Prolonged B lymphocyte depletion illustrates perfectly the antigen driven direct toxicity, provided by anti-CD19 CAR T cells and hence a theoretical immunodeficiency. Although B lymphocyte depletion has been profound in reported clinical studies, its durability appears as a sign of prolonged anti-tumor response. This condition is very close to that of patients with X-linked agammaglobulinemia^[97]. While B lymphocyte depletion increases the risk of opportunistic infections, this may be improved by intravenous immunoglobulin therapy. Although patient follow-up is relatively short, patients treated with anti-CD19 CAR T cells did not show until now any increase of bacterial infections. However, the development of this new technique will certainly be accompanied by the description of further new adverse events.

CONCLUSION

Immunotherapy represents certainly a great step forward in the treatment of AL. Because of the complexity of T cell repertory and its interaction with the immune system, there is, however, a long way to go before achievement of a complete and optimal understanding of this technology, as illustrated by the “on tumor/off target” paradigm. Furthermore, production of CAR T cells is time consuming, and still requires tremendous financial resources. The next challenges will be to improve cell isolation and culture of CAR-modified T cell production, to reduce the cost of the technique,

and therefore facilitate CAR T cells production and delivery in most institutions, beyond the academic research environment.

Abstract

Although advanced stage aggressive non-Hodgkin's

lymphomas and Hodgkin's disease are thought to be chemotherapy-responsive cancers, a considerable number of patients either relapse or never attain a remission. High-dose therapy (HDT) followed by autologous stem cell transplantation (ASCT) is often the only possibility of cure for most of these patients. However, many controversial issues still remain with respect to HDT/ASCT for lymphomas, including its role for, the optimal timing of transplantation, the best conditioning regimen and the potential use of localized radiotherapy or immunologic methods to decrease post-transplant recurrence. Recently, mainly due to the unavailability of carmustine, several novel conditioning protocols have been clinically developed, with the aim of improving the overall outcome by enhancing the anti-lymphoma effect and, at the same time, by reducing short and long-term toxicity. Furthermore, the better safety profiles of novel approaches would definitively allow patients aged more than 65-70 years to benefit from this therapeutic option. In this review, we will briefly discuss the most relevant and recent data available regarding HDT/ASCT in lymphomas.

Key words: Hodgkin lymphoma; Non-Hodgkin lymphoma; High dose therapy; Autologous stem cell transplantation; New drugs

Core tip: High-dose therapy (HDT) followed by autologous stem cell transplantation (ASCT) is considered the golden standard for the vast majority of patients with both Hodgkin and non-Hodgkin lymphoma, who either relapse or never attain a remission. However, several questions about HDT/ASCT still remain unanswered, also comprising, but not limited to, its role in newly diagnosed patients with advanced stage disease. The incorporation of novel drugs in both salvage and conditioning regimens has recently

revitalized the HDT/ASCT area, with several phase I-II trials performed during the last 5 years. This review will focus on the most recent data regarding HDT/ASCT in lymphomas.

INTRODUCTION

High-dose therapy (HDT) followed by autologous stem cell transplant (ASCT) is the therapy of choice for patients with chemosensitive, aggressive, relapsed non-Hodgkin lymphoma, basing on the results of the PARMA and CORAL study (NHL)^[1,2]. Moreover, HDT/ASCT is considered the standard of care for Hodgkin lymphoma (HL) patients in chemosensitive relapse^[3]. Different HDT regimens followed by ASCT are able to produce rates of disease-free survival (DFS) and overall survival (OS) of approximately 30% to 70%. Despite HDT/ASCT prolonged DFS, few major drawbacks still limit the utility of this approach for a wide patient population. As an example, the introduction of Rituximab in every-day clinical practice has dramatically reduced the number of patients addressed to HDT/ASCT, specially in front-line therapy. Up to now, no regimen was demonstrated to be superior to another in randomized trials^[4]. Therefore, novel strategies are urgently required. As a consequence, and due to the sudden unavailability of carmustine, the International Investigators have developed novel HDT/ASCT protocol in resistant/relapsed aggressive NHL or HD within the last 5 years, aiming to improve the outcome while reducing toxicity. In this paper, we will discuss the data emerging from few recent clinical trials testing HDT/ASCT in aggressive lymphomas.

CONDITIONING REGIMENS PRE-ASCT IN LYMPHOMAS

High dose chemotherapy and ASCT is the standard of care for patients with recurrent HL and NHL who fail immunochemotherapy upfront, improving long-term survival in 30% to 50%. Several factors impact on survival of lymphoma patients after HDT/ASCT. In this regard, the most important predictive factor is disease status at transplant (chemosensitive vs chemoresistant). Nevertheless, transplant related morbidity and mortality still remain relevant in influencing the outcome of the transplant procedure. Therefore, when planning an autologous transplant, the efficacy of HDT to eradicate residual disease after salvage therapy may be well balanced with toxicity to normal tissues, in order to

maximize the probabilities of the procedure of being successful. Despite the efforts made to further increase the therapeutic window of new high-dose regimens, at present we do not have an evidence that clearly demonstrates the superiority of a specific HDT regimen to the others.

BEAM (carmustine, etoposide, cytarabine, melphalan) regimen is considered the regimen of choice for patients with HL and NHL submitted to ASCT, due to its acceptable safety profile and a quite high antitumor efficacy. The transplant related mortality (TRM) of the BEAM regimen is quite low, depending mainly on disease status at transplant, infectious history and prior lines of therapy. Early, non-hematological toxicities of carmustine, such as nausea, vomiting, mucositis, hepatotoxicity, diarrhea and nephrotoxicity are well known, and worldwide Clinicians know how to manage them. However, late toxicities are still a matter of concern, in particular second tumor and interstitial non-infectious pneumonitis, which have been reported in 16%-64% of patients receiving carmustine-based conditioning regimens, being fatal in approximately 9% of the patients.

Accordingly, various scientists and cooperative groups still continue in this search for the holy Grail, focusing mainly on the incorporation of novel drugs, radioimmunoconjugates, monoclonal antibodies and/or other stimuli for the immunologic system during the early pre- and post- transplantation phases.

Hodgkin lymphoma

The results of the most important trials with HDT/ASCT in HD are listed in Table 1.

Ramzi *et al*^[5] reported the results of non-cryopreserved ASCT of 45 HL patients receiving an alternative CEAM regimen in which iv carmustine was substituted by oral lomustine (CCNU: 2 chloroethyl cyclohexyl nitrosourea). Forty-five relapsed/refractory HL patients underwent conditioning regimen with: lomustine 200 mg/m² on day-3, etoposide 1000 mg/m² on day-3 and day-2, cytarabine 1000 mg/m² on day-3 and day-2, melphalan 140 mg/m² on day-1. All 45 patients showed engraftment of infused stem cell. Grade 2 and grade 3 mucositis was seen in 64.5% of patients. TRM at 100 d was 2.2%. Median DFS was 20 mo (range: 4-60 mo). After a follow up of more than 2-year, the 2-year DFS in 30 evaluable patients was 77% and the 2-year OS was 84% (25/30 patients).

Czyz *et al*^[6] have retrospectively evaluated the efficacy of a modified BEAM regimen followed by ASCT in 132 patients relapsed/refractory HL patients. The 10-year OS and progression free survival (PFS) were 76% and 66%, respectively. Age > 45 years, more than one salvage regimens and chemoresistant disease at transplant were all predictive for poor OS in multivariate analysis.

In 2011 Shafey *et al*^[7] have retrospectively evaluated 73 patients with refractory/relapsed HL treated in a 15 year period with a double high-dose therapy consisting

Table 1 High dose therapy followed by autologous stem cell transplantation in Hodgkin lymphoma

HL: Hodgkin lymphoma; DICEP: Dose-intensive cyclophosphamide, etoposide, cisplatin; VTEPA: Vinorelbine, paclitaxel, etoposide and cisplatin; TECA: Thiotepa, etoposide and carboplatin; R/R: Relapsed/refractory; OS: Overall survival; PFS: Progression free survival.

of dose intensified cyclophosphamide, etoposide and cisplatin reinduction, followed by high-dose melphalan and ASCT. TRM was 1%. The 5-year PFS and OS rates were 61% and 80%, respectively. In multivariate analyses, response to reinduction therapy and DICEP and International Prognostic System score at relapse were the only factors independently predicting PFS and OS.

As already stated, the standard of care for refractory or relapsed HL patients is a salvage therapy followed by HDT/ASCT. However, patients with chemoresistant disease after salvage therapy have a small probability of achieving a long lasting response and a long overall survival. In 2006, the Emory University group tested in a phase I study, the combination of cytarabine with fixed doses of vinorelbine, paclitaxel, etoposide and cisplatin (VTEPA) as second salvage therapy in patients with resistant/relapsed lymphoma, showing an overall response rate (ORR) of 33%^[8]. In 2013 the same group further examined the effectiveness of VTEPA in 30 patients with relapsed/refractory HL^[9]. Among 27 evaluable patients, ORR was 70% (7 CR, 12 PR). All but 1 responding patients (66%) subsequently underwent ASCT. This therapeutic strategy (VTEPA + ASCT) produced a median PFS and OS of 28 and 38 mo from transplant, respectively.

In 2012 Di Ianni *et al*^[10], reported their experience with a novel HDT regimen including thiotepa, etoposide and carboplatin (TECA) in HL patients. From March 1999 to December 2005, 58 patients with primary refractory or relapsed were enrolled in a phase II study. The conditioning regimen consisted of etoposide (250 mg/m² days 1-4), thiotepa (166 mg/m² days 2-4) and carboplatin (266 mg/m² days 2-4). After salvage therapy, 46 patients had chemosensitive disease (30 CR + 16 PR), whereas 12 were chemoresistant. At transplantation, 30 patients were in CR, 16 in PR and 12 showed a chemoresistance to salvage chemotherapy. TRM was 0%. The global ORR was 79.3% (37 CR, 7 PR), but 12 patients still did not respond to therapy neither after HDT/ASCT. The 5-year DFS and OS were superior for relapsed patients with respect to primary refractory ones. After 5-year of follow-up, approximately 75% of patients were alive. Even if the idea of combining thiotepa with more conventional drugs was interesting, the results of this study are in line with other trials, given the high percentage (80%)

of chemosensitive patients at transplant. Hard-to-respond, chemoresistant patients (12/58, 20%) did not show any benefit from the thiotepa-containing regimen.

Non-Hodgkin lymphoma

The results of the most relevant studies with HDT/ASCT in NHL are listed in Table 2.

As for HL, the standard salvage therapy of relapsed/refractory aggressive NHL mainly relies on HDT/ASCT, hopefully in patients with chemosensitive disease. Nevertheless, reaching of long lasting DFS remains not easy.

Kim *et al*^[11] reported the results of a novel NEAM regimen, administered prior to ASCT, to 69 patients with resistant/relapsed NHL. The NEAM regimen, another, novel variant of the standard BEAM, consisted of mitoxantrone (12 mg/m² iv on day-6 to day-4), etoposide (100 mg/m²) and cytarabine (100 mg/m² iv every 12 h from day-6 to day-3), melphalan (single 140 mg/m² dose at day-2). TRM at day-100 was 2.9%. Median event free survival (EFS) was 17.9 mo, whereas estimated 2-year OS was 64.2%.

In 2012 Falzetti *et al*^[12] reported the results of the TECA (thiotepa, etoposide and carboplatin) regimen administered to 45 patients with NHL at various disease stage. TRM was 4.4%. The ORR was 77.8% (30 CR, 5 PR). Ten patients (22.2%) did not respond. The mean 5-year OS was 71.1%. Patients with low (1) International prognostic index (IPI) at diagnosis had a better ORR and 5-year OS were than for those with intermediate IPI (2 and 3).

Another strategy to increase efficacy of the conventional BEAM regimen is to add novel drugs in a new reinforced BEAM combo. In this regard, the University of Nebraska Medical Center group designed a phase I/II trial testing the safety and the efficacy of the addition of a proteasome inhibitor to standard BEAM prior to ASCT in resistant/relapsed indolent or transformed NHL (including T cell lymphomas) or mantle-cell lymphoma (MCL, only in first CR)^[13]. Patients received 4 doses of escalating bortezomib (0.8, 1, 1.3, 1.5 mg/m²) on day-11, day-8, day-5 and day-2 prior to ASCT. After the maximum tolerated dose (MTD, 1 mg/m²) was defined, other 20 patients entered the phase II to determine a preliminary ORR, PFS and OS with this regimen. As a whole, 42 (13 + 29) patients were enrolled. Non-hematologic side effects were

HL: Hodgkin lymphoma; RIT: Radioimmunotherapy; BeEAM: Bendamustine, etoposide, ara-C, melphalan; FEAM: Fotemustine plus etoposide, cytarabine and melphalan; NEAM: Mitoxantrone, etoposide, cytarabine, and melphalan; NHL: Non-Hodgkin lymphoma; R/R: Relapsed/refractory; OS: Overall survival; TT-Vp-Car: Thiotepa, Vepeside, carmustine; V-BEAM: Velcade plus standard BEAM.

comparable to those observed with other regimen, with the relevant exception of an increase in grade III peripheral neuropathy, related to the use of bortezomib, and in grade III gastrointestinal toxicity. TRM at day 100 was 0%. At 1 year after ASCT, 38 patients were evaluable for response; 32 (84%) were in CR and 1 (3%) was in PR, resulting in an impressive ORR of 87%. these results were better among patients treated in the phase II, for whom ORR was 89% (84% CR, 5% PR). PFS was 83% at 1 year and 32% at 5 years. OS was 91% at 1 year and 67% at 5 years. The authors performed also an exploratory analysis to determine whether this regimen was more effective in a given histological pattern, finding no statistical difference. Conversely, by comparing the results of bortezomib-BEAM with standard BEAM in an historic cohort of patients matched for histology at their Institution, the authors showed an advantage in both PFS and OS at 5 years for MCL patients (57% and 72% vs 43% and 50%, respectively), even if not statistically significant. Even if promising, in particular in MCL patients, the bortezomib-BEAM regimen discourages, due to the lack of an evident benefit and higher than expected toxicity, its further exploration in a randomized, phase III study.

In 2011 Visani *et al*^[14] reported the efficacy of increasing doses of bendamustine (160 mg/m², 180 mg/m² and 200 mg/m² given on day-7 and day-6) in addition to fixed doses of etoposide, cytarabine and melphalan (BeEAM regimen) administered as preparative regimen to ASCT. Forty-three patients with resistant/relapsed HL (*n* = 15) and NHL (*n* = 28) were enrolled, 9 in the phase I and 34 in the phase II study. No patients experienced dose limiting toxicity. TRM at day 100 was 0%. The follow-up period at the time of publication was 18 mo, with 81% being alive and disease-free at that time. Disease type (HL vs NHL) and disease status at transplant (chemosensitive vs chemoresistant) significantly influenced DFS. Interestingly, the authors updated their experience in 2014^[15], reporting a 72% PFS at 3 years, that allowed them to met the primary end-point of the study. Median PFS and OS were still not reached. Disease status at

transplant (chemosensitive vs chemoresistant) was still a stron predictor of outcome. Conversely, disease type (HL vs NHL) was no longer affecting PFS nor OS^[15].

By riding the same wave, Isidori *et al*^[16] recently reported the preliminary data of a phase II study to confirm the effectiveness of BeEAM as a preparative regimen for autologous stem cell transplantation in resistant/relapsed aggressive B-cell non-Hodgkin lymphoma patients. Thirty-seven patients (median age 56 years, range 19-69) with resistant/relapsed aggressive B-cell NHL were enrolled, up to now, in the study. Briefly, 27 patients had advanced stage disease (III-IV), 12 were primary refractory and 25 had relapsed. Thirty-three patients had good performance status (WHO 0-1), and 11 patients presented with 1 or more relevant comorbidities (range: 1-5). Nineteen patients were in II or subsequent CR after salvage therapy, whereas 16 were in PR and 2 had progressive disease. All patients engrafted, with a median time to ANC > 0.5 × 10⁹/L of 10 d. TRM at day-100 was 2.7%. Eight out of 37 patients presented a fever of unknown origin (21.6%), whereas 19 patients (51%) presented a clinically documented infection. One patient died due to an incomplete hematological recovery after transplant, producing an overall transplant related mortality of 2.7%. Twenty-seven out of 37 patients are evaluable up to now for response: 22/27 (81.5%) obtained a CR, 2/27 a PR, resultin in an ORR of approximately 90%. After a median follow-up of 9 mo from transplant (range 2-24), 5/24 patients relapsed, whereas 19/24 (79.1%) are still alive, in continuous CR. The Authors concluded that the BeEAM regimen preliminary confirmed its safety and its promising efficacy in resistant-relapsed aggressive B-cell lymphomas.

In 2010 Musso *et al*^[17] substituted carmustine with the chloroethylnitrosurea fotemustine (150 mg/m² on day-7 and day-6) in the standard BEAM (FEAM regimen). 84 resistant/relapsed HL and NHL patients were enrolled in this study. Non-hematological side effects were superimposable to those of the BEAM regimen, with 7 patients experiencing grade 4 mucositis, without any other relevant grade 4 toxicity. TRM at day-100

was 2.4%. Even if the FEAM HDT regimen showed a favorable safety profile, it is not possible to draw any conclusion regarding survival or long-term efficacy due to the short follow-up period of 17-mo only.

Another question that still remains unanswered is related to the relative efficacy of HDT/ASCT in NHL patient population treated with chemoimmunotherapy comprising rituximab front-line. As a fact, this is really a burning question, as all patients with B cell malignancies are treated upfront, at present, with anti-CD20 monoclonal antibody plus chemotherapy. Nevertheless, the utility of HDT/ASCT for NHL patients in first CR is still a matter of great debate.

Recently, the Southwest Oncology Group tried to answer, at least partly, this question by conducting a large, randomized trial testing HDT/ASCT as consolidation therapy, in comparison to standard chemoimmunotherapy^[18]. 397 patients were enrolled, and 370/397 received five cycles of CHOP with (47%) or without (53%) rituximab. Responding patients (CR + PR) were subsequently randomized to receive 3 other cycles CHOP ± Rituximab (control group) or one additional cycle of CHOP ± Rituximab followed by ASCT (transplantation group), conditioned with standard BEAM regimen or total body irradiation (12 Gy). The primary efficacy end points were 2-year PFS and OS. Of 370 induction-eligible patients, 253 were randomly assigned to the transplantation group (125) or the control group (128). Like many of the randomized trials and several meta-analysis, this study showed an improvement in PFS for the combined high-risk and high-intermediate risk who are chemosensitive to induction therapy. However, again and again, this study was not able to demonstrate, in randomized fashion, an advantage in OS for HDT/ASCT, neither for high risk patients^[18]. On the other hand, we have to keep in mind that 29% of patients who had a relapse or progression after standard therapy, were rescued with HDT/ASCT, resulting in a relevant bias for the analysis of a statistical OS benefit for HDT/ASCT over the control group. Finally, the study was not designed and powered to address subgroup-related question, and therefore any point in favor of HDT/ASCT for high risk patients is merely speculative.

The incorporation of new drugs into HDT regimen prior to ASCT in B-cell lymphomas has recently been helped by the development of radioimmunotherapy (RIT). The potential advantage of using radioimmun-conjugates, with or without chemotherapy, prior to ASCT, relies on the opportunity of delivering localized radiation therapy to the site of tumor. This allows to minimize the toxicity of total body irradiation, with the goal of decreasing relapse rate without adding toxicity to the conditioning regimen. At present, no study comparing RIT and standard radiation therapy has been done. However, few preliminary phase II studies with RIT as a part of a preparative regimen have produced encouraging results by showing a high safety profile, a low TRM and a preliminary efficacy.

Kruger *et al.*^[19] enrolled 16 patients with resistant/relapsed NHL in a phase II study testing ¹³¹I-rituximab-BEAM and ASCT. A single dose of ¹³¹I-rituximab was given on day-15, whereas standard BEAM started on day-6 prior to ASCT. Non hematological side effects were mild in grade, without any grade IV toxicity. All patients engrafted, with a 0% TRM at day-100. Results were encouraging, with 75% of patients being alive and disease free after a median follow-up of 44 mo from ASCT (range 4-108). Interestingly, each patient received only a limited whole body radiation of only 0.75 Gy.

Winter *et al.*^[20] conducted a phase I-II study in 44 patients with resistant/relapsed NHL, by adding yttrium-90 (⁹⁰Y) ibritumomab tiuxetan to standard BEAM and ASCT (Z-BEAM regimen). A significant proportion of patients (30%) entering the study had chemoresistant disease after salvage therapy. Non hematological toxicities were similar to those reported with standard BEAM. Two dose limiting toxicities occurred at 17 Gy dose level, which made 15 Gy the recommended dose for the phase II of the study. After a median observation time of 33 mo, the estimated 3-year PFS and OS were 43% and 60%, respectively. When looking at these results, it has to keep in mind the significant proportion of chemoresistant patients, who perform extremely poor with conventional HDT regimen.

Shimoni *et al.*^[21] randomized 43 patients with CD20 positive aggressive B-cell lymphoma to receive either Z-BEAM (*n* = 22) or standard BEAM (*n* = 21). Ibritumomab tiuxetan was administered at 0.4 mCi/kg on day-14 prior to ASCT. Non hematological toxicities were mild and comparable within the 2 groups. TRM at day-10 was 0% in both groups. As a whole, Z-BEAM did not show a significant advantage in OS with respect to standard BEAM. However, there was a trend in 2-year PFS and OS in favor of Z-BEAM (59% and 91% vs 37% and 62%, respectively). The Authors speculated that Z-BEAM could be superior to standard BEAM for patients receiving frontline chemoimmunotherapy containing Rituximab. However, the sample size of the study was very small, and the statistical analysis did not allow to draw any conclusion regarding the superiority of a regimen to another.

Another study with yttrium-90 Ibritumomab tiuxetan was conducted and published by Spanish Group in 2013^[22]. It was a prospective, multicenter, phase II clinical trial which enrolled 30 patients with induction failure or refractory B-cell NHL. Patients received ⁹⁰Y-ibritumomab tiuxetan at a fixed dose of 0.4 mCi/kg, 14 d prior to the BEAM chemotherapy. Non hematological toxicities were similar to those reported with standard BEAM, and TRM at day-100 was 0%. Intriguingly, the vast majority of patients (25/30) underwent to HDT/ASCT with chemoresistant disease. Therefore, this regimen produced an outstanding ORR of 70%, with 60% of patients obtaining a CR; estimated 3-year PFS and OS were 61% and 63%, respectively, and the median time of observation for surviving

patients was 31 mo. The Authors enthusiastically concluded that ^{90}Y -ibritumomab tiuxetan based HDT regimen prior to ASCT results in a terrific response rate, with promising survival in a group of refractory lymphoma patients with extremely poor prognosis.

Taken together, these results are in favor of RIT-based HDT regimen prior to ASCT, given the good toxicity profile and the promising efficacy. However, none of these studies was able to demonstrate a statistical benefit for the RIT-based HDT, probably also due to the small sample size of the trials. In conclusion, a large, randomized trial comparing RIT-BEAM and standard BEAM is warranted before drawing any conclusion and before recommending the use of RIT-HDT outside from controlled clinical trials.

With regards to T-cell lymphomas, the use of HDT/ASCT is still considered an "experimental" practice. In fact, only a small amount of prospective trials evaluating the impact of HDT/ASCT as consolidation of first-line therapy have been reported up to now^[23-25]. Even if the results coming from these studies suggest an improve in both DFS and OS when compared with chemo alone^[23-25], an important amount of patients is not able to perform frontline transplant, principally due to disease progression during induction chemotherapy, thus underlying the need for a better induction regimen. In relapsed T-cell lymphomas, HDT/ASCT produced results similar to those obtained in relapsed, aggressive B-cell lymphomas. Reported long-term DFS approaches 30% to 50%, making HDT/ASCT a valuable option in the therapeutic armamentarium for this indication. Conversely, the use of HDT/ASCT in refractory T-cell lymphoma produce extremely poor outcome, and other strategies could be preferred for this setting of patients. In conclusion, we think that there is room for HDT/ASCT as a part of first-line treatment, especially in responding patients. On the other hand, resistant or relapsed patients may be better addressed to allogeneic transplantation or to clinical trials.

Late complications of HDT followed by ASCT in lymphomas

Late complications among HL survivors are still a matter of concern. Several papers have reported high rates of second cancers, heart disease, pulmonary fibrosis, and infections^[26]. The recognition of these risks has resulted in modification of chemotherapy regimens and of radiation fields and doses^[26,27]. HDT/ASCT by itself is also affected by late *sequelae* of treatment, but specific data for the HL population are limited^[26,27]. Few studies identified predictors of post-transplant long-term quality of life specifically for patients with HL, who have higher rates of treatment-related late morbidity and mortality than patients with other cancer diagnoses^[26,27].

The most relevant study that evaluated the risk of late morbidity and mortality, among patients with relapsed/refractory HL after HDT and ASCT was performed by the MSKCC group^[28]. this study, conducted on 153 HL

patients treated with HDT/ASCT between 1985 and 1998 who survived ≥ 2 years after ASCT, demonstrated a risk ratio of second malignancy equal to 6.5 (95%CI: 3.6-10.7) when compared with the general population, but limited to 2.4 (95%CI: 1.4-4.05) when compared with patients with HL^[28]. In other words, the risk of developing a second tumor after HDT/ASCT was elevated if compared with the cancer risk in the general population, but was less pronounced when compared with patients with HL in SEER registry^[29].

Data on NHL are quite similar, demonstrating a higher risk of developing a second malignancy mostly for patients receiving TBI as a part of the preparative regimen to ASCT. However, to the best of our knowledge, large studies have not been conducted in this patient population.

Our guess is that, in the era of the TBI-free conditioning regimens, what really counts for the development of a second malignancies or a late effect (*e.g.*, cardiomyopathy) in lymphoma patients, is mainly the type and the dose of chemo- and radiation therapy performed before transplant, and only in a minimal extent HDT/ASCT.

CONCLUSION

High dose therapy followed by autologous stem cell transplantation has still a major role in the treatment of resistant/relapsed HL and NHL. The relevant advancements made with the incorporation of novel drugs and/or radioimmunoconjugates into preparative regimens translated in a higher PFS rate with respect to the historical standards. Furthermore, TRM and overall toxicities seem to be lower. However, data on the possible overall survival advantage given by the novel agents are still controversial, and probably only large, randomized phase III trials could pick a winner between the plethora of new drugs recently incorporated in novel conditioning regimens. Our personal experience with Bendamustine, used both in Phase II trials and everyday clinical practice, indicate the favorable safety profile of the BeEAM regimen, coupled with a relevant efficacy in a hard-to-treat population of resistant/relapsed lymphoma patients.

A different scenario could be represented by maintenance therapy with new drugs, such as Brentuximab Vedotin in HL or Ibrutinib or Lenalidomide in aggressive NHL, in patients chemoresistant who obtain at least a PR after HDT/ASCT. In this setting of patients, the use of a drug with a different mechanism of action and a manageable safety profile could help the physician in the path to cure of a highly resistant subpopulation of lymphoma patients.

Abstract

Stem cells are considered to be among the principle scientific breakthroughs of the twentieth century for the future of medicine, and considered to be an important weapon to fight against diseases, particularly those that have resisted the efforts of science for a long time. Human dental tissues have limited potentials to regenerate but the discovery of dental stem cells have developed new and surprising scenario in regenerative dentistry. Stem cell treatments are one example of the

possibility using adult cells sourced from patients' own bodies' means that it can be expected that in the near future such treatments may become routine at dental practices. The hope is that it will become possible to regenerate bone and dental tissues including the periodontal ligament, dental pulp and enamel, and that the creation of new teeth may also become feasible. In view of this possibility of achieving restoration with regenerative medicine, it can be considered that a new era of dentistry is beginning. Thus the aim of this review is to give dental professionals a brief overview of different stem cells sources and the latest findings and their implications for improving oral health and treating certain conditions of the human mouth and face.

Key words: Stem cells; Regeneration; Dental research

INTRODUCTION

Stem cell therapies could lead to novel cures and palliative treatments. Stem cell research has clinical implications considering cell repair, replacement or regeneration to improve organ function. Thus future studies will require the collaboration of researchers from different specialties, including stem cell biology, material science, and of course, basic and clinical dentistry.

The loss of hard or soft dental tissue not only harms the patient psychologically, but also causes atrophy of the tooth supporting tissues. Regeneration may define as restoring a deficient part by complete regeneration of its architecture and function. Dramatic tooth extraction, sever periodontitis, implant dehiscence defects, tumor, or congenital anomalies may lead to alveolar bone deficiencies^[1]. Alveolar bone defect regeneration techniques have many advances using minimally morbid techniques enhanced the success and patient acceptance^[2,3]. Successful regeneration techniques of the craniofacial bone deficiencies, are used to optimize therapeutic approaches to bone regeneration^[4].

Autogenous bone graft remains the preferred reconstructive method but have some limitations such as increased operative time for bone graft harvesting, donor site morbidity, graft resorption, and limited availability. Various types of bone graft have become available to overcome these limitations^[5,6]. There have been recent interest in the development of new grafting materials using allogeneic, xenogeneic and synthetic bioimplants for reconstructive bony procedures, and have been used as alternative for autogenous bone grafts^[7-9]. A new combination of protein therapy, gene therapy and cell therapy and tissue engineering had been successfully developed and considered to be a more efficient and safer therapeutic system for bone and soft tissue regeneration^[10].

Stem cells are nonspecific cells with powerful self-regeneration properties and they are capable of organizing other cell types in the body. They are also play an important role as those undifferentiated cells have precursor properties, capable of forming many different cell types and have the property of unlimited self-renewal. Within dentistry, the hope is to regenerate both bone and dental tissues, including the periodontal ligament, dental pulp and enamel, so that new teeth could even be created, even in the presence of caries, pulpitis and periapical diseases, which are the primary causes of tooth loss^[11].

"Stem cells" are precursor cells that can give rise to multiple tissue types. Totipotent stem cells are cells that can give rise to a fully functional organism as well as to every cell type of the body. *Pluripotent* stem cells are capable of giving rise to virtually any tissue type, but not to a functioning organism. Multipotent stem cells are more differentiated cells that can give rise only to a limited number of tissues. For example, a specific type of multipotent stem cell called a mesenchymal stem cell

has been shown to produce bone, muscle, cartilage, fat, and other connective tissues^[12,13].

The effectiveness of stem cells can be attributed to many factors such as: Stem cells can be expanded *ex vivo*, thus a small number of them can be sufficient to heal large defects or to treat diseases. Stem cells in the presence of vasculature may elaborate and organize tissues *in vivo*. Also they may play an important role in regulating local and systemic immune reactions of the host favoring tissue regeneration.

STEM CELL TYPES AND SOURCES

Stem cells have important criteria of self-renewable and the ability to differentiate into at least two different types of cell. Types of stem cells are determined based on their source and differ in regard to the types of cells into which they differentiate^[14,15].

Embryonic stem cells, they are pluripotent cells that can differentiate into any other type of cell^[14].

Adult stem cells, also called somatic stem cells, lack the potency of their embryonic counterparts, but have been used successfully to treat diseases. They can be harvested from an individual and, be used to regenerate tissue by autologous or allogeneic transplant^[14].

Induced pluripotent stem cells - adult stem cells having the potential to serve as the source of a large number of autologous stem cells, but the main drawbacks are their capacity for proliferation and concomitant potential for carcinogenicity^[16].

Bone marrow-derived mesenchymal stem cells can self-replicate and have been differentiated into osteoblasts, chondrocytes, myoblasts, adipocytes and other cell types. MSCs are often viewed as a yardstick of adult stem cells (Figure 1)^[17].

Adipose-derived stem cells (AS) are typically isolated from lipectomy or liposuction aspirates. AS have been differentiated into adipocytes, chondrocytes, myocytes, neuronal and osteoblast lineages. They have many advantages over other adult stem cell populations, as adipose tissue is available in large number and become easily accessible^[18].

Dental stem cells - recently these cells have been found in various dental tissues, such as Stem Cells from Human Exfoliated Deciduous teeth^[19], dental Pulp Stem Cells^[20], Periodontal Ligament Stem Cells (PDLSCs)^[21,22], while in dental papilla of wisdom teeth Stem Cells from Apical Papilla is present^[23] and researchers termed stem cell found in dental follicles of developing wisdom teeth as Dental Follicle Precursor Cells^[24-26].

There are some advantages of dental stem cells: (1) they are readily accessible and provide an easy and least invasive way to obtain them; (2) stem cell banking is a reasonable and simple alternative to harvesting stem cells^[27]; (3) they show good interaction with scaffolds^[28]; and (4) they have a high proliferative and multidifferentiation potential^[29-31].

