal cell morphology and karyotype, but no tumorigenicity. Our preliminary findings showed that the ES microenvironment may inhibit the apoptosis of the cells by activating telomerase *via* integrin the b1-FAK-PI3K/Akt, telomerase-p21-mitochondrial axis and FAK/Wnt signaling pathway^[18,144]; and (2) stromal microenvironment: the APCS limbal produced by lipase (not existing protease digestion)^[25,30] can retain the normal extracellular matrix, collagen lamellar micro ultrastructure. It can repair and maintain the stemness and proliferation ability of the limbal stem cells after it is transplanted to the limbal stem cell deficiency rabbit model. In short, the microenvironment can be used to obtain sufficiently pure seed cells with strong proliferation capability but no immunogenicity. The microenvironment plays an important role in cell therapy and is the basis for the long-term efficacy of the treatment. Establishment of seed cells using the microenvironment will make cell therapy return to

autologous cell transplantation. Maintaining the specific three-dimensional structure and the extracellular matrix to promote the proliferation and long-term survival of the transplanted cells^[145] has great meaning. Professor Ott *et al.*^[32] stated that acellular matrix has a natural extracellular matrix which can mediate and guide organ development and mediate repair and regeneration. The key steps for the best clinical efficacy of cell transplantation are the long-term survival of the seed cells and the reconstruction of the stem cell niche.

Progress in the research of stem cell therapy for the retinal and optic nerve diseases

Retinal stem cells and optic nerve repair: Retinal diseases such as age-related macular degeneration, Leber congenital amaurosis and cone rod dystrophy are caused by lesions of retinal neuronal cells, which have an irreversible pathological process of degeneration and damage of the retinal neuronal cells, causing serious visual impairment or even blindness which currently cannot be effectively treated. Since the stem cells have self-renewal and multi-differentiation potential abilities, using stem cells as donor cells for retinal diseases treatment has become a hot topic.

In 2000, Wirtschafter *et al.*^[83] found that groups of self-renewing cells in the ciliary epithelium of the adult mice can form neurospheres when they were cultured *in vitro*. They can be induced to differentiate into specific types of neuronal cells in the retina, such as the rod cells, bipolar cells and glial cells, indicating that retinal stem cells exist in adult mammalian eyes. Ballios *et al.*^[146] found that retinal stem cells (retinal stem cell, RSC) also exist in the ciliary margin zone in people of different ages. These cells have proliferative capacity *in vitro* and can be induced to differentiate into different retinal neurons. Some of these stem cells can migrate and integrate into the host retina and can even differentiate into photoreceptor cells. These studies suggested that RSCs from different sources of animals or humans can survive and migrate to the host retina layers after transplantation. Although the implanted RSCs can migrate into the retina and differentiate into a variety of retinal cells, most transplanted RSCs remain in the subretinal space or the vitreous body, while less can be integrated and induced to differentiation, so the efficiency is not ideal.

Meyer *et al.*^[147] transplanted GFP-labeled ESCs into mouse vitreous after induced differentiation and found that the transplanted cells can migrate into the entire retina layers and differentiate into retinal neurons cells with the expression of markers such as NeuN, calretinin and cPKC- α . In 2010, Parameswaran *et al.*^[148], using a similar method as embryonic stem cell differentiation, completed the differentiation of mouse iPS cells into retinal ganglion cells, which not only highly express the retinal ganglion cells

regulation gene *Ath5*, *Wtl*, *Brn3b*, *Rpfl* and *Irx2*, but also can specifically project upwards to the superior colliculus with the synapse structure formation which has a sensitive tetrodotoxin voltage-dependent sodium current. This fully proved that iPS cells can differentiate into retinal ganglion cells. In glaucoma and traumatic optic neuropathy, the regeneration of retinal ganglion cells may be the only way to restore vision. The finding that iPS cells can differentiate into retinal ganglion cells provides a new method for the treatment of such diseases.

Arnhold *et al.*^[149] found that the cones cannot survive without healthy rod cells. Therefore, it is difficult to achieve the aim of the treatment by simply transplanting the induced iPS cells into the retina of patients with retinitis pigmentosa because the rod cells will eventually die.

Stem cell treatment for retinitis pigmentosa:

Retinal pigment epithelium (RPE) is a single layer of epithelium with polarity and a rich pigment that is located between the neural retina and choriocapillaris layer. It can support the metabolism and activities of the retinal photoreceptor cells and phagocytose the outer segment photoreceptors. Recent studies show that the retinal pigment epithelium also has self-renewing stem cells that can be induced to form other cell types under suitable conditions.

RPE degeneration diseases caused by age-related macular degeneration (AMD), hereditary retinal degeneration, macular dystrophy and Stargardt disease result in the death of photoreceptors and neural retina and eventually cause blindness. There is currently no effective treatment for retinitis pigmentosa. The transplantation of the induced differentiated stem cells to establish the retinal pigment epithelium membrane *in vivo* has been studied extensively but it is still far from functional reconstruction. Thus, looking for new ways to stimulate the repair of RPE is an important research direction for the future. With the rise of regenerative medicine research, stem cell transplantation as a regenerative therapy becomes a hotspot for research. In the past decade, scholars induced bone marrow mesenchymal stem cells, iPS cells and embryonic stem cells to differentiate into retinal pigment epithelial cells but the process of differentiation into RPE cells is not clear and only a small fraction of cells can be differentiated into RPE cells. So, the research of finding the desired factors to directly induce cell differentiation is still very popular.

In 2010, Geron biopharmaceutical company (Geron, United States) sponsored the world's first clinical trial on using hESC to repair damaged nerves. Currently, the United States Food and Drug Administration has approved the ACT company (Advanced Stem Cell Technologies) to carry out two Phase II clinical trials on using embryonic stem cells to treat macular degeneration in the United States, dry AMD and juvenile macular dystrophy (Stargardt disease). This

time, they induced hESCs to differentiate into retinal epithelial cells with purity over 99%. Approximately 50000 retinal pigment epithelial cells were isolated and injected into the retina of two patients. Four months later, the researchers found that RPE had been completely replaced by the injected retinal epithelial cells. They measured the visual acuity of the two female patients and the data confirmed that the injected cells survived and largely improved their vision. Early data suggest that hESC therapy is not only safe but also efficient. The research paper was published in the world's oldest and most respected peer-reviewed medical journal, "The Lancet"^[150]. These results from ACT have brought new optimistic hope for stem cell research. This same study found that it is crucial that the transplanted cells can attach to the Bruch's membrane and integrate into the host RPE layer and survive to have a successful therapeutic effect^[149].

CONCLUSION

In summary, recent studies show that real cell therapy is not a simple supplement of cells. The interaction, interdependence, mutual promotion and supplementation between the transplanted cells and the microenvironment are more important. The microenvironment of the recipient can regulate the transplanted cell behavior and decide their fate. The transplanted cells cannot survive long-term without the support from the microenvironment of the recipient. The survived transplanted cells can not only completely replace the recipient's cells, but also supplement the sufficient quantity and function of the recipient's cells. More importantly, they are involved in the cellular microenvironment reconstruction so the stem cells obtain a stronger self-renewal capacity and proliferation ability. Therefore, in order to improve clinical cell therapy, we should pay more attention to the characteristics and components of each stem cell microenvironment and put efforts into understanding the regulation mechanisms of the stem cell microenvironment^[151].

Abstract

Cancer is a highly heterogeneous group of diseases that despite improved treatments remain prevalent accounting for over 14 million new cases and 8.2 million deaths per year. Studies into the process of carcinogenesis are limited by lack of appropriate models for the development and pathogenesis of the disease based on human tissues. Primary culture of patient samples can help but is difficult to grow for a number of tissues. A potential opportunity to overcome these barriers is based on the landmark study by Yamanaka which demonstrated the ability of four factors;

Oct4, Sox2, Klf4, and c-Myc to reprogram human somatic cells in to pluripotency. These cells were termed induced pluripotent stem cells (iPSCs) and display characteristic properties of embryonic stem cells. This technique has a wide range of potential uses including disease modelling, drug testing and transplantation studies. Interestingly iPSCs also share a number of characteristics with cancer cells including self-renewal and proliferation, expression of stem cell markers and altered metabolism. Recently, iPSCs have been generated from a number of human cancer cell lines and primary tumour samples from a range of cancers in an attempt to recapitulate the development of cancer and interrogate the underlying mechanisms involved. This review will outline the similarities between the reprogramming process and carcinogenesis, and how these similarities have been exploited to generate iPSC models for a number of cancers.

Key words: Induced pluripotent stem cells; Cancer; Model; Reprogramming

Core tip: Human induced pluripotent stem cells (iPSCs) represent a novel method for studying the mechanisms of cancer development and progression. Recently, a number of studies have generated iPSCs from human cancer cells and cell lines, which can then be used as a model for carcinogenesis. This review outlines the similarities that exist between pluripotent and malignant cells and summarizes available studies that have generated iPSC models of cancer.

INTRODUCTION

Cancer is a heterogeneous group of diseases that accounts for an estimated 14.1 million new cases and 8.2 million deaths annually, with the number of cases expected to increase to 24 million annually by 2035^[1]. Surgical removal, chemotherapy and/or radiotherapy have become the mainstay treatment for cancer. In recent decades research has focused on improving current drugs and developing targeted therapies specific to the defining biological properties of tumours. Despite the development of these therapeutic interventions, the death rate from cancer remains high. One major reason for this is the limitations of current representative pre-clinical models for human carcinogenesis, including the difficulty in growing and expanding primary cultures. Induced pluripotent stem cells (iPSCs) offer a relevant and unlimited system to study the development and progression of cancer. This review will discuss the current models for carcinogenesis, similarities between cancer and stem cells, and recent iPSC models of human cancers.

CURRENT MODELS

Cell lines developed from human tumours are often used to study carcinogenesis. These are inexpensive and can be maintained over lengthy periods; however prolonged culture can alter the characteristics of cells resulting in them becoming less representative of primary tumours^[2]. Alterations in gene expression with prolonged *in vitro* culture are also associated with the use of cell lines, with studies using microarray data from snap-frozen normal human tissue, primary tumour biopsy tissue and tumour-derived cell lines identifying that only 2% of tissue specific and 5% of tumour specific genes were expressed when compared to their equivalent tissue or tumour^[3]. Primary cell cultures better represent inter-patient heterogeneity which exists due to differences in tumorigenic cell properties and numbers, variation in cell of origin and frequency of mutations^[4,5], however cultures have a limited life span and are difficult to obtain, maintain and expand. A number of animal models for carcinogenesis exist and have greatly increased our knowledge of cancer. However, animal models are not fully representative of carcinogenesis in the human setting due to inherent species differences including organism size and longevity as well as cancer susceptibility^[6].

STEM CELLS IN DISEASE MODELLING

Stem cells are defined by their ability for self-renewal and differentiation into a range of cell types. Their ability to replicate indefinitely overcomes the limitations of current human tissue models as they are able to generate a limitless supply of human cells. Somatic stem cells are present within many organs

and are defined by their ability for both self-renewal and differentiation to maintain homeostasis^[7]. These cells could be used to model development and disease; however adult stem cells comprise rare populations that are not easily identifiable.

The first human embryonic stem cell line was derived from human blastocysts in 1998 by Thomson *et al*^[8]. Stem cells have two defining features; self-renewal and indefinite proliferation, meaning a limitless supply of tissue can be derived from these cells. Due to these properties, it is hoped that stem cells can be used as a system for disease modelling and drug discovery. However, research using human embryonic stem cells (hESCs) is hampered due to the ethical issues surrounding ESCs and the stringent restrictions enforced as a result.

An alternative to hESCs and adult stem cells are induced pluripotent stem cells (iPSCs), generated in a landmark study by Takahashi *et al*^[9]. From a screen of 24 candidates, 4 factors were identified which were able to reprogram mouse somatic cells to pluripotency; Oct3/4, Sox2, c-Myc and Klf4. These cells showed characteristics of ESCs including morphology, marker expression and the ability to form all three embryonic germ layers^[9]. Subsequently, the same four factors were shown to also have the ability to reprogram human adult dermal fibroblasts to iPSCs^[10]. An alternative cocktail of factors consisting of Oct4, Sox2, Nanog and Lin28 was also shown to generate iPSCs from human fibroblasts^[11]. Human iPSCs possess a number of features that are typical of ESCs including self-renewal and expression of ESC marker genes. Importantly, as for hESCs, iPSCs have the ability to differentiate both *in vitro*, via the formation of embryoid bodies (EBs) comprising all three germ layers and *in vivo*, as demonstrated by the formation of teratomas^[10]. The use of iPSCs also resolves the ethical issues associated with hESCs, a controversial topic due to the use of blastocyst stage human embryos to derive the cells^[12]. As iPSCs can be generated from somatic cells, they also show great potential for developing patient specific models of diseases, which can be used to study the underlying mechanisms of disease development and the efficacy of treatments^[13].

REPROGRAMMING VS CARCINOGENESIS

A number of similarities exist between the processes of reprogramming and carcinogenesis. Cancer cells have a number of defined characteristics including sustained proliferative signaling and replicative immortality^[14]. Stem cells also possess this intrinsic ability for both self-renewal and proliferation, highlighting their similarity to cancer cells.

Cancer stem cells

Tumours, like normal tissue, are heterogeneous populations of cells, varying in phenotype, function

Figure 1 Schematic illustrating normal stem cell expansion and the cancer stem cell model. Normal stem, transit-amplifying or differentiated cells can undergo oncogenic reprogramming resulting in generation of cancer stem cells (CSCs). Non-CSCs also demonstrate plasticity and can dedifferentiate to CSCs.

and gene expression^[15]. Furthermore, studies from a number of cancers have shown that not all cells can regenerate tumours upon injection into immunodeficient mice, a functional assay which is now used to identify cells termed cancer stem cells (CSCs)^[16]. CSCs can be defined as tumour cells which have the ability for both self-renewal to maintain the stem cell pool, and differentiation to the heterogeneous cell types which maintain the tumour^[17], and therefore share the quintessential properties of normal stem cells (Figure 1). Importantly, due to these properties, CSCs which survive chemotherapy are able to re-establish tumours^[18]. Whilst the origin of CSCs is not fully known, it has been suggested that CSCs could arise as a result of mutations in stem, transit-amplifying, differentiated or cancer cells leading to acquisition of malignant and/or stem cell properties^[19]. Understanding the process by which CSCs are generated and how they maintain tumours is critical to develop therapies which target this cell population and therefore prevent tumour recurrence.

CSCs were originally identified in acute myeloid leukemia, however putative CSCs have now been identified in solid cancers including breast, colon, brain, prostate, and lung cancer^[20]. These cells could be used to study tumours however they are difficult to isolate, particularly in solid tumours which are very heterogeneous and therefore are not fully represented by tissue samples taken from a single site within the tumour^[21]. Reprogramming of primary cells of interest derived from patients into iPSCs could allow generation of disease- and patient-specific models to study carcinogenesis and to further interrogate the CSC model. An interesting addition to the CSC model is the concept of tumour cell plasticity. A number of studies have shown that non-CSCs can dedifferentiate and acquire properties of stem cells, converting them to CSCs which can then maintain the tumour. In colorectal cancer, Wnt signaling induced by the tumour microenvironment activates CSC properties in differentiated cancer cells^[22], whilst transformed

human mammary epithelial cells can spontaneously convert to cells with a CSC phenotype both *in vitro* and *in vivo*^[23].

Cell reprogramming, clonal expansion and evolution

Carcinogenesis is a multi-step process consisting of initiation, promotion, conversion to malignancy and progression^[24]. Cancer is known to undergo clonal expansion throughout this process, resulting from an initial change or mutation in a single cell which confers a growth advantage allowing for enhanced proliferation and expansion of this population. Further mutations then occur within cells forming subpopulations which expand and continue to accumulate changes and mutations which further alter proliferation, cause loss of differentiation and enhance invasive potential, resulting in a malignancy which is genetically and phenotypically divergent from the normal tissue counterpart^[25]. Clonality is also a defining feature of stem cells, and is often used to measure the ability of such cells to self-renew^[26].

Role of epithelial-mesenchymal transition and its significance

Epithelial-mesenchymal transition (EMT) is defined as a conversion of cells from an epithelial to mesenchymal phenotype with loss of epithelial properties such as apical-basal polarization and cell-cell adhesion and gain of mesenchymal properties such as motility, degradation of the extracellular matrix and resulting invasiveness^[27,28]. This process is critical for normal development- during gastrulation for formation of the mesoderm, and also at subsequent stages such as neural crest formation and heart development^[29]. Similarly, EMT occurs during differentiation of ESCs^[30], whilst its opposing process mesenchymal-epithelial transition is necessary to reprogram cells to pluripotency^[31]. EMT has also been implicated in cancer with roles in a number of cancer hallmarks. The EMT inducers SNAIL1 and SNAIL2 correlate with relapse and survival in breast, ovarian and colorectal

cancers, suggesting that EMT is associated with poor outcome^[28]. Expression of EMT genes is also associated with cancer progression as these expression profiles are identified at the invasive front of a number of cancers including colon carcinoma, papillary thyroid carcinoma and some breast carcinomas^[28]. Furthermore, an EMT expression profile was shown to associate with development of metastasis in cutaneous malignant melanoma^[32].

TGF β , an inducer of EMT, has a dual role in cancer, acting as a tumour suppressor and activator of apoptosis whilst also promoting immune tolerance, invasion and metastasis^[33]. TWIST1/2 proteins, which also act as EMT inducers, are increased in a number of human cancers and prevent senescence in cancer cells by inhibition of the p53 and Rb pathways^[34]. Finally, EMT has also been implicated in resistance to chemotherapies, with evidence that a number of chemoresistant cell lines are induced to undergo EMT^[35,36].

Role of reprogramming factors in cancer

Transcription factors which play a critical role in reprogramming cells to pluripotency have also been identified in human cancers. Oct4 is a transcription factor with roles in embryogenesis^[37] which is expressed in all testicular germ cell tumours and also pre-malignant carcinoma *in situ* lesions^[38], as well as in breast, pancreas and colon cancer cDNA panels^[39]. Furthermore, induced expression of Oct4 in the somatic cells of mice results in epithelial dysplasia, providing further evidence of a role for stem cell genes in carcinogenesis^[40].

Immunohistochemical staining of a panel of oral squamous cell carcinoma (OSCC) patients identified an increased incidence of Oct4 expression with advanced stages of the disease, with enhanced nuclear staining in higher grade oral cancers^[41]. Transduction of primary human breast epithelial cultures with Oct4 generated colonies with self-renewal capacity, which similarly to oral squamous cells with overexpressed Oct4 showed enhanced expression of mesenchymal markers and a loss of epithelial markers. These cells were also highly tumorigenic, forming poorly differentiated, high grade tumours after injection into nude mice^[42]. Oct4 has also been implicated in cervical cancer with increasing numbers of Oct4 expressing cells in both carcinoma *in situ* and invasive cervical cancer compared to normal cervical tissue, suggesting a role for Oct4 in the development of cervical cancer. Overexpression of Oct4 in cervical cancer cell lines resulted in increased tumour volume and weight upon injection into mice, and decreased apoptosis both *in vitro* and *in vivo* compared to controls^[43].

MYC encodes the Myc transcription factor which regulates genes involved in cell growth and proliferation^[44]. Myc is a known oncogene and one of the most commonly altered genes in human cancers with copy number

alterations in 14% of cancer samples^[45]. Translocation of c-Myc from chromosome 8 to chromosome 2, 14 or 22 in Burkitt lymphoma cells was the first evidence for the role of Myc in cancer development^[46]. Myc translocation is also common in multiple myeloma where the oncogene is fused to an IgH or IgL locus in early carcinogenesis^[47]. Abnormalities at the c-Myc or I-Myc locus have been identified in 19/20 multiple myeloma cell lines and 50% of advanced primary cancers^[48]. Finally, Myc has also been implicated as a downstream target of deregulated Notch signalling which is apparent in T cell leukaemia, with the two molecules concurrently regulating leukaemic cell growth and proliferation^[49].

Myc has also been implicated in solid tumours. c-Myc amplification occurs in 25% of primary breast carcinomas with protein overexpression in 45% of breast tumours, and was significantly correlated with poorly differentiated and highly proliferative tumours^[50]. Overexpression of c-Myc mRNA is also thought to occur in 60%-80% of human colorectal adenocarcinomas^[51] and has been shown to enhance colon cancer cell angiogenesis *via* inhibition of HIF-1 α degradation and promotion of VEGF expression^[52].

Myc is overexpressed or activated in over 50% of human cancers, but in most human cells cannot independently induce tumorigenesis, instead cooperating with other events such as loss of p53 or overexpression of Bcl2 to bypass normal cell checkpoints and initiate carcinogenesis^[53]. Interestingly, the level of Myc expression has been shown to produce varying effects, with low level deregulated Myc resulting in proliferation alone whilst high levels of Myc overexpression are required to activate tumour suppressor mechanisms such as ARF induction leading to cellular apoptosis^[54].

As is the case with Oct4, Nanog expression correlates with poor survival in OSCC and also in nasopharyngeal carcinoma if co-expressed with Oct4^[41,55]. High levels of Nanog expression are also present in breast, lung, ovarian and colon cancer cell lines, and furthermore in cervical cancer Nanog expression increases with progression from cervical intraepithelial neoplasia to invasive cervical carcinoma and is associated with poorer prognosis. Inhibition of Nanog by siRNA decreased proliferation in a mouse model of colon cancer, implicating Nanog as a potential therapeutic target in the disease^[56].

Sox2 is contained within the most significantly amplified peak in lung and esophageal squamous cell carcinoma (SSC), identifying it as an oncogene for these cancers^[57]. Sox2 is also expressed in both mouse and human pre-neoplastic skin lesions and squamous cell carcinomas, but not in normal epidermis. Deletion of Sox2 in melanoma or SSC caused regression of tumours, and identified a number of genes involved in proliferation, stemness and cell survival which are regulated by Sox2, providing further evidence of a role for Sox2 in carcinogenesis^[58].

A number of studies have suggested a role for

Figure 2 Generation of induced pluripotent stem cells from both normal and malignant patient tissue could be used to model carcinogenesis and elucidate the mechanisms which underlie the stages of cancer development. iPSC: Induced pluripotent stem cell.

typical stem cell genes in carcinogenesis. An 11-gene stem cell-like signature found in primary prostate tumours can be used as a predictive tool for prostate, breast and lung cancer patients, amongst other cancer types^[59]. Construction of a gene module map by Chang *et al.*^[60] identified modules specific to adult and murine ESCs and found that the ESC module was activated in human epithelial cancers. Activation of these genes was associated with poorly differentiated breast tumours with an increased risk of metastasis and death, and was also associated with an increased risk of death in lung adenocarcinomas. The c-Myc oncogene was subsequently shown to induce the ESC-like module both *in vitro* and *in vivo*^[60], consistent with the well-described role of c-Myc in stem cell self-renewal^[61]. An ESC signature developed by Weinberg's group showed enrichment of stem cell genes in poorly differentiated and larger breast tumours and again this was associated with a poorer survival. The ESC signature was also associated with high grade gliomas and bladder carcinomas^[62].

Metabolism

Altered metabolism has been implicated in cancer due to the "Warburg effect" whereby cancer cells use glycolysis for energy production rather than mitochondrial oxidative phosphorylation^[63]. Aerobic glycolysis occurs in cultured cancer cells and pluripotent stem cells^[64]. This is mediated by uncoupling proteins (UCPs) which uncouple oxidative phosphorylation from glycolysis, including UCP2 which is thought to be important for pluripotency^[65] and is also increased in most human color cancers^[66] as well as showing high expression in 90% of ovarian carcinomas and 94% of breast carcinomas^[67]. Recent studies have found that during induction of pluripotency in somatic cells, genes involved in glycolysis are upregulated whilst those involved in oxidative pathways are downregulated, mediating a switch from oxidative phosphorylation to glycolysis^[68] in a similar manner to that seen in carcinogenesis.

CURRENT MODELS OF CARCINOGENESIS

The generation of iPSCs from human somatic cells heralds a new era in disease modelling, allowing the development of patient specific models. As previously mentioned, despite improvements in cancer treatment the disease is still a major cause of morbidity and mortality. The lack of a relevant model to study the development of cancers and their progression has limited research which is suitable for translation to the clinical setting. Generation of iPSCs from human cancer cells represents an opportunity to develop *in vitro* models of carcinogenesis for specific cancer types (Figure 2).

Recently, a number of studies have generated iPSCs from cancer cells with the hope of developing such a model (summarized in Table 1). One of the earliest attempts to generate iPSCs from malignant cells used retroviral transduction of Oct3/4, Sox2, Klf4 and c-Myc into cancer cell lines from pancreatic, liver, stomach and colorectal cancers. These cancer-derived iPSCs had slower proliferation and increased sensitivity to chemotherapeutic agents in comparison to their parental cells^[69].

iPSCs and chronic myeloid leukemia

Carette *et al.*^[70] generated iPSCs from the KBM7 chronic myeloid leukemia (CML) cell line. Interestingly, despite the sensitivity of the KBM7 cell line to imatinib, the iPSCs generated lost their BCR-ABL dependence and became resistant to imatinib^[70], the tyrosine kinase inhibitor which targets the BCR-ABL protein which defines CML^[71]. In a further study, Kumano *et al.*^[72] derived iPSCs from primary cultures from two CML patients and showed stem cell morphology and markers along with the ability to differentiate into haematopoietic progenitors which expressed the BCR-ABL fusion protein. Again, these iPSCs were generated from imatinib-sensitive patients but became resistant. Once differentiated, immature cells (CD34⁺38⁺90⁺45⁺) were identified which were resistant

Table 1 Current induced pluripotent stem cells models of carcinogenesis

iPSC: Induced pluripotent stem cells; PDAC: Pancreatic ductal adenocarcinoma; CML: Chronic myeloid leukaemia; JML: Juvenile myelomonocytic leukemia.

to imatinib and demonstrated phenotypic similarities to CML stem cells. This cell population may therefore be useful to interrogate the role of stem cells in CML and the mechanisms underlying the development of resistance^[72].

iPSCs and pancreatic ductal adenocarcinoma

iPSCs have also been used to study pancreatic ductal adenocarcinoma (PDAC), which currently has no suitable model. iPSC lines were generated from human tumours and injected into immunodeficient mice. After 3 mo, pancreatic intraepithelial neoplasia-like structures could be identified in 9 out of 10 teratomas, and by 9 mo solid tumours were present, suggesting that PDAC derived iPSCs can capture the process of carcinogenesis from pre-malignant lesions to the malignant phenotype. *In vitro* 3D culture of cells harvested from mice at 3 mo identified 25 proteins which were secreted by all teratomas, of which 8 have been previously reported in PDAC, pancreatic epithelial neoplasia or intraductal papillary mucinous neoplasms^[73]. However, although 9 patient samples were used in the study, only 1 iPSC line with a cancer genotype was generated from a single patient, which is consistent with other studies suggesting the difficulty of reprogramming malignant cells^[74].

iPSCs and juvenile myelomonocytic leukemia

A model of juvenile myelomonocytic leukemia using iPSCs derived from two patients has also recently been generated. Cells were able to differentiate to myeloid cells which showed phenotypic similarities to the primary tumours including enhanced proliferation, suggesting they could be a useful resource to model the disease^[75].

Gastrointestinal cancer and glioblastoma

iPSCs have also been generated from a number of gastrointestinal cell lines using retroviral transduction. These cancer-derived iPSCs showed reduced tumorigenic potential *in vivo* as well as increased sensitivity to anti-cancer drugs and decreased proliferative rate^[69]. This decrease in tumour forming ability is a concern for the use of cancer-derived iPSCs as it is thought that reprogramming cells removes epigenetic marks which are important for lineage identity and malignancy. However, lineage specificity may remain due to incomplete

reprogramming and can also be induced by differentiation. For example, in iPSCs derived from glioblastomas both lineage and cancer associated methylation marks were reset however during differentiation along the neural lineage cells maintained their malignant phenotype^[76,77].

Modelling carcinogenesis using non-malignant cells

An alternative method to study carcinogenesis using iPSCs is to reprogram normal cells to pluripotency and follow their development to interrogate the processes which contribute to cancer development (Figure 2). iPSCs are able to differentiate into all adult cell types and can therefore be used to model development of human tissues^[78]. iPSC models of organ and tissue development can then be monitored in real-time to identify any changes which may induce the onset of carcinogenesis. Recently, an *in vitro* model of skin was developed using iPSCs differentiated to keratinocytes and fibroblasts, providing an iPSC-generated *in vitro* model of a human organ^[79].

Alternatively, iPSCs from normal somatic cells could also be manipulated to study carcinogenesis through overexpression or silencing of oncogenes, tumour suppressor genes and other factors thought to play a role in carcinogenesis, or alteration of the microenvironment. The response of cells to these changes can then be studied to determine the roles of such factors in cancer initiation and progression.

CONCLUSION

Pluripotent cells and cancer cells share a number of characteristics including the ability for continual proliferation and self-renewal. iPSCs offer an opportunity to develop disease-specific models for carcinogenesis by reprogramming malignant cells. A number of studies have successfully generated iPSCs from human tumours and cancer cell lines and used them to study the underlying mechanisms of cancer. Generation of iPSCs from other cancer types is necessary to develop relevant *in vitro* models for carcinogenesis.

purification of human bone marrow mesenchymal stem cells. This marker has been shown to be specifically expressed by these cells. Thus, CD271 has been proposed as a versatile marker to selectively isolated and expand multipotent mesenchymal stem cells with both immunosuppressive and lymphohematopoietic engraftment-promoting properties. This review focuses on this marker, specifically on identification of mesenchymal stem cells from different tissues. Literature revision suggests that CD271 should not be defined as a universal marker to identify mesenchymal stem cells before culture from different sources. In the case of bone marrow or adipose tissue, CD271 could be considered a quite suitable marker; however this marker seems to be inadequate for the isolation of mesenchymal stem cells from other tissues such as umbilical cord blood or wharton's jelly among others.

Key words: Mesenchymal stem cells; CD271; Low-affinity nerve growth factor receptor; p75; Bone marrow

INTRODUCTION

In recent decades researchers have focused on regenerative medicine as a interesting option

for the treatment of different pathologies^[1,2]. Mesenchymal stem cells (MSC) are ideal candidates for cellular therapy due to their characteristics^[3]. MSC are viewed as clinically promising because of their differentiation capacity and pro-regenerative features^[4,5]. Moreover, MSC could be used for both autologous and heterologous transplant due to their low immunogenicity^[6]. Friedenstein *et al.*^[7] discovered bone marrow (BM)-MSC. They demonstrated that BM contains a population of cells with a high proliferative capacity that adhere to plastic. These authors were also the first to propose the capacity of these cells to form colonies from a single cell (the fibroblast-colony forming unit F-CFU)^[7-9]. Since Friedenstein *et al.*^[7] described MSC in the BM in the 70's several researchers have focused their attention on this type of adult stem cell. After their initial isolation from humans, MSC have since been successfully harvested from many other species including: mouse, rat, dog and horse^[10]. They have also been isolated from almost every type of tissue, including: BM, adipose tissue, liver, skeletal muscle, amniotic fluid, umbilical cord blood (UCB) or dental pulp^[11-14]. Due to the heterogeneity of the results obtained by many groups, the Mesenchymal and Tissue Stem Cell Committee of the International Society for Cellular Therapy proposes minimal criteria to define human MSC. They proposed three criteria to define MSC in culture: adherence to plastic, specific surface antigen expression and multipotent differentiation potential^[15]. All these criteria perfectly define MSC in culture, however the *in vivo* identification of MSC, before culture, is not as well established. In 1999, Pittenger *et al.*^[16] described a small percentage of MSC present in BM (0.001%-0.01%) so this could explain the difficulty in establishing the exact phenotype of MSC before culture^[16].

A suitable method of selection would allow the employment of MSC in different pathologies directly after their isolation or after their *in vitro* expansion. Pre-culture identification markers would ensure higher purity than that obtained with selection based on adherence to plastic. Many investigators direct their efforts towards find a marker or a combination of markers to ensure their selection.

Up until now, CD271 (LNGFR) has been described as one of the most specific markers for the purification of human BM-MSCs^[17,18]. CD271, also known as low-affinity nerve growth factor receptor (LNGFR), nerve growth factor receptor (NGFR), or p75NTR (neurotrophin receptor), belongs to the tumor necrosis factor superfamily^[19]. Taking into account that this marker has been the most commonly used in the isolation of BM-MSC this review will focus on to the identification of MSC from different tissues (Table 1).

BM

Several independent studies have confirmed the

specificity of CD271 on MSC isolated from BM. At the beginning of the last decade, Quirici *et al.*^[18], (2002) published that the anti-CD271 antibody is specific for a population of multipotent BM cells and suggested the use of this marker as an option for the selection of MSC from BM^[18]. The same year, Jones *et al.*^[20], conducted a study in which they carried out a cellular purification from BM with antibody-conjugated magnetic beads. They found that the D7-FIB-positive fraction contained not only all the CFU-F activity but also a unique population of CD45^{low}/LNGFR⁺ cells. These cells were adherent, proliferative, and multipotent following cell sorting and standard expansion^[20]. In 2006 the same group, suggested the need to find a way to count MSC based on the use of surface markers considering that up to this point researchers were using CFU-F assays for the enumeration of MSC. Published results demonstrate the use of flow cytometry as a rapid MSC detection method and suggested *in vivo* selection of the phenotype CD45^{low}/LNGFR⁺/D7FIB⁺^[21]. Following the studies started in 2002, Jones's group continued providing more data about this marker. In a comparative study, Jones *et al.*^[22] demonstrated that CD271 antigen (followed by CD146, CD106, D7-FIB, CD13 and CD166) remained one of the most selective markers for enriching progenitor cells from MSC of human BM. These results are supported by Kuçi *et al.*^[23,24], who published a study which demonstrated that the CD271 is an adequate marker for the selection of multipotent BM cells with immunosuppressive properties. Afterwards, the same group published another study in which they demonstrated that CFU-F activity was found only in the CD271⁺ cell fraction, whereas no CFU-F was observed in the CD271⁻ population^[24]. Flores-Torales *et al.*^[25], (2010) proposed the use of a single marker, CD271, for the selection of MSC from BM before culture. These authors maintain that the use of this marker would reduce costs and provide a rapid and simple way of obtaining MSC. However, a high percentage of CD271⁺ cells in BM and synovium co-express CD34, which disqualifies CD271 as a unique marker for the isolation of MSC. Nevertheless, these studies, among others, have confirmed the usefulness of CD271 in combination with other markers such as CD45 to isolate fresh BM-MSC. Poloni *et al.*^[26], (2009) carried out a selection of CD271 positive cells and cultivated them in a media supplemented with 10% allogeneic human sera, cells maintained the capacity to differentiate and no karyotypic variations were observed. Our group utilized this marker (CD271⁺/CD45⁻) to quantify the MSC population in BM samples obtained for cell therapy using flow cytometry^[27]. Recently Mabuchi *et al.*^[28] performed a comprehensive screening of putative surface markers to select the most useful ones for prospectively identifying a pure MSC population in human BM. They concluded that the combination marker CD271⁺CD90⁺CD106⁺ can

be used selectively to isolate the most potent and genetically stable MSC^[28]. Therefore, CD271 may be considered a suitable marker for determining MSC in BM.

It has been demonstrated that as the age of donors increases the number and potential for differentiation of BM MSC diminish^[29]. Taking into consideration that it is not easy to obtain such blood donors other sources for the obtention of MSC are required.

Adipose tissue is an interesting option for this end. MSCs can be isolated from fat tissue easily obtained by liposuction. It has been demonstrated that these cells are easily cultivated and have the capacity to differentiate into various cell lines^[30].

ADIPOSE TISSUE

In 2002 a type of stem cell from adipose tissue was isolated for the first time: adipose-derived stem cell (ADSC)^[31]. Since then, it has been demonstrated that adipose tissue provides an abundant source of MSC with similar yields to those obtained from BM. Furthermore, ADSC have a similar differentiation capability, morphology, and phenotype to MSC collected from BM^[31]. It has been shown in mice that p75NRT seems to be a useful marker for ADSC isolation^[32]. After this, Quirici *et al*^[33] selected CD271⁺ cells immune-magnetically from ADSCs in humans in a similar way as has been done from BM by others authors. CD271⁺ cells showed higher clonogenic and differentiation potential compared to plastic adherent ADSC. Thus these authors demonstrated the utility of this marker in the selection of ADSC cells^[33]. Cuevas-Diaz Duran *et al*^[31] used this marker to analyze if there was a relationship between donor's age and CD271⁺ cell yield in freshly isolated ADSC. They suggested that the proportion of CD271⁺ ADSC decreased with

age; however, positive cells were present in all age groups and their frequency was higher than what has been found in BM. Therefore, CD271⁺ cells from adipose tissue were proposed as the primary choice for tissue regeneration and autologous stem cell therapies in older subjects^[31].

The umbilical cord, placenta and placental membrane have been presented as cheap and attractive alternatives for the obtention of MSC^[34].

UMBILICAL CORD

The UC is the structure that connects the foetus to the placenta. The UC has two arteries and a vein wrapped in a gelatinous connective tissue called Wharton's jelly (WJ). The UC has characteristics ideal for procuring of MSC, because its use would not generate ethical conflicts, it is easily obtained and it is an abundant resource which is discarded^[35]. As described below, MSCs have been described from UCB and from WJ.

UCB

UCB was found to contain different populations of stem cells, a unique feature not shared with peripheral blood. Some authors propose that UCB derived MSC show high morphological and molecular similarities to BM derived MSC including the lack of hematopoietic surface antigens^[36]. The presence or absence of MSC in UCB has been quite controversial. A few researchers have denied the presence of MSC in UCB such as Yu *et al*^[37], (2004) whose results suggest that early fetal blood is rich in MSC however, the term UCB is not used. On the other hand, some authors propose the difficulty in obtaining MSC from UCB to be due to their low frequency, inferior to that in BM. Up until now, the literature does not

show interesting results regarding the obtention, isolation and purification of UCB MSCs. Some publications show that the MSC can be obtained in a low percentage of UCB units (20%-63%)^[38,39]. These data bring into question the possibility of considering the UCB as a resource for acquiring MSC^[40]. However, several authors have differentiated UCB-MSC *in vitro* to osteogenic, chondrogenic, neural and hepatic lineages successfully^[41-43]. Our group has not been able to identify MSC from UCB using conventional methods of adherence to plastic. We observed a heterogeneous population of adherent cells, with a rounded and spindle-shaped appearance^[44]. Our results are in concordance with Perdikogianni *et al.*^[45], (2008). We also used CD271 for the presence of cells from UCB expressing this marker. Our results showed no validity for this marker in this tissue and these data are in agreement with two studies published in parallel. Attar and coworkers showed that CD271 did not contribute to isolation of MSC from UCB^[46]. Watson *et al.*^[47], (2013) published that, CD271 is an efficient marker for MSC isolation from BM but failed to isolate MSC from UCB. Therefore, our experience and results from the literature suggest that CD271 is not a suitable marker for the identification of MSC from UCB without culture.

WJ

Thomas Wharton was the first to describe WJ in 1656. WJ is a gelatinous substance composed of various isoforms of collagen and proteoglycans. The principal function of WJ is to protect the arteries and veins from the compression and torsion that they can be subjected to. These provide a bidirectional flow, providing oxygen and nutrients that contribute to the adequate development of the foetus and eliminating waste and carbon dioxide^[48]. It has been demonstrated that human WJ-MSC present an elevated capacity for autoregeneration and have been compared with those obtained from BM^[39]. MSC derived from the discarded UC, more precisely WJ, offer a low-cost and pain-free collection method of MSC that may be cryogenically stored, and are considered extremely favorable for tissue engineering purposes^[35]. Data published by our group highlight the ineffectiveness of CD271 as a marker for the isolation of MSC from WJ before culture^[44]. These results are supported by data published by Margossian *et al.*^[35]. They studied the expression of CD271 *in situ* on fresh fragments of WJ and they observed it to be weakly expressed^[35]. Although few studies have focused on determining the effectiveness of this marker in WJ, those that have been carried out suggest that CD271 is not a suitable marker to identify MSC from WJ before culture.

PLACENTA

Human placenta, plays a fundamental and essential

role in fetal development, nutrition, and tolerance^[49]. Various reports have demonstrated that human term placenta is a plentiful source of MSC^[50,51]. Considering the complexity of the structure of the placenta, Parolini *et al.*^[49] published a paper in order to define, as clearly as possible, the region of origin and methods of isolation of cells derived from this tissue. This work arose out the first international Workshop on Placenta Derived Stem Cells, (March 2007). One of the main characteristics is the existence of four regions in the placenta: Amniotic epithelial, amniotic mesenchymal, chorionic mesenchymal and chorionic trophoblastic. From these regions, the following cell populations are isolated: amniotic epithelial cells, amniotic mesenchymal stromal cells, chorionic mesenchymal stromal cells, chorionic trophoblastic stromal cells^[49].

In 2007, Soncini *et al.*^[52], achieved the isolation of amnion mesenchymal cells (AMSC) and chorion mesenchymal cells (CMSC). These MSCs were isolated by a mechanical separation followed by enzymatic digestion. AMSC and CMSC show MSC characteristics, such as adherence to plastic, fibroblastic morphology and the capacity to form colonies. Both types of cells when analysed by flow cytometry show phenotypes similar to BM-MSC. Also, AMSC and CMSC demonstrate high plasticity when cultivated in adequate differentiating media, showing that these can differentiate into fat, bone and cartilage.

In order to isolate cells with MSC characteristics from human fetal membranes, AMSC and CMSC expressing CD271 were enriched by immunomagnetic isolation. CD271⁺ cells were demonstrated to possess higher clonogenic and osteogenic differentiation potentials than CD271-depleted fractions. Based on these findings, these authors suggest that amnion and chorion can be considered as a novel and convenient sources of adult MSC^[52]. Another study published in 2007 by Battula *et al.*^[50] confirmed the possibility of obtaining MSC from chorion; however, their results showed that CD271 is not an adequate marker for the identification of MSC. They demonstrated that CD271 is expressed only at negligible levels on naive placenta MSC. Nevertheless, they identified FZD9 (frizzled-9) as a novel marker for isolation of MSC from chorionic placenta and showed that cells with CFU-F capacity reside exclusively in the FZD9⁺ population^[50]. FZD proteins comprise a family (FZD1-10) of seven transmembrane-spanning receptors^[53]. Based on the literature, it is still not possible to confirm CD271 as a suitable marker for the isolation of MSC from placenta.

Because of their attractiveness, researchers have attempted to isolate MSC from many tissues and their existence has been documented in several of them. Here, we discuss some studies which have referred to the use of CD271 for the identification of MSC from tissues other than those discussed above.

OTHER SOURCES

Chong *et al.*^[54] in 2012 demonstrated that MSC from peripheral blood maintain similar characteristics and have similar chondrogenic differentiation potential to those derived from BM. Based on the literature, we have found just one reference which documents that CD271 positive selection can not help isolation of MSC from granulocyte colony-stimulating factor (G-CSF) mobilized peripheral blood^[55]. Another source is published by Jones *et al.*^[56], (2010). They showed that CD45^{low}CD271⁺ MSC are abundant in the trabecular bone cavity and indistinguishable from aspirated CD45^{low}CD271⁺ MSC. Moreover, MSC are found in human dermis. Vaculik *et al.*^[57] distinguished dermal MSC from differentiated fibroblasts. For this they selected CD271⁺ and SSEA-4⁺ cells from adherent dermal cells and checked their differentiation capacity. They observed that a CD271⁺ dermal population presented a greater potential for adipogenic, osteogenic and chondrogenic differentiation.

Besides CD271, several markers have been used in order to identify MSC before culture. Possibly one of the most commonly used markers for this purpose is Stro-1. After a complete review, Lv *et al.*^[58], concluded that Stro-1 expression appears not be a universal marker for MSC from different tissues. Another marker used to identify MSC is SSEA-4. It is an embryonic stem cell marker and it was documented in the isolation of genuine MSC from BM^[59]. Conversely, other authors reported no detection of SSEA-4 expressing cells in unsorted BM^[60,61].

Taken together, the data discussed in this review suggest that CD271 would not be considered as a universal marker to identify MSC before culture. In the case of BM or adipose tissue, CD271 could be considered a quite suitable marker for the isolation of MSC. As described in this review, several independent studies confirm the specificity of this marker in different tissues. However, CD271 is not adequate in the isolation of MSC from other tissues such as UC or UCB. Moreover, in the case of placenta contradictory results have been obtained by different groups. These contradictory results could be due to variations in the methodologies used by different laboratories. Hines *et al.*^[62] published an interesting study in which they demonstrated that membrane markers are notoriously dynamic and their expression can often be dependent on minor technical issues. Technical issues, indicating that the reproduction of results is the corner-stone of science^[62].

Due to the interest in MSC for their potential applications in the clinic, it is necessary to continue research in this field, in order to find a marker or markers for optimal selection and identification of MSCs without culture. This would allow the generation of purer cultures than those obtained by adherence to plastic alone and possibly direct application avoiding cultivation costs, time and risk of contamination.

that defy doctors and researchers around the world. Stem cells can be divided into three main groups: (1) embryonic stem cells; (2) fetal stem cells; and (3) adult stem cells. In terms of their capacity for proliferation, stem cells are also classified as totipotent, pluripotent or multipotent. Adult stem cells, also known as somatic cells, are found in various regions of the adult organism, such as bone marrow, skin, eyes, viscera and brain. They can differentiate into unipotent cells of the residing tissue, generally for the purpose of repair. These cells represent an excellent choice in regenerative medicine, every patient can be a donor of adult stem cells to provide a more customized and efficient therapy against various diseases, in other words, they allow the opportunity of autologous transplantation. But in order to start clinical trials and achieve great results, we need to understand how these cells interact with the host tissue, how they can manipulate or be manipulated by the microenvironment where they will be transplanted and for how long they can maintain their multipotent state to provide a full regeneration.

Key words: Stem cells; Stem cell therapy; Adult stem cells; Neural stem cells; Bone marrow stem cells; Mesenchymal stem cells; Olfactory ensheathing cells

Core tip: Adult stem cells are useful tools to treat various diseases, but we must first comprehend how they work to use their capacity at maximum. Ageing, inflammation, other stem cells of the host tissue and the co-transplantation with another stem cells type can change their profile and compromise the regeneration process. Having these barriers in mind, several researchers started to look more closely to adult stem cells. In this review we will show some interesting results from experimental and clinical trials at this group of stem cells.

Abstract

Stem cells represent a promising step for the future of regenerative medicine. As they are able to differentiate into any cell type, tissue or organ, these cells are great candidates for treatments against the worst diseases

INTRODUCTION

Stem cells represent a promising step for the future of regenerative medicine. As they are able to differentiate into any cell type, tissue or organ, these cells are great candidates for treatments against the worst diseases that defy doctors and researchers around the world.

Stem cells can be divided into three main groups: (1) embryonic stem cells, which are cells of the inner layer of the blastocyst and form the three primary germ layers (ectoderm, mesoderm and endoderm); (2) fetal stem cells, which are found in the embryo and form the various organs of the human body; fetal stem cells include neural crest cells, hematopoietic cells, fetal mesenchymal stem cells, fetal neural stem cells and pancreatic islet progenitors; and (3) adult stem cells, which are found in various regions of the adult organism, such as bone marrow, skin, eyes, viscera and brain (adult stem cells are also known as somatic stem cells).

In terms of their capacity for proliferation, stem cells are also classified as totipotent, pluripotent or multipotent. Totipotent stem cells have a high capacity for differentiation and can form a complete individual, but they lack the capacity for self-renewal. Pluripotent cells, on the other hand, are capable of differentiating into any of the 200 or more kinds of cells that make up the human body. Finally, multipotent cells give rise to cells of a specific tissue, *e.g.*, hematopoietic stem cells give rise to blood cells, while neural stem cells give rise to neurons and glia^[1,2]. Another group of stem cells that has been extensively studied in recent years includes induced pluripotent stem cells (IPS). IPS cells are adult differentiated cells that return to their pluripotent state by genetic engineering mechanisms. Some researchers believe these cells have great potential, but there have been numerous reports of extensive epigenetic and transcriptome aberrations with these cells, as well as tumor formation^[3,4].

ADULT STEM CELLS

Adult stem cells are multipotent cells that can differentiate into unipotent cells of the residing tissue, generally for the purpose of repair. These cells can be obtained from several different regions of the adult organism, they can be used for autologous transplantation and their great advantage resides in the fact that embryos do not have to be destroyed in order for these cells to be obtained^[5,6].

Regardless of the cell type chosen, there is a

relative degree of difficulty in extracting viable stem cells from their *in vivo* niche. There is approximately one hematopoietic stem cell for every 10000 bone marrow cells, and one mesenchymal stem cell for every 10000-100000 cells^[7]. For this reason, researchers use substances that can stimulate the growth of these cell populations as well as facilitate the process by which they are obtained. For example, G-CSF (granulocyte stimulating factor) stimulates the production of CD34⁺ hematopoietic stem cells that can be extracted by simple puncture of peripheral blood, which is less invasive than bone marrow aspiration. Other substances that enhance the isolation of adult stem cells are currently under investigation^[8].

Another issue of concern is the cell senescence related to the expansion time *in vitro*. Cell proliferation is decreased mainly due to telomerase activity, and several researchers have focused on telomerase activation in an attempt to increase and maintain population growth *in vitro*. However, it focusing only on correcting the shortened telomeres is not sufficient, and studies should focus on the role of other factors that participate in telomere maintenance, which may also play an important role in cell differentiation^[9].

Senescence of adult organisms has to be considered, given that cell function, potency and replication decrease with time, while mutations may increase. In the case of the nervous system, mutations may result in neuronal loss, abnormal cell function, increased neuronal longevity (resulting in an even greater accumulation of mutations) and decreased regenerative capacity after an injury. These findings have been reported in studies investigating cell proliferation during learning: while young animals showed better performance than older animals, pharmacological stimulation in the older animals led to improved performance, with the newborn neurons integrating into the existent neural circuits^[10-12]. Moreover, the aging of stem cell niches may contribute to the aging of stem cells, changing the organism's regulatory microenvironment, which in turn influences the aging process of other cells. To summarize can be quoted the influence of protein p53 expression levels: when expressed at low levels, it contributes to stem cell metabolic maintenance, but when expressed at high levels, it decreases the number of stem cells by inducing cell death, and the role of energetic metabolism and the production of reactive oxygen species that acts directly in stem cell niches^[13].

Another important feature of stem cells is their immunomodulatory power, which allows them to "feel" the environment and change their patterns of migration, interaction and survival. When transplanted into the lesion site, some stem cells interact with the proinflammatory environment, migrate to the site of injury and differentiate into the required cell type in order to effect repair. Moreover, some stem cells play an important role in the proliferation and migration of new cells to the site of injury. This helper profile has

been observed in neural stem cells and mesenchymal stem cells. In the case of mesenchymal stem cells, this function can play an important role in changing the macrophage proinflammatory profile into a proneurogenic role, once there is no longer an urgent need for a robust immune response^[14-16].

Understanding the biology of stem cells and their niches, as well as the mechanisms involved in their multipotent state, are basic criteria to achieve great experimental results and to take the next step towards clinical trials.

MESENCHYMAL STEM CELLS/BONE MARROW STEM CELLS

The bone marrow is the only organ in which two different types of stem cells coexist: the bone marrow stem cell (BMC, also called hematopoietic stem cell) and the mesenchymal stem cell (MSC, also called mesenchymal stromal cell). Bone marrow cells are responsible for generating blood cells, while mesenchymal stromal cells are responsible for supporting hematopoietic progenitors by regulating the niche microenvironment and by facilitating the maturation of blood cells. Mesenchymal cells can also be extracted from adipose tissue, umbilical cord, skin and placenta^[17,18].

Experimental studies have shown that MSCs can survive and migrate to the lesion site, prevent astrogliosis and microglial activation, and delay the loss of motoneurons. A comparative study between BMCs and MSCs showed that BMCs are relatively more effective in motor function recovery and have a higher survival rate^[18,19]. In clinical trials with BMCs, authors reported motor and sensory improvement, as well as improvement in patients' quality of life, with some being able to sit again and even get dressed with partial assistance^[19-23]. MSCs also showed great results when transplanted with T cells, controlling inflammatory activity in order to create the proper microenvironment for cell transplantation^[24]. The immunomodulating effect of MSCs has also been reported in other clinical trials and MSCs have been shown to play an important role as immunomodulators and angiogenic agents in drug resistant patients as well as in patients with cerebral palsy, critical limb ischemia and kidney transplants^[25-32]. In another study conducted with 40 patients, bone regeneration was achieved when a great number of CD34⁺ cells were transplanted to the lesion site, 20 patients achieved mature bone regeneration, even in the group that received a low number of cells 4 patients achieved bone regeneration. However, when transplanted together with MSCs, these cells were able to use paracrine and autocrine cross-talk up-regulation to achieve bone regeneration^[33].

Despite these positive results, several side effects were reported when MSCs from adipose tissue were

administered *via* the cephalic vein, including chest pain and tightness, mild fever, furuncle on the upper thigh, musculoskeletal pain, painful neck and shoulder, increased sputum, upper respiratory infection, urinary incontinence, urinary tract infection, aggravation of spasticity, neuropathic pain, pain exacerbation, headache, low thyroid stimulating hormone and somnolence^[34].

OLFACTORY ENSHEATHING CELLS

Neurogenesis in the olfactory system continues to take place even in the adult. Stem cells proliferate in the subventricular zone of the forebrain, generating neural progenitors that migrate to the olfactory bulb to create new interneurons. If an injury occurs, these neurons are immediately replaced through a surge in neurogenesis. Olfactory ensheathing cells (OECs) surround the axons of the sensory neurons in the olfactory epithelium and form synapses in the olfactory bulb in the brain. Due to their ability to guide the connections between the peripheral nervous system and the central nervous system, as well as their ability to differentiate into non-olfactory cell types, these cells are excellent candidates for cell transplantation^[35]. These multipotent cells have been extensively studied in cases of spinal cord injury, and authors have reported that transplants were safe and patients experienced motor and sensory improvement, as well as recovered bladder function and activity of several muscles below the injury level^[36,37]. In an amyotrophic lateral sclerosis (ALS) clinical trial conducted with OECs in China, researchers reported that patients experienced no benefits, two patients had severe side effects and one even died following transplantation^[38]. One theory contends that OECs should be transplanted together with neural stem cells in order to potentiate the growth of neural processes. OECs have been shown to stimulate axon regeneration by secreting growth factors, axon guidance molecules and basement membrane components. They also aid in tissue repair by effecting structural remodeling and support, modulating the immune system, enhancing neurotrophic and antigenic stimuli and metabolizing toxic macromolecules. Finally, OECs may be transplanted together with growth factor (*e.g.*, bFGF, or basic fibroblast growth factor) to sustain cell survival and proliferation^[39-41].

NEURAL STEM CELLS

Neural stem cells were first described by Altman in 1960 and have the potential to differentiate into any cell type in the central nervous system^[42-45]. It is known that adult neurogenesis occurs in two brain regions, the subventricular and subgranular zones of the dentate gyrus, and the spinal cord^[45].

Neural stem cells have been used to treat several neurologic conditions such as spinal cord injury, ALS, Parkinson's disease, traumatic brain injury, Huntington's

Table 1 Adult stem cells transplantations: Published clinical trials from the past 4 years

s disease and several demyelinating diseases. The main issues to consider when using neural stem cells are how the transplanted cells will interact with the host microenvironment, how the local immunological response will interfere with and prevent neurorestoration, and how the transplanted neural stem cells will modulate the microenvironment *via* paracrine and autocrine effects. These mechanisms need to be clarified before moving on to clinical trials. Several investigators have questioned the behavior of transplanted cells and several transplantation strategies have been tested, including co-transplantation with other stem cell types, T cells or neurospheres. Nevertheless, much work needs to be done in order to better comprehend how neural stem cells interact with the host tissue^[45-52]. Clinical trials have not shown statistically significant results, Moviglia *et al.*^[47] transplanted neural stem cells in seven patients with ALS and only in five patients were observed motor improvements. In their combined protocol the local immunological response were controlled by a T-cell vaccination before the transplants of NSCs, but authors agree that the transplantation of neural stem cells is safe and feasible^[46-49] (Table 1).

CONCLUSION

Adult stem cell transplantation represents a promising choice of treatment for the field of regenerative medicine, but several aspects must still be clarified before proceeding with clinical trials. More studies are needed to establish how to obtain a large population of adult stem cells and to ensure the safety and viability of the transplants. We must also understand these cells' mechanisms of interaction and how we can use these mechanisms to achieve full regeneration.

Based on the studies cited here, it is possible to affirm that in the near future we will have effective therapies against various diseases that affect and challenge the medical community and the population

at large.

epigenetic aberrations. The development of genomic instability is associated with mutations that contribute to cellular immortalization and transformation. Cancer occurs when cancer-initiating cells (CICs), also called cancer stem cells, develop as a result of these mutations. In this paper, we explore how CICs develop as a result of genomic instability, including looking at which cancer suppression mechanisms are abrogated. A recent *in vitro* study revealed the existence of a CIC induction pathway in differentiating stem cells. Under aberrant differentiation conditions, cells become senescent and develop genomic instabilities that lead to the development of CICs. The resulting CICs contain a mutation in the alternative reading frame of *CDKN2A* (ARF)/p53 module, *i.e.*, in either ARF or p53. We summarize recently established knowledge of CIC development and cellular immortality, explore the role of the ARF/p53 module in protecting cells from transformation, and describe a risk factor for genomic destabilization that increases during the process of normal cell growth and differentiation and is associated with the downregulation of histone H2AX to levels representative of growth arrest in normal cells.

Key words: ARF/p53 module; Cancer stem cells; Cancer-initiating cells; Differentiation; Genomic instability; H2AX

Core tip: Cancer usually develops in conjunction with genomic instability and multiple genetic mutations. Only a small number of cells, called cancer-initiating cells (CICs), are the progenitors of cancerous tissue; but how genomic instability and genetic mutations prompt CICs to develop is still unclear. Recent investigations have uncovered the existence of a pathway that could be responsible. This review explores how that pathway might induce the development of CICs, the tumor suppression mechanisms that must be abrogated in order for malignancies to occur, and the role of the alternative reading frame of *CDKN2A* (ARF)/p53 module/p53 module in protecting

Abstract

Cancers that develop after middle age usually exhibit genomic instability and multiple mutations. This is in direct contrast to pediatric tumors that usually develop as a result of specific chromosomal translocations and

normal cells from oncologic transformation.

INTRODUCTION

Somatic stem cells are responsible for the development and homeostasis of organs and other bodily tissues. Cancer-initiating cells (CICs), or cancer stem cells, are responsible for the development^[1,2], metastasis, and drug resistance^[3-6] of tumors. Although CIC characteristics are increasingly being well defined, how CICs develop remains unclear.

Unlike pediatric tumors, which usually develop as a result of very specific chromosomal translocations^[7,8] and epigenetic aberrations^[9,10], cancers that become more common around the age of 40 years exhibit extreme chromosomal instability (CIN) or microsatellite instability (MSI)^[11-14]. MSI occurs in cells that do not have adequate mismatch repair systems^[15-17], and CIN occurs in the presence of other types of repair deficiencies. The hereditary versions of myelodysplastic syndrome^[18], breast and ovarian cancers^[19-22], and skin cancers^[23-25] are examples of CIN. CIN can even occur in normal senescent cells^[26,27].

MSI and CIN usually do not occur together and are considered mutually exclusive. For example, 15% of colorectal cancers exhibit MSI, but most of the remainder exhibit CIN. There are also tumors that do not exhibit either MSI or CIN and result from DNA polymerase ϵ mutations, which interfere with proofreading functions and produce hypermutations^[28,29]. Massive genomic rearrangements occur in a wide variety of cancers^[30-32], and the unstable structures that result vary widely^[33,34]. Since only a very small number of CICs are necessary to produce a malignancy, what causes CICs to develop in the first place is an important question^[35,36].

In malignant cells, mutations in either alternative reading frame of *CDKN2A* (ARF) or p53 are common. The ARF/p53 module plays a major role in keeping normal cells from transforming into malignancies, so these mutations that interfere with ARF/p53 functioning show us how the barrier reactions performed by the ARF/p53 module normally work and the way genomic instability promotes the development of CICs.

EFFECTS OF GENOMIC INSTABILITY

Like cancer cells that develop because of genomic instability *in vivo*^[37-40], cells cultured *in vitro* can also be transformed and/or immortalized in association with either CIN- or MSI-type genomic instabilities^[26] and

mutations in the ARF/p53 module^[41]. Following serial proliferation, normal mouse embryonic fibroblast cells (MEFs) stop reproducing after a growth arrest command issued by the ARF/p53 module^[41]. This command prevents cells from immortalizing^[27,42], but immortality can develop if the genome is destabilized^[43], clearly demonstrating that genomic instability is a triggering event in cellular immortalization.

Genomic instability probably contributes to the induction of mutations in the ARF/p53 module^[27,42]. In MEFs, immortalization can result if genomic instability is induced and/or mutations occur in either ARF or p53 (Figure 1), but is blocked in cells with stable genomes that are under the continuous regulation of the ARF/p53 module^[27]. Healthy ARF/p53 regulation is essential for the prevention of cellular transformation and immortalization, but which functions of ARF and p53 are responsible for tumor suppression is controversial.

It was generally believed that p53 suppresses tumors by inducing apoptosis and senescence^[44-47], but recent studies have cast doubt on this hypothesis. For example, in multiple transgenic mouse models in which p53 cannot induce cell-cycle arrest and apoptosis after DNA damage, the number of malignancies that form as a result is not significantly higher than the rate of malignancies in normal mice^[48-50]. These observations raise questions regarding the exact role of p53 in tumor suppression. One hypothesis is that p53 regulates metabolism by inhibiting glycolysis^[51-53] and/or activating the mammalian target of rapamycin pathway^[52,54,55].

EFFECT OF MUTATIONS IN THE ARF/P53 MODULE

Because ARF and p53 are mutated in cancer cells in a mutually exclusive manner, it is likely that the p53 functions that are essential for cancer suppression are expressed under the control of ARF^[56]. Intriguingly, transgenic mice with an extra copy of *Arf* and *p53* (super-*Arf/p53* mice) exhibit both reduced rates of cancer and slower overall aging^[41]. Furthermore, MEFs derived from these mice rarely immortalize spontaneously. Therefore, it is likely that the roles of ARF and p53 in cancer suppression are involved in the maintenance of homeostasis *in vivo* and are primarily regulated at the level of individual cells. This cellular-level protection against transformation is generally associated with growth arrest and low levels of the histone H2A variant H2AX^[27,57], which is required for active cell growth^[58].

The downregulation of H2AX is governed by the ARF/p53 module^[27,42]. Growth-arrested cells in the liver, spleen, and other organs of healthy adult mice generally exhibit downregulated levels of H2AX, whereas immortalized/transformed cells, which have mutations in the ARF/p53 module, have normal H2AX levels and exhibit active growth^[27,57].

Figure 1 Model of cellular immortalization in association with genomic instability. As illustrated in mouse embryonic fibroblasts, immortality is induced by genomic instability and mutation of either Arf or p53. Growth arrest and the downregulation of H2AX protect mouse embryonic fibroblasts against immortalization. Because H2AX downregulation is dependent on the ARF/p53 module, cells with mutations in this module recover H2AX expression and growth activity. CIN: Chromosomal instability; MSI: Microsatellite instability.

As described above, cellular transformation is suppressed primarily by the induction of growth arrest and the downregulation of H2AX under the control of the ARF/p53 module. It is promoted by genomic instability and the mutations it produces. Unfortunately, when H2AX is downregulated, the mechanisms that repair lesions fail and this is a risk factor for the genomic instability and tumorigenesis seen in many hereditary cancers^[15-25]. Despite the aforementioned protective effect of H2AX downregulation, the risk of sporadic cancer development is probably due, in large part, to a reduction in H2AX levels and the associated repair deficiencies^[27]. In fact, cells without H2AX exhibit faulty homologous recombination and non-homologous end-joining during DNA repair^[59,60], which results in elevated genomic instability^[58].

CIC DEVELOPMENT IS DISTINCT FROM IMMORTALIZATION

Although immortalized MEFs develop in association with genomic instability and mutations in the ARF/p53 module^[26,41], the resultant cells do not exhibit robust tumor-forming ability unless they are pre-transformed by oncogenes^[61,62]. This observation illustrates the difference between immortalized MEFs and CICs. MEFs are differentiated cells and do not exhibit stem cell characteristics, but CICs act like stem cells in cancer-tissue development. In fact, CICs share a number of common characteristics with normal stem cells, including embryonic stem (ES) cells and induced pluripotent stem cells, but do not resemble immortalized MEFs with their high dependence on normal glycolysis^[63,64], sphere-forming ability, and expressed stem cell marker genes^[65-67]. Cancer tissues generally exhibit the "Warburg Effect" seen in normal stem cells that produce elevated glycolysis.

Transformation of normal stem cells into CICs after genomic destabilization

To truly understand cancer, we must discover how

genomic instability promotes the development of CICs. CICs may develop *via* multiple pathways. A recent study using normal murine ES cells as a model showed that one of these possible pathways might be created when normal stem cells are developing under unstable genomic conditions. Under aberrant differentiation conditions, ES cells with the ability to form normal mice develop high levels of DNA lesions. These lesions induce cellular senescence and genomic instability, ultimately leading to renewed growth in cells that harbor mutations in the ARF/p53 module^[68]. These cells exhibit a number of stem cell characteristics, including sphere formation and the expression of undifferentiated marker genes such as *Nanog*, *Klf4*, *Oct3/4*, and *Sox2*, even in a growth factor-poor medium containing 10% newborn bovine serum with no leukemia inhibitory factor. Furthermore, these cells possess tumor-forming ability and express c-Myc and CIC markers such as CD133, CD33, and CD34.

The fact that oncogenesis can be triggered by niche disruption supports this theory. For example, both leukemia and myelodysplasia develop after dysregulation of the stem cell niche^[69], and cancers often develop from stem cells that are injected at heterotopic sites^[70]. Stem cells growing in such an aberrant environment do not get what they need to maintain themselves properly and often transform into CICs^[70]. Another example is embryonal carcinomas that can develop from cells transplanted from the inside of blastocysts and from primordial germ cells derailed from the migration track^[71,72]. These *in vivo* and *in vitro* findings suggest that the genomic instability that leads to the development of CICs can be triggered by aberrations in the environment when stem cells are differentiating.

Because cancer development is initiated by CICs, these cells are considered promising targets for chemotherapy aimed at either killing them directly or getting them to differentiate^[73-75]. However, this strategy is not always successful, partly because CICs are so adaptable and plastic^[76,77]. In one study in

Figure 2 Model of cancer-initiating cell development. A: In normal tissues, stem cells are maintained in a specific niche and the niche environment is important both for stem cell maintenance and organ homeostasis; B: Niche disruption deranges the differentiation environment of stem cells, leading to the accumulation of DNA lesions and the induction of cellular senescence. Such DNA lesions trigger genomic destabilization, leading to the development of benign tumors that contain a small number of C: Pluripotent cells that eventually develop into; D: Cancer-initiating cells (CICs) that cause malignancies.

which CICs developed from ES cells, transformation was coupled with the acquisition of plasticity. ES cells start to differentiate in response to leukemia inhibitory factor withdrawal and become senescent when differentiation conditions are aberrant; but the CICs that result re-acquire stem cell characteristics as they develop genomic instability, even under conditions in which stem cells ordinarily do not thrive and cannot be cultivated^[68]. CICs that re-acquire stemness under these conditions maintain stem cell characteristics with great persistence, and it is difficult to get them to differentiate completely.

RELEVANCE OF *IN VITRO* MODELS TO CANCER DEVELOPMENT

Unlike *in vitro* malignancy transformation, *in vivo* cancer development has multiple steps that include abrogating organic regulation, which results in the development of benign tumors such as adenomatous polyposis coli mutations in the colon^[78,79], and losing the ARF/p53 module that leads to uncontrolled growth and the development of malignancies^[80,81]. Each organ in a complex animal is regulated by its own specific mechanisms that keep the organ in homeostasis, which can malfunction and allow tissues to become precancerous or malignant when the genome becomes unstable or the mutations affect the ARF/p53 module^[40,56].

CONCLUSION

Genomic instability contributes to the development of CICs by directly transforming somatic stem cells, reprogramming differentiated cancer cells, and a number of other mechanisms. Several lines of evidence suggest that one of these pathways is triggered by the disruption of the niche environment (Figure 2). Maintenance of the niche environment is essential for

somatic stem cell maintenance and differentiation and homeostasis (Figure 2A). The stem cell niche can be damaged by exogenous stresses that cause irregular stem cell differentiation, the accumulation of DNA damage, and the induction of senescence (Figure 2B). DNA damage often triggers genomic destabilization, which can promote the development of precancerous (Figure 2C) and cancerous (Figure 2D) lesions through the maintenance of small pockets of pluripotent stem cells that eventually become CICs.

If stem cells start to differentiate under unfavorable differentiation conditions, they become senescent, but can start developing again and reacquire stem cell characteristics when conditions change. Stemness recovered under these circumstances is associated with robust plasticity and the ability of these cells to self-renew, even under conditions in which normal stem cells do not thrive. Unfortunately, such cells do not differentiate completely and remain permanently in less developed states that often lead to malignancies.

cell or system is reportedly presents suggesting that adult stem-like cells in kidney can be practical clinical targets for kidney diseases. However, it is still unclear if kidney stem cells or stem-like cells exist or not. In general, stemness is defined by several factors such as self-renewal capacity, multi-lineage potency and characteristic gene expression profiles. The definite use of stemness may be obstacle to understand kidney regeneration, and here we describe the recent broad findings of kidney regeneration and the cells that contribute regeneration.

Key words: Stem cell; Label-retaining cells; rKS56; SP cells; CD24; CD133; Sca-1; Induced pluripotent stem; ES cell

Abstract

Human pluripotent cells are promising for treatment for kidney diseases, but the protocols for derivation of kidney cell types are still controversial. Kidney tissue regeneration is well confirmed in several lower vertebrates such as fish, and the repair of nephrons after tubular damages is commonly observed after renal injury. Even in adult mammal kidney, renal progenitor

INTRODUCTION

Recent developments in human pluripotent cells including both embryonic stem cells and induced pluripotent stem (iPS) cells^[1] are promising for clinical development of cell therapies and tissue

engineering^[2-4]. There is an urgent need for stem cell and regenerative medicine approaches to kidney diseases, because patients with end-stage kidney disease require lifelong dialysis treatment or transplantation that incurs a significant cost. Several established protocols for derivation of cardiomyocytes and neurons were already reported, but that for kidney cell types are still controversial. Recently human iPS cells were successfully differentiated into kidney lineage *via* OSR1 (+) cells^[5,6]. However metanephric progenitors were not induced from OSR1(+) cells^[7], and efficient differentiation of human pluripotent cells into intermediate mesoderm was reported by treatment the cells with glycogen synthase kinase-3 β inhibitor^[8]. Different from mammals, the capacity to regenerate kidney tissue is well confirmed in several lower vertebrates such as fish^[9]. Kidney regeneration, such as the repair of nephrons after tubular damages, is commonly observed after renal injury even in humans^[10,11]. Concerning adult mammal kidney, there are lots of evidences that suggest existence of renal progenitor system^[12-19]. Collectively, these results suggest the potential role of adult stem-like cells in kidney for practical clinical treatment of kidney diseases. In this review, we describe the localization and recent functional findings of kidney regeneration and the cells that contribute regeneration.

TUBULAR CELLS (LRC, RKS56, NFATC-1⁺, ALDH^{HIGH}, CD24⁺/CD133⁺, MRPC)

To identify the stem cells, BrdU-DNA labeling is commonly used to find slow-cycling cells because stem cells have a slow cell cycle. Slow cycling cells were also called label-retaining cells (LRC), and LRC in tubules were confirmed by several groups^[20-22] (Table 1). In rat kidneys, LRC were distributed among renal epithelial tubular cells^[20]. In 3 dimensional culture system, LRC formed tubule-like structure. Moreover, injected LRC into cultured metanephros formed nephrons and collecting ducts^[23]. rKS56 cells were established from proximal tubules (S3) by using microdissection of a single nephron^[24]. rKS56 cells expressed markers of an immature progenitor state such as c-Kit and Sca-1. When rKS56 cells were transplanted into acute kidney disease models, the cells differentiated into epithelium. A resident progenitor cells in proximal tubular (PTC) cell was identified by Nfatc1-P2-Cre reporter system^[25]. Nfatc-1-labeled PTC cells were apoptosis-resistant and proliferated to repair the damaged proximal tubule segment. ALDH activity was used to isolate cells with progenitor-like characteristics from the tubular fraction of the renal cortex^[26-29]. ALDH^{high} cells displayed typical stem cell properties such as sphere

formation and anchorage-independent growth. CD24/CD133 double-positive cells were localized in the tubular epithelium, and demonstrated clonogenic multipotency and self-renewal ability^[28]. Bombelli *et al.*^[30] recently proposed existence of CD133⁺/CD24⁻ renal stem cells but Romagnani reported that CD133⁺ renal stem definitely co-express CD24 in human kidney^[31]. Gupta *et al.*^[32] reported localization of stem-like cells around the tubules. They named the cells multi-potent renal progenitor cells (MRPC). By using similar culture condition used for culture of bone marrow-derived multi-potent adult progenitor cells, MRPCs were isolated from rat kidney. The plasticity of MRPC was confirmed by expression of endothelial, hepatocyte, and neural markers by RT-PCR and protein expression. When MRPC were injected under the capsule of an uninjured kidney or arterially into acute kidney injury model, the cells differentiated into renal tubules. However, differentiation/induction of matured kidney cells from MRPC *in vitro* was not confirmed yet.

RENAL PAPILLA (LRC, CD133⁺)

To identify the stem-like cells in kidney, Oliver *et al.*^[33,34] performed pulse label of rat and mouse pups by BrdU, and confirmed the existence of LRC cells in the kidney. LRC cells were very sparse in the kidney, but they found numerous LRC cells in renal papilla^[33]. In 3 dimensional culture, LRC cells in renal papilla spontaneously formed spheroids, and clones from single cell of LRC cells expressed both mesenchymal and epithelial markers. The papillary cells also differentiated to myofibroblasts and neuronal cells. In acute kidney injury model such as ischemic injury, LRC cells in papilla migrated to the upper papilla and formed a compartment of rapidly proliferating cells suggesting that the cells contributed to repair of kidney tissue^[34]. Papillary cells that expressed CD133 were also expressed nestin and embryonic cell markers (Oct3/4, Nanog, SOX2 and SSEA-4)^[35].

INTERSTITIAL SPACE (SCA-1⁺CD45⁻, SP, CD133⁺)

Several groups have found adult stem-like cells in murine kidney interstitial space using different approaches. Stem cell antigen-1 (Sca-1)-positive and CD45-negative cells were isolated from whole kidney tissue by magnetic assisted cell sorting and fluorescence activated cell sorting (FACS) sorting^[36]. The cells were negative for hematopoietic stem cell and lineage markers and located in the renal interstitial spaces. The differentiation of the cells into multi-lineage (myogenic, osteogenic, adipogenic and neural) was also confirmed. In acute kidney injury model, injected Sca-1⁺CD45⁻ cells contributed

Table 1 Localization and characteristics of adult stem-like cells in kidney

Localization	Characteristics	Species	Ref.
Tubular cells	LRC	Rat	[20-23]
	rKS56	Rat	[24]
	Nfactc-1 ⁺	Mice	[25]
	ALDH ^{high} /CD24 ⁺ /CD133 ⁺	Human	[26-29]
	MRPC	Rat	[32]
Renal papilla	LRC	Rat, mice	[31,32]
	CD133 ⁺	Human	[33]
Interstitial space	Sca-1 ⁺ /CD45 ⁺	Mice	[34]
	SP cell	Rat, mice, human	[38-41]
Bowman's capsule	CD133 ⁺	Human	[27]
	CD24 ⁺ /CD133 ⁺ /PDX ⁺	Human	[44-48]
	CD24 ⁺ /CD133 ⁺ /PDX ⁻	Human	[44-48]

LRC: Label-retaining cells; MRPC: Multi-potent renal progenitor cell; PDX: Podocyte marker.

kidney repair. To isolate hematopoietic stem cell-rich population in a single step, Goodell *et al.*^[37] stained cells with Hoechst 33342 dye and isolated the cells by FACS. The cells isolated by this method were named side population (SP) cells. This method was also used to purify a stem cell-rich population in various kinds of tissue. SP cells isolated from adult kidney demonstrated ability of self-renewal and differentiation into multiple lineages^[38]. SP cells isolated from adult kidney located in interstitial spaces, and secreted reno-regenerative/protective factors (HGF, VEGF, and BMP-7)^[39-42]. The injection of SP cells isolated from adult kidney cells into a model of acute kidney injury demonstrated the recovery of renal function^[39,40]. Interestingly, Inowa *et al.*^[43] confirmed the existence of kidney SP cells in human. Concerning CD133 positive cells, Bussolati *et al.*^[27] reported that the cells were localized to the interstitium, but not in glomeruli. Kidney CD133 positive cells lacked expression of hematopoietic markers and expressed Pax-2, an embryonic renal marker. Intravenous injection of kidney CD133 positive cells in SCID mice with glycerol-induced tubulonecrosis, the cells homed into the injured kidney and integrated in tubules.

BOWMAN'S CAPSULE

(CD24⁺CD133⁺PDX⁺, CD24⁺CD133⁺PDX⁻)

Some parietal epithelial cells (PEC) are reported to be adult stem-like cells^[44-47]. Sagrinati *et al.*^[45] confirmed the existence of PEC that expressed CD24, CD133 Oct-4 and Bmi-1 in the Bowman's capsule. CD24⁺CD133⁺ PEC were isolated by culture of capsulated glomeruli plated on fibronectin-coated dishes. CD24⁺CD133⁺ PEC showed potential of self-renewal and a high cloning efficiency. Transplantation of CD24⁺CD133⁺ PEC into acute kidney injury model significantly improved not only morphologic but functional kidney damage. Further characterization

using podocyte marker (PDX) of CD24⁺CD133⁺ PEC revealed a hierarchical population of the cells in a precise sequence with Bowman's capsule and exhibited heterogeneous potential such as differentiation and regeneration^[48]. CD24⁺CD133⁺PDX⁻ cells localized to the urinary pole could differentiate into both tubular cells and podocytes, but CD24⁺CD133⁺PDX⁺ cells localized between the urinary pole and vascular pole could differentiate into only podocytes. Transplantation of CD24⁺CD133⁺PDX⁻ cells reduced proteinuria and improved chronic glomerular damage in adriamycin-induced nephropathy models.

FUNCTIONAL REGULATION OF ADULT STEM-LIKE CELLS IN KIDNEY

As mentioned above, different kinds of adult stem-like cells in kidney have been reported, but their functional regulations were poorly understood. If it is possible to regulate multi-potent adult stem like-cell *in situ*, this can be a good regenerative treatment. Recently MyoR was reported to regulate regenerative function of kidney SP cells^[49], and such a molecule can be a good target for pharmacological treatment for kidney disease.

CONCLUSION

Several adult stem-like cells in kidney reportedly demonstrated multi-potency. However, it is impossible to get enough cells for cell therapy from the patient. The adult stem-like cell in kidney is expected to play key role to preserve kidney function, and the cells may be the good targets for pharmacological treatment. For cell therapy, iPS or ES cells might be applicable as in the case with neural and cardiac regeneration.

skin diseases. Thus, strategies for manipulating cell-ECM interactions are critical for treating wounds and a variety of skin diseases. Many of these strategies focus on epidermal stem cells, which reside in a unique niche in which the ECM is the most important component; interactions between the ECM and epidermal stem cells play a major role in regulating stem cell fate. As they constitute a major portion of the ECM, it is likely that integrins and type IV collagens are important in stem cell regulation and maintenance. In this review, we highlight recent research-including our previous work-exploring the role that the ECM and its associated components play in shaping the epidermal stem cell niche.

Key words: Stem cell niche; Epidermal stem cells; Integrins; Type IV collagen; MiR135b

Core tip: Epidermal stem cells reside in a unique niche within the skin, which is shaped by interactions between stem cell-associated integrins and components of the extracellular matrix. Here, we review literature evaluating the role that integrins play in epidermal stem cell maintenance and proliferation, and highlight methods that have been used to enrich for epidermal stem cells. We stress that by understanding the epidermal stem cell niche, new regenerative medicine applications can be developed.

Abstract

Within the epidermis and dermis of the skin, cells secrete and are surrounded by the extracellular matrix (ECM), which provides structural and biochemical support. The ECM of the epidermis is the basement membrane, and collagen and other dermal components constitute the ECM of the dermis. There is significant variation in the composition of the ECM of the epidermis and dermis, which can affect "cell to cell" and "cell to ECM" interactions. These interactions, in turn, can influence biological responses, aging, and wound healing; abnormal ECM signaling likely contributes to

Choi HR, Byun SY, Kwon SH, Park KC. Niche interactions in epidermal stem cells. *World J Stem Cells* 2015; 7(2): 495-501 Available from: URL: <http://www.wjgnet.com/1948-0210/full/v7/i2/495.htm> DOI: <http://dx.doi.org/10.4252/wjsc.v7.i2.495>

INTRODUCTION

The skin has epithelial and mesenchymal components^[1].

Figure 1 Skin structure involves the epidermis, dermis and hypodermis.

Normally, tissues consist of differentiated cells and a small number of stem cells localized to specific niches^[2]. Stem cell niches are specific microenvironments that determine stem cell number and affect stem cell mobility^[3]. Furthermore, the complex nature of stem cell niches allows for the formation of distinct structures specialized for different stem cell types^[4]. Epidermis is multilayered and is continually renewed and replaced by new cells, a process that results from the action of stem cells. It is known that the extracellular matrix (ECM) is a key component of the stem cell niche in the skin, and biophysical properties of the ECM (such as stiffness) also can affect cell fate determination^[4]. As epidermal stem cells express high levels of integrins, these cells are able to interact directly with the ECM^[1,4]. Thus, the interaction between stem cell-associated integrins and the ECM may be important in shaping the epidermal stem cell niche. In addition to the ECM and integrins, growth factors or mechanobiological factors can also affect stem cell fate^[4,5]. Furthermore, low oxygen tensions (hypoxia) are necessary to maintain undifferentiated stem cell phenotypes, and also influence proliferation and stem cell fate^[6]. However, among all of these factors, the ECM seems to play the largest role in shaping stem cell niches and stem cell behavior, and may thus have a major underlying role in physiological and pathological conditions.

SKIN STRUCTURE: A BRIEF OVERVIEW

Skin is composed of the epidermis, dermis, and hypodermis (Figure 1). Multilayered epidermis serves as the outer layer of the skin. Additional structures such as hair follicles and sebaceous glands are also found within the skin. Stem cell proliferation and differentiation are vital for the maintenance of the epidermis, and different pools of skin stem cells are located in the hair follicle (the bulge) and the interfollicular epidermis^[7,8]. Histologically, the lower layer of the epidermis is attached to the basement

membrane (BM), which separates the epidermis from the underlying connective tissue layer known as the dermis.

THE BASEMENT MEMBRANE AND THE EPIDERMAL STEM CELL NICHE

The BM of the epidermis contains distinct subtypes of laminin, type IV collagen, nidogen, and perlecan (a heparan sulfate proteoglycan); immunohistochemical staining and gene expression studies have demonstrated that there is considerable regional variation in the BM^[1]. The mechanical support provided by the BM is determined primarily by its type IV collagen scaffold; however, laminin is essential for the initial assembly of the BM *in vivo*^[9]. Integrins also demonstrate variable expression in different regions of the epidermis^[10], and these transmembrane proteins themselves have different kinds of combination (*i.e.*, $\alpha 2\beta 1$, $\alpha 3\beta 1$, and $\alpha 6\beta 4$). Integrins are the major receptors for ECM proteins, and interact with growth factors and cytokine receptors^[4]. Growth factors and morphogens can also directly bind to the ECM; this suggests that the ECM might integrate different types of signals in biological microenvironments. As a result, clinical applications of stem cells have emphasized the relationship between epidermal stem cells and the ECM^[4]. Recent research has sought to understand how the ECM and integrins cooperate with one another to form the architecture of the epidermal stem cell niche, and how they maintain the balance between stem cell renewal and differentiation^[4]. It is possible that variations within the ECM may create distinct environments that can potentially affect the properties of different stem cell populations^[1].

EPIDERMAL STEM CELLS: IDENTIFICATION, REGULATION, AND APPLICATIONS

Markers of epidermal stem cells and the epidermal stem cell niche

Stem cells are localized to “niches”—specific sites that regulate how stem cells participate in tissue maintenance and repair. In a niche, stem cell proliferation is regulated and these cells are protected from depletion^[11]. Interestingly, evidence suggests that cancer—a common cause of death—is also a stem cell-based disease. Cancer stem cells (CSCs) are a subset of cancer cells that demonstrate stem cell-like abilities—abilities that may induce tumor growth and tumor recurrence. CSCs also require a special “CSC niche” to regulate their stemness and proliferation, and as with endogenous stem cells, this niche prevents CSCs from being depleted^[12]. Thus, the stem cell niche is a key factor in the maintenance of stem cells.

In the skin, an increased level of integrins expression is considered to be a marker of epidermal stem cells^[13]. Although the expression levels of integrins in stem cells are only 2-3-fold higher than in stem cell progeny, this is sufficient to make stem cells more adhesive to ECM proteins^[14]. Based on these findings, we developed a simple method to isolate epidermal stem cells based on integrin expression. As epidermal stem cells express high levels of integrins, type IV collagen is a good candidate to bind epidermal stem cells^[14]. To purify epidermal stem cells, three keratinocyte populations were first characterized by their ability to bind type IV collagen: rapidly adhering (RA), slowly adhering (SA), and non-adhering (NA) cells. The expression levels of *p63* and *c-Myc* were also compared between cells in these three populations. It was concluded that RA cells could be easily isolated from the epidermis, and that these cells were likely epidermal stem cells^[15]. This research suggests that integrins may play an important role in the regulation of epidermal stem cells. Type IV collagen has not only been used to isolate epidermal stem cells, but has also been suggested to be directly involved in maintaining epidermal stem cells. Very recently, we reported that inhibition of miR135b could increase the proliferative potential of normal human keratinocytes^[16]. Our data demonstrated that type IV collagen is a target of miR135b, and that the inhibition of miR135b may improve the epidermal stem cell microenvironment and increase the proliferative potential of basal cells (Figure 2). These findings suggest that restoration of type IV collagen to the basement membrane is important for stem cell maintenance in skin. Microarray analysis also revealed differences in the expression of ECM proteins between hair follicle stem cells and other epidermal stem cells^[17]. These results suggest that integrins and type IV collagen are not the only proteins involved in determining the epidermal stem cell niche; ECM proteins are also important in shaping the niche within the interfollicular epidermis. Although no specific markers are available for the identification of epidermal stem cells, *p63* is commonly regarded as a potential epidermal stem cell marker, as *p63*^{-/-} mice fail to develop stratified squamous epithelia^[18].

The stem cell niche in regenerative medicine

An effective response of the body to injury depends on regenerative processes that maintain proper cell numbers and replace damaged cells. This "reparative" potential is determined by the presence of stem and progenitor cells, which respond to exogenous cues such as tissue damage. Therapeutic applications of stem cells address the biological constraints of these cells, the stem cell niche, and the location to which these cells are summoned to respond. Understanding the role of the stem cell niche is essential for the application of stem cells in regenerative medicine^[19].

A major concern in regenerative medicine is obtaining an adequate number of stem cells to treat

an injury or disease. For practical applications, one of the most important problems is the small number of stem cells. In order to overcome this challenge, researchers often expand the number of stem cells by *in vitro* culture; however, most stem cells begin to lose their stem cell character during this process. In many cases, replicating the niche environment in culture is critical to maintain stem cell characteristics^[20]. Similarly, "mimicking the native niche" has been shown to be important in tissue engineering of human corneal limbal crypts^[21]. As wound healing is a critical process that re-establishes the epithelial barrier following disease or injury, poor wound healing increases infection risk, causes patient morbidity, and may lead to the scar formation. If there is a defect in the stem cell niche, wound repair could be delayed by the abnormal response of stem cells to injury^[5]. Thus, understanding how to recreate the stem cell niche is key to regenerative medicine applications.

Integrins and niche interactions

Integrins are a complicated group of proteins that function as transmembrane receptors; these proteins either connect cells to one another, or to the ECM. Such connections trigger signal transduction pathways, which result in biological responses such as cell proliferation or cell motility. Fibronectin, vitronectin, collagen, and laminin are all ligands for integrins. However, other proteins can mediate cell-cell or cell-ECM interactions; these include cadherins, the immunoglobulin superfamily of cell adhesion molecules, namely, selectins, and syndecans.

Stem cells, whether multipotent or tissue-specific, embryonic or adult, are controlled by intrinsic transcriptional regulation and extrinsic signals^[22]. The extrinsic signals originate from the local microenvironment in which stem cells reside. It is well known that the ECM is an important component of the epidermal stem cell niche (see above). In the skin, high integrin levels can distinguish epidermal stem cells^[14], and now integrin expression can be used to enrich for stem cells in mixed cell populations^[23,24]. In our reports, on skin equivalents (SEs), addition of IGFBP-2 to culture media increased the expression levels of both $\alpha 6$ integrins and $\beta 1$ integrins in cultured keratinocytes, which are associated with an increased number of epidermal stem cells (*p63* positive cells)^[25] (Figure 3). Furthermore, it has been reported that activation of $\beta 1$ integrin decreases terminal differentiation^[26]. Signaling studies have demonstrated that the Erk/MAP kinase pathway, which acts downstream of $\beta 1$ integrins, provides a signal which inhibits differentiation^[26,27]. Collectively, these findings are consistent with previous reports that integrins are related to stem cell maintenance.

Integrin regulation and stem cells

Few studies have dissected how epidermal integrin expression and *ECM* gene expression are regulated. In our previous study, we reported that when hair

Figure 2 The inhibition of miR135b prolongs the stemness and proliferative potential of epidermal keratinocytes in skin equivalents models. **A:** Histology of skin equivalent (SE) models constructed with ib-mock-transfected or ib-miR135b-transfected keratinocytes, and immunohistochemical staining of these models for p63, proliferating cell nuclear antigen, type IV collagen, and integrin $\beta 1$, and integrin $\alpha 6$. Expression levels of p63, PCNA, type IV collagen, integrin $\beta 1$, and integrin $\alpha 6$ were increased in SEs generated from ib-miR135b-transfected cells; 1: ib-mock; 2: ib-miR135b; **B:** Fast-forward co-transfection of keratinocytes with “miRNA mimic” and “target protector”. 1: Negative control of miRNA mimic (10 nmol/L) and negative control of target protector (500 nmol/L); 2: miRNA mimic (10 nmol/L) and negative control of target protector (500 nmol/L); 3: MiRNA mimic and target protector (500 nmol/L). The inhibition of miR135b increases proliferation of keratinocyte via targeting type IV collagen; **C:** Real-time PCR analysis of gene expression in co-transfected keratinocytes. The housekeeping gene glyceraldehyde-3-phosphate dehydrogenase was used as an endogenous control. The result was same as (B). HE: Hematoxylin and eosin.

follicle dermal sheath cells were used to construct SEs, this resulted in increased epidermal thickness and increased expression of $\alpha 6$ integrins, compared to SEs generated from fibroblasts^[28] (Figure 4). Building upon this study, it was found that IGFBP-2 is a major factor produced by dermal sheath cells, which regulates the regenerative capacity of the skin; IGFBP-2 plays an important role in maintaining stem cell characteristics in human epidermal keratinocytes^[25]. These findings suggest that levels of integrins, which can be regulated by IGFBP-2, are vital for the maintenance of epidermal stem cell characteristics in the skin.

As it is well known that fetal wounds heal rapidly, we also evaluated the regenerative potential of and expression of integrins in neonatal keratinocytes and fibroblasts. When neonatal keratinocytes were used for epidermis reconstruction, expression of p63 was increased compared to adult keratinocytes; levels of integrins were also increased in this model^[28]. Recently, we also demonstrated that when neonatal fibroblasts were used to make a dermal substitute, both integrin and p63 expression increased (personal communication). Collectively, these results demonstrate that neonatal cells maintain a higher

Figure 3 Effects of IGFBP-2 on skin equivalents reconstruction. Skin equivalents (SEs) were cultured with rapidly adhering (RA) cells (A-E) or slowly adhering (SA) cells (F-O). Sections of SEs cultured under different treatments [media only (A-J) and 200 ng/mL IGFBP-2 (K-O)] and stained for hematoxylin and eosin (HE) (A, F, K), $\alpha 6$ integrin (B, G, I), $\beta 1$ integrin (C, H, M), p63 (D, I, N), and proliferating cell nuclear antigen or proliferating cell nuclear antigen (PCNA) (E, J, O). Addition of IGFBP-2 to culture media increased the expression levels of $\alpha 6$ integrins, $\beta 1$ integrins, p63, and PCNA in cultured keratinocytes. Original magnification 400 $\times$. Epidermal thickness was measured at 10 randomly selected locations using an Olysia Soft Imaging System (Olympus). Statistical analysis was performed using the Student's *t*-test. ^a*P* < 0.01 vs SA + no cytokine model.

regenerative potential compared to adult cells. This may result from the fact that neonatal cells have the

potential to express more integrins, which favors the environment of the epidermal stem cell niche.

Figure 4 Immunohistochemical staining for involucrin, filaggrin, keratin 1, and $\alpha 6$ integrin in skin equivalents generated from fibroblasts or dermal sheath cells. Sections of skin equivalents (SEs) produced using fibroblasts (A, B, E, F, I, J, M, and N) or dermal sheath cells (C, D, G, H, K, L, O, and P) were stained for involucrin (A-D), filaggrin (E-H), keratin 1 (I-L), and $\alpha 6$ integrin (M-P). SEs were cultured in complete medium in the presence (B, D, F, H, J, L, N, and P) or absence (A, C, E, G, I, K, M, and O) of ascorbic acid. Expression of involucrin, filaggrin, keratin 1, and $\alpha 6$ integrin was up-regulated in SEs of dermal sheath cells compared with SEs of fibroblasts. Original magnification: 400 $\times$ (A-P).

CONCLUSION

Many ECM genes are up regulated in epidermal stem cells. These proteins act as extrinsic signals that may affect stem cell fate. In this review, we have presented a general overview of ECM interactions, and discussed our previous reports demonstrating the important role that integrins and type IV collagen play in shaping the epidermal stem cell niche.

Abstract

Progressively loss of neural and glial cells is the key event that leads to nervous system dysfunctions and diseases. Several neurodegenerative diseases, for instance Alzheimer's disease, Parkinson's disease, and Huntington's disease, are associated to aging and suggested to be a consequence of deficiency of neural stem cell pool in the affected brain regions. Endogenous neural stem cells exist throughout life and are found in

specific niches of human brain. These neural stem cells are responsible for the regeneration of new neurons to restore, in the normal circumstance, the functions of the brain. Endogenous neural stem cells can be isolated, propagated, and, notably, differentiated to most cell types of the brain. On the other hand, other types of stem cells, such as mesenchymal stem cells, embryonic stem cells, and induced pluripotent stem cells can also serve as a source for neural stem cell production, that hold a great promise for regeneration of the brain. The replacement of neural stem cells, either endogenous or stem cell-derived neural stem cells, into impaired brain is highly expected as a possible therapeutic mean for neurodegenerative diseases. In this review, clinical features and current routinely treatments of age-related neurodegenerative diseases are documented. Noteworthy, we presented the promising evidence of neural stem cells and their derivatives in curing such diseases, together with the remaining challenges to achieve the best outcome for patients.

Key words: Alzheimer's disease; Huntington's disease; Neural stem cells; Parkinson's disease; Cell therapy; Neurodegenerative diseases

Core tip: Neural stem cells present throughout life of human. The cells can be distinguished from differentiated progeny by acknowledging a few key features, including proliferation, self-renewal, multipotency and molecular markers. These features make neural stem cells as an essential component in the development of nervous system and in maintaining cell number of adult nervous tissues following injury and diseases. Besides conventional treatments, neural stem cells have been proposed as a promising approach to cure patients with neurodegenerative diseases. Several animal studies showed the efficiency of neural stem cells in treating age-related neurodegenerative diseases, in particular

Alzheimer's, Parkinson's and Huntington's diseases.

INTRODUCTION

Neurodegenerative diseases are a global burden and often affect elderly population worldwide. The central and shared characteristics of neurodegenerative diseases are the loss of neuronal cells in either the central or peripheral nervous systems. Aging can cause chronic neurodegeneration, which results in the loss of particular neuronal subtypes over time. Parkinson's, Alzheimer's and Huntington's diseases are the three most dominant neurodegenerative diseases, found worldwide. In the brain, Alzheimer's and Huntington's diseases result in widespread loss of neurons, while Parkinson's disease involves the specific loss of midbrain dopaminergic neurons. In spite of an extensive effort to develop treatment against these neurodegenerative diseases, effective treatments still do not exist. Recently, cell therapy has been proposed as an attractive option, and the application of stem cell technology to regenerative medicine is rapidly progressed. Stem cell-based approaches are applicable for therapeutic purposes, for instance it might be possible to replace lost neurons or glia by transplantation of stem cell-derived nervous cells. Cell replacement might also be succeeded by activating endogenous neural stem cells in patients own brain to form new neurons and glia. In this review, we summarized clinical manifestations of the major age-related neurodegenerative diseases, in particular Parkinson's, Alzheimer's, and Huntington's diseases, together with their currently available treatments. The properties and characteristics of neural stem cells were presented, highlighting key features that enable neural stem cells to be a promising therapeutic material. Lastly, we documented evidence of neural stem cells and other stem cells to cure neurodegenerative diseases, especially Parkinson's, Alzheimer's, and Huntington's diseases.

CLINICAL MANIFESTATIONS OF AGE-RELATED NEURODEGENERATIVE DISEASES: ALZHEIMER'S, PARKINSON'S, AND HUNTINGTON'S DISEASES

Parkinson's disease (PD) is one of the most common movement malfunctions and affects nearly 1% in elderly population age over 60. The average age

of onset at 55 years, and the frequency increases markedly with age^[1,2]. There are several lines of studies proposing that genetic mutations or polymorphisms are correlated and can contribute to an increased risk of PD in senior population^[3]. Although genetics are only influenced a minor group of PD, the studies of genetic factors improve an understand of the pathophysiology of PD. An increasing number of genetic risks appear to be connected with PD, and many of them followed Mendelian inheritance rules, including alpha-synuclein gene (*SNCA*, PARK1/4), parkin gene (*Parkin*, PARK2), P-TEN-induced putative kinase 1 gene (*PINK1*, PARK6), Daisuke-Junko 1 gene (*DJ-1*, PARK7), and leucine-rich repeat kinase 2 gene (*LRRK2*, PARK8). These genes have been conclusively proven as a monogenic etiology for familial parkinsonism^[4]. To characterize PD, patients can be diagnosed by several key manifestations, including bradykinesia (slowness of establishing the voluntary movement and declination in speed of repetitive manners), resting tremor (4-6 Hz), and rigidity^[5]. A group of clinical outcome usually presents in an asymmetrical manner. The presences of a change in handwriting with micrographia, reduced sense of smell and facial expression, and loss of arm swing on one side of the body are often noted as early clinical features^[6,7]. When the disease progressively developed, gait instability, drooling of saliva, and impairment of postural reflexes will appear. Non-motor symptoms, such as neurobehavioral dysfunctions, insomnia, cognitive and sexual impairment may present in early or late stages of the disease progression. Depression and dementia are also common symptoms in non-motor presentation of PD's patients. A good response to levodopa treatment can differentiate PD from Parkinsonism due to other causes. The standard diagnosis for PD still relies on the neuropathological examination. All the cardinal signs of PD involve to motor disability in asymmetrical onset, without other causes of Parkinsonian syndrome and non-motor manifestations, including psychiatric symptoms^[8]. The UK Parkinson's Disease Society Brain Bank criteria is commonly used as a reference.

Alzheimer's disease (AD) is a progressively degeneration of the brain cortex, manifested by memory and intellectual decline, and progressive deficiency of daily-living activities^[9]. AD affects about 6% of the population aged over 65 years old worldwide. Age is considered the single utmost vital risk factor for AD ontogeny. Amyloid- β , oxidative stress, inflammation, and vascular injury appear to play an essential function in the neurodegeneration of AD^[10]. Multiple genetic defects have been associated to the development of AD. Initially, the molecular genetics of AD can be obtained from early-onset AD families with autosomal dominant patterns of inheritance. Highly penetrant mutations were identified in three genes: *APP*, *PSEN1*, and *PSEN2*^[11-13]. Interestingly, these genes are functionally participated in the processing of amyloid precursor protein. This suggests a central role of amyloid

precursor protein in AD pathology. Clinically, AD patients gradually evolve from the mildest to the most severe clinical manifestations of illness. Primarily, AD's patients present as an inability to restore newly acquired information, which can be examined by repetitively questioning. This short term memory impairment results from the atrophy of the hippocampus, especially the temporal horn^[14]. The clinical features are an amnesic type of memory dysfunction, deterioration of visuospatial, and language deficits^[15]. When the disease advances, devastation of other brain domains of cognition, including abstract thinking, language, judgment, calculation, and executive function, will develop. This impairment usually coincide with the aberration of art and social interpretations. AD patients evolve their symptoms from the loss of basic activities (e.g., dressing, eating, and bathing) to higher functions of activities in daily living (e.g., shopping, business management). Psychiatric and behavioural instabilities also progress over the course of AD. Emotional disorders (e.g., depression 25%-30%, anxiety 15%-25%, delusions in 20% of cases) and loss of initiation or apathy (up to 40%) commonly develop at early stage of AD and continue during disease progression. Motor and sensory dysfunctions, gait disorders, and other abnormal movements will appear at the late stage of the disease. The diagnosis of AD is frequently referred to the Diagnostic and Statistical Manual of Mental Disorders, fourth edition (DSM-IV) and the National Institutes of Neurologic and Communicative Disorders and Stroke-Alzheimer's Disease and Related Disorders Association (NINCDS-ADRDA) criteria^[16]. The gold standard of AD diagnosis is based on neuropathological findings of neuritic plaques (extra-neuronal β amyloid-containing plaques) and intra-neuronal neurofibrillary tangles in patient's brain tissues.

Huntington's disease (HD) is a rare inherited neurological disease, manifested by unwanted choreiform movements, psychiatric instabilities and cognitive deficiency^[17]. Disease onset is commonly between 30 and 50 years old and the patients with HD can present disease conditions at any time points during the disease progression. HD is a disease triggered by a repeated trinucleotide, CAG (more than 36 repeats), of Huntingtin gene located on the short arm of chromosome 4^[18]. Large duplication of CAG repeats are susceptible to replication error of the chromosome during meiosis, leading to extension or reduction of the CAG repeats^[19]. Choreiform movement is an early symptom, which causes limb incoordination and impaired function. This movement disorder is as a consequence of a selective neural cell death and atrophy in the putamen and caudate of the brain. Another significant feature in HD patients is an incapability to sustain a voluntary muscle contraction. The pattern of this symptom tends to change over time with other abnormal movements, such as rigidity, dystonia, and bradykinesia. HD patients might confront non-motor symptoms that could be more disturbing than motor symptoms, such as personality

changes, impulsivity, abnormal perceptions, lack of insight, and disability to learn new information or knowledge^[20]. Depression is also found and appears as a part of disease. Metabolic signs, for example weight loss and sleep problems, may contribute to depression of HD patients. A diagnosis of HD is relied principally on questionnaires, physical examination, family medical history, and neurological and psychiatric investigations. Brain imaging technology, in particular magnetic resonance imaging, can show structural alterations at specific locations in the brain affected by mutant Huntingtin protein. In spite of identification of the Huntingtin gene and other causative proteins, the mechanisms contributed to the pathogenesis and symptoms of HD remain largely elusive and this greatly hampers efficient development of clinical treatment.

CURRENT THERAPEUTIC APPROACH OF AGE-RELATED NEURODEGENERATIVE DISEASE

The early success in developing treatment strategies relied on the early understanding that PD is a DA deficiency disorder. Dopamine therapy is effective for improving both motor and non-motor symptoms in initial PD stage. Levodopa (LD) is considered as the most efficient and best accepted antiparkinsonian compound^[21]. Initiating levodopa as first-line therapy may achieve optimal outcomes in terms of patient function in the early years of the disease. Catechol-O-methyltransferase (COMT) inhibition increases the peripheral bioavailability of LD and reduces 3-O-methyldopa formation. The administration of COMT inhibitors with LD ensures a more stable plasma LD level and, consequently, it improves motor fluctuations. The use of COMT inhibitors improve the half-life of LD, and the triple combination carbidopa (CD)-LD-entacapone provide the most sustained LD plasma level^[22]. However, in long-term, this combination treatment is accompanied with the fluctuations of motor functions, dyskinesias and neuropsychiatric manifestations^[23]. Switching to alternative LD formulations, or supplementation of therapy with additional agents are general strategies for managing motor complications associated with LD. In addition, severe staged patients continually developed features that do not respond well to LD treatment, such as motor fluctuations, freezing episodes, autonomic dysfunctions, gait instability, dementia, and symptoms related to side effects of other medications^[24]. Surgical treatment is considered as an option for these patients who have motor fluctuations and dyskinesias, because these symptoms cannot be adequately managed by medications. The principal surgical option is deep brain stimulation, which has largely replaced neuroablative lesion surgeries for improving motor control^[25]. Next, the principal risk factor for AD is age. Several routinely-used drugs

can alleviate diseased conditions, but do not prove significant disease-improving effects^[26]. A number of therapeutic approaches intended at inhibiting disease progression are now developed into clinical trials. With disease advancement, brain degeneration in areas of memory, cognition, psychiatry, and movement, occurs to varying degrees. In clinical practice, non-medical interventions should be firstly tried, especially when symptoms are not causing distress to impact patients in daily living activity. Medical treatment for improving cognition, for instance acetylcholinesterase inhibitor, offers cognitive improvement (e.g., memory deterioration, language dysfunctions, and executive dysfunction,) and psychiatric repairment (e.g., depression, hallucination, agitation and delusion) in all stages of disease progression. The treatment with N-methyl-D-aspartate antagonist presents similar result, and this molecule can be applied in combination with acetylcholinesterase inhibitors in severe stage of AD patients^[27]. Many clinical trials aim to target at the generation and eradication of amyloid- β ($A\beta$) peptide, a dominant element of AD pathogenesis. Currently, the anti- $A\beta$ strategies are advancing with the increasing number of potential drugs. Direct interaction with $A\beta$ of small molecules could diminish $A\beta$ aggregation and deposition within the brain, thus reducing $A\beta$ -mediated synaptic dysfunction and neuronal cell death. The primarily anti- $A\beta$ drug to accomplish a clinical study was tramiprosate. Tramiprosate is a glycosaminoglycan derivative that binds to a single molecule of $A\beta$. The interaction of tramiprosate and $A\beta$ reduces the aggregation and toxicity of $A\beta$, while promote the clearance of $A\beta$ from the patient's brain. Although the treatment with tramiprosate was well tolerated, it fell short of an advantageous effect on the primary outcomes, which are the improvement on cognitive functions and clinical stages of AD patients. Another strategy to reduce $A\beta$ level within the brain is to minimize its production. Gamma secretase, a transmembrane enzyme, is reportedly required for $A\beta$ generation in several tissues, including brain. It cleaves at one end of the amyloid precursor protein, in which $A\beta$ is generated. Tarenflurbil, a non-steroidal anti-inflammatory drug, was found to lower the activity of gamma secretase enzyme, and, consequently reduce $A\beta$ production^[28]. In a Phase II of clinical trial in AD patients with mild-to-moderate symptoms, tarenflurbil was considerably safe and well tolerated; however, the beneficial effect of tarenflurbil on cognitive repairment was not observed^[29]. One possible explanation for the disappointing outcome of tarenflurbil is that oral administration cannot elevate the concentration of tarenflurbil inside the brain to be at sufficient level to reduce $A\beta$ production. An alternative approach focuses at modulating the abnormal aggregation of neurofibrillary tau protein, which is also another key feature of AD^[30]. Tau protein is a microtubule-associated protein, and found predominantly in neurons. Tau protein functions in

promoting and stabilizing the assembly of tubulin protein into microtubule filaments. In AD patients, hyperphosphorylation of tau protein is found in the cortex and hippocampus of the brain, and this could disrupt the original function of Tau protein. The hyperphosphorylated Tau results in self-assembly into paired helical filament structures that accumulate and form intraneuronal tangles, a neurotoxic agent. There are several compounds that can inhibit Tau-self aggregation. For instance, methylene blue, an extensively used histology dye, has been tested for its interference effect on Tau-self aggregation^[31]. This compound is currently experimented as a potential effective molecule for AD treatment, since a Phase II clinical study of methylene blue has been completed, and some outcomes suggested a drug benefit in a group of AD participants^[32]. Nevertheless, it is noted that there are no effective treatments available for AD at the present. Thus, the current strategy of AD management is to decrease symptoms and improve patient's quality of life. It is sensible to expect that, in the coming years, an optimal synergistic combination of these therapeutic compounds will be formulated, which will be able to modify neurodegenerative cascade and, therefore, reduce the global impact on the brain of this dreadful disease.

Lastly, the treatment of HD has been focusing on relieving motor dysfunctions (chorea), cognitive decline and psychiatric manifestations^[33]. Pharmacological treatment of Huntington's disease might not be necessary if symptoms are mild or not troublesome. Clinically, there are various potential drugs that show the capacity to correct the conditions of HD patients. Treating chorea is an important part of HD management, because it interferes to the quality of life of HD patients. Tetrabenazine was approved in 2008 by the United States Food and Drug Agency to control the involuntary periodic movements of the limbs and face, associated with chorea^[34]. Tetrabenazine is a central monoamine extingisher that reversibly binds to the type-2 vesicular monoamine transporter^[35]. Dopamine and glutamate transmission and interaction are one of the affected pathway in the HD brain. The aberrations of this can result in striatal and cortical connection dysfunctions^[36]. Therefore, most treatments, investigated at chorea, have targeted to these neurotransmitters and their receptors. Antipsychotic drugs, for instance clozapine, haloperidol, olanzapine, and, chlorpromazine, which act by reducing dopamine levels, are occasionally prescribed to lower chorea symptom^[37]. A side benefit of these antipsychotic drugs is that they also help controlling the HD-associated psychotic behaviors. Besides pharmacological treatment, physical and occupational therapy at the initial stages of the disease can correct motor dysfunction and locomotion, which is due to the fact that exercises can reinforce muscle strength and improve balance and posture of HD patients^[38]. Psychiatric therapy can help reducing stress, anxiety

Table 1 Characteristics and conventional treatment for Alzheimer's, Parkinson's and Huntington's diseases

Disease	Characteristics	Treatment	Ref.
Alzheimer's	Memory impairment Impaired reasoning and handling of complex tasks, poor judgment Changes in personality, behavior, or comportment	Medications: Cholinesterase inhibitors NMDA antagonist Non-medicals Psychological supports	[9,15,16,26,27,30]
Parkinson's	Motor symptoms (1) Rest tremor (2) Bradykinesia (3) Rigidity (4) Loss of postural reflexes Non-motor symptoms (1) Autonomic dysfunction (2) Cognitive/ neurobehavioral abnormalities (3) Sleep disorders (4) Sensory abnormalities such as anosmia, paresthesias and pain	1 Medications Dopaminergics: (1) Levodopa (2) Ergot dopamine agonists (3) Non-ergot dopamine agonists Non-dopaminergic: (1) COMT inhibitors (2) MAO-B inhibitors 2 Non-medicals Ablative lesions Deep brain stimulation	[1,6-8,23-25]
Huntington's	Choreiform movement Cognitive impairment Behavior and psychological disorders	Medications Symptomatic agents	[17,18,20,33,36]

NMDA: N-methyl-D-aspartate receptor; COMT: Catechol-O-methyltransferase; MAO: Monoamine oxidase.

and depression, as well as help managing with the emotional changes associated with the disease. Table 1 summarized characteristics and conventional treatment for Alzheimer's, Parkinson's and Huntington's diseases.

NEURAL STEM CELLS: PROPERTIES AND CHARACTERISTICS

Several lines of studies suggest that stem cells exist in the central nervous system (CNS)^[39]. Neural stem cells exist not only in the embryonic brain, but also in the adult nervous system of all mammals, including human. Neural stem cells can be distinguished from differentiated neurons by acknowledging a few key features, including proliferation, self-renewal, multipotency and molecular markers^[40]. These features make neural stem cells as an important element in CNS development and in maintenance cell number following injury and diseases or natural cell turnover.

Proliferation and self-renewal

To reach the correct number of differentiated cells in the CNS, neural stem cells have to be precisely controlled a balance between cell proliferation and differentiation during the embryonic CNS development. This balance is regulated by both stimulatory and inhibitory signals to converge the requirements of the tissues in which neural stem cells provide newly differentiated progenies. Proliferation potential is one of the most essential characteristics of neural stem cells and it was shown that neural stem cells in adult brain can be propagated *in vitro* for years^[41]. In order to generating a satisfactory number of neural stem cells, it is assumed that cell proliferation should be prevalent

in the early developmental timing, and that more cells differentiate into a specific cell type during the latter phases. This indicates that there is a high possibility for producing two undifferentiated daughter cells at early stages of development (symmetric division), and later cell division prefers the production of differentiated neurons and glial cells (asymmetric division). Neural stem cells residing in the developing neocortex undertake both symmetrical and asymmetrical divisions throughout their life span^[42]. Several pathways that interconnect to control cell proliferation have been well documented. Perhaps the best comprehensive studies are those cell signalling pathways that are triggered by growth factors. All types of neural stem cells are generally responsive to multiple family of growth factors; however, the exact set of growth factors should be exclusively required for neural stem cells at specific stages and could distinguish stage-specific neural stem cells. Early neural stem cells entirely respond to fibroblast growth factor2 (FGF2 or bFGF), and the loss of FGF ligands or FGF receptors results in a significant diminution of neural stem cell proliferation^[43]. On the other hand, the late emerging neural stem cells demand either FGF2 or epidermal growth factor for their proliferation^[44]. It is noted that cell self-renewal is tightly connected to this growth factor responsive potential. Self-renewal is considered as a pivotal identity of neural stem cells because it is indispensable for the cells to preserve themselves, therefore at least one of the progeny retains similar molecular characteristics to the mother stem cells. It is important to note that while a process of self-renewal occurs, neural stem cells may undergo changes in their abilities to produce different progeny during development^[45].

Multipotency

To be characterised as a neural stem cell in the CNS, a cell must contain a differentiation potential to give rise to neurons, astrocytes and oligodendrocytes^[41,46]. It is noted that neural stem cell plasticity is progressively restricted as development advances, for example early neural stem cells appear to be specified a wide range of phenotypes, from anterior to posterior parts of the brain, while late neural stem cells is only restricted to its origin^[47]. It was presented that adult neural stem cells exist mainly in two areas of the brain, subventricular zone (SVZ) and sub granular zone (SGZ), can be propagated *in vitro* for years^[41]. Neural stem cells in the SVZ can differentiate into olfactory neurons, while neural stem cells of SGZ differentiate into granular neurons of the dentate gyrus. However, when transplanting SVZ neural stem cells into dentate gyrus, they differentiate into calbindin-positive granular cells, while transplanting SGZ neural stem cells into the olfactory bulb, tyrosine- and calretinin hydroxylase-positive cells were observed. Furthermore, when transplanted into the developing eyes, hippocampal neural stem cells exhibited several morphological and immunological properties of retinal cells, including photoreceptors^[48]. This implies that the fate of adult neural stem cells could be influenced by environmental cues^[49]. In addition to the effects from environment, cell intrinsic programs also influence cell differentiation capacity. The robust intrinsic differences, with respect to distinct differentiation potential, has been shown to exist between neural stem cells isolated from different brain regions^[50,51].

Molecular markers

Many efforts have attempted to define neural stem cells according to their biological properties and molecular markers. In addition to those biological parameters, a series of immunoreactive antigens could also distinguish neural stem cells from others. Markers that define this population are now being developed; thus, they are commonly characterised retrospectively on the foundation of their behaviours. The evaluation of self-renewal of neural stem cells can be initially accomplished by the expression of specific molecular markers that can distinguish them from postmitotically differentiated cells. The successive expression of various intermediate filament genes has offered a useful system to classify distinct cell types during the early embryonic neural stem cells. The intermediate filament Nestin and Vimentin are exclusively expressed in the mitotically active cells during neural tube formation^[52]. Embryonic neural stem cells express several astrocytic markers, for instance brain lipid-binding protein, glutamate transporter, S100 β , RC2 and 3CB2^[53]. Together with their differentiation potential, these astrocytic features distinguish embryonic neural stem cells from other types of astrocytes and differentiated cells. On the

other hand, adult SVZ neural stem cells appear to be slowly proliferating and long-term BrdU-retaining cells, which express GFAP and the glycoprotein CD133 (Prominin-1)^[54]. Anatomical structures and comprehensive set of immunohistochemical markers help to ensure adult SVZ neural stem cell identity. A subset of these cells is identified by the expression of the intermediate filament Nestin, GFAP, transcription factor SOX2, and the RNA binding protein Musashi1, while absence of expression of the differentiated markers CD24, NeuN, and O4^[55]. In the SGZ of the dentate gyrus, a comparable subset of neural stem cells expressing GFAP, SOX2 and Nestin resembles to dormant or quiescent adult neural stem cells which can give rise to mature astrocytes and neuroblasts^[56].

An evolving regulatory networks governing neural stem cell identity is delineated by an integration of cell internal transcription factors with the cell extrinsic stimuli from an environment or culture conditions. Unrevealing how these regulatory network functions to control neural stem cells is essential to better understand of neural stem cell biology. Ultimately, it will also accelerate the progression of a novel targeted therapy by using neural stem cells for curing neurological disorders, for instance brain tumours, brain injuries, and also neurodegenerative diseases, for example HD, AD and PD.

POTENTIAL OF NEURAL STEM CELLS FOR TREATING AGE-RELATED NEURODEGENERATIVE DISEASES

Cell replacement by neural stem cell transplantation in the brain could alleviate pathological or functional deficits associated with diseases in the CNS. In addition to conventional clinical treatments, cell replacement therapy has offered the novel basis for the development of effective therapeutic strategies for human neurodegenerative diseases (Figure 1). It is hypothesised that the release of neurotransmitters and the production of neurotrophic factors from transplanted cells are possible mechanisms that promote neuronal regeneration in the damaged brain areas. PD is characterized by a vastly loss of midbrain dopaminergic neurons in the substantia nigra pars compacta and the striatum. It was reported that human fetal ventral mesencephalic tissues was successfully transplanted into the striatum of PD patients with advanced disease; however, this human tissue transplantation contains some limitation^[57]. For example, a sufficient amount of fetal tissues was challenging to obtain and the survival and integration of transplanted cells in patient's brains was found to be minimal^[58]. Besides, the development of abnormal movements was noticed in PD patients who have received embryonic nigral transplants. The potential propagation of Lewy body from host-to-graft tissues is also a serious concern^[59]. The generation

Figure 1 Neural stem cells as a therapeutic material for neurodegenerative diseases. Schematic image presents conventional treatments for Alzheimer's, Parkinson's, and Huntington's diseases. Neural stem cells serve as a potential therapeutic material, which can be obtained from several sources.

of dopaminergic neurons from stem cells could be considered as a practical and effective alternative for PD treatment. Previous studies demonstrated that dopaminergic neurons derived from human pluripotent stem cells contained comparable molecular profiling, biochemical and electrophysiological properties to human midbrain dopaminergic neurons^[60]. Importantly, the transplantation of dopaminergic neurons derived from human pluripotent stem cells can restore pathological conditions of the diseased animals, which are mice, rats and monkeys, without overgrowth of the neurons^[61]. Histological analysis of the brain indicated that the transplanted cells were well survived and integrated within the experimented animals. In addition to the derivation from human pluripotent stem cells, dopaminergic neurons can be generated by the direct conversion of human fibroblasts by overexpression of five key transcription factors, including *Mash1*, *Ngn2*, *Sox2*, *Nurr1*, and *Pitx1*^[62]. The direct reprogrammed dopaminergic neurons were positively stained for several markers for dopaminergic neurons, and showed characteristics of dopamine uptake and production. Moreover, dopaminergic neurons generated from fibroblasts provided symptomatic improvement when transplanted into a rat PD models^[62].

AD is classified by the degeneration and death of neurons throughout the brain, in particular in the basal forebrain, amygdale, hippocampus, and cortical areas. To date, AD therapy has been relied on small molecules designed to increase acetylcholine (ACh) concentration by inhibiting acetyl cholinesterase^[63]. Since these drugs are only supportive without potential protection or regeneration against progressive brain destruction, there is a need for an effective treatment and stem cell-based therapeutic approach should satisfy this requirement. Rodent AD models that received neural stem cells grafts exhibited an increased hippocampal synaptic density and improved cognitive function^[64]. Intraventricular transplantation of human neural stem cells overexpressing choline acetyltransferase (ChAT) sufficiently restored learning and memory ability of kainic-induced AD rats^[65]. In addition, a recent study demonstrated that human mesenchymal stem

cells can enhance autophagy in amyloid β -treated neurons and mice, thus promoting amyloid β clearance and increasing neuronal survival against amyloid β toxicity^[66]. Transplantation of human adipose tissue-derived mesenchymal stem cells into the brains of aged mice enhance the levels of ACh, and consequently improve the cognitive and locomotor functions of the mice^[67]. Interestingly, it was studied that ChAT-positive neurons could be directly generated from mesenchymal stem cells. These cells after transplantation could significantly improve learning and memory capacity of AD animal models^[68]. Nevertheless, there is still an argument raising whether mesenchymal stem cells can cross lineage boundaries and transdifferentiate into neuronal cells.

HD is an autosomal dominant neurodegenerative disorder, identified by uncontrolled choreic movement, cognitive disruption, and emotional instability. Initial cell-based therapy was examined by using human fetal striatal grafts and showed some clinical positive outcome in HD patients^[69]. However, the latter study found unpleasant results; grafted striatal tissues contributed to neural overgrowth and then tumour in an HD patient, who survived 5 years post-transplantation^[70]. The transplantation of neural stem cells and striatal grafts into rodent HD models demonstrated that the medium spiny neurons of transplanted cells could integrate and form neuron circuitry in the host brain^[71]. Transplantation of neural stem cells has been used not only to replace degenerated neurons, but also to protect striatal neurons against excitotoxic insults. Striatal injections of human neural stem cells into HD rodents showed incorporation into host tissues as well as migration to secondary sites associated with the disease pathology^[72]. In addition to primary cells, human neural stem cells derived from human embryonic stem cells could provide a viable source for cell therapy in HD. Previous works showed that neurons expressing striatal markers could be induced from human embryonic stem cells and brain transplantation of these human embryonic stem cell-derived neurons leads to behavioural recovery in the diseased animals^[73].

FUTURE PERSPECTIVE OF NEURAL STEM CELL-BASED THERAPY

Neurodegenerative diseases affect human well-being worldwide due to their devastating nature, cost, and lack of effective therapies. Although neural stem cells offer a great promise of treating these ailments, there are still several issues needed to be solved prior to the translation of neural stem cells into clinical setting. Several research groups around the world presented supportive data of the effectiveness of neural stem cells in correcting pathological conditions of neurodegenerative diseases; nevertheless, the exact mechanisms of how transplanted cells recover host brain function is not yet elucidated. Another important concern of neural stem cells after transplantation is the ability to migrate to the correct niche and the proper differentiation and maturation into desired neuronal cell types. And, importantly, if their growth cannot be appropriately controlled, neural stem cells may form tumor, which is more devastating condition than the original disease. Recent advance in cellular reprogramming can convert skin fibroblasts toward neural progenitor cells by chemical cocktail and hypoxia condition^[74]. These induced neural progenitor cells express multiple neuron-specific proteins, generate action potentials, and give rise to several neuronal subtypes. Generation of induced neural progenitor cells from non-neural lineages could have important implications for several purposes, including neurodevelopmental study, neurological disease modeling, and regenerative medicine application. In the near future, we might have a better understanding of pathogenesis of neurodegenerative diseases through patient-specific induced neural stem cells. The combination gene therapy with induced neural stem cell transplantation could formulate a new paradigm of therapeutic strategy to cure mutation-caused diseases^[75]. Altogether, while number of questions for neural stem cell application remain unanswered, the concerted efforts on neural stem cell research have already made a great progress toward cell replacement therapy in order to assure the best safety for patients.

hypoxic environment, and intracellular factors including genome stability, mitochondria integrity, epigenetic regulators, calorie restrictions, nutrients, and vitamin D. Secreted tumor growth factor- β and fibroblast growth factor-2 are reported to play a role in stem cell quiescence. Extracellular matrices may interact with caveolin-1, the lipid raft on cell membrane to regulate quiescence. N-cadherin, the adhesive protein on niche cells provides support for stem cells. The hypoxic micro-environment turns on hypoxia-inducible factor-1 to prevent mesenchymal stem cells aging through p16 and p21 down-regulation. Mitochondria express glucosephosphate isomerase to undergo glycolysis and prevent cellular aging. Epigenetic regulators such as p300, protein inhibitors of activated Stats and H19 help maintain stem cell quiescence. In addition, calorie restriction may lead to secretion of paracrine cyclic ADP-ribose by intestinal niche cells, which help maintain intestinal stem cells. In conclusion, it is crucial to understand the anti-aging phenomena of stem cells at the molecular level so that the key to solving the aging mystery may be unlocked.

Key words: Stem cells; Anti-aging; Quiescence; Micro-environment

Core tip: This review approaches anti-aging from aspect of stem cells. Stem cells may interact directly with their extracellular surroundings through caveolin-1, a lipid raft protein, to carry out and maintain stem cell functions. Mechanisms through hypoxia-inducible factor-1, glycolysis, and epigenetic regulators such as p300, protein inhibitors of activated Stats and H19 play crucial role in stem cell quiescence, and anti-aging regulations. Conversely, genomic instability such as DNA double-strand-breaks modulate cellular aging through the mammalian target of rapamycin pathway, which may lead to decreased lifespan.

Abstract

Scientific evidence suggests that stem cells possess the anti-aging ability to self-renew and maintain differentiation potentials, and quiescent state. The objective of this review is to discuss the micro-environment where stem cells reside *in vivo*, the secreted factors to which stem cells are exposed, the

INTRODUCTION

Definition of stem cells and stem cells aging

In 1881, Weismann *et al.*^[1] discovered that organ performance was influenced by the finite cell division of tissues. Followed by Hayflick *et al.*^[2] in 1961, who discovered that normal human cells have finite cell replication and lifetime which represents human aging. When cells reach maximal replicative capacity, it is a phenomenon termed cellular senescence, or cellular aging. Recent evidence supports the model that stem cells *in vivo* are retained in a quiescent state, which can be reactivated into cell cycle progression in response to extracellular stimuli even after prolonged period of quiescence. Upon stimulation, stem cells divide to yield undifferentiated progeny and also differentiated cells through subsequent rounds of proliferation^[3]. With self-renewal capability, stem cells pool assures a constant supply of stem cells, and also differentiated cells throughout an organism lifespan. However, loss of stem cells number or functionality with age can lead to profound consequences on tissue viability^[4]. Recent data suggests that stem cells aging is partly due to heritable intrinsic event such as DNA damage, changes in their niches and micro-environment^[3]. Through systemic influences, old tissues might be rejuvenated to a young state^[5]. The significant sign of aging in stem cell culture is a diminishing replicative capacity, in which the maximal population doublings of mesenchymal stem cells (MSC) are reported as 30-40^[6]. *In vitro*, MSC cellular aging is associated with the age of donor^[7]. Conversely, *in vitro* culture of embryonic stem cells (ESC) showed no loss of proliferative potency^[8]. Human MSC cultured *in vitro* have spindle-shaped fibroblastic morphology and usually cease to proliferate no more than 40 population doublings, with the cells becoming enlarged and more flattened^[9]. The increase in cell size is associated with aging *in vitro*^[10]. Unravelling these distinctive features of aging stem cell phenotype is critical to the success of therapeutic application of stem cells in the field of regenerative medicine with respect to tissue injury, degenerative diseases or organ declines that accompany aging^[11].

Anti-aging effects of stem cells

The involvement of MSC in cell replenishment and lifespan regulations^[12] is evident since aging is defined as the sum of primary restrictions in regenerative mechanisms of multicellular organisms^[13]. Recently, the best strategy suggested to "cure" aging due to

DNA damage is a rapid and effective elimination of the damaged stem cells by apoptosis^[14]. This theory implies that stem cells may conceive ability to limit and repair intracellular damage. For example, stem cells possess robust cell surface transporters that exclude toxins^[15], the machinery for double-stranded DNA breaks repair^[16], and the production of telomerase to ameliorate telomere shortening^[17]. Also, stem cells appear to have evolved multiple mechanisms such as senescence and apoptosis to sense damaged stem cell genome with malignant potential in order to limit replicative expansion^[3,18]. These tumor-suppressor mechanisms may contribute to stem-cell irreversible growth arrest^[3]. It is worthy to understand the impacts of aging on stem cells to propose valuable strategies, gather information for potential medical anti-aging interventions.

Definition of extrinsic factors that alter stem cells properties

Aging can lead to changes of not only properties and number of stem cells, but also the niche cells, which gradually lead to decline in homeostasis and tissue regeneration. Aging has both quantitative and qualitative effects on stem cells. The qualitative changes affect self-renewal, developmental potential, and interactions with extrinsic signals^[19]. Changes in the niche or micro-environment include amount and composition of extracellular matrix (ECM), altered expression of membrane proteins and lipids in niche cells that are in direct contact with stem cells, and changes in secretion of soluble paracrine or endocrine factors (Figure 1B). In the case of tissue injury or disease, factors released from damaged cells are altered, leading to inflammatory response^[11]. Micro-environment *in vivo* is comprised of a stem cell compartment, niche cells that support stem cells, and complex ECM including fibronectin, collagen (I and IV), heparin sulphate, chondroitin sulphate, and hyaluronan^[20]. The three different micro-environments: environmental enrichment, physical exercise and calorie restriction increased the number of newly regenerated neural cells in the dentate gyrus^[21]. Hyaluronan preserved differentiation potentials of MSC derived from mouse^[22]. Hyaluronan also maintained MSC derived from human placenta in a slow-cycling mode, which was similar to quiescent state^[23]. Besides, hyaluronan is widely reviewed to regulate stem cells behavior *via* cluster determinant 44, receptor for hyaluronan-mediated motility, lymphatic vessel endothelial hyaluronan receptor, hyaluronan receptor for endocytosis, liver endothelial cell clearance receptor, or toll-like receptor 4^[24]. A report implied that the activation of cells for productive tissue regeneration required a systemic micro-environment that maintains stem cells^[5].

The micro-environment where stem cells reside *in vivo* plays important role in maintaining stem cells properties, and in regulating stem cells aging. *In vivo*, the stem cells are tightly linked to their micro-

Figure 1 Stem cell maintenance and altered state during aging. A: Secreted growth factors, paracrine, calorie restriction, hypoxic micro-environment, ECM, and niche cells maintain stem cell functions. Quiescent, self-renewing, and multipotent status of stem cell are further maintained through intracellular hypoxia-responsive element, epigenetic and genomic regulators, and mitochondria; B: However, the status of stem cell is altered with decreased niche cells, fragmented ECM, increased genomic and mitochondria DNA damage, and increased ROS during aging. ECM: Extracellular matrix; ROS: Reactive oxygen species; SC: Stem cell.

environment such as ECM, and surrounding niche cells which promote self-renewal, maintain differentiation potential, maintain quiescence, regulate cell survival, homeostasis and also cellular lifespan (Figure 1). The adhesive protein N-cadherin on niche cells support stem cells; whereas integrins on stem cells and extrinsic regulators such as angiopoietin-1 (Ang-1), tumor growth factor- β (TGF- β), bone morphogenetic protein (BMP), thrombopoietin (TPO), wntless/integrated (Wnt), β -catenin (CTNNB) and osteopontin (OPN) play a role in stem cells quiescence^[25]. Hematopoiesis of hematopoietic stem cells (HSC) required the secreted factors, including stem cell factor, Ang-1, TPO, Wnt, NOTCH, OPN, chemokine stromal cell-derived factor-1 α (SDF-1 α), and direct interaction with integrin^[26]. Using genome-wide chromatin and transcriptional profiling of hair follicle stem cells *in vivo*, the hair follicle micro-environment triggered LIM homeobox-2 (LHX2) expression, which trans-activated genes that orchestrated cytoskeletal dynamics and adhesion^[27]. The removal of LHX2 led to disastrous cellular disorganization and polarization, loss of quiescence for hair follicle stem cells, loss of normal hair anchoring, as well as progressive transformation of the niche into a sebaceous gland^[27]. Since the extrinsic micro-environmental factors are required for maintaining the youth of stem cells, their interactions with stem cell membrane may also play important roles. Recently, a membrane lipid raft protein known as caveolin-1 (Cav-1), was reported to be involved in HSC quiescence and self-renewal, wherein Cav-1-deficient mice had impaired self-renewal and altered quiescent state^[28].

Furthermore, stem cells require growth factors, cytokines and mitogens for maintenance. The activation of the Wnt-Frizzled receptor with co-receptor LRP5/6 which target cytosolic CTNNB, and activation of the TGF- β receptor kinases 1/2 that phosphorylate Smads 2/3 helped maintain differentiation potential^[29]. TGF- β is a potent inhibitor of stem cell growth and cell cycle *in vitro*, and is suggested to be a regulator of stem cell

quiescence *in vivo*^[30]. Another micro-environmental factor, insulin-like growth factor-binding protein-2 (IGFBP2), used its C-terminus domain to support HSC survival and cell cycle^[31]. In addition, IGFBP2 promoted hMSC osteogenesis *via* interaction with integrin α -5^[32]. The BMP also interacted with fibroblast growth factor-2 (FGF2) through FGF receptor, which in turn activated Smad1, Smad5 and Smad8 to inhibit differentiation, and maintain quiescence in rat neural stem cells^[33]. Meanwhile, FGF2 signaling alone suppressed terminal astrocytic differentiation, and maintained rat neural stem cell potency during quiescence^[33].

MOLECULAR MECHANISMS OF STEM CELL ANTI-AGING

Hypoxia induced by micro-environment

Stem cells are maintained in a low oxygen environment or hypoxia in their native state. In general, 5% of pO₂ is the physiologically-relevant O₂ concentration in stem cells micro-environment. When 5% of pO₂ was exposed to the micro-environment, Wharton Jelly derived-MSC culture rejuvenated toward less differentiated, more primitive phenotypes^[34]. It also promoted and stabilized expression of OCT4A, NANOG, SOX2, and REX1 in induced pluripotent stem cells (iPSC)^[35]. Because 2% O₂ decreased mitochondrial DNA content^[36], this suggests that hypoxia-induced stem cell rejuvenation may be linked to energy metabolism *via* the mitochondria. Under condition of 1% O₂, hypoxia-inducible factor-1 (HIF-1) activation led to decreased extracellular signal regulated kinase, followed by decreased p16 expression^[37]. The decreased expression of the aging marker p16 helped MSC escaped cellular aging *in vitro*^[37]. A recent study further confirmed that 1% O₂ down-regulated DNA damage responsive molecules, including ATM/ATR, Chk1, and Chk2, and also cellular aging markers, including senescence-associated- β -

galactosidase, H3K9me3, heterochromatin protein 1- γ (HP1 γ), p53, p21, and p16^[38]. Since cellular aging is often accompanied with telomere length loss, it was observed that bone marrow MSC expanded under hypoxia (3% pO₂) for 15 d demonstrated telomere length maintenance; however, telomere length decreased over time under normoxia^[39]. Recently reported a major pathway that inhibits MSC senescence due to hypoxia is the HIF-1 α -TWIST pathway which down-regulated E2A-p21^[40]. In addition, hypoxia induced an immediate and concerted down-regulation of genes involved in DNA repair and damage response pathways (including *MLH1*, *RAD51*, *BRCA1*, and *Ku80* genes)^[36], which suggests that hypoxia plays a role in genome stability. Furthermore, p53 may suppressed HIF-1 translation through targeting pro-myelocytic leukemia (PML) protein, which activated the mammalian target of rapamycin (mTOR) pathway to induce aging (Figure 2)^[41,42]. Conversely, HIF-1 interacted with the aging marker p53 that led to p53 stabilization^[43], resulting to a pro-aging phenomena. Taken together, hypoxia provides stem cells with an anti-aging micro-environment and is required for healthy aging progression.

Genome stability linked to stress induced by micro-environment

The genome is like an internal turbine engine inside a cell that works perpetually throughout the life of cell. Without it, cell survival is impossible, and youth of cells cannot be maintained. In the 1950s, researchers Mortimer and Johnston stated that aging in yeast is accompanied by genome instability^[44]. In principle, there are three different modes of genome instability: mutations, mismatch repair deficiency and chromosomal instability^[45]. Mechanisms of genome instability linked to mammalian aging are stress-induced reactive oxygen species (ROS), telomere loss, and germ-line genetic variations for DNA repair^[46,47]. In addition, DNA damage caused by ROS was stated to elicit transient growth arrest, apoptosis and cellular senescence^[48]. In adult hematopoietic stem and progenitor cells (HSPCs), the histone deacetylase Sirt1 is linked to longevity^[49], DNA damage accumulation, and loss of progenitor cells. Under stress of Sirt1 ablation, HSPCs increased *Hoxa-9* expression, leading to increased DNA damage^[50]. Another sirtuin family protein, SIRT6, also regulates aging and genome stability. During DNA double-strand break repair, SIRT6 promoted DNA end resection in order to maintain genome integrity^[51]. Interestingly, a family member of p53, TAp63, prevented premature aging in skin cells as observed in TAp63^{-/-} mice by maintaining properties of epidermal and dermal precursors^[52]. The most prominent evidence that links genome stability with aging is the human disease known as progeroid syndrome. Defects in the DNA repair system known

as transcription-coupled excision repair (TCER) leads to progeroid syndrome^[53], wherein lesions in transcribed strand of active genes are repaired with defective TCER^[54]. In contrast to what is known about quiescence, the stem cells are prone to DNA damage accumulation while in quiescence. A previous study stated that following DNA damage, stem cells utilized non-homologous end-joining (NHEJ) repair system during quiescence; however, the NHEJ response is normally associated with genome rearrangement and abnormalities in HSC^[55]. In brief, genome stability is crucial for stem cells maintenance.

Mitochondrial property changes upon stem cells aging

Mitochondria play a significant role in the aging-induced signaling pathway since aging is generally characterized as a progressive decline of tissue and organ function accompanied by increased oxidative damage and mitochondrial dysfunction. Stem cells in the quiescent state appear to be less metabolically active and may be subjected to lower levels of cellular metabolism byproducts, mainly ROS. Since mitochondria are the sites for oxidative metabolism, ROS may inflict damage to its DNA and the organelle itself. Previously, functional analysis demonstrated altered mitochondrial morphology, decreased antioxidant capacities and elevated ROS levels in long-term cultivated young MSC as well as aged MSC^[56]. Another previous study stated that mice expressing a mutant form of mitochondrial DNA polymerase- γ led to HSC with compromised functions, indicating that mitochondrial integrity is crucial for stem cell maintenance^[57]. In addition, long-lived post-mitotic cells with acquired stem cell damage may be inherited by progeny cells since the mitochondrial DNA damage is passed down the generations. Recent evidence indicates that loss of a negative regulator of the *Ink4a/Arf* locus, also known as *Cdkn2a* or *BMI1*, is associated with decreased mitochondrial function, decreased electron transport flux, increased ROS concentrations, and loss of stem cell functions^[58]. Furthermore, hypoxic stimulation of glycolytic flux as well as inhibition of the p53 pathway^[59] partly stimulated glycolysis to improve stem cell pluripotency^[60] and also resulted in a younger cell phenotype. Interestingly, direct pharmacological modulation of energy metabolism or supplementation with glycolytic intermediates augmented reprogramming efficiency through glycolysis^[61]. Over-expression of the glycolytic enzyme, glucosephosphate isomerase (GPI), showed enhanced glycolysis and bypassed senescence with an increased resistance to oxidative DNA damage. In addition, depletion of GPI shortened cellular lifespan. Coincidentally, mouse embryonic stem cells, which are stem cells highly resistant to oxidative stress demonstrated a high level of glycolysis^[62]. Overall, these findings suggest that stem cells can utilize mitochondria to escape restrictions of cellular lifespan *via* an anti-aging mechanism (Figure 2).

Figure 2 Signals and regulators of anti-aging in stem cell. Up-regulation of phosphorylated Smad1, Smad5, Smad8 and Smad2, Smad3 proteins maintains stem cell quiescence. Epigenetic regulators p300, DNMT3A, and H19 also maintain stem cell quiescence. Hypoxia induces HIF-1 α , a key regulator of p21 and p16 to prevent cellular aging. Under hypoxic condition, mitochondria undergo glycolysis to maintain self-renewal, and lower ROS production. With genome integrity maintained, the mTOR pathway is deactivated. In addition, stem cells interact with ECM, secreted factors from niche cells, and adhesive proteins to further maintain stem cell functions. Epigenetics regulations

The process of aging is accompanied by nuclear architectural instability in the cell^[63,64]; however, there is a lack of evidence to show that DNA damage reduction can extend lifespan of cells *in vitro*. As a result, scientists have suggested that aging may also be caused by epigenetic regulations^[65]. Recently, protein inhibitors of activated Stats (PIAS1), a SUMO E3 ligase was shown to regulate HSCs self-renewal via GATA1 suppression by binding to GATA1 promoter region to recruit DNMT3A^[66]. Using genome-wide mapping at an enhancer associated histone mark H3Lys27 acetylation and p300 binding at promoter site, the nuclear factor-1 (NF1) protein family seemed to be required for neural stem cell (NSC) entry into quiescence^[67]. In addition, integrin alpha-6 was down-

regulated when the NSC entered quiescence^[67]. Interestingly, the imprinting alleles H19-Igf2 helped maintain HSC quiescence, wherein the maternal H19 region is differentially methylated (H19-DMR). Deletion of the H19-DMR led to Igf-Igfr1 activation and loss of quiescence^[68]. Previous findings suggested that Mym1 modulated histone modification of the Gfi1 promoter region in order to recruit Gata2 and Runx1 while maintaining HSC quiescence^[69]. Moreover, the rejuvenation of muscle cells, skin cells and bone marrow cells of mice were observed through systemic connection of one old mouse to another young mouse and were suggested to be modulated by epigenetics^[65].

Calorie intake

Apart from these, caloric restriction due to limited

calorie intake is also responsible for extrinsic signaling in stem cell maintenance and aging. In general, mechanisms involved during the stem cell quiescent state are different from those during active proliferative state. Calorie restriction led to up-regulation of cyclic ADP-ribose signaling in the intestinal niche cells known as Paneth cells, and induced proliferation of leucine rich repeat-containing G protein-coupled receptor 5-positive intestinal stem cells by inhibiting mTOR signaling^[70]. From the perspective of energy metabolism for various calorie consumptions, stem cells usually undergo glycolysis rather than oxidative phosphorylation. Under normoxia, MSCs switched to oxidative phosphorylation that led to three- to fourfold increase in senescence; however, hypoxia induced glycolysis in order to prevent oxidative stress-induced senescence and preserve MSC long-term self-renewal^[71]. Surprisingly, study stated that over-expression of phosphoinositide-dependent kinase may restore glycolytic metabolism in glycolytic-defective HSC^[72]. In general, native stem cell metabolisms are linked to increased glycolysis, limited oxidative metabolism, and resistance to oxidative damage^[73].

Nutrients

Nutrient-sensitive signaling pathways that are known to regulate organismal aging include the insulin-PI3K, Akt-FOXO, mTOR and AMPK pathways, which regulate the balance between quiescence and proliferation of stem cells during aging^[74-78]. Decreased activity of the mTOR and its target S6K1 homologs increased life span in yeast, nematodes, and fruit flies^[79]. The S6K1 is a ribosomal S6 protein kinase targeted by mTOR, and is a determinant of mammalian aging in the nutrient-sensitive signaling pathways^[80]. For the AMPK pathway, deletion of the AMPK regulator LKB1 (serine/threonine protein kinase 11) may lead to loss of mouse LT-HSC quiescence^[81]. In human ESCs and iPSCs, methionine deprivation resulted in rapid decrease of intracellular S-adenosylmethionine, which triggered stem cell differentiation, p53 and p38 activation, and reduced NANOG expression^[82]. With regard to lipid metabolism, various lipids and fatty acids regulated proliferation and differentiation of pluripotent stem cells and adult progenitors^[83], and albumin-associated lipids promoted self-renewal of hESCs^[84]. Biosynthesis of lipid such as cholesterol may influence progenitor cell differentiation, and inhibitors of cholesterol biosynthesis enhanced differentiation of mouse C2C12 myoblasts^[85]. Cholesterol is easily oxidized and may be converted to various oxidation products known as oxysterols. One of the major oxysterols is 7-ketocholesterol (7-KC), wherein increased 7-KC led to gradual changes in morphology of human adipocyte MSC, beginning with the loss of unidirectional alignment at lower concentrations, and leading towards loss of actin organization and loss of intracellular contact at higher concentrations^[86].

Vitamin D

Vitamins are important part of our diets and play some role in anti-aging of stem cells. It was reported that $1\alpha,25$ -dihydroxyvitamin D₃ ($1\alpha, 25(\text{OH})_2\text{D}_3$) delayed replicative senescence in primary hMSC; however, its pro-aging effects due to elevated systemic phosphate levels were seen in mouse models^[87]. Other findings suggested that vitamin D metabolism played a role in human osteoblastogenesis in hMSCs, in which both $25(\text{OH})\text{D}_3$ and $1\alpha,25(\text{OH})_2\text{D}_3$ mediated osteoblast differentiation in hMSCs through up-regulation of insulin-like growth factor-1^[88].