Figure 1 Mesenchymal stem cells are viewed as a yardstick of adult stem cells. A: Human mesenchymal stem cells (MSCs) isolated from anonymous adult human bone marrow donor after culture expansion (H and E staining); B: Chondrocytes derived from human mesenchymal stem cells showing positive staining to Alcian blue. Additional molecular and genetic markers can be used to further characterize MSC-derived chondrocytes; C: Osteoblasts derived from human mesenchymal stem cells showing positive von Kossa staining for calcium deposition (black) and active alkaline phosphatase enzyme (red). Additional molecular and genetic markers can be used to further characterize MSC-derived chondrocytes; D: Adipocytes derived from human mesenchymal stem cells showing positive Oil Red-O staining of intracellular lipids. Additional molecular and genetic markers can be used to further characterize MSC-derived chondrocytes^[16].

ROLE OF MESENCHYMAL STEM CELLS IN TISSUE REGENERATION

By chemotaxis Mesenchymal Stem Cells can migrate to tissues showing inflammation and injury in the organism^[32]. They can differentiate into different cell types, able to secrete a variety of cytokines, showing anti-inflammatory activity and create an anabolic microenvironment. Moreover, they play a role in regeneration of injured tissues by various means, as they directly differentiate into tissue-specific cells and thus substitute damaged or lost cells. On the other hand, they indirectly influence tissue regeneration by secretion of soluble factors. Thirdly, they are able to modulate the inflammatory response. So, they can effectively promote vascularization, cell proliferation, differentiation and modulate an inflammatory process^[33,34].

CHALLENGES IN STEM CELL BIOLOGY

Notable increase in the applications of craniofacial tissue engineering, among them is: (1) isolation of stem cells from several craniofacial tissues and their clinical therapeutic applications in the craniofacial structures; (2) several prototypes of the human-shaped temporomandibular joint condyle have been engineered with integrated cartilage and bone layers from a single

population of mesenchymal stem cells; (3) cell-based or non-cell-based tissue engineering of periodontium elements, including the periodontal ligament and cementum; (4) the application of stem cells, growth factors, and/or biomaterials in craniofacial bone engineering; and (5) adipose stem cells, with its efficient applications in facial soft and hard tissue reconstructive surgeries^[35].

Tissue engineering of the temporomandibular joint

Current approaches for replacing degenerated mandibular condyles suffer from deficiencies such as donor site morbidity, immune-rejection, implant wear and tear, and pathogen transmission. So, advances in the management of temporomandibular joint degenerative diseases have been established: (1) to promote matrix synthesis and tissue maturation of stem cell-derived chondrogenic and osteogenic cells (Figure 2)^[36]; (2) to enhance the mechanical properties of a tissue engineered mandibular condyle for ultimate in situ implantation into the human temporomandibular joint (Figure 3)^[37]; and (3) to facilitate the remodeling potential of a tissue-engineered mandibular condyle.

Periodontal tissue engineering^[35]

The modulation of the exuberant host response to microbial contamination that plagues the periodontal wound is considered as the main challenge. It clarified

Figure 2 Engineered neogenesis of human-shaped mandibular condyle from mesenchymal stem cells. A: Harvested osteochondral construct retained the shape and dimension of the cadaver human mandibular condyle after *in vivo* implantation; B: Von Kossa-stained section showing the interface between stratified chondral and osseous layers. Multiple mineralization nodules are present in the osseous layer (lower half of the photomicrograph), but absent in the chondral layer; C: Positive safranin O staining of the chondrogenic layer indicates the synthesis of abundant glycosaminoglycans; D: H and E-stained section of the osteogenic layer showing a representative osseous island-like structure consisting of MSC-differentiated osteoblast-like cells on the surface and in the center. Reproduced with permission from Biomedical Engineering Society^[36].

Figure 3 Design and engineering of minipig mandibular condyle. A: Original computed tomography scan of minipig mandible; B: Image-based design of condyle scaffold; C: Ppolycaprolactone (PCL) degradable polymer scaffold fabricated with selective laser sintering attached to the ramus; D: Regrowth of condyle following 3 months' implantation (new condyle shown in red circle); E: Comparison with normal condyle from contralateral side in Yucatan minipig^[37].

the interactions of multiple cell lineages including cementogenic cells, fibroblasts, and osteogenic cells. Regeneration of severe periodontal defects necessitates the attraction of endogenous periodontal tissue forming cells by growth factors.

As regard the periodontal ligament (PDL) function, a recent report identified stem cells in human PDL (PDLSCs) and found that PDLSCs implanted into nude mice generated cementum/PDL-like structures that resemble the native PDL as a thin layer of cementum that interfaced with dense collagen fibers, similar to

Sharpey's fibers (Figure 4)^[38,39]. Thus, the PDLSCs have the potential for forming periodontal structures, including the cementum and PDL.

Challenges in improving stem cell-based researches

Tissue engineered bone with customized shape and dimensions have the potential for the biological replacement of craniofacial bones, and segmental defects in the appendicular bones.

Stem cell therapy encompasses new technologies and therapies and poses many challenges in stem cell

Figure 4 Generation of cementum-like and PDL-like structures *in vivo* by PDSCs. A: After 8 wk of transplantation, PDSCs differentiated into cementoblast-like cells (arrows) that formed a cementum-like structure (C) on the surface of the hydroxyapatite tricalcium phosphate (HA) carrier; cementocyte-like cells (arrowhead) and PDL-like tissue (PDL) were also generated; B: BMSSC transplant was used as control to show the formation of a bone/marrow structure containing osteoblasts (arrows), osteocytes (arrowhead), and elements of bone (B) and haemopoietic marrow (HP); C: DPSC transplant was also used as a control to show a dentin/pulp-like structure containing odontoblasts (arrows) and dentin like (D) and pulp-like (Pulp) tissue; D: Immunohistochemical staining showed that PDSCs generated cementum-like structure (C) and differentiated into cementoblast-like cells (arrows) and cementocyte-like cells (arrowhead) that stained positive for human-specific mitochondria antibody. Part of the PDL-like tissue (PDL) also stained positive for human specific mitochondria antibody (within dashed line); E: Of 13 selected strains of single-colony derived PDSC, only eight (61%) generated cementum/PDL-like structures *in vivo* as shown at lower magnification (approximately 20). New cementum-like structure (C) formed adjacent to the surfaces of the carrier (HA) and associated with PDL-like tissue (PDL); F: The other five strains did not generate mineralised or PDL-like tissues *in vivo*^[38].

Figure 5 Use of stem cells for tooth formation *in vitro* and *ex vivo*. A tooth germ can be created *in vitro* after co-culture of isolated epithelial and mesenchymal stem cells. This germ could be implanted into the alveolar bone and finally develop into a fully functional tooth^[40].

research, such as: (1) biological challenges: Despite biological evidence showing that regeneration can occur in humans, complete and predictable regeneration still remains an elusive clinical goal (especially in advanced periodontal defects); (2) technical challenges: The technical challenges in stem cell therapy are associated with cell manipulations, scaffold materials and delivery systems; and (3) clinical challenges: Clinical challenges in stem cell-based periodontal therapy relate to immune rejection after administration, oncogenic properties of stem cells and functional integration of transplanted tissues into the host.

Stem cells for tooth engineering

Building a tooth logically requires the association/cooperation of odontogenic mesenchymal and epithelial cells. The recombination of dissociated dental epithelial and mesenchymal tissues leads to tooth formation both *in vitro* and *in vivo* (Figure 5). The bioengineered teeth have been produced in ectopic sites and with missing some essential elements such as the complete root and periodontal tissues that allow correct anchoring into the alveolar bone. Recently, a new approach has been proposed for growing teeth in the mouse mandible^[40].

CONCLUSION

For dental applications, stem cell therapy and tissue

engineering are gold solution for bone and soft tissue regeneration and provide hope of future application in humans within the next few years. Tissue engineering modalities will provide numerous clinical dental applications, including improved treatments for intraosseous periodontal defects, enhanced maxillary and mandibular grafting procedures, perhaps more biological methods to repair teeth after carious damage and possibly even re-growing lost teeth. This review highlights the sources and the regenerative therapies in the clinical practice of dentistry in the future.

Abstract

Embryonic stem (ES) cells are isolated from the

inner cell mass of a blastocyst, and are used for the generation of gene-modified animals. In mice, the transplantation of gene-modified ES cells into recipient blastocysts leads to the creation of gene-targeted mice such as knock-in and knock-out mice; these gene-targeted mice contribute greatly to scientific development. Although the rat is considered a useful laboratory animal alongside the mouse, fewer gene-modified rats have been produced due to the lack of robust establishment methods for rat ES cells. A new method for establishing rat ES cells using signaling inhibitors was reported in 2008. By considering the characteristics of rat ES cells, recent research has made progress in improving conditions for the stable culture of rat ES cells in order to generate gene-modified rats efficiently. In this review, we summarize several advanced methods to maintain rat ES cells and generate gene-targeted rats.

Key words: Embryonic stem cells; Transgenic rat

Core tip: Rat embryonic stem (ES) cells are thought to be an essential tool for creating transgenic rats. Since the method for establishing rat ES cells using signaling inhibitors was reported, numerous approaches have been made to propagate rat ES cells efficiently. Additionally, recent investigations have demonstrated the usefulness of the signal inhibitors for microinjection. In this review, we summarize the several advanced methods to maintain rat ES cells and generate gene-targeted rats.

INTRODUCTION

Rattus norvegicus, is widely used as a laboratory animal in many kinds of scientific field, such as biochemical, biomedical, and pharmacological studies. In 1828, albino mutants were brought into laboratories for physiological studies such as fasting studies. Since the nineteenth century, over 700 rat strains including inbred and outbred strains have been developed, and have been used for a multitude of studies^[1,2]. Rats offer some advantages over mice in some transplantation, behavior, and pharmacokinetic studies, because the larger size and greater intelligence of rats compared to mice enables ease of surgical operation, a large-volume of blood sampling, and assessment of high-level learning^[3,4].

In addition, it has been suggested that rats are a useful model for physiological studies owing to the heart rate of rats being closer than that of mice to the human heart rate^[2]. For these reasons, the publications involving rats outnumbered those involving mice for many years. However, far fewer scientific procedures have used transgenic rats than have used mice^[5]. One of the reasons for this disparity has been a lack of reliable methods to establish rat embryonic stem (ES) cells. Genetically modified mice have been routinely created using mouse ES cells with gene-manipulation technologies. These genetically modified mice have contributed greatly to scientific development since the first establishment of mouse ES cell technology in 1981^[6]. Meanwhile in rats, advancement of one of the gene-targeting technology using zinc-finger nucleases (ZFNs) allowed to generate the first knock-out rats in 2009^[7,8]. Microinjection of ZFNs into the pronuclei of rat embryos leads to the creation of knock-out rats. ZFNs are engineered proteins with DNA-binding and nuclease activity, which facilitates the targeted editing of genomes by creating double-strand breaks in the DNA at specified locations and promoting non-homologous end-joining. Moreover, a robust method to establish rat ES cells was reported in 2008^[9,10], and the generation of knock-out rats was achieved using rat ES cell-based technology in 2010^[11].

ESTABLISHMENT, CHARACTERIZATION, AND MAINTENANCE OF RAT EMBRYONIC STEM CELLS

Attempts for establishment of rat embryonic stem cells

Rat ES cells are isolated from the inner cell mass (ICM) of a blastocyst. Figure 1 shows a procedure for the establishment of rat ES cells (our unpublished data). The defining properties of ES cells are following; they are derived from an ICM with pluripotency; they have a stable, normal karyotype *in vitro*; they can be propagated indefinitely in theory without differentiation; they can differentiate spontaneously into multiple cell types representative of all three embryonic germ layers,

both in teratomas after grafting and *in vitro* under appropriate conditions; and they can give rise to any cell type in the body, including germ cells, when injected into host blastocysts^[12]. Many researchers attempted to establish rat ES cells by using the same conditions as those of mouse ES cells, namely leukemia inhibitory factor (LIF) in combination with bone morphogenetic protein (BMP) or fetal bovine serum (FBS). The rat blastocyst-derived cells cultured under these conditions expressed various embryonic stem cell specific markers such as stage-specific embryonic antigen-1 (SSEA-1), Oct4, and alkaline phosphatase, whereas the chimeric rats or teratocarcinoma derived from the rat blastocyst-derived cells were not confirmed^[13-15].

Establishment of rat embryonic stem cells using small molecules

In 2008, a robust and efficient method to establish mouse ES cells was reported by Ying *et al.*^[16], which are also applicable to establish rat ES cells. To maintain the pluripotent state of mouse ES cells, LIF activates the Janus kinase/signal transducer and activator of transcription signaling pathway, while BMP and serum activate the Smad and Mad Related Family signaling pathway^[17]. Differentiation of mouse ES cells is induced *via* activation of mitogen-activated protein kinase/extracellular signal-related kinase (ERK) kinase (MEK) pathway by the autocrine stimulation of fibroblast growth factor-4 (FGF4)^[18]. Ying *et al.*^[16] revealed that LIF, serum and BMP affect the downstream of ERK, and demonstrated that the inhibition of MEK and the FGF receptor (FGFR) maintains the pluripotency of mouse ES cells under serum-free conditions. Moreover, the self-renewal capacity of mouse ES cells was promoted by an additional inhibition of glycogen synthase kinase 3 (GSK3), as the GSK3 pathway is involved in the maintenance of ES cells in the undifferentiated state *via* β -catenin/Wnt signaling^[19-25]. These findings revealed that two types of culture conditions, a combination of the MEK inhibitor and GSK3 inhibitor (2i condition), and a combination of the MEK inhibitor, FGFR inhibitor, and GSK3 inhibitor (3i condition), enable not only the maintenance of mouse ES cells but also the "robust" and "effective" establishment of rat ES cells displaying all the defining properties of ES cells^[9,10,26-31]. The morphology of rat ES cells is rounded and loosely attached on feeder cells, unlike mouse ES cells; however, the rat ES cells express the same undifferentiated markers as mouse ES cells: Oct4, Nanog, Sox2, Rex1, FGF4, and SSEA1. Kawamata *et al.*^[26] succeeded in the establishment of rat ES cells even in FBS-containing medium using Rho-associated, coiled-coil containing protein kinase (ROCK) inhibitor and activin receptor-like kinase (ALK5) inhibitor in addition to the MEK inhibitor and GSK3 inhibitor, which cells showed the defining properties such as pluripotent markers, embryonic body formation, and normal karyotype (Figure 2; our unpublished data). Table 1 shows various attempts to establish rat ES cells, and the properties of the resultant cells.

Figure 1 Establishment of rat embryonic stem cells. A: E4.5 Blastocysts are isolated from Sprague-Dawley rats, and the blastocysts dissolved zona pellucida are put on mouse embryonic fibroblasts (MEF) feeders; B: After 7-10 d, the outgrowth formed from the blastocysts are dispersed, and transferred on MEF feeders; C: Approximately 7 d after culture, rat embryonic stem (ES) cells are appeared (our unpublished data).

Figure 2 Properties of the rat embryonic stem cells. The rat embryonic stem cells are established using the combination of four inhibitors and serum: mitogen-associated protein kinase/extracellular signal-related kinase kinase (MEK) inhibitor, glycogen synthase kinase 3 inhibitor, activin receptor-like kinase (ALK5) inhibitor, Rho-associated, coiled-coil containing protein kinase inhibitor and FBS. A: Expression of the pluripotent markers Oct4 and Sox2, and alkaline phosphatase staining; B: Embryonic body formation; C: Karyotype analysis by G-band staining (our unpublished data). DAPI: 4',6'-diamidino-2-phenylindole; FBS: Fetal bovine serum.

Improvement of rat embryonic stem cell culture efficiency

Numerous approaches have been made to efficiently propagate rat ES cells. Soon after the establishment of rat ES cells^[9,10], rat induced pluripotent stem (iPS) cells were established using the 2i culture conditions^[32,33].

The additional inhibition of ALK5 allowed to propagate rat iPS cells as a homogeneous population, with less spontaneously differentiated colonies as compared to the 2i condition without ALK5 inhibition^[32]. Furthermore, the inhibition of ROCK prevents from apoptosis in human ES/iPS cells and enhances their attachment on

feeder cells after enzymatic dissociation^[34,35]. These studies suggested that the addition of the ALK5 inhibitor and ROCK inhibitor to either the 2i or 3i condition promotes the efficient culture of rat ES cells. Kawamata *et al*^[26] confirmed the effect of the ROCK inhibitor on the self-renewal of rat ES cells by using Oct4-Venus-transgenic rat ES cells, in which cells were derived from the transgenic rats expressing the fluorescent Venus protein under the Oct4 promoter/enhancer. In a condition containing all the four inhibitors (the ROCK inhibitor Y-27632, the MEK inhibitor PD0325901, the ALK5 inhibitor A-83-01, and the GSK3 inhibitor CHIR99021) referred to as YPAC, a great number of colonies expressing the pluripotent markers Oct4 and alkaline phosphatase were appeared after single-cell enzymatic dissociation. In contrast, the rat ES cell colonies maintained withdrawal of the ROCK inhibitor from the YPAC condition expressed the pluripotent markers, but the colonies were sparse under the three-inhibitor condition compared to the YPAC condition^[26]. Kawamata *et al*^[26] concluded that the ROCK inhibitor promotes the attachment of rat ES cells on feeder cells, which leads to efficient culture expansion. Li *et al*^[36] compared the 2i condition with the YPAC condition, and concluded that rat ES cells could expand approximately

twice more under the YPAC condition than under the 2i condition, while maintaining the undifferentiated state. A combination of the serum and the 2i condition was also attempted for the culture of rat ES cells, and as a result, the addition of the serum enhanced the attachment of rat ES cells to feeder cells^[29]. However, the addition of serum triggers differentiation in the cultured ES cells, and may introduce unexpected side effects due to unknown factors within the serum^[37]. Actually, the expression level of a trophectoderm marker Cdx2 was three times higher in the rat ES cells cultured in the serum with YPAC than in the cells cultured in the serum-free 2i condition^[38].

Regulation of Cdx2 expression in rat embryonic stem cells

Cdx2 is the marker of trophectoderm cells, which is not expressed in mouse ES cells; hence, some studies attempted to find culture condition to repress the expression of Cdx2^[39,40]. It was reported that the expression of Cdx2 was related to the concentration of the GSK3 inhibitor. The low concentration of the GSK3 inhibitor 1.5 $\mu\text{mol/L}$ was found to maintain pluripotency and reduce Cdx2 expression; however, the higher concentration of the GSK3 inhibitor 3 $\mu\text{mol/L}$, which has

generally been used to establish and maintain rat ES cells, promotes the expression of Cdx2^[41]. In addition, a decrease in Cdx2 expression was reported by maintaining rat ES cells on Matrigel® or in suspension^[29].

Maintenance of chromosomal states in rat embryonic stem cells

One of the defining properties of ES cells is the retention of a normal karyotype after prolonged culture. However, the rat ES cells cultured under the 2i condition retained normal karyotypes fewer than 40%, which were lower than that found in mouse ES cells^[42]. It is known that the low germline-competence of mouse ES cells results from abnormal karyotypes^[43], and hence, the instability of karyotypes in rat ES cells would make germline transmission difficult. It is reported that the combination of the serum and YPAC improves the karyotype stability, which retains normal karyotypes with over 70%^[26]. The effect of YPAC on karyotype stability was clarified by Li *et al.*^[36] by the successful generation of germline-competent chimeric rats by using the highly passaged rat ES cells maintained under the serum-free YPAC condition, while the rat ES cells maintained under the 2i condition failed to contribute germline. These results suggest that the inhibition of ROCK and/or ALK5 in addition to the 2i condition can stabilize the karyotypes of rat ES cells.

DIFFERENTIATION OF RAT EMBRYONIC STEM CELLS INTO FUNCTIONAL CELLS

Only a few studies have reported a stable induction method to differentiate rat ES cells into functional cells *in vitro*. Cao *et al.*^[44] supplied a protocol to differentiate rat ES cells into cardiomyocytes, and showed that the functional properties of the differentiated cells were similar to those of rat fetal cardiomyocytes and mouse ES cell-derived cardiomyocytes. However, the efficiency of the cardiac differentiation of rat ES cells was approximately 40%; this was lower than that of mouse ES cells, which were differentiated with over 80% efficiency^[45]. Normally, the first step for *in vitro* differentiation of mouse ES cells is to induce cell aggregation into embryonic bodies (EBs), which can be accomplished in a relatively simple procedure using a differentiation medium containing serum. However, apoptosis was observed in rat ES cells during the formation of EBs in the differentiation medium^[26,44]. On the other hand, Peng *et al.*^[46] succeeded in efficient differentiation of neural precursors from rat ES cells. They demonstrated that the ROCK inhibitor facilitates the neural differentiation and the GSK3 inhibitor maintains the survivability of the differentiated cells, and high-efficiency neural precursor differentiation (90%) was achieved using the two inhibitors. For the survival of neural precursors differentiated from mouse ES cells, it is sufficient only in the ROCK inhibitor^[47]. Thus, optimized differentiation media for rat ES cells

are necessary to induce rat ES cells into functional cells efficiently. These media may facilitate not only *in vitro* studies but also *in vivo* studies such as the transplantation of rat ES cell-derived differentiated cells or grafts to animal models, which *in vivo* studies were not reported even though rats are more relevant to humans than mice.

GENERATION OF KNOCK-IN AND KNOCK-OUT RATS USING RAT EMBRYONIC STEM CELLS

Gene-targeting to rat embryonic stem cells

Gene targeting to rat ES cells has been explored in some previous studies. Tong *et al.*^[11] and Yamamoto *et al.*^[48] reported that the efficiency of homologous recombination was 1.12%–3.70% and 0.9%, respectively, while Meek *et al.*^[28] reported that the efficiency was similar to that of mouse and human ES cells. Moreover, the gene-targeted rat ES cells express the pluripotent markers to the same extent as the parent ES cells, and retain the ability to differentiate into all three germ layers^[28]. It was noted that serum was effective at minimizing the damage caused when electroporation was performed^[49]. In fact, Yamamoto *et al.*^[48] used 1% serum during their electroporation procedure. Such efforts are not necessary for the rat ES cells maintained in the condition developed by Kawamata *et al.*^[26], because the culture condition already contains 20% FBS.

Embryonic stem cell maintenance for creating knock-out rats

Soon after the generation of transgenic rats using rat ES cells^[26,50], the first study of targeted gene disruption in rats *via* homologous recombination in rat ES cells were reported by Tong *et al.*^[11]. Figure 3 shows a process of generating genetically-modified rats. Tong *et al.*^[11] succeeded in generating germline chimeric rats by selecting the colonies that formed a small, round, compact shape, and loose attachment on feeder cells, not the large or strongly adherent colonies. This finding provides a guideline to choose rat ES cell colonies for microinjection. Tong *et al.*^[11] found that over 65% of the large and strongly adherent colonies were polyploid, and concluded that such chromosomal abnormalities caused the failure of germline transmission, as the same as the case in mouse ES cells. Hence, the likelihood of successful germline transmission could be increased by the selection of small, loosely adherent rat ES cell colonies for the purpose of microinjection.

An unstable state of rat ES cells in recipient blastocysts after microinjection was also considered as a possible cause for failure to produce germline-competent chimeric rats. In order to study the fate of rat ES cells in recipient blastocysts, Kawamata *et al.*^[26] delivered CAG-AmCyan1-transgenic rat ES cells into recipient

Figure 3 Generation of embryonic stem cell-derived gene-modified rats. First, a gene of interest is introduced into rat embryonic stem (ES) cells. Next, the gene-targeted rat ES cells are injected into blastocysts and are incubated in embryo culture medium or YPAC medium. Then, the chimeric rat embryos are transferred into recipient rats. After that, gene-modified rats will be generated following breeding of the chimeric rats obtained from chimeric embryos.

blastocysts by microinjection. In the absence of YPAC, few cyan-positive cells were present in the blastocysts after 30 h incubation, whereas cyan-positive rat ES cells remained on the surface of the ICM when YPAC was used in both the injection and incubation media. It is reasonable that the addition of the ROCK inhibitor not only suppresses apoptosis, but also promotes adherence to the ICM. Some embryo culture media such as M2, M16, and KSOM have been generally used for the microinjection of mouse ES cells. Similarly, the use of the embryo culture media is also proposed for microinjection of rat ES cells^[51]. Specifically, embryos are washed in M2 medium after collection from pregnant rats, and the chimeric embryos are incubated in M16 medium after microinjection to allow recovery. However, the use of the YPAC medium might offer a superior microinjection method to the conventional methods.

Embryonic stem cell-based knock-out rats and their phenotypes

Two kinds of gene-targeted rats - p53-knock-out rats and protease-activated receptor-2 (Par-2) knock-out rats - have been developed using rat ES cell technology, by three groups^[11,48,52]. The p53-knock-out rats and p53-knock-out mice revealed differing phenotypes: only 4% of female rats homozygous for the p53 knock-out could survive, whereas the female mice homozygous for the p53 knock-out were normally present at weaning^[52]; the major tumor type of the p53-knock-out rats is hemangiosarcoma, while that of the p53-

knock-out mice is lymphoma^[53]; and developmental abnormalities associated with neural tube defects occurred more frequently in the female p53-knock-out rats than in those female mice^[54]. Such sexual distortion associated with the neural tube defects also cause in human^[55,56].

A phenotype of Par-2-knock-out rats were reported by Yamamoto *et al.*^[48]. The Par-2-knock-out rats showed a lack of responsiveness to PAR-2 receptor activating peptides, which clearly indicated the deficiency of Par-2 protein.

Rat models in studying human diseases

The transgenic rat model of Huntington's disease reflects more typical adult patient pathologies in comparison to the transgenic mice^[57]. The transgenic rat model of Alzheimer's disease, harboring mutant human transgenes for amyloid precursor protein and presenilin 1, manifests a complete repertoire of Alzheimer's disease pathological features and demonstrates a markedly greater abundance of soluble oligomeric amyloid- β peptides than mice harboring the same human transgenes^[58]. Moreover, the usefulness of transgenic rat models was shown in autism and fragile X syndrome researches. Transgenic rat models lacking disease-associated genes such as fragile X mental retardation 1 gene and neuroligin-3, and these mutations display traits that may be analogous to the characteristics of in their respective human diseases^[59].

Although gene knock-out strategies are a promising

tool to clarify the mechanism of human diseases such as those mentioned above, some human disease-related gene knock-outs are developmentally lethal. This problem can often be overcome through the use of conditional-knock-out animals, which enable site-specific and inducible gene deletion. Brown *et al.*^[60] first generated the conditional-knock-out rats *via* ZFN-mediated technologies. The system is based on Cre/loxP recombination system, and a target gene is modified by the insertion of two flanking loxP sites, enabling excision of the flanked (floxed) gene segment through Cre-mediated recombination. Conditional-knock-out mice are obtained by mating the floxed mouse line with a Cre-transgenic line, such that the target gene in the progeny becomes inactivated *in vivo* within the expression domain of Cre^[61,62]. To create the conditional-knock-out rats, Brown *et al.*^[60] mated the two strains: floxed allele-harboring rats and Cre allele-harboring rats, generated *via* pronuclear co-injection of a pair of ZFNs along with each donor plasmid.

PERSPECTIVES

Rats are used as the first-preferred animal species for *in vivo* tests of chemicals. In the meantime, *in vitro* alternative methods reflecting a response to chemicals have been demanded due to concerns about animal welfare. The use of the *in vitro* alternatives has many advantages: a decrease in the number of animals used, a reduced cost of animal maintenance, a smaller quantity of chemical needed for testing, and a shortening of the time essential to prepare for and conduct experiments^[63-65]. Rat ES cells could provide innovative *in vitro* screening models, as rat ES cells have an infinite proliferative capacity and can be

continuously supplied.

The generation of transgenic rats have been supported by not only rat ES cell-based gene-modification technology but also other new tools for gene modification such as ZFNs, transcription activator-like effector nuclease and clustered regularly interspaced short palindromic repeat^[66-68]. Table 2 shows the knock-out rats generated by using of rat ES cells and new gene-modification technologies. However, the new technologies carry a risk of off-target effects by site-specific nuclease activity, and require screening to detect targeted events. In contrast, using ES cell-based technologies allows researchers to easily approach the generation of genetically modified rats with the knowledge obtained from experience in generating genetically modified mice. Therefore, rat ES cell-based gene targeting is still an essential tool for gene modifications.

CONCLUSION

Exploring small molecules for the optimum culture conditions for rat ES cells opened up avenues for the generation of genetically modified rats. Although ES cell-based knock-out/knock-in rats have not been widely generated due to the karyotype instability of rat ES cells, further exploration of new combinations of small molecules and growth factors will facilitate germline transmission of genetically modified rat ES cell clones. Additionally, human ES cells with a naïve state could be created by above effort^[75]. As the phenotypes of gene-knock-out animals can be different among species, rats represent a valuable tool in which phenotypes can be generated and compared to those of mice with relative ease. Studies using a combination of both mouse and rat disease models will provide beneficial information to clarify the mechanisms of human disease, leading to the development of new drugs. We hope that many researchers again choose to utilize rat models for research, and establish a new platform for basic and clinical applications using gene modification technology.

ACKNOWLEDGMENTS

The authors would like to express the deepest appreciation to Yoshihiro Sumita and Tadayoshi Ueda whose comments and suggestions were of inestimable value for this manuscript. The authors also thanks to Aya Yoshimura (National Institute of Neuroscience) for technical advice, Luc Gailhouse (National Cancer Center Research Institute) for comments on this manuscript and Shigeyuki Ota, Lao Xintian, Makiko Morita, Hiroko Koreishi, Kenryo Furushima and Yasuyuki Tsutsumishita for their sincere encouragement.

Abstract

AIM: To devise a simplified and efficient method for long-term culture and maintenance of embryonic stem cells requiring less frequent passaging.

METHODS: Mouse embryonic stem cells (ESCs) labeled with enhanced yellow fluorescent protein were cultured in three-dimensional (3-D) self-assembling scaffolds and compared with traditional two-dimensional (2-D) culture techniques requiring mouse embryonic fibroblast feeder layers or leukemia inhibitory factor. 3-D scaffolds encapsulating ESCs were prepared by mixing ESCs with polyethylene glycol tetra-acrylate (PEG-4-Acr) and thiol-functionalized dextran (Dex-SH). Distribution of ESCs in 3-D was monitored by confocal microscopy. Viability and proliferation of encapsulated cells during long-term culture were determined by propidium iodide as well as direct cell counts and PrestoBlue (PB) assays. Genetic expression of pluripotency markers (Oct4, Nanog, Klf4, and Sox2) in ESCs grown under 2-D and 3-D culture

conditions was examined by quantitative real-time polymerase chain reaction. Protein expression of selected stemness markers was determined by two different methods, immunofluorescence staining (Oct4 and Nanog) and western blot analysis (Oct4, Nanog, and Klf4). Pluripotency of 3-D scaffold grown ESCs was analyzed by *in vivo* teratoma assay and *in vitro* differentiation *via* embryoid bodies into cells of all three germ layers.

RESULTS: Self-assembling scaffolds encapsulating ESCs for 3-D culture without the loss of cell viability were prepared by mixing PEG-4-Acr and Dex-SH (1:1 v/v) to a final concentration of 5% (w/v). Scaffold integrity was dependent on the degree of thiol substitution of Dex-SH and cell concentration. Scaffolds prepared using Dex-SH with 7.5% and 33% thiol substitution and incubated in culture medium maintained their integrity for 11 and 13 d without cells and 22 ± 5 d and 37 ± 5 d with cells, respectively. ESCs formed compact colonies, which progressively increased in size over time due to cell proliferation as determined by confocal microscopy and PB staining. 3-D scaffold cultured ESCs expressed significantly higher levels ($P < 0.01$) of Oct4, Nanog, and Klf4, showing a 2.8, 3.0 and 1.8 fold increase, respectively, in comparison to 2-D grown cells. A similar increase in the protein expression levels of Oct4, Nanog, and Klf4 was observed in 3-D grown ESCs. However, when 3-D cultured ESCs were subsequently passaged in 2-D culture conditions, the level of these pluripotent markers was reduced to normal levels. 3-D grown ESCs produced teratomas and yielded cells of all three germ layers, expressing brachyury (mesoderm), NCAM (ectoderm), and GATA4 (endoderm) markers. Furthermore, these cells differentiated into osteogenic, chondrogenic, myogenic, and neural lineages expressing Col1, Col2, Myog, and Nestin, respectively.

CONCLUSION: This novel 3-D culture system demonstrated long-term maintenance of mouse ESCs without the routine passaging and manipulation necessary for traditional 2-D cell propagation.

Core tip: The pluripotent nature of embryonic stem cells (ESCs) makes them an ideal source for cell-based therapeutics and regenerative medicine. Efficient and reproducible expansion of ESCs *ex vivo* is critical for high quality cells for translational applications. However, propagation of ESCs is technically challenging, and often leads to differentiation due to inefficient two-dimensional culture techniques *in vitro*. To mimic the three-dimensional microenvironment *in vivo*, self-assembling scaffolds made from thiol-functionalized dextran and polyethylene glycol tetra-acrylate were designed to encapsulate and propagate mouse ESCs. This culture

system is simple, robust, efficient and reproducible, permitting long-term maintenance of ESCs without routine passaging and manipulation.

INTRODUCTION

The pluripotent state of embryonic stem cells (ESCs) allows their use in a wide array of translational and clinical applications^[1]. Mouse ESCs have been used to investigate developmental and diseases processes, toxicology, cell-based therapeutics and regenerative medicine^[2,3]. Research performed using animal models^[4,5] and more recently human clinical trials^[6,7] have shown promising potential for ESCs in cell therapies, repair of damaged tissues and organs, and *in vitro* disease modeling. However, these applications require routine and efficient expansion of pluripotent ESCs and controlled differentiation to obtain a homogeneous population of cells. The pluripotency of ESCs is controlled by an intrinsic regulatory network^[8] and extrinsic factors including the microenvironment, organization and composition of the extracellular matrix (ECM), cell-cell signaling, and the temporal and spatial gradient of soluble factors^[9-12]. The complex relationship between stem cell fate and their native microenvironment results in a large discrepancy between *in vivo* and *in vitro* culture conditions effecting the quality of cultured cells^[13].

Conventionally, ESCs are grown in two-dimensional (2-D) plastic culture plates on mouse embryonic fibroblast (MEF) feeder layers or ECM components (such as gelatin and Matrigel)^[14]. Mouse ESCs can be maintained in their pluripotent state by the addition of soluble cytokines, such as leukemia inhibitory factor (LIF), to the culture media^[11,15]. However, reliance on MEF feeder layer, cytokines, and/or growth factors complicates maintenance of ESCs due to the potential transmission of xenogeneic pathogens and the fluctuation of lot-to-lot quality^[9]. Furthermore, the distribution of soluble factors in 2-D culture lacks the spatial gradient observed in three-dimensional (3-D) microenvironments, which can alter cell growth and fate determination^[16]. Studies have shown that the ECM composition and organization send mechanical signals for cell differentiation and the culture of ESCs in 2-D culture can signal differentiation into specific cell lineages^[17]. For these reasons, the maintenance of the self-renewing state of pluripotent ESCs and induced-pluripotent stem cells remains a challenge^[18]. In addition to strict culture media and growth conditions, ESCs require regular passaging (every 2 to 3 d).

Consequently, culturing of ESCs is laborious, expensive and requires a high level of expertise^[19].

In order to overcome the problems associated with 2-D culture, we hypothesized that 3-D culture may better mimic the *in vivo* environment supporting the growth and maintenance of ESC pluripotency. 3-D growth of ESCs can be facilitated by hydrogel scaffolds, composed of hydrophilic polymer networks, which emulate the fully hydrated native ECM and natural soft tissue^[20]. Hydrogel constructs incorporating drugs, cytokines, and growth factors have been shown to promote proliferation, directed differentiation, and integration of cells to regenerate target tissue^[21-24]. Recently, ESCs were cultured in 3-D hydrogel scaffolds but required routine passaging, much like 2-D cultures^[19,25].

Studies have utilized dextran-based hydrogels to promote neovascularization and differentiation of ESCs into endothelial cells^[24,26]. Whereas, thiol-functionalized dextran (Dex-SH) was combined with PEG functionalized with tetra-acrylate (PEG-4-Acr) to form chemically cross-linked hydrogels by a Michael-type addition for differentiation of chondrogenic progenitors^[27]. In this report, we developed a 3-D culture system for propagation and maintenance of mouse ESCs utilizing Dex-SH and PEG-4-Acr. Cells grown in the 3-D scaffolds proliferated for extended periods of time, and exhibited ESC characteristics including self-renewal and pluripotency. Interestingly, ESCs grown in 3-D scaffolds had upregulated expression of pluripotency genes. This novel culture system is efficient, reproducible and less cumbersome for long-term maintenance of ESCs without the routine passaging and manipulations associated with 2-D culture. These studies should help facilitate development of methods for expansion of high quality and homogenous populations of human ESCs, which are critically important for regenerative medicine and therapeutic applications.

MATERIALS AND METHODS

Maintenance and growth of ESCs

The mouse ESC line 7AC5, labeled with enhanced yellow fluorescent protein (EYFP/GFP), (ATCC, Manassas, VA) was cultured on irradiated MEF feeder layer with ESC medium containing high glucose Dulbecco's modified Eagle's medium (Invitrogen, Carlsbad, CA) supplemented with 10% fetal bovine serum (FBS, Aleken Biologicals, Nashville, TX), 0.1 mmol/L 2-mercaptoethanol (Sigma, St. Louis, MO), 0.1 mmol/L nonessential amino acids (Invitrogen), 1 mM sodium pyruvate (Sigma), and 1000 U/mL of leukemia inhibitory factor (LIF; Chemicon International, Temecula, CA) as previously described^[15].

Preparation of self-assembling scaffolds

Dextran (25 kDa, $M_w/M_n = 1.30$, Sigma) was functionalized with pendant SH groups at differing degrees of thiol substitution ranging from 4% to 34%, using a published method^[27]. Dex-SH was characterized by ¹HNMR spectroscopy using a 400 MHz Bruker Avance II

spectrometer (Bruker, Billerica, MA).

Hydrogel scaffolds were formed by mixing Dex-SH with PEG-4-Acr (20 kDa, Creative PEGWorks Winston Salem, NC) *via* a Michael addition reaction, as previously described^[22]. For this study, scaffolds were prepared with final polymer concentrations of 5% w/v. The molar ratio of thiol to acrylate groups used was 1:1.

Encapsulation of ESCs in self-assembling scaffolds

To encapsulate cells, Dex-SH and PEG-4-Acr were dissolved separately in culture medium and mixed with various concentrations (1×10^4 to 4×10^6 cells/mL) of ESCs, which were harvested at 70% confluency. Unless otherwise stated, ESCs were encapsulated at a concentration of 2×10^6 cells/mL. The resulting mixture was transferred to either a well of a 96-well plate or 1cc syringe for polymerization to produce fixed or floating scaffolds, respectively. Floating scaffolds were transferred from the syringes to 24-well plates. ESCs encapsulated in 3-D scaffolds were incubated the ESC medium and changed every 3 to 4 d or as needed. Cell growth was monitored by phase-contrast and confocal microscopy and analyzed by NIS Elements AR software (Nikon Instruments Inc., Melville, NY).

Swelling test

The degradation rate of floating scaffolds was determined by swelling tests performed under physiological conditions (37 °C). The initial dry weight (W_i) of the floating scaffolds was measured before incubation in ESC medium. At regular intervals, the scaffolds were removed from the medium to record the swollen weight (W_s) for analysis. The swelling ratio was defined as the difference between W_s and W_i divided by W_i ^[28,29]. The degradation time was determined by the time required to completely dissolve the hydrogel scaffolds of each condition prepared in triplicate.

Cell viability and proliferation assays

Cell viability was determined qualitatively by propidium iodide (PI, 1 mg/mL) (Fisher Scientific, Pittsburgh, PA) staining in triplicate experiments, and was visualized using fluorescent microscopy.

The quantitative analysis of cell growth in the scaffolds was determined by direct microscopic count using hemocytometer and PrestoBlue (PB) assays (Invitrogen), following the manufacturer's instructions. The scaffolds were incubated in PB solution for 4 h, before measuring the absorption of the solution at 570 nm and normalized to the reference wavelength of 600 nm using the Epoch microplate reader (BioTek, Winooski, VT). PB, a resazurin-based solution, was reduced proportional to the number of metabolically active cells to fluorescent resorufin.

Teratoma formation assay

For teratoma formation, ESCs were harvested following trypsin treatment, washed and re-suspended in PBS, and mixed with an equal volume of Matrigel (BD

Biosciences, San Jose, CA)^[30]. Cells (1×10^6) were subcutaneously injected (20 μ L) using a Hamilton syringe into 4-wk-old male immune-compromised SCID (severe combined immunodeficient)-beige mice (Fox Chase SCID Beige, Charles River, Wilmington, MA). Animals were anesthetized by inhalation of isoflurane gas for the injection of cells, and monitored daily. All efforts were made to minimize discomfort. After teratoma formation (3 to 4 wk), the animals were humanely euthanized by CO₂ overdose. Teratoma tissue was explanted, and flash frozen in liquid nitrogen for isolation of RNA using the RNeasy Midi kit (Qiagen, Germantown, MD)^[31]. Teratoma assays were performed in triplicate. All procedures involving animals were reviewed and approved by the Institutional Animal Care and Use Committee of Oakland University (IACUC protocol number: 14033).

Differentiation of ESCs

To differentiate ESCs, embryoid bodies (EBs) were prepared by the hanging drop method^[32]. EBs were cultured in ESC growth medium for differentiation into a myogenic phenotype. EBs treated with 10^{-7} mol/L trans-retinoic acid (RA) were cultured in β -glycerol phosphate (10 mmol/L; Sigma), and ascorbic acid (50 μ g/mL; Sigma) for osteogenic differentiation^[32]; TGF- β (10 ng/mL; Sigma), insulin (10 μ g/mL; Sigma) and ascorbic acid (50 μ g/mL; Sigma) for chondrogenic differentiation^[15]; and neurobasal medium (Invitrogen) supplemented with B-27 (10 μ L/mL; Invitrogen), L-glutamine (0.5 mmol/L; Sigma), penicillin/streptomycin (1 μ L/mL; Sigma) and bFGF (5 ng/mL) for neural differentiation^[33]. Cell morphology was monitored by light microscopy on a daily basis. Osteogenic cells were analyzed for calcium deposition by von Kossa staining^[32]. Proteoglycans produced by chondrogenic derivatives were visualized by alcian blue staining^[15]. Analysis of lineage specific markers was performed as described below.

Expression of genetic markers

Gene expression studies were performed using quantitative real time polymerase chain reaction (qRT-PCR). RNA was isolated from cells using the RNeasy Mini

kit (Qiagen). ESCs grown in 3-D scaffolds were flash frozen with liquid nitrogen, ground into a fine powder using a mortar and pestle, and homogenized using the QIAshredder column (Qiagen)^[34]. RNA was purified by treating with RNase-free DNase (Promega, Madison, WI) and cDNA was synthesized with the iScript kit (BioRad, Hercules, CA). PCR reactions were performed in a 10 μ L reaction volume using the BioRad CFX90 Real-Time PCR system and SsoAdvanced SYBR Green Supermix. The specific PCR conditions used were as follows: polymerase activation 3 min at 95 °C, 40 cycles of denaturation, 15 s at 95 °C; annealing, 20 s at 60 °C; and melt curve, 5 s/step at 60 °C-95 °C. The markers used in this study represent pluripotency, all three germ layers, as well as osteogenic, chondral, myogenic, and neural cell lineages. Primers (IDT Technologies, Coralville, IA) are listed in the supplemental material (Table 1). All reactions were prepared in triplicate and normalized to reference genes, Gapdh and β -Actin.

Immunofluorescence staining

Cells were fixed in 4% paraformaldehyde for 10 min, washed with PBS, permeabilized with 0.5% Triton X-100 (Sigma) for 10 min, and then blocked with 2% BSA (Sigma) for 1 h at room temperature. Fixed cells were treated with primary antibodies (1:100 diluted in blocking buffer), Oct4 (ab19857, Abcam Inc., Cambridge, MA), Nanog (sc-33760, Santa Cruz Biotechnology, Santa Cruz, CA), brachyury (sc-20109, Santa Cruz), NCAM (sc-10735, Santa Cruz), and GATA4 (sc-25310) overnight at 4 °C. Primary antibody treated cells were washed, and then stained with 1:200 diluted secondary antibodies, anti-rabbit Alexa Fluor 568 (A-11011, Molecular Probes, Eugene, OR) or Cy3-labeled anti-mouse IgG (072-01-18-06, KPL, Gaithersburg, MD, United States). Nuclei were counterstained with 1 mg/mL of 4',6-diamidino-2-phenylindole dihydrochloride (DAPI; Molecular Probes). Images were acquired using confocal microscopy.

Western blot assay

Cells were lysed in RIPA buffer with protease inhibitors (1 mmol/L PMSF) (Fisher Scientific), centrifuged at

12000 rpm for 20 min at 4 °C, and the supernatants were collected. Protein concentrations were determined by the Pierce 660 nm protein assay (Fisher Scientific,) using the NanoDrop 1000 spectrophotometer (Thermo Scientific, Wilmington, DE), with BSA as a standard. Equal amounts of protein (10 µg) of 2-D and 3-D scaffold grown cells were resolved on 12% SDS-polyacrylamide gels and transferred to nitrocellulose membranes (BioRad). Membranes were incubated for 30 min at room temperature in blocking buffer [5% non-fat dry milk in PBS containing 0.1% Tween-20 (PBST)]. The blocked membranes were then probed with 1:200 diluted primary antibodies overnight at 4 °C against Oct4 (Abcam), Nanog (Santa Cruz), Klf4 (ab21949, Abcam) and β-Actin (sc-130656, Santa Cruz). After washing with PBST, membranes were incubated with 1:10000 diluted horseradish peroxidase-conjugated secondary antibodies for 2 h at room temperature (Santa Cruz). Proteins on the membranes were detected by using an ECL chemiluminescence kit (BioRad) and by exposing the membranes to X-ray film. Finally, protein bands were analyzed using ImageJ (NIH, Bethesda, MA), normalized to β-Actin and expressed in arbitrary densitometric units.

Statistical analysis

All quantitative data were expressed as mean ± SE. One-way ANOVA analysis was performed on natural log transformed data, and analyzed for unequal variances. Post hoc tests used for multiple comparisons include Games-Howell analysis for PB analysis as well as Tukey and Dunnett's test for relative gene expression in qRT-PCR studies. Results with a *P* value less than 0.05 were considered to be significant (^a*P* < 0.05 and ^b*P* < 0.01). All analyses were performed using SPSS version 11.5 (SPSS Inc, United States). The statistical methods of this study were reviewed by Dr. Harvey Qu from the Department of Statistics at Oakland University.

RESULTS

Viability and growth of ESCs in the 3-D scaffolds

The viability of 3-D grown ESCs was not affected by encapsulation or the process of scaffold self-assembly. Cell growth increased over a period of 3 wk, as evident by the increase in the intensity as well as the number of EYFP/GFP expressing cells in fixed scaffolds (Figure 1A-B). PI staining of the scaffolds 1 d after culturing showed that a majority of the cells were viable cells (green) and contained only a small fraction (< 5%) of dead cells (yellow). Presence of dead cells could be due to damage resulting from trypsinization of ESCs used for encapsulation. When trypsinized ESCs were tested by trypan blue staining, a similar fraction of dead cells (about 10%) was observed, indicating that encapsulation did not cause cell death. However, it is interesting to note that unlike in 2-D culture, encapsulated dead cells did not lyse during 3-D culture. We speculate that the scaffold microenvironment

Table 2 Effects of thiol substitutions of Dex-SH on the rate of scaffold degradation

33%	37 ± 5
34%	37 ± 5

limited proteolytic activity. In our preliminary studies, the colony size of viable cells was restricted due to the limited swelling of fixed scaffolds (Figure 1A and B). We reasoned that if the scaffolds were allowed to swell freely, ESC growth and colony size would increase. Indeed, when ESCs were cultured in the floating scaffolds, cell growth and colony size increased in a time dependent manner (Figure 1C and D). Growth of encapsulated cells in floating scaffolds was confirmed by direct cell counts as shown in Figure 1E. After a lag period, ESCs grew at a generation rate of 36 h. A similar growth pattern was observed using PB staining. The results depicted in Figure 1F showed a continuous and significant increase in proliferation at 2, 3 and 4 wk of culture following a period of acclimatization. The highest increase in cell growth was observed between week 3 and 4, following which, the scaffolds degraded rapidly. Evidently, cell growth and colony size increased concomitant with reduction in scaffold integrity. Conceivably, scaffolds that retain integrity beyond 4 wk would continue to support the undifferentiated growth of ESCs.

Effect of composition and cell concentration on the rate of degradation of scaffolds

The polymer concentration and MW of Dex-SH and PEG-4-Acr, as well as the degree of thiol substitution of Dex-SH influenced the polymerization and degradation rate of scaffolds (Table 2), similar to previous reports^[23,27]. After preliminary evaluation, we selected Dex-SH (MW = 25 kDa) with 7.5% and 33% thiol substitution and PEG-4-Acr (MW = 20 kDa) at 5% w/v for further studies for propagating cells for various culture periods; these preparations yielded scaffolds that degraded without cells in 11 and 13 d and degraded with cells in 22 ± 5 d and 37 ± 5 d, respectively.

Scaffolds prepared using 7.5% thiol substitution of Dex-SH and various cell concentrations, ranging from 1 × 10⁴ cells/mL to 10 × 10⁶ cells/mL, exhibited different swelling profiles, although the initial swelling capacity of the scaffolds was similar. Scaffolds containing various cell concentrations (0, 2 × 10⁶ cells/mL or 4 × 10⁶ cells/mL) as shown in Figure 2A, exhibited comparable swelling ratios until day 9; after which, control scaffolds without cells degraded rapidly, followed by scaffolds prepared with 4 × 10⁶ cells/mL and finally scaffolds with 2 × 10⁶ cells/mL. Scaffolds with the higher number of cells (4

Figure 1 Cell viability and growth of embryonic stem cells encapsulated in self-assembling three-dimensional scaffolds. Enhanced yellow fluorescent protein-labeled ESCs were encapsulated (2×10^6 cells/mL) in fixed and floating scaffolds prepared using Dex-SH with 7.5% thiol substitution and PEG-4-Acr. Encapsulated cells were cultured in ESC medium and periodically cell growth was visualized using fluorescent microscopy. A and B: Live (green) and dead (yellow) cells in fixed scaffolds stained with PI at day 1 and week 3, respectively. While the viable cells increased with time, the number of dead cells remained constant. Scale bars = 100 μ m; C and D: Three-dimensional (3-D) confocal images of floating scaffolds representing ESC growth at day 3 and week 3, respectively; E: Growth of ESCs encapsulated in 3-D scaffolds was assayed by direct count using hemocytometer. Cells seeded in 3-D scaffolds (at 2×10^6 cells/mL) were incubated in ESC medium and counted at various time intervals. Data presented as cell number ($\times 10^6$ cells/mL) $\pm$ SE ($n = 3$) and plotted against the days of incubation; F: Quantitative determination of ESC proliferation in floating scaffolds at week 0, 1, 2, 3, and 4 of culture after staining with PB as analyzed by microplate reader. The results were expressed as the normalized absorbance $\pm$ SE ($n = 3$), with a significant increase in cell number, compared to initial ESC viability at time 0. $^aP < 0.05$ and $^bP < 0.01$ using one-way ANOVA with the non-equal variance hypothesis and Games-Howell multiple comparisons test. ESCs: Embryonic stem cells; Dex-SH: Thiol functionalized dextran; PEG-4-Acr: Polyethylene glycol tetra-acrylate.

Table 3 Cell concentration for optimal growth of embryonic stem cells under 2-D and 3-D culture conditions

Culture conditions	Cell concentration	
	(cells/mL)	(cells/cm ²)
2-D Culture	---	3×10^4 to 5×10^4 ^[33]
3-D Culture	1×10^4	1×10^3

3-D: Three-dimensional; 2-D: Two-dimensional.

$\times 10^6$ cells/mL) swelled to 2-fold of their initial weight and started to degrade on day 19 of culture. Whereas, scaffolds with a lower number of cells (2×10^6 cells/mL) swelled to nearly 3 times their initial weight and started to degrade on day 27 of culture. Furthermore, scaffolds prepared with the lower cell concentration (2×10^6 cells/mL) resulted in rapid clonal growth (Figure 2B; B1, B2) as compared to the higher cell concentration (4×10^6 cells/mL) (Figure 2B; B3, B4). Quantitative analysis of colony size showed a 2-fold increase in the mean diameter of colonies in scaffolds prepared with lower numbers of cells (Figure 2C). The scaffold supported the growth of encapsulated ESCs at concentrations as low as 1×10^4 cells/mL (or 10^3 /cm²), suggesting that low concentration had no effect on the cell viability (Figure 2D). Maintenance of ESCs at low concentrations

is more advantageous in 3-D culture compared to 2-D culture (Table 3), since low seeding densities in 2-D culture results in poor growth, decreased viability and differentiation of ESCs.

Expression of pluripotency markers in the 3-D scaffold cultured ESCs

To confirm whether 3-D grown ESCs maintained pluripotency, expression of selected ESC-specific markers was analyzed using qRT-PCR. The results depicted in Figure 3 indicate that expression of Oct4 and Nanog increased 2.8 and 3.0 fold, respectively in 3-D scaffold (prepared using 33% Dex-SH) grown ESCs as compared to cells grown under 2-D culture conditions. The expression of these markers significantly and successively increased in 3-D grown ESCs during 1, 2 and 3 wk. The expression of Klf4 also increased significantly (1.8 fold) above the level of 2-D grown ESCs but only during the second week of cell growth; whereas, the expression of Sox2 was not affected by 3-D culture. Concomitant with the start of degradation of the scaffolds at 6 wk of culture, expression of pluripotency markers gradually decreased to the levels of 2-D grown ESCs.

Immunofluorescence analysis of 3-D grown ESCs

Figure 2 Effect of cell concentration on the rate of scaffold degradation and embryonic stem cells colony size. **A**: Swelling tests of floating scaffolds prepared with 7.5% thiol substitution were used to compare the rate of degradation of scaffolds prepared with various cell concentrations (0, 2×10^6 cells/mL and 4×10^6 cells/mL). Scaffolds with and without ESCs were incubated in ESC medium and weighed periodically. Data expressed as the mean swelling ratio (W_t/W_i) $\pm$ SE ($n = 3$); **B**: Representative composite confocal images of ESCs grown in floating scaffolds encapsulating 2×10^6 cells/mL (B1 and B2) and 4×10^6 cells/mL (B3 and B4) at day-4 and day-18, respectively. Scale bars = 100 μ m; **C**: Quantification of ESC colony size in floating scaffolds encapsulating 2×10^6 cells/mL or 4×10^6 cells/mL at day-4 and day-18 of culture. Cell colony size was expressed as mean diameter (μ m) $\pm$ SE ($n = 3$); **D**: Growth of low concentrations of ESCs in 3-D scaffolds. Light micrographs of the scaffolds encapsulating 1×10^4 cells/mL at day-0 and day-7 (D1 and D2, respectively) and 1×10^5 cells/mL at day-0 and day-7 (D3 and D4 respectively). Scale bars = 100 μ m. ESCs: Embryonic stem cells; 3-D: Three-dimensional.

showed upregulation of protein levels of Oct4 and Nanog as evident by the increase in the fluorescent

intensity of cells stained with the respective antibodies (Figure 4A). Furthermore, expression of these proteins

Figure 3 Expression of pluripotent markers in three-dimensional grown embryonic stem cells. ESCs in scaffolds prepared with Dex-SH with 33% thiol substitution were cultured and analyzed for the expression of selected markers, Oct4, Nanog, Klf4, and Sox2 using qRT-PCR at week 0, 1, 2, 3, and 6. Results of experiments were expressed as the fold expression $\pm$ SE ($n = 3$) normalized to reference genes Gapdh and β -Actin, where a significant (^a $P < 0.05$ and ^b $P < 0.01$) increase of pluripotent marker expression was compared to initial 2-D grown ESCs (day 0), using one-way ANOVA with the non-equal variance hypothesis and Dunnett's multiple comparisons test. Results depicted showed upregulation of Oct4, Nanog, and Klf4, but Sox2 was maintained at levels similar to the control. Expression of Oct4 and Nanog was successively and significantly higher at week 1, 2 and 3 until the onset of degradation (week 6), at which point their expression was decreased to initial levels. ESCs: Embryonic stem cells; Dex-SH: Thiol functionalized dextran; qRT-PCR: Quantitative real time polymerase chain reaction; 2-D: Two-dimensional.

was analyzed by western blot and results are shown in Figure 4B. Similarly, levels of Oct4, Nanog and Klf4 were visibly increased in the 3-D grown cells when compared with the control. Quantitative analysis of the western blot confirmed the increase in Oct4, Nanog and Klf4 (1.9, 3.9 and 1.3 fold, respectively) compared to the control (Figure 4C); this was well correlated with the observed transcription levels of these genes.

Maintenance of pluripotency of 3-D grown ESCs was further investigated by subculturing under 2-D culture conditions (Figure 5A, A1-A3). They displayed typical compact colony morphology (even upon passaging five times) in 2-D culture and were indistinguishable from the initial ESCs seeded and grown in 3-D scaffolds. Expression of pluripotent genes in ESCs first grown in 3-D scaffolds for 2 wk and then subcultured under 2-D conditions were analyzed. The results depicted in Figure 5B showed that the expression of Oct4, Nanog, and Klf4 returned to levels comparable to traditionally 2-D propagated ESCs (Figure 5B).

Pluripotency of 3-D scaffold grown ESCs was further validated by *in vivo* teratoma assays using immune-compromised mice. The animals injected with 1×10^6 cells formed teratomas within 4 wk (Figure 6A and B). Analysis of explanted teratoma tissue showed expression of Brachyury, FGF5, and GATA4, suggesting differentiation of injected ESCs into cell lineages of all three germ layers (Figure 6C). Conceivably, the 3-D scaffold provided a microenvironment for upregulation of pluripotent genes, maintenance of pluripotency and

self-renewal of ESCs.

Differentiation of the 3-D scaffolds grown ESCs into various cell lineages

Differentiation potential of the 3-D grown ESCs was also studied *via* EB formation. The EBs from 3-D grown ESCs were allowed to spontaneously differentiate into all three germ layers, mesoderm, ectoderm, and endoderm and expressed specific protein markers such as Brachyury, NCAM, and GATA4 (Figure 7A). Furthermore, 3-D grown ESCs were induced to differentiate into various cell lineages, including osteogenic, chondrogenic, myogenic, and neural cell types. The results of differentiation depicted osteogenic derivatives that had the cobblestone appearance of osteoblast cells and were positive for calcium deposition as determined by von Kossa staining (Figure 7B, B1). Chondrogenic derivatives of 3-D grown ESCs were analyzed by alcian blue staining showing positive proteoglycan production (Figure 7B, B2). Light micrographs of myogenic derivatives of 3-D grown ESCs had spindle shaped morphology (Figure 7B, B3), while neural derivatives of ESCs displayed neurofilaments (Figure 7B, B4). Further analysis of the 3-D grown ESC derivatives revealed expression of cell-specific markers (Figure 7C) as determined by qRT-PCR; osteogenic, chondrogenic, myogenic, and neural derivatives expressed Collagen type 1 (Col1), Collagen type 2 (Col2), Myogenin (Myog), and Nestin, respectively. The expression of these cell-specific markers signified that 3-D grown ESCs maintained differentiation potential.

Figure 4 Protein expression of pluripotency markers in embryonic stem cells grown in two-dimensional and three-dimensional cultures. ESCs grown in two-dimensional (2-D) and in 3-D floating scaffolds (prepared with 33% thiol substitution) were analyzed by immunofluorescence staining and western blotting. A: Cells grown in 2-D culture and 3-D scaffolds for 2 wk were cultured on coverslips for 2 d and stained with primary antibodies, Oct4 and Nanog, treated with Alexa Fluor 568 conjugated secondary antibodies, and counterstained with DAPI. Confocal images depicted an increase in Oct4 and Nanog protein expression in 3-D scaffold grown ESCs compared to 2-D cultured cells; B: Western blot analysis showed increased expressions of Oct4, Nanog, and Klf4 proteins in ESCs grown in the 3-D scaffold for 2 wk compared to initial 2-D grown ESCs (day 0). Cell were lysed in RIPA buffer and aliquots containing an equal amount of protein (10 μ g) were subjected to 12% polyacrylamide gel electrophoresis, transferred to nitrocellulose membranes, and probed with antibodies against Oct4, Nanog, and Klf4; C: Quantitative analysis of western blots (normalized to β -actin levels) showed that Oct4, Nanog and Klf4 protein levels in 3-D grown cells were increased by 1.9, 3.9 and 1.3 fold, respectively, as compared to 2-D cultured controls. Representative results are shown. ESCs: Embryonic stem cells. DAPI: 4',6-diamidino-2-phenylindole dihydrochloride.

DISCUSSION

In this report, we described an alternative to traditional 2-D culturing of ESCs without the need for a MEF feeder layer and routine passaging. This method was developed utilizing two components, Dex-SH and PEG-4-Acr, for self-assembling 3-D hydrogel scaffolds. Evidently, this hydrogel scaffold better emulated the fully hydrated native 3-D microenvironment and supported the pluripotent growth of ESCs. This method eliminates laborious and time-consuming manipulations, which often results in the loss of ESC lines due to contamination of cultures or differentiation of cells.

The polymerization of Dex-SH and PEG-4-Acr, *via* a

Michael addition reaction, facilitated the self-assembly of the 3-D scaffolds and encapsulation of ESCs. Polymerization was dependent upon several factors including concentration and ratio of polymers, degree of thiol substitution of Dex-SH, and cell concentration. Optimal conditions for scaffold polymerization, cell encapsulation, and cell viability were achieved by varying these parameters. The results showed that higher the degree of thiol substitution of Dex-SH, the faster the polymerization of hydrogel. Consistent with a previous report^[27], the ratio and amount of Dex-SH and PEG-4-Acr also affected the formation and swelling properties of the hydrogel scaffolds. In one study, 10% w/v polymer concentrations were used to prepare Dex-

Figure 5 Three-dimensional grown embryonic stem cells were subcultured under two-dimensional culture conditions expressed normal levels of pluripotent markers. A: Light micrographs depicting cell morphology of the initial ESCs used for encapsulation (A1), cultured in three-dimensional (3-D) scaffolds for 2 wk (A2), and subsequently passaged 5 times in 2-D culture (A3); B: Expression of Oct4, Nanog, and Klf4 in ESCs grown in 2-D culture, 3-D grown ESCs, and 3-D grown ESCs, which were subsequently passaged 5 times in 2-D culture as determined by qRT-PCR. Results were expressed as the fold expression $\pm$ SE ($n = 3$) normalized to reference genes Gapdh and β -Actin where a significant (^a $P < 0.05$ and ^b $P < 0.01$) increase of marker expression was compared to initial 2-D grown ESCs, using one-way ANOVA and Tukey multiple comparisons test. Figure 6 Three-dimensional grown embryonic stem cells formed teratomas in severe combined immunodeficient-beige mice. Explanted teratoma tissues were analyzed for the expression of three germ layer markers. A: Gross images of tumor growth resulting from injection of 3-D grown ESCs. Tumor growth was observed in all mice injected ($n = 3$); B: Explanted tumor at 4 wk showed encapsulated, lobular and well-circumscribed gross morphology consistent with teratoma growth; C: Expression of germ layer markers, Brachyury, FGF5, and GATA4 representing mesoderm, ectoderm, and endoderm was analyzed by qRT-PCR. Results of tumor explants were expressed as fold expression $\pm$ SE ($n = 3$) normalized to reference genes Gapdh and β -Actin, and compared to initial cells injected *in vivo*. ESCs: Embryonic stem cells; qRT-PCR: Quantitative real time polymerase chain reaction..

Figure 7 Differentiation potential of three-dimensional grown embryonic stem cells. A: Embryoid bodies derived from ESCs grown in the 3-D scaffolds were allowed to spontaneously differentiate and analyzed by immunofluorescence staining with antibodies against all three germ layers. Confocal images depicted the presence of Brachyury, NCAM, and GATA4 protein expression, showing the potential of ESCs to differentiate into mesoderm, ectoderm, and endoderm, respectively; B: 3-D scaffold grown ESCs were also directed to differentiate via EB formation and selective induction media. Shown are light micrographs depicting cell morphology of ESC derivatives, osteogenic, chondrogenic, myogenic, and neural (B1, B2, B3, and B4 respectively). Osteogenic and chondrogenic derivatives were cultured for 4 wk and analyzed by von Kossa, and alcian blue staining, respectively. Osteogenic cell-specific ECM stained dark brown for calcium deposition (B1). Proteoglycan produced by chondrogenic derivatives stained blue; C: Expression of cell-specific markers in differentiated ESC derivatives expressed Col1 (C1), Col2 (C2), Myog (C3), and Nestin (C4) markers for osteogenic, chondrogenic, myogenic and neural cells, respectively. Results represent the fold expression $\pm$ SE ($n = 3$) normalized to reference genes Gapdh and β -Actin where a significant (^a $P < 0.05$ and ^b $P < 0.01$) increase of marker expression was compared to initial 2-D grown ESCs (day 0), using one-way ANOVA with the non-equal variance hypothesis. ESCs: Embryonic stem cells; ANOVA: Analysis of variance..