CONCLUSION

The direct connection between stem cell aging and organismal aging, and lifespan is yet to be defined. The onset of aging process is often believed to influence cellular lifespan based on lowered *in vitro* replicative capability of old MSC from older compared to MSC from younger individual. Whether the influence on replicative capability is caused by systemic organismal aging, or the altered state of MSC during aging process, remains a question. Stem cells are empowered with self-renewal and differentiation potentials, and stay quiescent for long period of time while preserving their functions. The dormant state, or quiescence, seems to preserve the youth of stem cells despite the passing of time. Nevertheless, evidence suggests that stem cell population and functions may decrease in old individuals. It is likely that the youthful phenotypes of stem cells are preserved as long as it takes in order to allow healthy aging process. In times of trauma, injury, environmental stress such as ultra-violet over-exposure, and psychological stress, the process of aging may be affected, and lifespan may be shortened. Through understanding the prospect of stem cell anti-aging phenomena, the therapeutic application of stem cells can be broadened, and perhaps, a direct link between stem cell anti-aging and longevity may be established.

Abstract

AIM: To investigate collagen patches seeded with mesenchymal stem cells (MSCs) and/or tenocytes (TCs) with regards to their suitability for anterior cruciate ligament (ACL) repair.

METHODS: Dynamic intraligamentary stabilization utilizes a dynamic screw system to keep ACL remnants in place and promote biological healing, supplemented by collagen patches. How these scaffolds interact with cells and what type of benefit they provide has not yet been investigated in detail. Primary ACL-derived TCs and human bone marrow derived MSCs were seeded onto two different types of 3D collagen scaffolds, Chondro-Gide® (CG) and Novocart® (NC). Cells were seeded onto the scaffolds and cultured for 7 d either as a pure populations or as "premix" containing a 1:1 ratio of TCs to MSCs. Additionally, as controls, cells were seeded in monolayers and in co-cultures on both sides of porous high-density membrane inserts (0.4 µm). We analyzed the patches by real time polymerase chain reaction, glycosaminoglycan (GAG), DNA and hydroxyproline (HYP) content. To determine cell spreading and adherence in the scaffolds microscopic imaging techniques, *i.e.*, confocal laser scanning microscopy (cLSM) and scanning electron microscopy (SEM), were applied.

RESULTS: CLSM and SEM imaging analysis confirmed cell adherence onto scaffolds. The metabolic cell activity revealed that patches promote adherence and proliferation of cells. The most dramatic increase in absolute metabolic cell activity was measured for CG samples seeded with tenocytes or a 1:1 cell premix. Analysis of DNA content and cLSM imaging also indicated MSCs were not proliferating as nicely as tenocytes on CG. The HYP to GAG ratio significantly changed for the premix group, resulting from a slightly lower GAG content, demonstrating that the cells are modifying the underlying matrix. Real-time quantitative

polymerase chain reaction data indicated that MSCs showed a trend of differentiation towards a more tenogenic-like phenotype after 7 d.

CONCLUSION: CG and NC are both cyto-compatible with primary MSCs and TCs; TCs seemed to perform better on these collagen patches than MSCs.

Key words: Anterior cruciate ligament rupture; Anterior cruciate ligament tenocyte; Dynamic intraligamentary stabilization system; Resazurin red assay; Mesenchymal stem cells; Real-time polymerase chain reaction; Histology; Scanning electron microscopy microscopy; Scanning electron microscopy

Core tip: Commercially available porcine or bovine-derived collagen type I and type III patches are cyto-compatible for anterior cruciate ligament derived tenocytes (ACL-TCs) and for bone-marrow derived mesenchymal stem cells (MSCs). The combination of commercially available collagen patches with MSCs and ACL-TCs seems to be suitable for application with a dynamic intraligamentary stabilization system, which represents a novel technique to fix a ruptured ACL. However, co-culture of MSCs with ACL-TCs did show signs of differentiation of MSCs towards a more TC-like phenotype after a short-term culture of 7 d.

INTRODUCTION

Anterior cruciate ligament (ACL) injuries represent one of the most common ligament injuries, estimated to impact 100000 to 200000 people annually in the United States^[1-4]. In Germany, the incidence of ACL ruptures is estimated at 32 per 100000 in the general population; in the active sports community, this rate is more than twice as high, at 70 per 100000^[1]. The ACL provides an essential mechanism for ensuring stability in the knee joint^[5]. The instability resulting from ACL injury not only impairs the functionality of the joint, but can also result in secondary damage to other structures, leading to arthritic changes^[1,6,7]. Current surgical treatment methods are thus focused on restoring stability of the knee, reducing pain and preventing osteoarthritis^[1,8,9]. The cruciate ligaments do not heal spontaneously; this has been attributed to a lack of a fibrin-platelet clot formation in ACL defects, which may be due to the synovial fluid surrounding the

cruciate ligaments into which blood from the ruptured stumps disperses, as well as to high levels of plasmin concentrations known to be circulating in the synovial fluid^[10]. Lack of spontaneous healing necessitates intervention to provide for alternative options to restore stability.

Given the clinical success of the dynamic intra-ligamentary stabilization approach in ACL repair^[11-13], the aim of this study was to provide insight as to whether the collagen patches-which are currently approved and marketed for cartilage and meniscus repair-are also suitable for ACL repair, and elucidate the extent to which they impact and interact with cells. For this purpose, we tested two commercially available collagen scaffolds with regards to cell viability, adherence and proliferation of seeded tenocytes (TCs), the primary cell type in ACL tissue^[14]. TCs are considered to be a specific subset of the category of fibroblasts^[14]. Ideally, the cells seeded on the scaffold would proliferate and modify the matrix, slowly reconstructing the original tissue.

Considering the difficulty of obtaining autologous ACL-derived TCs for common surgical use, we also used bone-marrow derived mesenchymal stem cells (MSCs), which can be easily harvested through bone marrow aspiration, cultured and stimulated to differentiate into a fibroblast phenotype^[2,6,15]. Several studies propose MSCs proliferate faster than TCs, and also exhibit a higher survivability *in vivo*^[15]. Additionally, current literature suggests that MSCs may have an anti-inflammatory effect, providing an additional benefit for their use in tissue engineering^[16]. We were particularly interested whether the MSCs would be able to stimulate the TCs in this *in vitro* experiment set up.

Due to the composition of the scaffold materials, we hypothesized that the patches would provide a suitable environment for TCs and lead to cell adherence as well as proliferation and collagen deposition. Furthermore, we expected MSCs to differentiate into a TCs phenotype in co-culture and even more so if cultured on collagen scaffolds rather than cultured on culture inserts. Currently, no unique marker profile for ligaments exists; thus, tendon-like cells are commonly distinguished using a combination of markers, including scleraxis, tenomodulin, tenascin-C, collagen I and collagen III^[6,14].

Here, we present analyses on cell compatibility for primary ACL-derived TCs and bone-marrow derived MSCs seeded on collagen scaffolds. We investigated the phenotype of these cells using real time real time polymerase chain reaction (RT-PCR) and biochemical analysis in order to judge the suitability of cell-seeded collagen scaffolds for the Ligamys surgery application to "boost" the healing process and possibly to improve the surgery's outcome. To the best of our knowledge, no studies have been previously published with this aim.

MATERIALS AND METHODS

Scaffolds and sample preparation

Two types of commercially available and CE label approved bio-resorbable collagen scaffolds were tested in the experiments: Novocart® (NC) produced by Tetec AG (Reutlingen, Germany), a B. Braun AG Company, and Chondro-Gide® (CG), produced by Geistlich Pharma AG (Wolhusen, Switzerland). NC is a biphasic collagen-chondroitin sulfate matrix of bovine origin; CG represents a porcine collagen bilayer matrix. Both scaffolds were specifically developed for human chondrocytes and are used clinically in connection with autologous chondrocyte transplantation and autologous matrix-induced chondrogenesis for cartilage regeneration. Here, we investigated these scaffolds for application in ACL repair (Figures 1 and 2). The NC and CG scaffolds comprise a porous sponge and an adhering compact membrane to protect the cells and the lesion. Cells were seeded on the porous side as intended by its application. The sponge itself consists of fibers, building a three-dimensional structure with interconnecting pores.

Prior to cell seeding, the scaffolds were cut in equally sized samples using an 8 mm sterile biopsy punch (Kai Medical, Polymed Inc., Glattbrugg, Switzerland) and then soaked in high glucose Dulbecco's Modified Eagle's Medium (HG-DMEM), (Gibco, Life Technologies, Zug, Switzerland) with 10% fetal calf serum (FCS) and 1 ×

penicillin-streptomycin (P/S) (all Sigma-Aldrich, Buchs, Switzerland). The patches were seeded with 40000 cells; in addition, material only controls were also cultured under the same culture conditions.

Cell source and culture

Primary ACL derived TCs were isolated from ACL tissue obtained from full-knee prosthesis surgery (ethical approval was obtained from the local committee: KEK registration 22-12-13). Primary TCs were isolated by cutting the tissue in smaller pieces of approximately 4 mm³ pieces, then washed in phosphate buffered saline (PBS) twice and digested overnight in collagenase 2 (Worthington, London, United Kingdom) at 37 °C, under constant shaking at 10 RPM. The released cells were filtered with a 100 µm cell strainer (BD Falcon, Switzerland) and seeded at a density of 1000 cells/cm² for monolayer expansion in HG-DMEM + 10% FCS. With written consent human bone marrow was obtained from patients ages 55-84 undergoing hip or spine surgery. The procedure was approved by the Ethics Office of the Canton of Bern (KEK # 187/10), all patients gave their informed consent prior to their inclusion in the study. Human MSCs were amplified from the mononuclear cell fraction after density gradient centrifugation (Histopaque-1077, Sigma) by selection for plastic adherence for 2-3 passages. The MSCs were expanded using α-Minimal Essential Medium (α-MEM) with 10% FCS, 100 µg/mL penicillin, 100 UI/mL

Figure 2 Overview of current regenerative approaches to improve anterior cruciate ligament rupture treatment in combination of the dynamic intraligamentary stabilization approach. A: First mesenchymal stem cells and/or primary ACL-tenocytes are pre-seeded on collagen patches (shown in blue); B: Ruptured ACL; C: DIS approach takes over major mechanical load and stabilizes the knee, whereas collagen patch wrapped around the ACL provides an ideal solution to improve clinical outcome. ACL: Anterior cruciate ligament; DIS: Dynamic intraligamentary stabilization.

streptomycin, and 5 ng/mL bFGF-2^[17].

Scaffold seeding

Scaffolds that were seeded contained either a single cell type-human MSCs or human TCs- or a combination of both cell types (Figure 3). For the samples containing co-cultures, the two cell types were mixed in a ratio of 1:1 prior to seeding; recent literature demonstrates that this provides the most effective ratio^[16]. All patches were placed in 12 well plates, and the samples were incubated for approximately one hour prior to adding 2 mL medium to each well, in order to give the cells time to adhere to the patch.

Monolayer cultures

In addition to the scaffold samples, we also grew monolayer cell cultures as well as co-cultures using translucent inserts (Falcon, 6 well cell culture inserts, 0.4 μ m PET high density pores, Falcon™, BD Biosciences, Allschwil) in 6 well plates (Falcon™). The single cell population monolayer controls served as reference samples for the real-time PCR results, while the

inserts allowed us to evaluate changes in MSCs gene expression in co-culture. Separating the MSCs and TCs cultures with inserts made it possible to attribute the relative gene expression results of cells in co-culture to the correct cell type. The pore size was chosen to facilitate cell-cell contact between the two cell types, without allowing for cell migration between the two cell populations. This setup allowed us to observe whether cell-cell contact permits differentiation of MSCs into TCs phenotype.

The co-culture for the gene expression analysis was set up as follows: culture inserts were seeded on the bottom with 100000 MSCs. Two hundred microlitre HG-DMEM medium with 10% FCS and 1 $\times$ P/S was added to the layer of MSCs. The inserts, bottom side facing up, were placed on a petri dish, covered with a beaker and placed in a 37 °C incubator for 1 h. Within this timeframe, the MSCs adhered to the insert, as has been shown in previous studies by our group^[18]. Subsequently, the other side of the insert was also seeded with the same number of TCs.

Resazurin sodium salt metabolic cell activity assay

Patches were incubated at 37 °C on a shaker for 5 h with resazurin red solution to measure mitochondrial activity as described in^[19]. Resazurin is a nontoxic, cell-permeable compound that is blue in color and virtually non-fluorescent. Upon entry into cells, resazurin is reduced to resorufin, which emits very bright red fluorescence. The amount of fluorescence or absorbance is proportional to the number of living cells (the linearity of transformation was evaluated based on primary cells) and corresponds to the cell's metabolic activity. The amount of fluorescence was monitored with a Softmax® M5 Pro Multi wavelength fluorescence reader (Molecular Devices, distributed by Bucher Biotec, Switzerland) at excitation 547 nm and emission wavelength 582 nm.

Quantification of DNA, glycosaminoglycan and HYP content

For biochemical analysis, dry-weight of each sample was measured and then each sample was digested with papain. We used the dimethylmethyle blue (DMMB) dye method to analyze the digested samples for sulphated glycosaminoglycans (GAGs), using bovine chondroitin sulfate as standard. Total collagen content was determined based on the hydroxy-proline content after acid hydrolysis and reaction with p-dimethyl-amino-benz-aldehyde and chloramine-T^[20,21].

RT-PCR

All samples were frozen down on day 0 and day 7 of each experiment, except for two samples collected during the pilot experiment, which were collected on day 8 (NC patch with TCs and NC patch with MSCs). RNA extraction was performed with TRI reagent [Molecular Research Center (MRC), Cincinnati,

Figure 3 Experimental design of *in vitro* testing of cyto-compatibility. All monolayer and collagen patch cultures were run for 7 d under standard culture conditions (37 °C at 100% humidity and 5% CO₂) in high glucose Dulbecco's Modified Eagle Medium and 10% fetal calf serum. MSC: Mesenchymal stem cell; TC: Tenocyte.

MA, United States], polyacrylcarrier (MRC), 100% molecular grade ethanol, 1-bromo-3-chloropropane (BCP, Sigma Aldrich), GenElute miniprep kit, and the AMP-D1 DNase I Kit which contains both DNase I and 10 × DNase Digest Buffer (all Sigma Aldrich). The same process was followed for all samples, except that the scaffold samples were subject to an additional step, since those samples had been snap frozen in liquid nitrogen on day 7 of the experiments and placed in -80 °C without any RNA protective solution. In order to perform RNA extraction on those samples, the scaffold samples were first ground using a mortar pre-cooled with liquid nitrogen, then immediately placed in a solution containing 1 mL TRI and 5 µL polyacrylcarrier. The samples were then centrifuged at 16000 g to separate the scaffold debris from the solution. cDNA synthesis was performed with the iScript cDNA synthesis kit (Bio-Rad Laboratories, Cressier, Switzerland). For each sample, 20 µL reaction mix was set up containing 10 µL RNA template (about 0.5-1 µg total RNA), 4 µL 5 × iScript Reaction Mix, 1 µL iScript reverse transcriptase and 5 µL nuclease-free water. After the incubation, the cDNA samples were diluted with 40 µL 1 × TE Buffer.

We evaluated the relative gene expression for the genes we were interested in using human primers (all Microsynth, Balgach, Switzerland; see Table 1 for a detailed list of primers). Separate forward and reverse primers were used to set up the reaction mix, which also contained iQ SYBR Green Supermix2X (Bio-Rad) and RNase free water. We tested ligament fibroblast markers including scleraxis, tenomodulin, tenascin-C,

collagen I and III^[6,22]. In addition, we tested for gene expression of two matrix metalloproteinases (MMPs, enzymes which regulate matrix turnover) MMP3 and 13, aggrecan and collagen type II. MMP3 (stromelysin 1) and MMP13 (collagenase 3) break down collagen and proteoglycans quickly and are known to play a role in ligament remodeling^[23]. Collagen II was used to test that the cells did not differentiate into chondrocyte-like cells. There has been some evidence of increased amounts of proteoglycans in pathological tendons; therefore, gene expression of aggrecan was also evaluated^[22]. To calculate relative gene expression, the Livak method ($2^{-\Delta\Delta Ct}$)^[24] was used, which makes use of both a calibrator sample and a normalizing reference gene; we applied 18S (ribosomal RNA) as the reference gene for all samples^[25]. Relative gene expression levels for samples were calibrated to day 0 reference samples. Day 7 TCs samples were compared relative to TCs at day 0; day 7 MSCs samples were compared relative to MSCs at day 0 (*i.e.*, expression = 1.0).

Microscopy techniques

Confocal laser scanning microscopy (cLSM) was used to confirm visually that cells are able to adhere and proliferate on the scaffolds in the first two experiments. Samples for the cLSM were stained using Vybrant membrane tracker dyes DiO (DiO = green, for MSCs) and DiI (DiI = red, for TCs) (both Molecular Probes, Life Technologies, Basel, Switzerland); these dyes are lipophilic carbocyanines, which integrate into the membrane^[26]. In addition, we also imaged the cells

on both sides of the culture inserts. This allowed us to confirm that the cells adhered to both sides of the culture insert and could therefore be evaluated with real-time PCR.

Further, additional samples were prepared during one experiment to be processed with scanning electron microscopy (SEM), as this method permits visualization of 3D structures on a very small scale. This technique also allowed us to see how the cells attach to the scaffold, as well as provided a more detailed visualization of the scaffolds themselves. On day 7, the samples were first washed with PBS to remove traces of serum, then fixed with 2.5% glutar-aldehyde. On the day of SEM sample preparation, the specimen were again washed with PBS prior to following a dehydration protocol using an alcohol series of increasing concentration, *i.e.*, 50%, 70%, 80%, 90% and 2 × 100%, with incubation periods of 10 min. Subsequently, the specimen were critical point-dried in a Bal-Tec CPD 030 (BalTec inc., Balzers, Liechtenstein) and sputtered with approximately 10 nm (30 mA for 30 s at 50 mm working distance), producing a 10 nm gold layer in a SCD 004 (BalTec inc.). Samples were then stored in an exsiccator until examination at 5 kV accelerating voltage in a Zeiss scanning electron microscope DSM 982 (Carl Zeiss, Jena, Germany).

Statistical analysis

Data were analyzed using the Kruskal-Wallis test unless otherwise noted, followed by Dunn's multiple comparisons test using the PRISM software package (GraphPad, La Jolla, United States, version 6.0e). RT-PCR data was tested using a *t*-test statistic and mean gene expression was tested if significantly different from a hypothetical value of 1.0. A significance value of $P < 0.05$ was specified to be significant. Where applicable groups were tested in 2-way ANOVA for treatment and culture time, multiple comparisons were then performed using Bonferroni's multiple testing. The statistics was checked by a biostatistics expert.

RESULTS

The experiments were meant to provide initial insight

into whether NC and CG collagen patches, which are currently being used in cartilage repair, are suitable for ACL repair. Thus, adherence and proliferation of cells was tested, as well as the collagen deposition and differentiation potential of cells.

Adherence, proliferation and matrix changes

CLSM and SEM imaging and the metabolic cell activity assay confirmed that both cell types, TCs and MSCs, adhere on the substrate and seem to proliferate on both patch types (Figure 4). The images seem to show, however, that MSCs decreased in cell number after 7 d.

Noteworthy, DNA content (Hoechst) of collagen scaffolds contained a relatively high amount of porcine/bovine DNA (Figure 5), which was confirmed by DNase digestion (data not shown). There was no significant change in DNA content among the groups over the 7-d culture period. The metabolic cell activity assay (see Figure 6) revealed increased cell activity on day 7 vs day 1 for all cell treatment groups, and a slightly higher absolute level of cell activity for all CG samples versus NC patches on a given day. The relative increase in cell activity level from day 1 to day 7 in both patch types was similar (Figure 6).

The non-parametric Kruskal-Wallis tests showed that cell type did not have a significant impact on the relative change in metabolic activity for either of the two patch types (Figure 6). Furthermore, we found no significant differences between NC and CG samples in terms of the relative changes in metabolic cell activity between the two patch types. While both patch types also showed an increase in absolute cell activity, as measured in RFUs, from day 1 to day 7 for every cell type, this trend was not significant for NC patches, but significant at an overall level for CG patches ($P = 0.0298$, $n = 4$). Dunn's multiple comparisons test for CG however revealed no significant P values for individual treatment groups (TCs, MSCs, premix) with different treatment lengths (Figure 6). However, after testing for 2-way ANOVA for time and treatment we found a significant effect ($P = 0.0001$) of culture time and found that activity increased over time for TCs and premixes ($P = 0.0237$ and $P = 0.0120$, respectively)

Figure 4 Z-projections of confocal laser scanning microscope images of 200 μm 3D-stacks through the collagen patches of mesenchymal stem cells and anterior cruciate ligament-derived tenocytes on day 1 and after 7 d of culture on NovocartTM and Chondro-GideTM. Cells were stained with VybrantTM DiO (DiO = green, MSCs) and DiI membrane tracker dyes (DiI = red, TCs) prior to seeding. Last row are scanning electron microscope pictures of the cell-seeded scaffolds after 7 d of culture showing adherence and shape of the MSCs and tenocytes on the scaffolds. Note that for Chondro-GideTM patches these are only images from TCs seeded scaffolds. For the NovocartTM patches the right most image is from an experiment containing a premix of cells, and the left most and center SEM image are from experiments with MSCs seeded scaffolds. MSC: Mesenchymal stem cell; ACL-TC: Anterior cruciate ligament-derived tenocyte; SEM: Scanning electron microscope.

Figure 5 DNA content of collagen patches. DNA content of collagen patches seeded with anterior cruciate ligament-derived tenocytes (TCs) and/or MSCs on NovocartTM and Chondro-GideTM normalized per dry weight per carrier for the collagen patches for day 1 and day 7 of the experiment (values are means $\pm$ SEM, $n = 3$ experiments for day 1, 4 experiments for day 7). Note the large amount of DNA present in material controls. MSCs: Mesenchymal stem cells.

Figure 6 Mitochondrial cell activity. Mitochondrial cell activity measured by resazurin red assay of collagen patches seeded with anterior cruciate ligament-derived tenocytes (TCs) and/or MSC on NC and CG normalized per dry weight carrier for the collagen patches for day 1 and day 7 of the experiment (values are means $\pm$ SEM, $n = 4$ experiments for CG and $n = 5$ experiments for NC). b denotes $P < 0.01$. MSC: Mesenchymal stem cell; NC: NovocartTM; CG: Chondro-GideTM; SEM: Scanning electron microscope.

(Figure 6). Previous studies suggested that pathologic tendons exhibit higher GAG content^[22]. We, therefore, measured

GAG content on day 1 and day 7 ($n = 3$). In all samples, there was a decrease in the amount of GAG from day 1 to day 7 (μg per mg of dry-weight, corrected for controls

Figure 7 Hydroxy-Proline and glycosaminoglycan content. A: HYP content assay; B: GAG of collagen patches seeded with anterior cruciate ligament-TCs and/or MSCs on NC and CG normalized per dry weight carrier for the collagen patches for day 1 and day 7 of the experiment (values are means $\pm$ SEM, $n = 3$ experiments for day 1, 4 for day 7); C: Percentage change of HYP to GAG ratio relative to day 1 of NC and CG patches. b denotes a significant $P < 0.01$. using day 7 sample with no cells as a baseline for all samples). No significant difference was found between the two patch types or cell types in terms of the relative changes of GAG measured (Figure 7A).

Hydroxy-proline (HYP) levels were measured in order to assess collagen deposition of the different cell types on the scaffold (Figure 7B). Data revealed no significant change in HYP over time. In line with the other analyses, the different cell types were not found to have a significant effect on the percentage change of HYP measured, neither for NC patches nor for CG patches. Also, the Kruskal-Wallis test did not reveal a significant difference between the two patch types. However, when the ratio of HYP/GAG was considered, the 2-way ANOVA for scaffold and cell treatment showed a significant relative change for the Premix group ($P = 0.005$) (Figure 7C).

Both cell types (TCs and MSCs) were analyzed individually with regards to the effect of different substrates (NC patch, CG patch, inserts or just well plates) on the relative gene expression for the genes of interest. A summary of the relative gene expression measurements is shown in Figure 8.

Relative gene expression revealed a significant down-regulation of TNMD for TCs grown on NC scaffolds ($P < 0.0001$) and for col2 in TCs grown on culture inserts ($P = 0.0121$) relative to day 0 controls (Figure 8A). Monolayer MSCs significantly down-regulated MMP3 ($P = 0.0065$) after 7 d of culture, whereas MSCs grown on culture inserts significantly up-regulated col3 ($P = 0.006$) and down-regulated MMP3 ($P = 0.0065$).

DISCUSSION

TCs gene expression

In line with expectations, both patch types showed a slight up-regulation of collagen I gene expression for TCs in comparison to TCs grown in monolayers (Figure 8). Scleraxis expression trended up on patches vs d0 but was in line with monolayer results (Figure 8). At the same time, both patch types did not result in a significant up-regulation of collagen II or aggrecan, compared to monolayer (Figure 8). These factors suggest that the cells did not differentiate into cells of a chondrocyte phenotype. Based on the non-parametric Kruskal-Wallis test statistic, the differences in relative

Figure 8 Relative gene expression of major extracellular matrix genes important for anterior cruciate ligament repair and mesenchymal stem cells differentiation grown on 3D collagen patches, i.e., Novocart™ and ChondroGide™. A: Gene expression of anterior cruciate ligament-derived tenocytes (TCs) relative to day 0 TCs; B: Gene expression of bone marrow-derived MSCs relative to day 0 MSCs (values are means $\pm$ SEM, $n = 4$ experiments for CG and $n = 5$ for NC). MSC: Mesenchymal stem cell; NC: Novocart™; CG: ChondroGide™; SEM: Scanning electron microscope.

gene expression between TCs cultured on NC or CG patches or in monolayers are not significant, which is in line with our initial hypothesis. We did observe significant changes of relative gene expression when tested with one-sample *t*-test. While gene expression levels for TCs on NC patches were not vastly different from those cultured on CG or in monolayers, TCs grown on NC significantly expressed less tenomodulin (TNMD) and do seem to express slightly lower levels for the ligament markers collagen type 3 (col3), tenascin- C (TNC) and scleraxis (SCX) relative to those two substrates (see Figure 8A).

At first sight, especially when considering these data in light of the metabolic cell activity results, it may seem that the CG patches provide a better environment for TCs. The metabolic cell activity measurements showed that cells grown on CG patches vs NC patches exhibited a slightly higher (yet statistically insignificant) absolute cell activity on any given measurement day, as well as a somewhat higher relative increase in cell activity from day 1 to day 7 of the experiments. However, this aspect needs to be carefully examined further.

It is possible that the culture time was not long enough to clearly discern significant differences

between patch types. MSCs and TCs were cultured for up to 28 d and checked for cell adherence with the use of CLSM and the cell tracker dyes. Studies related to osteogenesis show that osteogenic differentiation of MSCs can take up to four weeks, with an initial early differentiation phase taking place between day 5 and day 14^[27]. Conversely, it has also been shown that MSCs can show signs of differentiation into tenogenic phenotype after as little as seven days^[28]. It is also possible that the cells on the NC scaffolds first partially de-differentiated. The down-regulation of tenomodulin (TNMD) has been observed for cells that were cultured two-dimensionally^[29]. Since we observed a stronger down-regulation for cells cultured on NC than in monolayers, this may be interpreted as an indication of de-differentiation. This de-differentiation has been previously observed in monolayers as well as in organ cultures^[15].

Furthermore, scleraxis has been shown to modulate TNMD expression, such that the up-regulation of TNMD occurred several days after an up-regulation in scleraxis was observed^[30].

It is known that the structure of scaffolds can impact the cell morphology; ACL fibroblasts for instance orient parallel to collagen fibers. Cell shape

Table 2 Summary of the donor tissue that was used to harvest and expand primary cells, *i.e.*, bone marrow derived mesenchymal stem cells and anterior cruciate ligament-derived tenocytes and stage of passage for 3D culture experiment

on the other hand can impact cell differentiation^[30,31]. In fact, both patches were primarily constructed for use with chondrocytes. The manufacturer of NC patches clearly states that the patches are meant to induce a spherical morphology, which describes a chondrocyte phenotype. However, with SEM imaging we observed flat networks covering the NC patches. This observation was in line with the gene expression results, which demonstrate that the cells do not up-regulate genes, which are typical for chondrocyte phenotype. It would be interesting to re-evaluate all variables in experiments running for 14 or 21 d, to test whether this still holds true.

MSCs phenotype

MSCs cultured on patches showed a trend towards up-regulation of ligament markers versus MSCs monolayers, particularly on NC scaffolds. For instance, collagen III tended to be up-regulated on NC, with a more inconsistent expression for MSCs on CG (Figure 8). Scleraxis tended to be higher expressed on both patches compared to MSCs cultured in monolayers or on inserts (Figure 8). These results seem to indicate that MSCs are developing into a TCs phenotype on the patches. MSCs cultured with TCs, however, consistently up-regulated col 3 expression, a sign for early differentiation of the MSCs towards a more TC-like phenotype. Again, additional time might be required in order to draw more conclusive insights about the potential for MSCs to differentiate on the various substrates. However, interpreting the results of the RT-PCR data demonstrating a significant increase of col 3 in presence of TCs on culture inserts together with the significantly increased HYP/GAG ratio of "premix" of TCs and MSCs on the 3D patches (Figure 7C) could be interpreted as an early differentiation of MSCs shutting down gene expression of GAG and increasing collagen expression. A study related to tenogenic differentiation of rat MSCs showed that a significant change in expression levels for some ligament markers could already be detected after 7 d (tenascin-C as well as scleraxis); however, other markers were not up-regulated until a few days later (collagen I and III)^[28].

There were some inherent limitations in the cell types used in our study. Cells had to be obtained from

patients whom may already exhibit certain morbidities. TCs were provided from patients undergoing knee surgeries– either total knee arthroplasties or ACL reconstruction. Patient number 67, for instance, underwent ACL reconstruction due to a traumatic rupture, where the stumps were intra-operatively removed prior to graft insertion. It is possible that the cells cultured from these stumps may naturally exhibit slightly different characteristics, a topic that should be explored further. Moreover, it is also possible that the age of the donor plays a role in terms of the differentiation potential of the MSCs.

In this respect, it is also worth mentioning the existence of native ACL-derived autochthonous stem cells (ACL-SC), which already may exist in the tissue^[32]. Zhang *et al.*^[32] described the isolation and characterization of such plastic-adherent cells, which possess stem cell characteristic surface markers from healthy tissue samples. However, it is unknown whether these cells might still be present in more degenerated human tissue as analyzed in this study. An additional aspect that should be considered is the donor characteristics of cells (Table 2). In four out of five trials we had male MSC donors and in all five experiments, we had female TC donors (Table 2). The gender and age of the donors may have a hidden effect on the outcomes, including proliferation rates or differentiation ability. However, current evidence of the impact of gender and age is inconclusive^[33,34].

Imaging analysis

Confocal laser scanning microscopy (CLSM) images of CG patches showed less MSCs than TCs, both in the single cell culture of MSCs as well as when cultured together with TCs. The MSCs appear in a rounded shape in the CLSM images, as opposed to the TCs, which have a more elongated appearance. This is in line with the SEM results for the CG patches, on which we found rather roundish morphologies.

There seems a conflict in the data that the cell density on CG patches was decreasing for MSCs (Figure 4 lower panel) but DNA content (Figure 5) and cell activity (Figure 6) showed a steady-state and a trend of increased activity, respectively. We interpret this as a donor-specific phenomenon in the CLSM data.

Extracellular matrix and collagen patch environment

GAG and HYP values were also corrected for control values, as we registered significant amounts of initial GAG and HYP in our controls (Figure 7A and 7B), which was expected considering that collagen patches consist primarily of collagen 1 and 3. Correcting for the controls, we see a decrease in GAG per mg of dry-weight. This suggests that the MSCs are changing in phenotype and possibly produce less GAG over time if in direct 1:1 co-culture. Interestingly, comparing the relative change of the HYP/GAG ratio of day 7 relative to day 1 showed a significant effect of “premix” cells but there was no effect of the differences between the two scaffolds (Figure 7). The effect of cells was highly significant in the 2-way ANOVA ($P = 0.005$, Figure 7). Thus, premix of cells shifted the ratio between HYP/GAG towards lower production of GAG and slight increase of HYP.

In conclusion, the results of these 3D cell culture experiments demonstrate the potential of collagen patches for ACL repair^[4]. Using biochemical and imaging methods, we were able to demonstrate that primary TCs and MSCs can both be grown on the NC and CG patches, which were originally designed to induce a chondrogenic phenotype. Both TCs and MSCs adhere to and proliferate on the patches. Moreover, MSCs seem to show a tenogenic differentiation potential on these scaffolds as indicated by the significant increase of collagen type 3. Future work might consider the importance of alternative stimuli to accelerate healing such as the application of platelet rich plasma (PRP) or platelet rich fibrin (PRF). The problem with ACL-derived TCs and MSCs, which have to be expanded first *ex vivo* on plastics, is their clinical approval. With PRP on the other hand are unsolved issues about the reproducibility and the ideal dose of platelet concentrations^[35,36].

Further studies should be performed to evaluate additional aspects. First of all, it would be beneficial to run the experiments with a longer culture time. This would permit a more in depth analysis of the induced cell morphologies on the different patches, which could alter the survivability of the cells as well as the differentiation potential. Additionally, it would allow us to observe whether this changes the gene expression profile of the cells. It is also likely that longer culturing duration would lead to more pronounced differences between cell and patch types and be able to further support the trends we have observed so far.

Furthermore, studies should also be performed using mechanical loading. It has been shown that mechanical strain induces MSCs to differentiate into a TCs phenotype^[37,38]. It would be interesting to see whether the cells respond differently on the two patch types, subjected to equal parameters. Also, the mechanical properties of a scaffold are known to impact cell differentiation. In fact, several prior attempts at ligament or tendon repair have resulted in ectopic bone formation^[30]. Thus, further experiments

testing the impact of the mechanical properties would be helpful in evaluating the full potential of these patches. However, in these studies, it would be crucial also to look at bone-specific markers such as osteocalcin^[30].

In conclusion, while certain aspects should be examined in more depth, the use of collagen scaffolds for ACL regeneration is promising^[4]. The usage of a biological ACL repair model including collagen patches in a non-loading repair model seems a genius option to improve healing. What remains to be shown is whether mechanical loading improves the healing process or whether platelet rich fibrin PRF or PRP might be another option to be included at the site of rupture for the healing or whether it might be even hindering the healing process as has been recently proposed^[35,36,39,40].

ACKNOWLEDGMENTS

Rachel Horovitz collected cell culture data and provided input for the manuscript. Elena Calandriello assisted in biochemical assays. The imaging part of this study was performed with the facility of the Microscopy Imaging Center (MIC), University of Bern.

COMMENTS**Background**

Mesenchymal stem cells (MSCs) and anterior cruciate ligament (ACL)-derived tenocyte (TCs) are both potential source cells to be applied for the cell seeding of the dynamic intraligamentary stabilization for the fixation of ruptured ACLs. Current treatment options for non-fusions of ruptured ACLs are very limited.

Research frontiers

ACL injury is a common disease and the repair of ACL remains a challenge due to its limited self-regenerative ability. Despite the progression of reconstructive techniques for ACL repair, an ideal biological scaffold for ACL reconstruction is needed to improve clinical outcome, especially in the case of non-unions.

Innovations and breakthroughs

In this study, the authors present novel data on the regenerative technique to use commercially Food and Drug Administration (FDA)-approved collagen 1 and 3 scaffolds along with ACL-derived TCs and MSCs. They provide microscopy imaging data, biochemical data, and gene expression data of human derived primary bone-marrow derived MSCs and ACL-derived tenocytes. There was not much known how cell therapy could accelerate and improve healing for ACL ruptures in combination with a recently developed dynamic anchoring technique called Ligamys®. The combination of regenerative approaches involving TCs and MSCs transplantation along with commercially available FDA-approved collagen patches seems a straightforward approach, as the membrane is highly biocompatible and does not carry the mechanical force.

Applications

Cyto-compatibility for the collagen patches is a tool to explain good clinical outcome.

Peer-review

This paper compared two different collagen patches seeding with either bone marrow mesenchymal stem cells or primary tenocytes for possible anterior cruciate ligament repair. Chongrogide is composed of porcine collagen I and III as a bilayer membrane. Novocart is a biphasic, three-dimensional collagen-based matrix from bovine. Both collagen sponges have been used for cartilage repair. ACL injury is a common disease and the repair of ACL remains a challenge due to its limited self regenerative ability. Despite the progression of reconstructive techniques for ACL repair, an ideal biological scaffold for ACL reconstruction is needed. Thus, this study is of importance and experiments strongly suggest that the patches of collagen may be useful for anterior cruciate ligament repair.

World Journal of *Stem Cells*

World J Stem Cells 2015 April 26; 7(3): 535-668

Editorial Board

2010-2015

The *World Journal of Stem Cells* Editorial Board consists of 719 members, representing a team of worldwide experts in infectious diseases. They are from 44 countries, including Argentina (2), Australia (10), Austria (6), Belgium (3), Brazil (10), Canada (16), China (74), Cyprus (1), Czech Republic (5), Denmark (7), Egypt (2), Finland (3), France (19), Germany (36), Greece (1), Hungary (3), India (10), Iran (9), Ireland (4), Israel (10), Italy (52), Japan (55), Jordan (1), Malaysia (1), Mexico (1), Morocco (1), Netherlands (8), Norway (3), Portugal (1), Romania (1), Russia (3), Singapore (19), Slovakia (1), South Korea (45), Spain (17), Sweden (4), Switzerland (4), Thailand (1), Tunisia (1), Turkey (5), United Arab Emirates (1), United Kingdom (29), United States (233), and Venezuela (1).

ABOUT COVER

Editorial Board Member of *World Journal of Stem Cells*, Arash Zaminy, PhD, Anatomy and Cell Biology Department, Medicine School, Shahid Beheshti University of Medical Sciences, Evine 1985717443, Tehran, Iran

AIM AND SCOPE

World Journal of Stem Cells (*World J Stem Cells*, *WJSC*, online ISSN 1948-0210, DOI: 10.4252), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJSC covers topics concerning all aspects of stem cells: embryonic, neural, hematopoietic, mesenchymal, tissue-specific, and cancer stem cells; the stem cell niche, stem cell genomics and proteomics, and stem cell techniques and their application in clinical trials.

We encourage authors to submit their manuscripts to *WJSC*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

INDEXING/ ABSTRACTING

World Journal of Stem Cells is now indexed in PubMed Central, PubMed, Digital Object Identifier, and Directory of Open Access Journals.

© **The Author(s) 2015.** Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: The cells in the body orchestrate the unique roles of each organ through a cellular network. It is important to investigate alterations in cellular phenotypes and the regulation of genes, the genome and molecules in order to understand the origin of the cells. Insights into the changes in cellular features, including epithelial-mesenchymal transition, and recent database advances are described in this editorial.

Tanabe S. Origin of cells and network information. *World J Stem Cells* 2015; 7(3): 535-540 Available from: URL: <http://www.wjgnet.com/1948-0210/full/v7/i3/535.htm> DOI: <http://dx.doi.org/10.4252/wjsc.v7.i3.535>

Abstract

All cells are derived from one cell, and the origin of different cell types is a subject of curiosity. Cells construct life through appropriately timed networks at each stage of development. Communication among cells and intracellular signaling are essential for cell differentiation and for life processes. Cellular molecular networks establish cell diversity and life. The investigation of the regulation of each gene in the genome within the cellular network is therefore of interest. Stem cells produce various cells that are suitable for specific purposes. The dynamics of the information in the cellular network changes as the status of cells is altered. The components of each cell are subject to investigation.

THE GENOME AS A BLUEPRINT

Recently, pluripotent stem cells have played an increasing role in disease and developmental models, including the challenge of generating novel organs such as intestines^[1]. Stem cell differentiation is one of the mechanisms by which regenerative tissues are produced. In each cell, the genome encodes the plan for the life of the cell and the path for organizing each tissue. The gene segments travel through the genome to settle at the gene loci^[2]. Variations within the genome produce individual differences. Dramatic transitions of cellular phenotypes, such as the Warburg effect, occur in disease states such as cancer^[3,4]. Epigenetic alterations provide cellular identity and phenotypic diversity. RNA transcription is altered in cancer; this alteration is caused by somatic DNA translocation or mutation^[5]. Variants of genes such as *BRCA2* and *CHEK2* increase the risk of lung cancer^[6]. Genome sequencing of normal

cells has revealed the accumulation of mutations and differences in each cell lineage and tissue^[7]. Genome editing has recently been developed. Additionally, gene therapy using clustered regularly interspaced short palindromic repeats/Cas9 is an emerging technique^[8]. The construction and architecture of the genome are important for understanding the cell.

STEM CELL DIFFERENTIATION AND REPROGRAMMING

Definition of stem cells

Emerging roles for stem cells as sources for cell-based therapy remind us of the importance of the definition of stem cells^[9]. Stem cells are generally defined as cells with self-renewal and differentiation potential^[10]. Accumulating knowledge and insights have shown that stem cells are able to differentiate into several cell types in the body. However, a paradigm shift occurred after the discovery of induced pluripotent stem (iPS) cells that can be created by reprogramming differentiated cells with several factors^[11]. This finding may allow for a shift in the cell type of stem cells derived from differentiated cells in the body. Thus, the range of stem cells needs to be defined. Stem cells can be classified into two categories (Figure 1): (1) pluripotent stem cells, such as embryonic stem cells or iPS cells^[12-15]; or (2) tissue multipotent stem cells such as neural stem cells, hematopoietic stem cells or mesenchymal stem cells^[16]. Recently, *SNAIL* (*SNAIL*) has been reported to localize to the nucleus and to play a role in epithelial-mesenchymal transition (EMT) during the early stage of reprogramming of differentiated cells^[17]. EMT and mesenchymal-epithelial transition processes may promote the reprogramming of differentiated cells toward stem cells^[17]. Altered phenotypes and gene networks of stem cells have been reported, suggesting that the cells themselves have various gene dynamics during culture^[18]. Cancer stem cells may be included as stem cells in cancer states. In some cases, engineered differentiated cells with gene modification or genome editing may also be included as stem cells if the cells are reprogrammed.

Cancer stem cell phenotype transition

The cell phenotype transition has been observed in cancer stem cells (CSCs)^[19]. *SOX2*, which is a reprogramming factor, is a CSC biomarker in embryonal carcinoma cells and is related to stem-like cancer cells^[20]. Genome analysis of *SOX2*-silenced human embryonal carcinoma cell lines has revealed that the cellular networks of these cells are enriched for microRNAs that are regulated by *SOX2* and that are associated with EMT markers^[20]. In contrast, an epidermal growth factor receptor exon 19-deleted lung cancer cell line was induced to exhibit CSC-like phenotypes and EMT by *DDX3X* transfection^[21]. Moreover, *DDX3X* overexpression was reported to

induce *Sox2* up-regulation^[21].

CSCs are related to chemotherapy and radiation resistance in squamous cell carcinomas (SCCs)^[22]. The CSC population is diverse in SCCs; this diversity contributes to difficulty in cancer treatment^[22]. Understanding the mechanisms of CSCs and EMT are important for the development of novel therapeutics.

CELLULAR NETWORK INFORMATION

Epithelial-mesenchymal transition

Cellular networks characterize both cells and the body, and gene combinations are critical for the presentation of phenotypes^[23]. EMT is one of the mechanisms by which the cell phenotype transitions; dihydropyrimidine has been reported to induce EMT^[24]. EMT is associated with metastasis in tumor progression and is induced by Notch activation and p53 deletion in mice^[25]. Erythropoietin-producing hepatoma (EPH) receptors, which are receptor tyrosine kinases related to cancer, may be related to EMT signaling^[26]. EPH receptor A2 induces EMT via β -catenin activation, followed by Snail expression and *cadherin 1, type 1, E-cadherin (epithelial) (CDH1)* suppression^[26]. Wnt/ β -catenin signaling is inhibited by *SOX10*, leading to the inhibition of the growth and metastasis of digestive cancers^[27]. *SRY* (sex determining region Y)-box 10 (*SOX10*) inhibits EMT, which may be one of the possible mechanisms of cancer inhibition^[27]. *Frizzled2*, the Wnt receptor, induces EMT and cell migration through the noncanonical pathway^[28]. EMT is monitored by cell rigidity, and human equilibrative nucleoside transporter-1 suppression induces EMT in pancreatic cancer cells^[29]. EMT characterization is needed for further understanding cell type transition and cancer progression.

Classification of EMT features

EMT can be characterized by the following three features: (1) changes in cellular morphology; (2) increases in cellular motility; and (3) alterations in the expression of E-cadherin and N-cadherin^[29]. Cellular morphological changes are typically observed in the transition from connective-like cells to mesenchymal-like cells^[29]. The expression of *CDH1* is usually up-regulated in connective- or epithelial-like cells, whereas the expression of N-cadherin (*CDH2*) is up-regulated in mesenchymal-like cells^[29,30]. EMT is associated with tumor metastasis^[30]. The metastasis potential or invasiveness of cancer can be measured by the mechanical rigidity of the cells^[31,32]. Several genes are involved in EMT, including *BMI1 proto-oncogene, polycomb ring finger (BMI1)*, *hypoxia inducible factor 1, alpha subunit (HIF1A, HIF-1 α)* and *twist family bHLH transcription factor 1 (TWIST1, Twist)*^[33]. *HIF-1 α* , which is a key transcription factor, is up-regulated in gastric cancer. Additionally, network pathway genes, such as *NF κ B1*, *BRCA1*, *STAT3* and *STAT1*, and network hub genes, such as *MMP1*, *TIMP1*, *TLR2*,

Figure 1 Current variations and definitions of stem cells. Pluripotent stem cells include embryonic stem cells and induced pluripotent stem cells, which will differentiate into all cells in the body. Multipotent stem cells, including tissue stem cells, differentiate into several types of cells to create the parts of organs or of the body. EMT: Epithelial-mesenchymal transition; iPS: Induced pluripotent stem; ES: Embryonic stem; TS: Tissue stem.

FCGR3A, *IRF1*, *FAS* and *TFF3*, have been identified^[34].

GENE REGULATION IN DISEASE

Gene and molecule alterations

An abundant number of genes are regulated in cancer. Genes are regulated not only by transcription factors but also by microRNAs (miRNAs). miRNA-9 is up-regulated in esophageal squamous cell carcinoma, which may induce EMT and metastasis in cancer^[35]. CD151, which is a regulator of laminin-binding integrin function and signaling, represses EMT and canonical Wnt signaling, leading to the inhibition of ovarian tumor growth^[36]. Wnt/ β -catenin signaling is involved in EMT induction by the parathyroid hormone in human renal proximal tubular cells^[37]. Endothelin-1 and endothelin A receptor signaling, together with Wnt signaling, regulate EMT in epithelial ovarian cancer^[38]. Endothelin/ β -arrestin signaling and Wnt/ β -catenin signaling may be involved in chemotherapy resistance in cancer^[38]. Hypoxia-inducible factors (HIFs) play roles in Wnt signaling in human colon cancer cells^[39]. HIF-1 α depletion induces the reversal of EMT, and HIF-2 α silencing affects the expression of stem cell markers and increases β -catenin transcriptional activity under hypoxic conditions^[39]. The roles of HIFs in Wnt/ β -catenin signaling and in the surrounding networks are essential for understanding cancer cell phenotypes. The silencing of β -catenin *via* promoter methylation is also involved in the enhancement of non-small cell lung cancer invasiveness^[40].

Notch1, which is one of the important molecules in cancer signaling, is involved in Ras/phosphoinositide 3 kinase (PI3K)/Akt signaling in T-cell acute lymphoblastic leukemia (T-ALL)^[41], and PI3K and Notch1 may be targets for drug resistance in T-ALL^[41]. Sox2, which

is one of the reprogramming factors used to produce iPS cells, may be a regulator of EMT during neural crest development^[42]. The Wnt pathway induces the EMT pathway, and the inhibition of the Wnt pathway may be involved in the re-differentiation of human islet β -cells^[43]. Thus, the investigation of the molecules associated with EMT and disease is of interest^[44].

MOLECULAR COMMUNICATION

The gene and genome networks

Several megaprojects have been established in response to the genome projects, one of which is called the ENCyclopedia Of DNA Elements (ENCODE) Project, which aims to translate the human genome sequence into biological and health mechanisms^[45]. The ENCODE Project has identified functional elements in the genome (<http://www.genome.gov/ENCODE/>)^[46,47].

The cross-cancer alteration of genes and their networks can be examined in cBioPortal, which is a cancer genomics database (<http://www.cbioportal.org/public-portal/>)^[48,49]. The cBioPortal includes network analysis for the visualization of networks that are altered in cancer^[49]. The precise information obtained through network analysis has been reported in several studies^[50-53]. The sources of the networks are derived from pathways and interactions from the Human Reference Protein Database^[53], Reactome^[51], the Pathway Interaction Database created by the National Cancer Institute in collaboration with Nature Publishing Group (<http://pid.nci.nih.gov/>)^[52], and the Memorial Sloan-Kettering Cancer Center Cancer Cell Map, which are all included as source information in the Pathway Commons Project (<http://www.pathwaycommons.org/>)^[50]. Pathway Commons is an open pathway that includes interaction information for multiple species,

such as humans and model organisms^[50].

The web interface called Gene Expression Commons is an interesting tool for gene expression analysis and microarray data that can be analyzed with reference data to model biological relationships (<https://gexc.stanford.edu/>)^[54]. The amount of data available in these databases is increasing and includes data from microarrays, next-generation sequencing, and clinical data.

CONCLUSION

The cell is the fundamental unit of life. The investigation of gene and genome regulation is critical for a deep understanding of phenotypic alterations and of the origin of cells. The transition of cell characteristics, including differentiation, reprogramming and EMT, and cell-to-cell communications requires further investigation to reveal the cell of origin.

Abstract

Induced pluripotent stem cells (iPSCs) have been the focal point of ever increasing interest and scrutiny as they hold the promise of personalized regenerative medicine. However, creation of iPSCs is an inefficient process that requires forced expression of potentially oncogenic proteins. In order to unlock the full potential of iPSCs, both for basic and clinical research, we must broaden our search for more reliable ways of inducing pluripotency in somatic cells. This review surveys an area of reprogramming that does not receive as much focus, barriers to reprogramming, in the hope of stimulating new ideas and approaches towards

developing safer and more efficient methods of reprogramming. Better methods of iPSC creation will allow for more reliable disease modeling, better basic research into the pluripotent state and safer iPSCs that can be used in a clinical setting.

Key words: Reprogramming; Induced pluripotency; Stem cells

INTRODUCTION

The interest in cellular reprogramming spans basic science to clinical studies with the aim to understand the pluripotent state as well as to harness its potential to generate patient-specific therapies. These goals, while lofty, seem increasingly within reach. The first evidence of somatic cellular reprogramming was provided by the experiments performed by Gurdon *et al*^[1,2] which employed somatic cell nuclear transfer (SCNT) in *Xenopus laevis*. SCNT was later shown to be effective in mammals with the cloning of "Dolly" the sheep^[3,4] and has recently been shown to work in humans^[5,6]. SCNT requires enucleated oocytes to mediate virtually complete reprogramming of differentiated nuclei. Induced pluripotent stem cells (iPSC) were first described by Takahashi *et al*^[7,8] by overexpressing *Oct4*, *Sox2*, *c-Myc* and *Klf4*-transcription factors shown to

be essential for embryonic stem cell pluripotency. The discovery that forced expression of defined factors in differentiated cells could reprogram them to a stem-cell like state has had an enormous impact on the field of stem cell research. Advances in the creation of disease-specific stem cells are allowing us to gain previously unobtainable insights into a wide variety of diseases. Understanding the mechanics of cellular reprogramming will allow a greater understanding of developmental biology but will also translate into safe, reliable patient-specific cellular therapies.

Reprogramming is often thought of as a forward-moving process that relies on exposing the differentiated nucleus to factors that induce de-differentiation. Many groups have made strides in improving the methods of enforcing the expression of reprogramming factors^[9], increasing their efficiency^[10-12] and employing alternative reprogramming factors^[13-15]. Problematically, iPSC and to a lesser extent even SCNT-derived stem cells have been shown to be incompletely reprogrammed, leading to possible differentiation bias or unregulated growth during later differentiation^[16]. Incomplete reprogramming may also lead to unknown biases when studying disease-specific stem cells, potentially confounding results. Efficient, safe, and completely reprogrammed cells are a necessary step towards moving iPSC into the clinic. Toward this end, far less attention has been focused on eliminating endogenous factors (or their activities) which enhance cellular differentiation. Inhibition of these "negative" factors, rather than or in combination with enforcement of positive-acting factors, could lead to safer, more efficient and more completely reprogrammed iPSC. Below we summarize a number of such targets, including, as best understood, their mechanisms and their pros and cons for clinical implementation.

TRANSCRIPTION FACTORS

After the first description of iPSC, focus was turned towards finding modifiers of reprogramming. Repression of *p53*^[17], as well as its primary target gene *p21*, or addition of mutant *p53*^[18] markedly facilitates and expedites reprogramming of mouse and human cells^[19-23]. These studies proposed mechanisms by which p53 inhibits iPSCs generation, including induction of cell-cycle arrest, apoptosis and senescence. By virtue of its apoptotic induction following cellular DNA damage, p53 is a master regulator of genomic integrity and serves as a major tumor suppressor^[24-26]. p53, either directly or *via* pathway members, undergoes loss of function mutations in nearly every cancer. Often the cellular programs that are co-opted during the development of cancer are, in fact, reactivated features of stem cells^[27,28]. Reprogramming differentiated cells to pluripotent cells involves massive genomic changes that are not unlike some of the genomic changes that occur during cancer development. Indeed, despite the ability of p53 repression to enhance reprogramming

efficiency, p53-deficient cells can yield defective iPSCs with chromosomal aberrations, genome instability and malignant transformation^[18,20,29], further highlighting the link between reprogramming and tumorigenesis. Genomic integrity is a necessity for somatic cell reprogramming in order to create viable iPSC cells as well as in maintaining cellular identity. Inhibition of p53, while an interesting target for repression because of its enhancement of reprogramming, has inherent and serious risks.

The transcription factor Bright/ARID3A regulates reprogramming through direct de-repression of key pluripotency factors Oct4, Sox2 and Nanog^[30]. It has been shown to be a binding partner of Nanog^[31] as well as Oct4 and Sox2^[30] and is believed to function as a direct repressor of key developmental promoters. In culture, loss of Bright, either in through germline deletion, dominant negative inhibition, or shRNA mediated knockdown, is able to enhance standard reprogramming, induce pluripotency related genes and partially reprogram somatic cells to an ES-like state. Further, loss of Bright can induce complete reprogramming in the presence of LIF^[30]. Bright was first discovered as a B-cell specific factor^[32-34] and is critical for hematopoietic stem cell formation^[35]. Bright is known to interact directly with p53^[36] and is regulated by p53^[37]. It is possible that part of p53's influence on reprogramming may be a function of its regulation of Bright. Loss of Bright has further been shown to inhibit senescence in culture^[38], perhaps enhancing its reprogramming abilities. Bright is a tantalizing target for further analysis but there may be still as yet unknown factors which, like Bright, have multiple functions that work towards maintaining the differentiated state of the cell.

EPIGENETIC MODIFIERS

Epigenetic regulation of the genome is essential for proper gene expression and lineage commitment. As cells shift from a stem cell state into a lineage committed state, the genome goes through massive epigenetic changes from an "open" conformation to a "closed" conformation^[39]. During differentiation, global acetylation marks, typically associated with euchromatin, are reduced and global methylation markers that are associated with condensed or heterochromatin, are increased^[40], including H3K27^[41,42] and H3K9^[43,44] methylation, typically associated with inactive promoters and H3K4 methylation^[45,46], which is associated with active promoter regions. Heterochromatin is tightly packed chromatin that generally inhibits gene expression. This shift in chromatin structure and epigenetic marks is a necessary part of the differentiation process, silencing of genes that are no longer expressed in that tissue type. Underlying the critical nature of these epigenetic marks, it is often incorrect expression of silenced genes that contribute to the formation of cancer^[47], demonstrating their importance in gene regulation. Reprogramming can occur when "pioneer" factors such as Oct4, Sox2,

and Klf4 bind to enhancers near silenced chromatin and can then direct the binding of other transcription factors to these regions^[48]. Regions of the genome in fibroblasts, marked by H3K9me3, have been shown to be refractory to binding by Oct4, Sox2 and Klf4, however knockdown of H3K9 methylases increased reprogramming efficiency^[49] and the binding of “pioneer” factors to these regions^[50]. Thus, the structure and epigenetic marks of heterochromatin itself inhibits reprogramming by exogenous factors.

Stem cells often use bivalent domains to create “poised” promoters of important developmental genes^[51]. These bivalent domains are characterized by the repressive H3K27me3 and the activating H3K4me3 marks, thus repressing expression of these genes but allowing for quick upregulation in response to developmental signals^[52]. Bivalent domains are an important regulatory feature, allowing stem cells to repress the expression of key genes while keeping them “poised”. Epigenetic regulation of the genome is necessary for appropriate gene expression in both stem cells and differentiated cells^[40,41] and thus erasure of established epigenetic marks is a necessary part of reprogramming. Several histone deacetylase inhibitors have been shown to modulate reprogramming in both SCNT and iPSC^[53]. Valproic acid (VPA) is an extremely effective histone deacetylase (HDAC) inhibitor^[54] and is commonly used to enhance reprogramming^[55,56]. Other HDAC inhibitors have similarly been shown to enhance reprogramming in many different contexts^[53]. The complexities of the histone code, in particular methylation of histones, leads to an unclear picture of how inhibitors of methylation effects reprogramming^[57]. However, DNA demethylation agent 5'-Azacytidine has long been known to enhance reprogramming^[58]. Repression of AID, a cytidine deaminase, inhibits reprogramming in interspecies heterokaryons^[59] via promoter CpG demethylation^[59,60]. Inhibition of both DNA and histone methylating components of the polycomb repressive complexes 1 and 2 (PRC1 and PRC2) have been shown to inhibit reprogramming. Repression of histone methyl transferases SUV39H1^[61] and Dot1L^[62] as well as YY1^[63] enhanced reprogramming. Specifically, repression of the catalytic activity Dot1L reduced H3K79 methylation and increased reprogramming efficiency by 3-4 fold^[49]. DNA methylation and demethylation are crucial bottlenecks during reprogramming, but because of the complexities of the signals and their importance to appropriate gene expression, in looking for effective enhancers of reprogramming, targeted inhibition of specific methylation inhibitors may give a better results.

KINASES

The focus of understanding the mechanisms underlying reprogramming have typically concentrated on transcription factors and chromatin modifying factors. However, inhibition of select kinases has also been shown to increase reprogramming efficiency^[13,64].

Examples include the TGF- β r1 and SRC kinases, although only inhibition of TGF- β r1 was able to enhance reprogramming in the absence of VPA^[13]. Inhibition of TGF- β r1 allowed reprogramming to occur in the absence of Sox2 by inducing Nanog expression in intermediately reprogrammed cells that had been exposed to Oct4, Klf4 and c-Myc^[13]. A small chemical screen identified additional kinase barriers to reprogramming that include the MAP p38 kinase^[65], IP3K, which catalyzes synthesis of a crucial secondary lipid messenger required for Ca⁺ signaling^[66], and Aurora A kinase, which is essential for cell division^[67]. Inhibition of each of these enhanced iPSC cell formation, indicating that factors that may have more selected specificities beyond the transcription factors that activate them may be worthy factors for inhibition.

CONCLUSION

The potential of human embryonic stem (hESC) cells in the clinic has been understood long before science was able to deliver on that potential. The issues that may limit using hESC as a therapeutic, such as potential immune rejection and ethical concerns, has made iPSC cells a very attractive alternative approach. iPSC appear to have the same ability as hESC cells to differentiate *in vitro* and so it is hoped that they will be able to replace hESC cells therapeutically. The underlying problem is efficient creation of reliable, stable iPSC without gene integration^[68-71]. While there have been massive strides made in the field of reprogramming, there is still a lack of clinically useful methods for producing iPSC that have been shown to be safe in the long term^[16,72-74]. Future work must expand on creating more robust reprogramming protocols, rather than staying limited to established reprogramming methods. We must look at all the proteins and microRNAs in the cell, not just known transcription factors. We must look at both enhancers of pluripotency and repressors of pluripotency as possible targets. The field has advanced enormously in only a few short years; however in order to fully manipulate cell fate, we must be more inclusive when searching for cellular reprogramming factors and broaden our understanding of how cell fate is determined.

of pancreatic cancer. Even after the emergence of recent new targeted agents and the use of multiple therapeutic combinations, no treatment option is viable in patients with advanced cancer. Developing novel strategies to target progression of PC is of intense interest. A small population of pancreatic cancer stem cells (CSCs) has been found to be resistant to chemotherapy and radiation therapy. CSCs are believed to be responsible for tumor initiation, progression and metastasis. The CSC research has recently achieved much progress in a variety of solid tumors, including pancreatic cancer to some extent. This leads to focus on understanding the role of pancreatic CSCs. The focus on CSCs may offer new targets for prevention and treatment of this deadly cancer. We review the most salient developments in important areas of pancreatic CSCs. Here, we provide a review of current updates and new insights on the role of CSCs in pancreatic tumor progression with special emphasis on DclK1 and Lgr5, signaling pathways altered by CSCs, and the role of CSCs in prevention and treatment of PC.

Key words: Pancreatic cancer; Cancer stem cells; DclK1; Lgr5; Prevention; Treatment

Core tip: Despite aggressive treatment modalities, pancreatic cancer represents most lethal malignancy with uniform lethality. The pancreatic cancer stem cells (CSCs) have been found to be resistant to chemotherapy and radiation therapy. This review summarizes the important role of CSCs in pancreatic cancer tumor progression with emphasis on DclK1 and Lgr5 CSCs, molecular signaling altered by CSCs and the important role of pancreatic CSCs in prevention and treatment of pancreatic cancer.

Abstract

Pancreatic cancer (PC) has been one of the deadliest of all cancers, with almost uniform lethality despite aggressive treatment. Recently, there have been important advances in the molecular, pathological and biological understanding

Rao CV, Mohammed A. New insights into pancreatic cancer stem cells. *World J Stem Cells* 2015; 7(3): 547-555 Available from: URL: <http://www.wjgnet.com/1948-0210/full/v7/i3/547.htm> DOI: <http://dx.doi.org/10.4252/wjsc.v7.i3.547>

INTRODUCTION

Pancreatic cancer (PC) is a deadly disease with least survival compared to any other cancers. PC including pancreatic ductal adenocarcinoma (PDAC) is one of the leading causes of cancer deaths in both genders (men and women) in the United States and the seventh world-wide^[1,2]. Despite tremendous scientific effort for over three decades, PC remains almost uniformly lethal devastating disease with < 6% five-year survival. The incidence of PC has been increasing over the past ten years. In 2013, of 46420 people (23530 men and 22890 women) diagnosed with PC, 39590 people (20170 men and 19420 women) were expected to die in the United States^[1]. Worldwide, 338000 people were diagnosed with PC in 2012^[2]. Lack of early diagnosis and effective interventions are the major factors in the poor prognosis and dismal survival rates^[3-5].

Recently, stem cells of pancreatic cancer (CSCs)/ or cancer/tumor initiating cells that often are resistant to treatment have been identified^[6-9]. The CSCs occupying a very small part of the entire cancer tissue are the reasons for tumor resistance against conventional chemotherapy and re-growth of untreatable tumors. Although the CSCs exists a small population in the cancer tissues, very recent evidence shows that CSCs contribute to tumor initiation, growth, metastasis, and resistance to therapy^[6-10]. Cancer stem cell (CSC) research has achieved much progress in a variety of solid tumors, including pancreatic cancer to some extent^[11]. The identification of specific cell surface markers enabled purification of CSCs from different cell lines or clinical tissues/samples, leading to evaluate the nature of CSCs^[12-14]. Understanding of pancreatic CSCs may improve existing therapies and deepen insight into the role of CSCs in pancreatic cancer progression^[11].

In this mini-review, we will comprehensively focus on pancreatic CSCs with emphasis on DclK1 and Lgr5. Also, we review the signaling pathways altered by CSCs, and the role of CSCs in prevention and treatment of PC (Figure 1).

ROLE OF CSC IN PC

Little has changed over last three decades for 5-year pancreatic cancer survival despite introduction of new and targeted chemotherapeutic agents^[15]. It is primarily due to highly aggressive nature of the PC disease as majority of the patients' present late stage disease and doesn't respond to therapy thereby showing chemoresistance^[15]. Recently, attention has been focused on pancreatic CSC levels to find better ways to combat PC. Cell membrane markers have made possible the identification of CSCs. Pancreatic CSC populations account for less than 1% of all pancreatic cancer cells^[14]. The pancreatic CSCs identified so far are CD133, CD24, CD44, EPCAM, ESA, c-Met, Aldh1, and more recently DclK1 and Lgr5^[9-18]. These

pancreatic CSC markers are well known based on several xenograft studies. All these markers may mark themselves or co-express to show the CSC properties^[19-21]. CD133 pancreatic CSC cells co-express the CXCR4 receptor at the invading margins of human pancreatic ductal tumors^[14,19]. Other CSC markers that co-express (CD24⁺/CD44⁺/EPCAM and CD133⁺) show CSC properties making them often resistant to chemo and radiotherapy. However, complete overlap may not be found between these different CSC markers^[22].

Most drugs are unable to eradicate these pancreatic CSCs, and this is postulated to be one of the primary reasons for failure of chemotherapy that will lead to tumor relapse and metastasis. The pancreatic CSCs markers CD24, CD44, CD133, CXCR4, ESA and nestin were reported in pancreatic intraepithelial neoplasia and PDAC^[23]. Pancreatic CSC populations expressing the cell surface markers CD24, CD44, and ESA^[14,19,24] were observed to maintain their cell surface marker phenotype after repeated passages in immunocompromised xenografts mice^[12,14,19]. In another study, c-Met positive cells readily formed *in vitro* spheres but not the c-Met negative cells^[14,25]. Similarly, it was noted that cells expressing combinations of CD44 and c-Met showed increased tumor formation ability and to renew^[25]. Kim *et al.*^[18] reported that irrespective of CD133 status, the pancreatic cancer cells with high ALDH1 activity were resistant to chemotherapy-induced cell death and are highly tumorigenic^[14,18]. The MiaPaCa-2 sphere derived CSC like cells obtained from the xenograft tumors of the mice showed high expression of EpCAM, CD44 and EZH2^[14,26]. All of these CSCs have been reviewed elsewhere for pancreatic cancer. However, there are recent studies showing the CSC properties for two important makers DclK1 and Lgr5 in pancreatic cancer.

DclK1 and pancreatic cancer

DclK1 (Doublecortin-like kinase 1, formerly known as DCAMKL-1 or doublecortin and CaM kinase-like 1) initially was identified as a putative intestinal stem cell marker. Earlier studies have suggested that DclK1 may mark tumor-initiating cells in a variety of tumor types^[27-39]. DclK1 regulates several key oncogenes like c-MYC, KRAS, NOTCH1 and EMT^[32,33,39]. Moreover, DclK1 is also reported to be a pancreatic cancer stem cell marker and its expression is found to be upregulated in PDAC^[9,39]. In the pancreas and intestines, DclK1 has also recently been described as an undefined tuft/brush cell marker^[36,37]. We have empirically shown DclK1 expression in both murine and human pancreatic intraepithelial neoplasia (PanIN) and PDAC^[9]. DCLK1 is also expressed by isolated cells in the pancreatic duct and islets of normal mouse pancreas, and prior studies have suggested that these non-neoplastic DclK1-expressing pancreatic cells were associated with progenitor-like function^[31]. Further, it was shown that DCLK1HI/AcTubHI mouse PanIN cells display specialized morphology, unique patterns of gene expression, and enhanced PanIN

Figure 1 Schematic representation of the role of cancer stem cells markers during pancreatic cancer development, signaling pathways involved and cancer stem cells inhibition by various drugs by chemoprevention and/or chemotherapy. PC: Pancreatic cancer.

sphere-forming ability^[6]. The lineage tracing techniques using alternate DNA recombinases (e.g., Dre, Flp) or the development of non-Cre/lox-based methods for Kras activation in the murine pancreas will further the progress in this area. Multiple pathways that contribute to the CSC properties of DCLK1HI/AcTubHI pancreatic cancer cells were identified by using whole genome transcriptome analysis^[6]. Studies identified ABL1 and IGF1R to be highly expressed in DCLK1HI/AcTubHI cells, complementing ongoing preclinical and clinical evaluation of ABL1 and IGF1R pathway inhibition as new forms of targeted therapy for pancreatic cancer^[38,39]. These studies suggest that both invasive and preinvasive PC may depend on DCLK1 expressing cells with cancer stem cell capabilities. As in the case of intestinal tumorigenesis, targeting this cell population may have therapeutic potential in the treatment and/or chemoprevention of pancreatic cancer. Further, NPsiDCLK1 (nanoparticle-encapsulated siRNA) knockdown of DclK1 in the mouse xenograft lead to downregulation of important markers of pluripotency like SOX2, NANOG, OCT4 and KLF4 and EMT, and angiogenic factors^[40]. These data clearly supports a central regulatory role of DclK1 in pancreatic tumorigenesis^[39]. However, further studies are underway to evaluate the potential of DclK1 as pancreatic CSC and specifically target DclK1 along or in combination with other CSC markers.

Lgr5 and pancreatic cancer

Lgr5 also known as G-protein coupled receptor 49 (GPR49) or G-protein coupled receptor 67 (GPR67) or Leucine-rich repeat-containing G-protein coupled receptor 5 (LGR5) is the Wnt target gene that marks Wnt driven actively dividing stem cells^[41-43]. In the stem cell hierarchy, LGR5 is on a higher level than CD133, however, its expression and function in the tissues of pancreatic cancer is unclear. Recent studies investigated tissue expression of LGR5 and CD133

in resected pancreatic ductal adenocarcinoma who underwent resection and demonstrated cytoplasmic expression of LGR5 in the PC cells^[17].

The maturation lineages of proximal peribiliary glands to the distal pancreatic ductal glands start near duodenum where cells express pluripotency markers (SOX2, OCT4 and NANOG), self-replication, proliferation and early hepato-pancreas commitment (Lgr5, PDX1, SOX17, SOX9)^[44]. A biological framework for life-long pancreatic organogenesis is constituted by the biliary tree-derived stem cells and their connections to committed progenitors of the pancreas^[40]. In the normal pancreas, LGR5 is co-localized with insulin and Nanog in the beta cells clusters and is exclusively expressed in the islets of the Langerhans^[45].

Since, Lgr5 is a stem cells marker in various organs and acts as Wnt-agonistic R-spondins receptor, the Lgr5 positive stem cells from intestine, liver and stomach form organoids in three dimensional cultures that resemble the tissues of origin^[42,46,47]. In a normal adult pancreas, Lgr5 is not expressed when Wnt signaling is inactive under normal conditions^[48]. However, upon the injury, Wnt pathway is activated by partial duct ligation, and Lgr5 is concomitantly expressed in the regenerating ducts^[49]. It was observed that pancreatic duct or fragments in the RSPO-1 cultures initiate Lgr5 expression and develop into organoids that can clonally expand containing Lgr5 stem/progenitor cells^[49]. The histoanatomical distribution, prevalence, and tumor biological significance of LGR5 in gastrointestinal tract tumors (including pancreatic cancer) was tested on transcriptional and translational level in tissues of 127 patients (malignant and non-malignant). It was noted that the non-neoplastic tissue usually had very few scattered LGR5 positive cells. The corresponding malignant pancreatic cancers showed significantly more LGR5 positive cells at protein and mRNA levels compared with the non-neoplastic tissue^[50]. Lgr5 co-

expressed with other CSC markers Mushashi-1, CD44 and ADAM17 and the patients with high Lgr5 positive cells had shorter median survival^[50]. Future studies are required to understand the role and clarify the prognostic value of Lgr5 in the pancreatic cancer.

SIGNALING PATHWAYS ALTERED BY CSCS

Pancreatic cancer cells and pancreatic CSCs share many characteristics of the carcinogenesis process including self-renewal, proliferation and immortality and several signaling pathways. Researchers have identified several CSC specific markers. In a recent study, investigators detected high expression of CD24, CD44, Dcl1, CXCR4, ESA, and Nestin-positive cells in the low-grade PanIN, high-grade PanIN, and PDAC (pancreatic ductal adenocarcinoma) tumors with fewer in normal ducts^[9,12,13,51,52]. These studies clearly demonstrate that pancreatic CSCs correlate with the step-wise progression of pancreatic intraepithelial neoplasias (PanINs) (PanIN1-2-3) to PC (Figure 1). During this process of early tumorigenesis after Kras mutations, several of the transcription factors like Oct4 and Nanog gets overexpressed linearly with the PanIN progression to PDAC^[53]. Oncogenic Kras mutations in the pancreas activate important signaling pathways such as sonic hedgehog, Wnt, PI3K/AKT, Notch and PTEN, Bmi1 that lead the transformation of the normal pancreas to the malignant PanINs and PDAC^[54-59].