SH and PEG-4-Acr scaffolds to promote differentiation of ESCs^[23]. However, we determined that 5% w/v polymer concentrations were ideal to provide a scaffold microenvironment with a greater degree of flexibility and suitability for ESC growth. Mixing of cells with PEG-4-Acr prior to scaffold molding yielded homogeneous distribution of cells in both fixed and floating scaffolds. The 3-D scaffold grown ESCs displayed undifferentiated compact round colony morphology, even upon prolonged culturing. Previously, Gerecht *et al.*^[26] reported the potential of hyaluronic acid-based hydrogels in maintaining human ESCs with an undifferentiated morphology for 20 d. However, polymerization of hyaluronic acid-based hydrogels was achieved with ultraviolet light, a potent carcinogen. Whereas, self-assembly of the Dex-SH and PEG-4-Acr scaffold does not require a mutagenic catalyst, and ESCs can be maintained for over 6 wk. They also reported that at least 5×10^6 cells/mL to 10×10^6 cells/mL were required for cell growth and colony formation in the hyaluronic acid-based scaffolds. In contrast, we found that use of Dex-SH and PEG-4-Acr scaffolds supported ESC growth at concentrations as low as 1×10^4 cells/mL or $1 \times 10^3/\text{cm}^2$ in 3-D scaffolds. At concentrations below 1×10^4 cells/mL successful encapsulation in the scaffold was difficult to assess due to low cell density. Furthermore, low concentration may also affect the viability of the cells. In traditional 2-D culture, optimal maintenance of ESCs requires a much higher cell density (3×10^4 to 5×10^4 cells/cm²)^[33].

ESC self-renewal was not affected by the duration of growth in 3-D scaffolds as long as the integrity of the scaffold was maintained. Scaffold integrity also influenced the cell proliferation rate and colony size. ESCs grew at a slower rate with smaller colony size in fixed scaffolds. However, cell growth rate and colony size was less restricted in floating scaffolds. In agreement with previous reports^[35,36], we found that mouse ESCs doubled nearly every 12 h in 2-D culture, whereas the generation time for ESCs in the 3-D culture system was approximately 36 h. It has been reported that the growth rate of stem cells *in vivo* vary from a few hours to months depending upon the niche^[37]. In 2-D culture, ESCs reached near confluency in 3 d and started to differentiate, whereas the growth rate in 3-D was slower; the cells did not differentiate and continued to grow for up to 6 wk, limited only by scaffold degradation. Using the exponential cell growth formula $N = N_0 \times 2^g$, where N is the final cell number, N_0 is the initial cell number (2×10^6), and g is the number generations (25), the expected total number of cells after 6 wk of growth would be 134×10^{12} cells. The fact that ESCs grew for an extended period without the loss of cell viability and their self-renewal potential suggested that the 3-D culture system described here was superior to 2-D culture, which requires routine passaging.

In addition to the concentration of the scaffold components and degree of thiol substitution, cell con-

centration significantly affected the rate of scaffold degradation. Consistent with previous studies^[23], scaffolds without cells degraded earlier compared to seeded scaffolds (13 d vs 27 d, respectively) suggesting that the addition of cells improved the stability of the scaffolds. Moreover, scaffolds encapsulating a higher concentration of ESCs degraded faster and swelled less than scaffolds with lower concentration of ESCs. Consequently, ESC colony size was smaller in scaffolds with a higher concentration of cells as compared to scaffolds prepared with a lower cell concentration. In addition, encapsulated ESCs in floating scaffolds grew rapidly with larger colony sizes as compared to fixed scaffolds of similar composition. These results suggested that the swelling plasticity of the self-assembling scaffolds favorably promoted the growth and maintenance of ESC colonies. Previous studies also indicated that cell encapsulation increased integrity of the scaffold as compared to scaffolds without cells^[23]. However, in this report the effect of cell concentrations on scaffold integrity was not reported. Our observations indicated that higher cell concentrations inversely effected scaffold integrity suggesting that the cells may be producing factors that de-stabilize the scaffolds. The nature of these factors remains unknown.

ESCs grown in the 3-D scaffolds for 6 wk maintained their pluripotency and differentiation potential, as determined by their ability to spontaneously differentiate into cell types comprising all three germ layers. The EBs differentiated into osteogenic, chondrogenic, myogenic, and neural cell types, expressing cell-specific markers. These results indicated that the self-assembling scaffolds support the self-renewal and pluripotency of ESCs, even after prolonged periods of culturing. The pluripotency of 3-D grown ESCs was further confirmed by teratoma formation *in vivo*. Teratomas explanted from immune-compromised mice following injection of 3-D grown ESCs showed specific gene expression representing all three germ layers.

Interestingly, the expression of three pluripotency markers, Oct4, Nanog and Klf4, was higher in 3-D cultured ESCs as compared to 2-D grown ESCs both at a transcriptional and translational level. The expression of these genes remained at higher levels throughout the extended growth period (up to 6 wk) until the onset of scaffold degradation. In contrast, Sox2 expression levels in 3-D grown ESCs was found to be similar to the control (2-D grown ESCs). Although high expression of Nanog and Klf4 has been reported to enhance self-renewal and pluripotency^[38], overexpression of Oct4 has been implicated in spontaneous ESC differentiation^[39]. Contrary to this, we did not observe differentiation of ESCs grown in 3-D scaffolds. When 3-D grown ESCs were subcultured under 2-D culture conditions, expression of pluripotent markers returned to levels similar to 2-D grown cells. Previous reports^[40] also described differential regulation of stemness genes, with an upregulation of Oct4 but downregulation of Sox2 in ESCs cultured in three different scaffolds prepared

using PGLA, collagen and chitosan; whereas Nanog was only highly upregulated in chitosan scaffolds. Taken together with our findings, it can be argued that the scaffold microenvironments play an important role in influencing cell-matrix communication, thus effecting gene expression. It is also possible that cellular proteins may have interacted with thiol groups during the encapsulation step of self-assembly of the scaffolds resulting in alteration of their activities. Nevertheless, the underlying molecular mechanism responsible for the upregulation of pluripotent genes in ESCs grown in 3-D Dex-SH and PEG-4-Acr scaffolds remain unknown and warrants further investigation.

The findings reported here demonstrate a novel, efficient, reproducible, and simple approach to ESC cultivation. However, these results were obtained using mouse ESCs as a model, further studies are required to expand these results to human pluripotent stem cells. Previous attempts at 3-D cultivation of ESCs have required routine passaging^[19,25,26]. To our knowledge this is the first report that described a robust system for 3-D culturing of ESCs for extended periods without passaging or manipulation. These improvements in the maintenance of ESCs will help their use in translational research, disease modeling, stem cell therapies, and regenerative medicine.

ACKNOWLEDGMENTS

Oakland University Provost Graduate Student Research Award provided support for C. McKee. We would like to thank Dr. Bashir Kaskar for help with the synthesis and analysis of Dex-SH, Naimisha Reddy Beeravolu for her assistance with the western blot analysis and Dr. Harvey Qu for his evaluation of the statistical analysis.

COMMENTS

Background

Embryonic stem cells (ESCs) are capable of differentiating into any of the over 200 cell types found in the body, which makes them an ideal source for cell-based therapies and regenerative medicine. These applications require efficient and reproducible expansion of ESCs *ex vivo* for high quality cells, which then can be uniformly differentiated for clinical use. However, propagation of ESCs is technically challenging, laborious and expensive. Traditional ESC culture techniques are heavily dependent on cell adherence to two-dimensional (2-D) plastic culture plates, regular passaging (every two to three days) and xenogeneic feeder layers. This often results in differentiation and loss of cell lines.

Research frontiers

In order to overcome the problems associated with 2-D cell culture, few studies have reported the use of three-dimensional (3-D) scaffolds to propagate ESCs. However, these methods are not efficient and require the use of carcinogenic catalysts for polymerization of the scaffolds. Moreover, these techniques required routine passaging in order to maintain the pluripotency of ESCs.

Innovations and breakthroughs

A novel 3-D culture system was developed for propagation of ESCs for an extended period of time. In this system, ESCs were encapsulated upon self-assembly of 3-D scaffolds prepared with thiol-functionalized dextran and polyethylene glycol tetra-acrylate. The 3-D scaffold microenvironment supported the growth of ESCs while maintaining their pluripotency and self-renewal potential

for extended periods without passaging and extensive manipulation, which is required for 2-D culture of ESCs.

Applications

This new culture system should help develop methods of expansion for high quality and homogenous populations of ESCs, which are critically important for regenerative medicine and therapeutic applications.

Terminology

A scaffold is an engineered matrix formed from biomaterials mimicking the microenvironment and capable of supporting cell growth. In this study, self-assembling scaffolds were formed upon combination of two polymers, polyethylene glycol tetra-acrylate and thiol-functionalized dextran.

Peer-review

The authors designed a simplified and efficient system, which mimics the microenvironment *in vivo* for long-term proliferation and maintenance of ESCs. Furthermore, the culture system is efficient and reproducible and is expected to lead to further innovations.

World Journal of *Stem Cells*

World J Stem Cells 2015 September 26; 7(8): 1078-1144

Editorial Board

2010-2015

The *World Journal of Stem Cells* Editorial Board consists of 719 members, representing a team of worldwide experts in infectious diseases. They are from 44 countries, including Argentina (2), Australia (10), Austria (6), Belgium (3), Brazil (10), Canada (16), China (74), Cyprus (1), Czech Republic (5), Denmark (7), Egypt (2), Finland (3), France (19), Germany (36), Greece (1), Hungary (3), India (10), Iran (9), Ireland (4), Israel (10), Italy (52), Japan (55), Jordan (1), Malaysia (1), Mexico (1), Morocco (1), Netherlands (8), Norway (3), Portugal (1), Romania (1), Russia (3), Singapore (19), Slovakia (1), South Korea (45), Spain (17), Sweden (4), Switzerland (4), Thailand (1), Tunisia (1), Turkey (5), United Arab Emirates (1), United Kingdom (29), United States (233), and Venezuela (1).

ABOUT COVER

Editorial Board Member of *World Journal of Stem Cells*, Kumiko Saeki, MD, PhD, Director, Division of Stem Cell Therapy, Department of Disease Control, Research Institute, National Center for Global Health and Medicine, 1-21-1 Toyama Shinjuku-ku Tokyo 162-8655, Japan

AIM AND SCOPE

World Journal of Stem Cells (*World J Stem Cells*, *WJSC*, online ISSN 1948-0210, DOI: 10.4252), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJSC covers topics concerning all aspects of stem cells: embryonic, neural, hematopoietic, mesenchymal, tissue-specific, and cancer stem cells; the stem cell niche, stem cell genomics and proteomics, and stem cell techniques and their application in clinical trials.

We encourage authors to submit their manuscripts to *WJSC*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

INDEXING/ ABSTRACTING

World Journal of Stem Cells is now indexed in PubMed Central, PubMed, Digital Object Identifier, and Directory of Open Access Journals.

Abstract

A small subset of cancer cells that act as tumor initiating cells or cancer stem cells (CSCs) maintain self-renewal and growth promoting capabilities of cancer and are responsible for drug/treatment resistance, tumor recurrence and metastasis. Due to their potential clinical importance, many researchers have put their efforts over decades to unravel the molecular mechanisms that regulate CSCs functions. MicroRNAs (miRNAs) which are 21-23 nucleotide long, endogenous non-

coding RNAs, regulate gene expression through gene silencing at post-transcriptional level by binding to the 3'-untranslated regions or the open reading frames of target genes, thereby result in target mRNA degradation or its translational repression and serve important role in several cellular, physiological and developmental processes. Aberrant miRNAs expression and their implication in CSCs regulation by controlling asymmetric cell division, drug/treatment resistance and metastasis make miRNAs a tool of great therapeutic potential against cancer. Recent advancements on the biological complexities of CSCs, modulation in CSCs properties by miRNA network and development of miRNA based treatment strategies specifically targeting the CSCs as an attractive therapeutic targets for clinical application are being critically analysed.

Key words: Cancer stem cells; Drug resistance; Tumor recurrence; MicroRNAs; Cancer therapy

© The Author(s) 2015. Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: Cancer stem cells (CSCs) which are believed to be the prerequisite for metastasis and tumor recurrence, are endowed with ability to undergo symmetric cell division, capacity for self-renewability, long term proliferation and resistance to anti-neoplastic therapeutic drugs. Regulatory characteristics of microRNAs (miRNAs) which are the clusters of non-coding RNA molecules, include widespread changes in gene expression through gene silencing at post-transcriptional level and are dysregulated in human cancer. Over the past two decades, miRNAs have gained widespread attention due to their involvement in acquisition of stem cell-like properties, regulation and reprogramming by cancer cells during cancer progression. Many studies are coming up which document miRNAs as novel therapeutic tool in targeting CSCs functions, sensitizing them to apoptotic effects of anti-cancer drugs, and reducing tumor burden with no relapse in current clinical settings.

Garg M. Emerging role of microRNAs in cancer stem cells: Implications in cancer therapy. *World J Stem Cells* 2015; 7(8): 1078-1089 Available from: URL: <http://www.wjgnet.com/1948-0210/full/v7/i8/1078.htm> DOI: <http://dx.doi.org/10.4252/wjsc.v7.i8.1078>

INTRODUCTION

Despite high response rates to initial treatments including chemotherapy, radiotherapy or sometimes even after combinational chemotherapies, cancer remains the most lethal disease. Recent technological advancements and animal studies have validated the presence of small subset of cancer cells among the heterogeneous population of tumor cells and are known as cancer stem cells (CSCs) or tumor initiating cells. They have different biological properties, increased tumorigenic potential and are supposed to serve important role in drug resistance, tumor development and its recurrence. Anti-cancer therapies are being employed on the basis of their ability to shrink tumor cells, but CSCs survive and proliferate owing to an increased intrinsic (*de novo*) or acquired resistance to anti-cancer drugs. This makes the clinical therapy ineffective, leads to tumor recurrence and results in high mortality rates in cancer patients. Decreased expression of energy dependent transporters to retain drugs inside the cancer cells and increased efficacy of drug response by sensitizing these subset of cancer cells to drug induced apoptosis could be key mechanisms towards improved treatment of cancer. Therefore, there is an urgent need to understand the molecular mechanisms controlling CSCs population and functions to develop effective therapies to eradicate recurrence which is a real threat to complete cancer cure. Emerging evidences have suggested the critical involvement of protein-coding genes as well as non-coding RNAs (ncRNAs) including microRNAs (miRNAs) in various types of cancers and serve important role in CSCs functions. Recent findings on the miRNAs, responsible for the maintenance and regulation of CSCs properties like tumorigenicity and drug resistance, are briefly summarized in the later sections. Gaining further insight into the potential and therapeutic approaches by targeting CSCs using miRNAs as a tool would be helpful for deciphering and designing future strategies for human cancer treatment with better outcome by preventing metastatic progression and tumor recurrence.

CSCS

CSCs with tumor initiating potential constitute only a fraction of neoplastic cells and were first reported by Lapidot *et al*^[1]. These cells are endowed with the capacity of long term proliferation, ability to undergo symmetric cell division and seed new tumors by virtue of their intrinsic self-protection and self-renewal

capabilities. Capacity for self-renewal, propagation of differentiated progenitors and the expression of specific stem cell genes are some of the biological properties that are shared by both normal and CSCs. Accumulation of genetic and epigenetic alterations deregulate the basic stem cell biology and distinguish CSCs from the normal stem cells in their chemoresistance, enhanced tumorigenic and metastatic activities^[2]. Recent experimental studies have identified the activation of oncogenes and inactivation of tumor suppressor genes to be responsible for self-renewal ability and pluripotency of CSCs^[3]. Concept of heterogeneity among CSCs as stationary and migrating CSCs came into existence with the discovery of process of epithelial-to-mesenchymal transition (EMT). EMT is a crucial event which allows the stationary CSCs at the primary site to lose their epithelial character, morphological transition, and loss of cell-cell adherence. This transition imparts high motility to the stationary CSCs, which is a necessary requirement by migrating CSCs for local invasion and metastatic dissemination. The concept of migrating CSCs and especially EMT as a widespread mechanism of stem cell generation validates the dynamic nature of CSCs and strongly supports the current CSC theory^[4,5].

Over the past few years, number of studies have reported the isolation and characterization of CSCs for hematological malignancies including acute lymphoblastic leukemia, chronic myeloid leukemia, acute myelogenous leukemia, multiple myeloma and also for solid tumors of breast, colon, stomach, brain, lung, liver, skin, prostate, testis, ovary and pancreas^[6]. The subpopulation of CSCs are identified, isolated and characterized on the basis of capacity to form sphere-clusters with a high clonogenic efficiency, a stronger self-renewal ability and much higher levels of cell cycle markers which account for G1-S/G2-M phases progression, side population profile and stemness gene expression.

Stem cell maintenance, survival, self-renewal and differentiation of CSCs are known to be regulated by several signaling pathways and molecules. Notch, Wnt/catenin, sonic hedgehog, bone morphogenetic protein, receptor tyrosine kinase and TGF- β signaling pathways are studied to be aberrantly active in CSCs and regulate self-renewal activity, thereby play significant role in tumor initiation and development in various malignancies including breast, colorectal, prostate, pancreatic, glioma, leukemia and colon cancers^[7-11].

CSCs are not only the source of initial tumor formation, postoperative recurrence and metastasis but also contribute to chemo/radioresistance. High invasiveness and frequent recurrence due to the presence of inefficient DNA repair mechanisms, which render CSCs highly resistant to chemotherapeutic and ionizing radiations, are the main reasons for treatment failure and recurrent disease^[12,13]. Targeting the pathways and mechanisms behind the development of chemo/radioresistance, modifying the niche of cancer

cells, regulating the cellular response to damage by modulating apoptosis, cell cycle proliferation, DNA repair, invasion and differentiation functions might help in eliminating CSCs subpopulation and developing therapeutic strategies for complete cancer treatment with no relapse.

MiRNAs have gained widespread attention in modulating the CSCs functions through affecting the expression level of target genes and proteins that are involved in signaling pathways including cell proliferation and cell death. Recent advancements on the role of miRNAs in regulation and maintenance of tumor cells with stem cell properties are discussed in later sections.

MIRNAS AND THEIR REGULATORY FUNCTIONS IN CSCS

MiRNAs and its biogenesis

The most important advancement over the past recent years is the discovery of non-coding RNA families which are actively transcribed from the genome of many organisms and generate widespread changes by regulating vital biological processes. Among them, miRNAs are the novel small non-protein coding, evolutionarily conserved, 21-23 nucleotide long single-stranded RNA molecules. Many important diverse functions of miRNAs include the regulation of cellular differentiation, proliferation and apoptosis by regulating the stability or translational efficiency of target messenger RNAs which are expressed in tissue-specific or developmental stage-specific manner.

MiRNA-mRNA target recognition due to sequence complementarity of the *lin-4* miRNAs to multiple conserved sites within the *lin-14* 3' untranslated region (3'UTR) leads to the discovery of miRNAs way back in 1993 during genome study in *Caenorhabditis elegans* development^[13,14]. MiRNAs are randomly located in mammalian genome and the complex process of biogenesis begins in nucleus with the transcription of polycistronic primary-miRNA (pri-miRNA) transcript by RNA polymerases II and III^[15,16]. Hundreds or thousands of nucleotides long pri-miRNA transcripts with one or many stem loops, 5' capping and 3' polyadenylation, undergo further cleavage by nuclear microprocessor complex containing enzymes Drosha, RNA III endonuclease and double stranded RNA binding protein DiGeorge syndrome critical region 8 (DGCR8)^[17,18]. The resulting 70 nucleotide long pre-miRNAs are exported to cytoplasm by exportin 5 and Ran-GTP^[19]. Another enzyme, RNA III endonuclease known as Dicer, cleaves hairpin-like pre-miRNA into two complementary fragments and one of which is mature miRNA^[20]. Mature miRNA strand is then incorporated into the members of Agronaute protein family, which constitutes the catalytic portion of the multi-protein RNA-induced silencing complex (RISC). MiRNAs then direct RISC to target mRNAs which share sequence complementation in seed region that consists of nucleotides at position

2-8 of 5' end of mature miRNA. Complementation between the seed sequence and 3'UTR of target mRNA results in mRNA transcript degradation while imperfect complementation results translational repression^[21]. Nuclear pri-miRNA and cytoplasmic pre-miRNA cleavage steps and mature miRNA-target mRNA recognition sites are the potential therapeutic points against cancer by regulating miRNA processing, its biogenesis and miRNA functions (Figure 1).

Statistical methods and profiling studies validate the presence of miRNAs in close proximity to chromosomal breakpoints, cancer associated genomic regions and fragile sites where mutations/deletions can occur. Loss of tumor suppressive miRNAs and increased expression of oncogenic miRNAs enhance the expression of target oncogenes and repress the target tumor suppressor genes respectively. Deregulation of novel miRNAs expression leads to induction of anti-apoptotic activity, tumor invasion, drug resistance and metastasis and has been correlated with the pathogenesis of cancer. MiRNAs are present in complex regulatory circuits to regulate stem cells function and are being examined to play important role in generation of CSCs, maintenance of enhanced self-renewal capacities of CSCs, pluripotency and their neoplastic transformation into tumors (Figure 2).

MiRNAs in maintenance and regulation of CSCs properties

Many important functions of miRNAs in embryonic development and stem cells regulation in mammals are investigated. Dynamic expression profile of miRNAs in CSCs validates its significant role in controlling the self-renewal ability, pluripotency, differentiation of progenitor cells, prosurvival and antistress mechanisms (Table 1).

MiRNAs playing role in differentiation processes can either directly suppress the self-renewal state by suppressing the markers of pluripotency including Nanog, POU class 5 homoeobox 1 (POU5f1) also known as Oct4, Kruppel like factor 4 and sex-determining region Y-box containing gene 2 [Sox2, a crucial transcription factor for the maintenance of embryonic stem cell (ESC) pluripotency and the determination of cell fate], or stabilize the differentiated cell fate by targeting the transcripts that are regulated by the pluripotency transcription factors including *Oct4*, *Sox2*, *Nanog* and *Tcf3*^[22]. The transfection of let-7c, member of Let-7 family has been shown to rescue the differentiation defects in DGCR8^{-/-} cells by downregulating the stemness genes including *Oct4*, *Sox2* and *Nanog*^[22]. Negative feedback regulation between Lin-28, a marker of undifferentiated ESCs and Let-7 family members has been reported in mouse differentiated cells and embryonic carcinoma cells^[23]. Reduced patient survival and tumor relapse in human colon adenocarcinomas has been correlated with increased expression of Lin-28^[24]. Studies on inhibition of Sox2 and placenta-specific 1 gene by miR-126 has been reported in gastric

Figure 1 MicroRNA biogenesis, activity and potential therapeutic targets. Mature miRNAs are generated from hairpin-like longer primary transcripts by two sequential processing steps mediated by a nuclear (Drosha) and a cytoplasmic (Dicer) RNAase III endonuclease. MiRNA then directs RISC to target mRNAs which share sequence complementation between seed region at 5' end of mature miRNA and 3'UTR of target mRNA. Stability of miRNA:mRNA recognition and degree of complementation leads to translational activation but more commonly mRNA degradation and translational repression. Potential therapeutic target sites are shown which include steps during miRNA biogenesis and target mRNA recognition. 3'UTR: 3' untranslated region; RISC: RNA-induced silencing complex; miRNA: MicroRNAs; Ago: Agronaute.

carcinogenesis^[25].

First oncomiR reported as miR-17-92 polycistron has been examined to regulate c-Myc expression and accelerate tumor development in stomach, prostate, pancreatic, colon, lung and breast cancers. Novel stem cell specific miRNAs including miR-290, miR-302/367 and miR-371 clusters are identified in human ESCs and exhibit altered cell cycle profile and inhibit ESCs transition from self-renewal to differentiated state. Members of the miR-302 family has been shown to reprogram human skin carcinoma cells into pluripotent ESC-like state^[26].

Inhibition of tumor sphere growth *in vitro* and tumor formation *in vivo* upon restoration of miR-34 has been concluded to be associated with the suppression of growth of CSCs with biomarkers of CD44⁺ and CD133⁺ in human pancreatic cancer cells. These CSCs are deficient in miR-34 and show higher expression of Bcl-2 and Notch, which are the target genes for tumor suppressor like p53, and are involved in survival and self-renewal of CSCs. MiR-34 has been shown to inhibit the reprogramming through repressing pluripotency genes like *Nanog*, *Sox2* and *N-Myc*^[27]. Further research has confirmed that restoration of miR-34 directly regulates Bcl-2 and Notch target genes, activates caspase-3,

induces apoptosis, thereby could increase chemotherapeutic and radiotherapeutic sensitivities in pancreatic cancer cells^[28,29]. Suppression of tumorigenesis *in vitro* has been found to be regulated by miR-134 by downregulating the Notch target proteins and affecting G2/M phase of cells in human endometrial CSCs^[30]. Independent study by Park *et al*^[31], 2013 revealed the differential expression of 43 miRNAs and their putative target genes such as *p53*, *ErbB1*, *Notch*, *Wnt*, and TGF- β signaling pathways which are the key regulators for stem cells and are mainly involved in cell death, cellular development, cellular growth, proliferation and maintenance of cancer and stem cell in glioblastoma multiforme (GBM) which is the most aggressive primary brain tumor, and notorious for resistance to chemo/radiotherapy.

Owing to high degree of biochemical specificity and potency shown by miRNAs in regulating the multiple vital pathways that can significantly affect the cancer progression, development of miRNAs as therapeutic molecule in association with anti-cancer drugs provides immense opportunities to counteract chemo/radioresistance and improve treatment outcome in various human cancers. Recent advances in the mechanisms, co-delivery of therapeutic molecules using

Figure 2 MicroRNAs affect and regulate the key properties of cancer stem cells. Tumor microenvironment influences the maintenance and properties of CSCs. Secreted growth factors and cytokines from cancer cells, hypoxia, oncogene activation, DNA damage, errors in DNA repair and aberrant microRNA expression modify cancer cell functions by increasing the self-renewability, cell cycle exit and differentiation, epithelial-to-mesenchymal transition, migration, invasion and survival rate in CSCs thus promote cancer progression and or tumor recurrence. CSCs: Cancer stem cells.

nano-carriers and various advantages of combinational therapy in elimination of CSCs population and in complete cure of human cancer with no recurrence or metastasis are discussed in the subsequent section.

COMBINATIONAL THERAPEUTIC APPROACHES TO TARGET CSCS

MiRNAs involved in acquisition of stem cell-like properties, regulation and reprogramming by cancer cells during cancer progression are not only exploited as molecular biomarkers to predict the risk of metastasis, systemic treatment resistance, and disease relapse of patients with cancer but are also an important novel therapeutic tools to improve patient-tailored treatments based on the unique signatures of a patient disease. MiRNAs can function as tumor suppressors or oncogenes and thereby either silence or express hundreds of genes and at the same time, where one gene can be targeted by multiple miRNAs. Local administration

of miRNA-sponges which are the transcripts having multiple, tandem binding sites to the miRNAs of interest; antagomiRNAs/anti-miRNAs (highly chemically modified miRNA passenger strand) which include strong RNA binding analog locked nucleic acid in mixers with DNA, charged neutral anti-miRNA oligonucleotides like peptide nucleic acid, phosphorodiamidate morpholino oligonucleotides, 2'-modified anti-miRNA oligonucleotides such as 2'-O-methyl, 2'-O-methoxyethyl (MOE), 2'-fluoro/2'-methoxyethyl mixers (2'F/MOE) enhance binding affinity for their RNA targets, steric-block potency and biostability and induce inhibition of endogenous miRNA functions following miRNA- anti-miRNA oligonucleotide binding in a chemistry dependent manner^[32,33]. Expression levels of related miRNA families that share the same seed sequence can be effectively reduced by using synthetic mRNAs, which contain multiple binding sites for endogenous miRNAs^[34]. MiRNA replacement therapy is another important therapeutic intervention which is based on the systematic delivery of

Table 1 Some of the potential microRNAs involved in regulation of cancer stem cells

MicroRNAs	Transcript target	Relevance to cancer progression and its biological functions	Ref.
Upregulated microRNAs			
miR-1246	CCNG2	Pancreatic cancer: Induces chemoresistance and CSC-like properties	[53]
miR-495	E-cadherin and REDD1	Breast cancer: Promotes oncogenesis and hypoxia resistance	[54]
miR-371-373 cluster	Wnt/ β -catenin, DKK1	Many cancers: Promotes cell growth and invasive activity	[55,56]
miR-216a/217	Myc	Liver cancer: Regulates the properties of CSCs	[57]
	PTEN and SMAD7	Hepatocellular carcinoma: Increased proliferation, migration and metastatic ability	
miR-210	Nanog, Oct4 and EZH2	Pancreatic cancer: Increased cell migration and invasion	[58]
miR-191	BASP1, Wnt/ β -catenin	Lung cancer: Increased migratory potential and neoplastic properties	[59]
miR-130b	P53-induced nuclear protein 1	Acute myeloid leukemia: Regulates hematopoietic stem cells	[60]
miR-29a	P53-induced nuclear protein 1	Acute myeloid leukemia: Regulates hematopoietic stem cells	[61]
miR-21	Nanog, Oct4 and EZH2	Pancreatic cancer: Increased cell migration and invasion	[58]
miR-18	DLL4, inhibitor of Notch signaling	Glioma: Promotes tumorigenic potential of GSCs	[62]
Downregulated microRNAs			
Let-7	Lin-28	Colon adenocarcinomas: Promotes cell migration, invasion and transforms immortalized colonic epithelial cells	[24,63]
miR-487b	SUZ12, BMI1, WNT5A, MYC, and KRAS	Pancreatic cancer: Increased pluripotency	[64]
miR-451	SMAD 3 and 4	Lung cancer: Increased proliferation and invasion	
miR-326	Hh smoothened signal transducer	GBM: Controls GBM stem cells differentiation	[41]
miR-204	Sox4 and Ephrin receptor EphB2	Chronic myeloid leukemia: Increased cell proliferation and decreased apoptosis	[65]
miR-200 family	VEGFR1, VEGFR2 and EMT-related transcription factors	Glioma: Involved in GSCs self-renewal and invasion	[66]
miR-200a	ZEB1, ZEB2, SNAIL and SLUG	Pancreatic cancer: Regulates CSCs properties	[63]
miR-181	N-cadherin, ZEB1, vimentin, E-cadherin	Pancreatic cancer: Increased cell migration and invasion	[67]
	ATM	Breast cancer: Regulates the properties of CSCs	
	MYb	Acute myeloid leukemia: Blocking of myeloid differentiation	
miR-150			[69]
miR-143/145 cluster	KRAS2 and its downstream effector RREB1	Pancreatic cancer: Regulates CSCs survival	[70]
miR-145	Oct4, Sox2, Nanog, Klf4 as well as Kras and Rreb1	Pancreatic cancer: Increased pluripotency	[63]
miR-128	Histone methylation [H3K27me(3)], Akt phosphorylation, p21(CIP1) Bmi-1	Glioma: Increased self-renewal and proliferation	[71]
miR-107	Nanog, Oct3/4, and Sox2	Head and neck squamous cell carcinoma: Increased CSC proliferation	[72]
miR-100/let-7a-2/miR-125b-1 cluster	Myc	Liver cancer: Regulates the properties of CSCs	[56]
miR-34 family	Notch and Bcl-2	Pancreatic cancer: Involved in self-renewal of CSCs	[28,29]
miR-29b-1	CD133, N-Myc, CCND2, E2F1 and E2F2, Bcl-2, IAP-2, Oct3/4, Sox2 and Nanog	Osteosarcoma: Increased proliferation, self-renewal and chemoresistance	[73]
miR-27a	14-3-3 β , Bax and Bad	Acute leukemia: Regulate apoptosis	[74]
miR-23b	Cell cycle arrest	Glioma: Inhibits proliferation	[75]