Researchers have observed aberrant expression of Hedgehog during the PC initiation followed by progression of the pancreatic precursor PanIN lesions to pancreatic adenocarcinoma^[60]. This clearly underscores the importance of hedgehog signaling in a sequential development of PC. Recently, mounting evidence supports hedgehog signaling activation in pancreatic CSCs. Hedgehog pathway plays a significant role by regulating pluripotency maintaining factors like Oct4, Nanog, c-Myc, and Sox2 to the maintenance of stemness^[61-66]. Apart from hedgehog, increasing evidence suggests that Notch signaling activation was associated with molecular characteristics of CSCs in PC cases^[67,68]. This was shown by the studies that overexpression of Notch1 leads to increasing in the formation of pancreatospheres along with expression of the CD44 and EpCAM CSC surface markers. Other studies reported that expression of Oct4, Nanog, and PDX1 in Notch2 positive human pancreatic adenocarcinoma cells^[69]. The Oct4, Nanog and PDX1 are also considered as markers of self-renewal of pancreatic CSCs. Also, the expression of ALDH1 was associated with poor overall survival durations in PDAC patients^[70].

Newer studies illustrated involvement of PI3K/AKT signaling in pancreatic CSCs proliferation. In this direction, a recent study showed that CSCs like CD133 showed high levels of mTOR signaling in pancreatic adenocarcinoma. This underlines that the PI3K/AKT

pathway plays a prominent role in pancreatic CSCs^[71] consistent with significant inhibition of CD133 cells by the mTOR inhibitor rapamycin^[71]. However, the functions of Wnt signaling in pancreatic CSCs are less and poorly understood. Lgr5 is the Wnt target gene that is being recently explored as pancreatic CSC. Like other important signaling pathways, the Wnt/ β -catenin signaling pathway play a critical role in the pancreatic cancer development and progression.

ROLE OF PANCREATIC CSCS IN PREVENTION AND TREATMENT

Advances in the identification and characterization of pancreatic CSCs have created new opportunities for genetic targeting in treatment applications. Pancreatic CSCs are essential drivers for cancer progression and metastasis and are responsible for therapeutic resistance. Targetable cellular markers including CD24, CD44, CD133, ESA, ALDH1, c-Met, EPCAM, nestin, Lgr5 and Dcl1 have been employed to characterize pancreatic CSCs^[9-14,64]. Studies suggest that the use of the drugs that target PI3/AKT/mTOR, Hedgehog, c-Met and other developmental signaling pathways might deplete the populations of CSCs. Conceivably, multidrug combinations and multitargeting approaches will produce maximal anti-tumor efficacy by depleting resistant CSCs in PC^[72]. So far, no clinical studies have been aimed at targeting pancreatic CSCs specifically in PC patients. The pancreatic cancer precursors, PanINs, progress slowly over many years to the development of invasive PC^[3-5]. Hence, developing novel strategies to delay or inhibit progression of pancreatic cancer targeting CSCs are warranted. The K-rasG12D genetically engineered mouse (GEM) is an excellent model that shows the development of lesions closely resembling human PanIN's with progression to PDAC and it has been used successfully for chemoprevention studies^[5,8,72-78]. We have shown that licoferone, a dual COX-5-LOX inhibitor, exhibits chemopreventive efficacy against pancreatic cancer in p48^{Cre/+}-LSL-Kras^{G12D/+} mice in part by inhibiting CSCs^[72]. We have also shown that metformin, an anti-diabetic drug significantly prevents progression of pancreatic cancer by targeting in part CSCs^[8].

To date, there are no specific CSC inhibitors tested preclinically using GEMs or clinically in PC patients. Pharmacological or genetic inhibition of JNK leads to loss of stem cell properties in the pancreatic CSCs both *in vitro* and tumor. Furthermore, loss of Kras in kras mutant pancreatic CSCs led to the loss of stem cell characteristics by downregulation of the JNK pathway^[79]. Pancreatic cancers contain 1%-3% of CD133 positive cancer cells, some of which show high expression of CXCR4, a pro-invasive marker^[14]. The selective inhibition of CXCR4 signaling in CXCR4⁺ CSC cells by AMD3100 blocks tumor tissue invasion^[13,14], suggesting a potential role of CXCR4 in pancreatic tumor metastasis^[14]. Accordingly, it remains

possible that there is more than one type of CSC sub-population in pancreatic cancer tissues, which would be consistent with the known heterogeneity of most-human tumors^[14,24]. More preclinical animal and human clinical studies are warranted to evaluate the drugs for their specificity in targeting CSCs to inhibit the progression of PC. Combination of epigallocatechin-3 gallate (EGCG) and quercetin, and, Sulforaphane inhibited the self-renewal capacity of pancreatic CSCs *via* attenuation of the Hedgehog pathway^[62-65]. The GANT-61 is a Gli transcription factor inhibitor that inhibits pancreatic CSC viability and induces apoptosis^[61]. Together, blockade of hedgehog and mTOR signaling along with standard chemotherapy was found to eliminate pancreatic CSCs^[80]. Another hedgehog antagonist Vismodegib (GDC-0449), inhibits pancreatic CSC characteristics *in vitro*^[81]. Using GDC-0449, a human phase I clinical trial is ongoing^[82], which preliminarily suggest that GDC-0449 has good safety profile and antitumor activity for some of the locally advanced or metastatic solid tumors. Pancreatic cancer progression was inhibited by sulforaphane, green tea catechins and quercetin by inducing let7a miRNA and inhibiting Kras and ALDH1 activity^[82]. The 3-Bromopyruvate, a glycolysis inhibitor blocked CSC signaling in PC cell lines and the spheroids derived from patients^[83]. Also, chloroquine (antimalarial agent) decreased CSCs *in vitro* and *in vivo* in combination with gemcitabine by inhibiting the hedgehog signaling^[84].

An SRC inhibitor, dasatinib in combination with gemcitabine significantly reduced ALDH1 in MiaPaCa parental and gemcitabine resistant cells^[85]. A drug under phase 1 trial, Minnelide efficiently decreased CD133 cells in the tumors^[86]. Triptolide (plant derived Chinese medicine) is generally used for arthritis and cancer. In clinical trials it inhibited hypoxia-induced transcriptional signaling and EMT and CSC features in cell lines, decreased tumor growth *in-vivo*, and inhibited CSCs from patient tumors^[87].

Vaccine or antibody approaches are recently explored for pancreatic cancer inhibition. In the xenograft models and *in-vitro* cultures, anti-CD44 monoclonal antibodies decreased growth, metastasis and CSCs including downregulating CSC genes *Sox-2*, *Nanog* and *Rex1*^[88]. BMS-777067 (tyrosine kinase inhibitor) in combination with AZD8055 (mTOR inhibitor) successfully inhibited chemoresistant cancer cells and CSCs. However, BMS-777067 alone induces the polyploidy in the CSCs making them insensitive to the therapy^[89]. Cabozantinib downregulated c-Met, SOX2 and CD133 in the drug resistant PC cells and CSC spheroids and induced apoptosis^[90]. A kinase inhibitor XMD8-92 was shown to down-regulate Dclk1 and its downstream targets including KRAS, ZEB1, ZEB2, c-MYC, NOTCH1, OCT4, SOX2, SNAIL, SLUG, NANOG, KLF4, LIN28, VEGFR1, and VEGFR2 in the tumors of the xenografts^[90,91].

IMPLICATIONS AND FUTURE DIRECTIONS

It is now well-established that pancreatic CSCs contribute

to aggressive tumor phenotype resistant to radiation and chemotherapy^[8,14]. The molecular and pathological characteristics of the pancreatic CSCs are yet to be fully elucidated. Knowledge gained from the GEM models, and, isolation and identification of specific cancer stem cell markers and their characterization in tumor tissues will provide deep insights that will be of value in designing effective strategies for the development of chemoprevention and chemotherapy drugs that reduce tumor aggressiveness by specifically targeting CSCs^[8,14]. Although some pathways such as Notch and c-Met signaling are important for pancreatic CSC maintenance, other pathways like Wnt (Lgr5) and pathways related to Dclk1 that are required for pancreatic CSC activity must also be elucidated. Drugs targeting CSCs and their markers might modulate function of these CSCs^[8,14]. The validity of this approach was suggested by the finding that metformin, an anti-diabetic drug, displays anti-tumor effects due to the partially targeted elimination of CSCs in pancreatic cancer^[8,14]. Additional clinical and preclinical work is required to demonstrate conclusively the therapeutic benefit of metformin^[8,14,88], and CSC-targeting drugs in general, for the management of particular cancers^[8,14]. As such, CSCs are one of the best targets for cancer treatment. However, we need to improve our understanding of pancreatic CSCs and pancreatic cancer biology to develop optimal treatment (Chemoprevention and Chemotherapy) regimens. Effective treatment of pancreatic cancer could require the continued administration of conventional chemotherapeutic agents in combinations or along with agents that specifically deplete pancreatic CSCs. Pancreatic cancer could be effectively treated if the above conditions are met.

mesenchymal stem cells (MSCs)] are currently being studied as a cell-based treatment for inflammatory disorders. Experimental animal models of human immune-mediated diseases have been instrumental in establishing their immunosuppressive properties. In this review, we summarize recent studies examining the effectiveness of MSCs as immunotherapy in several widely-studied animal models, including type 1 diabetes, experimental autoimmune arthritis, experimental autoimmune encephalomyelitis, inflammatory bowel disease, graft-*vs*-host disease, and systemic lupus erythematosus. In addition, we discuss mechanisms identified by which MSCs mediate immune suppression in specific disease models, and potential sources of functional variability of MSCs between studies.

Abstract

Multipotent mesenchymal stromal cells [also known as

INTRODUCTION

Multipotent mesenchymal stromal cells [also known as mesenchymal stem cells (MSCs)] are currently being studied as a cell-based treatment for a variety of human diseases. MSCs initially received attention for their somewhat restricted multipotency, as MSCs can differentiate *in vitro* into cells of the mesoderm lineage such as adipocytes, chondrocytes, and osteocytes, but not cells of other lineages such as hematopoietic cells^[1]. In addition to multipotency, MSCs have demonstrated capacity for immunosuppression, suggesting that MSCs may be useful for the treatment of immune-mediated disorders^[2]. Importantly, several attributes of MSCs contribute to their practicality as a source for cell-based therapies. First, MSCs have a wide anatomical distribution and can be isolated from several human tissues such as bone marrow, adipose tissue, and dental pulp^[3-6]. Second, although MSCs are relatively rare within these tissues, their great capacity for self-renewal allows for the efficient expansion of these cells *in vitro* using simple cell culture methods^[7]. Thirdly, MSCs are non-immunogenic due to their low expression of antigen-presenting molecules^[8]. This allows MSCs to avoid generating an allogeneic response when transferred into an un-matched recipient, and therefore donor and recipients do not need to be well-matched for histocompatibility. Due in part to the efficiency with which MSCs can be prepared for clinical use, they have received much attention from the medical research community and their utility for use in regenerative medicine and immunotherapy has been tested in more than 100 clinical trials worldwide^[9].

Despite this intense interest, important questions regarding MSCs remain unanswered. Notably, clinical trials testing the effectiveness of MSC-based immunotherapy in treating inflammatory disorders and autoimmune diseases have produced mixed results^[10,11]. In some trials administration of MSCs helped to alleviate symptoms, while in others no effects relative to placebo were detected. These discrepant results may be due to variability in the immunosuppressive capacity among MSCs obtained from different tissue sources or expanded under different conditions *in vitro* prior to their injection into subjects^[12]. Understanding the source of this functional variability and finding ways to predict or alter the activity of a given lot of MSCs is an essential step toward achieving consistent clinical results from MSC-based therapies. Additionally, while multiple mechanisms have been identified as the means by which MSCs can mediate immune suppression, those most important for suppression *in vivo* are not well-characterized. Indeed the mechanisms most important for clinical efficacy may differ between diseases, and identifying those which are most important for a given disease will allow for more effective MSC-based therapies, and potentially give important insights into the disease itself.

Pre-clinical animal models of human diseases

have already been instrumental in the study of MSCs, and are likely to be useful tools for answering these remaining questions. Mouse studies were first used to demonstrate that MSCs possessed immunosuppressive function *in vivo*, and subsequently have helped to identify some mechanisms used by MSCs to mediate these effects. Importantly, MSC-mediated immune suppression is cross reactive between species in many animal models, allowing the effectiveness of human MSCs in suppressing inflammatory disorders to be evaluated experimentally in animal models. In this review article, we summarize what is currently known about the therapeutic effectiveness of MSCs *in vivo* in several widely-studied animal models of immune-mediated diseases. Additionally, we discuss mechanisms identified by which MSCs mediate immune suppression in specific disease models, and highlight important areas of research in the general field of MSC-related immunotherapy research. To avoid confusion, this review focuses exclusively on results obtained from animal studies, with an emphasis on MSC-mediated effects that have been demonstrated *in vivo*. A thorough and informative review of clinical studies using MSC-based cellular therapies has recently been published elsewhere^[12].

ANIMAL MODELS AND TREATMENT WITH MSC

Type 1 diabetes

Type 1 diabetes (T1D) is the result of an immune-mediated response against insulin-producing pancreatic β -cells^[13]. The autoimmune attack is largely mediated by T cells and in most patients will result in the complete loss of β -cell function. Individuals with T1D are therefore unable to produce insulin in response to increasing blood glucose levels and dependent upon exogenous insulin treatment for the remainder of their lives. Even with insulin replacement therapy, individuals with T1D are at risk of long-term complication arising from improperly-regulated blood glucose levels, such as retinopathy, kidney damage, and heart disease. Several animal models of T1D exist that are used to study both the immunological pathogenesis of the disease as well as the long-term consequences of β -cell loss^[14]. The non-obese diabetic (NOD) mouse strain is used as an animal model for spontaneous autoimmune diabetes, and disease in these animals appears to share many features with T1D in humans. Alternatively, autoimmune diabetes can be induced in several strains of mice and rats by treatment with a compound toxic to β -cells. Iterative treatment with low doses of streptozotocin (STZ) damages β -cells, and this damage attracts immune cells to the islet leading to insulinitis and eventually immune-mediated β -cell destruction. In all models of T1D disease progression can be monitored by measuring glucose levels in the blood or urine, with increases in glucose levels being associated with

progressive loss of β -cell function. Disease severity between groups can also be compared by histological examination of the pancreas of experimental animals for immune cell infiltration.

MSC-based treatment has been largely successful in treating the symptoms of autoimmune diabetes in animal models. In NOD mice, treatment with MSCs has been reported to protect mice if administered before disease onset^[15,16], and to reverse disease when administered after the onset of hyperglycemia^[17]. Interestingly, MSCs derived from NOD mice were unable to suppress disease in recipients, but those derived from BALB/c mice or the non-obese diabetes resistant strain were able to do so, suggesting that MSCs in the NOD mouse may have a defect in their ability to suppress immune responses^[16]. In these studies, MSC treatment was associated with a reduction in the frequency of inflammatory CD4⁺ T cells^[16,17] and an increase in the frequency of regulatory T cells^[15-17]. Similar results have been reported using an STZ-induced model in C57BL/6 mice, with syngeneic bone marrow-derived MSCs again reverting hyperglycemic animals to normal blood glucose levels^[18]. In a rat model of STZ-induced T1D, autologous bone marrow-derived MSCs treatment led to increased insulin secretion and sustained normoglycemia, with a shift in T cell cytokine production toward that of T_H2 cells^[19]. There is also evidence that MSC treatment can aid in tissue repair after the onset of disease, as human-derived MSCs homed to the pancreatic islets and led to an increase in islet frequency and insulin production in NOD/scid mice treated with STZ^[20]. Mouse-derived MSCs displayed similar behavior, homing to both the pancreas and kidney when injected into STZ-treated mice, and were associated with an increase in renal function relative to diabetic mice not receiving MSCs^[18]. The mechanisms used by MSCs to mediate these anti-inflammatory and tissue repair effects *in vivo* have yet to be determined.

The transplantation of allogeneic islets has been suggested as a treatment for patients with T1D, but the long term engraftment of these transplanted tissues has been difficult to achieve^[21]. Here the immunosuppressive capacity of MSCs may prove useful for preventing the rejection of transplanted islets as well as mediating islet repair immediately after transplantation. In STZ-induced diabetes models in rats^[22] and mice^[23], the long-term survival of islet allografts was significantly enhanced by co-transfer with MSCs. Notably, in a model of non-human primates (cynomolgus monkey), co-transplant of allogeneic bone marrow-derived MSCs intraportally with islets significantly enhanced islet engraftment and function, which was associated with increased number of regulatory T cells^[24]. In rats, MSC co-transfer led to a reduction in T_H1-associated cytokines and an increase in IL-10-producing regulatory T cells^[22]. In contrast, mouse MSCs reportedly mediated their immunosuppressive effects by the production of metalloproteinases that cleave the α chain of the IL-2 receptor (CD25)

from the surface of activated T cells, leaving these T cells hyporesponsive to IL-2^[23]. Collectively, MSC-based therapy has performed well in treating mouse models of T1D, both in suppressing the autoimmune attack of endogenous β -cells and in improving the maintenance of allogeneic islet allografts.

Experimental autoimmune arthritis

Rheumatoid arthritis (RA) is a common autoimmune disease characterized by chronic joint inflammation. It is thought that the disease is initiated when autoreactive T cells infiltrate the synovial tissue and secrete cytokines and chemokines, recruiting other immune cells to the joint^[25]. The resulting inflammatory milieu progressively damages the joint and surrounding tissues, a process that can be extremely painful and debilitating. The most commonly used animal model for the study of RA is the collagen-induced arthritis (CIA) model^[26]. In this model, a susceptible strain of mouse is injected subcutaneously at the base of the tail with an emulsion of complete Freund's adjuvant and type II collagen. This injection produces a potent T cell-mediated immune response to type II collagen that eventually leads to inflammation in the joints of the paws. In some cases a second booster immunization is given several weeks after the initial injection to increase disease incidence. The severity of disease can be quantified by scoring each paw on a scale from 0 (no inflammation) to 3 (severe inflammation), or by directly measuring any increase in paw width using a caliper. CIA shares many similarities with RA such as the presence of autoantibodies, the involvement of T_H1 and T_H17 cells in disease progression, and a strong link between disease susceptibility and the genomic region encoding for class II MHC molecules^[26].

Several groups have studied the efficacy of MSC immunotherapy in mouse models for RA and have generally found that MSCs can reduce both the incidence and severity of disease. In the CIA mouse model, intraperitoneal injection of allogeneic bone marrow-derived MSCs at the time of initial immunization significantly reduced incidence of disease, and administration of MSCs after disease onset had a therapeutic effect as well^[27]. A study using adipose-derived MSCs reported similar results, as mice receiving multiple doses of MSCs were less likely to show signs of joint inflammation and overall had a milder form of arthritis than those animals not receiving MSCs^[28]. Notably, this study also found that both human and murine MSCs could suppress autoimmunity in the CIA model. These results, along with another study showing that MSCs derived from rat bone marrow are effective as well^[29], suggests that at least some immunosuppressive mechanisms employed by MSCs are cross-reactive between species. Human MSCs derived from umbilical blood suppress CIA as well^[30]. Additionally, murine MSCs injected directly into inflamed joints reduced inflammation in an antigen-induced arthritis model^[31]. These results are in contrast with an earlier report which instead

found that administering MSCs after disease onset exacerbated disease rather than ameliorating it^[32]. It should be noted, however, that these experiments used an immortalized MSC-derived cell line rather than conventional MSCs. Additionally, this study and another using conventional murine MSCs found that despite their failure to suppress CIA *in vivo*, MSCs did suppress immune responses *in vitro*^[32,33].

The mechanisms through which MSCs inhibit experimental arthritis are still in question. Several groups have reported a decrease in levels of pro-inflammatory cytokine such as TNF α ^[27,29,30] or IL-6^[30], and increases in the anti-inflammatory cytokine IL-10^[29,30]. MSCs may also modulate the nature of the T cell response in CIA by reducing the frequency of T_H1 and T_H17 cells^[28,30], and/or increasing the frequency of T_H2 cells^[30,34]. MSCs appear to promote regulatory T cells as well, as several studies have observed an increase in regulatory T cell frequency after administration of MSCs^[27,28,30]. While T cells from MSC-treated mice are generally hyporesponsive, MSC treatment does not appear to effect T cell priming, suggesting that the immunosuppressive effects of MSCs occur after the autoimmune response is initiated^[30]. MSCs from mice deficient in IL-6 or iNOS production have partially impaired immunosuppressive function^[34]. IL-6-deficient MSCs released significantly lower levels of prostaglandin E2, suggesting that autocrine IL-6 may induce the production of anti-inflammatory lipid mediators by MSCs^[34]. Although MSC treatment clearly modulates the T cell response in CIA, it is currently not known if this effect is directly attributable to MSCs or rather an indirect effect of MSCs acting on other cells of the immune system.

Graft-versus-host disease

Allogeneic hematopoietic stem cell transplantation is used for the treatment of blood-derived malignancies and immune deficiencies^[35]. Graft-versus-host disease (GVHD), a major complication that occurs after transplantation, is the result of donor-derived immune cells mounting an alloreactive response against the recipient's tissues or organs. GVHD occurs in up to 50% of transplant recipients, and therefore is a significant source of the mortality associated with these therapies^[36]. Animal models are widely used to study the GVHD response by depleting endogenous hematopoietic cells in recipient animals by radiation or chemotherapy and reconstituting the immune system in these animals with allogeneic bone marrow cells^[37]. The progression of GVHD in animal models is frequently assessed by weight loss, survival, and histological examination of organs and tissues commonly affected by GVHD. It should be noted that experimental GVHD models can vary greatly, both in the details of the protocol used and in the degree of MHC mismatch between donor and recipient strains^[37].

The effects of MSC-based therapies in these animal

models have been widely-studied, with most reports observing that MSC infusion was effective in treating or delaying experimental GVHD. An early study reported that transfer of bone marrow cells from MRL/lpr mice into irradiated recipients resulted in a GVHD-like wasting disease, but recipient animals survived much longer when the bone marrow transfer was accompanied by a bone graft (presumably containing MSCs)^[38]. In a MHC-mismatched model (bone marrow from C3H/He into irradiated BALB/c mice), a single dose of bone marrow-derived MSCs at the time of bone marrow infusion allowed recipient mice to survive much longer than those receiving only bone marrow cells^[39]. Experiments using these same strains found that an immortalized MSC cell line could suppress GVHD in this model as well^[40]. MSCs derived from adipose tissue were also able to potentially extend the life of animals in a haploidentical GVHD model^[41]. It should be noted that these authors found that MSC treatment early in the course of disease was effective, but when MSCs were administered later little benefit was observed, suggesting that the timing of MSC treatments are critical in GVHD models^[41]. T cell-derived IFN γ may be an important factor as well, as MSCs treated with IFN γ prior to infusion are reportedly superior to untreated MSCs in increasing survival after bone marrow transplant^[42]. These authors also found that MSCs were unable to enhance survival if recipients received a transplant containing IFN γ -deficient T cells, suggesting that activation-induced production of inflammatory cytokines may be required for maximal immunosuppression by MSCs *in vivo*^[42].

A xenogeneic model has also been used to investigate the effects of human-derived MSCs on the progression of GVHD^[43-45]. In this model, human peripheral blood mononuclear cells (PBMCs) are infused into irradiated NSG mice^[46], where they proliferate and initiate a GVHD-like response against mouse tissues in the recipient. Three weekly doses of umbilical cord-derived human MSC starting at the time of PBMC infusion completely prevented GVHD and strongly reduced T cell proliferation *in vivo*^[43]. Timing was again critical, as treatment started several weeks after PBMC infusion failed to prevent GVHD^[43]. In other studies using a similar xenogeneic model, bone marrow-derived human MSCs^[44] or cord blood-derived MSCs^[45] were able to suppress GVHD as well. Treating MSCs with IFN γ prior to infusion enhanced the immunosuppressive capacity of MSCs, as IFN γ -treated MSC suppressed GVHD even when far fewer cells were administered^[44].

Other reports failed to observe any positive effect of MSC treatment in GVHD^[47-51]. Although these studies failed to observe *in vivo* effects, most reported that MSC were immunosuppressive *in vitro*^[47,48,50,51], and one found that animals receiving MSCs had reduced GVHD-mediated tissue pathology despite a lack of survival enhancement^[49]. These seemingly conflicting outcomes are potentially the result of variation in experimental

design as well as in the immunosuppressive capabilities of MSCs. As mentioned above, several studies found that the timing of MSC infusion was crucial for GVHD suppression^[41,43]. MSCs in general appear to intrinsically vary in their immunosuppressive capabilities depending upon the source animal, tissue of origin, isolation methods, passage number, and route of infusion. Variation can exist between MSC lots even when these variables are held constant, as demonstrated by a report showing that MSC lines isolated from the same mouse strain in the same laboratory can have drastically different immunosuppressive capabilities *in vivo*^[52]. Interestingly, these authors found no difference in the *in vitro* immunosuppressive capabilities of these independent MSC lines despite the difference in their effectiveness *in vivo*, suggesting that *in vitro* capabilities do not necessarily reflect *in vivo* function^[52]. The specific GVHD model chosen can also have an impact on experimental results, as murine MSCs are reportedly effective in preventing GVHD in a sibling transfer murine GVHD model, but can only delay disease when donors and recipients are MHC-mismatched^[53]. While most studies find that MSCs are capable of suppressing GVHD in animal models, it is essential to better understand the source of these discrepant results and find ways to predict if a given lot of MSCs will have immunosuppressive function *in vivo*. Elucidating the mechanisms MSCs use to mediate immune suppression in GVHD models should also be the focus of future work. Several groups have reported that T cells are inhibited in animals receiving MSCs, but the molecular mediators responsible for this phenomenon are largely unknown.

Experimental autoimmune encephalomyelitis

Multiple sclerosis (MS) is a disorder of the central nervous system (CNS) characterized by the progressive demyelination of nerves in the spinal cord and brain^[54]. The resulting loss of neurological function can lead to a wide variety of symptoms including pain, loss of sensation, muscle spasms, loss of coordination, vision problems, ataxia, difficulty of thinking, and emotional distress. The cause of demyelination in MS is thought to be an inflammation of the CNS caused by infiltrating immune cells^[54]. Autoimmunity in the CD4⁺ T cell compartment appears to play a central role in the pathogenesis of MS based upon evidence from animal studies and genetic association studies in humans identifying haplotypes of the MHC region associated with both susceptibility and protection from disease^[55]. The most commonly-studied animal model for MS is experimental autoimmune encephalomyelitis (EAE), an induced model for CNS inflammation^[56,57]. In these models, mice are immunized to induce an immune response to CNS associated antigens such as myelin oligodendrocyte glycoprotein (MOG) or myelin proteolipid protein (PLP). Alternatively, EAE can be introduced by the adoptive transfer of activated

myelin-specific CD4⁺ T cells. EAE can follow distinct clinical courses depending upon the mouse strain used and the specific antigen against which the immune response is raised, each reflecting different aspects of MS in humans. Immunizing C57BL/6 mice against MOG results in a progressive disease course, whereas SJL mice immunized against PLP display a relapsing/remitting form of the disease^[56]. The first sign of disease is usually a limp tail followed by weakness or paralysis in the hind limbs as demyelination progresses. Disease severity is often represented by a paralysis scoring system where individual animals are scored based upon the level of paralysis observed. Histological examination of the spinal cord for immune cell infiltration can also be used to give a quantification of disease severity.

The impact of MSC-based therapy in EAE has been extensively studied, with most of studies reporting a potent immunosuppressive effect. Mice receiving syngeneic bone marrow-derived MSCs showed a significantly milder disease course than that of untreated animals in a progressive EAE model^[58]. This effect was evident when MSCs were administered either before disease onset or at the peak of disease severity, but not when administered later in the course of disease. This result suggests that the improvement in neurological function mediated by MSCs is due to their immunosuppressive functions rather than their multipotency. MSCs were effective in suppressing EAE in a relapsing/remitting model as well^[59]. Allogeneic MSCs suppressed EAE with an efficiency similar to that of syngeneic MSCs^[60]. Human MSCs are effective in EAE models as well, as MSCs from both bone marrow^[61,62] and adipose tissue^[63] have been reported to suppress either progressive or relapsing/remitting forms of disease.

As in other T cell-mediated autoimmune mouse models, questions still remain as to the mechanisms of immune suppression mediated by MSCs in EAE. A reduction in the frequency of T cells secreting inflammatory cytokines accompanies the reduction in disease activity^[59,64], and T cells in mice receiving MSCs appear to be hyporesponsive to antigenic stimulation or anergic^[58,59]. Murine MSCs appear to mediate immune suppression at least in part by a novel pathway inhibiting the CCL2 chemokine axis^[64]. MSCs secrete several matrix metalloproteinases that can cleave MSC-derived CCL2, resulting in an isoform that inhibits rather than activates CCR2-expressing immune cells^[65]. This mechanism plays a key role in MSC-mediated inhibition of EAE, as MSCs from CCL2^{-/-} mice are unable to suppress disease^[64]. While this mechanism is clearly important in the EAE model, its role in other T cell-mediated autoimmune animal models remains to be tested. CCL2 signaling is especially important for infiltration of the CNS by inflammatory T cells, but MSCs may rely on other immunosuppressive mechanisms in other disease models where the CCL2/CCR2 signaling

axis is less involved in disease pathogenesis^[66,67]. Finally, a defect in MSC function may be important in the pathogenesis of EAE, as MSCs derived from mice with ongoing disease are unable to suppress disease upon transfer to autologous recipients^[68].

Inflammatory bowel disease

Inflammatory bowel disease (IBD) in humans refers to a family of disorders characterized by destructive inflammation of the colon or small intestine^[69]. Damage caused by chronic inflammation leads to a host of gastrointestinal symptoms such as severe cramps and abdominal pain, diarrhea, and weight loss. In severe cases affected parts of the intestines are removed surgically, sometimes requiring a permanent colostomy. While the causes of IBD are not well understood, CD4⁺ T cells are thought to play a key role in the disease^[70]. The most commonly studied animal models of IBD involve administering an agent that causes chemical damage to the intestine such as dextran sulfate sodium (DSS) added to drinking water or intrarectally-administered trinitrobenzene sulfonic acid (TNBS)^[71]. The intestinal injury allows immune cells of the lamina propria to come in contact with luminal contents such as enteric bacteria, triggering an inflammatory cascade that bears some resemblance to human IBD. Severity of disease can vary depending upon the strain of mouse used as well as the route and frequency of administration of the chemical used. The disease course can be monitored by progressive weight loss or the appearance of diarrhea and/or bloody stools, or assessed post mortem by measuring colon length and histological examination looking for damage and immune cell infiltration^[71].

Therapies using MSCs have been largely successful in treating disease in animal models of IBD. In a DSS-induced acute colitis model, adipose-derived MSCs suppressed most measurable disease outcomes and improved survival^[72]. This effect was observed when MSCs derived from either human or mouse tissues were used, and MSCs from allogeneic donors were as effective in treating disease as those from syngeneic donors^[72]. Similar results were obtained when colitis was induced by intrarectal administration of TNBS^[73]. Human MSCs derived from bone marrow, gingiva or cord blood were also effective in treating DSS-induced colitis in mice^[74,75]. MSCs from rats are capable of suppressing experimental colitis in both rats^[76] and mice^[77].

MSCs appear to suppress disease in IBD models through multiple mechanisms. Several studies have reported that MSC infusion increased the frequency of regulatory T cells accompanied by a reduction in T cells secreting inflammatory cytokines^[72,73,78]. In the DSS-induced colitis model, MSCs from mice deficient in Fas ligand (FasL) were unable to suppress disease^[77,78]. FasL and its receptor Fas are both essential molecules for maintaining T cell homeostasis, and signaling

downstream of Fas leads to the rapid induction of apoptosis in susceptible cells, including activated effector T cells^[79]. During the course of experimental colitis MSCs can induce FasL-mediated apoptosis in T cells, and this increase in the frequency of apoptotic cells indirectly leads to an increase in regulatory T cells, as macrophages engulfing the apoptotic T cells increase their production of TGFβ^[78]. Interestingly, MSCs from Fas-deficient animals were also unable to suppress colitis despite being able to induce T cell apoptosis *in vitro*. The loss of Fas in MSCs disrupted their ability to produce CCL2, suggesting that non-apoptotic Fas signaling is required for CCL2 secretion in MSCs^[78]. Therefore Fas-deficient MSCs are incapable of attracting T cells into close proximity for FasL-mediated killing^[78]. In this study, CCL2 secreted by MSCs acted as a chemoattractant, while in the EAE model MSCs were reported to secrete an isoform of CCL2 that antagonized CCR2 signaling and inhibited CCL2-mediated chemotaxis^[64]. How MSCs can use two forms of the same chemokine with opposing activities to mediate immunosuppression is currently unknown, as are the conditions that cause MSCs to produce one form of CCL2 over the other.

Systemic lupus erythematosus

Systemic lupus erythematosus (SLE) is a complex autoimmune disease that causes progressive and profound damage to a variety of organs and tissues^[80]. A hallmark of SLE is the presence of antibodies against nuclear antigens such as DNA or chromatin-associated proteins^[80]. Intranuclear antigens are rarely found in the extracellular space under normal conditions as dying cells are quickly cleared by phagocytic cells before intracellular contents are released. In patients with SLE, however, it is thought that an increase in the rate of cell death and/or defects in the mechanisms responsible for the clearance of dying cells results in the release of intranuclear contents. Once exposed, free chromatin is bound by autoantibodies resulting in large immune complexes. These immune complexes accumulate in certain places in the body and induce inflammation at these sites. Immune complexes frequently accumulate in the blood vessels surrounding glomeruli in the kidney in patients with SLE, leading to extensive tissue damage and loss of renal function^[80]. Other complications arising from SLE include increased risk for atherosclerosis, neurological problems, and inflammation of the heart or lungs.

The most commonly-studied animal models for SLE are mouse strains in which a lupus-like disease arises spontaneously. The model thought to best approximate the disease course seen in humans with SLE uses the first generation progeny of a breeding pair consisting of a New Zealand Black (NZB) mouse and a New Zealand White (NZW) mouse^[81]. The resulting hybrid mice (NZB/NZW F₁) develop anti-nuclear and anti-DNA antibodies along with a form of glomerulonephritis that resembles

that seen in patients with SLE. Another model uses mice with a mutation in the gene encoding Fas (lpr) on the MRL strain background. The immune cells of MRL/lpr mice cannot undergo Fas-mediated apoptosis, resulting in a pronounced lymphoproliferative disorder that leads to the development of anti-nuclear antibodies and subsequent glomerulonephritis^[81]. In both of these spontaneous models of SLE, progression of the disease can be tracked by assessing renal function and testing for the presence of anti-nuclear antibodies in the serum.

The effectiveness of MSC-based therapy in the treatment of animal models of SLE is still in question. Initial studies in the MRL/lpr model reported positive results. The infusion of allogeneic bone marrow-derived MSCs reduced serum levels of anti-DNA antibodies and improved renal function^[82]. Clinical improvement was accompanied by an increase in the frequency of regulatory T cells and a reduction of IL-17-producing CD4⁺ T cells^[82]. MSCs from human tissues suppressed disease in the MRL/lpr model as well, as infusion of human MSCs derived from either bone marrow^[83] or umbilical cord blood^[84] led to a reduction in anti-DNA antibodies, proteinuria, and renal pathology. Results obtained in the NZB/NZW F₁ model are more ambiguous, however. Human MSCs from umbilical cord blood had only a moderate effect on disease parameters and animal survival, despite markedly reducing serum levels of pro-inflammatory cytokines (IL-2, TNF α , and IL-12) and increasing anti-inflammatory cytokine concentrations^[85]. Similar results were obtained when MSCs derived from human embryonic stem cells were used, although only animal survival was considered in this study^[86]. In a study using MSCs from murine bone marrow, however, allogeneic MSCs unexpectedly exacerbated the disease, increasing titers of anti-DNA antibodies and deposition of immune complexes in the kidney^[87]. The MSCs used in this study were able to suppress T cell proliferation *in vitro*, suggesting that grossly dysfunctional MSCs are not to blame for this result^[87]. Considering these discrepant observations, it is premature to draw any conclusions regarding the effectiveness of MSCs in treating animal models of SLE.

Experimental autoimmune uveitis

Autoimmune uveitis is a group of heterogeneous and complex human eye diseases that are collectively a major source of vision impairment and blindness^[88]. Genetic and experimental studies suggest that autoimmune uveitis is mediated by a response against retina-associated antigens, with T_H1 and T_H17 cells playing an especially crucial role^[89,90]. Experimental autoimmune uveitis (EAU), the most commonly-studied animal model for human uveitis, can be induced in susceptible animals by immunization with retina antigens or transfer of retina-specific T_H1 or T_H17 cells^[91]. Most studies of MSC-based treatment in EAU have observed a potent immunosuppressive effect. In a mouse model

of EAU induced by immunization with a self uveitogenic peptide derived from the intraphotoreceptor binding protein, treatment with a single intraperitoneal injection of syngeneic bone marrow-derived MSCs was able to significantly attenuate EAU^[92]. Human-derived MSCs were effective in preventing EAU in this mouse model as well^[93]. EAU can be induced in rats using a similar protocol, and bone marrow-derived MSCs from both syngeneic and allogeneic donors were able to suppress EAU in recipient animals^[94,95].

While MSC treatment appears to be effective in EAU, little is currently known about how MSCs mediate disease suppression. Most studies report a decrease in production of pro-inflammatory cytokines accompanied by an increase in regulatory T cell frequency^[92-95]. T cells from MSC-treated rats showed reduced IFN γ and IL-2 production relative to those from untreated animals, along with a moderate increase in production of IL-10 and TGF β ^[95]. Additionally, MSC treatment reduced T_H17 cell frequency in the eye and the spleen while increasing the frequency of regulatory T cells in both locations^[95]. Whether MSCs modulate the T cell response in EAU directly or indirectly has not yet been conclusively demonstrated. Importantly, the mechanisms used to mediate immunosuppression may differ between species, as murine and rat MSCs induced regulatory T cells^[92,94,95], but human MSCs induced IL-10-producing B cells while having little effect on regulatory T cell frequency^[93].

UNANSWERED QUESTIONS: FUTURE PERSPECTIVES

MSCs are currently being studied for use in cellular immunotherapy, but the performance of MSC-based therapies in clinical trials has been inconsistent. In mouse studies MSCs have more frequently shown an immunosuppressive effect (Table 1), although several studies found that treatment with MSCs either had no effect on disease or worsened disease outcomes^[32,33,47-51,87]. These exceptions are informative and, considering the general bias against publishing negative outcomes, suggest that MSC performance in mouse models may be just as inconsistent as it has been in the treatment of human disease. Understanding the sources of this inconsistency is an essential step in improving MSC-based therapies, and using mouse models provides a practical means of doing so.

The variable outcomes seen in these studies could come from many different sources. First, the functional characteristics of MSCs may differ based upon the species or tissue or origin. Among mouse studies there currently exists no evidence that MSCs from a particular tissue are consistently more effective in suppressing immune responses, and MSCs from human, mouse, and rat tissues have all effectively treated disease in mouse models. Instead, intrinsic variation in MSC

Table 1 Immunomodulatory effect of mesenchymal stromal cells in animal disease models

Disease model	Anti-inflammatory MSC effects	Negative/neutral studies?
Type 1 diabetes	↑ Regulatory T cells (15-17, 19) ↓ Inflammatory T cells (16, 17) T _H 1 → T _H 2 (16, 19) ↑ Tissue repair (18-20)	None reported
Pancreatic islet transplantation	↑ Islet survival (22-24) ↑ Regulatory T cells (22, 24) ↓ T _H 1 cytokines (22) ↓ T cell responsiveness (23)	None reported
Experimental autoimmune arthritis	↓ Inflammatory cytokines (27, 29-31) ↑ Regulatory T cells (27, 28, 30, 34) ↓ T cell responsiveness (27) ↑ IL-10 (28-30) ↓ T _H 1/T _H 17 cells (28, 30) ↑ T _H 2 cells (30, 34)	No suppression (31-33)
Graft-vs-host disease	↓ Auto-antibodies (38) ↓ Inflammatory cytokines (39, 42, 44, 53) ↑ Regulatory T cells (40) ↓ T cell proliferation (44) ↓ T _H 1 cells (49)	Prevented disease, but no effect after disease onset (43, 47) No suppression (48, 50, 51) Reduced pathology but no effect on survival (49)
Experimental autoimmune encephalomyelitis	↓ T cell responsiveness (58) ↓ CNS infiltration (59-61, 64, 68) ↓ Auto-antibodies (59) ↓ Inflammatory cytokines (60, 64, 68) T _H 1 → T _H 2 (61) ↓ T _H 17 cells (64)	None reported
Inflammatory bowel disease	↓ Inflammatory T cells (72, 73, 78) ↓ Inflammatory cytokines (72-76) ↑ Anti-inflammatory cytokines (72-75, 78) ↓ Intestinal CD4 ⁺ T cell infiltration (72-74) ↑ Regulatory T cells (72-75, 78) ↓ Growth factor expression (76) ↑ FasL-mediated T cell apoptosis (78) ↓ T cell responsiveness (73)	None reported
Systemic lupus erythematosus	↓ Anti-DNA antibodies (82-85) ↑ Regulatory T cells (82) ↓ T cell frequency (83) ↓ T _H 17 cells (82) ↓ Plasma cells (82) ↓ Inflammatory cytokines (85) ↑ Anti-inflammatory cytokines (85)	Worsened disease, increased auto-antibodies (87)
Experimental autoimmune uveitis	↓ Inflammatory cytokines (93-95) ↑ IL-10 (93, 94) ↑ Regulatory T cells (92-95) ↓ Inflammatory T cells (95) ↓ T _H 1 cells (93) ↓ T _H 17 cells (93, 95) ↑ IL-10-producing B cells (93)	Not effective late in disease course, but effective before and shortly after disease onset (94)

MSC: Mesenchymal stromal cell.

lots may be the source of functional differences, as differences in immunosuppressive function can be seen even between MSC lots derived independently from the same mouse tissue in the same laboratory^[52]. This type of variation is likely to arise stochastically and therefore identifying biomarkers associated with *in vivo* MSC function may be useful in identifying particular lots of MSCs that are more likely to be effective *in vivo*. Mouse models provide a practical means of performing these experiments as human MSCs have proven effective in treating disease in many of these models.

While many immunosuppressive mechanisms have

been reported from *in vitro* studies of MSC function, far fewer have been identified using *in vivo* experiments^[96]. Several elegant studies reviewed here have shown that a particular mechanism is important for *in vivo* suppression in a particular disease model, but these mechanisms have yet to be confirmed in additional models^[23,34,65,77,78]. Indeed it may be the case that different immunosuppressive mechanisms are important in different disease models, and that MSC lots effective at suppressing one immune-mediated disorder are not necessarily effective in other models. Further work is required to establish if certain immunosuppressive

mechanisms are essential in multiple disease models, or if MSC immunosuppression is mediated by unique mechanisms depending upon the inflammatory context.

Collectively, the studies reviewed above demonstrate that MSC-based therapies are generally effective in treating animal models of several inflammatory conditions. Although most studies observed an immunosuppressive effect of MSC treatment, a few did not—mirroring the overall effectiveness seen in clinical trials of human MSC treatments. Understanding the sources of these inconsistent results may lead to means of improving the reliability of MSC-based therapies. Mouse models of immune-mediated disease provide a practical means of studying the variability of MSC immunosuppressive function and identifying general and model-specific mechanisms of immune suppression essential for effective MSC-based immunotherapy.

Abstract

Due to the increasing burden on healthcare budgets of musculoskeletal system disease and injury, there is a growing need for safe, effective and simple therapies. Conditions such as osteoporosis severely impact on

quality of life and result in hundreds of hours of hospital time and resources. There is growing interest in the use of low magnitude, high frequency vibration (LMHFV) to improve bone structure and muscle performance in a variety of different patient groups. The technique has shown promise in a number of different diseases, but is poorly understood in terms of the mechanism of action. Scientific papers concerning both the *in vivo* and *in vitro* use of LMHFV are growing fast, but they cover a wide range of study types, outcomes measured and regimens tested. This paper aims to provide an overview of some effects of LMHFV found during *in vivo* studies. Furthermore we will review research concerning the effects of vibration on the cellular responses, in particular for cells within the musculoskeletal system. This includes both osteogenesis and adipogenesis, as well as the interaction between MSCs and other cell types within bone tissue.

Key words: Mesenchymal stem cells; Mechanobiology; Osteogenesis; Whole body vibration; Adipogenesis, osteoporosis; Low magnitude, high frequency vibration loading

Core tip: Low magnitude, high frequency vibrations are attracting growing interest as a non-invasive therapy for a variety of different disorders. The number of studies aimed at elucidating the effects of vibration both *in vivo* and *in vitro* is increasing rapidly. This review aims to provide an introductory overview of the *in vivo* data for a broad range of human applications and animal models. *In vitro* work is covered in more detail, focusing in particular on studies concerning the effects of vibration on cells derived from the musculoskeletal system.

of musculoskeletal progenitor cells: Review of results *in vitro* and *in vivo*. *World J Stem Cells* 2015; 7(3): 568-582 Available from: URL: <http://www.wjgnet.com/1948-0210/full/v7/i3/568.htm> DOI: <http://dx.doi.org/10.4252/wjsc.v7.i3.568>

INTRODUCTION

Vibration or low-magnitude-high-frequency vibration (LMHFV) loading can be induced clinically by standing a subject on a vibrating platform or *in vivo* by applying LMHFV to cells within culture plates or 3D constructs. It is emerging as a potential stimulus for repair and regeneration of the musculoskeletal system with some preliminary evidence that the mechanism of action is *via* effects on mesenchymal stem cells^[1,2]. Clinical trial results are variable, however, as are the results in animal models and cell cultures. Differing loading procedures and parameters make it very difficult to compare between experiments. In this review we aim to provide a series of snapshots of human, animal and cell based trials on the effects on LMHFV loading and related stimuli, with a focus on mesenchymal cells and effects on the musculoskeletal system. This is not intended to be a meta-analysis or a comprehensive review of all studies in this area, but rather to indicate how much further interdisciplinary research needs to be done before we can elucidate the effects of vibration on stem cells.

Within the musculoskeletal (MSK) system, there are a variety of different tissues which work together to allow movement. These include bone, muscle, tendon and ligament, as well as other associated tissues such as blood vessels and nerves. All of these tissues are important in locomotion and posture and are affected by a variety of diseases and by age-related degeneration. It has been well demonstrated and reviewed elsewhere^[3-5] that mechanical stimuli are involved in maintaining the structure of these tissues. Too little or too much mechanical stimulation can perturb the cells' mechanobiological signalling pathways, ultimately leading to disruption in tissue structure. In bone, such studies have shown changes in bone formation due to unloading^[6], increased osteoblast activity with single periods of dynamic loading^[7] or the well-known example of humeral hypertrophy in the playing arm of professional tennis players^[8]. Due to an increasing population which is living longer, there is a growing burden on healthcare providers of age related diseases and disorders. In addition to this, many of the aging population are remaining active longer into their lives, putting more stress on their musculoskeletal systems and desiring more effective treatments for injury or degeneration.

One of the major problems for healthcare systems with an aging population is the incidence of osteoporosis, particularly in post-menopausal women. It is estimated to affect one third of women over 50, with changes in

oestrogen levels causing a reduction in the bone mass, leading to an increase risk of fractures. In Canada in 2010, it was estimated that \$2.3 billion dollars was spent on osteoporosis treatment (1.3% of the total healthcare expenditure). This estimate rises to \$3.9 billion when those in long term care with osteoporosis are included. Between 2007 and 2008, Canadian healthcare systems dealt with over 57000 acute care admissions and over 800000 hospitalised days^[9]. In Europe, there were 3.79 million osteoporotic fractures and 0.89 million hip fractures in the year 2000. The direct costs of treatment for such fractures is estimated at €31.7 billion and these costs are expected to rise to €76.7 billion by 2050^[10]. There is therefore great economic benefit to be derived from improving osteoporosis treatment and care.

There are many other MSK malfunctions which can lead to problems in mobility. Some, such as stroke-induced paralysis, may happen later in life and require suitable rehabilitation methods for older patients. Others, such as cystic fibrosis and osteogenesis imperfecta occur at birth and treatments are required to improve the quality of life in disabled children and adults. Degeneration of the MSK system is also a problem in patients with restricted movement, such as those under long term hospital care. There is a need in all of these situations to improve or maintain the structure and function of the different MSK tissues. It is also desirable in many cases that this is done without the need for an intensive exercise, particularly in those at high risk of fractures or falls or with limited mobility.

In the MSK system, many of the cells which produce and maintain the tissues come from a lineage of progenitor cells contained within the bone marrow. These cells are known as mesenchymal stem cells (MSCs) and similar cells are found in umbilical cord blood^[11] and vein^[12] and many adult tissues including skin^[13] and adipose tissue^[14,15]. Therefore, interventions that act on the whole body to improve MSK tissue structure likely have an effect on MSCs as well as mature MSK cells. MSCs are a multipotent stem cell, capable of differentiation along osteogenic, chondrogenic, adipogenic and myogenic lineages^[16-18]. Because they are multi- rather than pluripotent some researchers in the field prefer to use terms such as "multipotent stromal cell" or "mesenchymal stromal cell". It is thought that MSCs could be a potent tool for regenerative medicine, allowing the repair of many tissue types within the body. Regenerative medicine aims to develop methods to recruit or guide the MSC pool of cells *in vivo*, enabling them to more effectively augment healing. The related field of tissue engineering is a repair strategy in which stem cells are stimulated to differentiate towards a required lineage, usually *in vitro* and then implanted into a patient. Expansion of a patient's own cells may necessary for such therapies, due to the relatively low frequency with which these cells are encountered within the bone marrow (0.01%-0.001%)^[19,20]. These cells are also known to be immunomodulatory, reducing strong

inflammatory responses within tissues^[21-23]. There is some hope that allogeneic MSCs may be of use during therapy, allowing for a more immediate source of cells than patient expanded MSCs.

In vitro, the most commonly used methods to induce differentiation of MSCs involve glucocorticoids such as dexamethasone^[24], growth factors such as bone morphogenic proteins (BMPs)^[25,26] and other biochemicals such as ascorbic acid^[27] and β -glycerophosphate^[28] (for the deposition and mineralisation of bone matrix). For a general review of such methods, see Delaine-Smith and Reilly (2011)^[29]. For transplantation of stem cells or their use in tissue engineering, it may be possible to use chemical means to direct differentiation. For *in vivo* applications, the use of chemical agents will have other systemic effects and the cost of growth factors is prohibitive for most health services. Therefore non-biochemical means of stimulating MSCs could be very useful.

There is growing evidence that mechanical stimuli can be used to direct stem cell differentiation towards a variety of different tissue lineages, reviewed elsewhere^[30-33]. For example, in MSCs it has been demonstrated that the application of compression^[34], tension^[35] or bending of scaffolds^[36] can increase osteogenic differentiation. Other work has shown that microgravity can reduce the osteoblastic differentiation of human MSCs^[37]. *In vitro* work on such stimulation techniques may allow the development of methods to enhance recruitment and differentiation of such cells *in vivo* and allow more targeted therapies. The principle behind LMHF loading is that such vibrations are similar in to the tiny, short duration forces which are applied to bones through muscle action in resting. There is evidence that these small motions may be more important than high impact events in maintaining bone mass and aiding repair^[38].

The following sections of this review will cover the *in vivo* and *in vitro* use of LMHFV. The range of measures for *in vivo* treatments will be covered briefly, with a more in depth look at studies concerning cell behaviour and progenitor recruitment or differentiation in the MSK system. The final *in vitro* section will include studies on differentiated cells before continuing to consider the growing body of literature on progenitor differentiation.

WHOLE BODY VIBRATION - LMHFV *IN VIVO*

In the treatment of bone breakages, there is a need to ensure that appropriate mechanical cues are provided to the tissue in order that it is properly maintained and able to regenerate. Fixation devices, both internal and external, may be used to maintain the position of the broken bones in order to facilitate healing. Such devices can reduce the need to avoid weight-bearing on the limb, preventing disuse which is detrimental to the bone tissue. There are also defects that will not heal with fixation alone, leading to non-union

fractures. Where standard treatments have proved ineffective in repairing the bone tissue, there is a need to find alternative therapies for such patients. In addition, people with osteoporosis are at high risk of fracture and the best method of fracture prevention in this group is to maintain bone mass.

These clinical problems have led to the investigation of methods of mechanical stimulation to improve bone mass and healing, including LMHFV, applied by having the subject stand on a vibrating platform^[39-41]. The acceleration used during these experiments is usually very low (less than the acceleration due to gravity) and the magnitude is typically less than 1 mm. The frequency varies between studies, commonly ranging from 10 to 150 Hz. In addition to different inputs, a variety of different outcomes have been measured. These include bone mineral density (BMD), trabecular width or trabecular spacing and bone formation rate (BFR), but also include measures of balance^[42], likelihood of falls^[43] and jump height^[44]. In addition, other groups have considered the effects on MSC populations, such as number, location and differentiation capability^[1,45].

There are many *in vivo* studies which have looked at the amount and quality of bone after LMHFV stimulation. Large and small animal models have been used, as well as clinical human studies. In such clinical studies, LMHFV is often referred to as "whole body vibration"^[43,46-49]. Such studies have covered healthy patients or those with compromised skeletal systems, in particular post-menopausal women. The efficacy in treating other conditions, such as recovery after stroke^[50], improving the quality of life for disabled children (see Matute-Ilorente *et al.*^[51] for a review on this topic) or limb function in patients with chronic obstructive pulmonary disease^[52] have also attracted interest. Some studies have also included the ability of LMHFV to improve performance and training in athletes^[53] and cognitive performance in adults with or without attention deficit hyperactivity disorder^[47]. Studies have also used microvibration (20 Hz rocking platform) to improve the implantation rates of embryos undergoing IVF treatment^[54].

In the case of *in vivo* murine studies, animals are usually confined in a box or cage which can be vibrated in order to apply the LMHFV stimulation^[1,55-59]. It is worth noting that in such experiments the animals are able to move about freely during the stimulation period. As human participants are usually asked to stand still on a vibrating platform, this may explain some differences in results between the two species. Compliance in animal trials is assured as their whole environment is often vibrated, but is often low with human patients and may affect the potency of the treatment. The normal movement of the animals during the stimulation, such as running, resting or standing on two legs, will affect the transmissibility of the vibrations through the body, further altering the response to loading. The breadth of

studies reported in the literature cover different vibration conditions, with differing frequencies and accelerations (often provided as a multiple of the acceleration due to gravity, g). Ranges include 0.3-1.5 g and up to 90 Hz, applied over different timescales, in mice ranging from juvenile to old. With murine studies, researchers often consider several sites of interest (several bones for example) due to the ease of analysis after sacrifice. mRNA levels of markers of osteogenic activity are often measured, as well as the density of bone in different regions.

In young healthy patients, a study by Torvinen *et al.*^[44] noted an increase in jump height for patients after 8 mo of LMHFV treatment [25-40 Hz (2-8 g), 4 min/d, 3-5 d/wk]. This was not accompanied by any changes to bone mass, structure or turnover however. In studies of post-menopausal (PM) women, reported results include small increases in bone mineral density with high compliance (0.2 g , 30 Hz, up to 20 min per day, every day for one year)^[40], slight increase in BMD and no change in bone markers (0.2 g , 30 Hz, 2/d for one year)^[39] or improvements in femoral neck BMD and balance of the participants (12.6 Hz, 3 cm amplitude, 6 min x 1 min bouts, 3 sessions per week for 8 wk)^[42]. In another study combining exercise and LMHFV, a reduction in the number of falls in PM women was noted^[43]. The study included 15 min of LMHFV during a 60 min exercise program and also found no significant differences in the BMD of the spine or hip in the subjects. Such studies suggest that the LMHFV may be having effects on other parts of the musculoskeletal system to improve a variety of measured outcomes. LMHFV has also been shown to cause a small improvement in muscle power in PM women in a short term study, despite low compliance^[60]. Such studies vary in terms of length of treatment, outcomes measured and conditions applied however, creating many difficulties in analysing the usefulness of LMHFV. These differences are often compounded by low compliance and small study size, making it difficult to draw conclusions about the efficiency of LMHFV on the MSK system.

DISUSE AND DISABILITY

Vibration has been shown to be effective in the prevention of bone loss due to bed rest. Healthy students were subjected to 56 d of bed rest with or without treatment of vibration combined with resistive exercise^[46]. Vibration treatment was found to prevent the changes in muscles size and function, as well as bone volume, compared to the start of the study. Bone mineral content was also reduced in the control subjects but not those treated.

Muir *et al.*^[61] studied the effects of 30 Hz LMHFV (10 min per day, 0.3 and 0.5 g) during periods of bed rest and found that subjects retained muscle flexion strength but not extension strength. Subjects were also found to have better postural stability compared to

controls. Miokovic *et al.*^[62] looked at vibration combined with resistive exercise over 60 d bed rest, finding slightly improved pain scores in the vibrated compared to exercise along groups but no other significant differences. Holguin *et al.*^[63] found that LMHFV (30 Hz, 10 min per day) was able to reduce swelling in the intervertebral disc of human volunteers due to 90 d of bed rest, as well as reducing the reported incidence of back pain by 46%. Other work by the authors has shown that LMHFV (90 Hz, 0.2 g , 15 min/d for 4 wk) can preserve spinal disc mechanics during periods of unloading^[64]. This work was carried out using an animal model however, other examples of which are discussed later in this review.

From the current body of clinical data, LMHFV shows promise in a variety of disease states to improve tissue structure or quality of life. There are fewer studies showing beneficial effects of LMHFV in healthy patients, suggesting that LMHFV may be not be suitable for improving already healthy tissue.

TRANSMISSIBILITY

An important factor in the use of whole body vibration as LMHFV is the transmissibility of the vibrations through the rest of the skeleton. Work in human subjects by Rubin *et al.*^[65] studied the transmissibility of LMHFV through the spine and hip (15-35 Hz, 36 N). They found that for frequencies lower than 20 Hz, there was low transmission of the forces through the body. However, resonances of the vibrations occurred at higher frequencies, which may help explain why higher frequencies appear to be more effective. Kiiski *et al.*^[66] also investigated transmissibility of LMHFV, ranging from 0.05-3 mm amplitude and 10-90 Hz. They found amplification of the peak amplitude at low frequencies at the ankle, knee, hip and spine. At the spine, this occurred only for 10 Hz acceleration, rising to include 40 Hz by the ankle. Above 40 Hz, transmissibility was reduced 10 to 1000-fold. All subjects reported discomfort for vibration between 20 and 25 Hz for displacements larger than 0.5 mm (peak acceleration of 0.8-7.5 g), with one suffering numbness in the feet at 40 Hz (3 mm amplitude, 19 g). These observations suggest that high acceleration vibrations may not be suitable for LMHFV therapy as patients may be less likely to comply if the treatment was uncomfortable. The effects of these high acceleration conditions over the longer term are not well studied and it is not known whether this discomfort will translate to negative effects on the MSK system. The trial had a very small number of participants however and the use of external accelerometers may have affected the results. A recent review of the literature concerning osteoporosis treatments^[67] included a section on LMHFV, recommending parameters of 0.3 g , 25-45 Hz, as most positive studies fall within this range of frequencies stated, and upright posture. There were also several recommendations regarding contraindications, including cancer, severe diabetes and

recent surgery or implantation. The authors suggest that lower frequencies may be unsuitable as they can cause vibration in the internal organs and notes that accelerations higher than 1g have been observed to cause side effects such as back pain.

One study in disabled children used short bouts of LMHFV treatment (0.3g, 90 Hz, 10 min/d) 5 d per week over 6 mo and found increases in BMD in tibial and spinal regions compared to a placebo device^[68]. There were however no observed changes in diaphyseal bone or muscle parameters. The study noted problems with compliance and stance of the children during the vibration and speculated that variation in posture of the children during vibration therapy may have been one factor in the relatively minor benefits seen. This suggests that transmissibility is an important and unresolved issue for the successful application of LMHFV for therapeutic use.

ANIMAL MODELS AND LMHFV

Much as there have been a range of conditions tested in human trials of LMHFV, there are a broad spread of *in vivo* animal studies. These cover the use of large animal models in sheep to small animal models in rats and mice. Some studies use healthy animals while others have included ovariectomised animals to emulate post-menopausal conditions. Outcome measures and study lengths also vary greatly and this next section provides an overview of the animal models used so far with LMHFV studies.

In a large animal model of LMHFV, the application of vibration to the hind legs of sheep (30 Hz, 0.3g, 20 min/d) 5 d a week for one year showed improvements in the bone structure^[69]. Bone mineral content and trabecular number were increased, as well as the longitudinal stiffness and strength of the tissue. The trabecular spacing was seen to decrease, demonstrating bone adaptation and strengthening. Following on from this work, Judex *et al.*^[70] looked at the same vibration conditions and modelled the trabecular stiffness in different directions from the femoral condyle. The models predicted increases in the stiffness in longitudinal, anterior-posterior and medial-lateral directions through the tissue and more uniform distribution of off-axis loading. They also noted that the bone volume and connectedness of the tissue were increased in the vibrated group, demonstrating adaptations requiring bone remodelling.

OSTEOPOROSIS MODELS AND AGING MICE

As LMHFV offers a simple, non-invasive treatment with the potential to improve bone mass and structure, there many studies investigating its use for the treatment of osteoporosis. Therefore there are a large number of animal studies attempting to clarify the

possible benefits of vibration by using Ovariectomised (OVX) or aged rodents.

OVX rats or mice are a commonly used animal model of osteoporosis, where the animals develop osteoporosis-like symptoms (such as reduced BMD and decrease in trabecular number) in the months after ovariectomy^[71]. Work by Flieger *et al.*^[72] followed OVX rats for 5 or 12 wk post-surgery, some of which were treated with LMHFV 5 d per week (50 Hz, 2g, 30 min/d). Significant increases in BMD were found in the femur and tibia (vibrated compared to non-vibrated), which gave a non-significant increase in the fracture load of the femur. The strength of the femur, however, was lower for vibrated animals than for any of the SHAM groups, although there was a non-significant increase for OVX combined with vibration compared to OVX only. Oxlund *et al.*^[73] found that vibration was able to prevent the loss of bending and compressive strength seen in OVX rats. Vibration (0.5g 17 Hz, 1.5g 30 Hz, 3.0g 45 Hz) given for 30 min per day over 90 d prevented endocortical resorption and increased bone formation. Although an increase in BFR was also seen in the OVX only animals, the increase was greatest for the 45 Hz vibration condition.

A later study also demonstrated the prevention of the detrimental effects of ovariectomy by LMHFV^[58]. 3-mo-old rats underwent ovariectomy (OVX) or a sham surgical procedure (SHAM), after which they were left untreated for 3 mo such that the OVX group developed osteoporosis. At this time, half of the animals from the OVX and SHAM treatment groups received LMHFV therapy at 90 Hz (2 × 15 min/d, 7 d/wk for 35 d). Yield load and Young's modulus of the fourth lumbar vertebra were restored to the level of SHAM animals. These changes were accompanied by increases in density (particularly for lumbar trabecular bone). Increases were also found in trabecular bone area, trabecular number and width and both the percentage of cortical bone and BMD. The vibration stimulus was found to be anabolic regardless of the oestrogen levels in the animals.

LMHFV has also been tested to try and reduce the effects of secondary osteoporosis caused by glucocorticoid treatment^[74]. Three-month-old mice were placed into three groups-control, glucocorticoid treatment and glucocorticoid treatment with LMHFV. Five days per week for 9 wk animals were given saline (control group) or methylprednisolone (glucocorticoid groups) injections. Vibrations were applied at 60 Hz during the same period (1g, 30 min per day, 5 d per week for 9 wk). Glucocorticoids alone reduced weight gain, tibial bone mineral content (BMC) and trabecular number and increased trabecular spacing compared to controls. The animals given vibration therapy showed no difference in BMC compared to controls but higher trabecular number and lower spacing than the glucocorticoid only group. This suggests that LMHFV may be a suitable therapy for limiting drug induced

changes in bone quality, although further studies on this topic are necessary.

A longer term study by Wenger *et al.*^[59] in elderly mice (18-mo-old) found no change in the bone volume or strength but increased mineralisation in vibrated animals (0.5 and 1.5g, 32 Hz, 30 min/d for 12 wk). Mineralising surface was calculated histologically and the research examined the femur, radius and lumbar vertebrae of the animals. No changes due to vibration were seen in the lumbar spine, however in the femur there was an increase in high density bone. Vibration also reduced the number of pyridinoline crosslinks at both accelerations, suggesting a reduction in the breakdown of collagen. High density bone volume was increased at 0.5g, with an increase in osteoclast numbers at the higher acceleration. Both vibration conditions showed significant increases in mineralisation surface compared to controls. There was however no significant difference in failure load or stiffness of the radius between any vibration or control condition. This demonstrates that not only are the correct conditions necessary to have an effect on bone turnover, but slight changes to a regimen may be enough to alter the outcome.

Other studies have considered the site specificity of the responses to LMHFV^[75]. They used 0.7g LMHFV at a variety of different frequencies applied for 4 wk (10 min per day, 5 d per week) and studied several skeletal sites in mature male mice. They found that the low frequency used (8 Hz) increased resorption and reduced mineral apposition, weakening the skeleton. 90 Hz vibrations increased trabecular reorganisation and mineral apposition without affecting resorption. These effects occurred for different magnitudes in the vertebrae, tibia and femur, demonstrating the variable effects of LMHFV through the MSK system. The results also demonstrate that, under the wrong conditions, LMHFV may have negative effects on bone tissue.

Judex *et al.*^[76] studied vibration (45 Hz, 0.3g) for 10 min per day (5 d/wk, 21 d) compared to hindlimb unloading in a murine model. They found increased bone formation and mineralisation in the trabecular and periosteal regions of the vibrated tibia. After 4 d in the disuse condition, there were lower levels of mRNA expression for several markers of osteogenesis (col-I, osteonectin, osterix and MMP-2) but no changes were seen for the vibrated group. At 21 d, significant increases were seen for nitric oxide synthase, MMP-2 and RANKL in the vibrated group. The work suggests that short periods of vibration may be able to prevent the bone loss and reduction in osteogenesis which occurs during disuse. As has been seen in human studies, the best results in animal models are obtained in subjects with a lower than normal BMD. Animal models often show better results than human studies, which may be due to guaranteed compliance in the animals and lower rates in human cohorts. There are still many unanswered questions, particularly regarding the efficacy of higher acceleration vibration stimuli.

OSTEOGENESIS IMPERFECTA

Osteogenesis imperfecta (OI), in which the structural protein type 1 collagen is mutated, is another condition which may benefit from LMHFV intervention to improve bone mass and structure. The "brittle bones" which characterise the condition can cause limited to severe changes in stature, skeletal deformities and moderate to severe bone fragility^[77]. The condition is difficult to treat and while bisphosphonate drugs can be used to inhibit resorption, these affect the normal bone remodelling process and can prevent maintenance of healthy tissue. In a young mouse genetic model of OI, LMHFV (0.3g, 45 Hz) was applied 5 d a week for 5 wk, starting when the mice were 3-wk-old^[57]. They found that cortical bone thickness and area was increased for both OI and wild type mice in the tibia and femur, whereas trabecular bone volume was increased for the vibrated mice in the tibia. These changes were accompanied with an increase in femoral stiffness and yield load. They noted that there were only minor differences in bone apposition between the vibrated and sham groups, suggesting that the vibration reduced bone resorption.

FRACTURE HEALING

Several groups have studied the effects of LMHFV on the healing of fractures in murine models. Leung *et al.*^[78] used LMHFV at 35 Hz (0.3g, 20 min per day, 5 d per week) beginning 5 d after the creation of femoral fractures in 3 mo old rats. They found that a larger callus was formed by 2 wk of treatment and increased remodelling had occurred after 4 wk in the vibrated animals compared to those in a sham treatment group. The mechanical strength of the femur was also higher in the LMHFV group, suggesting that the treatment was able to enhance the fracture healing by altering accelerating callus formation and turnover.

Later work using the same vibration conditions studied the effects of LMHFV on fracture healing in rats treated with ibandronate (a bisphosphonate) to suppress bone remodelling^[79]. In this study, 6 mo old rats underwent ovariectomy and were left for 3 mo to develop osteoporosis. Rats then underwent surgery to create closed femoral fractures before receiving ibandronate treatment (with or without LMHFV), LMHFV alone or sham treatment. The vibration only group showed improved speed of callus reduction, increased mineral apposition and increased serum markers of bone turnover compared to all other treatment groups. This remodelling was disrupted by the bisphosphonate treatment, but the application of LMHFV during bisphosphonate treatment was able to reduce the delay in bone remodelling caused by the drug. This provides further evidence that LMHFV may be useful in mitigating the effects of bisphosphonate treatment by reducing the negative effects on bone remodelling.

In an OVX rat model, Shi *et al.*^[80] used LMHFV to

augment fracture healing in OVX rats compared to SHAM control animals. Animals were treated with LMHFV (35 Hz, 0.3g, 20 min/d) for 5 d per week up to 8 wk. In OVX animals, callus formation and mineralisation, as well as remodelling activity and energy to failure were reduced compared to the SHAM animals. LMHFV was found to improve fracture healing, with OVX + vib showing improved fracture healing compared to SHAM + vib. This suggests that the mechanical stimulus is more effective in animals with reduced oestrogen levels, but is anabolic regardless, similar to the findings by Sehmisch *et al.*^[58]. The effects of LMHFV on fracture healing in osteoporotic and normal bone have also been investigated in terms of angiogenesis^[81]. Vibration treatment improved blood flow and angiogenesis for both sham and OVX animals, and overall improved fracture healing.

Work at a higher vibration frequency (90 Hz, 4g, 15 min twice per day, 30 d) demonstrated some beneficial effects of LMHFV on fracture healing in OVX rats^[82]. Three months old rats underwent ovariectomy and showed severe osteopenia 10 wk post-surgery. At this point, both OVX and untreated rats underwent bilateral metaphyseal osteotomy of the tibia, before beginning LMHFV or sham treatment 5 d later. After 30 d of LMHFV or sham treatment, the group found that LMHFV had improved bridging of the fracture in the OVX but not the intact rats, as well as improving the densities of cortical bone and callus. They found a reduction in the stiffness and yield load of the tibia after vibration and suggest that this may be due to the high acceleration used for the LMHFV treatment, which is similar to the result seen by Flieger *et al.*^[72]. These studies suggest that it may be possible to use LMHFV to improve fracture healing, whilst reinforcing the idea that the conditions must be carefully tailored in order to prevent detrimental effects of LMHFV.

TENDON AND MUSCLE

Work investigating the effects of LMHFV on tendon structure has shown an increase in cross-sectional area, stiffness and strain to ultimate load. Sandhu *et al.*^[83] used a rat model and 5 wk of LMHFV (0.3g, 30 Hz, 5 d/wk) to study the flexor carpi ulnaris tendon. Their results suggest that LMHFV may also affect tendon tissue within the MSK system which may be useful for tendon healing if damage has occurred to a joint.

LMHFV has also been shown to affect muscle tissue. In skeletally immature mice, LMHFV was found to affect muscle structure in the soleus muscle^[56]. After 6 wk of stimulation for 15 min per day (0.3g, 45 Hz), the number of arterioles, venules and capillaries within the muscle fibre were reduced. This was significant in the end regions of the muscle. Although a reduction in vasculature to the muscle tissue may appear to be an undesirable adaptation to LMHFV, a study by Xie *et al.*^[84] under the same conditions showed increases in

the moment of inertia and area of the soleus muscle. The same study also found increases in trabecular and periosteal bone volume, bone marrow and cortical bone area but no change in osteoclast activity. These studies provide early evidence that LMHFV is capable of effecting different parts of the MSK system and may be able to aid regeneration in complex injuries to multiple tissues.

The variety of animal studies considered above demonstrate the range of interest in LMHFV as a therapy to affect the musculoskeletal system. These studies have been conducted in small, quadruped animals and as such may not be directly applicable to human conditions. Many of the studies also use 0.3g acceleration or 45 Hz, with results suggesting that these conditions in particular may provide beneficial effects. This matches with the recommendations of Katsuri for the use of LMHFV to treat osteoporosis in humans^[67]. The research does suggest that the technique is able to affect many different cell types to alter the properties of a variety of tissues including bone, tendon and muscle. In the case of bone, evidence suggests that LMHFV may be able to improve poor bone structure or aid in healing. If the conditions used in these studies are translated directly into human trials, such as in the work by Luu *et al.*^[85] discussed in the next section, it may help develop the understanding of LMHFV as a therapy.

LMHFV AND CELLS *IN VIVO*

The effects of LMHFV on cells *in vivo* have also been investigated in a range of studies, often in combination with measures of bone properties. Over 5 wk of vibration, Christiansen and Silva^[1] found several site specific responses to loading for a range of stimulation conditions. Adult mice (7-mo-old) were vibrated with accelerations of 0.1, 0.3 and 1g at 45 Hz (15 min/d, 7 d/wk) for 5 wk before sacrifice. Bone marrow was extracted and tibiae, femurs and L5 vertebrae scanned using micro CT. The 0.3g vibration condition showed no differences in bone volume over total volume compared to controls at any site, but was significantly lower than other vibration conditions in the L5 vertebra and proximal tibial metaphysis. Researchers noted that the distance from the vibration platform did not dictate the efficacy, nor was the response seen dose dependant. Although there was a decrease in the presence of progenitor cells, no increase in bone formation was seen. The ALP activity of adherent BMSCs, extracted from the bone marrow of these animals and cultured for 2 wk was not significantly different between any groups, however alizarin red staining showed a reduction in mineralisation for 0.1g (compared to 1.0g) and 0.3g (compared to control and 1.0g samples).

Work in mice has demonstrated that LMHFV may be used to inhibit adipogenesis, with 7 wk old mice undergoing a 15 wk treatment protocol^[86]. They applied LMHFV at 90 Hz (0.2g, 15 min per day, 5 d

per week) and found lower volumes of fat (normalised to body mass) for the vibrated compared to sham control groups. Their fat also contained lower levels of triglycerides, indicating a lower risk for the development of diabetes. The work also looked at the differentiation of adipogenic precursors in a separate experiment. Eight weeks old mice were irradiated with 15 kGy of gamma irradiation to kill the bone marrow before receiving an injection of MSCs from donor mice. The donor mice express green fluorescent protein in all their tissues, allowing the donor cells to be monitored *in vivo*. Mice were allowed one week to recover before receiving LMHFV or sham treatment for 6 wk. The group found that the vibrated mice had a lower ratio of GFP expressing adipocytes to MSCs compared to controls, as well as reduced weights of the epididymal fat pad, suggesting the MSCs were less disposed to adipogenic differentiation.

Work by Luu *et al.*^[85] demonstrated the effects of LMHFV on the osteogenic and adipogenic differentiation of MSCs in a diet-induced obesity mouse model. They also applied LMHFV at 90 Hz (0.2g, 15 min per day, 5 d/wk) to 7-wk-old mice, in this case for 12 wk and compared this to a sham control with no vibration. Twelve mice received a high fat diet only during the vibration period (prevention of dietary obesity), while another 8 started the diet at 4 wk of age (reversal of obesity). In the prevention group, mice treated with LMHFV for 6 wk showed increased MSC numbers compared to controls, upregulated transcription of Runx2 and downregulation of peroxisome proliferator-activated receptor γ (PPAR γ), suggesting a more osteogenic lineage with reduced adipogenic behaviour. After 12 wk of treatment this translated to increased bone volume fraction and reduced weight gain compared to the controls. However, in the mice starting the high fat diet at 4 wk of age, there were no differences in adiposity or bone volume between control and vibrated animals, suggesting LMHFV is not able to reduce existing obesity.

Interestingly, the group translated this work into a human trial in young women with low BMD, reported in the same study^[85]. After 12 mo treatment they found an increase in BMD in the spine and no significant change in visceral fat area compared to the start of the study in LMHFV treated patients. In the control group, there was no change in BMD and an increase in fat, suggesting that the technique is also able to increase osteogenesis and reduce adipogenesis in humans. Both this work and that by Rubin *et al.*^[86] suggest that LMHFV is able to inhibit adipogenesis in MSCs as well as increasing osteogenesis. This reduction in adipogenesis may be a beneficial side effects of LMHFV treatment, but the research also suggests it will not be suitable as a method to reduce pre-existing obesity.

In a hindlimb unloading murine model, Ozcivici *et al.*^[45] compared 15 min of weight bearing each day (HU animals) to the same period of vibration (HU + vib, 0.2g, 90 Hz). This was carried out for 3 wk, at which point

animals were sacrificed or underwent a further 3 wk period of reambulation, continuing with the same sham (RA) or vibration (RA + vib) treatments. For animals sacrificed prior to reambulation, the study found no difference between sham and HU + vib conditions for trabecular bone fraction. However, the animals which had received the vibration stimulus showed several changes at a cellular level. The osteogenic MSC and osteoblast populations were found to be greater and HU + vib animals also showed a smaller osteoclast surface. Reambulation magnified these differences, with a greater increase in bone volume, MSC population, osteoblast surfaces, BFR and a higher ratio of bone-lining osteoblasts to marrow adipocytes (RA + vib compared to RA). They conclude that, although vibration does not prevent the bone loss due to disuse, there are improvements in cellular function which may enhance long term recovery. The work suggests that the overall effects on bone fraction may be due to an effect of LMHFV on MSCs within the bone marrow.

A recent study investigated the use of LMHFV to accelerate wound healing in a diabetic mouse model^[55]. 30 min of LMHFV (0.4g, 45 Hz) was applied for 7 or 14 d after wounding of the skin and compared to sham loading controls. There was an increase in angiogenesis and granulation tissue formation seen at day 7 in vibrated animals. By day 14, this had led to accelerated wound closure and re-epithelialisation. The study monitored levels of growth factors and cytokines associated with promoting healing, with increases in the vibrated group for IGF-1, VEGF, monocytes chemotactic protein-1. Additionally, while there was no effect of vibration on CD11b⁺ cells in the wounds, CD11b⁺ cells displayed a less inflammatory phenotype.

In a model of granulosa cell tumours in mice, LMHFV has been shown to help mitigate the associated osteopenia^[2]. LMHFV (0.3g, 90 Hz, 15 min bouts) was applied 5 d per week over the course of a year and found no significant changes in survival rates of the animals. They found increases in the bone volume in vibrated mice, as well as reductions in tumour incidence and the number of organ systems involved. The research also found that the number of MSCs in the bone marrow were significantly lower in vibrated mice and those lacking pathology, suggesting that they may play a role in the disease progression.

All of these studies suggest that LMHFV is having effects on a variety of cell types *in vivo*, particularly the proliferation and differentiation of MSCs. Possible benefits include increasing osteogenesis and reduction of adipogenesis. The studies suggest that higher frequency LMHFV (90 Hz) at a lower acceleration (0.2g) may be able to stimulate progenitor cells within the bone marrow. However, more studies at 0.3g covering the effects on MSCs *in vivo* will help to clarify the effects.

LMHFV AND *IN VITRO* CELL STUDIES

In order to better understand the mechanisms of

responses to LMHFV and to identify which cells types are involved, many *in vitro* studies have been undertaken. For bone, there are several possible responsive cell types including osteoblasts, osteoclasts or their progenitors. As a variety of other effects have been seen *in vivo*, such as those on muscle and tendon, there may be further cell types which are responsive to LMHFV. *In vivo* stimulation of tissue forming cells also has applications in the field of tissue engineering where mechanical forces have been well demonstrated to modulate tissue formation by cells, but it is difficult to design bioreactors and stimulation regimens that could be scaled up for clinical and commercial use. LMHFV stimulation may be an appropriate method for the application of mechanical forces to variety of scaffold types and complex geometries, as well as allowing the stimulation of multiple samples within standard culture apparatus.

Experiments conducted *in vitro* include the use of different cell types as well as vibration parameters (frequency, amplitude, duration, number of applications, timeframe). One cell type often used to study osteogenic differentiation with LMHFV is the MC3T3-E1 cell line, a murine osteoblast precursor line. A variety of different outcomes have also been measured, including mRNA expression of different molecules, matrix expression and deposition and prostaglandin E₂ (PGE₂) release.

Dumas *et al.*^[87] looked at the effects of LMHFV on MC3T3-E1 cells and also the ability of the ECM they deposited to affect MSC attachment and differentiation. The cells were stimulated with 15-40 microstrain (measured as deformation of the cell culture dish) at 400 Hz (20 min per day for 1, 3 or 7 d) and demonstrated increased nitric oxide (NO) secretion, upregulated mRNA for fibronectin, osteopontin, bone sialoprotein and collagen I, with no changes to cell number or viability. The matrix produced by these cells was then decellularised and used to culture C3H10T1/2 cells, a murine MSC cell line. The cells on these matrices were cultured for 7 d with or without LMHFV treatment and exhibited increases in cell attachment, focal adhesions and osteogenic mRNA on the matrices from vibrated cells. The cells also reduced expression of adipogenic mRNA, suggesting the matrix and vibration treatment may promote osteogenesis of recruited MSCs as well as inhibiting adipogenesis. This is in agreement with the *in vivo* work discussed earlier within this review^[86,88], providing further evidence for the effects of LMHFV on adipogenesis in MSCs.

Rat BMSCs have also been seeded into scaffolds derived from human bone and subjected to LMHFV (0.3g, 40 Hz, $\pm$ 50 μ m) for 30 min every 12 h, up to 2 d^[89]. Cells were found to attach to the scaffolds and produced higher levels of ALP than those cultured in 2D. LMHFV decreased the cell proliferation rate (measured on days 7 and 10), but increased expression of Cbfa1, ALP, col I and OCN. They also studied extracellular signal-regulated kinase 1 and 2 (ERK1/2) involvement and found that ALP activity was

reduced when the ERK1/2 pathway was inhibited.

Short bouts of LMHFV (5 min, 5, 30, 60 or 100 Hz) of varying amplitude were shown to promote the release of NO and PGE₂ in MC3T3-E1 cells^[90], molecules involved in the *in vivo* response of bone to mechanical loading. The study found no changes in cell shape, alignment or detachment with any of the treatments. When measured 30 min post vibration, there were correlations with increasing maximum acceleration for NO (increasing) and PGE₂ (decreasing) secretion. mRNA for Cyclooxygenase 2 (COX-2), a signalling molecule downstream of PGE₂, was also increased 2 fold by 100 Hz vibration compared to 5 and 30 Hz and 1.5 fold vs 60 Hz. It may be important to note that the vibration in this case was applied along the plane of cell attachment, whereas in many studies the LMHFV are applied perpendicular to this. It is not yet known whether this may produce differential effects as there have been no studies directly comparing the two planes of vibration.

After one hour treatment of MLO-Y4 osteocyte-like cells with LMHFV (0.3g, 30, 60 or 90 Hz), Lau *et al.*^[91] found increases in the amount of mRNA for COX-2, particularly at a 90 Hz vibration condition (344% increase). mRNA levels of receptor activator of nuclear factor kappa-B ligand (RANKL), an osteoclastogenic factor, as well as the soluble receptor protein RANKL and PGE₂ secretion, were found to be reduced in the vibrated cells. Conditioned media from the vibrated cells was also found to inhibit osteoclast formation (number of multi-nucleated cells present) and resorption. This suggests that LMHFV may be able to stimulate osteocytes to inhibit resorption in response to the LMHFV. Li *et al.*^[92] investigated the effects of low intensity pulsed ultrasound (LIPUS) on the interaction between osteocytic and pre-osteoblast like cells. They used 1.5 MHz stimulation on MLO-Y4 murine osteocyte-like cells (3 mm from the LIPUS source) and placed the conditioned media onto MC3T3-E1 pre-osteoblastic cells. Twenty four hours after vibration they saw increased NO and PGE₂ secretion in the MLO-Y4 cells. Conditioned media (collected one hour post vibration) inhibited proliferation in the MC3T3-E1 cells, also causing an increase in the ALP activity of these cells, suggesting osteoblastic differentiation.

Work looking directly at osteoclast precursors found a possible inhibition of osteoclast formation^[93]. They used murine osteoclast-like cells RAW264.7 and applied LMHFV (4 Hz, 20 μ m displacement) for one hour a day over 3 d and examined the mRNA and protein levels for DC-STAMP (dendritic cell-specific transmembrane protein) and the P2X7 receptor P2X7R, both membrane bound markers of osteoclast fusion. They saw inhibition of mRNA and protein production for DC-STAMP, which suggests the inhibition of osteoclast fusion had occurred. In a model of a BRU using scales taken from goldfish and placed in culture, LMHFV of varying acceleration (0.5, 1, 2, 4, 6g) for 5 or 20 min per day showed changes in osteoblast and osteoclast activity after 6 and 24 h^[94]. The ALP activity in scales was found to

increase with increasing acceleration, accompanied by a decrease in osteoclast activity (measured by tartrate-resistant acid phosphatase activity). These results were evident at 24 h, with the largest decrease in osteoclast activity for 2g. However, although the goldfish scale contains both osteoblasts and osteoclasts, it has a very different macrostructure to that of bones making it difficult to compare with other model systems.

Other studies have compared the effects of LMHFV with high magnitude strain (HMS) on the adipogenic differentiation of MSCs. Sen *et al.*^[95] used C3H10T1/2 cells and 90 Hz vibration (< 10 microstrain) compared to low frequency HMS (0.17 Hz, 20000 microstrain). They compared pauses within the loading regimen to longer periods of vibration and followed adiponectin expression as a measure of adipogenesis. They found that HMS over 2 or 6 h prevented adipogenesis in the cells, as well as two 20 min bouts separated by at least one hour rest period. The LMHFV was only able to suppress adipogenesis with the two 20 min bouts separated by more than one hour, with a 3 h pause proving better than one or two hours. The inclusion of indomethacin to induce adipogenesis inhibited the effects of the LMHFV but not the HMS treatment. The addition of BMP-2 promoted an osteogenic response with the LMHFV treatment.

A further study was carried out investigating the effects of LMHFV (termed sub sonic vibrations) on 3T3-L1 pre-adipocytes, an embryonic derived cell line^[96]. This study used horizontal vibration looking at cell proliferation (3 d, 10, 20, 30 and 40 Hz) and adipogenic maturation (6 d, 10, 20, 30 and 45 Hz). They found that 20 and 30 Hz LMHFV decreased cell proliferation and increased adipogenic gene expression. Increased triglyceride levels within cells were seen for the 10, 20 and 30 Hz vibration conditions. Although the work discussed previously^[86-88] showed a reduction in adipogenic gene expression in MSCs, this evidence suggests that LMHFV may increase adipogenesis in cells that are already of the adipose lineage, which would not be a desirable effect *in vivo*. The *in vivo* data on obesity and LMHFV, which demonstrated a lack of reduction in already obese animals^[85,86], seems to confirm that LMHFV cause more activity in cells of the adipose lineage, but may be able to mitigate their commitment to this lineage initially.

Interestingly and contradicting the theory that vibration promotes osteogenesis; MSCs from rat bone marrow were found to have lower matrix mineralisation and mRNA for osterix after 6 d period of vibration^[97] compared to controls. The cells were subjected to vibration at 0.3g and 60 Hz for one hour per day (6 d with one rest day). There were no changes to cell proliferation, ALP activity or mRNA levels for a variety of osteogenic genes (ALP, col-I, OPN, BSP, RUNX-2, OCN). The group hypothesise that, rather than having a direct effect on MSC differentiation, LMHFV may have anabolic effects on bone by causing osteocyte signalling, which in turn affects MSC differentiation.

However, many of the *in vivo* studies which have looked at differentiation of MSCs following LMHFV have found increased osteogenic behaviour. This may be due to the differences in cellular environment and vibration transmission between 2D cultures and cells in the 3D *in vivo* environment.

C2C12 murine myoblasts were found to undergo changes following short periods of LMHFV stimulation (5, 8 or 10 Hz, 0.4 mm amplitude, 10 min/d)^[98]. After 3 d, expression of collagen I and decorin were increased for the 8 and 10 Hz vibration conditions. MyoD and myogenin expression was seen to increase in a time- and dose-dependent manner. There were no changes observed in the cell cycle, but 8 and 10 Hz vibration increase myotube number and length (6 and 9 d of vibration). Vibration also increased the fusion of myocytes in a dose dependant manner. This suggests that the cells are promoting vascularisation, which may aid tissue regeneration *in vivo*.

Much of the *in vitro* work discussed above shows beneficial effects on osteogenic cells, which may lead to the beneficial effects seen in some animal models *in vivo*. The lack of interaction between different cell types however means that it is difficult to know whether the effects seen *in vitro* can help direct therapies *in vivo*. Transmission of LMHFV through muscle, fat and bone may alter the effects on MSCs and differentiated cells, leading to reductions in the efficacy of treatment compared to cell signalling responses and differentiation markers seen in cultured cells.

HUMAN CELLS *IN VITRO*

Reported effects of vibration on human cells are summarised in Table 1. As well as the large number of studies on animal cells and cell lines, there is a growing body of work using human cells and cell lines to investigate the possible mechanisms of action of LMHFV. SAOS-2 cells, a human osteosarcoma cell line, were subjected to 30 Hz vibrations (11 mm displacement) once per day for 4 d^[99]. The cells displayed decreased proliferation and increasing mRNA levels for ALP, collagens I and III, osteonectin and fibronectin, suggesting more osteogenic behaviour. Further work by the group looked at the osteoblastic differentiation of human adipose derived MSCs^[100]. They applied LMHFV at 30 Hz to cells for 28 d and found evidence of improved matrix calcification at day 21. They also noted strong increased in the expression of collagen I and osteopontin on day 14 in the vibrated samples when cultured in osteogenic medium, which was not maintained at 21 d. Slightly higher total protein levels were found in vibrated samples compared to non at 21 d, but this effect was lost by 28 d. As many *in vivo* studies do not show any benefits of LMHFV in healthy patients, it is possible that the therapy affects disrupted bone balance, but does not provide any further benefit when normal

Table 1 Summary of effects of low magnitude, high frequency vibration on human cells *in vitro*

Prè <i>et al</i> ^[100]	Adipose derived MSCs	30 Hz, 45 min/d, 28 d	Increase in col-I and osteonectin expression in vibrated group on day 14, lost by day 21. Increased mineralisation in vibrated group at 21 d, lost by day 28
Kim <i>et al</i> ^[102]	MSCs (2 donors)	0.3g, 30 Hz for main study. Applied for 10 min/d, 5 d a week for 21 d	Vibration increased ALP activity (days 7, 14 and 21), mRNA (ALP, osteopontin and VEGF) upregulated at day 7. No changes (bone sialoprotein or osteonectin mRNA). In osteogenic media, LMHFV increased the calcium deposition in cultures
Uzer <i>et al</i> ^[103]	Adipose derived MSCs	30 and 100 Hz, 0.15, 1 and 2g. 30 min per day for 3-14 d	Cell number increased over 3 d for all conditions. Mineralisation at 14 d increased for 100 Hz and 30 Hz (2g). Prevented cytoskeletal remodelling to negate the effects
Zhang <i>et al</i> ^[104]	Peridontal ligament stem cells	0.3g (10, 20, 30, 40, 50, 60, 90 and 120, 150 and 180 Hz), 20 min/d to 5 d	LMHFV decreased proliferation, ALP activity highest at 30 Hz. Osteocalcin expression was highest at 40, 50, 60, 90 and 120 Hz. Levels of col-I, RUNX-2 and osterix increased at 40 and 50 Hz
Wolchok <i>et al</i> ^[105]	laryngeal fibroblasts	100 Hz and 3.4g (1 s vibration followed by 2 s pause), 6 h followed by an 18 h rest for 21 d	Enhanced secretion of TGFB-1, fibronectin, collagen, increased construct stiffness. Increased gene expression of range of matrix molecules
Cho <i>et al</i> ^[106]	Umbilical cord stem cells	10, 20, 30 and 40 Hz, continuous for 5 d	Increased mRNA and protein levels (MAP2, NF-L and NeuroD1). Time dependant increases in O4 and ERK (12 h at 40 Hz)
Choi <i>et al</i> ^[107]	Adipose derived MSCs	10, 20, 30 and 40 Hz, continuous for 4 d	30 Hz increased astrocyte, oligodendrocyte and neuronal markers, inhibited adipogenesis. Increasing frequency reduced cell proliferation. Time dependant changes in ERK phosphorylation
Edwards and Reilly ^[101]	hES-MP 002.5 cells	0.3g and 15, 30, 45, 60 Hz, one bout 4 min	Increased ALP activity at 60 Hz 48 h post vibration

LMHFV: Low magnitude, high frequency vibration; VEGF: Vascular endothelial growth factor; ALP: Alkaline phosphatase; ERK: Extracellular regulated protein kinases.

bone formation is achieved. The ability to accelerate the initial healing or rebalance of bone formation still has the potential to be a useful therapy.

Our own research with LMHFV and a mesenchymal progenitor cell line, hES-MP 002.5 (Cellartis) has shown promising effects on osteogenic differentiation in 2D^[101]. We found evidence that LMHFV at 0.3g was able to affect the cell number and osteogenic activity of these cells in 2D culture. Forty-eight hours following a single 45 min bout of vibration, ALP activity was significantly increased for vibration at 60 Hz. This was not seen at lower frequencies tested or 24 h post vibration.

Kim *et al*^[102] investigated the use of LMHFV for osteogenic differentiation of hMSCs from two different donors. They applied vibration for 10 min per day (5 d per week to 21 d) at a variety of frequencies and accelerations (10, 20, 30 and 40 Hz and 0.1-0.6g in 0.1g increments) before choosing 0.3g and 30 Hz for the main experiments. Cell proliferation was affected by vibration in a dose dependant manner, with increases in cell number at 30 and 40 Hz conditions on day 2. This increase was not maintained at 5 d however. ALP activity was increased in vibrated samples on days 7, 14 and 21, with mRNA for ALP, osteopontin and VEGF also upregulated at day 7. There were no changes to bone sialoprotein or osteonectin mRNA at this timepoint. When cells were cultured in osteogenic media, LMHFV increased the calcium deposition in cultures, suggesting the vibration has increased osteogenesis.

With LMHFV *in vitro*, there is the likelihood of shear stress occurring in the culture plate due to the movement of media within wells. Uzer *et al*^[103] used LMHFV to apply shear stress to human adipose derived stem cells for 30 min a day (3-14 d). They looked at several vibration conditions (0.15, 1 and 2g, frequencies

of 30 and 100 Hz) and characterised the resulting shear stress (0.04-5 Pa). Over the first 3 d of culture, cell number increased for all conditions, with the greatest increases seen for the conditions with lowest induced fluid shear. After 14 d, mineralisation was increased for all accelerations at 100 Hz and for the 2g acceleration at 30 Hz. By disrupting cytoskeletal remodelling, they demonstrated that MSC differentiation was not only regulated by shear stress (as occurred in low stress conditions), but is influenced by cytoskeletal remodelling.

Work by Zhang *et al*^[104] on human peridontal ligament cells studied a large range of frequencies (10, 20, 30, 40, 50, 60, 90 and 120, 150 and 180 Hz) at 0.3g acceleration. They applied the vibration stimulus for 20 min per day for up to 5 d. The study found decreased proliferation and a frequency dependant increase in osteogenic markers. ALP activity was highest at 30 Hz, while osteocalcin expression was higher at 40, 50, 60, 90 and 120 Hz. Levels of col-I, RUNX-2 and osterix increased at 40 and 50 Hz.

Other research studying horizontal vibration investigated the effects of paused vibration on human laryngeal fibroblasts^[105]. This study involved vibration at 100 Hz and 3.4g (1 s vibration followed by 2 s pause) for up to 21 d. Vibration was applied for 6 h followed by an 18 h rest and was shown to increase gene expression for matrix and matrix related molecules. These included TIMP1, TIMP3, col1 and col IX, lysyl oxidase, TGFB1, syndecan, laminin, connective tissue growth factor and PDGF. In addition, there was enhanced secretion of TGFB-1, fibronectin, collagen and an increase in construct stiffness for low values of strain.

In one study^[106], LMHFV (termed sub sonic vibration) was applied at a variety of frequencies (10, 20, 30 and 40 Hz) to human umbilical cord MSCs continuously for

5 d. In this case, the group was interested in neuronal differentiation and found increased in both mRNA and protein levels for several factors including MAP2, NF-L and NeuroD1. They also found time dependant increases in O4 and ERK for 12 h of LMHFV at 40 Hz. A second study^[107] assessed the neuronal differentiation of human adipose-derived MSCs, applying LMHFV at the same frequencies over 4 d. RT-PCR was used to investigate both neuronal and adipogenic markers with upregulation at 30 Hz and found that astrocyte, oligodendrocyte, and neuronal markers were significantly increased while inhibiting adipogenesis. Increasing frequency was shown to reduce the cell proliferation. They also noted time dependant changes in ERK phosphorylation, concluding that the LMHFV promoted differentiation to astrocytes and oligodendrocytes through activation of the ERK pathway.

CONCLUSION

The appeal of low magnitude, high frequency vibrations to act as a mechanical stimulus and improve a range of functions within the MSK system has led to an ever growing body of research. The technique is relatively simple to apply, often needs only short periods of stimulation to show some effect and is suitable for those with fragile bones or limited motion. The response varies between different studies, patients and conditions, however, making it problematic to define a predictable set of responses. For healthy subjects, there are often no apparent benefits to the treatment, which suggests that the LMHFV stimulus provides similar mechanical cues to normal daily activities in healthy patients and therefore provide no benefit to bone mass or structure unless there is an underlying condition. There are many studies showing benefits of LMHFV using an acceleration of 0.3g or 45 Hz vibration, suggesting these conditions may be particularly effective for the MSK system. Higher frequency vibration, such as 90 Hz, has also show some efficacy at low accelerations (0.2g). Evidence is building to suggest that accelerations higher than that due to gravity (> 1.0g) may be undesirable, causing some negative effects on bone and mild discomfort in human patients.

In vitro investigation of LMHFV has also produced a wide variety of data, with new research being published at an increasing rate. As with the *in vivo* studies, the range of conditions tested, outcomes measured and goals of the research is very varied, making it difficult to identify common trends. There is increasing evidence that LMHFV has the power to affect the differentiation of stem cells, particularly MSCs. When more of this data is made available, it may be possible to understand how LMHFV might improve the MSK system and aid in the repair of other tissues in the body. Work with primary human cells from multiple donors may provide insights into which patients may be most likely to benefit from

LMHFV treatments when conducted alongside *in vivo* investigations. There is also a need for more human trials based directly on small animal studies, using the same outcome measures where possible, to further our understanding of the applicability of these animal models and their relevance to human treatment with LMHFV. Both types of work may help stratification of the therapy to target patients who are likely benefit from the treatment. In general, the use of LMHFV to improve the condition of the MSK system in patients who are not able to maintain high levels of activity or exercise therapy shows promise, but there is still much work to be done on understanding the mechanisms, side effects and benefits to patients.

of any *Hox* gene expression, but these transcription factors are activated in varying spatial and temporal patterns defining the development of various body regions. In the adult body, *Hox* genes are among others responsible for driving the differentiation of tissue stem cells towards their respective lineages in order to repair and maintain the correct function of tissues and organs. Due to their involvement in the embryonic and adult body, they have been suggested to be useable for improving stem cell differentiations *in vitro* and *in vivo*. In many studies *Hox* genes have been found as driving factors in stem cell differentiation towards adipogenesis, in lineages involved in bone and joint formation, mainly chondrogenesis and osteogenesis, in cardiovascular lineages including endothelial and smooth muscle cell differentiations, and in neurogenesis. As life expectancy is rising, the demand for tissue reconstruction continues to increase. Stem cells have become an increasingly popular choice for creating therapies in regenerative medicine due to their self-renewal and differentiation potential. Especially mesenchymal stem cells are used more and more frequently due to their easy handling and accessibility, combined with a low tumorigenicity and little ethical concerns. This review therefore intends to summarize to date known correlations between natural *Hox* gene expression patterns in body tissues and during the differentiation of various stem cells towards their respective lineages with a major focus on mesenchymal stem cell differentiations. This overview shall help to understand the complex interactions of *Hox* genes and differentiation processes all over the body as well as *in vitro* for further improvement of stem cell treatments in future regenerative medicine approaches.

Abstract

Hox genes are an evolutionary highly conserved gene family. They determine the anterior-posterior body axis in bilateral organisms and influence the developmental fate of cells. Embryonic stem cells are usually devoid

Core tip: *Hox* genes are involved in embryonic development as well as in repair mechanisms in the adult body, thus

regulating cell fate. These genes have also been found to be driving factors in various stem cell differentiations *in vitro* and *in vivo* which makes them interesting tools for future improvements in stem cell therapies. Therefore, this review outlines the involvement of *Hox* genes in various stem cell differentiations with a major emphasis on mesenchymal stem cell differentiations.

Seifert A, Werheid DF, Knapp SM, Tobiasch E. Role of *Hox* genes in stem cell differentiation. *World J Stem Cells* 2015; 7(3): 583-595 Available from: URL: <http://www.wjgnet.com/1948-0210/full/v7/i3/583.htm> DOI: <http://dx.doi.org/10.4252/wjsc.v7.i3.583>

INTRODUCTION

The life expectancy of the overall population has increased in most countries, accompanied by an increase in injuries, diseases, and age related degenerative diseases. Thus, reconstructions of hard and soft tissues are an increasing challenge in regenerative medicine^[1]. Stem cells could help to overcome these restrictions using their self-renewal and differentiation properties, with or without biomaterials or artificial scaffolds^[1-3]. Numerous sources are known from which stem cells can be isolated, often with a varying differentiation potential^[4]. Additionally, the commitment might depend on the body site from which the stem cells were isolated^[4,5]. *In vivo*, stem cell fate is determined according to tissues and thus extracellular but also intracellular factors, among them p53, purinergic receptors, collagens, parathyroid hormone-related proteins, or homeobox (*Hox*) genes^[6-9]. The later are the central players in determining regional specificity in the developing embryo and not astonishingly also in numerous differentiations^[10].

The *Hox* gene family consists of 39 members, which are clustered in four paralogous groups and are numbered from 1-13 within the groups. During embryogenesis, *Hox* genes show an expression pattern which is specific for each body region, commonly referred to as the *HOX* code. They are an evolutionary highly conserved collection of genes binding to various DNA recognition sites and thus influencing a cell's developmental fate in a huge variety of species, while determining the anterior-posterior body axis^[11] (Figure 1). The precise function of these genes is achieved by their specific temporal and spatial activation over the course of life. Due to this role in embryonic and adult developmental stages, *Hox* genes are expected to also have fundamental influences on the differentiation of various stem cells *in vivo* and *in vitro* towards their respective lineages. There have been studies which directly identified *Hox* gene involvement in stem cell differentiations, and others which suggest their role based on observed effects of *Hox* genes in *in vivo* or *in vitro* tissue development. It has been speculated that the code may contribute to maintaining the stem cell

character in certain niches, since it is also regulated on an epigenetic level^[12].

This review will outline the *Hox* profile of various stem cells, and discuss the wide range of findings concerning *Hox* genes in stem cell differentiations gathered over the last decade. The nomenclature used for *Hox* genes in this study is according to the current regulations, meaning that *Hox* genes related to findings in mice and rats are written with the first letter capitalized, whereas the following are in small capitals (e.g., *Hoxc8*). For findings in human and chicken, all letters are capitalized (e.g., *HOXC8*). Understanding the principle behind the role of *Hox* genes in differentiations and development may provide improved possibilities to alter stem cell fate *in vitro* and *in vivo*, and therefore might result in new or improved approaches in regenerative medicine.

Therapeutic approaches are more and more based on the use of mesenchymal stem cells (MSCs), due to their easy accessibility and handling compared to other kinds of stem cells. Hence, we put specific emphasis on the differentiation lineages of MSCs within this review.

HOX TRANSCRIPTION FACTORS IN STEM CELLS

Embryonic stem cells

Embryonic stem cells (ESCs) can be gained from the inner cell mass of the blastocyst and are therefore derived from an early stage embryo^[13,14]. They are characterized by various markers, having the most significant surface markers SSEA-1, SSEA-3, SSEA-4 as well as TRA-1-60 and TRA-1-81^[15]. Additionally ESCs are positive for the transcription factors NANOG and OCT3/4^[16,17]. Their pluripotency, the potential to differentiate into each cell lineage and all types of cells of the body, and the proliferation rate causes huge interest in this stem cell type^[18,19]. An active repression of *Hox* clusters has been demonstrated in various studies. On the other hand *Hox* genes are activated when differentiation processes take place^[20]. However, it is not known which *Hox* code exactly commits these cells into the different lineages, yet^[20].

Hematopoietic stem cells

Hematopoietic stem cells (HSCs) are the best characterized type of adult stem cells^[21]. They can be obtained from bone marrow, cytokine-mobilized peripheral blood, and cord blood^[22]. HSCs are characterized with the antigen cell-surface markers CD34, C-KIT, TIE, and CD133/AC133 and they lack CD38, LIN, and CD45RA^[23]. These stem cells differentiate into all kinds of blood cell lineages serving the reconstruction of the lymphohematopoietic system^[24]. In general, the *HOXA* cluster plays a role in hematopoiesis^[25], but the expression of *HOXB4* which directs transition from the embryonic to the adult hematopoietic program is a major factor as

Figure 1 Roles of *Hox* genes in the organisms and the cell^[135-140].

well^[21].

Neural crest cells

Neural crest cells (NCCs) are multipotent cells exclusively present in vertebrates^[26]. These cells are not only found in the early embryonic development but are also present in various neural crest-derived tissues in the fetal and adult organism^[27]. NCCs are located in between the neural epithelium and epidermis in the neurulating vertebrate embryo^[26]. After they have undergone epithelial-mesenchymal transition the NCCs migrate within the embryonic tissue to the respective location and undergo differentiation^[28]. This stem cell type commits towards facial cartilage, bone and connective tissue as well as neural and glial cells of the peripheral nervous system. Additionally, they are able to differentiate into skin pigment cells, mesenchyme and in restricted locations into smooth muscle cells^[29]. NCCs are characterized with the markers p75NTR, AP-2 α and the transcription factors MSX1, MSCX2 and SLUG in the pre-migratory state^[30]. In post-migratory state, embryonic and adult cell markers can be distinguished as follows: in the embryo, adult gut and bone marrow p75 is present, whereas SOX10 is found in the dorsal root ganglia of the embryo and in the adult bone marrow. As an additional marker NESTIN is suggested because it is present in the adult heart and embryonic boundary cap cells. Other markers are MUSASHI in the adult heart, SCA1 and CD34 in the adult cornea as well as SLUG and SNAIL in the adult bone marrow^[26]. Usually there are no *Hox* genes expressed in NCCs^[31]. However data has been found where *Hoxa2* and *Hoxd9* can be induced in mouse trunk neural crest cells by retinoic acid, a major factor triggering differentiation^[32]. Additionally, *Hoxd3* has been shown to have an impact on the formation of somitic mesoderm and neural crest-derived structures during mouse development^[33].

MSCs

MSCs are multipotent adult stem cells which can be *in*

vitro differentiated towards lineages of mesenchymal tissues^[7,34,35], which is in line with their natural repair function in the body where they regenerate mesenchymal tissues like bone, cartilage, muscle ligament, tendon and adipose tissues^[7,36]. In addition it has been described that these stem cells can also differentiate towards lineages of the other two germ layers, such as towards endothelial cells, hepatocytes^[37], or neurons of the ectoderm^[38]. MSCs are found in the stroma of various tissues or organs such as bone marrow, umbilical cord, wisdom teeth and adipose tissues^[5,7,39]. Defined characteristics of these stem cells are the plastic adherence under standard culture conditions, the presence of the antigen surface markers CD73, CD90 and 105 and the absence of CD34, CD45, CD14 or CD11b, CD79a or CD19 and HLA-DR^[40]. Since *Hox* genes are involved in organ formation and regeneration, it is not astonishing that the degree of *Hox* gene expression in various adult stem cell populations differs which enables the discrimination of adult stem cells by the respective *Hox* expression pattern. Cord blood-derived MSCs (CB-MSCs) and unrestricted somatic stem cells (USSCs) are gained from cord blood. Whereas CB-MSCs are positive for *HOXA9*, *HOXB7*, *HOXC10* and *HOXD6*, USSCs resembling the profile of typical ESCs are negative for *Hox* genes. In CB-MSCs and USSCs it has been demonstrated that this expression code is in line with the differentiation potential of stem cells: CB-MSCs can be differentiated towards the adipogenic lineage whereas USSCs generally can be committed towards all three germ layers and show nevertheless no adipogenic differentiation. *HOXB7* and *HOXD6* expression has also been shown in bone marrow-derived MSCs that generally have a similar expression profile as MSCs derived from adipose tissue. Amnion- and decidua-derived MSCs can be distinguished using *HOXC10* expression^[41]. Taken together, a distinct expression of *HOXA5* and *A10*, *HOXB6*, *B7*, *HOXC4*, *C6*, *C8*, *C9* and *C10* as well as *HOXD3* and *D8* is observed in MSCs derived from different human sources^[42]. In murine MSCs the expression of *Hoxb2*, *b5*, *b7* and *Hoxc4* has

Table 1 *Hox* gene expression in various kinds of stem cells

Type of stem cell	<i>Hox</i> expression	Role of <i>Hox</i>
HSC	<i>HOXA</i> cluster <i>HOXB4</i>	Hematopoiesis and its transition from embryonic to adult program
MSC	<i>HOXA5</i> , 10 <i>HOXB6</i> , 7 <i>HOXC4</i> , 6, 8, 9, 10 <i>HOXD3</i> and <i>D8</i>	Degree of <i>Hox</i> expression pattern differs in the different sources and determines differentiation potential
ESC	None	Active repression of <i>Hox</i> genes until commitment starts
CSC	Various	Overexpression of <i>Hox</i> genes present in undifferentiated cells and down-regulation <i>Hox</i> genes present in differentiated cells
	<i>HOXA9</i>	Hematopoiesis
	<i>HOXB7</i> , <i>C6</i> , <i>C8</i>	Vascularization
	<i>HOXA4</i> , <i>D10</i>	Colon carcinoma
NCC	<i>HOXD3</i>	Formation of somitic mesoderm- and neural crest-derived structures
iPS	None	Active repression of <i>Hox</i> genes until commitment starts

HSC: Hematopoietic stem cells; MSC: Mesenchymal stem cells; ESC: Embryonic stem cells; CSC: Cancer stem cells; NCC: Neural crest cells; iPS: Induced pluripotent stem cells.

been shown, which regulate self-renewal and influence the differentiation of other stem cells^[43].

Cancer stem cells

Cancer stem cells (CSCs) are cancer cells with the capability of both, self-renewal and differentiation, which are the typical characteristics of any stem cell^[44]. These stem cells are multipotent, clonogenic, have the capability to induce new tumors and eventually create heterogeneous cell lineages in tumors^[45]. Accordingly they are thought to be responsible for progression of cancer, cancer metastasis, and therapy resistance of cancers^[46]. In addition, the recurrence and spreading of cancer might be due to CSCs that remain in residual tumors after surgery and treatment. It was suggested that a tumor contains different stem cell like populations due to reduced cell differentiation within a tumor and this heterogeneous population also includes CSCs^[44,45]. DNA damages may render tissue stem cells to become CSCs on their way from a stem cell to a fully differentiated cell. However, instead of dying at the different levels of differentiation like normal tissue stem cells do these cancer precursors do not differentiate normally but accumulate forming tumors^[47]. Conclusively, this population differs in marker expression and growth capacities^[45]. In general CSCs can be characterized by the presence of the markers CD24, CD29, CD44, CD90, CD133 and CD166^[44,45]. In some cancers it has been observed that *Hox* genes are upregulated which are normally restricted to undifferentiated or proliferative cells, and *vice versa* a down-regulation has been shown of those *Hox* genes which are normally present in fully differentiated cells^[48]. For instance, *HOXA9* seems to play a role in acute myelogenous leukemia^[49]. *HOXB7*, *HOXC6* and *C9* transcription factors function in intima formation and vascularization in vascular-wall multipotent stem cells, which is in line with vascularization being important for cancer metastasis^[50]. Further, colon carcinomas

show an overexpression of *HOXA4* and *HOXD10* which distinguishes colonic stem cells from colon carcinoma cells^[51].

Induced pluripotent stem cells

Induced pluripotent stem cells (iPS) have similar characteristics as ESCs including pluripotency and immortality^[52]. As can be seen in Table 1, both stem cell types are generally negative for *Hox* gene expression. iPS cells are generated by introducing four defined transcription factors into somatic cells, which are OCT3/4, SOX2, KLF4, c-Myc or NANOG, and Lim2b replacing the later two^[53,54]. In the meantime, several somatic cells can be reprogrammed such as fibroblasts, hepatocytes, keratinocytes and circulating T-cells, also with a reduced set of transcription factors, ranging from four factors to one factor with respect of the target cell^[55]. Both, ESCs and iPS cells are characterized by the pluripotency markers NANOG, OCT3/4, ERAS, ESG1 and ECAT as well as TRA-1-60^[53,56]. As iPS cells can differentiate into the same lineages as ESCs, which is the differentiation into all cell types of the three germ layers^[57], the *Hox* gene expression is similar as well. It is repressed as they are quiescent and up-regulated when the differentiation processes start^[58].

HOX TRANSCRIPTION FACTORS IN VARIOUS DIFFERENTIATIONS

Hox expression in adipogenic differentiation

The understanding of adipose tissue as an organ with a detrimental effect on the whole organism, due to its secreted adipokines, led to increased studies during the last decades, since the number of obesity patients rises all over the world. A dysfunction of adipocytes in obese patients can, *e.g.*, lead to diabetes type II and cardiovascular diseases^[59], the leading cause of death in industrialized countries. Thus understanding the

molecular mechanisms in adipogenesis has therefore gained much importance.

Hox gene expression in developing adipocytes has been studied in the pre-adipogenic committed murine cell line 3T3-L1, where *Hoxa4*, *a7*, and *Hoxd4* are involved in the differentiation towards adipocytes^[60]. In human adipose tissue-derived stem cells (hAT-SC), *HOXC8* expression is drastically down-regulated during adipogenesis and almost vanishes in mature adipocytes. However, the down-regulation does not arise from a change of RNA expression, but is rather due to post-translational modifications by miRNAs. Forced expression of *HOXC8* in hAT-SC inhibits adipogenesis to a certain extent, indicating that this *Hox* gene has a functional role during the differentiation of these stem cells towards adipocytes^[61].

There is also evidence that *HOXA1*, *A4* and *HOXC4* are directly involved in the differentiation and further generation of human white and brown adipose tissue^[62]. Additionally, the *Hox* gene expression pattern is varying in adipocytes derived from different fat deposits within the human body. This pattern is also reflected in the *in vitro* differentiation of human primary pre-adipocytes isolated from the respective region. For instance pre-adipocytes isolated from the abdominal fat depot show an increased expression of *HOXA5* and *HOXB8* during differentiation towards adipocytes, as compared to gluteal pre-adipocytes, where *HOXA10* expression is higher, and *HOXC13* expression is exclusively restricted to gluteal pre-adipocytes^[63]. Due to this variation in the expression pattern, a general statement about the *Hox* gene expression in differentiating adipocytes would not be sensible.

Understanding the principles of *Hox* signaling in white and brown adipose tissue formation might help prevent health damage in obese patients, such as the development of diabetes and consecutive the metabolic syndrome.

***Hox* expression in chondro-osteogenesis**

Understanding the development of joints and bones is of interest in many fields of research, including regenerative medicine. However, the complete formation of limbs and other hard tissues involves various types of cells and a complex interplay between them. Three main tissue types can be attributed to bone and joint formation, namely tendons, cartilage and bone. Chondral tissue is the first to develop in limb formation, and its condensation is needed for correct bone development. Of great importance in tissue engineering are the underlying signaling pathways and proteins involved^[64]. By investigating the *Hox* gene expression in chondrocytes and osteoblasts, both, *in vitro* and *in vivo*, bone formation and regeneration might be improved in the future, since in both cell types *Hoxa2* and *Hoxd9* have been shown to be significantly regulated. *Hoxa2* is up-regulated in bone regeneration of rats after post-fracture day 10, whereas *Hoxd9* is down-regulated

after this time period^[65]. In mice, *Hoxa2* impairs chondrogenesis in the mesenchymal-to-chondrocyte differentiation step leading to a proportionate short stature. Additionally, in a *Hoxa2* gain-of-function mice model molecular regulators for an endochondral ossification are decreased^[66]. In normal mouse development, *Hoxa2* inhibits chondrogenesis and intramembranous ossification as well as bone formation when forcedly expressed in osteoprecursors^[67]. Forced *Hoxa2* expression in cells committed to undergo chondrogenesis also leads to chondrodysplasia and delayed cartilage mineralization and ossification, but does not affect proliferation of the chondrocytes^[68]. Interestingly, *Cbfa1* induction might inhibit *Hoxa2* caused impairment of osteogenic differentiation *in vivo*^[67]. In addition, overexpression of *HOXA2*, and expression of *HOXA3* and *HOXB4*, abolishes the ability of neural crest cells in the rostral domain to differentiate into skeletal structures in chicken^[69]. The expression of certain *Hox* genes seems to inhibit skeletogenic differentiation, particularly jaw formation. In cranial neural crest cells there are specific regions where *Hox* expression or suppression, respectively is essential for appropriate development. In detail *Hoxa2* inhibits *Sox9*, resulting in an impeded development of neural crest cells into ectomesenchymal stem cells and thus no osteochondral progenitors can form in mice. The absence of *Hoxa2* leads to a migration of *Sox9* into areas where *Hoxa2* is normally expressed which induces ectopic chondrogenesis^[70]. In addition, *Hox* genes suppress osteochondrogenesis in more posterior neural crest cells *via* epigenetic mechanisms^[32]. *Hoxa2* exerts an inhibitory effect in differentiation of chondrocytes, but is needed during bone formation. This effect is not related to the patterning function of *Hoxa2*, since it occurs in various tissues independent of their embryonic origin. Moreover, the ossification process itself is not affected by the *Hoxa2* misexpression^[68].

Hoxc8 as well as *Hoxd4* regulate chondrogenesis in a dose dependent manner in mice. *Hoxc8* does not block chondrogenesis, but alters the progression of chondrocytes and their differentiation pathway, leading to an accumulation of proliferating precursor cells, which negatively interfere with the progression of differentiation. A transgenic model for *Hoxc8* and *Hoxd4* signaling in chondrogenesis has been suggested, but the proposed effects have not yet been proven in *in vitro* culture systems with postnatal derived chondrocytes^[71,72].

In *Hoxa11* and *Hoxd11* double mutant mice, chondrogenesis is initiated normally. Pre-chondrocytes express *Sox9* and type II collagen necessary for further differentiation. However, mesenchymal condensations, which later give rise to the radius and ulna, differ in shape and size from non-mutants^[73]. Prehypertrophic cells within these condensations do no longer undergo their differentiation pathway towards hypertrophic chondrocytes. *Hoxa11* and *Hoxd11* double deficient

mice have shorter limb formation and development postnatal, together with delayed ossification, suggesting that these two *Hox* genes are important regulators in mammalian chondrogenesis^[73]. This is in line with the finding that *HOXA11* is expressed only in tissues which do not undergo chondrogenesis in chicken^[74].

Also, *Hox* genes generate a positional memory in skeletal stem cells, influencing their differentiation potential. Murine skeletal progenitors derived from the mesoderm maintain *Hoxa11* expression, whereas mandibular bone progenitors derived from the neural crest are negative for *Hox* expression. Thus an appropriate expression of *Hox* genes provides instructions for site-specific differentiation and function of stem cells *in vivo* and *in vitro*^[75].

Similar as already discussed for the adipogenic lineage commitment, the expression pattern of *Hox* genes in stem cell differentiations towards the osteogenic lineage varies according to the extraction site of the adipose tissue-derived stem cells. *Hoxa4* and *a5* expression is decreased in flank-derived MSCs differentiated towards osteoblasts, compared to the level in abdomen-derived stem cells, but *Hoxa4* is dominantly expressed in arm-derived stem cells. *Hoxc8* and *Hoxd4* on the other hand show a similar expression pattern in stem cells derived from the abdomen, arm, flank or thigh^[76].

Genes within the D family of the *Hox* cluster are suggested to play a role in the condensation of MSCs and the further development into chondrocytes. In detail, *HOXD9* and *HOXD13* were found to be distinctly expressed in developing chondrocytes within MSCs from the chicken limb bud. The inhibition of *HOXD10*, *D11*, and *D13*, respectively, inhibits chondrogenesis^[77]. This is in line with the finding that *HOXD11* was found to act on initial cartilage condensation phases and later growth phases within the bone of chicken, whereas *HOXD13* acts at later stages of bone development. Correspondingly, misexpression of *HOXD13* is associated with a shortening of long bones^[78]. This is supported by data derived from mice where *Hoxd13* and to a lesser extent *Hoxd12* were found to be essential for bone formation. A defect in one of these *Hox* genes leads to limb malformations and shorter bones^[79]. Especially *Hoxd13* seems to be responsible for the genetic switch from long bone to short bone formation^[80]. But also *Hoxd10* affects mouse limb development by impairing proper growth of skeletal elements^[81]. Large fractures heal by processes very similar to bone formation during development, apart from remodeling and inflammatory responses^[5].

The strict *Hox* gene patterning that could be observed in *Drosophila melanogaster* is even more complex during bone formation in vertebrae. In *D. melanogaster* genes closer to the DNA 5'-end are expressed strictly posterior and the more 3' located *Hox* genes are strictly anterior. In agreement with that a knockout of *Hoxd9* has revealed a more posterior impaired growth

in the spine of mice than a knockout of *Hoxd13*^[82].

As already mentioned *Hoxd13* is more essential for proper bone formation than *Hoxd12*, but defects in either of these *Hox* genes lead to a shortening of bones and limb malformations^[79,81]. However, functions missing in knockout mice lacking a certain *Hox* gene may be compensated by other *Hox* genes. Hence, the severity when lacking either one of two *Hox* genes may be far less than if both *Hox* genes are knocked-out^[82,83]. Cases where a *Hox* gene on both alleles is dysfunctional always show more severe bone malformations^[79,81]. Also, stem cells from various sources show an origin-specific *Hox* expression profile. Therefore, it is of great importance to match the *Hox* code of the cells subject to transplantation to the tissue of interest. It has been shown that USSCs, which are *in vivo* *Hox* negative and lack the potential to differentiate into the adipogenic lineage, gain this potency after these cells have been altered in their *Hox* expression profile in a co-culture model with CB-MSCs or bone marrow-derived stem cells. This however also affects the chondrogenic and osteogenic differentiation potential of USSCs^[84]. The positional memory may hence be altered under the influence of *Hox* genes, but side effects have to be taken into consideration.

An indirect link between *Hox* expression and bone formation was examined recently. BMP4 (bone morphogenic protein) as well as BMP7 elevates the expression of KDM6B, which then causes a removal of H3K27me3 that normally inhibits *Hox* expression. Even though BMP is among other tasks directly responsible for bone formation this secondary function might further aid in the development^[85].

A well understood example for how *Hox* genes are involved in bone formation is *HOXA10*. Again a BMP, here BMP2 induces *HOXA10* which subsequently interacts directly with RUNX2, a main and early regulator of osteogenesis-specific gene expression^[86,87]. This is supported by the finding of Gordon and colleagues^[88] that Pbx1 is able to repress this *Hoxa10*-mediated osteogenic differentiation by blocking recruitment of chromatin remodeling factors and that overexpression of *Hoxa10* increased the expression of osteoblast-related genes, osteoblast differentiation and mineralization^[89].

Once bone and cartilage have been formed, they are connected to the musculature *via* tendons. Influencing the proper development and regeneration of tendons and striated muscle is therefore of great medical importance. However, little is known to date about the involvement of *Hox* genes in their developmental processes. The first and only data are about the autopodal *Hox* genes *HOXA13* and *HOXD13* inducing *Six2* expression, which is a transcription factor present in developing tendon precursors, even in areas where it normally would not occur, such as the zeugopods of a chicken limb-bud^[90]. Further investigations are therefore required to be able to improve overall limb regeneration with the help of stem cells under the influence of *Hox* genes.

Hox expression in cardiovascular lineages

Regeneration and repair of the cardiovascular system is a major field of research in the scientific community, since it is the main cause of death with up to 50% in industrialized countries^[91]. After transplantation of human bone marrow-derived stem cells into a murine adult heart, a limited number of cells survived and over time showed morphological and molecular changes, resembling the phenotype of host cardiomyocytes^[92]. This has been reproduced in various studies and with a variety of donor tissues and hosts *in vivo* and *in vitro*^[93,94]. Thus MSCs hence provide a valuable source for repairing injured myocardium in theory, but the underlying mechanism of differentiations towards myocytes and the cells of the blood vessels, *e.g.*, endothelial and smooth muscle cells, has to be understood thoroughly to improve the outcome of such treatments. Knowing about changes in *Hox* gene expression in stem cell types and animal models may in the future help improve the differentiation of MSCs into cardiomyocytes for the transplantation into patients.

HOXA1 deficiency can cause cardiovascular diseases in mouse models as well as in human patients, which suggests its role in cardiomyocyte differentiations^[75,94-98]. TCDD can inhibit mouse embryonic stem cell differentiation towards cardiomyocytes. During this inhibition *Hoxa10*, *a13*, *a7*, *Hoxb9*, *Hoxc8*, *c9*, *Hoxd1*, *d4*, *d9*, *d13* are upregulated, whereas *Hoxb1* is down-regulated. In detail, *Hoxb4* and *Hoxd3* are upregulated with a lower dosage of 10 pmol/L TCDD and down-regulated at a dosage of 100 pmol/L TCDD. *Hoxa9*, *Hoxb3*, *b8*, *Hoxc6* are down-regulated at a dosage of 10 pmol/L TCDD whereas upregulated at a dosage of 100 pmol/L TCDD^[99]. In accordance to these findings, *Hoxa10* has been found to impair murine cardiac differentiation *in vivo*^[100].

In the vasculature, *HOXA11* and *A13* impact myogenic differentiation, as they repress MyoD expression and therefore initiation of myogenic differentiation in chicken limb muscle precursors transfected with these *Hox* genes^[101]. Retention of *Hox* gene expression profiles and positional identity has been found in muscle cells and MSCs *ex vivo*^[75,95-98].

The genes of the paralog groups *Hox6-10* show a higher expression pattern in smooth muscle cells (SMCs) of the athero-resistant thoracic aorta compared to SMCs of the athero-susceptible aortic arch in mice, rat, and pork. This pattern is consistent in human ESCs which were differentiated into precursors of the thoracic aorta and the aortic arch, respectively, which also suggests a possible involvement of the above mentioned *Hox* genes in specific SMC differentiation processes of ESCs^[102]. In vascular wall-resident multipotent stem cells (VW-MPSCs), *HOXB7*, *HOXC6* and *C8* are expressed in high levels compared to human pluripotent ESCs, mature aortic smooth muscle cells and human umbilical cord endothelial cells^[50]. Silencing of these *Hox* genes in VW-MPSCs leads to a

reduction in their in-gel (Matrigel) sprouting capacity, hence suggesting a decreased differentiation potential without affecting proliferation^[50]. Finally it has been found that in myogenic cells *Hox* gene expression is down-regulated *via* hypermethylation^[103].

Changes in *Hox* gene expression over the differentiation time course can also be observed in the stem cell differentiation towards endothelial cells. When mouse ESCs are differentiated towards endothelial cells, *Hoxa3* and *Hoxd3*, which drive angiogenesis and endothelial cell sprouting in adults, show a peak expression at day three of differentiation. Their expression declines over the following days of differentiation, whereas *Hoxa5* and *Hoxd10* arise from a low expression profile at day three of differentiation to a high expression profile over the course of time. In addition, these two *Hox* genes are involved in maintaining a mature quiescent endothelial cell phenotype^[22]. This suggests an involvement of *Hoxa5* and *Hoxd10* in the differentiation of ESCs towards endothelial cells, whereas *Hoxa3* and *Hoxd3* rather mark an immature angiogenic endothelium and/or the onset of angiogenesis^[22]. This has been confirmed by others who found that *Hoxd10* suppresses angiogenesis, while *Hoxd3* and *Hoxb3* promote angiogenesis^[104,105].

Interestingly, the expression profile of *Hox* genes in human ESCs from leukemia prone infants is changed which might account for the impairment of hematopoietic cell differentiation in favor of endothelial cell fate. In these cells, *HOXA9*, *A13*, *HOXB2*, *B3*, *B4*, *B5*, and *B6* are strongly up-regulated^[106]. Next to this, *HOXA9* is down-regulated in endothelial cells derived from endothelial progenitor cells from systemic sclerosis patients, suggesting an involvement of this *Hox* gene in endothelial cell differentiation or mal-differentiation^[107].

During the differentiation of human bone marrow-derived MSCs towards endothelial cells four *Hox* genes were found to be significantly altered in their expression profile. *HOXA7* and *HOXB3* expression is increased, whereas the expression of *HOXA3* and *HOXB13* ceased^[108]. Also, *HOXB5* up-regulates vascular endothelial growth factor receptor-2 which leads to an augmented endothelial cell precursor differentiation. Consequently, *HOXB5* has also been proven to enhance endothelial cell sprouting and coordinated vascular growth in chicken^[109]. A variety of *Hox* genes have already been found to influence cell fate in favor of endothelial and smooth muscle cell lineages, but the exact mechanisms need to be made clearer in order to use them as transcription factors in regenerative therapies.

Hox expression in neurogenesis

Neurodegenerative diseases are also becoming more and more prominent within an aging population. Repairing the neurological systems within the body has been difficult ever since, due to its complexity. A detailed understanding of molecular processes involved in the development and differentiation of neuron precursors is of crucial

Figure 2 Major signaling pathways involved in *Hox* gene expression. Predominantly posterior 5' *Hox* genes are activated by BMP and Wnt signaling. *Hox* genes closer to the 3' end of a chromosome, which are mainly expressed anteriorly, are activated by retinoic acid pathways^[120,141-150]. BMP: Bone morphogenic protein; RARE: Retinoic acid response element.

Table 2 <i>Hox</i> genes play a role in various differentiations		
Differentiation	<i>Hox</i> gene expression	Ref.
Adipogenesis	<i>a4, a7, d4, A1, A4, A5, A10, B8, C4, C8</i> ↓, <i>C13</i>	[60-63]

Neurogenesis	<i>a2, b1, B4</i>	[110-112,114-116]

Small capitals: Murine; Large capitals: Human and chicken; ↑: Up-regulation; ↓: Down-regulation.

importance. Since *Hox* genes control the anterior-posterior (AP) segmentation, the 3' genes in the *Hox* cluster are more prone to play a role in neurogenesis, and the paralog groups 1-4 have restricted expression borders in the hindbrain. The remaining paralog groups 5-13 reveal an anterior expression border in the spinal cord. This AP segmentation translates to the migration of neural crest cells^[12]. In mouse models, *Hoxb1* is essential for the correct development of rhombomeres at early embryonic stages, since it naturally induces neural stem cells towards a hindbrain identity, and has also been shown to be involved in the differentiation, maturation and maintenance of facial nerves^[110,111]. Murine *Hoxa2* and *Hoxb1* can individually and as the sole additional factor induce motor neuron development, even in sections where they are usually not present^[112]. In mice deficient for *Hoxb1* expression, facial neurons do not properly form^[113]. Also, *HOXB4* has been found to be a crucial factor in driving neuronal differentiations in the neural tube^[114]. Further, since the

disruption of *Hoxa1* in mice leads to malformations of the hindbrain, a role for this *Hox* gene in murine neurogenesis has been suggested^[115,116]. Retinoic acid (RA) has been established as an essential factor for adult neurogenesis. Embryonic stem cells treated with RA almost exclusively differentiate into neurons and develop a *Hox* expression profile^[117]. Many *Hox* genes contain retinoic acid response elements (RAREs) which supports the finding that they are involved in RA-induced differentiation of ESCs^[118]. RAREs have been found in *Hoxa1, a4, Hoxb1, b4*, and *Hoxd4*^[12,119-128]. In fact, several *Hox* genes have been found to be strongly up-regulated in differentiations where RA was present^[118]. The interaction between RA, *Hox* genes, and other signaling molecules has been visualized in Figure 2. During embryonic stem cell differentiation, highly conserved elements in the *Hox* gene clusters are epigenetically modified, so that adult spinal cord progenitors express a distinct *Hox* expression profile^[129-131]. The further investigation of *Hox* genes in neurogenesis therefore promises a better insight into the possible

therapies to treat neurodegenerative diseases and should be pursued.

CONCLUSION

Degenerative diseases are one of the major problems arising within a population with high average age. The complex biological systems in the human body have made the development of regenerative therapies a challenging project. Much effort has been put into using stem cells and various signaling molecules for this purpose over the last decades. In this review, we have discussed the expression of *Hox* transcription factors in various types of stem cells and their role in differentiation. Interestingly already the stem cell source has an impact on the *Hox* gene expression in the respective stem cell type. *Hox* genes provide valuable possibilities to influence stem cell differentiations. Either single *Hox* genes or small groups have been found to directly influence the course of several differentiations, but detailed molecular changes under this influence are mostly not yet known. Additionally, many *Hox* genes have only revealed an indirect effect, or have been investigated in *in vivo* development but not in stem cell differentiations. Future studies need to be performed to investigate whether the suggested *Hox* genes, as summarized in Table 2 for mesenchymal stem cell lineages, actually have a functional role in the *in vitro* differentiation of stem cells. Additionally, the effects must be tested *in vivo* to evaluate their therapeutic potential in tissue repair and regeneration^[132]. As a consequence of the observed results it is suggested that cells which have their *HOX* code deleted regain plasticity and can be reprogrammed, similar as it has already been shown in iPS cells^[133,134]. In addition to this and similar to iPS cells, also the epigenetic profile must be considered. We summarized that next to the histological compatibility of donor and host tissues the *HOX* code must be taken into consideration in regenerative therapies. In conclusion, the further investigation of *Hox* genes in stem cell differentiations is an interesting research field in regenerative medicine to improve tissue repair in injury, disease and aging.

Abstract

Human cell types affected by retinal diseases (such as age-related macular degeneration or retinitis pigmentosa) are limited in cell number and of reduced accessibility. As a consequence, their isolation for *in vitro* studies of disease mechanisms or for drug screening efforts is fastidious. Human pluripotent stem cells (hPSCs), either of embryonic origin or through reprogramming of adult somatic cells,

represent a new promising way to generate models of human retinopathies, explore the physiopathological mechanisms and develop novel therapeutic strategies. Disease-specific human embryonic stem cells were the first source of material to be used to study certain disease states. The recent demonstration that human somatic cells, such as fibroblasts or blood cells, can be genetically converted to induce pluripotent stem cells together with the continuous improvement of methods to differentiate these cells into disease-affected cellular subtypes opens new perspectives to model and understand a large number of human pathologies, including retinopathies. This review focuses on the added value of hPSCs for the disease modeling of human retinopathies and the study of their molecular pathological mechanisms. We also discuss the recent use of these cells for establishing the validation studies for therapeutic intervention and for the screening of large compound libraries to identify candidate drugs.

Key words: Drug screening; Human pluripotent stem cells; Disease modeling; Retinitis pigmentosa

Core tip: Human pluripotent stem cells (hPSCs) are usually evoked for their potential for regenerative medicine. However, beside these aspects, novel interests raise from the potential of hPSCs to model human diseases including retinopathies. In this review, we describe how these cells allow the study of the molecular mechanisms leading to some form of retinopathies through the development of retinal specific cell type derived from the differentiation of hPSCs. We also discuss the use of hPSCs cellular models for the validation of gene therapy and for drug screening purpose.

INTRODUCTION

Retinal diseases, such as age-related macular degeneration (AMD) and retinitis pigmentosa (RP) are the leading causes of blindness in the developed world, collectively affecting to different degree as many as one-third of all people over the age of 75^[1-3]. This burden is predicted to increase with the ageing of the population in Western countries.

RP is one of the most common inherited diseases of the retina (retinopathies). It is estimated to affect 1 in 3500 to 1 in 4000 people in the United States and Europe. Genes involved in RP are numerous (<https://sph.uth.edu/retnet/disease.htm>) and can affect specifically retinal pigment epithelium (RPE) or photoreceptors or both. Forms of RP and related diseases include Usher syndrome, Leber's congenital amaurosis, rod-cone disease, Bardet-Biedl syndrome, and Refsum disease, among others^[4]. RP is traduced clinically with a gradual decline in vision as a consequence of photoreceptor cells (rods and cones) dying either from cell autonomous origin or secondary from a defect of RPE cells, which support their survival.

Up to now, there is no curative treatment for these pathologies. Among others (for review, see^[5]), the more promising areas of research for RP therapies include gene therapy aimed at restoring defective genes, and cell transplantation to replace defective or dead cells.

Gene therapy has been shown to improve visual function in inherited retinal diseases^[6,7]. Most gene therapies involved integration of vector DNA into the specific cells of retina^[8,9] and even combine RNA interference (RNAi)-based gene silencing with gene replacement in RP^[10,11]. While promising, gene therapy aiming at restoring gene defects in the RPE (like *RPE65*) shows limitations. Indeed, the prerequisite to this type of gene therapy is to know precisely the defective gene (need the genotyping of each patient) and a second limitation is to develop a gene delivery candidate drug for each one of the defective genes (cost-intensive). Moreover, recent data from preclinical and clinical studies show that, despite stabilization of vision during the follow-up period, patients treated by *RPE65* gene therapy still undergo photoreceptor degeneration^[6].

The other strategy consists on the replacement of died or defective cells by transplantation procedures. The eye has numerous advantages for developing cell therapies as all tissues of the eye are surgically accessible, transplanted cells can be monitored by microscopic analysis and the inherent amplification of the visual system means that relatively small number of rescued cells or transplanted cells could

have a detectable effect on vision. Moreover the ocular immune privilege might greatly simplify immunosuppressive treatment after transplantation. Initial subretinal transplant studies employed tissue-specific stem cells obtained from human fetuses, known as retinal progenitors^[12]. Extension of this work revealed that post-mitotic photoreceptor precursor cells are optimal for retinal integration and restoration of retinal structures^[13-16]. Unfortunately, in human embryonic development, both retinal progenitor and photoreceptor are generated relatively late (*i.e.*, 14 and 24 wk of gestation respectively^[17-20]). The serious ethical implication of this fact, coupled with the practical reality of the relatively small number of photoreceptor precursor cells that can be obtained from a pair of fetal donor eye make it quite unlikely that this cell will be used to any meaningful extent in the treatment of human retinal disease.

In that context, scientists developed new strategies to overcome these constraints. Moreover, a better comprehension of the different molecular mechanisms leading ultimately to RP or AMD is crucial in order to find new treatments. Current animal models of RP are not available for the hundreds of causal mutations. That's why human pluripotent stem cells (hPSCs) lines are rapidly changing the strategies scientists can implement to understand pathological mechanisms and cure genetic diseases.

In this review, we focus on the different opportunities concerning the use of human pluripotent stem cells for the disease modeling as well as the future challenges of such research. We also develop the recent improvements in the genetic manipulation of human pluripotent stem cells and the consequences of these on disease modeling and drug screening for retinal diseases. Finally the availability of such human cellular models allowing the validation of therapeutical strategies as unexpected as gene therapy will be discussed.

hPSCs

Two main sources of hPSCs are described: human embryonic stem cells (hESCs) and human induced pluripotent stem cells (hiPSCs). hESCs are pluripotent cells harvested from the inner cell mass of day-5 human blastocysts that are leftover from *in vitro* fertilizations^[21]. hiPSCs are reprogrammed somatic cells that share many similarities with hESCs^[22,23]. Pluripotency is key to the derivation of cell phenotypes that are relevant for disease, including those that are essentially inaccessible in any other way (*i.e.*, post-mitotic retinal cells). Unlimited self-renewal provides easy access to the biological resource of interest^[24].

iPSCs have been generated from a range of primary cell types, including fibroblasts, keratinocytes, lymphoblasts, chord blood cells, mesenchymal stem cells and even RPE cells (Figure 1). Each cell type has its own characteristics in terms of the number of factors needed for reprogramming

Figure 1 Schematic diagram summarizing the issues to consider when modeling retinal diseases with human pluripotent stem cells. Choice of disease (monogenic vs polygenic); Type of pluripotent stem cells (hESCs and/or iPSCs); for iPSCs: selection of cell type to reprogram (fibroblasts, keratinocytes, blood cells), selection of reprogramming method (retrovirus mediated, non-integrative); choice of quality control for iPSCs characterization (genetic analysis, pluripotency, teratoma assay); differentiation to relevant cell types (photoreceptors, RPE); disease phenotype characterization (molecular characterization, expression studies, genetic rescue); applications (drug screening, toxicological testing, new molecular mechanisms). hESCs: Human embryonic stem cells; iPSCs: Induced pluripotent stem cells; RPE: Retinal pigment epithelium.

and the dynamics of derivation (for review^[25,26]). The generation of iPSCs from older individuals is more difficult and less efficient than the generation of iPSCs from young individuals^[27]. To help overcome this limitation, a variety of different reprogramming factors, reprogramming enhancers, and cell types have been evaluated^[27-39] (Figure 1). Of the accessible cell types used for iPSC generation, the reprogramming of keratinocytes has been shown to be as much as 100-fold more efficient and at least twofold faster than the reprogramming of dermal fibroblasts^[40]. Moreover, the keratinocytes-derived iPSCs are more similar to embryonic stem cells than those generated from fibroblasts^[41]. Finally, for disease modeling, non-integrative methods should be preferable to integrative ones even if less mandatory than for cell therapy programs.

hPSC-derived retinal cells are valuable new tools for investigators seeking to understand and treat degenerative retinal diseases. These cells will allow scientists to explore the pathophysiology of human diseases in ways that were previously possible only in some animal models. The need for better models, given our poor understanding of the pathogenesis of complex diseases and the dismal predictive record of animal models and tumor-derived cell lines push towards the use of hPSCs for modeling diseases in a dish.

DISEASE MODELING OF RP

Any disorder confirmed or suspected to have genetic basis can be modeled, but the choice of which disease to model depends on a number of considerations^[42]. Not all diseases will be equally easy to model. For example, one should consider modeling monogenic and early-onset diseases than polygenic and late-onset diseases, as it would reproduce better aspects of the diseases (Figure 1). Monogenic diseases modeling will allow for a more carefully controlled comparison with genetically corrected cells and demonstration that the disease

phenotypes observed are really caused by the original mutation. Commercial and academic repositories offer primary cell lines or immortalized cell lines for use in research. Most, if not all, disease-causing mutations will be specific to the cell context and affect some cell types more than others. For certain purposes, working with cell lines could be difficult even impossible. This is the case for most retinopathies affecting cells that are not available for biopsies. Genetic disorders of the eye are so numerous that multiple examples exist of conditions that primarily affect photoreceptor cells, ganglion cells, RPE cells, retinal vasculature, choroidal vasculature and eye development. hPSCs systems can offer the possibility to model disease that show a non-cell-autonomous component as both component (*i.e.*, RPE and photoreceptors) can be differentiated from hPSCs and then eventually co-cultured.

Several groups attempted to reconstitute retinal tissue *in vitro* using mice or human cells. A variety of different protocols, utilizing both two- and three-dimensional culture systems, have succeeded in deriving photoreceptor precursor cells from less differentiated precursors^[43-60]. *In vitro* generated organs from hPSCs constitute powerful systems to model human diseases and perform large-scale drug screening.

Within the spectrum of primary retinal disorders, genetic diseases of the RPE are perhaps the most promising candidates for hiPSCs and re-seeded onto a variety of substrates^[61]. RPE cultured from multiple sources, including hPSCs, has been shown to adopt a mature phenotype, and exhibit key physiological functions *in vitro*^[47,62-64].

EXPLORING MOLECULAR MECHANISMS OF RP

Several studies have been published describing disease modeling using hPSCs. Singh and collaborators recently developed a hiPSC-RPE "model in a dish" of Best

vitelliform macular dystrophy (BVMD)^[65]. BVMD is caused by a defect in the RPE gene *BEST1*, which results in the subretinal accumulation of photoreceptor waste products, *i.e.*, lipofuscin, and fluid, leading to secondary photoreceptor death and central vision loss. Using physiological stressors, they reproduced some of the cellular defects observed in the disease and suggested a role of intracellular calcium regulation and oxidative stress in the mechanism of disease^[65]. Similar conclusions were made with other RP models^[66] involving endoplasmic reticulum stress. In this study, several hiPSCs lines were created from 5 patients carrying mutations in different genes involved in RP (RP1, PRPH2, RHO, RP9). After 120-150 d of culture, mature photoreceptors (Rhodopsin positive) derived from all cell lines died, reproducing features observed in the diseases. One line, RP9, showed a much lower level of rhodopsin expression and has higher levels of oxidative stress. Using a slightly different differentiation protocol and using integration-free hiPSC, this research team and others confirm that patient-specific rod cells may recapitulate RP features *in vitro* and could be appropriate model to study retinal degenerative diseases^[67,68]. hiPSC-derived retinal precursors were also used to identify a likely disease-causing homozygous mutation in a gene that had not been previously reported to be associated with disease^[50]. In a more recent study, the same group combined Next-Generation and Sanger sequencing to identify disease-causing USH2A (responsible for Usher syndrome type I) mutations in an adult patient with autosomal recessive RP^[51]. Moreover, by grafting the mutated photoreceptors into mice model of the disease, they showed that the mutation might act *via* post-developmental photoreceptor degeneration rather than during development.

Finally, hPSCs could model systems to study retinal development and implication of specific transcription factors. Phillips *et al.*^[69] (2014) generate hiPSC from a patient with a mutation in the transcription factor visual systems homeobox 2 (VSX2 also known as CHX10) homeodomain. They showed that, using differentiation protocols in order to obtain optical vesicles (OV), mutated hiPSC-OV failed to produce bipolar cells and demonstrated delayed photoreceptor maturation^[69].

All these studies highlight the potential of retinal cells derived from hPSCs to help to identify pathophysiological pathway for targeted development of therapies and decipher key factors in retinal development.