CCNG2: Cyclin-G2; DKK1: Dickkopf-1; PTEN: Phosphatase and tensin homolog; BASP 1: Brain abundant, membrane attached signal protein 1; ATM: Ataxia telangiectasia mutated; Myb: Myeloblastosis protooncogene protein; RREB1: Ras-responsive element binding protein-1; IAP-2: Inhibitor of apoptosis 2; CCND2: Cyclin D2; GSC: Glioma stem cell; CSC: Cancer stem cell; REDD1: Regulated in development and DNA damage responses 1; Myc: Myelocytomatosis viral oncogene; SMAD7: Homologs of caenorhabditis elegans protein small body size and drosophila protein mothers against decapentaplegic family member 7; Oct 4: Octamer-binding transcription factor 4; EZH2: Enhancer of zeste homolog 2; P53: Tumor protein 53; DLL4: Delta like ligand 4; SUZ12: Polycomb repressive complex 2 subunit; BMI1/Bmi-1: BMI1 proto-oncogene, polycomb ring finger; WNT 5A: Wingless-type MMTV integration site family, member 5A; KRAS: Kirsten rat sarcoma viral oncogene homolog; SMAD3 and 4: Homologs of caenorhabditis elegans protein small body size and drosophila protein mothers against decapentaplegic family member 3 and 4; Hh: Hedgehog; Sox 4: Sex-determining region Y-box containing gene 4; EphB2: Ephrin type-B receptor 2; VEGFR1: Vascular endothelial growth factor receptor 1; VEGFR2: Vascular endothelial growth factor receptor 2; EMT: Epithelial-to-mesenchymal transition; ZEB1: Zinc finger e-box binding homeobox 1; ZEB2: Zinc finger e-box binding homeobox 2; E-cadherin: Epithelial-cadherin; Klf4: Kruppel like factor 4; H3K27 me (3): Histone H3K27me3 (trimethyl Lys27); Akt: Protein kinase B; Bcl-2: B-cell lymphoma 2; E2F1: E2F transcription factor 1; E2F2: E2F transcription factor 2; Bad: Bcl-2-associated death promoter; Bax: Bcl-2-associated X protein; P21 (CIP1): Cyclin-dependent kinase inhibitor 1A; GBM: Glioblastoma multiforme.

miRNA mimics into the cytoplasm of target cells to gain tumor suppressor functions. Inducing miRNA-mediated biological processes or blocking specific targets either could reverse the development of cancer or delay tumor growth^[35]. Besides this, based on the relationship between expression of miRNA-regulated target genes

and their reaction to drug therapies, some other miRNAs are explored which can mediate molecular target drugs and regulate chemosensitivities and chemoresistances of cancer. Experimental evidences document that the co-administration of CSCs with either antagomiRNAs/anti-miRNAs or miRNA mimics along with potential

Table 2 Targeting cancer stem cells with specific microRNAs as a potential combinational therapeutic strategy in human cancer

Co-delivery of microRNAs/anti-cancer drug	Biological functions	Cancer type	Ref.
Oncogenic microRNAs			
miR-9/temozolomide	Inhibit the expression of drug efflux transporter, P-glycoprotein	Glioblastoma multiforme	[39]
miR-21/metformin, 5-Fluorouracil and Oxaliplatin	Target Wnt/ β -catenin	Colon cancer	[38]
miR-125b/temozolomide	Target PIAS3, which contributes to reduced STAT3 transcriptional activity and subsequent decreased expression of MMP-2 and -9	Glioblastoma	[40]
miR-125b/temozolomide	Target pro-apoptotic Bcl-2 antagonist killer 1 and sensitize CSCs to temozolomide induced apoptosis	Glioblastoma	[76]
Tumor suppressor microRNAs			
miR-612/cisplatin, 5-Fluorouracil	Target Wnt/ β -catenin, regulate EMT and inhibit cell proliferation, migration, invasion, and metastasis	Liver cancer	[48]
miR-205/gemcitabine	Decreased tumor cell population and increased apoptosis	Pancreatic cancer	[42]
miR-200c/docetaxel	Reduced TUBB3 level, and reversed EMT	Gastric cancer	[43]
miR-146a/cetuximab	Target Numb to stabilize β -catenin, regulate EMT, direct ACD-to-SCD switch	Colorectal cancer	[77]
miR-145/metformin, 5-Fluorouracil and Oxaliplatin	Target Wnt/ β -catenin	Colon cancer	[38]
miR-34 family/5-Fluorouracil	Repression of c-Kit by p53	Colorectal cancer	[45]
miR-34a/doxorubicin	Target Notch1 and reduce cancer stem cell properties	Breast cancer	[44]

STAT: Signal transducer and activator of transcription; PIAS3: Protein inhibitor of activated STAT; MMP: Matrix metalloproteinase; ACD: Asymmetrical cell division; SCD: Symmetrical cell division; EMT: Epithelial-to-mesenchymal transition; CSC: Cancer stem cell; MMP: Matrix metalloproteinase; TUBB3: Tubulin beta class III.

anti-cancer drugs can better sensitize cancer cells to promote apoptosis and autophagy, downregulate efflux transporters, revert EMT and inhibit tumor angiogenesis and could be employed as a more popular therapeutic approach for better clinical outcome in the treatment of human malignancies (Figure 3).

Viral vectors like lentiviral/adenovirus vectors are efficient delivery systems for miRNAs but toxicity and immunogenicity are the major hurdles for their clinical use. MiRNAs enclosed into non-viral particles, nanoparticles (NP) to form micelle-like structures for their effective delivery and enhanced stability in circulation. Some of the commonly used NPs for miRNAs delivery include polycationic-liposome hyaluronic acid, neutral lipid 1,2 dioleoyl-sn-glycero-3 phosphatidylcholine, polyethyleneimine, dendrimers, protamine, atelocollagen, poly(lactide-co-glycolide) particles, gold- or silica-based inorganic NPs. Binding of tumor specific ligands to NPs or conjugation with different compounds that have specific affinity with tumor cells ensure tissue-specific targeted delivery of miRNAs^[36]. Some of the significant recent work being conducted in cancer cell lines and or animal models to understand the cellular processes that regulate CSCs functions and investigate the therapeutic effects of miRNAs and add new dimensions in cancer treatment, are being discussed here (Table 2).

The effects of knockdown of miR-21 expression include induced apoptosis, reduced cell proliferation, invasion, and colony formation ability of colon tumor cells, inhibited G1/S cell cycle transition and increased sensitivity of cancer cells to 5-Fluorouracil (5-FU) chemotherapy. Direct targeting of human mut S homolog 2 and indirect regulation of the expression of thymidine phosphorylase and dihydropyrimidine dehydrogenase

by miR-21 confirms its important role in enhancing the sensitivity of 5-FU resistance of colon cancer cells. Re-emergence of chemotherapy-resistant CSCs could be one of the possible reasons for recurrence in colon cancer^[37]. The synergistic effect of increased miR-145 and reduced miR-21 expression which target Wnt/ β -catenin signaling pathway along with co-delivery of metformin, in combination with 5-FU and oxaliplatin, has been examined inducing cell death in chemoresistant colon cancer cells, inhibiting colonospheres formation and enhancing colonospheres disintegration in the treatment of recurring colon cancer^[38]. The delivery of synthetic Cy5-tagged anti-miR-9 to the resistant GBM cells has been observed to reverse the expression of the drug efflux transporter, P-glycoprotein and stimulate the sensitization of GBM cells to temozolomide, as shown by increased cell death and caspase activity^[39]. Experimental studies by Shi *et al*^[40], 2014 demonstrate the therapeutic effects of miR-125b inhibitor in enhancing the invasion-prevention activity of temozolomide in glioblastoma stem cells through targeting PIAS3 [protein inhibitor of activated signal transducer and activator of transcription (STAT)], which contributes to reduced STAT3 transcriptional activity and subsequent decreased expression of matrix metalloproteinase-2 (MMP-2) and MMP-9.

The cooperative effect of miR-451 (having a target site for SMAD in its promoter region) in combination with imatinib mesylate treatment in dispersal of GBM neurospheres and reduced tumorigenicity in glioblastoma validates this co-treatment as a new potential drug against the stem-cell like characteristics of glioblastoma^[41]. The delivery of combinational formulations of gemcitabine and miR-205 conjugated

Figure 3 Effective novel tumor therapies. Conventional chemo- and radio-therapeutic drugs target the bulk of tumor cell population and lead to tumor shrinkage. Cancer stem cells however develop resistance to these drugs and as a result of genotoxic insults, tumor cells relapse. MicroRNA approach along with the chemo and radiotherapeutic drugs as a novel treatment strategy target transit amplifying cells as well as differentiated cancer cells and induce differentiation in cancer stem cells thereby remove the bulk of tumor and also the source of cancer.

copolymers in pancreatic cancer cells effectively reversed chemoresistance, invasion and migration by inducing apoptosis and inhibiting the growth and proliferation of CSCs^[42]. In another study, synergetic effects of targeted delivery of miR-200c and docetaxel (DOC) by gelatinases-stimuli NPs on inhibition of CSCs and non-CSC cancer cells in gastric cancer has been verified. The treatment of cancer cells with miR-200c/DOC NPs has been shown to significantly enhance the cytotoxicity of DOC, possibly by decreasing tubulin beta 3 Class III (TUBB3) level and reversing EMT, thereby affect tumor cell viability, migration and invasion^[43]. Ectopic expression of another tumor suppressor, miR34a has been studied to reduce CSCs properties and increase sensitivity to doxorubicin treatment by directly targeting Notch1 in chemoresistant breast cancer cells^[44]. c-Kit has been established as a new direct target of miR-34 where p53-induced miR-34 microRNA family mediated repression of c-Kit *via* a conserved seed-matching sequence in the c-Kit 3'-UTR, result reduced chemoresistance to 5-FU, reduced migration/invasion and stemness, further proves the hypothesis that this regulation interferes with several c-Kit-mediated effects in colorectal cancer cells^[45]. Recent preliminary studies document the tumor growth inhibition in human non-small cell lung cancer xenografts and KRAS-G12D

transgenic mouse model or the elimination of self-renewing breast CSCs upon therapeutic delivery of Let-7 mimics^[46,47]. Up-regulation of miR-30e with tumor suppressor functions by downregulating BCR-ABL (Breakpoint cluster region-Abelson murine leukemia viral oncogene homolog 1) expression in chronic myeloid leukemic cells has been examined to render therapeutic efficacy against this disease. Owing to presence of putative target site for miR-30e in the 3' UTR of the *ABL* gene, enforced expression of miR-30e in K562 cells has been shown to suppress proliferation and induce apoptosis of these cells and sensitize them to imatinib treatment^[48]. Attenuation of EMT by retaining epithelial cell morphology, reducing the levels of α -smooth muscle actin and increasing the levels of E-cadherin in human kidney proximal tubular epithelial cells has been observed after enforced expression of all the three members of miR-106b-25 cluster (miR-106b, miR-93 and miR-25) in salivarnolic acid B^[49].

Protective functions of decreased expression of oncogenic miR-21 and increased expression oftumor suppressor miR-138 regulated by α -solanine has been shown in prostate cancer. These therapeutic effects have been experimentally examined to be mediated by suppressing extracellular signal-regulated kinases and phosphatidylinositol-3 kinase - serine/threonine kinase

signaling pathways, inhibiting EMT, reducing proliferation and inducing apoptosis^[50].

Systemic administration of cationic lipid NP/pre-miR-107 significantly has been shown to retard tumor growth by 45.2% compared to NP/pre-miR-control by decreasing the expression of miR-107 targets including protein kinase C ϵ , cyclin-dependent kinase 6, and hypoxia-inducible factor 1- β . NP/pre-miR-107 further has been shown to reduce the cancer-initiating cell population and dampen the expression of the core embryonic stem cell transcription factors, Nanog, Oct3/4, and Sox2 and inhibit the clonogenic survival, cell invasion, and cell migration of head and neck squamous cell carcinoma cells^[51].

Overexpression of miR-612 has been shown to suppress the stemness of hepatocellular carcinoma by reducing the number and size of tumorspheres, clone formation in soft agar and relieve the cancer cells from drug resistance to cisplatin and 5-FU by targeting Wnt/ β -catenin signaling, thereby control EMT-associated stem cell-like traits^[52].

Diverse cellular pathways that modulate CSCs functions act in concert with various molecular events and promote tumor initiation, progression and metastasis. Over the past recent years, emergence of miRNAs and molecular-targeted therapies has intensified research in the development of miRNA based therapeutic agents for cancer treatment with improved clinical outcome. Preclinical therapeutic data on mechanistic regulation of metastasis by miRNAs from *in vitro* studies need to be reevaluated in genetically engineered animal models which could further help us to provide new insights into clinical applications of miRNAs. Understanding the complex network of biological properties of CSCs, their control by multifunctional miRNAs and potential involvement of miRNAs in the development of anti-cancer drug resistance, reversion of cancer stemness and thereby rendering advanced cancers more susceptible to long term control are some of the open challenges to design novel strategies that can be used in preventive and treatment settings as an adjuvant to current cancer therapeutics.

CONCLUSION

CSCs which reside as a subset in many cancers are capable of self-renewal, tumor initiation, recurrence, metastasis, conferring resistance to anti-neoplastic drugs are still considered as huge obstacles on the way to cure cancer. This highlights the need to design strategies and therapeutics that specifically target and kill CSCs to eliminate cancer. Over the past few years, small ncRNAs, called miRNAs, have gained widespread attention in molecular biology due to their involvement in DNA translational control, their impression on mRNA and protein expression levels, and their ability to reprogram molecular signaling pathways in cancer. Differential miRNA profile in CSCs make them as potential biomarkers for aggressive tumor biology and

therapeutic resistance and their biological specificity in targeting the various properties of CSCs make them strong targets for improving the response to anti-cancer drugs by sensitizing these cells to enhanced apoptotic effects of drugs. Novel anticancer therapies are based on the manipulation of oncogenic or tumor suppressor miRNAs by reducing or increasing their expression levels respectively. Success of using miRNAs as specific drug target in clinically relevant animal models as well as in preclinical development has been tested and determined by normal organ morphology, blood chemistries, serum cytokine levels, significant tumor regression and prolonged survival.

Abstract

The complement pathway is best known for its role in

immune surveillance and inflammation. However, its ability of opsonizing and removing not only pathogens, but also necrotic and apoptotic cells, is a phylogenetically ancient means of initiating tissue repair. The means and mechanisms of complement-mediated tissue repair are discussed in this review. There is increasing evidence that complement activation contributes to tissue repair at several levels. These range from the chemo-attraction of stem and progenitor cells to areas of complement activation, to increased survival of various cell types in the presence of split products of complement, and to the production of trophic factors by cells activated by the anaphylatoxins C3a and C5a. This repair aspect of complement biology has not found sufficient appreciation until recently. The following will examine this aspect of complement biology with an emphasis on the anaphylatoxins C3a and C5a.

Key words: Complement activation; Embryonic and adult stem cells; C3a; C5a; Tissue repair

Core tip: This review article provides an overview over the scenarios, where complement activation contributes to tissue repair and regeneration through its effect on stem and progenitor cells, which is an area that needs further investigation.

INTRODUCTION

Complement activation cascade

Complement is an effector system present in blood

Figure 1 Schematic presentation of the complement pathways with emphasis on outcomes relevant to tissue repair and regeneration. The complement system can be activated by three pathways, two of which are part of innate immunity, the alternative and lectin pathways, whereas the classical pathway is normally initiated by immunoglobulins. All routes converge on the cleavage by complex enzymes referred to as C3 convertases of component C3 (Mr: about 195000) to C3a (Mr: about 8500) and C3b (Mr: about 185000). As a consequence of C3b deposition on C3 convertase, C5 convertase is created that acts similarly producing from component C5 (Mr: about 196000) the activation peptide C5a (Mr: about 11000) and C5b (Mr: about 185000). The anaphylatoxins, C3a and C5a, are important for elaboration of mechanisms of wound healing and regeneration. These small mediators are recognized by their cognate receptors: C3aR and C5aR/C5L2 that are GPCRs found on a diversity of cells inclusive of immune cells, endothelial cells, differentiated repair cells, and stem cells. In addition C3b and its split product iC3b, C3d are recognized by receptors inclusive of CR1-4 that assist clearance of microorganisms, cellular debris, immune complexes, and apoptotic cells. The ultimate outcome of complement activation is the formation of the MAC that is a transmembrane pore (100 Å) assembly that embeds in target cell membranes. In the absence of proximal phospholipid membranes, the terminal components of complement associate into complexes referred to as SC5b-9. These are probable heterogeneous and contain multiple copies of vitronectin and clusterin (apolipoprotein J). Because vitronectin in an oligomeric state can present the canonical tripeptide, Arg-Gly-Asp, to integrins on a variety of restorative cells, such as fibroblasts and keratinocytes, SC5b-9 may have a wound healing function. MAC: Membrane attack complex; MSC: Mesenchymal stem cells; HDL: High density lipo-protein; HSC: Hematopoietic stem cells; PMNs: Polymorphonuclear cells.

consisting of about 30 soluble proteins and 15 cellular receptors. Although it has been known for over a century that complement is a participant in host immunity, it has recently become generally realized that complement is a contributor to a variety of non-immune functions inclusive of resolution of inflammation, clearance of apoptotic cells, angiogenesis, wound healing, stem cell recruitment and activation, as well as repair processes^[1-6].

There are three routes of complement activation, the alternative pathway, the lectin pathway, and the classical pathway (Figure 1). All of these converge on the specific cleavage of component C3 (Mr: about 195000) by C3 convertase to yield the split products C3a (Mr: about 9000) and C3b (Mr: about 185000).

The alternative pathway activation is brought about by contact with large complex polysaccharides such as those found on microbial cell walls. This pathway is commenced by a diminished capacity to inactivate C3

convertase on a carbohydrate surface by the control factor H as well as pattern recognition by properdin and possibly contact activation by C3^[7-11]. Factor B combines with initially deposited C3b along with the stabilizer properdin to compose this pathway's C3 convertase, which consists of properdin, C3b, and Bb^[12].

The lectin pathway is started by special collagen containing C-type lectins (collectins), namely mannan binding lectin (MBL) and ficolins, which recognize carbohydrate patterns typically characterized by high mannose content, for example mannan that is a component of the coats of a variety of yeast, fungi, and other microorganisms^[13]. Proteases, referred to as mannan binding protein associated serine proteases link to fixed MBL to cleave C4 and C2 generating the complex enzyme C3 convertase (C4b, C2a)^[14].

The classical pathway can be initiated by IgG subclasses 1, 2, 3 as well as by IgM. Once tagged by

immunoglobulins, the collectin, C1q, links to these, along with C1r and C1s to evoke the cleavage of C4 and C2 resulting in the assembly of a C3 convertase (C4b, C2a), which has the same composition as that formed by the lectin pathway^[15].

Additional C3b deposition onto either the alternative or classical pathway C3 convertases changes these into C5 convertases (C3b₂, Bb, P or C4b, C3b, C2a)^[16,17]. These complex enzymes are now competent to process component C5 (Mr: about 196000) into C5a (Mr: about 11000) and C5b (Mr: about 185000)^[18].

Basic biology of C3a and C5a

The small activation peptides, C3a and C5a, Figure 1 are in inflammation and germane to this review in wound healing and regeneration^[19]. Both C3a and C5a, collectively referred to as anaphylatoxins, cause vasodilation, smooth muscle contraction, and increase vascular permeability^[20-22]. Although C3a can be generated in greater abundance than C5a, the latter has greater specific inflammatory potential^[21,23]. C5a especially is known for its ability to evoke chemotaxis of immune cells such as neutrophils and eosinophils^[24,25]. Both C3a^[23,26-28] and C5a^[21,24,26,29-31] can stimulate an oxidant burst in granulocytes, but the response of these cells to C3a is considerably weaker and more transient than that to C5a^[24,25,30,31]. In particular C3a fails to chemo-attract circulating leukocytes *in vivo*^[25]. Apart from the weak response of leukocytic C3aRs, the response to C3a *in vivo* would be expected to be limited largely to the interstitial space, since C3a is inactivated by serum carboxypeptidase N (CPN)^[32].

The anaphylatoxins are recognized on target cells by G-protein coupled receptors (GPCRs)^[33-35] coupled primarily to Gi. Unusually, C3aR has a long second extracellular loop that is important for binding C3a^[33,34].

C5a is recognized by two distinct GPCRs, C5aR (CD88) and C5L2, but only the former is coupled to Gi proteins, whereas the latter is enigmatic because it is not connected to a signal transduction pathway, and its biological role has not been established^[36]. Several investigations have assigned roles for C5L2 inclusive of an anti-inflammatory function^[37] and as a decoy-scavenger receptor^[38], but it has also been argued from studies using C5L2 knockout mice that this receptor is important for C5a-mediated signal transduction in neutrophils, macrophages and fibroblasts^[39]. Thus the true biological roles of C5L2 to date are not established^[40].

The anaphylatoxins are inactivated by plasma CPN (EC 3.4.17.3), a tetrameric protein (Mr: about 260000) that can excise basic amino acids from the carboxyl-termini of C3a, C5a, as well as bradykinin and other polypeptides^[32,41,42].

Whereas C3a desArg completely loses its activity^[43], C5a desArg retains a small fraction of its specific activity for neutrophil chemotaxis^[24,32].

The receptors for the anaphylatoxins are not restricted to immune cells as C3aR and C5aR are found

on a variety of non-immune cells^[44]. These include differentiated cells that can be important for wound healing and regeneration: mast cells^[45], tenocytes^[46,47], chondrocytes^[48,49], synoviocytes^[50], smooth muscle cells^[51], endothelial cells^[52-54], alveolar epithelial cells^[55], mesangial cells^[56,57], and regenerating hepatocytes^[58]. In addition various stem and progenitor cells express the C3aR and C5aR^[2,59-61] including HSC, mesenchymal stem cells (MSC)^[61], NSC^[2], and dental pulp progenitor cells^[62]. Table 1 shows a list of the cell types that express C3aR and C5aR and their function.

Late-acting components of the complement system

While the C3b portion of C3 binds to the surface of pathogens leading to greater internalization by phagocytic cells, C5b, the remaining split product of C5, assembles with complement C6, C7, C8, and polymeric C9 to form the membrane-spanning membrane attack complex (MAC), which lyses bacteria, but which can also damage eukaryotic cells. Finally, a C3b cleavage product, iC3b can bind to the β 2-integrins CR3 (CD11b/CD18) and CR4 (CD11C/CD18) on phagocytic cells facilitates the clearance of apoptotic cells.

There are multiple modalities which inhibit complement activation or the formation of the MAC; these include the plasma proteins factor H and C4b-binding protein and the membrane-anchored complement receptor 1 (CR1/CD35), membrane cofactor protein (CD46), decay accelerating factor or CD55, and MAC-inhibitory protein (CD59). As the plethora of inhibiting factors indicates complement activation has to be fine-tuned to provide optimal protection from infection without causing inflammatory tissue injury.

Sites of complement synthesis and activation

While complement proteins in the circulation are primarily produced by the liver except for the late acting complement components in particular C7 which are produced by monocytes/macrophages^[63,64], it has become apparent that production and activation of complement proteins can happen in a localized fashion in many different parts of the body^[65-68], and one would expect prolonged activation by the anaphylatoxins C3a and C5a under such conditions because of the absence of CPN in the interstitial space.

Role of complement activation in inflammation

The important role of complement in the defense against infection comes, however at a price: excessive complement activation plays a role in numerous disease processes ranging from ischemic reperfusion injury^[69-71] to asthma^[72], acute lung injury^[73,74], glomerulonephritis^[75], rheumatoid arthritis^[76], Alzheimer's disease^[77], multiple sclerosis and demyelination in general^[78,79], and age-related and genetic macular degeneration^[80-83]. In some instances the specific injurious complement pathway components have not been distinguished^[75,76], in others C5a^[69-71,77,80] or the MAC are the clear culprits^[79]. A role

ERK: Extracellular signal-regulated kinase; EMT: Epithelial-to-mesenchymal transformation; NGF: Nerve growth factor; MSC: Mesenchymal stem cells; SDF: Stromal-cell derived factor; HSPC: Hematopoietic stem and progenitor cells; CSPC: Cardiac stem and progenitor cells; NSPC: Neural stem and progenitor cells; ESC: Embryonic stem cells; MAC: Membrane attack complex.

for C3a was only seen in a mouse asthma model^[72] and a mouse model of laser-induced macular degeneration, where the presence of the C3aR was associated with increased angiogenesis^[80], which is detrimental in the retina, but which could support repair following ischemic insults in other tissues.

It should be noted here that C5a appears the major culprit responsible for most of the observed pathologies, and that specific C5/C5a inhibition preserving the early steps of complement activation could be highly advantageous in some circumstances.

ROLE OF COMPLEMENT ACTIVATION IN TISSUE REPAIR

Complement mediated inflammation leading to resolution and clearance

While the inflammatory aspect of complement activation has long been emphasized, it has been largely ignored that complement activation contributes also to resolution of inflammation and tissue repair with few

reviews covering this aspect^[4,84-86].

In particular, C3a has anti-inflammatory and regenerative effects^[2,61,87-91]. In fact the regenerative potential of C3/C3a dates way back phylogenetically, as its expression is prominently up-regulated in mesenchymal cells in the regeneration zone in amphibians undergoing limb regeneration^[92]. Furthermore, recent findings indicate that the C3aR on mesenchymal cells plays an important migration-directing role during early vertebrate development in zebra-fish^[93]: Neural crest cells mutually attract each other *via* C3a and the C3aR forming clusters of migratory mesenchymal cells. Such collective cell migration is a phenomenon crucial for morphogenesis. It remains to be seen, whether C3a and the C3aR play the same role during mammalian embryonic development.

While C5a also has regenerative effects for instance by its effects on the liver^[94,95], neurons^[96], osteoblasts^[97], and dental pulp progenitors^[62], these properties are often overshadowed by the strong inflammatory reaction caused by the activation of leukocytic C5a receptors,

which are involved in most of the pathologic conditions described above.

However, it should also be considered that inflammation itself constitutes a first step in wound healing. C3a and C5a can lead to an increase in vascular permeability^[21,98], which is important for wound healing as it aids the flow of chemical and cellular entities necessary for repair and regeneration while facilitating waste removal^[99].

Although swelling is traditionally seen as a characteristic of inflammation, edema is also necessary for the resolution of inflammation and restoration of functional tissue because an increase in vascular permeability facilitates entry of repair and restorative cells. Specific to this theme is the function of histamine. C3a and C5a both are chemotactic for mast cells and both are inducers from these cells of histamine release^[100-102]. Histamine due to its potent vasodilation activity can induce swelling, but histamine is also required for skin wound healing as demonstrated using Kit mutant mice that are mast cell deficient. These animals are unable to secrete mast cell derived histamine, and the animals were found to have a defective response to cutaneous wound healing^[103].

The increase in vascular permeability facilitates the recruitment of monocytes that can respond to C5a mediated chemotaxis gradients^[104], and these cells are crucial for "cleanup" functions. Today it is understood that clearance of debris and apoptotic cells is an important activity necessary for subsequent wound healing, and complement along with pentraxins have been shown to participate in this activity^[105,106]. Indeed the clearance function was probably the original function of the complement system dating all the way back to metazoans^[107].

The collectins C1q and MBL are important for enhanced phagocytosis by monocytes and macrophages of modified lipoprotein complexes, immune complexes, and apoptotic cells^[108-111]. Apoptotic cells present exteriorized phosphatidyl serine that can be recognized at an early stage by the lectin domains of members of the collectin family^[112-114]. Apoptotic cells, debris or immune complexes tagged by C1q or MBL are identified by monocytes and macrophages bearing CD91 that can be in complex with a collectin receptor, calreticulin^[115-117]. The facilitated uptake of these "disposables" has been referred to as macropinocytosis^[118].

In addition to recognition of pathogens, debris and dead cells by members of the collectin family, fragments of C3 are important for clearance functions. C3b is susceptible to processing by Factor H and I to iC3b that can be cleaved further into C3d and C3c^[119]. C3 fragments are recognized by receptors such as CR1 (CD35), CR2 (CD21), CR3 (CD11b/CD18), CR4 (CD11c/CD18), and CRIg found on Kupffer cells, monocytes and macrophages, which are immune adherence receptors that facilitate removal of opsonized microorganisms, immune complexes and apoptotic cells^[120,121].

Complement and angiogenesis

The importance of angiogenesis in wound healing and regeneration has been clearly understood^[122]. The process has been categorized in three continuous overlapping phases: inflammatory, proliferative, and remodeling^[122].

Some aspects of participation in inflammation inclusive of increase in vascular permeability induced by C3a and C5a have already been discussed, but these mediators have additional functions that indirectly support angiogenesis. C5a but not C3a has been shown to induce an upregulation of gene expression on endothelial cells for adhesion molecules E-selectin, ICAM-1, and VCAM-1^[123,124]; the upregulation of these adhesion molecules facilitates extravasation of immune cells inclusive of monocytes that are important for debridement, remodeling and angiogenic mediator secretion^[125]. Angiogenesis requires restructuring of the extracellular matrix by controlled proteolysis, and the anaphylatoxins were reported to increase the levels of MMP-1 and MMP-9 in monocytes^[126] and to be secretagogues of MMP-9 from granulocytes^[127].

Both C3aR and C5aR are found on cultured endothelial cells, but these mediators use different signal transduction pathways and the response to C3a is more transient^[52]. Both the anaphylatoxins up-regulates chemokine production in endothelial cells^[53], but only C5a is chemotactic for human umbilical vein endothelial cells (HUVECs)^[52] and microvascular endothelial cells^[54]. Moreover, it was reported that C5a could induce not only migration of cultured microvascular endothelial cells but proliferation and ring formation as well^[128].

C3a and C5a were found to increase vascular endothelial cell growth factor (VEGF) in human culture retinal pigment epithelial cells, and when the anaphylatoxins were injected intravitreally into normal mice, an increase in VEGF within the retinal pigment epithelial-choroid layer of the retina was observed^[80]. Others found that C5a but not C3a induced VEGF synthesis and secretion from a retinal pigment epithelial cell line^[129]. Furthermore, both C3a and C5a were reported to induce production and secretion of VEGF from MSC^[91]. Although there is no *in vitro* evidence that C3a and C5a are directly angiogenic, they have been shown to be angiogenic in *in vivo* situations^[80,130,131], perhaps in response to angiogenic factors that the anaphylatoxins induce in cells in the proximity as just described.

In summary, C3a and C5a can contribute to the inflammatory and proliferative phases of angiogenesis, and thus the anaphylatoxins can be viewed as factors with indirect angiogenic potential; however, it is necessary to mention that one publication is in apparent contradiction to this view, namely investigators studying experimental retinal neovascularization published that C5a is anti-angiogenic^[132]; however, these investigators were examining murine models of retinopathy of prematurity and hypoxia induced retinal vascularization, and these observations though correct may not be of a

general nature.

ROLE OF COMPLEMENT ACTIVATION IN SPECIFIC REPAIR PROCESSES

Role of complement activation in liver regeneration

Although tissue regeneration is very limited in mammals, the mammalian liver has retained an amazing capacity for regeneration following viral infection, exposure to toxins or surgical resection. This regeneration can occur at the hepatocyte level in cases of acute liver injury, although liver stem and progenitor cells appear to contribute in more chronic conditions.

The complement activation products C3a and C5a play an essential role in regeneration of the liver parenchyma^[87,95]. After experimental CCl₄ induced liver toxicity or partial hepatectomy, mice deficient in C3 or C5 exhibited defective regeneration and a higher frequency of mortality^[87]. Furthermore, C5a was demonstrated to be a growth factor for regenerating hepatocytes, and blockage of the C5aR in experimental liver regeneration experiments resulted in the inability of hepatocytes to proliferate leading to defective liver restoration^[58,94].

However, the role of complement activation is a double-sided sword in hepatic regeneration and the MAC was found to be the principle mediator of hepatic ischemia reperfusion injury^[133], which creates a dilemma, since the early components of complement activation, C3a, and C5a are necessary for liver regeneration. However, targeted inhibition of MAC formation with CR2-CD59 significantly improved survival after partial hepatectomy in mice^[133], while retaining the benefit of complement activation and anaphylatoxin production.

EFFECTS OF COMPLEMENT ACTIVATION ON MSC AND OTHER MESENCHYMAL CELLS

MSC and tissue repair

MSC are rare, often perivascular cells found in all tissues that are able to differentiate into all types of connective tissue lineages including osteoblasts, adipocytes and chondrocytes. Furthermore, these cells produce a variety of angiogenic and trophic factors^[134,135] and possess anti-inflammatory properties^[136-138]. Owing to the immune-evasive properties of MSC, allogeneic MSC transplantation is generally accepted. Because of all these properties MSC have started to find clinical application in a variety of diseases ranging from myocardial infarction^[139] to graft vs host disease^[140] and have found attention in the context of acute lung injury^[141].