GENE EDITING AS A NEW TOOL TO ACCESS TO HUMAN DISEASE CELLULAR MODELS

The identification and functional validation of sequence variants affecting diverse human traits, including disease susceptibility, is essential for the understanding of human biology and disease mechanisms. Considering the limited number of individual lines often used to model disease mechanisms and the high incidence of line-to-

line variations, the possibility of wrongly attributing to a disease-causing mutation a phenotype that is in fact the result of the uneven distribution of such alterations in control and diseased groups needs to be considered seriously. When disease-specific hPSCs are used to identify novel aspects of disease mechanisms, rather than simply to replicate already known pathological features, internal (isogenic) control experiments such as genetic correction or more classical gain- and loss-of-function experiments are extremely valuable^[24]. While classical gene-targeting technology *via* homologous recombination in mouse embryonic stem cells has proven a powerful tool to dissect gene function^[70-72], this approach has been quite inefficient when applied to hPSCs^[73]. The development of site-specific TALEN- or CRISPR-based genome editing approaches is proving to have great utility for endogenous gene correction in many cell lines^[74-76], including hPSCs^[77-79]. A major advantage of these approaches is that unlike exogenous gene addition in which promoter strength and multiplicity of infection may require patient-specific adjustment, TALEN- and CRISPR-mediated corrections have the advantage that the gene remains under the control of the endogenous promoter. Acting as "DNA scissors", they induce double strand breaks (DSB) at desired genomic loci, triggering the endogenous DNA repair machinery. Processing of DSB by the error-prone nonhomologous end-joining pathway leads to small insertions and deletions (Indels) useful for generating loss-of-function mutations, whereas error-free homology directed repair enables targeted integration of exogenously provided DNA sequences for introducing precise nucleotide alterations or knocking reporters.

Unlike other editing tools, the guide RNAs used for CRISPR/Cas9-based genome editing can be generated relatively easily. The guide RNAs used in this system requires the presence of an adjacent motif, downstream of a 17-20-nucleotide DNA target, termed the protospacer^[80-84]. Complementary guide oligonucleotides can be synthesized, annealed and subsequently ligated into a bicistronic vector-expressing scaffold RNA and a modified Cas9 nuclease optimized for efficient targeting of human cells^[85,86]. Recent study has shown that by combining these gene editing tools (*i.e.*, TALEN and CRISPR) they have developed a genome-engineering platform, named iCRISPR, that enable rapid and highly efficient biallelic knockout hPSCs for loss-of-function studies, as well as homozygous knocking hPSCs with specific nucleotide alterations^[87].

Another strategy could be to use adenovirus in order to replace the mutated gene in hiPSC derived from patients. This was done by Yoshida *et al.*^[68], who generated hiPSC from somatic cell of an RP patient carrying a heterozygous mutation in the rhodopsin gene^[88]. They observed that rod cells had reduced survival rate. To confirm that the phenotype was due to the expression of mutant rhodopsin and not by genetic polymorphism, they used helper-dependent adenoviral vector to replace the mutated gene and

reverted the phenotype observed. Moreover, replacing the wild-type gene reconstructed the pathological condition^[68].

HPSCS FOR THE VALIDATION OF THERAPEUTIC INTERVENTIONS

A number of potential therapeutic interventions are strictly specific to human cells or tissues, such as biotherapies based upon targeting human gene/mutation with RNA interference, exon skipping, and therapeutic antibodies. With these approaches, the uses of classic animal models of RP for experimental or preclinical validation are often not enough informative. Obtaining sufficient cellular material to conduct a wide range of tests, from the initial assessment of therapeutic claim to the final quality of assurance process before clinical batch release, can be challenging.

Some diseases are so rare that it is not economically possible to bring a treatment through the regulatory gauntlet and into clinical availability. One possibility to overcome this issue would be to use cells or tissues created from a patient's own cells to test the molecular efficacy of a viral-mediated gene therapy, including the optimal level of expression, and then deliver that therapy to one eye in a compassionate use manner. Moreover, some genes have a very narrow range of therapeutic dose such that overexpression could be as harmful as under expression^[89]. The first human gene therapy trial for a retinal disease was performed in 2008 in patients with Leber congenital amaurosis (LCA), a congenital blindness resulting from the breakdown of an important metabolic pathway in the RPE but with long-lasting preservation of the photoreceptors. LCA arises due to mutations in the RPE-specific gene, *RPE65*^[90]. Prior to clinical trials, preclinical trials are usually performed on animal models. Many mouse models have been generated that are defective for a gene causing a specific retinal dystrophy, however, certain of these models have proven asymptomatic^[91] or lethal^[92]. Moreover, in general, the mouse eye poorly mimics the situation in the human eye due to its small size and structure. Larger animal models are more appropriate for testing the biodistribution of a gene therapy vector and for ascertaining long-term efficiency and safety. The dog eye is particularly suitable as it resembles the human eye, except for the absence of a macula and foveal pit, in size, and many retinal diseases in man have canine counterparts^[93]. However, for certain diseases, the identification of a corresponding canine model has proven elusive. Thus, taken together, for a growing number of diseases (and this holds true for disorders affecting other tissues), human cell culture is becoming an essential complement to animal disease research^[94]. The results obtained from gene therapy studies in a human system, coupled to *in vivo* studies using animal models, could lead more rapidly to preclinical gene therapy studies indeed a phase I clinical trial.

For pigmentary retinopathies for which an appropriate animal model does not exist, like choroideremia^[95] evaluating the biochemical restoration of a normal cellular phenotype after gene therapy could provide complementary approaches to *in vivo* animal models that investigate systemic effects that are essentially beyond the reach of *in vitro* studies^[96].

hPSCs FOR DRUG DISCOVERY

Many drugs that work in animal models have not performed well in human clinical trials^[97,98]. This discrepancy could be attributable among other proposed reasons to species variation or incomplete phenotype recapitulation. Numerous studies have now showed that retinal cells derived from hPSCs are closely enough representatives of their *in vivo* counterparts^[60,99] that they could be used for identifying and evaluate pharmacological agents capable of mitigating degenerative retinal diseases. High-throughput drug screens of differentiated hPSCs-derived cells have been suggested as a means for drug discovery and personalized medicine^[100-102]. To date, there have been few publications looking at using hPSCs for drug discovery in retinal diseases. Meyer *et al.*^[47] reported the restoration of OAT (Ornithine Amino Transferase) enzyme activity in gyrate atrophy hiPSC-RPE following vitamin B6 treatment. In their study, Jin *et al.*^[66] showed that treatment of the rhodopsin-positive cells (photoreceptors) with α -tocopherol led to a significant preservation of these cells in RP9 cell line. This study provides proof of principle that hPSC technology is useful in screening for drug responses across numerous related, yet genetically distinct retinal diseases. Even if, major advances have been made to differentiate retinal progenitors from hPSCs, the differentiation effect could vary from various hPSC lines. In a very elegant study, Ferrer *et al.*^[103] developed highly efficient methods to differentiate, expand and authenticated iPSC-RPE in parallel to their use in high-throughput assay. The RPE cells were derived from iPSCs and grown in 96- and 384-well plates. They demonstrate differential expression of eight genes in iPSCs, iPSC-derived RPE at two differentiation stages, and primary human RPE using this multiplex assay. This assay provides the basis to screen for compounds that improve RPE function and/or maturation and target disease pathways^[103].

CONCLUSION

Regenerative medicine based on stem cells is likely to make important contributions to the cure of human blindness. This is the main focus of the public creating both fears and hopes. However, it remains only the visible part of the iceberg. Indeed, as described in this review, hPSCs are essential to model disease specific conditions closed to the patient context. They contribute to the development of pharmaceutical compounds that will be identified for efficacy in disease

specific cellular of hPSCs derivatives and for which toxicity will be tested in the same cells. Moreover, hPSCs provides valuable complement to animal models by either highlighting species-specific differences or further validating the observations already made in rodents or larger animals.

Abstract

Stem cell pluripotency and differentiation are global processes regulated by several pathways that have been studied intensively over recent years. Nitric oxide (NO) is an important molecule that affects gene expression at the level of transcription and translation and regulates cell survival and proliferation in diverse cell types. In embryonic stem cells NO has a dual role, controlling differentiation and survival, but the molecular mechanisms by which it modulates these functions are not completely defined. NO is a physiological regulator of cell respiration through the inhibition of cytochrome c oxidase. Many researchers have been examining the role that NO plays in other aspects of metabolism such as the cellular bioenergetics state, the hypoxia response and the relationship of these areas to stem cell stemness.

Key words: Pluripotency; Differentiation; Nitric oxide; Metabolism; Hypoxia; Stem cell

© **The Author(s) 2015.** Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: Increasing research interest has focused on the role of nitric oxide (NO) in regulating many physiological functions such as metabolism, the hypoxia response, pluripotency, and stem cell differentiation. NO has been proven to act as a powerful agent for promoting the maintenance of cell pluripotency and survival, thus

explaining how it can act as an alternative factor for the maintenance of certain cultured cell lines.

Role of nitric oxide in the maintenance of pluripotency and regulation of the hypoxia response in stem cells. *World J Stem Cells* 2015; 7(3): 605-617 Available from: URL: <http://www.wjgnet.com/1948-0210/full/v7/i3/605.htm> DOI: <http://dx.doi.org/10.4252/wjsc.v7.i3.605>

INTRODUCTION

Nitric oxide (NO) is a short-lived free radical synthesised *via* the L-arginine to L-citrulline pathway, which is mediated by nitric oxide synthase, NOS1 (neuronal NOS), NOS2 (inducible NOS), and NOS3 (endothelial NOS)^[1], in most animal cells^[2]. NO reacts with molecules such as oxygen, superoxide or metals, nucleic acids, and proteins. NO is quickly oxidised into nitrate and nitrite, which are now considered as non-inert products because they are a source of NO through their reduction by reductase enzymes when the endogenous L-arginine/NOS pathway is dysfunctional^[3]. In addition to serving as a germicide in the immune system as part of the inflammatory response and as a neurotransmitter in the central nervous system, NO acts as a second messenger and has multiple biological effects implicated in a variety of physiological functions in mammals, such as the regulation of blood pressure *via* smooth muscle relaxation and inhibition of platelet aggregation^[4-7]. Moreover, it has been shown that it affects gene expression at the level of transcription and translation and regulates cell survival and proliferation in diverse cell types^[8,9]. Furthermore, NO plays a role in growth, survival, proliferation, differentiation, as well as in the pathology of illnesses such as cancer, diabetes, and neurodegenerative diseases^[10,11]. In addition, it has been reported that NO is involved in the control of heart functions and cardiac development^[12,13].

The presence and concentration of other free radicals are critical factors that influence the effects of NO on cellular processes. For example, it has been described that low concentrations of NO inhibit cytochrome c oxidase (CcO), which catalyses the final step of the mitochondrial transport chain, competing with O₂ in a reversible manner^[14,15]. Nevertheless, high levels of NO may cause nitrosylation of protein thiols and perhaps the removal of iron from iron-sulphur centres^[16,17]. CcO, as catalyst of the central step of oxidative phosphorylation and adenosinetriphosphate (ATP) generation, regulates cellular oxygen consumption. The physiological concentration of NO modulates CcO activity, depending on the concentration of intracellular oxygen and the redox state of CcO. This interaction between CcO and NO allows the detection of changes in oxygen concentration and the initiation of adaptive responses. This indicates that NO

might be a physiological regulator of cellular respiration and metabolism. Furthermore, NO has been described to have an important role in regulating the hypoxia response^[15,18,19].

On the other hand, it has been reported that low concentrations of NO have a direct effect on processes such as cell proliferation and survival^[8]. In RINm5F cells homeostatic concentrations of NO (1-10 µmol/L) can initiate signalling pathways implicated in survival actions^[20]. Moreover, higher NO concentrations, induced by the inflammatory response, can cause oxidative and nitrosative stress, and apoptosis. These actions are partly responsible for cell death in chronic and degenerative diseases. Pharmacological treatment with high NO concentrations promote embryonic stem cell (ESC) differentiation^[9,21-23]. However, the functional significance of high NO concentrations on differentiation *in vivo* has not yet been demonstrated.

It has been clearly shown that NO has an important role as regulator of many physiological functions, and has thus become a target of interest in the fields of metabolism, the hypoxia response, pluripotency, and stem cell differentiation. This review aims to describe the progress on understanding the role of NO in these interrelated biological processes.

MECHANISM OF NO ACTION IN STEM CELL BIOLOGY

The downstream effects of NO can be mediated in cyclic guanosine monophosphate (cGMP) dependent or independent ways^[24-26]. When acting independently of cGMP, it has been shown that NO interacts with metal complexes, oxygen (O₂), super-oxide anion (O₂⁻) and CcO^[15]. These interactions have different effects depending on the amount of NO present. Protein nitrosylation and nitration can occur when NO interacts with oxygen species, which happens more frequently at high levels of NO^[27]. On the other hand, cGMP-dependent effects are mediated by the NO receptor, soluble guanylylcyclase (sGC). sGC is a heterodimeric hemoprotein composed of alpha (sGCα) and beta (sGCβ) subunits^[28]. NO activates sGC by interacting with its hemo group and catalysing the conversion of GTP into cGMP. cGMP controls a variety of physiological effects in several tissues by interacting with downstream effectors such as a family of cGMP-dependent protein kinases (PKG), cGMP-dependent phosphodiesterases, and cyclic nucleotide gated channels^[24]. In addition, triple NOS knockout mice, where NO production is abolished, have been shown to have a reduced survival rate and lower numbers of offspring^[29]. Thus, it was proposed that NO/cGMP signalling plays a significant role in embryonic development and cell differentiation. This hypothesis has gained additional support from studies that show differential expression and function of various NO signalling components in ESCs and differentiated cells^[25,26,30]. Although it remains unclear whether the

action of NO on stem cell biology is mediated *via* the cGMP pathway, it has been shown that the effects of NO on bone marrow stem cell potency and differentiation are independent of the sGC-cGMP pathway^[31,32]. Recent studies have also shown that NO can regulate protein function *via* the nitrosylation of sGC cysteine residues^[33]. Indeed, NO has been reported to modulate transcription factor function *via* Cys-nitrosylation^[34]. It was concluded that the effects of NO on stem cell pluripotency and differentiation are independent of the sGC-cGMP pathway^[5]. The mechanisms by which NO modulates the differentiation of ESCs remain unclear. Intriguingly, NO appears to act independently of the LIF/Stat3 pathway, as NO does not induce Stat3 phosphorylation in ESCs^[8]. Moreover, the expression of Nanog is LIF/Stat3 independent, and Nanog over-expression in the absence of LIF is able to maintain ESC pluripotency^[35].

NO REGULATES STEM CELL PLURIPOTENCY AND DIFFERENTIATION

The study of stem cells has gained considerable interest in recent years because they potentially offer an unlimited source of cells for therapeutic purposes. Many research groups have participated in efforts to expand and characterise populations of ESCs and induced-pluripotent stem cells (iPSCs), and to identify ways of directing their differentiation towards particular tissue types. In this context, the identification of small molecules that act on specific cell signalling pathways involved in embryonic development might be instrumental in the design of protocols that can efficiently control cell "stemness" and stem cell differentiation.

NO is, potentially, one such small molecule, with evidence supporting a dual role for it in the control of ESC differentiation and tissue morphogenesis. It is important to note that the effects of NO on differentiation and the maintenance of pluripotency are dose dependent. Moreover, while it is generally considered to be an inducer of apoptosis^[36,37], it has also been shown to protect certain cell types from programmed cell death^[38].

NO has been demonstrated to have the potential to influence the proliferation and differentiation cascades of certain cell types but its effect varies widely from cell to cell. For example, the proliferation and differentiation of human skin cells is modulated by NO^[39], a finding that helps explain the pathophysiology of human skin diseases. NO causes growth inhibition of immortalised human oral keratinocytes and primary oral cancer cells (HN4) mainly *via* apoptotic cell death induced indirectly by stimulating the differentiation of both immortalised and malignant oral keratinocytes^[2]. This suggests that the generation of NO in human skin diseases is not directly associated with local cell destruction, in contrast to observations in several other human diseases^[39].

Our group has reported that the exposure of ESCs to

low concentrations of the NO donor, diethylenetriamine NO adduct (DETA-NO), prevents the loss of expression of self-renewal genes and blocks mouse and human ESC differentiation. Similarly, constitutive NOS3 over-expression in cells grown under LIF withdrawal conditions maintained the expression of pluripotency markers^[8]. On the other hand, exposure to high concentrations of DETA-NO promotes the differentiation of mouse ESCs (mESCs) by down-regulating *Nanog* and *Oct4*, the two master genes that control the pluripotent state^[9].

Low concentrations of NO modulate pluripotency gene expression

It has been shown that low amounts of DETA-NO (2-20 μ mol/L) delay the differentiation of human embryonic stem cells (hESCs), since the addition of NO induces an increase in the expression of *Nanog*, *Oct4* and *Sox2* to levels even higher than when cells are cultured with basic fibroblast growth factor (bFGF). Moreover, the cell surface antigen SSEA-4, which disappears following five passages under bFGF withdrawal, is retained when the growth medium is supplemented with NO. In addition, NO represses some differentiation markers (*Brachyury*, *Gata4*, *Gata6*, *Fgf5* and *Fgf8*), which are present in the absence of bFGF. Similar observations were also seen in mESCs grown in the absence of LIF and supplemented with NO, which also induced *Oct4* and *Nanog* protein expression, together with a decrease in the expression of the aforementioned early differentiation genes (Figure 1). Constitutive over-expression of NOS3 in cells cultured in the absence of LIF protected them from apoptosis and promoting cell survival^[8].

NO has also been shown to play an important role in other cell types, such as multipotent resident cardiac stem cells and adult bone marrow cells (BMCs)^[40,41]. NOS3-generated NO plays an important role in cardiomyocyte proliferation and maturation during early neonatal heart development^[42]. Furthermore, a recent study using a porcine model has shown that activation of the NO pathway directs BMCs toward a preferential cardiomyogenic phenotype and also stimulates cell proliferation^[43].

Genomic studies carried out by our group indicate that low concentrations of NO in mESCs regulate apoptosis, survival and the hypoxia response, areas that will be looked at more closely in the remainder of this review.

Regulation of differentiation by high concentrations of NO

NO plays an important role in development: It has been reported that NO may act as an essential negative regulator of cell proliferation during tissue differentiation and organ development in *Xenopus* and *Drosophila*. In addition, NO production is crucial for the establishment of ordered neuronal connections in the fly's visual system, indicating that NO affects the

Figure 1 The dual roles of nitric oxide in stem cell pluripotency and apoptosis. Low amounts of nitric oxide (NO) induce the expression of Nanog, Oct4 and Sox2. This confers protection from apoptosis by down-regulating proapoptotic genes including Casp7, Casp9, as well as up-regulating the anti-apoptotic genes Bcl-2 and Birc6. High NO concentrations promote apoptosis markers, such as Poly (ADP-ribose) polymerase degradation, cleaved caspase-3, and increased p53 protein levels. Cells expressing *Hsp70*, a cyto-protective gene, are resistant to oxidative stress and enter into a differentiation program. Differentiation events are initiated by the down-regulation of Nanog and Oct4 and the expression of definitive endoderm markers, such as *Pdx1* and *Gata4*.

acquisition of differentiated neural tissue^[7]. Moreover, blocking NO production in neural precursor cells (NPCs) isolated from the ventricular zone of postnatal mice, resulted in increased proliferation^[44]. In ESCs, it has been demonstrated that NO generation is required for cardiomyogenesis, since NOS inhibitors prevent the maturation of terminally-differentiated cardiomyocytes (CMs). Moreover, it has been shown that the differentiation of mESCs toward a cardiac phenotype is arrested by NO synthase inhibitors, which can in turn be readily rescued by NO donors^[13]. NOS2 and NOS3 isoforms are prominently expressed during the early stages of cardiomyogenesis until NOS expression starts to decline around E14.5^[13]. In the same context, undifferentiated ESCs are known to express high levels of NOS3. During differentiation, NOS3 levels decrease, whereas NOS2, NOS1, sGC α 1, sGC β 1, and PKG levels significantly increase, suggesting that NO could be involved in the early differentiation events or physiological processes of ES cells or ES derived-cell lineages^[25].

On the other hand, high DETA-NO concentrations (0.25-1.0 mmol/L) promote mESC differentiation by down-regulating Nanog and Oct4 expression. The repression of Nanog by NO is dependent on p53 activation associated with covalent modifications, such as Ser315 phosphorylation and Lys379 acetylation. In addition, exposure to high DETA-NO concentrations (0.5 mmol/L) increases the expression of definitive endoderm markers, such as FoxA2, Gata4, Hfn1- β and

Sox 17 (Figure 1)^[9].

The use of NO in differentiation protocols for the generation of different germinal lines: The first report of an efficient differentiation protocol using mESCs treated with NO was published by Kanno *et al.*^[45] in 2004. They demonstrated that NO promoted differentiation in part through its effects on cell survival, leading to the differentiation of mESCs into CMs^[45]. Other groups have identified the role of cGMP signalling components and NO in cardiac development, as well as molecules that may regulate early cardiomyogenesis in ESCs *via* NO-dependent pathways, such as polyphenol curcumin and ascorbic acid^[25,46-48]. In addition, it has been shown that other signalling pathways besides NO are involved in oxytocin-stimulated cardiomyogenesis^[49].

It has been reported that NO is involved in vascular tissue differentiation. Because of the pivotal role played by NO in the biology of endothelial cells (ECs)^[50] and its role in angiogenesis^[51], it was hypothesised that it may also play a role in endothelial development. This was tested by studying the effect of differential expression of NO signalling components, or conversely of NOS inhibition, on endothelial differentiation. These studies indicate that NO is important for later endothelial development and function, although other signalling pathways appear to play a greater role in early development^[52]. Although differentiation protocols for generating ECs from ESCs do not include NO-like active small molecules, the expression of endothelial NO synthase in these cell types is considered to be a characteristic of mature ECs^[53,54]. Moreover, it has been demonstrated that NO/cGMP signalling molecules regulate neural lineage commitment and govern neural precursor differentiation, suggesting that NO/cGMP signalling contributes to the development of neural precursors and enhances the differentiation of precursors toward functional neurons^[55,56]. Furthermore, it was reported that NO exposure to NPCs leads to a decrease in neuronal differentiation paralleled by an increase in astroglial differentiation. Neuron restrictive silencing factor1/repressor element-1 silencing transcription factor has been shown to play an essential role in the regulation of neurogenesis and is required for NO-mediated neural to glial fate induction^[57].

It has been reported that NO modulates the growth and differentiation of human erythroid and myeloid cells from CD34⁺ BMCs *in vivo*^[58], promotes bone and chondrocyte terminal differentiation^[59], stimulates pre-adipocyte differentiation in rat^[60] and mediates osteoblastic differentiation^[61].

Bone marrow multipotent adult progenitor cells (MAPCs) can be purified and cultured from humans, rats and mice. MAPCs express Oct4 and are able to differentiate into multiple cell lineages including endothelial cells and neurons^[62,63]. Importantly, NO appears to play a key role in both the maintenance of MAPC multipotency as well as in promoting their endothelial differentiation. In fact, it has been shown that NO inhibits the proliferation of MAPCs when treated with high concentrations of different

NO donors. In addition, NO promotes the endothelial differentiation of MAPCs through a cGMP-independent-mechanism^[5].

A protocol for inducing the differentiation of ESCs into definitive endoderm has been developed in our laboratory. Exposure of mESC to 0.5 mmol/L DETA-NO induces early differentiation events with the acquisition of an epithelial morphology and expression of definitive endoderm markers, such as FoxA2, Gata4, Hfn1- β and Sox 17. This phenotype was increased when cells were also treated with valproic acid for 10 d^[9].

CONTROL OF APOPTOSIS AND SURVIVAL BY NO

Many reports have indicated that NO down-regulates pro-apoptotic response in mESCs and up-regulates anti-apoptotic responses by regulating Bcl2 family proteins^[64]. mESCs over-expressing Bcl2 are characterised by long-term maintenance of an undifferentiated state and pluripotency. In addition, these cells maintain their potential to differentiate into mature cell types^[65]. This role of NO depends on its local concentration. At low non-toxic levels, NO induces resistance to tumour necrosis factor- α (TNF α)-induced hepatotoxicity^[66], inhibits Fas-induced apoptosis in B lymphocytes^[67], and modulates CD95-induced apoptosis in T-lymphocytes^[68]. Moreover, in carcinogenesis, low NO levels can promote the development and growth of tumour cells, while high levels may be toxic to them^[2]. It has been proved that low concentrations of NO donors can protect murine bone marrow stromal cells against spontaneous apoptosis^[32].

We have reported that NO generation by NOS3 overexpression and low levels of DETA-NO contribute to the survival of pancreatic beta cells through the activation of IGF-1 and insulin-induced survival pathways^[23]. Our group has also reported that low level exposure (2-20 μ mol/L) to DETA-NO protects ESCs from apoptosis. These NO actions involve: (1) decreased caspase-3 activity, combined with the degradation of Poly (ADP-ribose) polymerase; (2) decreased expression of pro-apoptotic genes, such as *Casp7*, *Casp9*, *Bax* and *Bak1*; and (3) increased expression of the anti-apoptotic genes, *Bcl-2* and *Birc6* (Figure 1). Similarly, constitutive NOS3 over-expression in cells deprived of LIF protects them against apoptosis^[8].

On the other hand, several studies show that NO induces apoptosis in different cell types, including pancreatic beta cells^[69,70], thymocytes^[71], hepatocytes^[72], among others^[73,74]. It has been reported in ESCs that the nitrosative stress induced by exposure to high levels of DETA-NO, induces apoptotic events in part of the ESC population. Other parts of the ESC population are resistant to nitrosative stress and express the cytoprotective genes, heme-oxygenase-1 and Hsp70. Moreover, the resistant cells enter into a differentiation program (Figure 1)^[9].

NITRIC OXIDE, HYPOXIA AND STEM CELL METABOLISM

As we have seen in the previous sections, there is very clear evidence indicating that NO can regulate cell pluripotency and differentiation, but, as mentioned at the beginning of this review, the molecular mechanisms behind these functions are still unclear^[8]. The metabolic profile of pluripotent stem cells (PSCs) undergoes substantial changes during differentiation. Indeed, there is a shift from glycolytic to oxidative metabolism^[75]. On the other hand, cellular response to hypoxia is also involved in the control of pluripotency. Hypoxia affects many physiological processes during the early stages of mammalian ontogeny, as it is a key feature of this stem cell niche. Moreover, it has been reported that low oxygen tension and low NO concentrations prevent the differentiation of hESC colonies and are required to maintain the majority of cells within a colony in a fully pluripotent state^[8,76]. Therefore, in this review we will address the relationship between NO and the regulation of cellular respiration, as well as how they combine to effect cellular responses to hypoxia, energy metabolism and pluripotency.

PSC metabolism

PSCs have a short G₁ cell cycle phase, which acts to limit the growth and differentiation potential of PSCs^[77]. To facilitate rapid cell duplication, PSCs must balance energetic and biosynthetic demands, which is similar to what happens in cancer cells. Several studies have shown that mESCs, hESCs and iPSCs have an elevated dependence on glycolysis under aerobic conditions compared to differentiated cell types^[78-81]. In cancer cells and human PSCs, a high glycolytic flux provides sufficient ATP and anabolic precursors for rapid proliferation, with the pentose-phosphate pathway generating ribose-5-phosphate for nucleotides and NADPH-reducing power for nucleotide and lipid biosynthesis^[82,83]. Thus, aerobic glycolysis is a common feature of PSC and cancer cell metabolism in culture^[84,85].

During PSC differentiation, energy production is mainly obtained from oxidative phosphorylation. Studies on mitochondrial morphology and mitochondrial DNA have shown that ESCs contain fewer mitochondria, in a less mature state than in differentiated cells^[83]. The maximum human PSC respiration capacity is limited and it has been suggested that low expression of electron transport chain complex IV cytochrome c oxidase subunits, which donate electrons to oxygen, may be the cause of this decreased level of respiratory activity^[86].

Efforts are being made to understand the molecular mechanisms that regulate energy metabolism in PSCs and the changes that occur during differentiation or reprogramming events. Glycolysis-regulating enzymes, including hexokinase and lactate dehydrogenase, are highly expressed in PSCs and maybe controlled by the mammalian target of rapamycin and phosphoinositide

3-kinase (PI3K) signalling pathways, which regulate glycolytic genes in other cell contexts. Glycolytic and Mitochondrial Oxidative Phosphorylation (OXPHOS) pathway gene expression and DNA methylation patterns also change during pluripotency reprogramming^[80]. A number of possible mechanisms for the low levels of respiration and ATP production in PSCs have been reported, including limited pyruvate access to mitochondria due to an inactive pyruvate dehydrogenase (PDH) complex and the expression of uncoupling protein 2 (UCP2)^[78,81]. The same mechanisms have also been found in cancer cells. The PDH-mediated conversion of pyruvate to acetyl-CoA and its entry into mitochondria is blocked in hypoxic cancer cells by hypoxia inducible factor-1 α (HIF1 α), which induces pyruvate dehydrogenase kinase 1 (PDK1) expression and inactivates PDH phosphorylation^[87]. Also, several types of cancer overexpress UCP2^[87]. In addition to these examples, other mechanisms have also been proposed for the hypoxia response of PSCs but all with the same end result, *i.e.*, reduced energy production by OXPHOS and increased flux through the PSC glycolytic pathway.

HIF regulates pluripotency

PSCs have distinct metabolic requirements and cell reprogramming requires a shift from oxidative to glycolytic metabolism^[78-81]. However, it is still unknown how stem cells activate mitochondrial oxidative phosphorylation pathways during differentiation.

Human iPSCs are usually reprogrammed from somatic cells and are metabolically similar to hESCs^[78,80]. Therefore, a metabolic switch from an oxidative to a highly glycolytic state ought to take place during iPSC formation. The dependency of stem cells on glycolysis to produce ATP could be an adaptation to low oxygen tensions *in vivo*, given that hypoxia appears to be a key feature of "stemness"^[88,89]. Supporting this idea, low oxygen levels have been shown to be beneficial for hESCs, adult stem cells^[76,90-92] and cancer cells^[93,94].

HIF-1 α and HIF-2 α have essential roles during development. Increasing evidence suggests that HIFs can activate factors involved in pluripotency and regulate stem-cell properties in both cancerous and normal cells. For example, it has been suggested that HIF-2 α activates one of the core pluripotency master genes such as *Oct4*^[76,93-98]. This and other evidence indicate that HIF is a regulator of stem cell properties^[88,99-102]. Because of this, there is now a high degree of interest in understanding the hypoxia mechanism involved in cell reprogramming and the maintenance of pluripotent states.

NO regulates mitochondrial respiration and modulates metabolic changes

It has been reported that NO interacts with oxygen bound to CcO, the last enzyme of the electron transport chain^[15]. CcO is located on the inner mitochondrial membrane and contains two heme and two copper

centres. The cytochrome's heme iron and copper molecules (in their reduced form) constitute the binding site for oxygen as it catalyses the reduction of oxygen to water. This process is related to the transport of protons into the mitochondrial inter-membrane space. In this last step, water is generated from oxygen and protons to drive the ATPase^[103]. During normoxia the enzyme is predominantly in an oxidised state, while during hypoxia the reduced state predominates. CcO has a greater affinity for NO than for oxygen, suggesting that this interaction may be significant under certain physiological conditions. If true, it would make NO a physiological regulator that acts directly on the mitochondrial respiratory chain^[14,15,104]. This reaction and its biological consequences are dependent on the redox state and turnover of CcO, the *in situ* oxygen concentration and the activity of NO synthase^[105].

At high oxygen and NO concentrations, CcO is in its oxidised state and NO is metabolised into nitrite and nitrate; whereas at lower oxygen concentrations, CcO is mainly reduced and NO is not metabolised. Thus, under lower oxygen concentrations, NO accumulates in the intracellular microenvironment, with important implications for the balance between glycolysis and OXPHOS. Interaction between NO and CcO changes the availability of intracellular oxygen and the generation of reactive oxygen species (ROS). This results in changes to cell signalling pathways, especially oxygen-sensitive ones, which determine the nature of cellular hypoxia responses^[106].

At low oxygen concentrations mitochondrial ATP generation decreases due to reduced respiratory activity. This results in increased levels of its precursor, AMP, and activation of AMP-activated kinase (AMPK), which is a critical regulator of cellular energy homeostasis and crucial for adapting to low oxygen (hypoxic) conditions^[107]. The activation of AMPK promotes catabolic pathways, including glucose transport, gluconeogenesis, respiration, and the use of oxygen-independent energy sources. Moreover, it acts to down-regulate anabolic pathways.

NO inhibits mitochondrial respiration and increases glycolysis, thus maintaining normal cellular ATP levels (Figure 2). It has been reported that astrocyte energy production is maintained following NO-mediated inhibition of CcO by up-regulating glycolysis^[19]. After the NO-induced inhibition of respiration, there is a cGMP-independent increase in the activity of 6-phosphofructo-1-kinase, a master regulator of glycolysis^[108], and an increase in the concentration of its most powerful positive allosteric activator^[109], fructose-2,6-bisphosphate (F2,6P2). Also, it has been shown that NO-induced glycolysis activation is dependent on the phosphorylation of AMPK resulting in increased 6-phosphofructo-2-kinase activity and protection against apoptosis^[19]. On the other hand, it has also been described that NO regulates HIF-1 α ^[18]. This activity of NO is an important additional mechanism by which NO might modulate cellular

Figure 2 The role of nitric oxide as a regulator of mitochondrial function, metabolism and the hypoxia response. The wide range of functions controlled by nitric oxide (NO) is a consequence of its dose-dependent dual roles. Physiological concentrations of NO inhibit cytochrome c oxidase in a reversible manner in competition with O₂. This interaction depends on NO and oxygen concentrations and the redox state of the enzyme. Because of this, it has been reported that NO might be a regulator of cell respiration, modulating metabolic changes responsible for an increase in glycolytic pathway flux to maintain energy homeostasis. On the other hand, NO can also regulate the hypoxia response through hypoxia inducible factor-1α (HIF-1α). In a normoxic microenvironment, NO induces HIF-1α accumulation in a mitochondrial-dependent and -independent manner. Hypoxia conditions promote delayed cell differentiation. These facts indicate that NO might maintain pluripotency *via* regulation of metabolism and the hypoxia response. EM: Energy metabolism.

responses to hypoxia in mammalian cells (Figure 2).

NO and the hypoxia response

Most cells respond to exposure to low oxygen concentrations through the activation of hypoxia-responsive genes such as erythropoietin, NOS2 and glycolytic enzymes. This adaptive response to hypoxia is mediated by HIF-1α, which regulates the expression of a large number of genes that control cellular responses to reduced oxygen availability^[110].

HIF is composed of two subunits, the constitutively-expressed beta-subunit (HIF-1β), and the alpha subunit (HIF-1α), whose expression is highly sensitive to oxygen concentration and accumulates rapidly under hypoxic conditions^[111,112]. HIF-1α protein degradation is tightly regulated by oxygen levels through two mechanisms, both involving HIF-1α hydroxylation. The first consists of the prolyl hydroxylation of two HIF-1α proline residues, targeting the protein for E3-ubiquitin-ligase mediated ubiquitination. This complex contains the von-hippel-lindau tumour suppressor protein (VHL), which binds to hydroxylated HIF-1α. The second mechanism is mediated by asparagine hydroxylation of HIF-1α residues located in a protein domain that is involved in interaction with the p-300 transcription activator. The result of this hydroxylation is the inhibition of target genes. Under hypoxic conditions, the hydroxylation of HIF-1α does not occur. This allows HIF-1α to dimerise with HIF-1β and translocate to the nucleus. Once in the nucleus, the dimer recruits the p300 and CBP co-activators, which induces the expression of its transcriptional targets, *via* binding to hypoxia-responsive elements (HERs), located in the

promoter region of target genes^[113,114].

Mitochondria play an important role in sensing cellular oxygen concentrations. Studies using pharmacological inhibitors have shown that the hypoxic regulation of HIF-1α is dependent on mitochondrial function through inhibition of the respiratory chain^[115,116]. As NO inhibits CcO, it is possible that NO modulates the hypoxia response through HIF-1α.

NO regulates the accumulation of HIF-1α

Numerous studies have shown that NO affects HIF-1α accumulation. However, there is some controversy as to whether it promotes HIF-1α stabilisation^[117-119] or HIF-1α destabilisation^[120-122]. Moncada *et al.*^[6] demonstrated that NO-induced HIF-1α regulation occurs *via* both mitochondria-dependent and -independent pathways (Figure 2). This work was performed using the HEK-293 cell culture model where NO was generated inside cells in a finely controlled manner using a tetracycline-regulated inducible NOS2 expression system. They demonstrated that NO concentrations of 400 nmol/L prevented the accumulation of HIF-1α under hypoxic conditions, in a mitochondria-dependent manner. This study, also showed that intracellular high NO levels (> 1 μmol/L) always resulted in HIF-1α stabilization, under both hypoxic and non-hypoxic conditions. They found that activation of NOS2 sufficient to yield approximately 1 μmol/L NO, at elevated oxygen concentrations, resulted in significant HIF-1α accumulation, even when there was sufficient oxygen for prolyl hydroxylation-mediated HIF-1α degradation. This observation and those described by other authors^[117-119,123], strongly suggest that HIF-1α accumulation by NO is independent of oxygen

concentration. Moreover, this activity was shown to be independent of any action on the respiratory chain, since it was not affected by compounds that inhibit mitochondrial respiration at different stages and also occurred in cells lacking a functional respiratory chain. In this case, it is possible that the stabilisation of HIF-1 α was the result of S-nitrosylation of thiol groups of the HIF-1 α protein^[119,123] or by the direct inactivation of prolyl hydroxylases (PHD) by NO as suggested by Metzen *et al.*^[124].

NO inhibits HIF-1 α accumulation in a concentration-dependent manner in cells subject to a low oxygen concentration (3%O₂) which would normally allow HIF-1 α levels to increase^[18]. Under hypoxia, endogenous NO (400 nmol/L) destabilises HIF-1 α by inhibiting mitochondrial respiration, thus increasing the cytosolic oxygen concentration where PHD2 is mainly located^[125,126].

Unlike the destabilising effect of NO on HIF-1 α , its effect promoting HIF-1 α accumulation was correlated with inhibition of cell respiration and could be mimicked by all mitochondrial respiration inhibitors, indicating that it is dependent on the respiratory chain. However, under normoxia (21%O₂) and 1 mmol/L of DETA-NO, HIF-1 α accumulates in a way that mimics the stabilising effect observed at high NO concentrations under hypoxia. Interestingly, this explains why, although all other inhibitors completely destabilise HIF-1 α , NO does not, since its stabilising effect is apparent even at intermediate NO concentrations, something not seen for the other inhibitors. It has been proposed that the destabilising effect of NO on HIF-1 α may be due to the inhibition of Complex I-dependent generation of superoxide anion (O₂^{•-}), and consequently, peroxynitrite (ONOO⁻)^[122]. In conclusion, at low concentrations, NO has the ability to destabilise HIF-1 α under hypoxia, an effect that is mitochondria-dependent, while at high concentrations, it can stabilise HIF-1 α in a mitochondria-independent manner. It is also possible that the effect of low NO concentrations is part of its physiological regulatory mechanism related to the inhibition of CcO. The stabilisation of HIF-1 α by high NO concentrations and its synergy with the hypoxic stabilisation of HIF-1 α may play a role in pathological conditions such as inflammation, degeneration and cancer, in which high concentrations of NO, hypoxia and HIF-1 α stabilisation have been described^[18,125,126].

There are various potential mechanisms by which NO regulates HIF-1 α activity. First, NO donors, as well as other growth factors^[127,128], stimulate HIF-1 α translation by activating the PI3K/Akt pathway^[129]. Second, the NO donors S-nitrosoglutathione (GSNO) and S-nitroso-N-acetylpenicillamine (SNAP) increase HIF-1 α accumulation by inhibiting the interaction between VHL and hydroxylated HIF-1 α , without blocking PHD2-mediated hydroxylation^[124,130,131]. Third, biotin switch assays have revealed that endogenous and exogenous NO produce the S-nitrosylation of the HIF-1 α trans-activation domain (amino acids 727-826)^[132,133] and the oxygen-dependent degradation domain^[123,134]. Fourth,

direct inhibition of HIF-1 α asparagine hydroxylation activity by SNAP permits interaction between HIF-1 α and p300/CBP^[130]. Fifth, the dependence of VHL recruitment on proline hydroxylation^[124] is controversial, as some authors reported that GSNO and SNAP inhibit it, while others have shown that SNP, PAPA NONOate, and MAHMA NONOate increase it^[135]. However, using a specific antibody, Li *et al.*^[134] were able to detect proline-hydroxylated HIF-1 α . It was also reported that mouse HIF-1 α Cys533 is nitrosylated and that this S-nitrosylation does not inhibit proline-hydroxylation^[134].

Park *et al.*^[130] concluded that SNAP blocks VHL recruitment but not HIF-1 α proline hydroxylation. This inhibitory effect is reversed by reducing agents such as vitamin C and Fe (II)^[130]. They proposed that NO increases p300/CBP recruitment, not by HIF-1 α Cys800 nitrosylation, but by inhibiting HIF-1 α *via* asparagine hydroxylases. They also suggested that SNAP inhibited this enzyme by oxidation of the Fe (II) in its catalytic core or by nitrosylation of some cysteine residues^[136].

CONCLUSION

In this review we have studied in detail the actions of NO on specific cell signalling pathways involved in embryonic development, placing emphasis on the regulation of the hypoxia response. We have extensively analysed the dual role of NO. Low NO concentrations delay stem cell differentiation, inducing the expression of Nanog, Oct4 and Sox2, and the activation of survival pathways. At high concentrations, NO induces differentiation events with the expression of early differentiation markers as well as promoting apoptosis.

Due to these activities, NO represents a promising tool for culturing pluripotent cell lines in an undifferentiated state, as it has been proved that it consistently promotes the maintenance of pluripotency and survival. Thus, NO could enhance the pluripotency-promoting activities of factors such as LIF or bFGF. Moreover, studies based in the generation of chemically-defined xeno-free media using NO to maintain pluripotency are being carried out by our group, which would not only reduce costs, but also would avoid animal contamination issues.

Stem cell culture under hypoxic conditions helps prevent spontaneous differentiation. This is relevant for the design of better strategies for directing differentiation towards specific cell types. The generation of hypoxic cell culture microenvironments can be costly, such as maintaining bioreactors with hypoxic atmospheres. Knowing how NO regulates cellular respiration opens up the possibility of using exposure to low NO levels to mimic the hypoxia response under aerobic conditions by inducing HIF-1 α . Activation of this master hypoxia response regulator would up-regulate glycolytic genes and help maintain energy homeostasis.

On the other hand, high NO levels can be used to develop differentiation protocols for differentiating pluripotent cells into the three germinal lines (ectoderm, mesoderm and endoderm). In this context, NO has been

used to differentiate cells to cardiomyocytes, vascular and endothelial tissues, neurons, astrocytes, erythroid and myeloid cells, bone, chondrocytes and definitive endoderm. To sum up, the studies reviewed here underline the diverse range of potential applications for NO in stem cell biotechnology.

Abstract

Intracerebral hemorrhage (ICH) is a very complex pathology, with many different not fully elucidated etiologies and prognostics. It is the most severe subtype of stroke, with high mortality and morbidity rates. Unfortunately, despite the numerous promising preclinical assays including neuroprotective, anti-hypertensive,

INTRODUCTION

Marginal or no success was achieved from decades of research for therapeutic alternatives for intracerebral hemorrhage (ICH)^[1,2]. Despite the numerous promising preclinical assays including neuroprotective, anti-hypertensive, and anti-inflammatory drugs, only symptomatic treatments are currently available^[2,3], which motivates the search for new alternatives. In this context, cell therapy emerged as a promising tool^[4-6]. However, more than a decade has passed, and there is still much to be learned not only about stem cells, but also about ICH itself, and how these two pieces come together. It is clear that achieving a more detailed knowledge of each involved element is crucial to obtain better results.

INTRACEREBRAL HEMORRHAGE: A SEVERE AND HETEROGENEOUS PATHOLOGY

Epidemiology

Cardiovascular diseases (CVDs) are the leading cause of morbidity and mortality worldwide. In 2008, nearly 17.3 million people lost their lives because of CVDs (30% of all deaths); of these, 6.2 million (35.8%) were to cerebrovascular accidents^[7], alternatively referred as stroke. Among CVDs, coronary artery disease is responsible for the highest mortality rate on a worldwide basis, followed by stroke^[7]. However, stroke mortality rates surpass those of the coronary artery disease in some world regions, like East Asia, Africa, and South America^[8].

There are two types of stroke: ischemic and hemorrhagic. This review will focus on nontraumatic ICH, which corresponds to spontaneous leakage of blood within the brain parenchyma or ventricular spaces^[1]. ICH is the most lethal subtype of stroke, often causing immediate death^[9]. Secondary brain injuries may lead to delayed fatality when death does not occur shortly after the onset. One-year and five-year survival are estimated to be around merely 46% and 29%, respectively^[10]. Beyond that, surviving patients are usually left with many limitations in motor and cognitive functions. Overall, ICH is less frequent than its ischemic counterpart, but the proportion fluctuates depending on the ethnic and racial group. Among Chinese people, for example, ICH accounts for about 33% of stroke cases, vs 12% in white populations^[11]. On the same hand, global incidence of ICH per 100000 person-years is estimated to be around 24.6, reaching 51.8 in Asian populations^[12].

Risk factors

High blood pressure is the major risk factor for CVDs^[13], particularly ICH^[14,15]. As a matter of fact, it is estimated that about 50% of ICH cases are caused by chronic

hypertension^[1]. There is a well established liaison between regular consumption of alcoholic beverages and high blood pressure, being this effect independent of age, body mass, smoking habits and physical activity^[16-18]. Hypertension and ICH incidence are also linked to other lifestyle-related risk factors, such as smoking^[19,20], physical inactivity^[21], and high dietary sodium and/or fat consumption^[22,23]. About 20% of cases are due to amyloid angiopathy, being this the second cause of ICH^[24]. Amyloid deposition incidence is primarily associated with increasing age^[25-27], but genetic factors also play an important role^[28]. Oral anticoagulant intake is other important risk factor, which not only increases ICH risk, but also has higher intrinsic death rates^[29,30]. Other relevant risk factors are obesity, diabetes mellitus, high blood cholesterol and other lipids, brain tumors, aneurysms, cerebrovascular malformations, cavernous angiomas, and arteriovenous fistulae^[23,31].

Pathophysiology

As previously stated, hemorrhagic events in brain parenchyma or ventricular spaces are included in ICH. Bleeding associated with chronic hypertension usually originates from microaneurysms near or at bifurcations of penetrating brain arterioles which emanate from basilar arteries or anterior, middle, or posterior cerebral arteries^[1,32,33]. In most cases, intraventricular hemorrhage is a consequence of ICH, resulting from hematoma expansion to the ventricular space^[1]. This phenomenon increases mortality in nearly five times^[34]. In more rare occasions, hematoma may extend to the subarachnoid space^[31]. Amyloid angiopathy associated ICH is commonly lobar, often extending into the subarachnoid space and ventricles^[35]. Size and location of hematoma are determinant factors in the disease outcome^[36]. For example, even though patients commonly experience continued bleeding or rebleeding^[37], the latter phenomenon is more recurrent in amyloid angiopathy-derived ICH^[38].

Initial injuries are consequent of mechanical disruption of adjacent brain tissue by physical compression due to hematoma formation^[1,31,39]. Most hematoma enlargement occurs in the first hours following ictus, but this growth can extend for many hours^[40,41]. Disruption of the blood-brain barrier implies in the formation of plasma-derived perihematomal edema^[42], which grows rapidly in the first two or three days and reaches full extension about fourteen days after ICH onset^[43,44]. Edema evolution can be described in three phases^[45]. In the first few hours, hematoma expands and retracts as a result of coagulation, depositing serum molecules in the surrounding tissue. In two to three days, inflammatory mediators come off from circulation. In the third and last phase, erythrocytes suffer degradation, which culminates in hemoglobin toxicity. Thrombin and iron from erythrocytes play major roles in secondary injuries^[9,46]. In fact, iron overload seems to be related to the formation

of the perihematoma zone^[47]. This area surrounds the edema and includes viable but very vulnerable tissue^[45].

CELL THERAPY IN INTRACEREBRAL HEMORRHAGE ANIMAL MODELS

Rat: The animal model of choice

Most of the present ICH pathophysiology knowledge derives from studies in animal models. After all, animals assays offer many research advantages, such as the possibility to work with homogeneous groups by the control of variables concerning the subjects (*e.g.*, age, weight, feeding, activity, genetics, *etc.*), and the ICH itself (*e.g.*, time and site of the injury onset and its intensity). Moreover, this kind of study permits various types of biological assays from surviving subjects at any stage of the pathology.

By far, the majority of ICH studies on animals are performed on rodents, mostly on rats. This choice is understandable, once rats are cheap and convenient to house, easy to manipulate, have a plethora of related products for the most diverse purposes, and have a well described anatomophysiology, which, overall, shares considerable similarities with humans in cerebrovascular parameters^[48]. However, there are some important differences that should not be underestimated or neglected.

White matter paucity in rat brains limits the similarities with the human condition^[32]. Human brain proportion of white/gray matter shares more similitude with that of porcines and primates, but both are incomparably more expensive and complicated to handle if compared to rats^[49]. In addition, if compared to humans, rats also have anatomical disparities in brain perforating arteries, as well as anatomical and biochemical differences in the basal ganglia^[50]. It is important to notice that both structures have fundamental involvement in ICH model, especially considering that the commonest experimentally induced ICH is intrastriatal. Actually, this fact is probably included among the reasons why ICH prognostic differs so much in some parameters between rats and humans (more on these matters in the next section). Thus, even though rodents provide advantages as experimental models, multiple species should be used for more trustworthy results^[51]. Additionally, rats and mice are also different in many anatomophysiological aspects^[52], and tests should not be limited to either of the two.

Intracerebral hemorrhage replication

Bacterial collagenase injection is the most widespread method to induce ICH in rats, followed by autologous blood injection (ABI). The latter is one of the earliest methods developed to replicate ICH in rats. In this model, blood is collected from a superficial vessel and is injected directly into the brain, usually in the striatum^[53]. The application of this protocol should be limited to

blood toxicity and edema formation studies, once very important aspects of ICH pathology are absent, like small vessel rupture and hematoma expansion^[54]. Moreover, especially in rats, ABI implies in exaggerated inflammatory response as a consequence of hemoglobin crystallization^[55].

Collagenases are enzymes that break collagen peptide bonds^[56]. Consequently, intracerebral injection of bacterial collagenase leads to the breakdown of the basal lamina of blood vessels, establishing the leakage of blood within the brain^[57]. Through this method, rebleeding is present and functional impairments are more long lasting than that of ABI model^[57]. Also, application is simpler^[49]. However, dissolution of endothelial basal lamina causes ICH in an unnatural manner^[32].

Even though collagenase injection model mimics ICH with more success than ABI, both show relevant limitations^[54]. As previously stated, the standard collagenase and blood site of injection is the striatum, which differs importantly from the human counterpart in biochemical and anatomical features^[50]. In top of that, ICH is often not restricted to single anatomical regions in humans, while this is what is achieved with both models^[58]. Lastly, but certainly not least, both models comprise intracerebral injections. Therefore, some significant ICH unrelated injuries must be done in order to access the target structures: animal scalp and periosteum must be cut open, a hole must be drilled in the skull, and most importantly, a needle must perforate all brain superjacent structures^[59].

As tacit in the Pathophysiology section of this review, ICH is a disease with multiple etiologies, which directly affect the prognostic. More than that, the role played by the ICH causing factors is probably unrestricted to the way the pathology is going to have a start, but is also determinant how it is going to evolve^[49]. For example, it is deductible that ICH disrupted by anticoagulant intake develops differently, as hematoma might probably include uncoagulated blood^[60].

Even though ICH affects mostly humans with chronic hypertension and advanced age, preclinical studies are predominantly conducted using young and healthy animals. The absence of comorbidities presumably implies in unrealistic outcomes and weaker translational power. Aware of this limitation, many efforts have been made on the last years to develop and use models with characteristic risk factors. ICH related functional outcomes are known to be more severe and long lasting in older^[61-63] and chronic hypertensive^[64] rats. The latter develop spontaneous ICH with location and distribution consistent to what is observed in hypertensive humans^[32]. However, spontaneous chronic hypertension-derived ICH is hard to model, once animals tend to develop ischemic stroke instead of ICH^[65].

Prognostic analysis of experimentally induced ICH

ICH in rats and humans have remarkably different prognostics. Human ICH is generally followed by

important long lasting or permanent cognitive and motor impairments. In contrast, rats subjected to ICH exhibit no (or at least not long lasting) cognitive deficits^[58,66]. Brain structural disparities might play a crucial role in this matter, implying in different affected structures^[58]. Motor function impairments in rats are present and well described, but undergo notable recovery in few weeks^[67]. Moreover, in rats, edema reaches full extension three to four days after ICH onset^[68], whereas in humans it takes weeks^[69]. Although there is much to be discovered in this matter, rat superior neurogenesis and/or neuroplasticity may explain these dissimilarities^[70].

Many behavioral tests are used to assess ICH outcome. Among the most used are the modified limb placement test (mLPT)^[71] and the modified neurological severity score (mNSS)^[72]. In both tests, rats are subjected to a set of simple sensorimotor tasks that evaluate different aspects of neurological function. A score is attributed to the performance in each task, resulting in a final sum that ranges from 0 to 14. Both mLPT and mNSS are theoretically consistent, simple to perform, and cost-free, dismissing the need for complex training and special equipments. However, both tests should be always applied by blinded investigators, preferably the same ones for every session. If such attention is present, it is commonly unknown, as it is not always mentioned. Evaluating rat behaviors through mLPT and mNSS can be considerably subjective and interpretative tasks, relying strongly on the observer sensitivity and judging parameters. Importantly, the small score amplitude (0-2 in mLPT and 0-1 in mNSS) attributed to each parameter may lead to significant variations in the final result. Thus, expectations of any nature and level should be absent in the assigned investigator for trustworthy results. Additionally, more than one single test should be applied for more solid assertions.

Last but not least, pathophysiological features of ischemic and hemorrhagic stroke diverge in many ways^[73]. Thus, great caution should be taken when comparing findings from each disease.

Stem cell types and clinical applications: An ever-emerging science

Stem cells are characterized by ability of self-renewal (production of identical copies of themselves) and capability to differentiate into distinct functional cells. Cells with capability to differentiate into any body cell are called totipotent. These cells are only found in the earliest stages following fertilization. Embryonic stem cells (ESCs) are mostly pluripotent, meaning that they are able to mature into cells of the three germ layers (endoderm, mesoderm, and ectoderm). Unfortunately, ESCs are very difficult to isolate, and their use is very limited and even avoided due to ethical, social and religious concerns^[74]. Induced pluripotent stem cells (iPSCs) were developed to work around ESCs major issues. iPSCs are generated from somatic cells reprogrammed by the introduction

of few defined factors^[75]. However, as embryonic stem cells, iPSCs can potentially generate teratomas after transplantation^[76-78]. It happens as a result of their propensity for uncontrolled self-renewal and triploblastic differentiation^[79].

Somatic stem cells are multipotent, thus possessing the ability to differentiate into only certain cell types. As they can be found in adult tissues, they are sometimes referred as "adult stem cells". This term, however, is misleading and should be avoided, once the embryo starts containing somatic stem cells shortly after implantation^[80]. Mesenchymal stem cells (MSCs) are somatic stem cells present in virtually all organs^[81]. They are able to differentiate into mesodermal cell lineages, like osteoblasts, chondrocytes, adipocytes, and myoblasts^[82,83]. Some groups, however, showed that MSCs can be induced to differentiate into neurons, but is debatable if they are functional^[84]. Bone marrow and adipose tissue have been the preferred sources for MSCs, and cells from each origin are biologically different^[82,85]. Bone marrow-derived stem cells (BMSCs) were the first to be discovered, and are the most tested in preclinical assays. However, if compared to BMSCs, adipose-derived stem cells (ASCs) are simpler and less invasive to harvest, as large amounts of these cells can be obtained *via* liposuction with local anesthesia only^[86,87]. If ASC allogeneic applications become someday proven to be safe, fat from liposuctions can be utilized for stem cell cultures instead of being discarded. Moreover, adipose tissue yields more stem cells than any other source^[88]. For example, ASCs are more frequent in adipose tissue than BMSCs are in bone marrow in a 100 to 500 fold difference^[86]. Although considered very promising^[89,90], ASC use is relatively recent if compared to BMSCs. Thus, more studies are needed in order to effectively evaluate advantages of one over another on particular purposes, concerning efficacy, safety, *etc.* Neural stem cells (NSCs) are multipotent and can differentiate into neurons, astrocytes, and oligodendrocytes. Even though NSCs might initially sound as the most appropriate for nervous system diseases like ICH, the isolation of these cells is a complicated and delicate procedure^[91].

Umbilical cord-derived stem cells (UCSCs) are the most used cells from perinatal tissues. Controversy still exists if UCSCs are MSCs or MSC precursors, as they differ in morphological and behavioral aspects^[83]. UCSCs are harvested from umbilical cord or umbilical cord blood (UCB) from newborns^[92,93], which are presently treated as medical waste. Thus, the isolation method completely avoids donor morbidity^[94]. UCSCs are very abundant and show high proliferative capacity^[94,95]. UCB contains mononuclear cells that are mostly leucocytes, but it also contains UCSCs. Importantly, 0.6% of umbilical cord blood mononuclear cells are multipotent stress-enduring (Muse) cells. Muse cells are a non teratogenic pluripotent cell type that was recently isolated not only from UCB, but also from dermal fibroblasts, bone marrow, and adipose tissue^[79,96,97].

Autologous stem cell transplantation guarantees the absence of immune rejection. However, depending on the circumstances, this might not be feasible. For instance, somatic stem cells require several weeks in culture to achieve sufficient proliferation^[91]. Additionally, the harvested cells themselves may not be appropriate in number and/or quality for therapeutic purposes (e.g., in case of elder patients). More than that, harvesting might be a painful and complicated procedure to the patient (e.g., BMSCs). Cells from perinatal tissues could be used for autologous administration, but this practice would be very resource demanding, comprising long term storage of the isolated cells in freezers until they are eventually needed^[98].

It is not consensual if allogeneic delivery of MSCs would lead to immune rejection. Actually, many findings with somatic stem cells showed that they possess immunosuppressive action, not being rejected by the host organism^[99-102]. If lack of immune rejection becomes confirmed for allogeneic somatic stem cell transplants, this would certainly represent the preferred option, making it possible that cultured cells are readily available for the patients. ESCs, by the other hand, are known to trigger immune responses following allogeneic transplantation. Taking that into consideration, research is being conducted in order to inhibit donor-host immune reactions^[103].

Stem cell therapeutic effects and underlying mechanisms

It was in the beginning of the last decade that stem cells started to be considered as a treatment for neurological disorders. Back then, the expected therapeutic mechanism was very simple: stem cells were expected to repopulate the damaged tissue, differentiating into functional neurons and glial cells^[104,105]. Actually, a considerable number of earlier studies have mistakenly concluded that MSCs and UCBCs could in fact differentiate into functional mature neurons and astrocytes, but these findings were contested^[84,106]. NSCs are the only type of somatic stem cell capable to differentiate into functional mature nervous cells. But again, probably it is not the main action underlying NSC therapeutic effects. The underlying mechanisms are presently recognized to be far more complex, and are still not fully understood.

Evidence show that therapeutic effects primarily emerge from the release of trophic factors, cytokines, and microRNAs that stimulate endogenous mechanisms of repair^[106-109]. In consonance with this, in a recent work, Jeon *et al*^[110] reported a modest, yet significant recovery in rats subjected to ICH treated only with ASC extract. Additionally, different research groups already reported that endogenous NSCs are stimulated and recruited to the injury site in response to exogenous stem cell injection^[111,112]. In fact, the injury itself seems to stimulate stem cells, exogenous and endogenous, to migrate to the perihematoma perimeter^[113-117] and to promote proliferation and plasticity^[108,111,118,119].

These restorative reactions are probably consequent of the secretion of trophic factors, which is the most likely mechanism underlying apoptosis prevention as well^[111,113,119-121]. The same is true to the intensified angiogenesis, presumably due to elevated VEGF release^[66,113,122,123]. Hematoma area reduction is also often observed^[66,115,119,121,124], but not always^[112-114,117]. Likewise, decrement of brain edema volume is a commonly stated benefice^[113,125,126]. Stem cells are also seen to exert important anti-inflammatory effects in the injury site^[66,113,125,126], being known to modulate the action of dendritic cells, and B and T lymphocytes^[127-129]. Stem cells were linked to astrocyte and microglia response modulation as well^[130]. In fact, recent findings showed that some glial cells within the oligodendrocytic and astrocytic lineages present progenitor and neural stem cell functions, with active response to brain injury^[131,132].

Preclinical studies: an heterogeneous approach for an heterogeneous disease

Present available data concerning stem cell therapy for ICH derives from investigations conducted with notably different approaches. Many stem cell administration routes have been tested, but it remains unclear which is the best option. Findings in ICH model support that cervical vein delivery is inefficient^[133], whereas good outcomes were already observed following stem cell delivery in brain parenchyma^[66,111,113-116,121,126,134-137], lateral ventricle^[120,133], tail vein^[117,119,122,124-126,138,139], and carotid artery^[133,140,141]. However, each one of these alternatives has drawbacks. Intracerebral and intracerebroventricular routes are very invasive alternatives, hardly representing the best clinical options. In this sense, intravascular injections are incomparably more feasible and less troublesome, and allows injections with higher cell doses^[142]. However, due to their size, stem cells were reported to get trapped in the lungs, liver and spleen and to cause embolisms, following tail vein and intracarotid injections, respectively^[143-145]. Importantly, the latter adversity can be surpassed with slower injection rates^[143], a generally overlooked variable. It was reported that carotid artery delivery favors cell migration to the brain if compared to tail vein delivery route^[146]. However, no differences in this aspect were seen when comparing carotid artery and jugular vein stem cell injections^[147]. Additionally, concerning intravascular transplantation, the potential of other systemic interactions is of unknown impact, being the safety of this route debatable.

Recently, efforts have been devoted to the development of new cell administration routes. Among these, intranasal cell delivery represents a promising alternative for the treatment of neurological disorders. Not only intranasal administration is simple and noninvasive, but also avoids potentially dangerous systemic interactions^[148-151]. Positive results were reported following the delivery of growth factors^[152-154] and MSCs^[155-158] following experimentally-induced ischemic stroke in rodents. To our knowledge to

date, no intranasal delivery trials were conducted on the treatment of ICH using MSCs.

Some comparative studies using different routes have been made on ischemic stroke models. Findings comparing cell migration and possible systemic adversities resulting from different stem cell injection routes represent potential lessons to apply in future ICH model investigations.

Stem cells have been delivered at many different times after experimental ICH onset, ranging from one hour to two months following ictus (Table 1). Apparently, earlier NSC transplantation (acute phase) is particularly important in intravenous delivery^[126]. Interestingly, in the same study, time matter seemed to be indifferent when stem cell injection was intracerebral. Also working with NSCs, other group tested the effects of different carotid artery injection times. Acute phase delivery, in this case, returned the worst therapeutic effects^[140]. In late transplantation studies, intracerebral stem cell implantation was performed only two months after ictus. Even so, good functional and morphological outcomes could be observed^[111,136]. It is also important to keep in mind that ICH dynamics in rats and humans, as previously discussed, are clearly different in many aspects, including temporality. Thus, time windows in these different organisms are proportionally divergent, e.g., 24 h after ICH onset, rodents and humans suffer

from different pathological actions, due to the different paces in the development of the pathology.

The ideal amount of cells and vehicle to be injected is another unanswered question. The only studies performed with variations in that parameters used the tail vein route^[122,122,124]. BMSC injection of 1 million cells was more therapeutically effective than half of it^[122,122]. UCMCs were also more effective in the highest tested amount (16 million cells), reducing injury area with more success^[124]. However, apart from this studies, the most common quantity injected in the tail vein is of 3 million cells, suspended in 1 or 2 mL of saline solution^[117,119,124,125]. The amount of intracerebrally grafted cells varied up to 25 fold among studies^[66,113,115,121,136]. Interestingly, in general, the vehicle volume is not necessarily proportional with the number of cells in suspension (Table 1).

Most of the aforementioned findings, however, are very hard to counterweigh and take as conclusive. Not only the time window after ICH varied between studies, but also the cell type, amount, and injection site. Moreover, it must be never forgotten that rats and humans are different organisms, and studies in more models must be performed before calculating the extrapolation to human applications. As stated in previous sections, different stem cell types have different attributes, and knowledge is in its youth about how all these divergences may affect ICH outcome.

CONCLUSION

In this review, we highlighted that there is still much to be learned about ICH and stem cells, both individually as interacting with each other. The approaches adopted by different groups were diverse, concerning not only the outcome evaluation, but also ICH induction and stem cell treatment protocols. Although it is important to perform tests under diverse conditions, more comparative studies should be motivated, including different times for interventions, stem cell types, quantities, and delivery sites. Homogeneity of all implicated variables except the one to be tested is imperative for the improvement of our understanding, preventing waste of hopes and resources in forthcoming human ICH trials.

vessels and bone cells. Therefore, cells that participate in vasculogenesis and osteogenesis play a pivotal role in bone formation during prenatal and postnatal periods. Nevertheless, spontaneous healing of bone fracture is occasionally impaired due to insufficient blood and cellular supply to the site of injury. In these cases, bone regeneration process is interrupted, which might result in delayed union or even nonunion of the fracture. Nonunion fracture is difficult to treat and have a high financial impact. In the last decade, numerous technological advancements in bone tissue engineering and cell-therapy opened new horizon in the field of bone regeneration. This review starts with presentation of the biological processes involved in bone development, bone remodeling, fracture healing process and the microenvironment at bone healing sites. Then, we discuss the rationale for using adult stem cells and listed the characteristics of the available cells for bone regeneration. The mechanism of action and epigenetic regulations for osteogenic differentiation are also described. Finally, we review the literature for translational and clinical trials that investigated the use of adult stem cells (mesenchymal stem cells, endothelial progenitor cells and CD34⁺ blood progenitors) for bone regeneration.

Key words: Bone tissue; Mesenchymal stem cells; Tissue engineering; Osteogenesis; Angiogenesis; Endothelial progenitor cells

Core tip: Mesenchymal stem cells and blood derived progenitor cells have the potential to open new horizon for the treatment of bone defects. Numerous preclinical and clinical studies demonstrated angiogenic and osteogenic potential of these cells. Additional research is required in order to improve isolation and expansion techniques, as well as long term studies to follow the safety of this cellular approach.

Abstract

Bone is a highly vascularized tissue reliant on the close spatial and temporal association between blood

INTRODUCTION

Incidence of bone fractures that require hospitalization is estimated to be 1 million in the United States alone. About 5%-10% of these fractures present delayed healing or nonunion and represent a major treatment challenge in orthopedic reconstructive surgery^[1]. Current gold standard surgical technique for reconstruction of large bony defects involves autologous bone blocks harvested from the fibula, iliac crest, scapula, and radius^[2-5]. These procedures require extended hospitalization and a secondary donor site with associated morbidity and complications. In addition to their surgical complications, these techniques are unpredictable and associated with significant graft resorption^[6,7]. As an alternative to autologous bone block, recent developments in bone tissue engineering, gene and stem cell therapy are currently examined. A tissue engineering approach offers several potential benefits, including the lack of donor site morbidity, decrease in technical sensitivity of the repair, and most importantly, the ability to closely mimic the *in vivo* microenvironment in an attempt to recapitulate normal bone development^[8].

BONE COMPOSITION

The bone comprises of inorganic and organic components. Two thirds of the bone volume consists of inorganic mineral salts: calcium, phosphate, carbonate, citrate, hydroxyl and ions (magnesium, sodium and fluoride) in the form of hydroxyapatite crystals^[9]. The organic component is composed of 99% collagen type-1^[10] as well as several growth factors osteocalcin, osteonectin, phosphoproteins, proteoglycans and bone morphogenic proteins (BMPs)^[11].

In addition, the bone consists of cellular components: pre-osteoblasts, osteoblasts, osteocytes and osteoclasts. Osteoblasts originate from pluripotent mesenchymal cells, characterized as mononucleated, cuboidal cells located at bone margins. Their life span is between 3 d (in young rabbits) and 8 wk (in humans). Osteoblasts produce the inorganic bone matrix (un-mineralized osteoid) and supervise the mineralization process by secretion of alkaline phosphatase. At the end of the process several osteoblasts remain entrapped in the matrix that they have secreted, and develop into osteocytes^[12]. These cells are considered mature osteoblasts. Only 10%-20% of the osteoblasts develop into osteocytes. Osteocytes are smaller than osteoblasts, have a larger nucleus to cytoplasm ratio and have a large number of

processes which provide intercellular communication. Osteocytes are thought to be the cells responsible for bone regeneration, thus their presence is crucial^[13,14]. The process of bone formation is followed by bone resorption. This process is carried out by osteoclasts that secrete enzymes and reduce the pH at the resorption site. Osteoclasts are large, multinucleated, polarized cells with a life span of 15-20 d. These cells originate from hematopoietic precursors of monocytes in the bone marrow, thus comprise phagocytic properties^[15].

EMBRYONIC BONE DEVELOPMENT

The development of bone tissue is controlled by tightly regulated programs of cell proliferation, differentiation, survival, and organization. The bone tissue derives from mesenchymal condensations in which osteochondral progenitors give rise to either chondrocytes to form the cartilage or osteoblasts to form the bone^[16]. Within the mesenchymal condensations, cells differentiate into chondrocytes or osteoblasts, and form cartilage and bone under the control of various transcription factors. Differentiation of mesenchymal cells into chondrocytes leads to the production of cartilage structures of the future bones of all the skeleton, except for the craniofacial skeleton and the clavicle. Through the process of endochondral ossification, the cartilage structures are subsequently replaced by bone and bone marrow. In the craniofacial skeleton and the clavicle, differentiation of mesenchymal cells into osteoblasts produces intramembranous bones directly from the mesenchymal condensations through the process of intramembraneous ossification^[17]. It is well known that bone mineralization during endochondral and intramembraneous ossification is tightly coupled with angiogenesis^[18].

BONE REMODELING

Bone remodeling occurs throughout life. During this process small amounts of bone are resorbed by the activity of osteoclasts, followed by the recruitment of osteoblast precursors that differentiate and replace the amount of the removed bone^[19]. The remodeling process takes place at anatomically distinct sites, termed basic multicellular units, that are dispersed throughout the skeleton^[20]. An exact coupling between bone resorption and bone replacement is essential for successful bone remodeling. Thus, bone resorption by osteoclasts has to be matched with the generation of osteoblasts from precursor cells in order to replace the resorbed bone^[21]. In the coupling between bone resorption and bone formation several factors are involved, such as growth factors released from the matrix, secreted and membrane-bound factors of osteoclasts, signals from osteocytes, signals from immune cells and signaling taking place within the osteoblast lineage^[22].

FRACTURE HEALING AND TREATMENT OF NONUNION

The biologic process of fracture healing is complex and impacted by various factors including the recruitment of stem/progenitor cells from the bone marrow to the fracture site. The healing occurs *via* rapid bone regeneration followed by osteoclast-mediated remodeling, resulting in new bone with structural integrity and a geometrical configuration similar to that prior to the injury^[2,23]. In most cases, healing is uneventful, but in some cases delayed or impaired healing occurs. The absence of proper blood supply, improper stability, soft tissue damage and different host features such as age, osteoporosis and smoking have been found to contribute to failure in achieving complete restoration. Nonunion fracture is a dramatic example of poor healing and is defined as non-consolidation at the fracture site within 6 mo^[4,5,24]. Autologous bone graft is the gold standard treatment for nonunion fractures. Bone block may be harvested from the iliac crest, fibula or calvaria and transplanted at the recipient site. Bone block stimulates bone regeneration by serving as a scaffold for new bone growth (osteoconduction); moreover it contains cells [osteogenesis, *e.g.*, mesenchymal stem cells (MSCs) and osteoblasts] and growth factors (osteinduction). However, this technique has several disadvantage such as donor-site morbidity, pain and prolonged hospitalization^[2-5].

MICROENVIRONMENT AT OSSEOUS TISSUE HEALING SITE

Healing of small bone defects and bone fractures involves complex and well coordinated interactions between cells, cytokines, and a mechanically stable environment with adequate blood supply^[25] to generate new bone instead of a fibrous scar^[26]. This complex dynamic process begins with secretion of pro-inflammatory cytokines from aggregated platelets, such as interleukin-1 (IL-1), IL-6 or tumor necrosis factor- α , which have chemotactic activity towards endothelial cells, fibroblasts, lymphocytes and monocytes-macrophages^[27]. Transforming growth factor β 1 (TGF β 1) plays a key role in this process due to its potent chemotactic and proliferative effect on mesenchymal stem cells, therefore modulate the recruitment of bone cells to the healing site^[28]. In addition, TGF β 1 induces the production of extracellular bone matrix proteins such as collagen, osteopontin, and alkaline phosphatase from MSCs and osteoblasts^[29]. BMPs and vascular endothelial growth factor (VEGF) are additional growth factors that induce osteogenesis and angiogenesis^[30,31]. BMPs belong to the TGF- β superfamily and induce the formation of both bone and cartilage by stimulating the cellular events of mesenchymal progenitor cells. VEGF induces angiogenesis that is crucial for delivering

oxygen and progenitor cells to the site^[26].

RATIONALE FOR USING ADULT STEM/PROGENITOR CELLS FOR BONE REGENERATION

In the process of bone development and bone healing MSCs and adequate vasculature play a central role. Therefore, cell-based therapy strategies to enhance bone regeneration utilize MSCs and endothelial progenitor cells (EPCs).

MSCs contribute to the maintenance of various tissues, especially bone, in adults^[32]. In 2006, the International Society for Cellular Therapy proposed that cells with the following characteristics should be considered as MSCs: (1) cells adherent to plastic in culture; (2) presence of CD105, CD73 and CD90 but absence of CD34, CD45, CD14 or CD11b, CD79 α or CD19, and HLA-DR molecules; and (3) cells with the capacity to differentiate into osteoblasts, chondrocytes and adipocytes^[33]. MSCs can be isolated from the bone marrow, placenta, umbilical cord blood, adipose tissue, muscle^[34], brain^[35], kidney, heart and many others^[36]. While these cells share common characteristics, they are distinctive, and reflect aspects of their tissue of origin^[37]. In animal models, transplantation of MSCs formed ectopic bone and improved healing of bone defects^[38,39]. In clinical trials, MSCs regenerate bone in non-union long bone defects^[40] in children with osteogenesis imperfecta^[41] and in maxillofacial surgeries^[42,43]. However, several difficulties concerning the use of MSCs still exist: (1) their aspiration involves an invasive procedure and morbidity^[44]; (2) age-dependent decline exists in their proliferation and osteogenic differentiation potentials^[45]; and (3) inadequate vascularization to MSC composite graft that causes malfunction and death of the transplanted cells^[46].

In 2009, a novel study presented a successful use of blood derived endothelial progenitor cells to heal critical size bone defects^[47]. Circulating EPCs were discovered in 1997 by Asahara *et al.*^[48] and Murohara *et al.*^[49]. EPCs participate in neovascularization^[50], angiogenesis, vascular repair, blood-flow recovery after tissue ischemia, distraction osteogenesis^[51,52], fracture healing^[53], bone regeneration^[54], and have osteogenic potential^[55]. EPCs are mainly located in bone marrow and mobilize into the circulation under the guidance of signals such as granulocyte colony-stimulating factor (G-CSF), VEGF, basic fibroblast growth factor, placental growth factor, erythropoietin, or stromal-derived factor-1 (SDF-1) in order to home to ischemic sites^[56,57]. EPCs can be isolated from peripheral blood, cord blood or bone marrow^[58] and classically described as cells expressing a combination of an endothelial marker (VEGF receptor-2) and hematopoietic progenitor markers (CD34/CD133). However, this definition is under debate, since none of these markers are fully specific^[59,60].

In vitro culture of mononuclear cell fraction in specific

conditions consistently produces two distinct EPC subtypes: early EPCs and outgrowth endothelial cells^[61] (that are also known as endothelial colony-forming cells^[62] or late EPCs because of their late appearance in culture). Early EPCs live < 7 d in culture and have a spindle shape morphology and limited proliferation potential. These cells are CD133, CD31, CD45, VEGFR-2 and CD14 positive^[63]. Late outgrowth EPCs emerge 2-3 wk after seeding from the nonmyeloid cell population (CD14 and CD45 negative), present a cobblestone morphology, have a high proliferation potential, express CD34, CD144, and VEGF-R2, but are negative for CD133, CD45 and CD14^[63].

Both populations are capable of inducing neovascularization, but with a different mode of action. Whereas early EPCs have limited capacity for population doubling and induce only transient angiogenesis, late outgrowth EPCs can expand to more than 100 population doublings^[64]. Early EPCs exert an angiogenic effect mainly by paracrine effect (secretion of proangiogenic growth factors), whereas late outgrowth cells were thought to produce the effect by direct engraftment and may differentiate to osteoblasts in a proper environment^[55].

G-CSF-mobilized CD34 positive cells

The use of G-CSF was suggested as a favorable method to harvest abundant CD34⁺ cells from adult peripheral blood^[65]. This alternative approach to isolate EPC was introduced in order to avoid EPC culture and to overcome the scarcity of these cells in the circulation (0.0001% of total mononuclear cells in peripheral blood of human adults)^[66]. These cells are also known as endothelial and hematopoietic progenitor cell-rich population and present phenotypic characterization that includes endothelial and hematopoietic markers: positive for CD133, CD31, c-Kit, and CD45 but negative for kinase insert domain protein receptor and CD14. Reverse transcription-polymerase chain reaction (RT-PCR) analysis of these cell revealed weak expression of CD31 and osteocalcin^[65]. *In vitro* and *in vivo* experiments using these enriched CD34⁺ cells demonstrated angiogenic and osteogenic properties similar to expanded EPCs^[67]. Peripheral blood and cord blood CD34⁺ cells were used to enhance tissue neovascularization in several preclinical models: stroke induction in immuno-compromised mice, wound healing in diabetic mice, peripheral nerve injuries and spinal cord injuries^[68-71]. Based on the belief that improved neovascularization may be an attractive strategy for bone healing, several studies were conducted to investigate the efficacy of circulating CD34⁺ cells for bone fracture healing and found promising results^[67,72,73].

MECHANISMS OF ACTION IN BONE REGENERATION

The idea of stem cell therapy relies on two possible

mechanisms of action: (1) Direct pathway - this process starts with homing of the transplanted cells to ischemic or damaged site. This is followed by integration of the cells into the site and differentiation into cells specific to the tissue^[74]; and (2) Indirect, paracrine pathway-transplanted cells secrete peptides (growth factors, interleukins, *etc.*) that modify the environment and recruit resident cells (MSCs and EPCs) to the regenerating site^[75].

Homing of transplanted cells into ischemic or injured site allows systemic application of the cells. This includes the recruitment of the cells along a gradient of chemokines and their receptors. The CXCR4-CXCL12 and CX3CR1-CX3CL1 systems are reported to be involved in MSC migration, and among them, SDF-1 alpha and CXCR4 (the SDF-1 receptor) are strong mediators of MSCs and EPCs^[76-80].

Following integration into the damaged site, the fate of the cells will be determined by environmental cues and allow osteogenic differentiation of the cells. The osteoblastic differentiation of MSCs was demonstrated *in vitro* by culturing the cells in the presence of ascorbic acid, inorganic phosphate (beta glycerol phosphate), and dexamethasone. *In vivo* studies have suggested that transplantation of adult stem cells derived from one tissue are able to engraft into developmentally unrelated tissues and, in certain cases, contribute to their regeneration^[81]. Nevertheless, since *in vivo* transdifferentiation of the cells is more difficult to prove, it was suggested that the supposed differentiation was actually a result of fusion between donor and host cells^[82,83]. The second mechanism by which MSCs contribute to bone formation is through indirect paracrine effect. MSCs secrete trophic agents and pro-angiogenic factors [angiopoietin (Ang)-1, -2, Ang-like-1, -2, -3, -4, VEGF, and fibroblast growth factor-2] that recruit resident MSCs to the site of injury and promote angiogenesis that is indispensable for tissue reconstruction^[84].

There is only little data regarding the role of EPCs in bone healing. Early outgrowth EPCs exert an angiogenic effect mainly by product secretion, whereas late outgrowth cells were thought to produce the effect by direct engraftment. Direct incorporation of transplanted EPCs into intima layer of blood vessels was demonstrated in several *in vivo* models^[48,54,85]. The indirect role of late EPCs to sustain MSC survival and function was demonstrated in an ectopic subcutaneous model^[46]. According to this study, EPC-derived paracrine factors *via* platelet-derived growth factor BB/platelet-derived growth factor receptor- β signaling regulate MSC engraftment^[46]. The mechanism of action of CD34⁺ cells was suggested by Kuroda *et al.*^[86] and includes differentiation of the cells into osteoblasts or endothelial cells and engraftment in the fracture healing site. To confirm this hypothesis, transplanted human cells were labeled in the fracture site using human specific antibodies (immunohistochemistry). Furthermore, human specific endothelial and osteoblastic markers

were identified in the fracture site using RT-PCR. Additional mechanism of CD34⁺ cells in bone healing can be attributed to their paracrine effect, especially VEGF secretion. Recruitment of resident rat endothelial cells and osteoblasts to the fracture site was demonstrated following human CD34⁺ cell transplantation. Moreover, injection of VEGF antagonist reduced the vasculogenic and osteogenic effect that was observed following transplantation of CD34⁺ cells into fracture healing sites^[86].

EPIGENETIC REGULATION IN BONE REGENERATION

Epigenetic mechanisms play essential roles in stem cell maintenance and differentiation during bone regeneration processes^[87,88]. During the differentiation of stem cells into osteogenic cells specific genes are up-regulated, while others are repressed. Epigenetic regulation is a crucial mechanism involved in the control of the complex, dynamic gene expression pattern during stem cell differentiation. Epigenetic modifications lead to functional relevant alterations in the genome without any changes in the nucleotide sequence^[89]. Well known examples for epigenetic modifications are DNA methylation and histone modifications^[90]. During DNA methylation, through the enzymatic activity of DNA methyl-transferases (Dnmts), a methyl group is covalently bound to the carbon 5 of the cytosine in the CpG sites of the genome^[91]. Methylation of cytosine results in the down-regulation of gene expression^[90]. In contrast, the absence of DNA methylation is crucial for gene expression^[92]. During bone regeneration DNA methylation is essential. As such it has been documented that CpG methylation of the osteocalcin promoter significantly decreases during *in vitro* osteoblast differentiation of MSCs and thus leads to the up-regulation of osteocalcin expression^[87]. In addition, hyper-methylation of the LIN28 promoter (a gene responsible for the maintenance of stemness) reduces LIN28 expression during osteoblast differentiation and hence facilitates osteogenesis^[93].

Gene transcription is also regulated by histone modifications^[90]. Histones are positively charged proteins that tightly bind to the negatively charged phosphate-sugar backbone of the double stranded DNA. Histone binding to the DNA modulates the accessibility of the DNA for transcription factors^[94]. The most investigated histone modifications are acetylation and methylation. Acetylation, mediated by histone acetylases, of the histone's lysine residue reduces the positive charge of the histone and thus decreases histone binding to the DNA. This in turn increases DNA accessibility for transcription factors and hence leads to increased gene expression. On the other hand, histone deacetylases remove acetyl from histones and therefore enhance histone binding to the DNA. This leads to a closed chromatin structure, reduced DNA accessibility for transcription factors and

thus decreased gene expression^[95]. Histone acetylation plays an important role during bone regeneration. It has been shown that during osteoblast differentiation both the promoter and the coding region of osteocalcin contain high levels of acetylated H4 and H3 histones, pointing to increased transcriptional accessibility to these sites. Furthermore, it has been demonstrated that down-regulation of histone deacetylase 1 is an important process for osteogenesis^[96].

Histone methylation often occurs on lysine and arginine residues. Histone methylation is tightly controlled by the balanced activity between methyl transferases and demethylases^[95]. Histone methylation is involved in osteogenic differentiation of MSCs. It has been demonstrated that the activation of CDK1 promotes osteogenic differentiation of MSCs through phosphorylation of EZH2, the catalytic subunit of PRC2, that in turn catalyzes the methylation of histone H3 on lysine 27 (H3K27)^[97].

The above mentioned examples are only a few describing the complex involvement of epigenetic regulation in bone regeneration. The importance for the understanding of epigenetics in osteogenic differentiation of stem cells gains growing attendance among scientists coping with the development of new technologies for bone regeneration.

TRANSLATIONAL STUDIES

Cell-based pioneer studies in the field of bone regeneration used non-expanded bone marrow derived MSCs. Autologous bone marrow MSCs were used to treat patients with genetic bone metabolism diseases^[41] as well as nonunion fractures^[40]. However, due to the limited number of MSCs in the bone marrow (0.01% of bone marrow cell population) the results following non-expanded MSC transplantation are unpredictable^[98]. Few years later, technological developments in MSC culture allowed expansion and characterization of these cells. The osteogenic potential of expanded, purified and identified MSCs was extensively studied, with conflicting results^[42,99]. These inconsistent results can be related to several factors that influence MSC function: donor related differences (species, age, systemic disorders), insufficient vasculature to the grafted area that caused malfunction and apoptosis of the cells^[46] and inadequate osteoblastic differentiation of the transplanted cells *in situ*. To overcome these disadvantages, attempts were made to improve osteogenic differentiation of MSCs by genetic modification^[100] and to enhance vascularization of the graft^[101,102]. MSCs that were engineered to express an osteogenic growth factor such as BMP2 and implanted *in vivo* were shown to differentiate and contribute to the process of bone formation^[103-106]. According to their results MSC-BMP2 induced new bone formation in orthotopic (bone defect) and ectopic (intramuscular) models. Histological analysis revealed that MSCs-BMP2 differentiated into osteoblasts and became integrated

in newly formed bone alongside recipient cells that also had differentiated into osteoblasts. In contrast, MSCs that were not genetically transformed survived in the damaged tissue as undifferentiated or fibroblastic cells^[98]. Since early vascularization of the graft is crucial for successful bone regeneration, Kumar *et al.*^[101] examined the vasculogenic and osteogenic potential of MSC expressing BMP2 and VEGF (alone or in combination). In the dual therapy group, improved vasculogenesis preceded increased bone healing, suggesting that increased vascularity during the bone-healing process allows continuous flow of all the necessary nutrients and cells needed for bone regeneration. Another approach to improve vascularization of MSC-composite graft was presented by Koob *et al.*^[102] who used co-culture of human umbilical vein endothelial cells (HUVECs) and MSCs. HUVECs and MSCs were seeded alone or in combination into xenograft scaffolds and implanted into calvarial critical-sized defects. Neo-vessel formation was considerably higher in the co-implantation group, suggesting that implanted MSCs supported HUVEC-triggered neovascularization. In addition, implanted MSCs effectively supported bone formation in calvarial defects. However, the human HUVEC-derived neo-vasculature did not improve MSC-triggered bone regeneration in this orthotopic critical-sized defect model^[102].

With the novel discovery of circulating EPCs^[48], and the detection of cells expressing endothelial markers in newly regenerating bone tissue^[107], a new idea to treat bone defects using EPCs was considered. Transplantation of autologous late outgrowth EPCs into critical size gap in sheep tibiae revealed full bridging at 3 mo in 6 out of 7 EPC-transplanted defects while non or minimal new bone formation was observed radiographically in 8 sham-operated defects^[47]. These authors also suggested that the effect of EPC is not limited to vasculogenesis. When sheep EPCs were sub-cultured under osteogenic conditions, they changed their morphology and formed nodular aggregates (1-2 mm diameter) following 1-2 wk incubation and stained positively for markers of osteoblastic differentiation^[55]. These results were confirmed by other research groups that showed promising results with late EPCs^[108,109]. However, none of them utilized expanded human late EPCs. This could be related to difficulties in human late EPC culturing that demands further improvement. The negligible concentration of circulating EPCs in humans is probably the main obstacle in this process; however, their concentration increases following trauma, bone fractures, malignancy, tissue ischemia, physical activity and GM-CSF administration^[110]. Contrary to the difficulties arising with human late EPC culture, early human EPCs (that have only limited proliferation capacity) are more accessible, therefore can alternatively be used. Seebach *et al.*^[54] compared healing of critical size defect in athymic rats following transplantation of human early EPCs/bone marrow MSCs/and coculture of EPCs + MSCs. Early vascularization was significantly improved

in the EPC + MSC group or EPC group. Bone formation increased significantly when treated with co-culture of MSCs + EPCs and to a lesser extent in the MSC group. Surprisingly, transplantation of early EPCs that increased early vascularization failed to enhance bone formation. Therefore, it is suggested that there is a synergistic effect and that the initial stage of neovascularization by EPCs is considered to be crucial for complete bone regeneration by MSCs in the late phase^[54].

EARLY CLINICAL FINDINGS - BONE REGENERATION USING AUTOLOGOUS STEM/PROGENITOR CELLS

One of the leading research groups in the field of bone regeneration recently published a randomized controlled clinical trial in which human autologous cells were transplanted into bone defects with promising results. Bone repair cells were produced from bone marrow aspirates, isolated, cultured and characterized. Flow cytometry demonstrated that these cells were enriched for mesenchymal and vascular phenotypes. Cell suspension was absorbed onto a gelatin sponge that was transplanted into the extraction site and covered by a bio-absorbable collagen barrier membrane. Six weeks later, a biopsy of the regenerated site revealed highly vascularized, mineralized bone tissue formation^[111]. Promising results were also reported following transplantation of human autologous bone marrow derived MSCs to augment cleft palate and maxillary sinus^[112,113]. Orthopedic use of bone marrow MSCs to treat long bone fractures was also recently reported^[114]. Autologous osteoblasts, isolated from bone marrow and cultured in osteogenic conditioned medium, were transplanted into the fracture two weeks post internal fixation. They showed statistically significant acceleration of fracture healing in the experimental group that was treated with cells compared with the nontransplanted group. Importantly, none of these studies reported on significant inflammatory reaction or serious adverse effects.

From a clinical point of view peripheral blood progenitor cells are more accessible compared with bone marrow derived MSCs. Therefore attempts are made to isolate, culture and transplant blood derived progenitor cells into bone defects. The first clinical case of tibial nonunion treated with peripheral blood progenitors (G-CSF-mobilized CD34⁺ cells) was published by Kuroda *et al.*^[115]. In this case report, delayed healing and nonunion were observed following primary operation that included transplantation of autologous iliac bone block. Nine months later, mobilized CD34⁺ cells were transplanted into the site and resulted in bone union without any symptoms including pain and gait disturbance^[115]. Encouraged by these results, the same research group began a phase I /II a clinical trial: Autologous local transplantation of G-CSF-mobilized

peripheral blood CD34⁺ cells for patients with tibial or femoral nonunion^[110]. Five days following G-CSF injection, each patient's cells were magnet sorted to separate the CD34⁺ cells. Treatment included autologous transplantation of G-CSF-mobilized peripheral blood CD34⁺ cells suspended in atherocollagen gel. Radiological fracture healing at 12 wk was achieved in five of seven (71.4%) patients, which was greater than the threshold (18.1%) predefined by the historical outcome of standard care.

SAFETY OF ADULT STEM CELL TRANSPLANTATION

Clinical trials that assessed the safety of MSC transplantation for the treatment of graft-vs-host disease, ischemic heart disease, spinal cord injury, and systemic lupus erythematosus, did not find any significant adverse effect^[116-120]. Nevertheless, studies that investigated the role of MSCs in tumor-genesis found that MSCs have the ability to interact with tumor cells, support tumor angiogenesis and tumor development by providing the matrix required for new vessels and tumor cell scaffolding^[121,122]. Therefore, the potential of MSCs to facilitate growth of preexisting occult tumors raised concerns^[123,124]. *In vitro* transdifferentiation of MSCs was also reported but may be related to contamination with cancer cells^[125,126].

EPCs initiate vasculogenesis, as such, these cells play a critical role in pathological vasculature in tumor growth^[121] and metastasis^[127]. Recent clinical studies demonstrated an increase in the amount of circulating EPCs in patients suffering from malignant tumors and in cases of invasive or recurrence of the disease^[128,129]. These observations underline the need for careful phenotypic, functional, and genetic characterization of EPCs/MSCs before cell administration or therapy. Also, the question of whether patients should be treated with autologous, or donor-derived progenitor-cells remains to be addressed.

PROSPECTIVE

There is a significant clinical need to develop innovative approaches for the treatment of large bone defects, nonunion fractures and alveolar bone atrophy. In recent years, many efforts are being made to regenerate bone using stem cells and progenitor cells. While animal studies and limited human studies have shown efficacy of bone marrow derived MSCs and circulating EPCs, the mechanisms by which these cells improve bone regeneration are still unclear. Numerous factors restrict the clinical use of stem cells: immune rejection of cells that are not of autologous origin; limited amount of available cells for transplantation that requires *in vitro* cell expansion with xenograft materials; donor related differences (*e.g.*, age and systemic conditions) that affect cell function and the absence of potency test

that can predict the *in vivo* function of cells before transplantation. Moreover, safety and regulation of these procedures have to be performed before clinical trials. To overcome these drawbacks, new technologies that will allow increasing the amount of cells available for transplantation and standardization of growth conditions need to be developed. In addition, understanding the mechanisms of action will enable a breakthrough in bone regeneration induced by cells.

research. Embryonic stem cells (ESCs), induced pluripotent stem cells (iPSCs) and adipose derived mesenchymal stem cells (ADMSCs) are the focus in current endeavors as a source of different retinal cells, such as photoreceptors and retinal pigment epithelial cells. The aim is to apply them for cell replacement as an option for treating retinal diseases which so far are untreatable in their advanced stage. ESCs, despite the great potential for differentiation, have the dangerous risk of teratoma formation as well as ethical issues, which must be resolved before starting a clinical trial. iPSCs, like ESCs, are able to differentiate in to several types of retinal cells. However, the process to get them for personalized cell therapy has a high cost in terms of time and money. Researchers are working to resolve this since iPSCs seem to be a realistic option for treating retinal diseases. ADMSCs have the advantage that the procedures to obtain them are easier. Despite advancements in stem cell application, there are still several challenges that need to be overcome before transferring the research results to clinical application. This paper reviews recent research achievements of the applications of these three types of stem cells as well as clinical trials currently based on them.

Core tip: Several retinal diseases are based on different retinal cell layer degenerations. Some of them have no treatment to date. Advances in stem cell therapy are considered a realistic option. In contrast to the early stage, the late stage of these diseases requires treatment techniques based on cell replacement. Currently, a few are in clinical trials using the sources of embryonic stem cells, induced pluripotent stem cells and adipose derived mesenchymal stem cells. The focus is mainly to enhance the output of these techniques, securing faster implementation and patient safety. Nevertheless, there

Abstract

The relevance of retinal diseases, both in society's economy and in the quality of people's life who suffer with them, has made stem cell therapy an interesting topic for

are many challenges still to resolve.

INTRODUCTION

The retina is a very complex peculiar tissue which has ten different layers, namely retinal pigment epithelium (RPE), photoreceptor outer segments, outer limiting membrane, outer nuclear layer, outer plexiform layer, inner nuclear layer, inner plexiform layer, ganglion cell layer, nerve fiber layer and inner limiting membrane. The cells and membranes of these layers are interconnected and in constant physiochemical communication to maintain retinal homeostasis, anatomy and functional integrity. An alteration or damage in any of these layers can impair these communications, thereby affecting the normal homeostasis, anatomy and functions of the retina^[1]. It can result in an onset of retinal diseases which can lead into visual impairment or blindness.

An example of this is the dry form of age-related macular degeneration (AMD) in which the damage affects four interconnected layers: the RPE, photoreceptor, Bruch's membrane and the choriocapillaris^[2]. Post stimulation of damage events, the RPE degenerates finally and consequently the photoreceptor also degenerates, leading to blindness^[2]. In addition to AMD^[2-4], currently there are many other retinal diseases, such as retinitis pigmentosa^[4,5] and diabetic retinopathy^[4,6], and eye diseases, such as glaucoma and non-arteritic anterior ischemic optic neuropathy, in which damage occurs on different retinal layers (Table 1). Thereby, it provokes retinal cell degeneration that results in vision loss in patients with the disease. Remarkably, some retinal diseases have no treatment yet although their impacts on daily life and social and economic consequences are very high.

All the retinal diseases mentioned already cause degeneration and loss of the retinal cells. It is logical to think that the replacement of damaged retinal cells with healthy ones could be a therapeutic option but it is necessary to have a suitable source of the cells. Stem cells are very prominent and promising for treatment development because they have shown very positive results so far. They have the advantage over the patient's adult retinal cells, solving the various issues of treatment development, including the gene related issues. The impact of retinal diseases on daily life and the social and financial consequences enforce the need for research of stem cells-derived therapies applied to human trials as fast as possible without forgetting issues of the safety and ethics^[7]. Because of this, there are several ongoing research studies about this topic.

This review focuses on recent achievements of the applications of embryonic stem cells (ESCs), induced pluripotent stem cells (iPSCs) and adipose derived mesenchymal stem cells (ADMSCs) in retinal repair. It also describes the clinical trials based on the use of these three types of stem cells and deals with the disadvantages of the use of each of these stem cells.

Stem cells have also shown neuroprotective effects on degenerating retinal cells which could be applied to delay or stop the cellular damage events; thus, it could be useful to treat retinal diseases in their early stage. However, this review mainly focuses on cell replacement therapy which is applicable in the late stage of retinal degeneration diseases. This review article is based on the approaches used in published articles. It does not describe the biological mechanisms involved in each approach in detail but only describes recent advances in research that seem interesting for performing an *in vivo* test, thus transferring the results to the clinic in a short period.

ESCs

ESCs are pluripotent stem cells which means they can differentiate into ectoderm, mesoderm and endoderm cells. However, some ESC cells lines show more differential potential towards a particular lineage than others do. For example, it has been found that human ESC H7 has good differentiation potential into beating cardiomyocytes but is weak into ectodermal lineages^[8], whereas human ESC Regea 08/023^[9] has better ectodermal than beating cardiomyocytes differentiation potential^[8]. Which lineage of the ESC and protocol will be used in the experiments to achieve the research objective have to be considered in the decision making.

The ESC pluripotent characteristics have allowed several studies to be performed in which differentiating these cells into both neural^[10-12] and epithelial retinal cells^[13-15] has been achieved. A very crucial step is to successfully achieve establishing a method of ESC differentiation to obtain a good number of healthy differentiated retinal cells with no gene related issues because, as described above, different retinal layers are affected with executed cellular degeneration events. A specific type of cells to replace a retinal layer is needed. On the other hand, ESCs have also been used to obtain neural^[16,17] stem cells, multipotent cells which can differentiate into limited cells types including neuroretinal cells.

ESC differentiated cells could be used to replace the damaged cells of the retina. There are many published methods for this purpose. However, it is very important that the cells can be grown and differentiated in standard culture conditions. The viral-free standard culture conditions are preferable to minimize the risks associated with a virus in cellular transplantation. ESCs have been used to obtain neural stem cells by using small molecules such as CHIR99021 and SB431542. It

Table 1 Summary of retinal diseases and the type of cells affected in each case

Retinal disease	Type of cells affected
Age-related macular degeneration	Photoreceptors and retinal pigment epithelial cells
Glaucoma	Retinal ganglion cells and their axons
Non-arteritic anterior ischemic optic neuropathy	Retinal ganglion cells
Retinitis pigmentosa	Photoreceptors
Diabetic retinopathy	Neural retinal cells

has been found that they protect photoreceptors and visual function. Hence, obtaining this type of cell by using small molecules has the advantage that they are obtained efficiently and without the use of virus which could produce a risk^[4]. Thus, they could be used as a potent cell source for treating degenerative retinal diseases^[16].

ESCs have been also used to obtain progenitor retinal cells which can be differentiated to specific retinal cells such as photoreceptors. There are many published methods for this purpose but identifying an effective and efficient method is crucial if performing a human clinical trial. Amirpour *et al.*^[17] compared three methods of obtaining photoreceptors using co-culture of the RPE with retinal progenitor cells differentiated from ESCs. In two of them, the RPE were indirectly co-cultured on filters for 1 and 2 wk respectively, with retinal progenitors cells differentiated from ESCs. The filter blocked the two layers coming in to physical contact, although they were in chemical communication using the different cell secreted biomolecules. The third one was a direct co-culture of both types of cells for 2 wk. They concluded that direct co-culture with the RPE improved the expression of late photoreceptor markers such as arrestin. In another method, Decembrini *et al.*^[10] produced a transgenic mouse ESC line following a three-dimensional (3D) culture method. The combination of these transgenic cells coupled with a 3D culture system allowed achieving the production of a secure and renewable source of photoreceptors compatible with transplantation^[10]. Previously, it was demonstrated that ESC-derived photoreceptor precursor cells were able to integrate when transplanted into degenerated adult mouse retina. In addition, the transplanted cells matured toward outer segments and formed synaptic connections^[11]. In this study, the 3D neuroepithelial cyst culture system was used to achieve the differentiation of ESCs into photoreceptor precursors. In addition, current investigations showed that hypoxia seems to play an important role in making differentiation of mouse ESCs towards the photoreceptors more effective and efficient. Thus, the study of using mouse ESCs culturing under hypoxic conditions provides an important method that can be used to improve modeling of retinogenesis *in vitro*^[12]. Thus, to obtain photoreceptors and in all studies in general, the method used to culture the cells is crucial for the results obtained. Comparing the results of different previous studies for planning new strategies of a method development should be considered.

These studies and their produced results are essential for advances in photoreceptor replacement therapy. As stated above, ESCs are a source of neural stem cells^[16,17] and photoreceptors^[10-12] but they are also able to differentiate into RPE cells^[13-15] which play an important role in the pathogenesis of many retinal diseases, including AMD. Diniz *et al.*^[13] studied the survival of human ESC-derived RPE transplanted in the subretinal space of immunocompromised nude rats. The results of this study^[13] showed that these cells could survive for several months and the obtained results were enhanced when cells were transplanted as a polarized monolayer of the hESC-RPE rather than as a cell suspension. Nevertheless, RPE is a layer of polarized cells which execute different functions at the apical and basal portion.

Most standard culture conditions of stem cell differentiation methods contain animal generated products such bovine serum, fetal calf serum, *etc.*, as nutrient supplements. However, when the cells are transplanted in humans, animal serum could result in host rejection^[18-20]. Therefore, serum-free medium was used in many studies. During the growing and differentiation of ESCs into RPE under serum-free conditions, the cells were found to express several genes which encode a family of proteins known as aquaporins. These proteins are responsible for allowing passive water transport through the RPE^[14]. Thus, this study added a property to ESC differentiated RPE which is essential for retinal homeostasis and functional integrity. Cell replacement therapy is very effective when it repairs the damaged functional properties of a cell layer as well as acquiring the cell phenotype. Hence, this is an important area of study in which the search for effective methods are currently focused^[3,15].

Recently it was reported, as stated above, that it is possible to generate RPE from ESCs using a 3D neuroepithelial cyst culture of these stem cells. This method could also be used to produce other types of neuronal cells in addition to RPE^[15]. It is also very favorable to minimize the host rejection issues if a cell culture method can produce different types of cells.

Despite all the advantages of ESCs, tumor formation is considered an important risk for the clinical application of these stem cells^[21]. Hence, teratoma formation must be studied and controlled for each method before successfully carrying out a clinical trial^[22]. It has been proved that the use of a method which achieves differentiation of ESCs and thus secures the loss of its pluripotency is related to less tumor growth when

the cells were transplanted in animals^[12,13]. The study showed a lack of tumors in immunocompromised nude rats transplanted with the well differentiated ESC-derived RPE. It supports the theory that the risk of this side effect could be minimized in immunocompetent recipients^[13]. It found that WNT signaling cascade plays an important role in tumor formation and therapeutic functionality of ESC-derived retinal progenitor cells^[21]. Such studies exploring signaling cascade roles could support developing an effective cell replacement therapy. Nevertheless, ethical concerns, limited cell sources and the related high incidence of malignant transformation restrict the wide application of ESCs in retinal repair.

Currently, there are some registered clinical trials using ESCs to treat retinal diseases (<http://www.clinicaltrials.gov/>): (1) (NCT01469832) Safety and Tolerability of Sub-retinal Transplantation of Human Embryonic Stem Cell Derived Retinal Pigmented Epithelial (hESC-RPE) Cells in Patients with Stargardt's Macular Dystrophy (SMD); (2) (NCT01691261) A Study of Implantation of Human Embryonic Stem Cell Derived Retinal Pigment Epithelium in Subjects with Acute Wet Age Related Macular Degeneration and Recent Rapid Vision Decline; (3) (NCT01674829) A Phase I / II a, Open-Label, Single-Center, Prospective Study to Determine the Safety and Tolerability of Sub-retinal Transplantation of Human Embryonic Stem Cell Derived Retinal Pigmented Epithelial (MA09-hRPE) Cells in Patients With Advanced Dry Age-related Macular Degeneration (AMD); (4) (NCT02122159) Research With Retinal Cells Derived From Stem Cells for Myopic Macular Degeneration; (5) (NCT01344993) Safety and Tolerability of Sub-retinal Transplantation of hESC Derived RPE (MA09-hRPE) Cells in Patients with Advanced Dry Age Related Macular Degeneration (Dry AMD); (6) (NCT01345006) Sub-retinal Transplantation of hESC Derived RPE (MA09-hRPE) Cells in Patients with Stargardt's Macular Dystrophy; and (7) (NCT01625559) Safety and Tolerability of MA09-hRPE Cells in Patients with SMD.

INDUCED PLURIPOTENT STEM CELLS

Human induced pluripotent stem cells (hiPSCs), generated by somatic cells reprogramming, have been a strong attractive focus of researchers in recent years. This is due to its feasible application in transplantation for cell replacement therapies for retinal diseases. However, it needs intensive investigation in the laboratory and subsequently in early-phase human clinical trial to improve the differentiation, transplantation and integration of the cells, with the goal of obtaining maximal therapeutic efficacy^[7].

Like ESCs, iPSCs are able to differentiate in several retinal cells, such as the photoreceptors^[23], RPE^[24-29], retinal ganglion like cells^[30,31] and retinal progenitor cells^[27,32]. In addition, these stem cells can form optic vesicle-like structures that could be used as a model

system to study the development of the retina^[33].

Using iPSCs of swine, their differentiation into photoreceptors in cell culture has been achieved. In addition, when these cells were transplanted into the subretinal space of pigs, it was found that they integrated in the retina previously damaged with iodoacetic acid^[23]. On the other hand, this study used the pig as an animal model for a retinal stem cell transplantation study, which could be taken into consideration for future transplantation studies. The pig and human eyes show some similarities in anatomical and histological structure and thus provide the opportunity to translate the research results to human clinical use in a short period.

Regarding iPSC derived RPE, the sheets of the differentiated RPE cells have been found to be very similar in morphology and physiology to the native RPE, which is not the case for the RPE cells in suspension. Furthermore, they have other advantages, such as traceability due to the autologous property, the strong coverage of the lesion when they are transplanted and reduction of the risk of graft rejection, mainly in diseases with a disrupted blood-retinal barrier^[24]. Despite the mentioned advantages, the surgical method of sheet transplantation is more complicated and invasive in comparison with cell suspension transplantation^[24]. This important issue must be resolved before planning a clinical trial with any constructed cell sheet.

The RPE plays an important role in the retina, regulating many functions including its participation in the visual cycle. Thus, it is a crucial layer for maintaining vision function. Human iPSC derived RPE in cell culture express proteins related to visual cycle. In blind mice, these RPE cells with a functional visual cycle were transplanted and it was found that they reestablished in part the visual function of mice. This result supports the possibility of the use of these cells for treatment of retinal degenerative diseases^[25]. Generating a functional monolayer of RPE cells showing native RPE characteristics, such as pigmentation, morphology, specific marker expression, polarized membrane, vascular endothelial growth factor secretion and phagocytic activity, in large amounts from human iPSCs by using simple methods has been achieved. The modifications done in this simple method with respect to the standard method were the amplification of human iPSC by clonal propagation. Furthermore, enrichment of the RPE cells has been achieved by serial passages as an alternative to mechanical picking^[26]. In another study, developing an easy method to differentiate iPSCs into the RPE and also into retinal progenitor cells has been achieved. Thus, it provides useful data for reducing the time necessary for translating the results to the clinic. This method consists of culture of confluent human iPSCs without using Matrigel or serum in a proneural medium^[27]. However, it is necessary to control cell passaging during their culture for maintaining the features of human iPSC derived RPE. It was found that in fourth passage of culture the morphological and functional characteristics of the cells were changed^[29].

Thus, these studies provide enough advances for exploring the feasible application of human iPSC derived RPE.

Like ESCs, iPSCs were also used to obtain neural progenitors. In both *in vitro* and *in vivo* studies, neural progenitors derived from human iPSCs showed their differentiation potential into retinal cells. In a study^[32], these cells were transplanted into rats with injured optic nerves and the results showed that there was a rescue of injured optic nerves due to the stem cell-mediated neuroprotective effect on the retinal ganglion cells. This confirmed that iPSCs maintain a stem cell neuroprotective property that could be applicable in developing neuroprotective property based treatments for retinal diseases. However, as mentioned earlier, this review focuses only on cell replacement therapy for retinal diseases.

In addition to these three types of cells, it is also possible to produce retinal ganglion like cells from iPSCs. Applying methods for induction of the adenoviral genes, retinal ganglion like cells were produced faster than what could be produced using lentiviruses. This was due to a more efficient reprogramming process executed inside the cell when mediated by adenoviruses. There was no viral genomic integrations if adenoviruses were used in the study, *i.e.*, these cells were free of exogenous gene integration. In this study, the resulting cells were derived from the mouse fibroblast and they showed electrophysiological characteristics^[30]. The fibroblasts were obtained more easily in sufficient amounts for a patient than the ESCs and their successful reprogramming resolves to an extent the issues related to finding an appropriate cell source and the ethics compared to ESCs. Recently it was reported that the ciliary body derived cells showed higher reprogramming efficiency than the fibroblasts for producing iPSCs; thus, it could be also overcome the issues related to the ocular origin^[34]. However, the concerns related to the autologous cell nature and the surgical complications of obtaining the cells from a patient could discourage the use of ciliary body derived cells.

Furthermore, it has been hypothesized that iPSCs play a role in retinal ischemia and reperfusion (I/R) injury. In a rat model of this retinal disease, iPSCs without c-Myc (oncogene that contributes significantly in tumor formation) were injected subretinally^[35]. Results of this study showed that transplanted non-c-MYC iPSCs rescued I/R retinal damage induced in rats and reduced the tumorigenicity. Thus, it confirms the suitability of iPSCs for treating this disease. Besides this disease, transplantation studies in animals are continuously showing positive results for the feasibility of iPSC application in cell replacement therapy for retinal diseases.

iPSCs are an important renewable source of cells, with all that it means for both medicine and basic research^[36]. Despite numerous challenges that remain, iPSCs could be a realistic option for cell replacement treatment in the future for patients with retinal diseases

that are still untreatable and need replacement of the damaged cells. Thus, it could play a significant role in research strategies to slow down or stop the disease progression or could completely treat the disease and probably enhance visual function^[37].

As stated above, there are still challenges for the application of iPSCs^[37] which need to be overcome before translating the advances to the clinic, such as the risk of leading to malignant tumors^[36]. Unlike ESCs, iPSCs have the advantage of being used for autologous transplantation. Consequently there will be fewer immune rejections, although on the other hand, personalized cell therapy has a high cost in terms of both economics and time^[38]. Therefore, several researchers have a common goal^[26,27] to develop an easy method that could reduce these disadvantages.

Currently there are some registered clinical trials using iPSCs to treat retinal diseases (<http://www.clinicaltrials.gov/>): (1) (NCT02162953) Development of Induced Pluripotent Stem Cells from Patients with Best Disease and Other Inherited Retinal Degenerative Diseases; and (2) (NCT01432847) Generation of induced pluripotent stem (iPS) Cell Lines from Somatic Cells of Participants with Eye Diseases and from Somatic Cells of Matched Controls.

ADMSCs

ADMSCs are a source of adult stem cells which can be obtained by a minimally invasive procedure, liposuction, followed by adequate processing to achieve a population of cells with the desired characteristics^[4]. This is an easier, more accessible and safer source of mesenchymal stem cells than the bone marrow^[6]. In addition, they can be easily expanded under standard culture conditions without progressive culture and enrichment and with a lower risk of contamination^[6,39]. Thus, this is a very important source for obtaining mesenchymal stem cells (MSCs) in large numbers. MSCs are highly significant for patients with retinal diseases, including diabetic retinopathy (DR), AMD and retinitis pigmentosa (RP)^[4].

DR is a common ocular complication in diabetic patients which involves microvascular and neurodegenerative diseases^[6]. ADMSCs could be an effective part of the therapy for the DR since it has been found that these cells homed in to the injured retina and differentiated to form astrocytes and photoreceptor-like cells when injected intravenously in streptozotocin diabetic rats. Besides, ADMSCs were able to reduce blood glucose levels and repair the blood-retina barrier breakdown that occurs in this disease^[6].

AMD is a neurodegenerative disease associated with aging which progressively leads to loss of the central vision. Damage is produced at the RPE, from the posterior extended to the photoreceptor. The RP involve a set of hereditary diseases characterized by degeneration of both types of photoreceptor cells, rods and cones. Patients with RP progressively lose vision, night vision in adolescence, side vision in young adulthood and central vision in later

Table 2 Summary of the routes of administration of stem cells

Type of stem cells	Route of administration	Species used	Ref.
ESC-neural stem cell	Subretinal and intravitreal	Rat	Lu <i>et al</i> ^[16]

ESC: Embryonic stem cells; iPSC: Induced pluripotent stem cells; ADMSC: Adipose derived mesenchymal stem cells.

life^[5]. Both diseases involve photoreceptor cell death. Therefore, studies of MSCs mainly target two aims: cell replacement and neuroprotection. These stem cells have been differentiated into many cell types, including retinal progenitor cells^[40] and RPE^[41], which confirms their application in cell replacement therapy for retinal diseases. In addition, these cells have been found to exert paracrine effects showing neuroprotective effects on RPE damage *in vitro*^[42]. These properties of these cells were confirmed in animal transplantation studies. Hence, ADMSCs are a potent source of cells with properties that could be applicable in developing treatment.

In a transplantation study, when human ADMSCs were injected in the vitreous cavity, they survived and integrated in the rat eye but were found to cross the blood-retina barrier and migrate to non-targeted organs. Thus, it could be a risk for transplantation in patients. This must be taken into consideration in the strategies of further investigations and before performing a clinical trial^[43]. These MSCs show many advantages in terms of a good source of cells with minimum complexity to obtain in sufficient amounts and develop treatments based on the application of their properties. Nevertheless, there are still several questions about these cells that need to be answered. Therefore, further research is needed to understand the action mechanisms of these cells and when they could be transplanted^[39].

Currently there are some registered clinical trials using ADMSC to treat retinal diseases (<http://www.clinicaltrials.gov/>): (1) (NCT02024269) Study to Assess the Safety and Effects of Cells Injected Intravitreally in Dry Macular Degeneration; and (2) (NCT02144103) Effectiveness and Safety of Adipose-Derived Regenerative Cells for Treatment of Glaucomatous Neurodegeneration.

ROUTES OF ADMINISTRATION OF ESCs, iPSCs AND ADMSCs

The present review describes both *in vitro* and *in vivo* studies. In the latter, researchers have used different routes of administration of the stem cells for evaluating

the safety and efficacy of their approaches. The subretinal space^[10,11,13,16,21,23-25,35] is a place most frequently used to inject the stem cells, but intravitreal^[16,32,43] and intravenous^[6] administration have also been used. Table 2 presents a summary of the routes of administration of each type of stem cells discussed in this review.

CONCLUSION

In the last few years, there have been important advances in the area of stem cells which have made their application in cell replacement feasible. It could be used as a cell replacement therapy for untreatable retinal diseases where cells cannot be recovered due to cell damage. A type of stem cells, the MSCs, are useful as neuroprotective agents, but also, the use of stem cells would not prevent apoptotic progression (the main cause of these diseases) and this is an important and still unresolved problem. The advances in both approaches should be taken into consideration as realistic therapeutic options for developing treatments for untreatable retinal diseases. However, before applying these advances to clinical therapy, it is necessary to perform extensive investigations to improve the processes of obtaining, differentiation and implantation of these cells to overcome the challenges which are still present.

implantation embryonic cells, and thus were called embryonic stem cells (ESCs). More than a decade later, pluripotent cells were isolated from the ICM of human blastocysts. Despite being called human ESCs, these cells differ significantly from mouse ESCs, including different morphology and mechanisms of control of pluripotency, suggesting distinct embryonic origins of ESCs from the two species. Subsequently, mouse pluripotent stem cells were established from the ICM-derived epiblast of post-implantation embryos. These mouse epiblast stem cells (EpiSCs) are morphological and epigenetically more similar to human ESCs. This raised the question of whether cells from the human ICM are in a more advanced differentiation stage than their murine counterpart, or whether the available culture conditions were not adequate to maintain those human cells in their *in vivo* state, leading to a transition into EpiSC-like cells *in vitro*. More recently, novel culture conditions allowed the conversion of human ESCs into mouse ESC-like cells called naïve (or ground state) human ESCs, and the derivation of naïve human ESCs from blastocysts. Here we will review the characteristics of each type of pluripotent stem cells, how (and whether) these relate to different stages of embryonic development, and discuss the potential implications of naïve human ESCs in research and therapy.

Key words: Naïve pluripotent stem cells; Epiblast stem cells; X chromosome inactivation; Human embryonic stem cells

Core tip: Mouse embryonic stem cells (ESCs) are the *in vitro* equivalent of the epiblast of preimplantation embryos. Human ESCs on the other hand, although also pluripotent, appear to be in a more advanced developmental stage than their murine counterpart. Recently, several reports described culture conditions able to support mouse ESC-like human ESCs, called naïve human ESCs. Here we will review the search for human naïve ESCs, discussing their biological and

Abstract

Normal mouse pluripotent stem cells were originally derived from the inner cell mass (ICM) of blastocysts and shown to be the *in vitro* equivalent of those pre-

practical relevance.

FROM THE MOUSE EMBRYO TO EMBRYONIC STEM CELLS

The mammalian preimplantation development is a process of cell multiplication and differentiation from the zygote to the totipotent blastomeres at the cleavage stage, and then to the pluripotent cells at the blastocyst stage. During preimplantation development, cell lineage specification and spatial segregation result in two cell fate decisions, which are believed to be sequential. The first segregation is into the trophectoderm, involved in the formation of the fetal portion of the placenta, and the inner cell mass (ICM) at the early blastocyst stage. The second segregation divides the ICM into the primitive endoderm, that origins parietal and visceral endoderm of the yolk sac^[1], and the epiblast, which will give rise to the embryo proper^[2] (Figure 1).

Mouse embryonic stem cells (ESCs) are derived from the ICM of blastocysts and represent the epiblast lineage *in vitro*^[3,4]. They are able to maintain an undifferentiated state (self-renewal) and to differentiate into tissues from all three germ layers *in vitro* and *in vivo*. In addition, when reintroduced in preimplantation embryos, mouse ESCs are able to get incorporated and give rise to all tissues of the resulting chimera.

In the pluripotent state, mouse ESCs are characterized by the presence of transcription factors such as OCT3/4^[5] and Nanog^[6], expression of alkaline phosphatase and specific cell surface glycoproteins such as stage-specific embryonic antigen 1^[7], and high telomerase activity^[8]. In addition, like the epiblast lineage *in vivo*, female mouse ESCs have not undergone random X chromosome inactivation (XCI), and will do so upon differentiation *in vitro*^[9].

Maintenance of the undifferentiated state of ESC *in vitro* is greatly dependent on exogenous factors. The first mESC derived were maintained in medium conditioned by teratocarcinoma cells^[4], or co-cultured with irradiated mouse embryonic fibroblasts (MEF) in an enriched culture medium which guaranteed self-renewal^[3,10]. Later, maintenance of pluripotency was shown to be dependent on myeloid leukemia inhibitory factor (LIF), a molecule which induces differentiation of M1 myeloid leukemia cells^[11]. LIF belongs to the interleukin-6 cytokine family and binds to a heterodimeric receptor consisting of the LIF-receptor and gp130^[12]. LIF acts on mESC self-renewal mainly by activating Stat3 (signal transducer and activator of transcription 3) through the LIF/Stat3

pathway^[13]. In addition, different matrices and scaffolds are also important for maintenance and/or determination of cell fate^[14].

HUMAN ESCS

The first lines of human ESCs were established in 1998 from the ICM of human blastocysts, in culture conditions equivalent to those of mouse ESCs^[15,16]. Subsequently, it was shown that instead of LIF, bFGF was required for the prolonged culture of human ESCs in the pluripotent state^[17].

Despite being derived from preimplantation embryos in apparently the same stage of development, human ESCs differ from their murine counterparts in many ways, including morphology (flat vs domed shaped colonies), passage in culture (clusters vs single cell passage), growth factors dependence (bFGF and TGFβ/ACTIVIN/NODAL vs LIF/STAT3 signaling)^[16], genomic stability^[18], and the epigenetic state of the X chromosome^[19,20]. Furthermore, control of induced specific differentiation of mouse ESCs was shown to differ from human ESCs in many cases^[21], where protocols established with mouse ESCs do not necessarily yield the same differentiated cell population from their human counterpart. This suggests distinct epigenetic states and/or developmental pathways between ESCs from the two species.

Regarding the X chromosome, although female human ESCs in a pre-XCI status equivalent to that of mouse ESCs have been described^[22], this appears to be an unstable epigenetic state, which is lost with time in culture leading to pluripotent cells with one active and one inactive X chromosome^[19,23,24]. This suggested that human ESCs may be in a different developmental stage than mouse ESCs. However, the kinetics of XCI during human pre-implantation development is still not clear, and thus it is not known whether human ESCs are indeed the *in vitro* equivalent of the epiblast lineage, or whether they are altered during establishment/culture by the current *in vitro* conditions^[25,26].

INDUCED PLURIPOTENT STEM CELLS

A novel source of pluripotent stem cells was established in 2006: those derived through nuclear reprogramming of somatic cells by exogenous expression of Oct4, Klf4, c-Myc and Sox2^[27]. These induced pluripotent stem cells (iPSCs) were first established from mouse fibroblasts, and the same strategy was able to convert human fibroblasts also into a pluripotent state^[28].

Human and mouse iPSCs are equivalent to their embryo-derived counterparts human and mouse ESCs, respectively^[27,28], regarding morphology, growth factor dependence and XCI state. Thus, human and mouse pluripotent stem cells derived from developmentally equivalent cells (adult fibroblasts) are still distinct in several important aspects. This may suggest that

Figure 1 First two cell segregations during preimplantation embryonic development. A: In blue, cells from the inner cell mass (ICM) in the early blastocyst, and white, cells from the trophoblast; B: At the late blastocyst stage, cells from the ICM segregate into cells from the epiblast (green) and the primitive endoderm (orange).

the differences between pluripotent stem cells from the two species are not due to distinct origins of the starting embryonic cell, but rather to distinct pathways defining and controlling pluripotency.

MOUSE ESCS

Indirect evidence that human ESCs are not the developmental equivalent of mouse ESCs came from the establishment of pluripotent SCs derived from the epiblast of post-implantation mouse embryo-epiblast stem cells (EpiSCs)^[29,30]. Although these cells form teratomas when injected in SCID mice, when injected into preimplantation embryos EpiSCs do not integrate to form chimeras like mouse ESCs do. EpiSCs keep their pluripotency *in vitro* when cultured under human ESCs' conditions, present the same flat colony-morphology of the human cells, and are in a post-XCI state. In addition, EpiSC and human ESCs present expression profiles characteristic of the epiblast, suggesting that indeed the human pluripotent cells have embryonic origin distinct of mouse ESCs, and similar to mouse EpiSC.

Therefore, two distinct classes of pluripotent SCs were defined: ground state, or naïve-pluripotent SCs, like mouse ESCs/iPSCs; and primed-pluripotent SC, like human ESCs/iPSCs and mouse EpiSCs, which are in a latter developmental stage^[31]. And thus, the question was rephrased: can human naïve ESCs be established?

In 2009, Bao *et al.*^[32] demonstrated that mouse EpiSC were able to revert to the more primitive epigenetic state of ESCs just by culture in LIF/MEFs. After few passages, ESC-like cells started appearing among EpiSCs, and eventually a sub-line of reprogrammed epiblast ESC-like cells was derived. As part of the reprogramming, the cells reactivated the inactive X chromosome, changing into a pre-XCI state like mouse ESCs and iPSCs. Thus, if mouse EpiSCs could be reverted into ESC-like cells, could human ESCs also be reverted into a naïve pluripotent state by simply changing media conditions?

CONTROL OF PLURIPOTENCY BY SMALL MOLECULES

One important improvement in the dissection of the

pluripotent state was the demonstration that it was not dependent on external stimuli like serum and MEFs, but instead that pluripotency could be maintained by inhibition of endogenous signaling by mitogen-activated protein kinase (MEK), fibroblast growth factor (FGF) receptor tyrosine kinase and glycogen synthase kinase 3 (GSK3). This led to the development of the 3i culture condition, which involves small molecules-inhibition of GSK3, MEK and FGF receptor tyrosine kinase signaling by small molecules CHIR99021, PD18352 and SU5402, respectively^[33]. While inhibition of GSK3 promotes cell growth and viability, inhibition of FGF receptor tyrosine kinase blocks phosphorylation of MEK, thus hampering its action in promoting cell commitment (Figure 2). In comparison, in the original culture conditions of mouse ESCs, LIF acts only in blocking cell commitment, which would be one step later that ERK phosphorylation, and other factors present in serum and secreted from MEFs promote cell growth and viability^[13,34].

Subsequently it was found that inhibition of MEK by PD0325901 was more potent and could substitute both PD18352 and SU5402, in what was called 2i media (CHIR99021 + PD0325901)^[33,35]. The 3i/2i culture conditions allowed the derivation of germ line competent pluripotent stem cells from other species like rat^[36,37] and pigs^[38-43].

Therefore, could this media support derivation of human naïve ESCs? Although one report described the generation of apparently naïve hiPSCs in 3i media^[44], those results were not replicated by any other group, nor were the human cell lines derived ever used in other reports. Thus, by the lack of publications at that time on the derivation of human naïve ESCs, it became obvious that those relatively simple conditions that worked for many mammalian species were not enough for human cells.

Nevertheless, small molecules took the spot light in pluripotent stem cell research, including epi-drugs like inhibitors of DNA methyltransferases and histone deacetylases, shown to have important roles on cell reprogramming and maintenance of pluripotency^[45].

HUMAN NAÏVE ESCS

Indeed, it was subsequently shown that naïve human

Figure 2 Maintenance of pluripotency by leukemia inhibitory factor and small molecules. Green arrows indicate activation, red blunted lines indicate inhibition. The pluripotent cell must self-renew without committing to any specific cell type. This may be achieved by promoting self-renewal and inhibiting commitment by LIF; or by small molecules (in *italics*) which inhibit (1) signaling through the FGF receptor tyrosine kinase, thus inhibiting commitment; and (2) GSK3, promoting self-renewal. Adapted from^[53]. LIF: Leukemia inhibitory factor; FGFr: Fibroblast growth factor receptor-specific tyrosine kinase; GSK3: Glycogen synthase kinase 3; MEK: Mitogen-activated protein kinase.

pluripotent SCs could only be obtained in 2i when expression of exogenous reprogramming factors was maintained in the cells^[46,47]. Generation of hiPSCs with constant ectopic expression of Oct4, Sox2, Klf4, c-Myc, and Nanog in the presence of LIF lead to human pluripotent SCs with behavior in culture and ease to be genetically manipulated equivalent to those of mouse ESCs^[46]. Similarly, ectopic induction of Oct4, Klf4 and Klf2 in human ESCs in 2i/LIF media reprogrammed the cells into a naïve state transcriptionally similar to that of mouse ESCs, including the reactivation of the inactive X^[47]. Nevertheless, both strategies required continuous expression of the exogenous factors for maintenance of the naïve state.

The next year, Wang *et al.*^[48] reported the efficient generation of exogenous factor-independent naïve hiPSC by transient expression of *Oct4*, *c-Myc*, *Klf4*, *Sox2*, *Rarg* and *Lrh-1* in adult fibroblasts, demonstrating a pivotal role of retinoic acid receptor signaling in reprogramming. However, to our knowledge their results were not replicated by any other group.

After a hiatus of almost two years on reports of naïve human PSCs, within 3 mo four articles described the identification of culture conditions adequate for culture and/or derivation of human naïve ESCs and iPSCs without expression of external factors^[49-52] (Table 1). The first report performed a functional screen of 16 small molecules able to support *OCT4* expression in hiPSCs in LIF/2i. This led to the identification of a combination of 7 factors (including bFGF) able to maintain hiPSCs in a naïve state and to support derivation of naïve human ESCs from blastocysts^[49]. When introduced to mouse embryos, the naïve cells were able to contribute to the formation of E10.5 chimeras, a hallmark of mouse ESCs and not EpiSCs.

In another report, based on the finding that *NANOG* expression is higher in the epiblast of human pre-

implantation epiblast than in human ESCs^[53], Chan *et al.*^[50] tested 11 small molecules that would increase *NANOG* expression in hESCs. They identified a combination of 3 factors that rewired human ESCs into a naïve state responsive to LIF, which was required for self-renewal of the cells (Table 1). In addition, the authors showed that the naïve cells had an expression profile more similar to that of human blastocyst cells than conventional (or primed) human ESCs.

A third report of conditions for naïve human PSCs derivation and culture described a simpler strategy, where human ESCs were exposed to histone deacetylase inhibitors for a few passages before being transitioned to 2i media with bFGF^[51] (Table 1). The 2i + bFGF also supported the derivation of a new line of naïve human ESC that could then be transitioned in to 3i media with LIF. Nevertheless, the efficiency of derivation was very low, and cells in 3i + LIF showed significantly higher rates of differentiation than those kept in 2i + bFGF. Furthermore, although cloning efficiency of the naïve human ESC line established was twice of the primed cell line, it was still relatively low (20%) when compared to other reports, whereas there was no improvement of cloning efficiency of naïve H1 compared to the original primed H1. Thus, the strategy appeared to generate cells in an intermediate naïve state.

Another alternative media for maintenance of transgene-expression free naïve hiPSCs was described by Valamehr *et al.*^[52] (Table 1). While developing culture conditions for high throughput generation of hiPSCs, the group developed a media containing inhibitors of ROCK, GSK3 and MEK pathways, LIF and bFGF that allowed long term culturing of naïve hiPSCs derived in a previously described cocktail of small molecules^[54]. Although those naïve hiPSCs did not have mouse ESC-like morphology, they showed high survival rates in single-cell dissociation, and appeared to be in a pre-

Table 1 Comparison between different protocols to convert/derive human pluripotent stem cell into naïve stem cell

¹Compounds used in most works; ²Addition of MEFs. nt: Not tested; ALKi: Inhibitor of transforming growth factor-beta superfamily type I activating; TGFB1: Receptor-like kinase (ALK) receptors; BMPi: Inhibitor of bone morphogenic protein; BRAFi: Serine/threonine-specific protein kinase participating of RAS-RAF-MEK-ERK signaling transduction cascade; FGF: Fibroblast growth factor; FGF2: Fibroblast growth factor 2; FGFRi: Fibroblast growth factor receptor (FGFR)-specific tyrosine kinase inhibitor; GSKi: Glycogen synthase kinase inhibitor; H3K27me3: Tri-methylation of lysine 27 on histone H3; hESC: Human embryonic stem cells; hiPSC: Human induced pluripotent stem cells; IGF1: Insulin-like growth factor 1; JNKi: Inhibitor of c-Jun N-terminal kinase; LIF: Leukemia Inhibitory Factor; MAPKi: p38 mitogen-activated protein kinase inhibitor; MEKi: Mitogen-activated protein kinase inhibitor; Pan-RTKi: Receptor tyrosine kinase (RTK) Inhibitor; ROCKi: Inhibitor of Rho-associated coiled-coil containing protein kinase; STAT3i: Signal transducer and activator of transcription 3 inhibitor; TGFB1: Transforming growth factor beta 1; Xa: Active X chromosome; Xi: Inactive X chromosome; XIST RNA: RNA FISH signals from X-inactive specific transcript - XIST.

XCI state.

More recently, Theunissen *et al*^[55] performed an alternative functional screen of small molecules able to support growth of human naïve ESCs based on the finding that naïve pluripotent stem cells use the distal while primed cells used the proximal enhancer of *OCT4*. Using a GFP-reporter gene under the control of the distal enhancer of *OCT4* in human ESCs, the authors screened a kinase inhibitor library in the presence of 2i/LIF, identifying a combination of 5 compounds which, together with Activin A and FGF, supports conversion of primed into naïve human ESCs and the derivation of new naïve human ESCs and iPSCs (Table 1). It is important to note that, although these converted or newly established naïve cells had the expected dome-shaped morphology and expression profile more similar to mouse ESCs than to primed human ESCs, they presented a few undesired characteristics, namely, (1) high frequency of aneuploidies, and (2) XCI. The authors suggest that, rather than limitations of their “naïve” cells, these may represent differences between naïve human and murine ESCs.

HUMAN NAÏVE ESCS: FACT OR ARTIFACT?

Which brings us to a crucial point: what is a human naïve ESC? When searching for the human naïve pluripotent state, are we looking for the *in vitro* equivalent of the human epiblast, or for a human pluripotent stem cell as amenable to manipulation in culture as mouse ESCs? Depending on the goal, the characteristics of the resulting naïve human cells can be very different.

The methods for culturing human primed ESCs

have significantly improved in the last 10 years with the development of defined and feeder-free culture conditions and of solutions to substitute manual passage. Nevertheless, these cells are still harder to culture and to genetically manipulate than their mouse counterpart. Thus, the development of culture conditions that make human ESCs behave like mouse ESCs may facilitate their use in research and therapy, regardless of whether this naïve state has any relevance as a model for human development. In that case, we know that these human naïve ESCs should have enhanced proliferation, be passaged as single cells (high cloning efficiency), be genetically stable and amenable to efficient genetic manipulation *in vitro*. In addition, being in a pre-XCI state and undergoing random XCI upon differentiation would be desirable for the generation of naïve hiPSCs to model X-linked diseases^[56].

On the other hand, if the goal is to obtain cells that model the pluripotent epiblast from human blastocysts, then we must step back and look at what we know about these cells *in vivo*. Despite the difficulties in studying the human embryo, enough has been done to know that there are significant differences between human and mouse blastocysts so that one cannot completely extrapolate data from one species to the other^[57]. For instance, at the blastocyst stage, while *Oct4* expression is restricted to epiblast cells in mouse^[58], it is also found in the human trophectoderm^[59]. Thus, the organization and/or the markers of pluripotent cells in the human blastocyst may differ from mouse.

Recent advances in single-cell RNA sequencing (RNAseq) have allowed the study of expression profiles of individual cells during human pre-implantation development^[53,60]. Analysis of RNAseq data from 30

single-cells derived from human blastocysts identified three distinct clusters corresponding to cells from the epiblast, primitive endoderm and throphectoderm. Furthermore, comparison of the expression profile of human epiblast cells with human ESCs at different stages of derivation showed that, although similar, there are significant changes in gene expression in the embryo-derived cells at the initial primary outgrow of hESCs^[53]. That is not surprising given that the cells are adapting to the *in vitro* conditions, but how distinct can they be while still modeling the epiblast *in vitro*? It will be interesting to do the same comparison in mice in order to evaluate whether these changes between murine epiblast and ES cells are less accentuated. Nevertheless, it would be reasonable to use the single-cell RNASeq data from human blastocysts as a signature of “true” naïve human ESCs. Indeed, Chan *et al.*^[50] showed that the expression profile of their naïve human ESCs was more similar to those of single cells from human blastocysts. The same analysis should be performed with the other reported naïve human ESCs for comparison.

Regarding XCI, the kinetics of the process is very well characterized during mouse preimplantation development, starting at the two-cell stage with the imprinted inactivation of the paternal X (pX) in all cells of the embryo. Then, at the blastocyst stage, cells of the ICM reactivate the pX, and go through a second wave of XCI, where each cell will randomly choose the Xi. In contrast, much less is known about the XCI status of the human preimplantation embryo, and results are conflicting^[23]. It would be extremely valuable if “true” naïve human ESCs were in a pre-XCI state like their murine counterpart in order to study the mechanisms of this epigenetic phenomenon *in vitro*. However, we still don't know whether this would represent the *in vivo* situation, and thus, whether the pre-XCI state is a prerequisite for being a “true” naïve human ESC.

While this manuscript was in revision, Wang *et al.*^[61] showed that small populations of naïve human pluripotent SCs exist within cultures of primed human ESCs and iPSCs. These naïve cells can be purified and maintained in 2i/LIF media. In addition, the authors identified increased expression of the primate-specific endogenous retrovirus HERVH as a genetic signature of naïve human pluripotent SCs, which can be used for the development of culture conditions to support human naïve PSC culture. More importantly, the study of HERVH-associated transcription during human pre-implantation embryonic development may provide more insights into this still much-unknown process.

In conclusion, in the last year different culture conditions were developed that support the derivation and growth of human ESCs more similar to mouse ESCs. Whether the distinct methods generate similar or distinct epigenetic states of human pluripotent SCs, and more importantly, which of these potentially naïve human pluripotent SCs are more similar to the cells of

the human epiblast remain to be determined. These studies will have great impact on the establishment of a good *in vitro* model for human embryonic development.

PubMed from January 2004 to December 2013. Studies which performed smart modifications on conventional bone scaffold materials were included. Scaffolds with controlled release or encapsulation of bioactive molecules were not included. Experiments which did not investigate response of cells toward the scaffold (cell attachment, proliferation or osteoblastic differentiation) were excluded.

RESULTS: Among 1458 studies, 38 met the inclusion and exclusion criteria. The main scaffold varied extensively among the included studies. Smart modifications included addition of growth factors (group I -11 studies), extracellular matrix-like molecules (group II -13 studies) and nanoparticles (nano-HA) (group III -17 studies). In all groups, surface coating was the most commonly applied approach for smart modification of scaffolds. In group I, bone morphogenetic proteins were mainly used as growth factor stabilized on polycaprolactone (PCL). In group II, collagen 1 in combination with PCL, hydroxyapatite (HA) and tricalcium phosphate were the most frequent scaffolds used. In the third group, nano-HA with PCL and chitosan were used the most. As variable methods were used, a thorough and comprehensible compare between the results and approaches was unattainable.

CONCLUSION: Regarding the variability in methodology of these *in vitro* studies it was demonstrated that smart modification of scaffolds can improve tissue properties.

Key words: Bone tissue engineering; Scaffold; Growth factor; Nanoparticle; Extracellular matrix

Abstract

AIM: To improve osteogenic differentiation and attachment of cells.

METHODS: An electronic search was conducted in

Core tip: Currently, special attention has been directed to the design of new scaffolds by adding bioactive molecules and nanoparticles. "Smart scaffolds" in bone tissue engineering not only act as cell delivery materials, but they are also responsive to their environment and therefore

stem cells are more likely to attach, proliferate and differentiate on them. These scaffolds can be fabricated by adding either of growth factors, extracellular matrix proteins or nanoparticles to the bone substitutes using various techniques. These modifications can enhance the *in vitro* response of bone scaffolds toward cells.

Motamedian SR, Hosseinpour S, Ahsaie MG, Khojasteh A. Smart scaffolds in bone tissue engineering: A systematic review of literature. *World J Stem Cells* 2015; 7(3): 657-668 Available from: URL: <http://www.wjgnet.com/1948-0210/full/v7/i3/657.htm> DOI: <http://dx.doi.org/10.4252/wjsc.v7.i3.657>

INTRODUCTION

Tissue engineering is a helpful alternative strategy for conventional treatments in medicine. It was defined by Langer and Vacant^[1] as “an interdisciplinary field of research that applies the principals of engineering and life sciences towards the development of biological substitutes that restore, maintain, or improve tissue function or a whole organ”. Bone tissue engineering uses life sciences and engineering to aid the function of injured bone tissue *via* a triad of artificial extracellular matrix (ECM) scaffold, stem cells that can become osteoblasts and growth factors^[2,3]. The efficacy of this combination has been studied in animals^[4-6] and humans^[7-9]. Mesenchymal stem cells, the most common source of osteoprogenitor cells, can be derived from bone marrow^[10-13], adipose tissue^[14-16], and dental and periodontal tissues^[17-19]. Growth factors, such as bone morphogenic proteins (BMPs), have the capability to modulate stem cell activity towards bone regeneration^[20-24].

Scaffolds play a key role in bone tissue engineering providing a 3-dimensional environment for cell seeding and proliferation as well as filling bone defects while providing mechanical competence during bone regeneration^[25-27]. Osteoconductivity, porosity and biodegradation are the required properties for a scaffold to be successful in bone tissue engineering, enhancing bone formation and angiogenesis and supporting attachment and proliferation of osteoblasts^[28]. In this context, various scaffolds such as hydroxyapatite HA, tricalcium phosphate (TCP), collagen, chitosan, polycaprolactone (PCL), and poly(lactic-co-glycolic acid) (PLGA), have been used^[2,3].

Recently, tissue engineers have focused on structural design and surface properties of scaffolds. Various modifications such as addition of bioactive molecules or nanoparticles can enhance attachment and proliferation of stem cells on the scaffold^[29-31]. These “smart scaffolds” improve osteogenic differentiation of stem cells leading to a more responsive reaction to changes in their surrounding environment^[32]. The current study reviews newly developed scaffolds and their smart modifications.

MATERIALS AND METHODS

Study selection

Papers relevant to *in-vitro* experiments on newly fabricated smart scaffolds were reviewed. Three modifications were considered as smart namely: (1) addition of nanoparticles; (2) addition of ECM-like molecules; and (3) addition of growth factors. Studies which performed these smart modifications on conventional bone scaffold materials were included. Scaffolds with controlled release or encapsulation of bioactive molecules were not included. Experiments which did not investigate response of cells toward the scaffold (cell attachment, proliferation or osteoblastic differentiation) were also excluded.

Search strategy

An electronic search was conducted in PubMed limited to English language, relevant publications from January 2004 to December 2013 with available full texts. Published papers on smart scaffolds were found using the following keywords alone or in combination: bone tissue engineering, smart scaffold, xenograft, xenogenous bone, allograft, allogeneous bone, bone substitute, bovine bone matrix, allogenic bone, xenogenic bone, coat*, surface modification, surface enhancement, biofunctional*, bioact*, biomimet*, nano*, extracellular matrix, collagen and growth factor.

Initial paper selection was done by reviewing titles and abstracts of all selected papers. The full texts of potentially suitable articles were obtained for final assessment according to the exclusion and inclusion criteria. The reports of the most relevant data were included and analyzed in a qualitative manner.

Statistical analysis

This study was a literature review and no statistical method was used in this study.

RESULTS

Figure 1 demonstrates the design of the current review. The initial search resulted in 1458 articles. Following the screening of titles, abstracts and full texts, 38 papers had the criteria for review.

Growth factors

Eleven experiments were studied (Table 1) for scaffold modification; in all these studies, surface coating *via* growth factors to increase scaffold activity was used (Figure 2A). In addition, modification of architecture and spatial conformation of the main scaffold was performed^[38]. The main scaffold differed in each study. The most commonly used scaffold was PCL, followed by TCP, PLGA, Bio-Oss, Calcium/magnesium-doped mesoporous silica, calcium phosphate cement, collagen, carbon nanotubes, TolAIII fusion-osteopontin-switch tag and glutaraldehyde cross-linked gelatin (GTG). The most

Figure 2 Type of modification method and smart materials in each category. A: Methods for growth factor addition; B: Methods for ECM molecules addition; C: Methods for nanoparticles addition; D: Growth factors added; E: ECM molecules added; F: Nanoparticles added. ECM: Extracellular matrix.

commonly applied growth factor was BMPs including BMP-2, BMP-4 and BMP-7 (Figure 2D). Different methods were used to add BMPs to the main scaffold: attachment of BMP-4 to scaffolds by cross linking conjugating techniques, deep and dry methods for addition of BMP-2 to Bio-Oss and using a set of nanoparticles providing the release of BMP-2. Scaffold fabrication methods varied vastly among studies.

Regarding the study methods, bone marrow mesenchymal stem cells (BMMSCs) were used in 6 experiments, while different type of cells such as neonatal rat calvarial osteoblast cells, Human osteosarcoma cells (MG63Cs), sarcoma osteogenic cells (SaOS-2Cs) and immortalized mouse myoblast cells (C2C12Cs) were used in other studies. In almost all studies, cell viability was assessed with alkaline phosphatase (ALP) activity assay and the best results were obtained using new compositions compared to control groups. In just one study, no meaningful changes were observed^[41]. One study used luciferase activity as their major assay^[38]. In 2 studies, real time

polymerase reaction assay was used with different biomarkers such as: BMP-2, Runt-related transcription factor 2 (Runx-2), Osteopontin, P-smad and collagen 1.

ECM-like molecules

Among 67 articles, which used ECM-like molecules to enhance scaffold properties, 13 experiments were studied (Table 2). Type of scaffold modification in 10 studies was surface coating. In 1 study, architectural and spatial conformation was performed on the scaffolds^[48], and in 2 experiments collagen fibers were electrospun in conjugation with polymer and ceramic components to form a fibrous scaffold (Figure 2B)^[45,52]. Xu *et al.*^[30] produced a new composite scaffold by combining collagen, bioglass, hyaluronic acid and phosphatidylserine. In a study by Lechner *et al.*^[44], fibrinogen was added to bone tissue core. In their study, CD31 was assessed before and after treatment with newly developed scaffold by fluorescent-activated cell scan techniques and their results showed 100-fold increase in expression of CD31 marker^[44]. The most

commonly used ECM-like molecule was collagen 1. Other molecules were fibrin, collagen IV, and hyaluronic acid (Figure 2E). The main scaffolds used were TCP, HA, PCL, bioactive glass nanofiber, octacalcium phosphate, Bio-Oss and Bioglass. Scaffold fabrication methods varied vastly among included studies.