Limitations of MSC therapies as used today

However, in the rush to the clinic, survival of the transplanted MSC has not been sufficiently considered, and there have been failed clinical trials using MSC - in spite of promising results in animal models^[142-146],

and the full regenerative potential of these cells has not been harnessed due to poor tissue homing and limited cell survival following transplantation. Successful clinical trials will require additional information about the mechanisms by which MSC repair injured tissues, about the optimal route of administration, and about means of increasing their survival at a site of tissue injury. It is surprising, how little there is known about MSC recruitment and survival *in vivo* for a cell type that is being investigated in numerous clinical trials. Various means of improving MSC homing^[147], growth factor production^[148,149] and survival^[150] are being pursued as ways to improve the therapeutic efficacy of MSC, but usually different means are used to achieve each one of these goals. It is hypothesized here that C3a can improve all of these functions, since we postulate that the C3a-dependent regenerative capacity of MSC seen in amphibians^[92] has been preserved in mammalian tissue repair.

MSC and complement activation

Although MSC have various anti-inflammatory and immune-evasive properties^[151] - including the ability to inhibit the proliferation of allogeneic T cells, low levels of expression of MHC class I and II proteins, the ability to convert inflammatory M1-type macrophages to repair-type M2 macrophages, and secretion of the complement-inhibitory factor H^[152], - they are not fully protected from complement induced injury themselves, and complement activation appears to be involved in the demise of MSC following allogeneic transplantation^[151,153]. One would wish that such basic complement biology had been considered before using allogeneic MSC in clinical trials. Incubation of MSC with complement active human plasma resulted in the deposition of C3c and iC3b on the cell surface of the MSC and C3a and soluble C5b-9 detection in the supernatant^[90], indicative of complement activation, which could be prevented by various means of complement inhibition.

In addition, MSC as well as osteoblasts express components of the complement cascade themselves^[154] including C3, C5^[155], the C3aR and C5aR^[61] and the cell surface complement regulators CD46, CD55, and CD59^[155]. Furthermore, MSC engineered to up-regulate CD46, CD55, and CD59 protected these cells from complement-mediated cell lysis *in vitro* and *in vivo*^[156].

Effect of C3a and C5a on MSCs

MSC show tropism for areas of tissue damage^[157,158], but it is controversial which chemotactic factors are responsible for this. In leukocytes a large degree of cell recruitment to an area of tissue injury depends on chemokines and C5a, but the role of chemokines in trafficking of MSC is unclear with widely contradictory findings^[158-162]. Since MSC are chemo-attracted by C3a and C5a *in vitro*^[61], we hypothesize that complement activation is an important player in attracting MSC to an area of tissue damage *in vivo*. C3a and C5a can be locally generated at the surface of MSC which contact serum^[90]

in close proximity of C3aRs and C5aRs expressed by MSC; it is possible that this may circumvent access to CPN-mediated inactivation of the anaphylatoxins C3a and C5a. In addition to being potent chemoattractants for MSC^[61], C3a and C5a increase the survival of MSC under conditions of oxidative stress^[61], which would be encountered in an area of tissue injury. Indeed C3/C3a may be a survival factor for MSC^[163]. Furthermore, C3a, - and to a lesser degree C5a, - induce the production of trophic and angiogenic factors by MSC including VEGF, basic fibroblast growth factor (bFGF), platelet derived growth factor, IL-6, and IL-8^[91], and supernatants from C3a-stimulated MSC are angiogenic for HUVECs *in vitro*^[91]. The increased production of growth factors by MSC stimulated with C3a or C5a was largely due to activation of NF κ B^[91], but in contrast to other cell types, in which C3a and C5a cause NF κ B activation such as monocytes/macrophages^[164], this does not lead to the concomitant release of the inflammatory cytokines TNF- α and IL-1 β , thus converting a normally inflammatory pathway into one that supports regenerative processes. For TNF- α this occurs through promoter inactivation^[165], while IL-1 β production in MSC appears to be blocked at the level of protein processing.

We propose that C3a and C5a play a physiological role in MSC-dependent tissue repair by recruiting MSC to an area of tissue injury, by increasing MSC survival under challenging conditions, and by increasing the production of trophic, angiogenic and anti-inflammatory factors by these cells. It is also suggested that pretreatment of MSC with C3a, -C5a is considered too inflammatory - prior to transplantation may increase the repair capacity of MSC by augmenting the ability of the MSC to survive in an area of tissue damage and by inducing increased production of angiogenic and anti-inflammatory factors.

In addition, it has also been reported that complement C1q is a chemoattractant for MSC^[166].

It is also worth mentioning that C3a and C5a cause prolonged activation of the ERK^[61], Akt^[61], NF κ B^[91], and Stat3^[167] pathways in MSC and other stem cells, which are the same pathways that are activated by bFGF albeit with differing routes of activation, and it will remain to be seen whether C3a or C5a have a similar effect as bFGF in maintaining stem cells in the undifferentiated state as has been suggested for C5a in embryonic stem cells (ESC)^[168].

MSC are not the only mesenchymal cells expressing complement components and responding to complement activation. Myoblasts express the complement components of both the alternative and classical pathways (C1q, C1r, C1s, C2, C3, C4, factor B, factor H, factor I^[169,170], as well as the C3aR, and they spontaneously activate allogeneic complement, but are themselves protected from self-killing due to expression of high levels of CD46 and CD59^[171]. Finally, scratch-injured tenocytes showed increased proliferation and survival in the presence of C3a^[46].

Role of complement activation on bone formation

Consistent with the role of complement activation during limb regeneration in amphibians^[92] described above, it has been suggested some time ago that complement activation may be important in cartilage-bone transformation during fracture healing and that the alternate complement activation pathway may be involved^[172]. Like their MSC precursors, osteoblasts are able to express the key complement proteins C3 and C5^[155] and express the C3aR and C5aR, which both mediate osteoblast migration^[97]. Expression of the C5aR was highly up-regulated during osteogenic differentiation^[97], but later during osteoblast to osteocyte differentiation complement genes were greatly down-regulated^[173].

Although osteogenic differentiation of MSC can occur in the absence of C3a or C5a, it is accelerated in the presence of C3a or C5a in a C3aR and C5aR-specific fashion as shown with receptor-specific inhibitors in Figure 2A: After two weeks of osteogenic differentiation in the presence of fetal calf serum (FCS) that was not heat-inactivated, *i.e.*, complement proteins had not been inactivated, Alizarin red staining of calcium salt deposits indicated moderate staining in FCS, which was significantly augmented, when C3a or C5a had been added to the media. However, by 3 wk the difference between these groups was largely diminished (results not shown). If heat-inactivated FCS (FCS) replaced the FCS, osteogenic differentiation was still further delayed but the addition of C3 or C5 partially substituted for the presence of serum complement components (Figure 2B) indicating that the differentiating cells themselves must have provided the necessary complement components.

Consistent with these *in vitro* findings, delayed fracture healing was observed in C3 or C5-deficient mice which received a standardized femur osteotomy^[174]. C5-deficiency also resulted in poor quality bone^[174], indicating that complement activation plays an important role in fracture healing. However, under chronic conditions the osteogenic effect of complement activation is a double-edged sword, because it can also result in vascular calcification during the atherosclerotic process, where MSC-derived C5aR participation has been shown recently^[175].

Role of complement activation in cardiac repair

Following cardiac infarction extensive necrosis of ischemic cardiomyocytes activates complement. The ensuing infiltration of the infarct zone with neutrophils and monocytes serves to clear the injured site from dead cells and debris, and initiates reparative pathways.

However, there is little doubt that complement activation plays an injurious role in the acute phase of myocardial infarction mostly in the context of C5a-mediated reperfusion injury and neutrophil influx^[176-178], but clinical trials inhibiting at the level of C5 have been unsuccessful^[179] indicating that even in this early phase, complement activation is not all deleterious.

Figure 2 Complement activation accelerates osteogenic differentiation of bone marrow mesenchymal stem cells. MSC were cultured in osteogenic media (α -MEM containing 16.5% FCS, not heat inactivated, 10 nmol/L dexamethasone, 20 mmol/L β -glycerolphosphate, and 50 μ mol/L ascorbic acid 2-phosphate) for the indicated time. Osteogenesis was detected by alizarin red S staining. A: All cells were cultured in the presence of the carboxypeptidase inhibitor 2-mercaptomethyl-3-guanidinoethylthiopropionic acid (80 nmol/L) to maintain C3a and C5a activity. C3a (100 nmol/L) or C5a (10 nmol/L) were added during the first 3 d of cultures in the presence or absence of the C3aR inhibitor SB290157 (1 nmol/L) or the C5aR inhibitor W-54001 (1 nmol/L). Both C3a and C5a accelerated calcification in a C3aR and C5aR specific fashion as detected by Alizarin red staining on day 14; B: Osteogenesis was considerably delayed in heat-inactivated FCS (FCS), in which complement components are inactivated. Addition of either C3 or C5 partially reconstituted the effect of FCS. Alizarin staining on day 21; C: Quantitation of the alizarin staining of figure 2B following solubilizing in acid SDS solution. FCS: Fetal calf serum; MSC: Mesenchymal stem cells.

Furthermore, even C5a appears to be protective in several models of cardiac hypertrophy, where C5/C5aR knockout mice fared worse than wild type mice^[180].

The beneficial effect of complement activation becomes more apparent in the more chronic situation, where complement activation contributes to tissue

repair^[181]: C3-deficiency in C3 knockout mice exacerbated myocardial dysfunction four weeks after coronary artery ligation showing more scar tissue, and decreased cardiac stem/progenitor cells (CSPC) in the infarct zone^[181]. Both murine and human CSPC express C3aR and C5aR, are chemo-attracted by C3a

and C5a, and show greater proliferation in the presence of the anaphylatoxins^[182]. It remains to be seen, whether they also produce more angiogenic factors as described above for MSC stimulated with C3a or C5a, which would be a further advantage in the context of cardiac repair. In CSPC C3a or C5a also induced several genes associated with - unwanted - myofibroblast differentiation *in vitro*^[182], but it remains to be seen, whether this is relevant *in vivo*.

Effect of complement activation on HSC

Like any tissue damage, myeloablation by radiation or chemotherapy activates complement resulting in the generation of the complement activation peptides C3a and C5a^[59,60]. Following bone marrow transplantation fast and efficient homing to and engraftment in the bone marrow is important. In this scenario SDF-1 is the most important chemotactic factor, which chemo-attracts hematopoietic stem and progenitor cells (HSPC) to the bone marrow and retains them there through the CXC chemokine receptor 4 on these cells^[183,184].

While HSPC express the C3aR, C3a itself does not appear to be a direct chemo-attractant, but it augments the chemotactic responsiveness of HSPC to gradients of SDF-1 as well as to sphingosine-1-phosphate and ceramide-1-phosphate^[59,60,185,186]. *In vivo*, mice deficient in complement C3 exhibited delayed engraftment of HSPC^[60]. This effect was specifically mediated by the C3aR as shown when HSPC from C3aR^{-/-} mice were injected into irradiated wild type mice, which resulted in a significant delay in recovery of leukocytes and platelets and decreased committed progenitors in the bone marrow^[187]. Similarly, engraftment of human CD34⁺ cells treated with a C3aR inhibitor showed impeded engraftment in nonobese diabetic/severe combined immune deficiency mice^[187].

C3a also contributes to the retention of HSPC in the bone-marrow as C3^{-/-} or C3aR^{-/-} mice showed accelerated mobilization of HSPC into the peripheral blood following administration of granulocyte colony-stimulating factor (G-CSF)^[188]. This retention mechanism is not limited to HSPC, but also applies to their neutrophil progeny, and indeed the C3aR protects from ischemic intestinal injury due to reduced neutrophil mobilization, and increased neutrophil accumulation causes exacerbated injury in C3aR deficient mice^[189]. Indeed, decreased neutrophil mobilization in wild type vs C3aR^{-/-} mice may explain the increased mortality observed in C3aR^{-/-} mice in an endotoxin shock model^[190], although the mechanism was not reported for this model.

C5-deficient mice also exhibited impaired HSPC engraftment: In this scenario the role of C5 cleavage leading to the formation of soluble MAC resulted in increased adhesion of HSPC to bone marrow stromal cells and augmented secretion of SDF-1 by the bone marrow stroma^[191]. However, HSPC do not express the C5aR themselves, and C5 deficient mice show

reduced HSPC mobilization following the administration of G-CSF^[192], which causes complement activation. Apparently, granulocytes, which are released into the circulation in response to C5a formation, pave the way for HSPC to egress from the bone marrow perhaps due to MMP9 release, which facilitates HSPC mobilization^[192].

Effect of complement activation on neurons, neural stem and progenitor cells

It has been known for some time that neurons express both C3aR^[193] and C5aR^[194], and that these two receptors protect from neural cell death^[193-195]. This protective effect is not limited to differentiated neurons, but already functions in neural stem and progenitor cells, which express both C3aR and C5aR. C3-deficient mice showed deficits in both basal and ischemia-induced neurogenesis^[2], and C3aR expression was essential for basal neurogenesis^[2], while C5aR expression made no difference in this respect^[196]. Consistent with these results, C3a protected from ischemic insult-induced memory impairment in neonatal mice^[197].

In vitro, C3a could induce neuronal differentiation of neural progenitor cells^[89], and increased the chemotactic response to low concentrations of SDF-1^[89] similar to the situation with HSPC. In addition, C3a protected from NMDA neurotoxicity, but only in the presence of astrocytes^[198], which suggests that C3a-stimulated astrocytes, which express the C3aR^[199], were the primary target, and that they in turn protected through the production of NGF and other neurotrophic factors^[200]. However, in a mouse model of ischemic reperfusion injury, C3aR inhibition had the opposite effect resulting in increased neuroprogenitor proliferation and suppressed T cell infiltration^[201]. The reasons for such opposing results are not clear, although it is possible that the last model includes a larger inflammatory response that may cancel out any direct effect of C3a on neuronal progenitors and/or astrocytes. Specific pathways by which complement activation protect neural stem and progenitor cells await further elucidation.

Interestingly complement C1q, - in the absence of other components of the complement cascade increased neuron viability and neurite outgrowth and prevented α -amyloid-induced neuronal death *in vitro*^[202] and *in vivo*^[203]. Neuroprotection was promoted by activation of the transcription factor cAMP responsive element binding protein and by increasing LRP1B and GPR6 expression^[203]. Furthermore, in retinal neurons, TGF- β signaling regulates C1q expression, which in turn is necessary for synaptic pruning^[204]. Indeed, complement activation plays a role during a process called synaptic elimination in new-born mice^[205], where either C1q or C3 deficiency resulted in failure of synaptic elimination^[205], implying the classical complement cascade in this process. Interestingly, C1q^{-/-} mice presented with signs of epilepsy due to increased excitatory synaptic connectivity^[206].

Complement involvement during embryonic development

ESC only express a limited number of proteins of the complement cascade including C6, C7, C8, C9, factor I, H, properdin/factor D, and complement component 1r, s and q receptor, and beta polypeptide^[207,208]. However, a recent report indicates that they may also express C5 and the C5a receptor^[168] and more importantly that C5a promotes survival and maintenance of the pluripotent state of ESC in the absence of bFGF^[168], the standard addition to maintain human ESC in the undifferentiated state. While this report awaits further validation, it highly suggests that complement activation presumably with the support of maternal complement components plays a role in embryonic development from the very beginning.

It is known that the maternal complement system plays a crucial role starting early on during fetal development and that it is essential for the maintenance of fetomaternal tolerance. In mice Cr1/Crry (complement regulatory protein) deficiency is embryonically lethal, but the embryos are rescued in C3-/- mothers^[209]. Indeed, ESC are more susceptible to complement mediated cell lysis than differentiated cells, and this pathway may contribute protection from teratocarcinoma formation during pregnancy^[210]. Complement activation has, however to be finely regulated during pregnancy, since excessive activation of this pathway in later pregnancy is associated with miscarriage^[211] and preeclampsia^[212-215].

There is limited knowledge about the role of complement in early vertebrate development with much of the information derived from lower vertebrates. While further investigation using mammalian models is surely required, the existence of these complement pathways during amphibian development indicates that complement activation is a phylogenetically preserved ancient process during embryogenesis. In xenopus complement components are extensively expressed during development starting during the gastrula/early neurula stage^[216] with organ-specific expression patterns during early organogenesis. C1qA, C3 and C9 are strongly expressed in the early neural plate, while C1qR and C6 are expressed at the periphery of the neural plate presumably in the neural crest^[216,217] preceding the development of hematopoiesis. At this point C3 and C3aR show a predominantly mesodermal expression. Interestingly, neural crest cells, a multipotent embryonic cell population undergo epithelial to mesenchymal transition (EMT) in xenopus and zebrafish in a fashion reminiscent of metastasizing cancer cells and it is following this EMT transition that they express both C3 and the C3aR^[93]. These cells form cohesive clusters of migrating cells that are co-attracted *via* C3a and the C3aR and this process is necessary for collective migration of these cells^[93] suggesting that C3aR/C3a contribute to the intricate mass cell movements of the developing embryo.

In rats C3 derived from the visceral yolk sac is an embryotrophic factor between days 9.5 to 11.5 post

conception^[218], - however no further details have been elucidated.

Evidence for a role of C3a in fetal tissue regeneration comes from studies on embryonic chick retina regeneration. In this model C3a can induce complete regeneration of the ablated chick retina from stem/progenitor cells *via* Stat3 mediated up-regulation of IL-6, IL-8, and TNF- α ^[219]. However, there was an optimal concentration of C3a that induced regeneration, while very high concentrations caused apoptosis, indicating that fine-tuning of the C3a/C3aR axis is necessary, perhaps not surprising since the cytokines produced by C3a stimulation may serve as growth factors at low concentrations, but become highly inflammatory at higher concentrations.

Beyond the early effect of C5a stimulation on ESCs mentioned above, C5a and the C5aR play a continued important role during mammalian development: They are both expressed during the period of neurogenesis in mice and humans^[220], and while C5aR knockout mice show no congenital defects under normal pregnancy conditions, they present with a wide variety of congenital malfunctions due to neural tube defects ranging from anencephaly to scoliosis and anophthalmia, if the mothers are folate deficient^[220].

Soluble complement C5b to 9: Possible roles for vitronectin and clusterin in wound healing and stem cell biology

Complement evolved to destroy microorganisms, and one effector outcome of complement activation is the assembly within target cell membranes of a multiprotein complex referred to as the MAC. This consists of one molecule each of C5b, C6, C7, C8 and multiple copies of C9 (6 or more). In its complete form the MAC creates a transmembrane pore of 100 Å that destroys the functional integrity of cellular membranes^[221,222].

In the absence of proximal phospholipid membranes the terminal components of complement form a soluble complex referred to as Soluble complement C5b to 9 (SC5b-9), which was initially described as having a composition of one molecule each of C5b through C8 and three units of C9 and vitronectin^[223]. Later it was also shown to contain clusterin (apolipoprotein J)^[224], which is known to be a component of a subclass of high-density lipo-protein (HDL) particles^[225]. Although the term "SC5b-9", as originally conceived designated a soluble form of the terminal complement complexes, it is probable that these assemblies are heterogeneous with some containing vitronectin and others clusterin presumably associated with HDLs. Whether heterogeneous or not, indications exist that these macromolecular composites may be adaptive for recovery from injury.

Vitronectin, a known matrix and adhesive protein, circulates in human plasma in an inactive state in which its heparin linkage region and integrin binding site, containing the canonical Arg-Gly-Asp sequence, are buried^[226,227]; however, as a consequence of

oligomerization and conformational change these regions on the protein can interact with glycosaminoglycans (GAG) and integrins^[228,229]. GAGs are a fundamental constituent of the extracellular matrix that will necessarily become exposed upon tissue damage. Furthermore, vitronectin binding integrins, $\alpha\beta_{1,3,5,8}$ and $\text{IIb}\beta_3$, are found on a variety of cells responsive to injury inclusive of platelets, fibroblasts, myoblasts, vascular smooth muscle cells, and endothelial cells^[230-232].

Thus incorporation of plasma derived vitronectin into damaged ECM can be seen as a beneficial response that facilitates wound healing because this arrangement can help dock and anchor restorative cells. Furthermore, because vitronectin is known to bind growth factors such as insulin like growth factor^[233], it may be speculated that vitronectin in context of SC5b-9 could deliver the growth mediators to a wound site.

It is also conceivable that complexes of SC5b-9 containing clusterin may also contribute to host recovery from injury. Clusterin is found in HDL containing apolipoprotein A-I but not apolipoprotein A-II^[224,234-237]. HDL particles are highly heterogeneous, and whereas HDLs were originally ascribed to function for reverse cholesterol transport, it is now realized that these operate for a diversity of biological roles inclusive of transport of hormones and bioactive lipids, inflammation regulation, clearance, and immune defense against parasites and microorganisms^[238-241].

Although investigations about the interface of HDLs and stem/progenitor cell biology are just commencing, a few publications suggest that this will be a fruitful topic for future research. For example HDL can promote MSC proliferation by interaction with Scavenger receptor class B member 1^[242]. Also HDL have been shown to advance endothelial cell precursor migration and proliferation^[243].

We leave it an open question as to whether HDL-associated SC5b-9 can facilitate wound healing through influence on stem and progenitor cells.

CONCLUSION

Although complement is best known for its role in inflammation, increasing evidence has accumulated that emphasizes that complement activation and in particular the complement split products C3a and C5a play a role in many scenarios of tissue repair. Table 1 shows a compilation of cell types expressing C3aR and C5aR and the function of these receptors on any particular cell. However there are still many gaps in our understanding of the role of complement activation outside the inflammatory axis. A more complete understanding of the effects of complement activation in stem cell biology will contribute to improve the therapeutic potential of these cells.

Abstract

Endogenous "stem cell niche" (SCN) accompanying vessels contains immune system components which *in vivo* determine differentiation of multi potent stem cells toward proper cell types in given tissue. Combinations of sex steroids may represent novel chemical approach

for neuronal areas of regenerative medicine, since they cause transformation of vascular smooth muscle stem cells into differentiating neuronal cells. Circulating sex steroids are present during pregnancy and can be utilized where needed, when various embryonic/fetal tissues develop from their stem cells. Utilization of induced regeneration of tissues (regenerative medicine) is expected being more effective in sudden failures of younger individuals carrying intact SCN, as compared to established chronic disorders caused by SCN alteration. An essential component of SCN are monocyte-derived cells exhibiting tissue-specific "stop effect" (SE) preventing, for instance, an aging of neuronal cells. Its alteration causes that implantation of neuronal stem cells will also result in their differentiation toward aging cells. When we repair the SE by supply of circulating mononuclear cells from young healthy individuals, we may be able to provide novel regenerative treatments of age-induced neural diseases by sex steroid combinations. Questions regarding some age-induced body alterations are also addressed.

Core tip: Sex steroid combinations have been found to transdifferentiate *in vitro* the vascular smooth muscle cells into neurons. Therefore, utilization of sex steroid combinations may enable regeneration of neural tissues affected by acute/traumatic disorders. In aging individuals, however, an altered immune system components in the stem cell niche may be unable to preserve regenerating cells in the functional stage due to the immune system regression with age advancement. This could be improved by transfer of blood mononuclear cells from young healthy individuals. Beside that, the local and systemic utilization of honey

bee propolis alone has been found to ameliorate some age-induced disorders.

INTRODUCTION

To deal with regeneration of tissues, we need to better understand their preservation in the appropriate functional state. Under normal embryonic and fetal development, the normal tissue function is established and programmed to last for certain period of subsequent life. In other words, even in normally developed individuals, functional longevity in distinct tissues is different. The most extended functional tissue life is established for such tissues that evolved functionally as earliest, and the opposite applies for those which functionally developed as the latest, with variations between these states. For instance early developing functional human heart can work for one hundred years, while the proper function of late developing fetal ovary will last for a much shorter period. In reality, the ovarian dysfunction is initiated between 35 and 40 years of age, due to the age-induced alteration of the ovarian stem cell niche (SCN). Due to the absence of corpora lutea during fetal immune adaptation toward self tissues, they are considered to be a "graft", which results in their cyclical rejection during menstrual cycles in adulthood (reviewed in^[1]). The corpus luteum rescue during pregnancy accompanies immune tolerance of fetal allograft, and both effects required for successful pregnancy are considered to be caused by trophoblast-derived chorionic gonadotropin and other endocrine factors^[2,3].

The perivascular tissue-specific SCN enables regeneration of tissues from endogenous stem cells. We still do not have a detailed information regarding role of SCN in distinct tissues. The intent of the current regenerative medicine is to deal with a replacement of dysfunctional cells with various types of exogenous stem cells, utilizing for instance induced pluripotent stem cells (iPSCs), embryonic stem cells (ESC), or somatic stem/progenitor cells, which are able to differentiate into functional cells of particular tissue^[4]. Such an approach, however, carries a number of complications, including ethical concerns, immune responses toward implanted cells, possibility of teratoma development, lack of ability of implanted cells to regenerate, failure of their cell cycle, lack of their preservation in functional stage, and apoptosis^[5-7]. Moreover, most attempts to establish ESC from large mammals have failed^[8] and human iPSCs develop into teratomas when tested in immunosuppressed animals^[9]. Recent observation also indicates

that iPSCs carry a genome methylation memory of their former differentiation history, which might alter their therapeutic utilization^[10].

Another possibility is to stimulate autologous pluripotent stem cells to develop *in situ* into functional cells. Such approaches eliminate some of the hurdles mentioned above but don't deal with concerns about the success of the return of regular tissue function^[5]. Chronic disorders are expected to be caused by an altered tissue-specific SCN which causes permanent tissue damage. Of particular interest are SCN alterations stimulating degeneration of functional tissue cells toward apoptosis in degenerative diseases.

An essential role in the maintenance of tissues by SCN plays so called "stop effect" (SE) encoded at monocyte derived cells (MDC) in tissue-specific manner. The SE enables tissue cells to differentiate into the proper stage for their function, but not beyond. Stage of cellular differentiation needed for proper tissue function differs among the tissues. For instance brain neural cells should be prevented to undergo advanced differentiation toward apoptosis, while superficial cells of epidermal stratified epithelium should differentiate into apoptotic squamous cells for the proper epidermal function and protection. The SE is established epigenetically, during the fetal immune adaptation. Lower or higher cellular differentiation during that period than required for proper tissue function will cause dysfunction of that tissue during subsequent life (reviewed in^[1]). In aging individuals, there is a "shift up" of the SE, causing age-induced functional diseases, *e.g.*, Alzheimer's disease.

In other words, improper function of tissues is caused by altered tissue-specific SCN, and may result in either functional immaturity or aging of such tissues.

Utilization of stem cells alone will not improve altered tissue function unless we will be able to induce the SCN repair^[1] either endogenously or by allogeneic body rejuvenation (reviewed in^[11]).

Utilization of animal models for the treatment of degenerative disorders was slightly encouraging as compared to the human experimental trials^[6], possibly due to the persistence of an unaltered tissue-specific SCN after initiation of a disorder in otherwise normal healthy animals.

WHAT IS THE SCN?

Stem cells in distinct tissues are present in a perivascular location of microvessels as pericytes that function as mural vascular cells^[12]. They secrete growth factors which stimulate constitutional tissue progenitor cells^[12]. Some pericytes exhibit properties of mesenchymal stem cell and exhibit nuclear reprogramming into such cells as testicular Leydig cells^[13], cardiomyocytes^[14], cartilage and bone^[15], and neural and neuronal type cells^[16]. Pericytes and neural cells originate from the neural crest^[17], but from different germ layers. The functional behavior of SCN is modulated by autonomic innervation^[18], which influences numbers of

pericytes and inhibits or enables their activity^[19,20].

Another essential component of the perivascular SCN are MDC accompanying microvasculature. Depletion of MDC in one testis alters differentiation of Leydig cells from their precursors^[21] represented by vascular pericytes^[13]. Circulating CD14+ primitive MDC (pMDC) play important roles in tissue morphostasis, in addition to their roles in the immune responses^[22]. The pMDC enable division of progenitor cells and influence by SE the persistence of tissue-specific cells in the epigenetically encoded particular differentiation state^[1]. Hence, the MDC exhibit several roles in the perivascular SCN.

The SCNs accompanying body microvasculatures represent basic "tissue control units" incorporated into a more complex tissue control system (TCS)^[1], which shows distinct diversity between the tissue types. The tissues differ in their proper stage of cellular differentiation, ranging between stem cells and cellular apoptosis. Extent of cellular differentiation of certain tissues ceases relatively early, e.g., skeletal muscle or brain. A moderate stage of proper cellular differentiation is present in gut epithelium, where intraepithelial lymphocytes are involved, and cellular apoptosis with binding of immunoglobulin is required for the proper function of stratified epithelium of epidermis and uterine ectocervix (reviewed in^[1]).

Developmental tissue alteration prior reaching its functional stage will cause its permanent immaturity, e.g., muscular dystrophy. On the other hand, when differentiation of tissue cells is enhanced toward higher stage then required for their proper function, the autoimmune and degenerative diseases, e.g., rheumatic diseases, atherosclerosis, or Alzheimer's disease, will occur^[23,24].

17 BETA ESTRADIOL IN VASCULAR SMOOTH MUSCLE CELL CULTURES AFTER TESTOSTERONE, PROGESTERONE AND TESTOSTERONE + PROGESTERONE TREATMENT

Our former research^[25] has shown that initial utilization of estradiol (E2) is necessary to induce transdifferentiation of ovarian stem cells (OSCs) and granulosa cells to the neural stem cells (NSC) and neurons following subsequent progesterone (PG) + testosterone (TS) application. However the transdifferentiation was also sometimes observed after PG + TS alone, because of the PG and TS transformation into E2 by aromatase. This possibility was investigated in smooth muscle cell (SMC) cultures. Fresh and spent control medium exhibited E2 1050 ± 150 pg/mL and 1477 ± 742 pg/mL SEM only. However TS pre-treatment caused significant E2 increase (22086 ± 4650 pg/mL) and PG pre-treatment was even three times more efficient (71920 ± 9090 pg/mL). An addition marked E2 increase was

observed after pretreatment with PG + TS (198202 ± 40088 pg/mL)^[16]. This observation indicates that cultures with PG and TS also contain significant E2 levels. It is apparent that vascular SMC contain aromatase capable to cause conversion of PG and TS into E2.

Estradiol is also produced in extragonadal localities, such as vascular SMC and brain^[26]. The SMC associated with vessels exhibit aromatase and 17 beta-hydroxysteroid dehydrogenase type I, which transform estrone produced by aromatase into the final E2^[27]. This indicates that, similarly to *in vitro* experiments, *in vivo* treatment with PG and TS may cause a transdifferentiation of vascular SMC into pluripotent stem cells and induce a differentiation of neural/neuronal cells in those locations, which require that.

THE PG AND TS COMBINATION CAN BE SUFFICIENT

The high PG + TS combination is virtually absent in adult human females or males. The combinations of E2 + PG or E2 + TS we not found to transdifferentiate OSCs or vascular SMC into vascular stem cells and neurons. Suitable sex steroid combinations may, however, be present in the brain as neurosteroids^[28]. Our observations^[16,25] indicate that E2 + PG + TS or PG + TS combinations (assuming E2 is created by aromatase of target cells) could be considered.

During human prenatal development the estrogens, progestogens, and androgens are physiologically present in the circulation of developing fetus^[29]. This indicates that such sex steroid combination is not harmful for the fetal development and it may act where actually needed, e.g., for the proper brain development.

Some studies indicate that utilization of PG limits central nervous system damage after injury, inhibits a loss of neural cells (CNS), and stimulates brain function (reviewed in^[30]). This may be caused by an effect of supplied PG and *in situ* aromatase-created E2. Yet, utilization of PG + TS combination can accelerate levels of E2 and cause vascular SMC differentiation into neural cells. This may work well for injured brain or spinal cord in younger individuals.

VASCULAR SMC

Since vascular SMC accompany as pericytes all vessels, including the CNS, their ability to differentiate into neural cells is of particular interest. Utilization of all three sex steroid combination can cause a fast conversion into pluripotent stem cells. Such cells can thereafter differentiate into mature vascular SMC. These cells, known as vascular pericytes, influence properties of endothelial cells and participate in the functional ability of blood vessels. Pericytes can serve for differentiation of other types of cells^[31]. Collectively, the vascular SMC accompanying capillaries and post-capillary venules^[32] can serve in various sites (brain, muscle, bone marrow, kidney, lung, vessels, liver, thymus and spleen) as

mesenchymal stem cells^[33-36]. The mesenchymal stem cell populations in distinct tissues showed alpha smooth muscle actin expression, which suggests their origin from alpha smooth muscle actin positive pericytes^[37].

Taken together, systemic or local (spinal cord injury) utilization of sex steroid combinations alone can represent a regenerative chemical approach with a perspective of improvement of neurological and vascular diseases, without a need to develop and implant particular stem cells *in vitro*.

A preservation of normal tissue functions continues to decline with age advancement, in association with a decline of the immune system function. For instance it has been shown that the immune system components play an essential role in the renewal of ovarian follicles during the prime reproductive period (till 38 ± 2 years of age), when the human female fertility is well preserved. After that period, however, women's fertility begins to decline along with age-induced alterations of immune system functions, beginning from the age of 35 years^[38]. Due to the cessation of ovarian follicular renewal the ovaries begin to preserve aging oocytes unsuitable for regular or assisted reproduction (reviewed in^[11]).

Simultaneously, additional alterations of certain tissue functions, like type 2 diabetes mellitus accompanied a pathology of pericytes^[39] and degenerative neuronal diseases associated with apoptosis of neurons^[40] may occur due to the age-induced shift up or lost SE of MDC. This indicates that regenerative medicine could be more successful in the treatment of acute tissue alterations in younger individuals with preserved appropriate SE of MDC than in chronic or age induced tissue disorders^[41], unless there is an improvement of altered SE, for instance by a transfer of circulating mononuclear cells from young healthy individuals, as recently suggested^[11].

CELLULAR REGENERATION WITHOUT CELLS

The regenerative medicine of neurologic disorders is currently expected to utilize *in vitro* developed NSC implanted into the CNS with expectation of renewal and repair of altered or degenerated mature neuronal cells. Such cells may be collected from CNS and expanded by growth factors with mitogenic effects^[42,43]. Another origins of NSC are represented by ESC, blood from umbilical cord, amnion cells, stem cells from bone marrow, and blood-derived CD133+ cells^[44-47]. After some passages, such cells can be differentiated into NSC by fibroblast growth factor-1, 12-O-tetradecanoylphorbol-13-acetate, which is an activator of protein kinase C, isobutylmethylxanthine, which is a non-specific inhibitor of phosphodiesterases, and either by forskolin, representing protein kinase A activator, or by all-trans-retinoic acid and 2-mercaptoethanol^[48]. Such substances, however, can't be utilized for an *in vivo* treatment.

Another possibility is a "systemic regenerative therapy" or "*in situ* regenerative treatment" by substances capable to cross blood-tissue barrier, e.g., the blood-brain barrier, due to their low molecular weight.

We have also realized that combinations of sex steroids are capable to transdifferentiate directly vascular SMC cultures, which have been shown to exhibit receptors for sex steroids^[49-51], into the neural and neuronal cells^[16], as pericytes accompany microvasculature of all tissues, including CNS.

It was also observed that appearance of vascular SMC stem cells can be induced by combinations of sex steroids, and such stem cells within few days develop back into mature SMC^[16]. Sex steroids may stimulate renewal of vascular pericytes, which play by themselves an important role in the physiology of vessels. They influence endothelial cell properties and contributions to the proper vascular functions. Moreover, pericytes were considered to represent precursors for certain types of cells^[31], e.g., cardiomyocytes^[14]. Therefore, systemic regenerative treatment may also improve vascular disorders, e.g., type 2 diabetes, which is closely twisted together with microvascular pericytes throughout the body^[52], improve functions of vessels affected by atherosclerosis, and induce regeneration of cardiomyocytes affected by myocardial infarction. Therefore, systemic and *in situ* treatment with sex steroid combinations may represent a novel regenerative approach for the stem cell therapy without the cells.

SEX STEROID ROLE IN THE NEURAL SCN

Depletion of androgens with age advancement in men is accompanied by depression and memory alteration. Decline of TS concentrations several years precede the diagnosis of Alzheimer's disease. The therapy with androgens, however, did not show any improvement of cognitive memory in altered aging individuals. Beside gonads and adrenals, some sex steroids are also produced within the brain. Such sex steroids are eventually called neurosteroids (reviewed in^[28]).

Sex steroids could stimulate neuronal regeneration from persisting NSC, since they cross the blood-brain barrier and associate with their receptors important for the regulation of emotions, cognition, and behavior^[53]. It appears, however, that utilization single sex steroid, such as androgen, does not prevent or treat neuronal degeneration (see above).

COMBINATIONS OF SEX STEROIDS AND REGENERATIVE STEM CELL THERAPY WITHOUT THE CELLS

The consideration of sex steroid treatment provided below is based on the sex steroid doses utilized for other clinical applications. It is recommended that, before any clinical trial, relevant doses of sex steroid combinations are tested in animal studies.

Figure 1 Sex steroid doses and combinations in vascular smooth muscle cell cultures. Reprinted from^[68] with permission, ©Page Press Publications. A-D: Control (A), vehicle (B), high estrogen (E2 60 microM) (C), and high testosterone (TS 60 microM)-treated cultures of vascular SMC showed no morphological changes (D); E: High progesterone treatment (PG 60 microM) was, however, associated with occasional neuronal type cells; F: This was not observed in cultures with diluted progesterone (PG 20 microM); G: Cultures with high PG and high TS showed numerous neural type cells; H: Cultures with diluted PG and high TS showed direct nuclear transdifferentiation into neuronal type cells with branching extensions; I: Diluted estradiol and PG and high TS caused formation of undifferentiated stem type cells. Open yellow arrowheads indicate neural/neuronal type cell bodies, green arrowheads indicate extensions. Green arrowhead in panel I indicates bubble-like anchor. Ctr: Control; E: Estradiol; Ed: Estradiol diluted; P: Progesterone; Pd: Progesterone diluted; PT: Progesterone + testosterone; Veh: Vehicle; TS: Testosterone; PG: Progesterone.

The *in vitro* studies were performed in order to approach a question on which sex steroid combinations and their doses could be effective for the regenerative treatment. Figure 1A and B show that control cultures and media with a vehicle alone exhibited no transdifferentiation into neuronal type cells. When 60 microM E2 (Figure 1C) or 60 microM TS (Figure 1D) was applied, no changes were observed next day after the treatment. The 60 microM PG, however, showed sporadic emergence onset of neuronal cells as indicated by yellow arrowhead in Figure 1E. They exhibited typical neuronal extensions (green arrowheads). Such concentration of PG in tissue culture is relevant to the 16 mg/kg PG density, which was reported to diminish death, gliosis, and functional defects following trauma-induced rat brain alterations^[54]. Therefore, the PG alone could exhibit certain protective effect *in vivo*. Decrease of PG to 20 microM, however, exhibited lack of the *in vitro* effect for an emergence of neural cells - see Figure

1F.

Combination of 60 microM PG with 60 microM TS, caused frequent appearance of small NSC shown by yellow arrowhead in Figure 1G, exhibiting some extensions (see green arrowheads). Therefore, many new NSC could develop using PG along with TS. In other words, the TS significantly potentiated a small PG neuronal effect.

When a reduced dose of PG (20 microM) was utilized with 60 microM TS, the cultured SMC exhibited a transdifferentiation to the well differentiated cells of neuronal type (see yellow arrowhead in Figure 1H) - note the branching extensions indicated by green arrowheads.

The dose of *in vitro* used PG is relevant to PG suppositories (200 mg), utilized 2 times a day to prevent a miscarriage or a preterm labor^[55,56]. Relating the TS dose, it corresponds with weekly intramuscular androgen 600 mg injections, which were tested in human males^[57,58]. Therefore, 400 mg PG daily with weekly 600

mg TS could be considered to treat dysfunctions of CNS.

In vitro utilization of a small concentration of E2 (12 microM) along with 20 microM PG and 60 microM TS, caused a development of many stem type cells in vascular SMC cultures (see yellow arrowhead in Figure 1I) exhibiting bubble-like anchors (green arrowhead). Within few days such stem type cells differentiated backward into typical mature SMC^[16]. Therefore, it is possible to consider that vascular disorders might be treated with such therapy. The E2 12 microM dose used *in vitro* is relevant to 120 mg in humans. For hormone-replacement therapy a transdermal 17 beta-estradiol 50 mg was reported to be used twice a week^[59].

As mentioned above, the pericytes were proposed to represent pluripotential stem cells for other cell types^[31], incorporating cardiomyocytes^[14]. Utilization of all three sex steroids, *i.e.*, PG daily + TS weekly + 50 mg of E2 twice a week during about four weeks could contribute to vascular regeneration after the stroke occurrence or for cardiomyocyte regeneration after the heart infarction.

It is considered that aging humans, and those having a possibility of inherited CNS or heart and vascular alterations, could be prevented by annual PG + TS or E2 + PG + TS combinations used about four weeks to prevent such disorders. Because the E2 could be derived from other two sex steroids, the PG and TS treatment might be sufficient. Such sex hormone supplementation might also be effective for the acute trauma of spinal cord, stroke, or myocardial infarction.

WHAT THE REGENERATIVE MEDICINE OPTIONS MIGHT BE

It is currently expected that the regenerative medicine should replace altered functional cells with newly developed mature cells formed from implanted stem cells or by *in vitro* reprogramming of already differentiated cells from one cell type into a needed distinct one.

In some instances, it might be possible to use the therapy resulting in the *in situ* transdifferentiation of *in vivo* existing autologous progenitor cells, *e.g.*, by substances crossing the blood barrier for the treatment of neurological diseases.

Utilization of exogenous sex steroids could be a preferred option since they are naturally occurring during the life vs other possible chemical approaches for regenerative medicine without the cells. Since regeneration of tissues is dependent on the homeostatic function of the immune system components^[1,60], and the immune system exhibits progressive regression since 35 years of age^[38], the effect of sex steroid combination is expected to be more effective in younger individuals, whose tissues exhibit normal ability to regenerate. Therefore, such treatment could be more effective in sudden traumatic and ischemic disorders of younger individuals exhibiting preserved SCN and TCS exhibiting regular function. In contrast, the degenerative

diseases caused by an altered function of the TCS will not be treatable, unless its normal components are restored, for instance by a blood transfusion from a young healthy individuals (see below).

IS THERE A POSSIBILITY TO AMELIORATE AGING?

Heterochronic parabiosis between aged and young mice was reported to improve the activity of progenitor tissue cells by the blood serum^[61]. Subsequent studies supported this proposal (reviewed in^[11]). The issue of rejuvenation by young blood is, however, more complex than the serum content alone. Blood transfusion, beside serum with immunoglobulins, polynuclear leucocytes and erythrocytes, contains immune system-related mononuclear cells, which are important for the morphostasis of various tissues as the components of the complex TCS^[62]. Numerous studies have shown that the cells of the immune system, beside immunity, participate in regeneration of tissues and healing of the wounds. The TCS is involved in the regulation of tissue-specific cellular regeneration, preservation of developed cells in the proper functional state, and in the maintenance of each tissue in the proper quantity of the cells (reviewed in^[1]).

There are several problems with heterochronic parabiosis. Firstly, this is an animal approach which has no therapeutic use in human beings *per se*. Secondly, long lasting heterochronic parabiosis has been shown to alter the young animal by the old animal blood components^[63]. Thirdly, and most importantly, the utilization of a single dose of blood serum from young to older individual can not be expected to exhibit any long lasting rejuvenation of the recipient's tissues, and the same can be expected after the whole blood transfusion. Regarding the blood transfusion, it can only be utilized as a partial blood volume replacement for two reasons - to prevent an overdose of erythrocytes and to improve a proportionality between the young and aged blood.

Yet, the partial blood replacement with a temporary rejuvenation may have some therapeutic utilization, for instance to temporarily enable gonadal function in order to produce new gametes for the treatment of infertility. Longer lasting tissue rejuvenation after partial blood replacement will require an accompanying stimulation of the immune system morphostatic functions by the honey bee propolis or drugs with similar effects - reviewed in Ref.^[11].

Regarding the role of the immune system related cells in tissue morphostasis, it has been shown that after a partial hepatectomy or unilateral nephrectomy the immune system is specifically activated to repair the liver or kidney tissue depletion. The T lymphocytes initiate and then stop the growth of the liver or kidney until the morphostasis reappears^[64]. Our observations from the ovarian physiology indicate that the active

tissue growth is dependent on pericytes releasing Thy-1 differentiation glycoprotein, the most primitive member of the immunoglobulin gene superfamily^[65]. Activity of pericytes for Thy-1 release is inhibited by vegetative innervation in the sites, where regeneration is not needed. In other words, the neural system regulates proper tissue quantity, and immune system cells stimulate the regeneration when asked to do so by the Thy-1 release from pericytes.

In addition, the incidence of malignant diseases progressively increases with age advancement. Albeit a single accidental consumption of an unprocessed shiitake mushroom caused a common severe skin erythema with pruritus^[66] lasting for a couple of weeks. This immune system systemic hypersensitivity, however, successfully eradicated a rectal cancer. The subsequent weekly consumption of small amounts of unprocessed shiitake mushrooms in salads was without skin reaction and prevented cancer relapse and any occurrence of malignancy for many years thereafter^[67].

An elaborated immunotherapy, consisting of human gammaglobulin to unblock antibodies against alloantigens, a single dose of cyclophosphamide to eliminate immune system support of cancer progression (see Ref.^[1]), followed by two separate blood transfusions to enhance immune system reactivity against cancer alloantigens, and weekly intradermal applications of Bacterinum adnexitidicum to booster a reversion of immunosuppression, was capable to induce within few months a gradual regression of advanced human ovarian cancer, including complete regression of ascites and severe liver metastases, accompanied by a regeneration to the regular liver size (for details see Ref.^[67]).

CONCLUSION

Available data indicate that sex steroid combinations will represent a novel approach of regenerative medicine enabling stem cell therapy of neuronal alterations without the cells. In other words, this approach can enable utilization of endogenous pluripotent cells to differentiate into new neurons where needed. Sex steroid levels are high during pregnancy in both the mother and the fetus, and do not alter their bodies in general, but contribute to the fetal development and its immune tolerance by the mother. Utilization of sex steroids in aging individuals exhibiting alteration of neuronal tissues may, however, not be effective, unless its morphostasis mediated by the immune system, is improved. A combined treatment with sex steroid combinations to enable a transdifferentiation of vascular pericytes into neuronal cells, and with a partial blood replacement (500 mL blood withdrawal with immediate replacement of the same fresh blood volume from the young healthy individual) can cause a temporary brain tissue rejuvenation, possibly including improvement of the Alzheimer's disease. To preserve the achieved regeneration will require a permanent utilization of drugs stimulating immune system role in normal tissue

morphostasis, as reported for the honeybee propolis.

The age advancement is also accompanied by malignancy development. Early cancer development in untreated individuals can be eradicated by a consumption of unprocessed (rough) shiitake mushrooms. The regression of advanced and metastasizing cancers in otherwise previously untreated patients could be achieved by an elaborated immunotherapy. The patients who had undergone a prolonged and/or high dose or long lasting cytostatic therapy, high dose irradiation, excessive surgery, and exhausted cases close to death, are unlikely to respond the elaborated immunotherapy of cancer.

Abstract

Stem cells are of global excitement for various diseases including heart diseases. It is worth to understand the mechanism or role of stem cells in the treatment of heart failure. Bone marrow derived stem cells are commonly practiced with an aim to improve the function of the heart. The majority of studies have been conducted with acute myocardial infarction and a few has been investigated with the use of stem cells for treating chronic or dilated cardiomyopathy. Heterogeneity in the treated group using stem cells has greatly emerged. Ever increasing demand for any alternative made is of at most priority for cardiomyopathy. Stem cells are of top priority with the current impact that has generated among physicians. However, meticulous selection of proper source is required since redundancy is clearly evident with the present survey. This review focuses on the methods adopted using stem cells for heart diseases and outcomes that are generated so far with an idea to determine the best therapeutic possibility in order to fulfill the present demand.

Key words: Bone marrow stem cells; Mesenchymal stem cells; Induced pluripotent stem cells; Heart diseases; Progenitor cells; Stem cells

Core tip: Heart diseases are most common all over the world and any form of treatment would be well appreciated to enable successful well-being in the patients. Though there are enormous efforts attempted to handle heart diseases, there has been no propounded evidence so far to utilize a particular source of cells globally. In this regard, if the responses all over the

world are collectively segregated to a global database, there may be options to identify the best suitable cell source that provides effective cure.

Stem cells: An eventual treatment option for heart diseases. *World J Stem Cells* 2015; 7(8): 1118-1126 Available from: URL: <http://www.wjgnet.com/1948-0210/full/v7/i8/1118.htm> DOI: <http://dx.doi.org/10.4252/wjsc.v7.i8.1118>

INTRODUCTION

Cardiac diseases have become a major cause of death worldwide^[1-4]. Common causes of heart failure are ischemia, hypertension, coronary artery disease and idiopathic dilated cardiomyopathy. Up to 40% of cardiac patients are predominantly affected by diastolic dysfunction, although the left ventricular (LV) systolic function is mostly unaffected^[5]. There are established medical and surgical procedures available for cardiac patients but these standard therapeutic modalities have not been much responded^[1,6,7]. Cardiac risks are also associated with other complications^[8-10], which thus gives an steady increase in the number of patients looking for an effective treatment option that can sustain their normal well-being. There is an urge for alternative therapies that can fulfill the present overwhelming demand^[6,11]. Cardiac diseases trigger damage to cardiomyocytes that affects the heart muscles and there is a possibility of scar formation that will overload the blood flow and eventually stretch the cardiac cells. This ultimately leads to heart failure and commonly, deaths^[12].

The current situation is therefore mostly favorable for alternative treatment possibilities that can improve the disease considerably at least with respect to the rate of survival or quality of life^[13-15]. Recent evidence on cell based therapies has suggested improvement in cardiac function and regeneration of the damaged tissue^[16]. It is stated that cell therapy has got potentials to do what standard drugs cannot do by replacing the damaged tissues with healthy tissue. Drugs have been demonstrated to slow the progression of heart failure, but none have shown their potential in reversing the process. However, the physiological perspectives have not shown any clear picture with cell therapies as it is difficult to estimate the cell survival and monitor cells *in vivo*^[17,18] along with their low engraftment rate^[18]. Valid doubts and concerns are raised for the existing use of stem cells for heart diseases and it is elaborated that although regenerative medicine has lots of hopes, results have not substantiated their importance in the in-house tentative studies^[19]. There are some important factors that need to be considered such as appropriate selection of the cell type, number of cells required and appropriate route of administr-

ation that can help regeneration. Routes of injection generally include catheter-guided transendocardial, intracoronary, transvenous, and transepicardial injections^[20]. The selected cells should have a control over their migration, proliferation and differentiation *ex vivo* and also *in vivo*^[21]. Even though the mechanisms of action pertaining to cell therapies are not very clear, studies in comparison with routine therapies have shown promising results by significantly improving vessel density, inhibiting apoptosis of myocytes, and decreasing fibrosis and increasing survival rate even in non-ischemic heart failures^[22,23]. There are other reports available with similar strategy to improve the survival of transplanted cardiac progenitor cells^[24-27].

The progress of cell therapy is reported in Mayo Clinic proceedings as breakthroughs that have reached certain milestones and expectations that have a high prospect towards imminent benefits. The six major breakthroughs are summarized as: (1) safety establishment in intracoronary delivery; (2) possibility of therapeutic regeneration; (3) allogeneic cell therapy; (4) increasing mechanistic insights; (5) sparkling clinical efficacy; and (6) progress to phase 2 and 3 studies^[28]. Cell therapy has shown enormous progress since its application in 1998 and this lightning speed is progressing towards eliminating the underlying cause of heart failures and handling the control over the damage^[29]. Different cell types have been used to treat heart diseases^[30-32]. There are potential benefits with the application of cardiac progenitor cells and induced pluripotent stem cells (iPSCs) as a promising approach to bring true myocardial regeneration^[30].

The advent of iPSCs is also under remarkable consideration to model heart disease^[33]. Stem cells have been suggested to be promising new therapeutic usage for heart diseases because of their remarkable proliferative and differentiation capacity that can supply specific cell types along with the viable functioning of heart muscles^[12]. Evidence has shown that resident cardiac stem cells have got potentials to turn into cardiomyocytes *in vivo*^[31]. There are other well-known and commonly available sources of progenitor cells from bone marrow, adipose tissue, and skeletal muscle or cells circulating in blood that are capable of improving myocardial function^[11,34].

Although there are waves of research undertaken with stem cells or any cell therapy applications, *in vitro* studies are required to explore which is of high priority to advance with the strategies to tailor clinical applications and the task is highly challenging^[35]. Appropriate selection of patients, informed consent and periodic patient monitoring are important factors to be reviewed by expert panel independent of investigators while opting for clinical trials^[36,37]. While manufacturing stem cells, parameters like screening and testing for pathogens have to be carried out with utmost precision. Generation of consistent batches while manufacturing is highly recommended for therapeutic derivative of stem cells and this has to be carried out in aseptic conditions

withstanding robust quality programs that qualify regulatory expectations which are suitable for clinical use in patients. It is also necessary to validate the procedures for transplant and confirm the regeneration of infarcted heart^[38,39]. Overall, it is expected that the strategies adopted from routine therapies into stem cell-based therapies, have glorious potentials to increase the efficacy of treatment^[40]. This review thus focuses on the studies attempting to assess various alternative therapeutic applications for heart diseases and to suggest the best suitable and effective source that has produced better success rate.

CURRENT PROGRESS IN ROUTINE THERAPIES

Heart disease continues to be the main cause of death though there is a considerable decline in the death rate with the advancement in medicine since 1999. Nonetheless, medical care has not been successful in reversing the loss of functional cardiomyocytes^[41]. The surgeries being attempted for diagnostic cardiac catheterizations, coronary artery bypass graft procedures, cardiac pacemaker procedures, percutaneous transluminal coronary angioplasty procedures and heart valve procedures are all very expensive since they require hospitalizations, post-surgical care, etc. They consume enormous time to handle the recovery process. Still, evidence suggests that cardiovascular diseases are not prevented though the lethality has been reduced considerably^[42]. Presently, the treatment options vastly carried out for cardiovascular function include organ transplantation, surgical reconstruction, and usage of mechanical or artificial devices or administration of metabolically derived products^[43]. Benefits have been associated with inotropic therapy, ventricular assist devices and hospice care. Recommendations are given towards the use of angiotensin-converting enzyme inhibitors as a first line of treatment in patients with reduced LV systolic function with ejection fraction $\leq 35\%$ -40%^[44]. For normal ventricular ejection fraction, beta-blockers, isosorbide dinitrate plus hydralazine are being considered^[45].

In this context, researchers have been encouraged to identify better strategies to image the detection and monitoring of cardiovascular disease progression. Biotech industries have also been progressing in different scenarios with other therapeutic possibilities which with mutual understanding between the pharmaceutical industries and medical specialists, may aim to bring options that provide immediate recovery along with cost effective strategies^[3,46]. Interest relies on the targeted delivery of alternatives such as stem and progenitor cell populations that has also kindled the combinatorial use of genes to treat cardiovascular diseases. However, challenge depends on the host environment where it has poorly retained the survival of implanted cells and thus it requires the delivery of

cells transfected or transduced *ex vivo* with genes that can enhance resistance to apoptosis in order to provide protection from the stressed microenvironment that can enable the improved function of the engrafted cells to appreciate better therapeutic outcome^[47].

ROLE OF ALTERNATIVE MODALITIES IN RESTORATION OF HEART FUNCTION

Mesenchymal stem cells

Even after maturation, cardiomyocytes have limited flexibility. The recovery of heart function after structural damage is less possible. Mesenchymal stem cell (MSC) therapy is predicted to be a promising area of research for regenerating damaged cardiac tissues. MSCs lack both major histocompatibility II and T-cell co-stimulatory signal expression and thus are immune-privileged. When MSCs are delivered systematically, they own a unique ability to enter into the specific sites of myocardial damage. There are mechanisms by which MSCs promote cardiac tissue regeneration. Data generated from several studies reveal that MSCs are therapeutically valuable and play a great role in cardiac diseases. In future, MSCs could be used for cell-based therapy for cardiac diseases.

MSCs are generally derived from any tissue sources. In the translational research MSCs used are mainly derived from bone marrow. Specifically, for cardiac repair or cardiac disorders, the MSCs used are derived from bone marrow^[48]. Several studies are carried out to understand the mechanism of action of MSCs in cardiac repair. One of the studies conducted by Yang *et al.*^[49] demonstrated that a combination of statin along with bone marrow derived MSCs intramyocardial injections improved the efficiency of cardiomyocyte differentiation by 4-fold in a swine model.

Numerous preclinical studies are carried out using large animal models to understand the efficacy of MSC therapy for cardiac diseases. In these studies, stem cells are delivered to the heart *via* peripheral intravenous infusion during the open heart surgery. It can also be administered through catheter-based intracoronary infusion. The studies carried out after delivery of MSCs showed that intramyocardial injection had the highest retention rate of cells^[50]. Among all the preclinical studies carried out with MSCs for cardiac diseases, surgical injection was the most commonly used method to deliver MSCs^[51-53].

Though there are varieties of sources of MSCs, there has been particular interest in adipose lineage MSCs which were found to be easily available and successful in several preclinical studies. Several studies were carried out by the administration of adipose derived MSCs for myocardial infarction (MI), which were found to be successful^[54].

Hematopoietic stem cells

Many clinical trials are carried out to improve the re-

covery of cardiac function. There were several favorable and unfavorable results during the course of time. In many of the studies, bone marrow mononuclear cells were injected. Nevertheless, detailed studies are to be carried out to understand the fate and effects of transplanted cells^[55-58]. It is understood that bone marrow contains heterogeneous populations of cells, generally Hematopoietic stem cells (HSCs) and MSCs^[59].

Apart from these, bone marrow also has different progenitors of myeloid and lymphoid lineages. Several studies indicate that both HSCs and MSCs are reported to acquire the phenotype of cardiomyocytes in syngeneic or xenogeneic recipients. Even though various studies were carried out, none of them quantitatively analyzed the regenerative capacity. Nevertheless, there is evidence shown by Norol *et al.*^[60] in nonhuman primate models that HSCs do not differentiate into cardiomyocytes or into endothelial cells in the infarcted myocardium. Apparently, the growth factors produced locally does not have any positive effect on the regeneration of myocardium^[60]. It is well known that HSCs are a unique source of adult stem cells that are easily accessible. It is documented that HSCs were used to induce neoangiogenesis to treat ischemic vascular diseases. HSCs subsets also contain endothelial precursors that are AC133+, which are considered to be major requirements in patients with ischemic and refractory peripheral vascular or coronary artery diseases^[61].

Endothelial progenitor cells

Endothelial progenitor cells (EPCs) consist of a heterogeneous group of cells which originates from multiple precursors within the bone marrow and are present in different stages of endothelial differentiation. The existence of endothelial dysfunction forecasts the consequences in patients who suffer with cardiovascular risk factors and persons with coronary artery disease. EPCs possess the ability to home to sites of vascular injury. Thus, EPCs could be easily adopted for therapeutic uses related to angiogenesis. Several studies conducted in coronary artery disease (CAD) patients revealed that they had reduced number of EPCs. They also had reduced number of circulating EPCs^[62-65].

Bone marrow derived EPCs will be mobilized to stimulate angiogenesis and will attenuate tissue ischemia for CAD and peripheral arterial disease (PAD). Further to this, clinical trials carried out with different animal models favor the application of EPCs as a potential therapeutic agent in cardiovascular diseases^[66,67].

Usage of EPC capture stent is also in practice. EPC capture stent is a device which uses the ability of bone marrow derived EPCs to repair damaged arterial segments. This instrument is manufactured in such a way that the surface of EPC antibody contains a covalently coupled polysaccharide intermediate coating with anti-human CD34 antibody and it is attached to a stainless steel stent. Once the stent is placed, the circulating EPCs will be attracted to CD34 antibodies and

will be directed to differentiate into mature endothelial cells to form functional endothelium layer^[68].

There are several studies ongoing to understand the effects of pharmacotherapies with EPCs in cardiac patients. EPC behavior and mechanisms are also elucidated in several studies conducted in patients with cardiovascular disease (CVD), CAD, heart failure and PAD. There are several promising studies showing that EPCs could be used as a novel therapy for CVD^[69]. However, there are several limitations with EPCs due to its paucity of circulating cells. The efficacy of the treatment using EPCs can be obtained by increasing the cell number by concentrating and transplanting or by functional improvement using *ex vivo* augmentation.

iPSCs

Usage of iPSCs emerged as a novel therapy for the treatment of cardiac diseases. It has also attracted much attention and is considered to be the promising cell source for patient specific cell therapy^[70]. Major advantage of iPSCs are that the clinically relevant number of cells could be generated easily when compared to adult stem cells and that they are associated with a less risk of immune rejection when compared to embryonic stem cells^[71].

iPSCs are generally engendered from adult somatic tissues with precise reprogramming. Studies prove that iPSCs have many similarities to human embryonic stem cells especially in terms of morphology, proliferation, feeder dependence, surface markers, gene expression, epigenetic status, promoter activities, telomerase activities, *etc.*^[72]. A study was conducted in a mouse model of MI, and human iPSCs were induced in this model. The results disclosed that the mice had regenerated myocardium, smooth muscles and endothelial tissue, restoring post ischaemic contractility performance and electric stability^[73]. Even though, several studies and clinical trials were carried out to understand the efficacy of iPSCs in cardiac repair. When it comes to gene therapy, the integration of viral vectors in the genome remains unanswered. These viral vectors in the genome might promote malignancy. Apart from that, these virus-encoded genes can act as oncogenes. Thus, the clinical application of iPSC derived cardiomyocytes appears to be a distant possibility at present. However, the advent of different study models will resolve the issues in the future.

Bone marrow derived mononuclear cells

Although many cell types have been attempted, there have been promising outcomes with crude extracts of bone marrow derived cells. Utilization of such resources not only minimizes time but also may be useful in reducing the cost of expenses of application^[74]. Recent use of bone marrow derived mononuclear cells (BMMNCs) in heart diseases has been able to improve LV function, and increase the myocardial perfusion, but has not produced any significant change in the

Figure 1 Illustration to show the requirement of a database for identifying alternative cell therapy for cure of heart diseases.

scar tissue^[75,76]. A double blind study of a total of 16 patients after previous placebo injection has described the improvement in angina symptoms and myocardial perfusion with the infusion of BMMNCs in chronic myocardial ischemia patients^[77]. However, Heesch *et al.*^[78] have shown that the application of BMMNCs to ischemic cardiomyopathy patients when injected, has profoundly reduced the neovascularization and thus limited its therapeutic potential for cell therapy. However, the reduced neovascularization is mostly reported to be impaired with aging, which is largely attributed to aged BMMNCs, but ageing does not affect the revitalization of neovascularization in the murine host with the transplantation of young BMMNCs^[79]. Although the results have been more commented, scientists overall are not in favor of using BMMNCs because the small number of undifferentiated cells is unlikely to be effective^[74].

Genetically modified cells

Genetic modifications of stem cells will result in enhanced efficacy. Genetically modified stem cells can be utilized for different diseases. A number of diseases can be treated now with them. Various strategies like pre-treatment with growth differentiation factors or cytokines, pre-conditioning like hypoxia and genetic modifications to overexpress anti-death signals are developed. It was Mangi *et al.*^[80] who first genetically modified MSCs to overexpress Akt which are resistant

to apoptosis *in vitro* and *in vivo*. They proved that there was a drastic improvement in cardiac function in an MI rodent model^[80]. Further work on this showed that Akt transduction stimulates MSCs to produce paracrine factors which are advantageous to infarcted heart post-engraftment^[81,82]. In another experiment transfected MSCs with bFGF showed an increased survival and cytoprotection in hypoxic condition^[83] (Figure 1).

CHALLENGES TOWARDS FUTURE DEVELOPMENT

It is clearly understood that there are underlying challenges for the identification of well-deserved type of regenerative therapy. The majority of cell types are under clinical trials but the results have been heterogeneous. Causes have been predicted to be poor survival, proliferation, engraftment and differentiation of engrafted cells. Ultimately, the objective is to increase the functional ability of stem cell before and after transplantation^[4,84]. The concern thus lies in the knowledge on structural and functional characteristics of stem cell-derived cardiomyocytes, and their capability to integrate with host tissue^[85,86]. Concerns need to be imparted for appropriate selection of patients with clear understanding about the variability of disease condition. Prospective outcomes have to be confirmed by the anatomical and histological examinations with

a large number of studied patients in order to analyze significant observations^[87]. With the prevailing methods for achieving an alternative approach to deal with heart diseases, the approach that would in future be available for the treatment is believed to possess more effective delivery methods and growth and storage methods^[17].