Regarding the study method, in the majority of studies cell differentiation was assessed with ALP activity assay and higher activity was reported for experimental scaffolds compared to control groups. In addition, various methods were applied to assess cell attachment, proliferation and differentiation. In 6 studies, the cell type was BMMSCs; whereas in other studies MG63Cs, SaOS-2Cs, osteoblast precursor cells (MC3T3-E1Cs), adipose-derived stem cells (ADSCs), and mouse bone marrow cells (MSST-2 Cs) were used.

Nano particles

Among 85 articles, which used nano particles to enhance scaffold properties, 17 were studied (Table 3). Type of modification was surface modification and scaffold architecture in 5 studies; in another 6 experiments, spatial conformation was performed. Others fabricated new scaffolds by adding nanoparticles to the scaffold composition (Figure 2C). The main scaffold on which modifications were made varied in the studies. These scaffolds included PCL, chitosan, PLGA, gelatin, TCP, poly L-lactic acid (PLLA), single-walled carbon nanotubes, polyamide and HA. Nanoparticles of HA were the most commonly added particles followed by nano fibrous PCL, nano diamond, amorphous calcium phosphate nanoparticles, nano silica, nano apatite, magnetic nanoparticles and nano-sized bioactive glass (Figure 2F). Different fabrication techniques were applied: flame spray pyrolysis, sonication, thermally induced phase, electrospun, blunt-end needle tip and gamma high voltage. Scaffold fabrication method varied vastly among the included studies.

Regarding the study method, various tests were performed to assess cell viability, attachment, proliferation and differentiation. ALP activity assay, 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide assay, 5-[3-(carboxymethoxy)phenyl]-3-(4,5-dimethyl-2-thiazolyl)-2-(4-sulfophenyl)-2H-tetrazolium inner salt assay, bicinchoninic acid assay, bone Gla protein activity and Alamar blue assay were among these tests. In 5 studies, PCR test was used to assess level of gene expression. Various biomarkers were used in each study such as ALP, OCN, Runx-2, bone sialoprotein, TGF- β 1, BMP-2, collagen 1 and integrin subunits together with myosins. In 10 cases, cell type used in the study was BMMSCs. Other cell types used in the studies were: Mouse bone marrow cells (7F2Cs), MC3T3-E1Cs, osteoblastic cells (ROS 17/1.8 Cs), human airway fibroblast cells, ADSCs, MG63Cs, primary human osteoblasts-like cells and rat calvarial osteoblast cells.

bone regeneration. The most relevant applied methods to design smart scaffolds are surface modification by adding nano particles such as nHA and adding an ECM-like molecule such as collagen or growth factor like BMP-2 to the scaffold. Factors such as scaffold material, fabrication method and type of modification defining the physical, chemical and mechanical properties of scaffolds need assessment. Due to the variability of influencing factors including methodology and scaffold properties, the results were not comparable to determine the most successful design. *In vitro* tests for analyzing the behavior of the fabricated scaffolds vary among the studies. The source of cells also influences the results, and qualitative report of cell migration, attachment, infiltration and differentiation must be similar to compare the results. The results of included *in vitro* experiments demonstrated that smart design of scaffolds supported cell attachment, proliferation and differentiation.

Modification

Surface modification of scaffold materials was the most commonly used design. However, when implanting the graft materials, their surfaces are covered with ECM proteins and molecules and thermodynamic forces cause surface absorption. This issue is commonly overlooked. Alteration of surface properties influences cell adhesion. In addition, surface plays a role in cell migration towards the scaffold and stem cell differentiation. Addition of either HA or collagen to the outer surface of polyethylene terephthalate (PET) caused greater attachment of rat bone marrow cells to the surface and deposition of an HA layer on the surface^[69]. The morphology of attached cells mimics that of more differentiated cells. Although chemical modification of scaffold surface affects cell to scaffold response, effect of material design on cell behavior should also be considered^[70]. Hatano *et al.*^[71] demonstrated that cell differentiation is affected by surface roughness. In the cited study, rougher surfaces caused expression of osteoblastic markers.

Growth factors and bioactive molecules

Understanding the physiological processes of bone regeneration and the involved regulating molecules is necessary to enhance bone repair. Several attempts at adding these molecules to scaffolds were demonstrated (Tables 1 and 2). Regulating molecules include growth factors and other proteins found in bone ECM.

In the reviewed studies, BMPs seemed to be more frequently used in the scaffolds compared to other growth factors. BMPs induce osteogenic differentiation of stem cells and osteoprogenitor cells, and their efficient and safe use in human was licensed in 2001. In addition, growth factors like BMPs and vascular endothelial growth factors can accelerate healing processes^[72,73]. Chemically conjugated BMP-2 on PCL scaffolds caused significantly greater ALP gene expression compared to un-treated PCL scaffolds^[37]. In a study by Lu *et*

DISCUSSION

This study reviewed current trends in smart scaffolds for

Table 3 Description of included studies which modified the scaffolds by addition of nanoparticles

Ref.	Scaffold	Fabrication	Type of modification	Cell type	Tests and results
Kim <i>et al</i> ^[54] , 2006	PLGA + nHA	SC/PL and GF/PL	New composition fabrication	RCOCs	Average cell density: GF/PL = 2.4×10^6 cells/scaffold (86.5% increase) SC/PL = 2.1×10^6 cells/scaffold (69.7% increase) ALP activity: GF/PL = 0.6 mol/min per 10^6 SC/PL = 0.5 mol/min per 10^6

al^[41], results indicated that spatial immobilization of BMP-4 in a collagen-PLGA hybrid scaffold caused high expression of osteogenic genes and supported cell adhesion and proliferation^[41]. In 2005, Yang *et al*^[33] evaluated the effect of BMP-4 immobilization on GTG scaffolds on NRCOC activity. A significant effect of BMP-4 was reported after 4 wk. The cited study also showed greater cell attachment and osteoblast differentiation, higher Gla-type osteocalcin (Gla-OC) activity and larger mineralizing nodules following co-culture of osteoblasts with BMP-4 immobilized scaffold. The same results were achieved using BMP-2. Dai *et al*^[40] reported that rhBMP-2 significantly promoted the osteogenic differentiation of BMMSCs, by enhanced expression of Runx-2, osteopontin, osteocalcin and bone sialoprotein. On the other hand, combination of BMP-4 and PLGA scaffold resulted in a reduction in ALP activity^[41]. Although BMPs seem to have positive effects on the function of scaffolds and cells, their regularity and efficacy constraints limit their clinical application.

Surface of scaffolds can be modified by proteins and plasma treatment. Immobilization of proteins like integrin and laminin on the scaffold surface not only facilitates cell adhesion but also increases the surface

wettability^[74]. To add a mixture of fibrin and hyaluronic acid, multihead deposition system and fibrin-thrombin shell formation were used^[50]. Using immobilized RGD peptide (Arg-Gly-Asp) improved cell adhesion from 71.6% to 80.7% and increased ALP activity^[49]. Similarly, high cell proliferation, differentiation and viability were reported following addition of other ECM molecules to scaffold surfaces^[34,47].

On the other hand, although biomolecules like growth factors and ECM proteins can improve scaffold properties, these molecules do not tolerate severe chemical conditions or high temperature and only soft fabrication methods like sol-gel, which does not allow interconnected porous scaffold synthesis, are applicable^[75].

Nano particles

Nano particle addition to the scaffold is another way to improve scaffold properties. The most commonly applied nanoparticle was nano-HA, which provides osteoconductivity while the main scaffold provides the porosity. This combination resembles organic/inorganic nature of the bone matrix and mimics the nano-sized characteristics of natural bone^[26]. Addition of nano-

HA to scaffold doubled the expression of osteogenic genes^[67] and increased osteoblastic attachment^[63]; whereas osteocalcin gene expression level in PLLA-nano diamond composites was 3 times less than in the PLLA scaffold^[59]. Ye *et al.*^[58] produced a composite scaffold containing nano non-stoichiometric apatite and poly-epsilon-caprolactone, which had well-interconnected pores encouraging cell proliferation, migration and stimulation.

Future prospects

In vitro studies are generally considered as primary steps for evaluating newly developed materials. These experiments evaluate cell viability, attachment, proliferation and differentiation on new scaffolds by various methods. Although some factors like the effect of recipient bed, body fluids and interaction between different cell types cannot be evaluated in *in-vitro* experiments, they are useful to analyze the behavior of materials toward cells omitting individual characteristics of animal or human models. However, animal and clinical studies are necessary to assess the regenerative ability of materials *in-vivo*. A systematic review on *in-vivo* bone tissue engineering studies by Khojasteh *et al.*^[2] demonstrated that only few animal experiments used smart modification of scaffolds; most of which, were addition of BMP-2. It seemed that the application of BMP-2 with stem cells such as ADSCs and BMSC in TCP scaffolds significantly enhanced osteogenesis^[2]. Use of growth factors such as BMP-2 in combination with scaffold and stem cells could complete the classic tissue engineering triangle. However, the results of *in vitro* studies showed that addition of ECM-like molecules and nano-particles also induced osteoblastic differentiation. The most common composite used in bone tissue engineering was found to be polymer-ceramic and use of smartly modified scaffolds in animal models has been relatively fewer^[76]. Compared to the large number of *in-vitro* studies assessing the properties of newly developed materials, *in-vivo* application of these smart scaffolds and the effect of structural features and surface modification on *in-vivo* bone regeneration have yet to be studied.

In conclusion, comparing smart scaffolds to other presently available conventional materials shows great advantages, as they have the ability of *in-situ* osteoblastic differentiation induction and interesting biological functions. The more we understand the fundamentals of cell proliferation, differentiation and mechanisms of osteoblast adhesion, the better we can design smart materials. The researches now aim to design and synthesize composite materials made from fusion of different kinds of synthetic and natural materials. Surface treatment for facilitating cell attachment and differentiation and fabrication of strong scaffolds that can tolerate physiological forces are the main challenges in this regard. *In-vitro* studies should be performed primarily using standard methods

followed by *in-vivo* investigations. Combination of stem cells and smart scaffolds with a modulus of elasticity of the same magnitude as that of natural bone, and incorporating growth factors may complete the bone tissue engineering triad. Several factors including material, fabrication and modification methods as well as physical, chemical and mechanical properties may determine bone scaffold features. Considering the variability of *in-vitro* methodology of researches and variety of scaffolds, a thorough and comprehensible comparison between the results and approaches of these *in vitro* experiments was unattainable. However, the results of the included *in-vitro* studies indicate that incorporation of growth factors and other bioactive molecules as well as nano-particles as smart modifications can enhance cell differentiation, proliferation and attachment and therefore may improve new bone formation. The current study presented various types of smart modifications, which may provide an acceptable design to approach *in-vivo* and *in-vitro* hard tissue engineering.

COMMENTS

Background

Scaffold, cells and growth factors are the three main parts of bone tissue engineering. Currently, special attention has been directed to the design of new scaffolds by adding bioactive molecules and nanoparticles. Hydroxyapatite-based scaffolds carry cells to bone defects and provide an extracellular matrix (ECM). By changing the physical and chemical properties of the bone substitutes, smart interaction with seeded cells such as acceleration of differentiation, increasing in proliferation and attachment of the cells has been reported. It seems that these "smart modifications", can improve osteogenic differentiation and attachment of cells; therefore, they can better respond to their surrounding environment.

Research frontiers

Surface modification of scaffold materials was the most commonly used design. However, it is not clear how surface would influence bone regeneration *in vivo*. This study reviewed current trends in smart scaffolds for bone regeneration. Adding nano particles such as nHA and adding an ECM-like molecule such as collagen or growth factor like bone morphogenetic protein (BMP)-2 to the scaffold increase bioactivity of synthetic materials.

Innovations and breakthroughs

Several factors such as scaffold material, fabrication method and type of modification defining the physical, chemical and mechanical properties could affect *in vitro* experiments. Due to the variability of influencing factors including methodology and scaffold properties, the results were not comparable to determine the most successful design. Overall conclusion shows that in most studies smart design of scaffolds supported more cell attachment, proliferation and differentiation.

Applications

Although use of growth factors such as BMP-2 in combination with scaffold and stem cells could complete the classic tissue engineering triangle and result in bone regeneration *in vivo*, *in vitro* studies suggest that addition of ECM-like molecules and nano-particles also might have same results as BMP-2. The efficacy of these modifications should be assessed *in vivo*.

Peer-review

The matter of the review is interesting.

Volume 7 Number 4 May 26, 2015

ABOUT COVER

Editorial Board Member of *World Journal of Stem Cells*, Anskar YH Leung, Associate Professor, Division of Hematology and Bone Marrow Transplantation, Department of Medicine, Room K418B, K Block, Queen Mary Hospital, Pok Fu Lam Road, Hong Kong, China

AIM AND SCOPE

World Journal of Stem Cells (*World J Stem Cells*, *WJSC*, online ISSN 1948-0210, DOI: 10.4252), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJSC covers topics concerning all aspects of stem cells: embryonic, neural, hematopoietic, mesenchymal, tissue-specific, and cancer stem cells; the stem cell niche, stem cell genomics and proteomics, and stem cell techniques and their application in clinical trials.

We encourage authors to submit their manuscripts to *WJSC*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

INDEXING/ ABSTRACTING

World Journal of Stem Cells is now indexed in PubMed Central, PubMed, Digital Object Identifier, and Directory of Open Access Journals.

Abstract

Spermatogonial stem cells (SSCs) are the germ stem cells of the seminiferous epithelium in the testis. Through the process of spermatogenesis, they produce sperm while concomitantly keeping their cellular pool constant through self-renewal. SSC biology offers important applications for animal reproduction and overcoming human disease through regenerative therapies. To this end, several techniques involving SSCs have been developed and will be covered in this article. SSCs convey genetic information to the next generation, a property that can be exploited for

gene targeting. Additionally, SSCs can be induced to become embryonic stem cell-like pluripotent cells *in vitro*. Updates on SSC transplantation techniques with related applications, such as fertility restoration and preservation of endangered species, are also covered on this article. SSC suspensions can be transplanted to the testis of an animal and this has given the basis for SSC functional assays. This procedure has proven technically demanding in large animals and men. In parallel, testis tissue xenografting, another transplantation technique, was developed and resulted in sperm production in testis explants grafted into ectopical locations in foreign species. Since SSC culture holds a pivotal role in SSC biotechnologies, current advances are overviewed. Finally, spermatogenesis *in vitro*, already demonstrated in mice, offers great promises to cope with reproductive issues in the farm animal industry and human clinical applications.

Key words: Cell culture; Spermatogonial stem cells; Spermatogenesis; Pluripotency; Transplantation; Fertility

© The Author(s) 2015. Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: This article reviews the current body of knowledge on biotechnological applications of spermatogonial stem cells (SSCs). SSCs are the founding adult germ stem cells of the sperm producing process spermatogenesis. SSCs belong to the male germline and can be expanded *in vitro* in several species. Through mechanisms not fully understood they can derive pluripotent stem cells *in vitro*. Thus, they can be genetically modified with some advantages over embryonic stem cell-based technologies. SSCs can be transplanted to homotopical or ectopical locations, offering great potentials in fertility related issues and regenerative clinical applications in domestic or wild animals and men.

Aponte PM. Spermatogonial stem cells: Current biotechnological

advances in reproduction and regenerative medicine. *World J Stem Cells* 2015; 7(4): 669-680 Available from: URL: <http://www.wjgnet.com/1948-0210/full/v7/i4/669.htm> DOI: <http://dx.doi.org/10.4252/wjsc.v7.i4.669>

INTRODUCTION

Spermatogonial stem cells (SSCs), the germ stem cells of the seminiferous epithelium in the testis are the founder cells of a sperm producing stem cell system called spermatogenesis. SSCs were initially regarded as unipotential cells. Nowadays, however, current knowledge about SSCs has expanded to new limits and the general concept of SSCs as cells just supporting the production of the terminally differentiated sperm has rather radically changed. As a result of continuous and elaborate SSC biology research, the manipulation of this special cell type offers novel biotechnological solutions to contemporary human problems. SSCs are the only adult stem cells capable of transmitting the genome of a given species from one generation to the next, while at the same time having the capacity to convert into pluripotent stem cells^[1-3]. They can also give rise to cells from the basic three embryonic layers *in vitro*, which opened new opportunities for regenerative medicine^[1]. Since SSCs are adult cells, they do not bring about ethical concerns as occurs with the use of embryonic stem (ES) cells. However, the use of SSCs is not without risk, since they show some issues regarding epigenetic inheritance, as such a topic will be covered later on this article.

The faculty of SSCs to deliver genes over generations makes them a valuable vehicle for transgenesis techniques. This is particularly important for gene targeting in domestic animals, in which, contrary to laboratory rodent species, the techniques involving SSCs are still not feasible. In this process, SSC culture plays a central role in the exploitation of the unique properties of SSCs for biotechnological applications. Historically, the characterization of the SSC niche *in vivo* gave the basis for SSC culture conditions, especially SSC population expansion *via* self-renewal in several species, included men. A stem cell niche consists of a microenvironment with supporting cells and a corresponding signal exchange that regulates self-renewal and differentiation of the stem cells. Accordingly, SSCs are located in the seminiferous epithelium, near the basement membrane and the niche environment normally contains factors produced by neighboring somatic cells (sertoli cells, leydig cells, and peritubular myoid cells), the basement membrane and in particular the vascular network, near where SSCs are preferentially located^[4]. This microenvironment in the testis provides signals to control stem cell self-renewal, differentiation, or survival, guaranteeing a normal cell kinetics in spermatogenesis^[5,6].

SSC behavior *in vitro* could be further investigated thanks to the development of germ cell transplantation

assays, which allow functional verification of the presence of SSCs (see the topic Germ cell transplantation). The addition of certain growth factors to the culture media, in particular glial cell line-derived neurotrophic factor (GDNF), and the availability of a functional SSC assay, allows SSC populations to be expanded during long term culture, an advance first made in rodent models.

SSC biotechnologies are being aimed to solve fertility related issues (*i.e.*, fertility restoration in oncological patients, infertility treatments and reproduction of endangered species). They also provide important developments in germplasm preservation and the emerging technology of spermatogenesis *in vitro*. Finally, several of these applications require species-specific knowledge of SSC culture conditions as well as transplantation techniques, two aspects that will be covered in this article (for a summary of the biotechnological approaches that involve the use of SSCs, see Figure 1).

SSC ISOLATION AND CULTURE

SSC isolation procedures have been described for several domestic species and humans^[7-14]. SSCs are isolated by enzymatic digestion, usually involving two steps of various combinations of proteolytic enzymes (commonly, collagenases I or IV, trypsin, hyaluronidase and DNase I). From this enzymatic digestion, a germ cell suspension is obtained that now has to go through at least one type of purification methods, but more often a combination of them (Zheng *et al*^[15], 2014 summarize the current enriching methods for SSC isolation). There are two groups of purification methods, one group based on the SSC phenotype, like fluorescence activated cell sorting (FACS) and magnetic activated cell sorting (MACS), and the other utilizes physical methods, like differential plating, extracellular matrix selection and density gradient sedimentation^[15]. Simple models for SSC isolation include the use of young animals^[16], cryptorchid animals^[17], vitamin A deficient animals^[18], but SSC isolation becomes more complex when their source is the adult testis with full spermatogenesis. In this scenario, all differentiating germ cell types are present and SSCs represent a smaller proportion (see the topic SSC markers). Most recent articles in which SSC isolation is carried on, include one phenotype-based method and one or more physical methods. Most researchers do not use a functional assay (germ cell transplantation) to unambiguously identify the isolated germ cells as SSCs. They instead characterize the germ cell colonies arising during culture by means of immunohistochemistry or RT-PCR, aiming to identify gene products or RNA expression respectively (see the topic SSC markers). MACS is the most widely used technique nowadays. It is simple and inexpensive, but relies on specific SSC markers usually present in subsets of the SSCs, therefore sub-sampling the

Figure 1 Overview of biotechnologies involving spermatogonial stem cells. Fertility preservation includes fertility restoration in oncological patients after therapeutic agents are administered that produce germ cell damage, strategies for infertile male patients and reproduction of endangered species. Gene dissemination represents the possibility to use several low-genetics animals to disseminate elite genes in animal production operations. Culture involves maintenance, survival, expansion and possibly genetic manipulations of spermatogonial stem cells (SSCs). Germ stem cells (GSCs), that is, SSCs that self-renew *in vitro*, therefore proliferating and expanding. Multipotent germ stem cells (mGSCs), which spontaneously appear in culture from within the SSC population, showing pluripotency properties^[2].

general SSC population. Interestingly, one group, in a recent work, produced an enriched human SSC suspension by using MACS and the marker ITGA6 (alpha 6 integrin) together with a proper authentication of SSCs through the germ cell transplantation assay^[11]. A recent novel approach for SSC isolation involved the combination of traditional isolation methods with testicular tissue grafting (see the topic Germ cell transplantation). In this work, adult mouse testis tissue was grafted into the dorsal skin of immunodeficient mice and after 2-4 wk the researchers observed the depletion of advanced differentiating germ cells of the seminiferous epithelium. Afterwards, the tissues left only with undifferentiated type A spermatogonia (a population including the SSCs) were recovered. The SSCs were isolated from the tissues, which were not only able to proliferate *in vitro* but also to recapitulate spermatogenesis in receptor testes devoid of endogenous spermatogenesis and furthermore to produce offspring through the original donor derived sperm^[19]. This method, although perhaps not as practical as MACS, results in a larger true SSC population since the whole array of markers confirm the phenotypic profiles of SSCs.

Culture conditions for SSC propagation *in vitro* were first developed in mice^[16,20]. This was the base for the development of domestic animals SSC culture systems^[7-10,21-25]. Most of these systems have in common the use of GDNF and serum. Common growth factors, besides GDNF, include LIF, FGF2 and EGF^[26], however important responses of SSCs regarding maintenance, survival and growth *in vitro* are dependent on age, species and even the strain of the donor animals^[27]. Very recently, a feeder/serum-free culture was established for mice SSCs^[28] and this method was improved for maintenance of SSCs^[29].

This represents a big advance because serum, when present, introduces unknown variable factors into the culture systems^[27] besides promoting the growing of contaminating somatic cells^[2]. Current efforts are being made to set up functional human SSC culture systems^[11,30,31].

SSC DIFFERENTIATION *IN VITRO*

Normally, SSCs self-renew during the steady state cell kinetics of spermatogenesis. They do so to maintain the undifferentiated pool while at the same time producing daughter cells that enter the differentiation path, ultimately generating sperm^[32]. Thus, the production of sperm *in vitro* requires culture conditions favoring the pathways of sperm production and not self-renewal. Going through the meiosis step of germ cell differentiation *in vitro* was one of the most difficult steps for many research groups. This fact hindered the progress in this particular research area for many years. An spermatogenesis *in vitro* system going beyond that developmental stage and traversing spermiogenesis was achieved and mouse sperm could be generated when testicular tissue was set on the liquid/gas interphase^[33]. This system included a very simple culture medium and testicular tissues came from young animals^[34]. One of the main features of this culture system is the preservation of the cytoarchitecture of the testis, that is, maintaining the structure of SSC niches. The reconstitution of spermatogenesis *in vitro* from SSC suspensions has proven more challenging. Some groups have obtained sperm *in vitro* by using testicular cell suspensions from prepubertal animals but three dimensional support matrices are necessary^[35,36]. Although these successful systems have been developed for sperm production

in vitro with rodent species, it is not yet foreseeable that these techniques can be translated to a clinical setting in the near future. Human SSC differentiation in culture systems is still under investigation at the present time.

The exciting possibility of producing sperm *in vitro* has large implications for farm animal industries, human fertility restoration, preservation of endangered species and many other associated technologies related to mammalian reproduction. For instance, in the cattle industry, keeping animals in large facilities would be a thing of the past when renewable SSC pools from elite bulls produce high numbers of sperm in Petri dishes at small biotechnological facilities. In many cases of human infertility it would just be enough to have one healthy SSC derived (and possibly engineered) sperm to produce offspring through assisted reproduction technologies (ARTs). Autologous SSC culture systems could be set for individuals before oncological treatments and sperm generated *in vitro* could be cryopreserved for later use to fertilize an egg and produce offspring from these patients. This way, the danger of reintroducing malignant cells back into the patient could be avoided. SSC banking could then become possible, as another mean for germplasm preservation in many species. Moreover, the cumbersome step of transplanting genetically modified SSCs to a receptor male in order to recapitulate spermatogenesis and thus obtain transgenic sperm could then be omitted. In addition, these techniques could also provide means for preserving endangered species, for instance, animal populations with very few individuals that at the moment of dying could have their SSCs collected for sperm to be produced in the laboratory.

SSC MARKERS

The characterization of SSCs is an important tool to study their presence on culture systems and during other techniques. SSCs, representing only the 0.03% of germ cells in the testis^[37], and the more numerous type A spermatogonia committed to differentiate, are morphologically undistinguishable. Furthermore, there is no general consensus on the phenotypic profile of SSC as this may vary among different species^[38] and there seems to be no unique SSC marker. In general, some phenotypic characteristics of SSCs have been advanced thanks to the molecular dissection of the SSC niche in the testis. Within the testis, Sertoli cells are the main cell type involved in the SSC niche^[39]. The key factor GDNF, secreted by Sertoli cells, promotes SSC proliferation^[40,41]. Any receptors expressed in SSCs that bind self-renewal promoting ligand molecules from the niche define their stem cell phenotype and constitute potential SSC markers^[42]. That is the case of the widely accepted marker GFR α 1, the receptor for GDNF in SSCs^[43]. In domestic animals, besides GFR α 1, another important marker for both gonocytes (perinatal germline stem cells) and SSCs is THY1^[44-46].

In monkeys, SSCs express the phenotype (CD90+ DC49f⁺ CD117⁺), SSEA-4⁺ PLZF⁺^[47]. Apparently, SSEA-4 seems to be conserved in humans^[48]. SSCs from humans also express GPR125^[49], besides GFR α 1^[50]. Another human SSC marker that adds to the known panel is ITGA6^[51]. Recently, a new SSC gene product has been reported: PAX7, that might represent a definite common SSC marker for several species including mice, cats, dogs, pigs, bulls, monkeys and humans^[52].

SSC PLURIPOTENCY

Pluripotent stem cells so far considered for regenerative medicine strategies include inner cell mass derived ES cells^[53,54], somatic derived induced pluripotent stem cells (iPS cells)^[55], fetal derived embryonic germ (EG) cells^[56] and SSC derived multipotent germ stem (mGS) cells^[57,58]. All of these cells form teratomas when injected to seminiferous tubules or subcutaneous tissue of immunocompromised mice and contribute to chimera formation when injected to a blastocyst. When SSCs are placed in culture they proliferate in the presence of GDNF. This growth factor is produced by Sertoli cells in the testis, stimulating SSCs to self-renew^[41]. SSCs proliferating in culture are designated germ stem cells (GS) cells^[16]. They are unipotent, genetically and epigenetically stable, do not produce teratomas and do not contribute to chimera^[59]. Extraordinarily, while in culture, they can spontaneously derive multipotent germ stem cells (designated mGS cells) at a low frequency (1 out of 30 testes)^[58]. They represent SSCs with pluripotency, sharing not only ES cell traits such as self-renewal properties, tumorigenicity and chimera production but also genomic and epigenetic abnormalities^[2]. Pluripotent germ cells from the testis can circumvent some of the typical objections or technical limitations of other pluripotent cells (*i.e.*, ES cells and iPS cells) for their use in therapeutic purposes. These limitations include issues in cell proliferation, cell differentiation, genetic stability, allogenicity and ethical/religious issues (reviewed in^[60]). Remarkably and unlike other pluripotent cells, the conversion of GS cells into mGS cells occurs on a dedifferentiation process not dependent on genetic manipulations, which opens important theoretical possibilities for these technologies to be translated into clinical applications in regenerative medicine. Nevertheless, despite all the promising traits of mGS cells, caution is required on the grounds of their genetic and epigenetic behavior. Although GS cells maintain a normal karyotype, genomic imprinting, and SSC activity during long-term culture^[59], mGS cells are unstable and tend to accumulate genomic and epigenomic abnormalities^[2,61]. Also, GS-like cells derived from mouse fetal germ cells had SSC activity but some of the produced offspring had abnormal genomic imprinting patterns, which were also transmitted to future generations^[56]. SSC-derived pluripotent cells

are able to generate very diverse tissues while in cell culture^[1,3]. For instance, differentiated tissues appear in culture from a specific subpopulation of mouse mGS cells that show a pluripotent cell phenotype (POU5F1⁺) while at the same time expressing SSC proteins (c-Kit⁺)^[62].

All in all, SSCs show excellent perspectives for applications in regenerative medicine. According to the "organ niche" theory, developmental failure in organogenesis caused by defective genes, can be compensated by xenogeneic pluripotent stem cell transplantation into genetically affected blastocysts^[63]. The pluripotential cells would then integrate into the embryo, resulting in chimera formation with colonization of stem cells of xenogeneic origin in the organ forming niches during development. This has been demonstrated through animal models such as mouse and pigs to successfully generate functional kidneys^[64] and pancreas^[63,65]. SSC-derived pluripotent stem cells, with all their inherent advantages, could be used for these purposes.

Although the current advances in the generation of testicular pluripotent cells in rodents are unquestionable, similar results in the humans have been controversial. Although one work demonstrated teratoma formation and pluripotency markers expression^[66] on these cells, tumors showed a relatively small volume^[67]. Several other groups have produced allegedly human mGS cells as well, but these cells, although expressing several pluripotency markers, do not produce teratomas when transplanted into the skin of immunocompromised mice^[68-70]. In fact, one group recently found that human testicular embryonic-like cells (allegedly mGS pluripotent cells) do not possess a transcriptome similar to that of human ES cells but rather have the phenotype of mesenchymal stem cells (MSCs), therefore, concluding that these cells are not pluripotent and most likely not of germ cell origin but instead mesenchymal^[71]. Current knowledge of human SSC culture conditions probably is insufficient and do not emulate the mouse SSC culture environment that has allowed the generation of mGS cells in this species. For further progress to be made, the exact mechanisms of SSC reprogramming need to be addressed. For instance, we know that primordial germ cells from the fetal period convert to ES-like pluripotent cells^[72] via the AKT signaling pathway^[73]. A very recent study found that spontaneous SSC reprogramming would be caused by unstable DNA methylation with involvement of the Dmrt1-Sox2 signaling pathway^[74]. However, more research is required to successfully obtain human mGS cells. This will require very specific culture conditions and the molecular dissection of SSC pluripotency, all of which should continue to be investigated.

GENE TECHNOLOGIES AND SSC

ES cell-based transgenesis technologies are well

developed and routinely used in the context of mouse species. However, SSCs can be used for a more straightforward route to transgenesis. ES cells, after genetically intervened, are injected into blastocysts with the hope of successful integration and contribution to the germline, which not always can be guaranteed. By contrast, SSCs are already constituents of the germline. Some other important differences with ES cells make SSCs best suited for mutagenesis (Table 1), especially in species for which ES technologies are not feasible or physiological limitations exist like in farm animals. Additionally, unlike mice, some farm animals, primates and humans are uniparous species as a consequence of not producing large numbers of oocytes under normal physiological conditions. In addition, these species go through lengthy periods of time to attain puberty and sexual maturity. SSC genetic and epigenetic stability keep these cells committed to the germline phenotype so that they do not tend to differentiate into other lineages^[59]. This trait makes their potential role for gene therapies clinically safer than other pluripotent stem cells. The use of SSCs for transgenesis in farm animals in comparison to ES cell-based technologies in mice is depicted in Figure 2.

Another alternative for knockout (KO) animal production is nuclear transfer of genetically modified somatic cells, but these cells have limited proliferation capacities, the technique shows inefficient offspring production and postnatal degenerative problems. For these reasons, cloning does not efficiently compete with ES cells or SSC technologies for gene targeting.

Due to their potentials, SSCs have been used to generate KO animals in several species. Transgenic mice generation by using SSCs was first accomplished with the use of retroviral vectors, however with low efficiency^[75]. Later on, with the advent of GS cells (SSCs that proliferate *in vitro*) this cell type could be expanded *in vitro* and genetically modified through vectors (viruses or plasmids) with drug resistant genes to allow for the detection of SSCs carrying the transgene. These SSCs were transplanted to recipient mice and took over the spermatogenetic functions in the new environment to ultimately produce transgenic sperm. Transgenic heterozygous males with transgene carrying sperm were mated with females and progeny was produced, near 50% of which carried the transgene^[76]. This illustrates the importance of an optimal culture system in order to expand SSC populations and thus increase the efficiency of the transgene incorporation. Soon after, sophisticated techniques added to the gene function modification toolbox such as the CRE/LoxP system for conditional gene targeting, was successfully adapted to the use with SSCs^[77]. Interestingly, SSC mediated rat transgenesis was achieved in 2007^[78] while parallel efforts with ES cells on this species were only successful until 2010^[79]. Just recently, ES cells from domestic animals could be obtained for gene targeting goals^[80]. Advances with farm animal SSCs continued in parallel. For instance, goat transgenic

Table 1 Summary comparison of characteristics of embryonic stem cells and spermatogonial stem cells in the context of transgenesis techniques

Trait	Embryonic stem cells	SSCs
Mutagenesis technical status	Available for mice. Many genes mutated	Experimental level in mouse ^[75] , rats ^[78] , goats ^[81] , pigs ^[82]
Source	Embryo	Adult testis
Age of derivation	Embryonic period	Postnatal period
Ethical/legal concerns	Yes	No
Efficiency		5 × to 10 × higher than with ES cells
Cell differentiation state	Undifferentiated - pluripotent	Differentiated up to germ-line
Tumorigenesis	Produce teratomas	Do not produce teratomas
Chimera formation	(+)	(-)
Germline gene transmission	Do not transmit genes from one generation to the next	Transmit genes from one generation to the next
<i>In vitro</i> phenotype	Colonies with tightly attached cells	GS cells loosely attached (easily dissociated with trypsin) ^[2]
Speed of growth	Faster	Slower
Requires other non-transfected SSCs during culture	No	Yes ²
Karyotype	Variable - unstable ¹	Normal - stable
Epigenetics	Variable - unstable DNA methylation pattern	Normal - stable DNA methylation pattern
Offspring	Abnormal	Normal

Otherwise specified, information presented is based on^[2]: ¹Often lose their germ cell potential due to trisomy^[16]; ²Spermatogonial stem cells (SSCs) that proliferate in culture (GS cells) require specific non-transfected SSC densities during the process of drug selection^[118]. ES: Embryonic stem.

Figure 2 Alternative ways to exploit stem cells to produce transgenic animals. A: Standard method (well developed in the mouse): Embryonic stem cells (ES cells) are obtained from a donor mouse blastocyst. These cells are cultured and genetically modified (usually, DNA sequences are inserted on a gene of interest to disrupt its expression or gene knockout). ES cells are injected into another mouse blastocyst so that they can integrate into the embryo (chimera formation) with the hope that some of them will contribute to the male germline. In this case, donor germline cells will undergo homologous recombination (meiosis) in the testis after animals are born and develop towards puberty. The male animals will be heterozygous for the mutated gene and when crossed with their (also heterozygous) sisters, offspring will be obtained homozygous for the transgene; B: Transgenesis technique involving spermatogonial stem cells (SSCs), particularly useful for farm animals, for which ES cell technologies are not feasible. SSCs from postnatal animals can be expanded in culture, subject to gene targeting and transplanted to a recipient foreign testis. This way, steps used with ES cell technologies become redundant (Figure 2B, inside the box). With the advent of spermatogenesis *in vitro*, even the SSC transplantation procedure will not be necessary. Cryopreservation techniques for SSCs are already available.

sperm for human growth hormone was derived from male goats that had been transplanted with SSCs previously manipulated *in vitro*^[81]. In a report from the same group, pig embryos, transgenic for a reporter gene (enhanced green fluorescent protein), could be obtained after oocytes were fertilized with transgenic sperm from culture transduced and later transplanted SSCs^[82]. Very recently, bovine gonocytes were transduced through a lentivirus vector and the reporter transgene product proved the success of the

procedure^[83]. In dogs, a species with a strong potential to provide new models for human genetic diseases, SSCs have been characterized, cultured, genetically modified and allogeneically transplanted with eventual collection of transgenic sperm^[84].

GERM CELL TRANSPLANTATION

SSC transplantation is an important tool for several other biotechnological applications such as gene

Figure 3 Species differences on anatomical points for spermatogonial stem cell injection for transplantation. The transplantation procedure for spermatogonial stem cells (SSCs) is simple in the mouse. In this species, (A) there is a single efferent duct emerging from the rete testis, which is easy to cannulate to inject SSCs (arrow). In most farm animals and men (B) several efferent ducts emerge from the testis, a reason why transplantation of SSCs is often done by injection of SSCs into the rete testis (arrow) with ultrasound guidance.

therapy or fertility restoration. The first SSC successful transplantation was reported in 1994 in the pioneering work of the Brinster's group^[85]. Inspired on original hemopoietic fundamental transplantation work^[86], this research group isolated germ cells from a donor mice that were later unequivocally identified as SSCs on a recipient mouse testis after injection into the seminiferous tubule system, based on their property to regenerate spermatogenesis in the foreign testicular niche (for a comprehensive review on this technique see^[87]). This allogeneic type of transplantation is presently the basis for the functional assay to detect true SSCs in experimental models. The technique could be developed due to the presence of a single, easy to cannulate efferent duct in mouse species and to the fact that the mice strain used was immunocompromised. Unfortunately, this SSC transplantation procedure is technically demanding in species with several efferent ducts because, in these species they tend to be short, thin and highly convoluted (Figure 3). This anatomical condition corresponds to most farm animals^[88], primates^[89] and humans^[90].

Xenogeneic transplantation of SSC cell suspensions into the mouse testis has been attempted by several groups^[91]. For the first time, SSCs from a foreign species (rat) not only were able to colonize mouse seminiferous tubules but also to differentiate and produce normal rat sperm^[92]. However, attempts with other SSC donor species showed that the farther apart in phylogenetical distance is the donor species from the mouse (recipient species), the lower level of progress of differentiation in spermatogenesis from the transplanted SSCs will be achieved within the foreign seminiferous epithelium environment (for details on SSC transplantation into the mouse testis, involving different donor species, see^[91]). Accordingly, domestic animals and human beings as SSC donors are among

those species in which this technique is not yet successful. Thus, on these and many other species, functional assays to unequivocally detect the presence of their SSCs are very necessary.

Allogeneic SSC transplantation (SSCs transplanted from a donor animal to a recipient testis of another animal, both from the same species) has proven difficult in species other than rodents, particularly in large animals. Besides anatomical difficulties, each species seems to require specific technical protocols. Allogeneic transplantation has been attempted in several farm animals, including pigs, goats and bulls^[93-95]. For instance, transgenic sperm from a donor goat could be unequivocally identified in a recipient buck semen, meaning that transplanted SSCs could colonize and regenerate the spermatogenetic process in the unrelated testis^[96]. When the limitations of these techniques are overcome they will facilitate several of the biotechnological applications described on this article. One aspect that still needs to be addressed is the method for depletion of endogenous spermatogenesis in recipient animals. This is typically performed by using either chemical compounds like the alkylating agent busulfan or alternatively testis irradiation. However, protocols need to be species optimized, which requires further research^[97,98]. SSC transplantation could also be used for gene delivering purposes in order to increase the frequency of certain genes in animal populations. This would be particularly useful in extensive systems of livestock production, in which animals reproduce through natural service. Surrogate males could be transplanted with SSCs that over-express certain genes linked to increased production traits or from elite bulls in order to disseminate the desired genes in a population. Endangered species could also be benefited with such technologies. For instance, SSCs from the wild species to be preserved could be transferred to a

phylogenetically related domestic animal embryo and this way become incorporated into the germline to eventually produce exotic sperm^[99,100], this way saving the endangered germplasm.

As an alternative to SSC transplantation into testicular environments, a new technique was developed in which whole testicular tissue explants (containing SSCs attached to their niche) from the desired species are placed in ectopical places such as the back skin (subcutaneous tissue) of immunocompromised mice. This approach was first successfully tried with mouse testis tissue (donor) grafted into mouse skin (recipient)^[101,102]. This technique was designated testis tissue xenografting. When xenotransplanting testicular tissues from prepubertal animals (with only undifferentiated germ cells, including SSCs), complete spermatogenesis developed within the transplanted testicular tissues under the sponsoring of the host (mouse) vascular environment and intrinsic steroidogenesis of the donor tissue. This technique has been so far successful with a wide range of donor species including hamsters, rabbits, dogs, cats, sheep, goats, horses, bovines, alpacas and monkeys^[103]. Work has also shown that testicular tissue pieces can be cryopreserved and later used with this technique in various species^[104,105].

Tissue xenografting has represented a step forward in SSC biology that circumvents many of the current limitations the transplantation of germ cell suspensions into the seminiferous tubules of foreign recipient animals. This technique has been privileged by researchers during the recent years because of the positive outcomes in a range of very dissimilar species. Recently, a related technique was developed in which no whole tissue pieces are transplanted into the mouse skin but instead an assorted cell suspension composed of germ cells and testicular somatic cells, including Sertoli cells. Interestingly, all these cells reassemble under the mouse skin and testicular tissue becomes organized in a process that has been called *de novo* testicular morphogenesis^[106,107]. This novel technique has been tested with testicular cell suspensions from rats^[108], mice^[109], pigs^[110], sheep^[111] and recently from a wild pig, the peccary^[112]. Testis xenografts have produced so far fertile sperm in pigs and the related peccaries^[112-114] demonstrating that SSCs present in the testicular tissues show a correct functioning that leads to the production of viable normal sperm within the body of a foreign species.

FERTILITY RESTORATION

Infertility is one of the critical side-effects of oncological treatments in humans and particularly in children, an effect which is caused either by chemotherapeutic agents or irradiation. A proposed solution for this problem is the restoration of fertility *via* SSC transplantation. Since many of the patients in this situation are prepubertal (*i.e.*, do not yet produce

sperm), a current approach consists on banking testicular tissue or cell suspensions prior to the oncological treatment and submitting the patient to an autologous transplantation of the preserved material if fertility problems arise later in life^[115] (for recent advances in the methods for preservation of fertility on young male human oncological patients see the comprehensive review from Goossens *et al*^[116], 2013). A word of caution is valid regarding safety issues when malignant diseases are managed with transplantation procedures. Invariably, cells suspensions including SSCs to be transplanted should be devoid of cancer cells. In experiments with rats, only as few as 20 leukemia cancer cells were enough to produce the disease when transplanted into healthy rat testis^[117]. It is unknown to what extent this is reproducible in humans, but as an obvious measure, cell suspensions should be screened and positively selected for SSCs and/or negatively selected for cancer cells, through approaches such as FACS or special culture conditions^[116]. An alternative approach would be to use testis xenografting or allografting with the hope to restore the spermatogenic process ectopically to a degree just enough to produce a few sperm to be later used with ARTs. Nevertheless, although already developed for several animal species (see the topic on Germ cell transplantation above) testicular xenografting requires further investigations to be implemented in humans. In general, more research in monkeys and humans is still needed, particularly on safety issues.

FINAL REMARKS

The tremendous progress in SSC research during the last decade is undeniable. Appropriate conditions for SSC long-term culture are already widely known for the most important experimental model: the mouse, but research efforts are still being made to develop culture systems suitable for humans and other species, altogether with the study of the very specific SSC nutrient requirements. Advances such as SSC *in vitro* mutagenesis are already possible in the mouse. The imminent unraveling of the molecular mechanisms of SSC pluripotency will bring about many other interesting biotechnological possibilities. The long-awaited accomplishment of SSC transplantation techniques for farm animals and humans is under current development, despite the widespread use of testis xenografting in many species with high rates of success. Finally, spermatogenesis *in vitro* is already possible for laboratory species, so important applications in regenerative medicine and animal reproduction are expected.

Abstract

In orthopedics, tissue engineering approach using stem cells is a valid line of treatment for patients with bone defects. In this context, mesenchymal stromal cells of various origins have been extensively studied and continue to be a matter of debate. Although mesenchymal stromal cells from bone marrow are already clinically applied, recent evidence suggests that one may use mesenchymal stromal cells from extra-embryonic tissues, such as amniotic fluid, as an innovative and

advantageous resource for bone regeneration. The use of cells from amniotic fluid does not raise ethical problems and provides a sufficient number of cells without invasive procedures. Furthermore, they do not develop into teratomas when transplanted, a consequence observed with pluripotent stem cells. In addition, their multipotent differentiation ability, low immunogenicity, and anti-inflammatory properties make them ideal candidates for bone regenerative medicine. We here present an overview of the features of amniotic fluid mesenchymal stromal cells and their potential in the osteogenic differentiation process. We have examined the papers actually available on this regard, with particular interest in the strategies applied to improve *in vitro* osteogenesis. Importantly, a detailed understanding of the behavior of amniotic fluid mesenchymal stromal cells and their osteogenic ability is desirable considering a feasible application in bone regenerative medicine.

Key words: Mesenchymal stromal cells; Amniotic fluid; Amniotic fluid mesenchymal stromal cells; Amniotic fluid stem cells; Osteogenesis; Bone regeneration

Core tip: Several papers regarding the osteogenic differentiation potential of cells isolated from amniotic fluid have been published so far with particular attention to various feasible approaches to improving differentiation both *in vitro* and *in vivo*. Hence, an overview is necessary on the data reported up to now in order to understand the potential of amniotic fluid-derived cells in bone regenerative medicine. This review takes a general look at the current state-of-the-art of the osteogenic ability of amniotic fluid-derived cells and the different strategies available to improve bone regeneration.

Pipino C, Pandolfi A. Osteogenic differentiation of amniotic fluid mesenchymal stromal cells and their bone regeneration potential.

INTRODUCTION

In the last few decades degenerative lesions of the musculoskeletal system have become increasingly common, leading to social and economic problems, and intensifying the demand on medical services^[1]. Common examples are temporary and permanent disability due to osteoarthritis or fractures caused by loss of bone mass such as osteoporosis or osteopenia, particularly in the elderly. In the younger population widespread active lifestyles including sport activities have increased the possibility of bone and cartilage damage. Moreover, bone defects mostly emerge from trauma, tumor resection and congenital malformation. So far, the most effective clinical method for the reconstruction of large bone defects is the use of autogenous bone grafts, commonly harvested from the posterior iliac crest and transplanted into a local bone defect^[2]. The weakness of this method is the surgical stress the patient undergoes in extracting bone with possible subsequent inflammation and donor site morbidity. Furthermore, the quantity of extractable bone is limited.

Recently, advances in the field of stem cells have come to represent a valid alternative to this method^[3]. Nowadays there is growing interest in therapies based on mesenchymal stromal cells (MSCs) as a potential effective treatment for bone defects. MSCs are multipotent cells with the potential to engender a range of specialized cell types, such as osteoblasts, chondrocytes and adipocytes^[4]. The mesenchymal progenitor cells in the bone marrow are able to differentiate into osteoblasts following the influence of multiple osteogenic signals^[5,6]. In particular, after fracture MSCs of bone marrow are transferred to the site of bone injury through peripheral blood, thus enhancing the healing potential of local MSCs^[7]. In this condition, bone morphogenic proteins (BMPs) play an important role. Indeed, osteoblastic differentiation begins when the BMPs bind their receptors activating the transcription factors runt-related transcription factor 2 (Runx2) and Osterix, and subsequent downstream osteoblast specific genes, through activation of a Wnt/LRP5 cascade, which is crucial in bone mass modeling^[5,8,9].

Regarding the principal signaling pathways involved in MSC differentiation, various evidences have suggested that during cultivation *in vitro*, an inverse relationship exists between the commitment of MSCs toward osteogenic and adipogenic lineages^[10]. Several cell signaling cascades are involved in this cell fate decision between osteo- and adipogenesis^[11]. The master regulator of osteogenesis is Runx2, the gene target of many signaling pathways, including but not limited to transforming growth factor-beta 1 (TGF- β 1), BMP^[12],

Wingless type (Wnt)^[13], Hedgehog (HH)^[14], and (NEL)-like protein type 1 (NELL-1)^[15].

Thus, considering the crucial role of MSCs in bone healing, the strategy of using the osteogenic potential of such cells transplanted into the bone defect seems promising^[7,16].

Mesenchymal stromal cells derived from bone marrow (BM-MSCs) have been used in clinical trials for the treatment of bone defects^[17]. However, bone marrow aspiration is a difficult, invasive and painful procedure for the donor. The amount of BM-MSCs is usually between 0.001% and 0.01% of the total population and, in addition, the BM-MSC number and differentiation potential may be affected by increasing donor age. This implies an extensive *in vitro* expansion of such cells before transplantation, thus increasing the risk of possible differentiation induction and epigenetic modifications^[18]. On the other hand, the use of allogeneic BM-MSCs for bone repair is unsuitable due to immune rejection^[19].

As an alternative, mesenchymal stromal cells can be found in various adult organs and tissues^[20], including blood^[21], adipose tissue^[22] and dermis^[23]. Although sharing similar properties, these MSCs from various sources have different gene expression profile and differentiation ability^[24].

Mesenchymal stem-like cells have also been recognized in fetal blood, liver and bone marrow^[25]. In this regard, Guillot and colleagues have shown that first trimester fetal blood, liver, and bone marrow MSCs possess greater osteogenic differentiation potential than adult BM-MSCs^[26]. They found through quantitative real-time RT-PCR that 16 osteogenic specific genes (*OC*, *ON*, *BSP*, *OP*, *Col1*, *PCE*, *Met2A*, *OPG*, *PHOS1*, *SORT*, *ALP*, *BMP2*, *CBFA1*, *OSX*, *NOG*, *IGF1*) were more expressed in fetal MSCs under basal conditions and were up-regulated during osteogenic differentiation both *in vitro* and *in vivo*^[26]. These cells are more primitive than adult MSCs^[25], therefore potentially promising for therapeutic use in regenerative medicine, even if isolating them is subject to considerable public unease.

An alternative approach could result from the use of MSCs derived from extra-embryonic tissues, which possess the advantage of being isolated from tissues normally discarded after birth, hence exempt from ethical concern, such as amniotic fluid, umbilical cord and placenta^[27-29].

This review will focus on the biological properties of MSCs isolated from amniotic fluid (AF-MSCs) with particular attention to their *in vitro* osteogenic differentiation potential with a view to possible final application in bone regenerative medicine (Figure 1). Of note, these cells possess a greater proliferative capacity, lower immunological reactivity and lower risk of graft-versus-host disease than those derived from adult bone marrow^[30]. Importantly, compared with other MSC sources, such as umbilical cord blood-derived MSCs, AF-MSCs are more easily isolated and show better proliferation ability^[31].

Figure 1 *In vitro* and *in vivo* application of amniotic fluid-derived cells. Amniotic fluid-derived cells isolated from amniotic fluid samples obtained following ultrasound-guided amniocentesis (1) for genetic test (2), could be *in vitro* expanded (3). These cells may be genetically manipulated and transplanted back into the same fetus (4). AF-derived cells can be used unselected (AF-MSCs) or selected for CD117 (AFSCs) (5). Both cellular populations can be *in vitro* differentiated in 2D (6) or 3D (7) culture conditions. They represent an ideal *in vitro* model for testing osteoinductive molecules (8) and for *in vivo* autologous or allogeneic transplantation for bone repair (9). Alternatively, they could also be banked (10) and adopted post-thawing.

In particular, AF-MSCs are autologous to the foetus representing an attractive source for the treatment of perinatal disorders such as congenital malformations^[32,33]. Hence, affected children could benefit from their own cells which could be banked, expanded in culture or properly engineered and implanted in the neonatal period. In addition, AF-MSCs are semi-allogeneic to each parent, therefore potentially useful for the other members of the family^[34].

Moreover, the beneficial effect of AF-MSCs observed in preclinical studies, such as lung injury^[35], ischemic heart^[36], acute bladder injury^[37], neovascularization^[38], encourages their future application in regenerative medicine tissue engineering.

AMNIOTIC FLUID-DERIVED CELLS

Human amniotic fluid, contained within the amniotic cavity, begins to appear at the second week of gestation. It surrounds the growing fetus, protects from outside injury and acts as the vehicle with the mother^[30]. It contains a variety of cells arising from all three germ layers (ectoderm, mesoderm and endoderm) routinely obtained for prenatal diagnosis of fetal abnormalities during second trimester pregnancy, through a minimally invasive technique. Amniotic fluid cellular composition substantially depends on the gestational age^[27]. Most of the cells present in the amniotic fluid are terminally differentiated and have low proliferative capacity^[32]. Three major cellular types can be classified based on morphological, biochemical and growth characteristics: epithelioid, amniotic fluid and fibroblastic cells^[39].

Interestingly, a population that expresses the surface antigen c-kit (CD117), stem cell factor receptor, can be isolated from amniotic fluid. These cells, named amniotic fluid stem cells (AFSCs), represent about 1% of the total cells^[40]. It should be noted that, mesenchymal stromal cells (AF-MSCs) with a multilineage differentiation potential are present in the amniotic fluid^[41,42].

AF-MSCs are highly proliferative with a normal karyotype after long-term *in vitro* culture and do not form teratomas when transplanted *in vivo*^[43]. They do not display any hematopoietic molecular markers (CD14, CD31 and CD45), while they express the intracellular stemness markers TERT, SOX2 and Nanog and the surface adhesion molecules CD29, CD58, CD166 and CD90^[44].

The absence of HLA-DR and presence of HLA-ABC suggest that these cells may be applicable in immune-mediated disorders as well as in the treatment of graft-versus-host disease^[43]. It is also important that AF-MSCs display a broad differentiation potential toward multiple lineages (*i.e.*, adipogenic, chondrogenic, myogenic and osteogenic)^[34]. They possess an intermediate differentiation potential between embryonic (pluripotent) and adult cells with advantages over both. Compared to adult cells, AF-MSCs possess greater differentiation potential and more primitive properties with fewer accumulated mutations^[45]. Respect to embryonic stem cells (ESCs), AF-MSCs possess the advantage to do not form teratomas when transplanted *in vivo*. Indeed, although ESCs are pluripotent cells which maintain high plasticity and extensive self-renewal capacity, possible host immune rejection after allotransplantation and the formation of tumors when injected undifferentiated or partially differentiated *in vivo*, raise safety concerns^[46-48]. Furthermore, their clinical use is limited by ethical issues due to the need to isolate them from the inner cell mass of a blastocyst^[49].

In the last few years methods able to generate patient-specific pluripotent stem cells (iPSCs) from adult cells have been developed to overcome the limitations associated with ESCs^[50,51]. Such iPSCs, obtained through the ectopic expression of defined transcription factors (Oct4, Sox2, Klf-4, c-Myc), are molecularly and functionally similar to ESCs. They show similar morphology and growth properties, express pluripotency markers, are able to generate germline-competent chimeras and form tumors when injected into immune-compromised mice^[51]. Although iPSCs

allow one to overcome both the ethical and the tissue compatibility problems of ESCs, current studies are still investigating the safety profile of these cells for therapeutic application^[52]. The main limitation related to iPSC generation is the use of retroviruses or lentiviruses, which could cause mutagenesis leading to a risk for teratogenesis.

Therefore, given the easier accessibility and the faster availability of a great number of AF-MSCs in culture in comparison to iPSCs, AF-MSCs may hold great promise in regenerative medicine.

However, since iPSCs seem one of the most promising future sources of stem cells for tissue regeneration, research is going ahead to find the best cell source to reprogram and develop alternative methods for generating pluripotent cells using non integrating systems. In this context, recent evidences has suggested that cells derived from amniotic fluid are more easily and rapidly reprogrammed than adult cells^[53-55]. More recently, iPSCs have been developed from amniotic fluid cells without ectopic factors by culture in an appropriate medium^[56], thus reinforcing their potential application in cellular replacement therapies.

These important features, together with the high proliferation rate, ease of retrieval and more stable profile, provide a convincing proof-of-principle for potential autologous application of AF-MSCs for bone regeneration in perinatal applications^[57]. Furthermore, a bank of such cells is achievable and may in the future provide a plentiful source for autologous therapy in adulthood as well as for transplantation into HLA-matched recipients.

IN VITRO OSTEOGENIC DIFFERENTIATION

The osteogenic differentiation capacity of AF-derived cells obtained from various sources (human, sheep, mouse and rat) has been broadly documented^[39,40,58,59]. Some studies have reported the great potential of c-kit selected amniotic fluid cells prior to osteogenic differentiation^[40], while others have demonstrated that unselected cells are also able to properly differentiate into osteo-specific cells^[13,41,44,60]. In this review we mainly discuss the *in vitro* osteogenic differentiation of AF-MSCs with occasional mention of papers in which authors use c-kit selected cells, named AFSCs (Table 1). It should be pointed out that, compared to BM-MSCs, AF-MSCs have higher self-renewal capacity and are more potent for lineage-specific differentiation^[40]. Therefore, considering also their more easily isolation and the great number of available cells, AF-MSCs may represent excellent candidates for cell replacement therapies^[61]. Of note, even if there are other MSC sources easily available, like adipose-derived MSCs, the osteogenic capacity of such cells compared to BM-MSCs is now still debated^[62].

The conventional protocol applied to induce osteogenic differentiation of AF-MSCs consists of basal medium, such as Dulbecco's modified Eagle's medium, supplemented with 10% Fetal Bovine Serum, β -glycerolphosphate, ascorbic acid and dexamethasone (standard osteogenic medium). For the purpose of assessing *in vitro* differentiation, protein and gene expression of specific osteogenic markers [e.g., alkaline phosphates (ALP), Collagen type I, bone sialoprotein, osteocalcin, RUNX2] are usually evaluated in addition to specific colorimetric assays, such as ALP, Alizarin Red S and Von Kossa staining.

However, various approaches have been applied to improve and accelerate differentiation of amniotic fluid-derived cells into osteogenic cells. Attempts have been made to produce osteoblastic cells from amniotic fluid samples in a very short time, using a single step culture procedure, which allows a 20-d reduction in culture time^[60].

One notes that several studies have demonstrated how such osteoinductive molecules are able to improve the osteogenic differentiation process^[44,63-68].

In detail, then, AF-MSCs transfected with a defective adenoviral vector expressing human lim mineralization protein 3, an intracellular positive regulator of osteoblast differentiation, showed downregulation of stemness kruppel-like factor-4 and then increased osteogenic differentiation^[63].

Again, Simvastatin, a 3-hydroxy-3-methylglutaryl-coenzyme A reductase inhibitor able to act on cholesterol endogenous synthesis, has been shown to be efficient in stimulating new bone formation. When added to osteogenic differentiation medium, Simvastatin was able to induce massive osteogenic differentiation of AF-MSCs, as observed by Alizarin Red S staining, and increased expression of typical osteogenic genes, such as osteopontin (OPN) and osteocalcin^[64].

Herbal medicines have also been used to improve the osteogenic differentiation of AF-MSCs. Naringin, the main active compound of Chinese herbal medicine (*Rhizoma drynariae*), proved able to enhance osteogenic differentiation, increasing ALP activity and the expression of the osteogenic specific markers OPN, Collagen I, bone morphogenetic protein 4 (BMP4), RUNX2, β -catenin and cyclin D1^[66].

Another traditional Chinese herbal medicine commonly used in treating orthopedic disorders, Curculigoside, was found to have a positive effect on the osteogenic differentiation of human AFSCs^[65].

Moreover, during osteogenic differentiation of both amniotic fluid and dental pulp stem cells, the *in vitro* addition of Ferutinin, a phytoestrogen able to prevent osteoporosis caused by ovariectomy-induced estrogen deficiency, was efficacious in enhancing the production of a calcified matrix^[67].

It has been noted that, in co-culture with osteoblasts obtained from the differentiation of dental pulp stem cells AF-MSCs prove able to generate osteoblasts. The same effect was observed when AF-MSCs were

Table 1 Studies describing *in vitro* modification of standard culture condition to induce osteogenic differentiation of AF-derived cells

Cell source	Methods to induce osteogenic differentiation	Ref.
hAF-MSCs	Culture in standard osteogenic medium on sandblasted and acid etching titanium (SLA titanium)	[60]
hAF-MSCs	Transfection with a defective adenoviral vector expressing human LMP3	[63]
hAFSCs	Standard osteogenic medium plus curculigoside	[65]
hAFSCs	Standard osteogenic medium plus naringin	[66]
hAFSCs	100 μ mol/L 2P-ascorbic acid, 100 nmol/L dexamethasone, supplemented with different concentrations of Ferutinin	[67]
hAF-MSCs	Induction of miR-21	[71]
hAFSCs	Medium containing 50 nmol/L rhBMP-7, 50 mg/mL ascorbic acid, and 10 mmol/L β -glycerophosphate on nanofibrous or solid walled scaffolds	[86]
hAFSCs	10 nmol/L dexamethasone, 6 mmol/L β -glycerol phosphate, 50 mg/mL ascorbic acid 2-phosphate, 50 ng/mL L-thyroxine on electrospun nanofiber meshes	[88]

hAFSCs	Standard osteogenic medium on microfibrillar starch and poly(ϵ -caprolactone) scaffold	[90]
hAFSCs	Medical-grade poly- ϵ -caprolactone scaffold	[91]
hAFSCs	Standard osteogenic medium on collagen matrix derived from porcine bladder submucosa matrix and poly (lactide-co-glycolide)	[92]
hAFSCs	Standard osteogenic medium on construct composed of collagen type I	[93]
hAFSCs	α -MEM plus 17% FBS, 1 μ mol/L dexamethasone, 6 mmol/L of β -glycerol phosphate, 50 μ g/mL ascorbic acid 2-phosphate, and 50 ng/mL thyroxine on biomaterial named Skelite	[38]

MSCs: Mesenchymal stromal cells; AF-MSCs: MSCs isolated from amniotic fluid; AFSCs: Amniotic fluid stem cells; LMP3: Lim mineralization protein 3.

cultured in the conditioned medium of osteoblasts-differentiated dental pulp stem cells^[69].

Moreover, some findings show that microRNAs (miRNAs) are involved in determining the fate of stem cells^[70]. For example, a recent paper has shown the role of miR-21 in accelerating osteogenesis of AF-MSCs^[71]. In that work two cellular populations were isolated from amniotic fluid: spindle-shaped (SS) and round-shaped (RS). Interestingly, induction of miR-21 was found to accelerate osteogenesis more in the SS population than in RS cells^[71].

Finally, human AF-MSCs analyzed by an atomic force microscope during osteogenic differentiation showed a decrease in cell elasticity, which is typical of mature osteoblasts; thus the mechanical properties of AF-MSCs again add to the interest in applying them in bone regenerative medicine^[72].

Up to now, little is known about the cues regulating the AF-MSCs' ability to differentiate to osteoblasts. In depth study of the mechanism involved in the osteogenesis of AF-MSCs may hence help to develop standard protocols for clinical application in bone regenerative medicine. In this context, there is some evidence to suggest a role by the canonical Wnt signal pathway in bone formation as activation of this pathway stimulates osteoprogenitor proliferation and osteogenesis of human MSCs^[73,74]. Wnt signaling is also involved in AF-MSC commitment toward osteogenesis^[13].

Recently, we identified for the first time, the presence of Calcium Sensing Receptor (CaSR) in ovine and human AF-MSCs^[44,68]. CaSR, originally cloned from parathyroid glands, acts by controlling the secretion of parathyroid hormone in response to changes in extracellular calcium levels^[75]. However, it is well known that CaSR plays an important role in controlling osteoblasts as well as in osteoclast

recruitment, differentiation and survival *via* multiple intracellular signals^[76]. Interestingly, we observed that CaSR expression in both ovine and human AF-MSCs increased at the membrane when cells were treated with calcimimetic R-568, a molecule able to modulate bone cell metabolism *via* CaSR^[77]. This effect was abolished by CaSR allosteric inhibitor Calhex-231 and by selective inhibitor NPS-2143. Importantly, downregulation of CaSR by a gene-silencing approach confirmed the crucial role of CaSR in supporting osteogenic differentiation^[44].

These findings support the role of calcimimetics in the osteogenic differentiation of AF-MSCs, and suggest a strategy to develop therapy against bone injury.

Although the aforementioned studies have shown that AF-MSCs can be made to differentiate into osteoblasts *in vitro*^[40,41] and some pathways have been investigated, more studies and clinical trials are needed before AF-MSCs can be applied clinically for *in vivo* bone regeneration.

TISSUE ENGINEERING APPROACHES FOR *IN VIVO* BONE REGENERATION

For a long period time autogenous bone grafting was considered the gold standard for *in vivo* bone regeneration^[78]. Because of its limited availability and potential donor site morbidity, several bone substitutes have been successfully tried as an alternative, combining principles of biology and engineering. *In vivo* bone regeneration based on tissue engineering using scaffolds offers a plausible way of creating a favorable microenvironment for cells^[79].

The choice of an appropriate scaffold along with selection of the best suited cell source is currently

Table 2 Studies describing *in vivo* osteogenic differentiation of AF-derived cells

Cell source	Scaffold	Animal model	Ref.
oAF-MSCs	Magnesium-enriched hydroxyapatite/collagen-based scaffold	Sheep model of sinus augmentation	[85]
hAFSCs	Nanofibrous or solid walled scaffolds	Midsagittal incision made on the dorsa and two subcutaneous pockets created using blunt dissection on male outbred thymic nude mouse model (nu/nu)	[86]
hAFSCs	Fibroin scaffolds compared to collagen and poly-D,L-lactic acid scaffolds	Dorsal mid-sagittal incision made on the dorsa and two subcutaneous pockets were created using blunt dissection male outbred rats	[89]
hAFSCs	Microfibrous starch and poly(ϵ -caprolactone) scaffold	Subcutaneous implantation into the dorsal side of athymic female nude rats	[91]
hAFSCs	Construct composed of collagen type I	Critical-sized rat calvarial defect after oral administration of phytoestrogen ferutinin	[93]
hAFSCs	Biomaterial Skelite	Subcutaneous implantation in the back of CD-1 nu/nu mice	[38]

MSCs: Mesenchymal stromal cells; AF-MSCs: MSCs isolated from amniotic fluid; AFSCs: Amniotic fluid stem cells.

being widely studied.

As discussed above, the advantages of using amniotic fluid-derived cells are well established. Their high proliferation and osteogenic differentiation ability, together with the possibility of autologous or non-immunogenic transplantation and the absence of teratoma formation, makes possible a three-dimensional application of amniotic fluid cells in bone regeneration.

In general, a scaffold is a three-dimensional construct able to support adhesion, proliferation, and function of appropriate cells^[78]. Stimuli mimicking the *in vivo* bone environment are needed for tissue-engineered constructs. It is well known that the bone regeneration ability of MSCs is mainly due to their paracrine effects^[80]. They secrete bioactive substances that are able to enhance migration, proliferation, and differentiation of the neighboring resident cells^[81,82]. Thus, what is required is the right combination of cells and the most appropriate support and factors.

Various synthetic and non-synthetic scaffolds have been employed to support osteogenic differentiation of AF-MSCs. One commonly used non-synthetic scaffold is collagens, which are present in the bone tissue, where they stimulate MSCs to differentiate into osteoblasts, initiating new bone formation^[78]. This natural scaffolds are frequently used for their high availability, biological plasticity, biocompatibility, biodegradability and non-toxicity^[83,84].

It has been found that osteoblasts obtained from AF-MSCs were able to adhere and grow well on SLA (Sandblasted and Acid Etching) titanium surfaces, materials commonly utilized in dental implantology, as revealed by electron microscopy observation^[60].

Berardinelli *et al.*^[85] have demonstrated that a biomimetic commercial scaffold (magnesium-enriched hydroxyapatite (MgHA)/collagen-based scaffold) engineered with ovine AF-MSCs improves bone regeneration in a sheep model of sinus augmentation. Of note, the surface of this commercial scaffold was able to entrap a very high concentration of cells (1×10^7 cells/cm²) under dynamic cultural conditions. The osteoinductive properties of this scaffold, together with

the potential of ovine AF-MSCs clearly accelerated the formation of new bone.

Human AFSCs seeded on nanofibrous (NF) or solid walled (SW) scaffolds were induced in rhBMP-7-containing medium for 7 d and implanted into male outbred thymic nude mice (nu/nu). Six weeks after implantation, bone formation was found on scaffolds as noted by von Kossa staining with greater mineralization on NF than SW scaffolds^[86].

Synthetic NF scaffolds were developed with a morphology similar to that of natural collagen fibers, the aim being to mimic the morphological function of collagen fibers^[87].

Human AFSCs were differentiated on electrospun nanofiber meshes and compared to BM-MSCs. In these experimental conditions, the cells displayed a delay in alkaline phosphatase activity, but elevated mineral deposition after 4 wk in culture, compared to BM-MSCs^[88]. The nanofiber mesh scaffold possesses high porosity, large surface-area-to-volume ratios and size scale similar to extracellular matrix components. It allows the attachment of the cells and act as an efficient vehicle to deliver them to a defective site. A study by Maraldi *et al.*^[89] demonstrated that mineralization of hAFSCs tended to be enhanced on fibroin scaffolds, better than collagen and poly-D,L-lactic acid scaffolds. The cells were pre-differentiated on scaffolds for one week and then bone formation *in vivo* was determined after subcutaneous implantation into immune-suppressed rats^[89].

Again, human AFSCs were able to proliferate and differentiate into the osteogenic phenotype, producing mineralized extracellular matrix similar to BM-MSCs in 2D culture conditions^[90]. Moreover, when seeded on microfibrous starch and a poly(ϵ -caprolactone) scaffold, AFSCs successfully differentiated into osteogenic cells. The high porosity of the scaffold influenced the sequential development of osteoblastic cells and improved the osteogenic differentiation process. Some differences from BM-MSCs were observed in the expression of RunX-2, collagen I and ALP activity, denoting that cells from different origins may express different osteogenic markers at different times^[90].

In addition, AFSCs were also able to produce mineralized matrix within porous medical-grade poly-ε-caprolactone (mPCL) scaffold. The latter has good mechanical stability, large surface area and high porosity, allowing the attachment of AFSCs and extracellular matrix deposition. The construct, composed of an mPCL scaffold and AFSCs pre-differentiated for 28 d, was succeeded in producing seven times more mineralized matrix when implanted subcutaneously on the dorsal side of athymic female nude rats^[91].

The same cells also proved able to adhere to a composite scaffold formed of a collagen matrix derived from porcine bladder submucosa matrix and poly(lactide-co-glycolide). In this condition, the osteogenic differentiation of AFSCs was improved, as revealed by increased mineralization and upregulation of osteogenic genes^[92]. Indeed, the combination of natural scaffold with synthetic polymers was able to provide a microenvironment to facilitate the osteogenic differentiation.

More recently, a construct composed of collagen type I and AFSCs was used to evaluate bone regeneration in critical-sized rat calvarial defect after oral administration of phytoestrogen ferutinin^[93]. Interestingly, 4 wk after implantation, the construct had reconstructed almost 70% of the critical-size defect^[93]. Collagen type I, the major component of the extracellular matrix, facilitated cell adhesion and bone-forming cells in the defect site.

Another interesting study, by Mirabella *et al.*^[38] demonstrated that AFSCs loaded onto a biomaterial named Skelite and subcutaneously implanted in the back of CD-1 nu/nu mice gave rise to mineralized bone. Skelite disk is composed of silicon stabilized tricalcium phosphate biomaterial with a porosity of approximately 60% and an open structure similar to bone. However, they found that AFSCs did not have a direct role in new bone formation, but contributed to host progenitor recruitment and vessel formation in the engineered bone.

The unique features of AF-derived cells combined with the interesting results obtained in animal models of skeletal damage (Table 2) make them promising for the regeneration of bone tissue. Thanks to their immunosuppressive properties, allogeneic transplantation of AF-MSCs may be applied in various orthopedic conditions, and cell banks may be set up for regenerative medicine (Figure 1). However, more accurate understanding of the behavior and homing of AF-MSCs *in vivo* is necessary before they can be clinically applied. Moreover, additional studies are required to improve implanted cell survival and to ascertain the best biomaterial and the optimal combination of cytokines and growth factors.

CONCLUSION

One purpose of bone regeneration is to find the most appropriate source of stem cells for clinical application together with the best bio-compatible support.

Bone marrow harvesting requires invasive procedures while the MSC number and differentiation potential decline with increasing age of the donor^[94].

MSCs from extra-embryonic tissues are easily accessible. Moreover, their osteogenic potential and their safety in humans have been already tested. What is more, considering the high number of MSCs that can be isolated from amniotic fluid, a possibility of banking these cells adds greater promise of their clinical application. Furthermore, the osteogenic commitment of AF-MSCs could be enhanced by using appropriate osteoconductive scaffolds and osteoinductive growth factors^[90].

Although these cells are very promising, therefore, in order to apply them for bone regeneration further investigations are needed to select the safest and most efficient cell-based approach. Certainly the results obtained so far are most promising: preclinical and clinical studies should be continued, thus opening new insights in the foreseeable future.