Researchers are working on to effective management of the challenges for the utilization of stem cell therapy wherein, newer strategies are being adopted for the combination of cells with bioengineering techniques that may improve the efficacy considerably^[88]. However, approaches dealing with the utilization of epicardium-derived cells and cardiomyocyte progenitor cells have synergistically shown better impact in cardiac function which is believed to be because of complementary paracrine actions^[89]. Whatever the sources have been utilized or approached such as embryonic stem cells, iPSCs, adult stem cell lineages, bone marrow derived stem cells, or MSCs, it is widely acceptable that there is enormous hope underlying the usage of stem cell therapy as a clinically viable alternative for heart diseases^[90] and the direction that the research is progressing is believed to be perfect which requires clear understanding and revival of the attempted trails to progress with newer ideas and accomplish the ultimate goal.

Challenges are still prevailing for the application of cell therapy to the patient. Considering the complications in delivery of the stem cells to the patient, three factors are to be taken into consideration: the type and nature of injury, timing of the therapy, and the ability of the cells to engraft the host myocardium^[82]. There is a huge dilemma regarding the best time for stem cell delivery to patients. Several studies carried out in this field prove that early time points will be ideal for stem cell transplantation^[91]. Choosing of best stem cell type also plays a crucial role in transplantation and engraftment ability to host myocardium. Recent studies indicated that transplanted cells are vulnerable to hostile ischemic environment. Thus, they will tend to disappear in a few days^[92]. Several investigations are going on to improve the microenvironment and engraftment followed by survival.

CONCLUSION

Even though the mechanisms of action for all these stem cell based therapies are not well established, it remains a promising field of research. However, a major obstacle in this arena is the poor viability of implanted stem cells for cardiac repair. The strategies reviewed here are for the augmentation and development of appropriate approaches for the treatment of cardiac disorders. Attempts performed using a specific kind of cell type by any organization are claimed to provide efficient results in comparison to the other. This has created disputes in pursuing cell types that can generate positive outcomes and thus has deliberately given poor understanding amongst the physicians.

Involvement of cell therapy possibilities has therefore anonymously diminished though it is under immediate purview. Future challenges pertaining to the application hence depend on the clear validation of the cell therapy with respect to source, mode of application, dosage and expected outcome. Reciprocation of these results is vital in order to pursue the technology.

Ethical constraints are also major hurdles to circumvent the use of alternative strategies which needs to be clearly framed considering the benefits that medical arena would acquire. Adult stem cells in this regard, have proven safe and generated decent outcomes. We suggest that, instead of exploiting research knowledge to fewer more decades, concentration towards the ultimate requirement is very important. The studies generated so far with various alternative treatment modalities for heart diseases worldwide can be collectively segregated in a common database and significance with the available data can be generated to find the best and viable source of approach that proves effective for heart diseases. In case of any discrepancy with the results, the reciprocation of the data can be attempted in order to obtain a solution.

Abstract

AIM: To investigate whether we could create natural autologous tissue patches in the subcutaneous space for organ repair.

METHODS: We implanted the following three types of inert foreign bodies in the subcutaneous tissue of rats to produce autologous tissue patches of different geometries: (1) a large-sized polyvinyl tube (L = 25 mm, internal diameter = 7 mm) sealed at both ends by heat application for obtaining a large flat piece of tissue patch for organ repair; (2) a fine polyvinyl tubing (L = 25 mm, internal diameter = 3 mm) for creating cylindrically shaped grafts for vascular or nerve repair; and (3) a slurry of polydextran particle gel for inducing a bladder-like tissue. Implantation of inert materials was carried out by making a small incision on one or either side of the thoracic-lumbar region of rats. Subcutaneous pockets were created by blunt dissection around the incision into which the inert bodies were inserted (1 or 2 per rat). The incisions were closed with silk sutures, and the animals were allowed to recover. In case of the polydextran gel slurry 5 mL of the slurry was injected in the subcutaneous space using an 18 gauge needle. After implanting the foreign bodies a newly regenerated encapsulating tissue developed around the foreign bodies. The tissues were harvested after 4-42 d of implantation and studied by gross examination, histology, and histochemistry for organization, vascu-

larity, and presence of mesenchymal stem cells (MSCs) (CD271+CD34+ cells).

RESULTS: Implanting a large cylindrically shaped polyvinyl tube resulted in a large flat sheet of tissue that could be tailored to a specific size and shape for use as a tissue patch for repairing large organs. Implanting a smaller sized polyvinyl tube yielded a cylindrical tissue that could be useful for repairing nerves and blood vessels. This type of patch could be obtained in different lengths by varying the length of the implanted tube. Implanting a suspension of inert polydextran suspension gave rise to a bladder-like tissue that could be potentially used for repairing heart valves. Histologically, the three different types of tissue patches generated were organized similarly, consisting of three layers, increasing in thickness until day 14. The inner layer in contact with the inert material was avascular; a middle layer that was highly vascular and filled with matrix, and an outer layer consisting of loose connective tissue. MSCs identified as CD271+CD34+ cells were present in the medial layer and around major blood vessels at day 4 but absent at later time points. The early-harvested tissues, endowed with MSCs, could be used for tissue repair, while the later-harvested tissues, being less vascular but thicker and tougher, could be used as filler tissue for cosmetic purposes.

CONCLUSION: An autologous, vascularized tissue patch of desired shape and size can be created in the subcutaneous space by implanting different types of inert bodies.

Key words: Autologous tissue patch; Foreign body; Subcutaneous implantation; Mesenchymal stem cells; CD271; CD34

Core tip: While much progress has been made in man-made tissue patches for organ repair, their clinical success has been bogged down by their inability to get promptly vascularized *in vivo*. We describe a methodology for creating tissue patches of several possible shapes/sizes in the subcutaneous tissue utilizing the foreign body reaction. These patches are endowed with a rich capillary network, abundant mesenchymal stem cells, and other accessory cells that support the viability of the tissue. Such *in vivo* generated patches for tissue repair promise to be safer, more readily vascularized, and stable for longer period in the body.

INTRODUCTION

There is an unmet need to develop biocompatible tissue patches for repair of various diseased organs such as ischemic heart, large open wounds, vascular defects, damaged nerves and many others. Much progress has been made in creating engineered tissue patches using polymer scaffolds (which mimic tissue matrix) or processed xenogeneic biomaterials seeded with functional cells, endothelial cells, paracrine growth factors, and fetal or adult stem cells^[1-7]. The complexity of these constructs is necessitated by the need to have an immediate blood supply to the patch for survival of the seeded endothelial and functional cells. A myriad of growth factors (from stem cells) should also be available in the patch to rapidly form the new vasculature that would connect with the host blood vessels. Despite such advances the constructs have proven to be sub-optimal in performance. There is the problem of core degradation of the construct and the lack of integration of the seeded functional cells with the host tissue cells, probably arising from lack of adequate blood supply in the construct^[3,8]. The failing patches could occasionally end up being a source of dying cells and thus causing adverse reactions rather than benefit. A multitude of accessory supporting cells other than endothelial cells are needed to form the desired new blood vessels and maintain the integrity of an avascular patch^[9-14]. Because many of these cells are not readily available and several others remain unknown, these patches remain poorly perfused *in vivo*. A natural autologous tissue patch containing stem cells, other supporting cells, and more importantly, a functional vasculature, would be a good solution to the problem.

We present here a methodology for creating tissue patches in the subcutaneous space of different shapes and sizes that are richly endowed with mesenchymal stem cells (MSCs), microvessels and interstitial cells. The principle behind the technique is to implant an inert material in the subcutaneous space which elicits a "foreign-body reaction" leading to the formation of a highly vascular, newly regenerated tissue surrounding the foreign body. Using this approach we have created vascularized tissue patches of various shapes and identified the time after implantation when the MSC population is highest in the new tissue for the purpose of using them as grafts for tissue repair.

MATERIALS AND METHODS

Preparation of inert materials for subcutaneous implantation

The following types of inert materials were implanted in the rat subcutaneous space: (1) large-sized polyvinyl tube (Polyvinyl chloride 180; Nalgene Nunc International, Rochester, New York) (L = 25 mm, internal diameter = 7 mm) sealed at both ends by heat application for obtaining a large flat piece of tissue patch

Figure 1 Gross appearance of tissue patch obtained by implanting a large-sized polyvinyl tube (L = 25 mm; ID = 7 mm) in the subcutaneous space of a rat and extracted after 4 d. The implant was completely encapsulated by a *de novo* tissue (A) after tissue that could be conveniently stripped off the implant to obtain a flat piece of tissue patch (B) after patch. Note the high vascularity of the encapsulating tissue.

for organ repair (Figure 1); (2) fine polyvinyl tubing (L = 25 mm, internal diameter = 3 mm) for creating cylindrically shaped grafts for vascular or nerve repair (Figure 2); and (3) a slurry of polydextran particle gel for inducing a bladder-like tissue. Polyvinyl chloride after polyvinyl bodies were sterilized by immersing them in 70% ethanol, then washed vigorously with sterile saline and air-dried before implantation in the rat. Polydextran slurry was made from Sephadex-25 (course; particle size 100-300 μm diameter; General Electric Healthcare Bio-Sciences, Pittsburgh, Pennsylvania, United States). The polydextran particles were pre-swollen in water and sterilized by suspending them in 70% ethanol for 2-3 h followed by removal of ethanol and re-suspension in 10 volumes of sterile saline. After allowing the particles to re-swell for several days in sterile saline, excess saline was removed and the slurry adjusted to a particle: saline ratio of 1:1 (vol/vol) for use.

Surgical placement of the inert materials in rats

All the animal experiments were reviewed and approved by the Institutional Animal Care and Use Committee of the John H. Stroger, Jr. Hospital of Cook County. The animal protocol was designed to minimize pain or discomfort to the animals. The animals were acclimatized to the laboratory conditions for 2 wk prior to experimentation and given food and water *ad libitum*.

Figure 2 Gross appearance of the tissue patch obtained by implanting a fine polyvinyl tube (L = 25 mm; ID = 3 mm) in the subcutaneous space of a rat after 4 d. A: Shows the construction of the polyvinyl tube; B: Shows the *de novo* tissue encapsulating the fine polyvinyl tube implant. The tissue could be gently slipped off the tube for creating a cylindrically shaped graft for tissue repair. Note the high vascularity of the tissue in (B). ID: Internal diameter.

All animals were euthanized by barbiturate overdose (150 mg/kg body weight pentobarbital).

Sprague-Dawley males rats (250-300 g) were anesthetized with intraperitoneal sodium nembutal (5 mg/100 g wt) and their thoracic-lumbar region was shaved and cleaned with alcohol/povidone. For implantation of inert materials a small incision was made on one or either side of the region. Subcutaneous pockets were created by blunt dissection around the incision into which the inert materials were inserted (1 or 2 per rat). The incisions were closed with silk sutures, and the animals were allowed to recover. In case of the polydextran gel slurry 5 mL of the slurry was injected in the subcutaneous space using an 18 gauge needle.

Rats were sacrificed at day 4, 7, 14, 21, 35 and 42 after implantation of the three types of inert materials ($n = 3$ rats at each time point for large and fine polyvinyl tube and $n = 2$ at each time point for polydextran; total rats used = 48).

Harvesting and processing of the subcutaneous tissue patch for gross and histological examination

At day 4, 7, 14, 21, 35 and 42 after placement in the subcutaneous space the inert bodies were harvested aseptically. The tissue encapsulating the materials was removed according to the type of tissue required. For obtaining a flat piece of tissue, the tissue encapsulating the large polyvinyl tube was removed by cutting along the length of the tube as shown in Figure 1. For obtaining a cylindrical tissue as for a vascular graft, the encapsulating tissue from the finer polyvinyl tube was gently slipped off the tube as shown in Figure 2. The bladder-like tissue from the polydextran slurry injected rats was separated from the adhering connective tissue using blunt dissection (Figure 3).

For histological examination samples of the three tissues were fixed in 4% para-formaldehyde for 24 h with vigorous shaking. The fixed tissues were then paraffin embedded in the manner that the inner and

Figure 3 Bladder-like *de novo* tissue obtained 14 d after injecting a slurry of poldextran gel particles in the subcutaneous space of a rat. A: The bladder-like tissue enclosed the injected gel particles; B: By piercing the balloon-like tissue the polydextran particles could be removed from the tissue to deflate the bladder. The tissue could then be used in a variety of ways including as a cusp for cardiac valve repair after cutting it appropriately to the required curvature.

outer aspects of the tissues were histologically recognizable. Approximately 5 μm thick sections were obtained on glass slides for routine histological staining (trichrome) and histochemistry described below.

Histochemical staining

Indirect immunofluorescence, double immunofluorescence or immune-phosphatase techniques were performed on 4–6 μm thickness sections of paraffin embedded tissue patches. Sections were deparaffinized before staining.

For indirect immunofluorescence, the sections were treated with citrate buffer (pH = 6) at 100 °C for 10 min for antigen retrieval followed by 10 min incubation with sodium borohydride (4 mg/mL) to minimize auto-fluorescence. Sections were incubated with the primary antibody (mouse anti-proliferating cell nuclear antigen (PCNA) (Millipore, Temecula, CA) or mouse anti- α -smooth muscle actin (α -SMA) (Sigma, Saint Louis, MO) at 4 °C overnight. Next day the sections were incubated for 1 h at room temperature with the appropriate secondary antibody [anti-mouse IgG linked to Alexa Fluor 633 (Invitrogen, Eugene, OR)] and mounted with Prolong Gold anti-fade reagent containing 4',6-diamidino-2-phenylindole (DAPI) to counterstain nuclei with blue fluorescence (Invitrogen, Eugene, OR).

For double immunofluorescence, the protocol followed was as described above with the difference that the overnight incubation was with both primary antibodies [goat anti-CD34 (R and D, Minneapolis, MN) and mouse the anti-CD271 (Abcam, Cambridge, MA)] at the same time. Next day, the sections were incubated with the secondary antibodies [anti-mouse IgG linked to Alexa Fluor 633 and also anti-goat IgG linked to Alexa Fluor 488 (Invitrogen, Eugene, OR)] at the same time for 1 h at room temperature followed by mounting with Prolong Gold anti-fade reagent containing DAPI (Invitrogen, Eugene, OR).

For immune-phosphatase, the sections were treated with 75 mmol/L borate buffer (pH = 10.0) at 121 °C for 10 min for antigen retrieval. Sections were incubation with goat anti-collagen type IV (Southern Biotechnology Associates, Birmingham, AL) overnight, followed by incubation with corresponding alkaline phosphatase conjugated secondary antibody. The reaction was detected with alkaline phosphatase substrate (red) (Vector Laboratories Burlingham, CA) and finally mounted in 1:1 water: glycerol solution.

Negative controls consisted of sections in which the primary antibodies were omitted. All slides were examined and digitally photographed using a fluorescent/optical microscope (Nikon, New York, NY). Merge panels for immunofluorescence and double immunofluorescence were performed with Adobe Photoshop CS6 software (Adobe Systems, San Jose, CA).

RESULTS

Tissue patches obtained after implanting various inert materials in the subcutaneous space

When a large-sized polyvinyl tube implant was placed in the subcutaneous space and extracted after 4 d, the implant was completely encapsulated by a *de novo* tissue (Figure 1A). The *de novo* tissue could be conveniently stripped off the implant as shown in Figure 1B to obtain a flat piece of tissue patch. The patch could be tailored to the size and shape required. The size of the flat tissue patch depended on the size of the original inert material implanted, as long as the size and shape of the implant conformed to the available subcutaneous space.

A cylindrically shaped tissue patch could be obtained by implanting a fine polyvinyl tubing (Figure 2A) and removing the cylindrical tissue by slipping off the tissue from the implant like removing a “sock” (Figure 2B). This type of patch could be obtained in different lengths by varying the length of the implanted tube (not shown).

Injecting a slurry of poldextran gel particles in the subcutaneous space induced an unusual tissue patch in the form of a sealed bladder or pouch. While the day 4–7 bladder tissues were too delicate to handle, the day 14 tissue was strong enough to be obtained as an integral bladder (Figure 3A). The bladder-like tissue enclosed the injected gel particles. By piercing the balloon-like tissue the polydextran particles could be removed from the tissue to deflate the bladder (Figure 3B). The tissue could potentially be used in a variety of ways including as a cusp of a required curvature for repair of solid tissues or heart valves.

Gross appearance and histology of the de novo tissue surrounding the inert material

All the three types of tissue showed similar histology with regard to the inner and outer aspect of the tissue. The inner aspect of the tissue represented the surface

Figure 4 Histology of the *de novo* tissue patch at various times after implantation of the inert body in the subcutaneous space (trichrome stained). Black arrows show the inner aspect of the tissue in contact with the inert body. A: The tissue at day 4 showed an inner layer consisting of one or two-cell thick mononuclear cells but devoid of blood vessels. The medial layer was 4-6 cell thick and contained microvessels (red arrows) and fibrous matrix (blue stain). The outer layer consisted of loose connective tissue; B: At day 7-14 the tissue was histologically better organized into inner, medial and outer layers. The inner layer in contact with the inert material was thicker, consisted of mononuclear cells but devoid of extracellular matrix and blood vessels. The medial layer was thicker than at day 4, consisting of fibroblastic cells, rich network of microvessels (shown in Figure 5) and extracellular matrix. The outer layer remained loose but contained large blood vessels (white arrows); C: Between day 35-42 the granulation tissue appeared slightly thicker and more compact than day 7-14 tissue with the inner layer becoming less distinguished than at day 7-14 and merging with the medial layer. Also, this layer showed reduced number of blood vessels and increased amounts of extracellular matrix arranged in parallel sheets. The outer layer remained unchanged.

in contact with the inert material and the outer aspect represented the surface away from the inert material and in contact with the surrounding connective tissue. We have chosen to describe the histology of the tissue obtained from the large-sized polyvinyl tube as

Figure 5 Vascularity of the medial layer of the subcutaneous tissue patch 14 d after implantation of the inert body. Microvessels were revealed by immune-staining for collagen type IV, shown earlier to stain newly formed blood vessels^[15]. Green arrows point to the inside aspect of the tissue patch in contact with the inert body. Note the absence of blood vessels in the inner layer.

representative of all others.

Implanting any of the three types of inert material in the subcutaneous tissue induced a *de novo* tissue which completely surrounded the foreign body as a capsule by day 4. The tissue at day 4 grossly appeared thin and filmy but well vascularized (Figure 4A). The inner layer consisted of one or two-cell thick mononuclear cells (20-40 μm) but devoid of blood vessels. The medial layer was 4-6 cell thick (100-150 μm) and contained microvessels and fibrous matrix. The outer layer (300-400 μm) consisted of loose connective tissue.

At day 7-14 the *de novo* tissue appeared thicker and stronger than at day 4 and histologically better organized into inner, medial and outer layers (Figure 4B). The inner layer in contact with the inert material was approx. 100 μm thick, consisted of mononuclear cells but devoid of extracellular matrix and blood vessels. The medial layer was thicker (200-300 μm), consisting of fibroblastic cells, rich network of microvessels and extracellular matrix. The outer layer remained loose but contained large blood vessels. The high vascularity of the medial layer at this time point is shown in Figure 5 by immune-staining sections for collagen type IV, shown in our previous study to reveal newly formed blood vessels^[15].

Between day 35-42 the granulation tissue appeared slightly thicker than day 7-14 tissue but was tougher and more fibrous to touch. Histologically this tissue appeared more compact with the inner layer becoming less distinguished than at day 7-14 and merging with the medial layer. Also, this layer showed reduced number of blood vessels and increased amounts of extracellular matrix arranged in parallel sheets. The outer layer remained unchanged (Figure 4C).

Proliferating layer and myofibroblasts in the *de novo* tissue patch

Because the tissue patch was found to be a dynamic tissue between day 4-42 after implantation of the inert body, it was important to determine the growing edge

Figure 6 Tissue patch at various times immune-stained for proliferating cell nuclear antigen to determine the proliferating edge of the tissue. We found that the patch was a continually growing tissue with the inner aspect (side in contact with the inert body shown by yellow arrows) and the medial layer staining positive for PCNA (red) at all times tested (A: Day 4; B: Day 7-14; C: Day 35-42), suggesting that the patch was growing from inside to outside. Sections were counterstained with DAPI to counterstain nuclei blue. PCNA: Proliferating cell nuclear antigen; DAPI: 4',6-diamidino-2-phenylindole.

of the tissue. The tissues were immune-stained for PCNA to identify the proliferating cells in the patch. We found that the patch was a continually growing tissue with the inner aspect (side in contact with the inert body) and the medial layer staining positive for PCNA at all times tested (Figure 6), suggesting that the patch was growing from inside to outside.

The tissues were immune-stained for α -SMA, a marker of myofibroblasts, to identify the source and organization of the fibrous material identified in the medial layer of the tissue patch. At day 4-7, α -SMA was found to be associated with blood vessels as expected, but little extracellular α -SMA was observed at these

times (Figure 7). At later time points there was more and more of α -SMA observed in the extracellular areas (not shown), which by day 35-42 had stratified and compacted itself in parallel to the length of the implants (Figure 7), consistent with the tissue being tougher and fibrous to touch.

Location of MSCs in the *de novo* tissue

It has been recently recognized that CD34+CD271+ cells mark the presence of MSCs in a tissue^[16-20]. Tissue patches from days 4-42 were immune-stained for CD34 and CD271 to identify the location of MSCs. We found that MSCs were clearly identifiable in the stroma of the medial layer of the tissue patch at day 4 after the implantation of the inert body but rarely seen at day 7 or after (Figure 8). Also, MSCs were found to be concentrated in the vicinity of major blood vessels in the medial layer at day 4 but never at day 7 or after (Figure 9).

DISCUSSION

We demonstrate that the subcutaneous space is an effective and convenient compartment to create an autologous tissue patch of desired shape and size for the purpose of repairing organs or tissues. By implanting inert material of different shapes and sizes we obtained newly regenerated tissues of corresponding shapes and sizes containing abundant blood vessels, multitude of other functional cells, and importantly, also MSCs in a matter of 4 d. These early-harvested tissues, which were highly vascular and abundant in MSCs, could potentially be used for tissue repair. When the *de novo* tissues were allowed to grow for longer times the tissues obtained were less vascular but thicker and tougher. Such tissues could be applied for structural support or as a filler tissue for cosmetic purposes.

There are several advantages of using subcutaneous tissue patches as described in this report compared to patches made of synthetic materials and seeded with cultured cells^[1-7]. First and foremost is the autologous nature of the subcutaneous patch which can be created in the patient's own body. Clearly, such patches will be safer because they will be better tolerated immunologically in the patient body than patches made from xenogenic or synthetic materials^[21]. Second, the subcutaneous patches will have a ready-made vascular system for the perfusion of blood through the entire body of the patch. Man-made patches have the problem of core degeneration because of lack of vascularity which results in patch failure and the possibility of adverse reactions because of necrotic foci in the patch. Thirdly, these *in vivo* created patches contain other important accessory cells including interstitial cells which create matrix to provide body and integrity to the patch, and pericytes which provide support to the developing blood vessels during their integration with the host blood vessels.

Figure 7 Tissue patch at various times immune-stained for α -smooth muscle antigen to determine the organization of the extracellular matrix in the patch. At day 4-7, α -SMA was found to be associated with blood vessels as expected, but little extracellular α -SMA was observed at these times. At later time points there was more and more of α -SMA observed in the extracellular areas (not shown), which by day 35-42 had stratified and compacted itself in parallel to the length of the implant, consistent with the tissue being tougher and fibrous to touch. Sections were counterstained with DAPI to counterstain nuclei blue. Side in contact with the inert body is shown by yellow arrows. α -SMA: α -smooth muscle antigen; DAPI: 4',6-diamidino-2-phenylindole.

Figure 8 Localization of mesenchymal stem cells in the *de novo* tissue patch induced in the subcutaneous space by an inert body. CD271 cells were immune-stained by a red fluorescent probe, CD34 cells by a green fluorescent probe and all nuclei (counterstained in the merge picture only) by DAPI. MSCs identified as CD271+CD34+ were clearly identified in the medial layer of the tissue patch at day 4 after the implantation of the inert body (white arrows in the merged picture), but rarely seen at day 7 or after. Light blue arrows indicate the inner aspect of the tissue patch. MSCs: Mesenchymal stem cells; DAPI: 4',6-diamidino-2-phenylindole.

The efficacy of autologously created *in vivo* patches in repairing functional organs is highlighted by the omentum which, either as an attached (with vascular connection intact) or detached tissue (severed vascular connection), has proven to be successful in repairing ischemic heart, spinal cord, and bony fractures^[22]. More recently, we showed that the omentum is capable of being activated to a state in which its content of MSCs and blood vessels become several fold higher^[23,24]. In this state it could be used for regenerating endocrine damaged pancreas, liver and kidney^[25-27]. Notwithstan-

ding the utility of the activated omentum in regenerating tissues, its use has been greatly restricted by the difficulty of obtaining the tissue from the abdominal cavity which necessitates laparotomy, a risky surgical procedure. A similar patch created in the subcutaneous tissue, as described here, is clearly less risky to the patient.

The presence of an intact and functional vascular system in a tissue implant is clearly a factor which favors its success *in vivo* with respect to survival and integration with the host tissue. Consistent with this

Figure 9 Localization of mesenchymal stem cells in the vicinity of major vessels at day 4 after implantation of an inert body in the subcutaneous space. MSCs, identified as CD34+CD271+ cells (white arrows in the merge picture), were found to be concentrated in the vicinity of major blood vessels in the medial layer at day 4 but never at day 7 or after (not shown). The merge section was counterstained with DAPI to counterstain nuclei blue. MSCs: Mesenchymal stem cells; DAPI: 4',6-diamidino-2-phenylindole.

premise, pre-vascularized man-made tissue patches for later implantation have proven to be longer-lasting than un-prevascularized patches^[28,29]. Because of the preformed capillary network in such constructs, whether created *in vitro* or *in vivo*, they were able to anastomose with the host vasculature and thereby perfuse the construct promptly after *in vivo* implantation^[12,28,30,31]. The strategies used for prevascularization of synthetic scaffolds involve the sandwiching of pro-endothelial cells and myoblasts on the scaffolds which are subsequently placed in tissue culture, resulting in capillary network formation^[32]. Another alternative is to pre-implant the

construct on the omentum or in the renal pouch^[29,30], a tissue known to induce angiogenesis in tissue grafts, resulting in a rich network of capillaries penetrating the construct. However, there are drawbacks to these approaches which need to be overcome for better outcomes: (1) the technology to create such capillary network *in vitro* is labor intensive, expensive, and difficult in terms of controlling quality; (2) pre-implanting the construct on the omentum (or renal pouch) for pre-vascularization, is unsafe due to the risk of infections by the surgical procedures required, as mentioned above; and (3) such patches have yet the potential problem of safety because of the use of allogeneic cells and materials for their production. In light of the above considerations a tissue patch created in the subcutaneous tissue overcomes many of the problems inherent in man-made patches.

The finding of MSCs in the subcutaneous patch we describe herein is not surprising considering that the patch is a newly regenerated tissue and must involve such cells to create an organized tissue. Earlier we had shown that the subcutaneous patch also contained cells which expressed CXC chemokine receptor 4 (CXCR4), the receptor for stromal cell derived factor-1 (SDF-1), a protein which is released by injured tissues^[15]. The presence of CXCR4 has been considered to be a stem cell marker based on the rationale that an injured tissue releasing SDF-1 would attract the CXCR4 bearing bone marrow cells for repair. One outstanding problem in the field of MSCs is the lack of validated markers to identify them, especially in an intact tissue. While many cell markers in blood cells have been described as representing MSCs there is a dearth of knowledge on such markers to identify MSCs in a solid tissue. We therefore believe there may be many other cell-specific stem cells in addition to the CD34+CD271+ we found in this tissue.

In summary, we demonstrate here that it is convenient to create a tissue patch of preferred shape and size in the subcutaneous space. A patch created in the subcutaneous tissue was highly vascularized, and contained MSCs and other accessory cells, which should endow it with the ability to successfully graft to an injured tissue and augment its healing.

ACKNOWLEDGMENTS

The authors wish to thank Lev Rappoport, MD and Sethupathi Periannan, MD for help with histological processing and animal surgeries respectively. COMMENTS

Background

Despite much progress in the development of engineered tissue patches for organ repair these constructs often fail from lack of adequate blood supply. A

natural autologous tissue patch containing a functional vasculature and stem cells would overcome such problems. The authors created such autologous tissue patches of different geometries by implanting three types of inert foreign bodies in the subcutaneous tissue of rats.

Research frontiers

There is an unmet need to develop biocompatible tissue patches for repair of various diseased organs such as ischemic heart, large open wounds, vascular defects, damaged nerves and many others. Much progress has been made in creating engineered tissue patches using polymer scaffolds or processed xenogeneic biomaterials seeded with functional cells, endothelial cells, paracrine growth factors, and fetal or adult stem cells. Despite such advances the constructs have proven to be sub-optimal in performance. There is the problem of core degradation of the construct and the lack of integration of the seeded functional cells with the host tissue cells, probably arising from lack of adequate blood supply in the construct. A natural autologous tissue patch containing stem cells, other supporting cells, and more importantly, a functional vasculature, would be a good solution to the problem.

Innovations and breakthroughs

The authors demonstrate in this manuscript that it is possible to create an autologous tissue patch of preferred shape and size in the subcutaneous space. A patch created in the subcutaneous tissue is highly vascularized, contains mesenchymal stem cells (MSCs), and other accessory cells, which should endow it with the ability to successfully graft to an injured tissue and augment its healing.

Applications

Availability of an autologous tissue patch containing MSCs, as described herein, will open up the possibility of repairing diseased or injured organs of patients in a safe and effective manner.

Terminology

Although creating man-made patches for tissue repair have been described, they contain synthetic materials and cells grown outside the body, which make such patches bio-incompatible and unsafe for implanting in patients. An autologous tissue patch on the other hand is one which is created in the patient itself making them completely bio-compatible and safer to use in the patient. A synthetic or natural tissue patch implanted in the patient's body must be sustained by blood. If the patch lacks built-in blood vessels the patch will quickly die and fail. On the other hand if the patch already has blood vessels in it (functional vasculature) it has a better chance of survival and functionality.

Peer-review

Authors reported their successful challenge to create a vascularized, ready-to-use patch by an extremely feasible method of subcutaneous implantation of polyvinyl tubes. Their technique will contribute to therapeutic development for the treatment of acute tissue injuries. The only one regrettable point is that they did not present a case where the implanted patch eventually improved the repair of injured tissues. It is best for the authors to prove the efficacy of their patches in their future works.

Abstract

AIM: To establish an easily-handled method to isolate mesenchymal stem cells (MSCs) from coagulated human bone marrow samples.

METHODS: Thrombin was added to aliquots of seven heparinized human bone marrow samples to mimic marrow coagulation. The clots were untreated, treated with urokinase or mechanically cut into pieces before culture for MSCs. The un-coagulated samples and the clots were also stored at 4 °C for 8 or 16 h before the treatment. The numbers of colony-forming unit-fibroblast (CFU-F) in the different samples were determined. The adherent cells from different groups were passaged and their surface profile was analyzed with flow cytometry. Their capacities of *in vitro* osteogenesis and adipogenesis were observed after the cells were exposed to specific inductive agents.

RESULTS: The average CFU-F number of urokinase-treated samples ($16.85 \pm 11.77/10^6$) was comparable to that of un-coagulated control samples ($20.22 \pm 10.65/10^6$, $P = 0.293$), which was significantly higher than those of mechanically-cut clots ($6.5 \pm 5.32/10^6$, $P < 0.01$) and untreated clots ($1.95 \pm 1.86/10^6$, $P < 0.01$). The CFU-F numbers decreased after samples were stored, but those of control and urokinase-treated clots remained higher than the other two groups. Consistently, the numbers of the attached cells at passage 0 were higher in control and urokinase-treated clots than those of mechanically-cut clots and untreated clots.

The attached cells were fibroblast-like in morphology and homogeneously positive for CD44, CD73 and CD90, and negative for CD31 and CD45. Also, they could be induced to differentiate into osteoblasts and adipocytes *in vitro*.

CONCLUSION: Urokinase pretreatment is an optimal strategy to isolate MSCs from human bone marrow samples that are poorly aspirated and clotted.

Key words: Coagulated marrow sample; Mesenchymal stem cells; Isolation; Urokinase

Core tip: It is usually difficult to isolate mesenchymal stem cells (MSCs) from bone marrow samples that have been coagulated due to inappropriate marrow aspirations or in the setting of pathologically hypercoagulable state. In this study, the authors found that urokinase pretreatment could dissolve stem cells from the clots. The MSCs were fibroblast-like in morphology and homogeneously positive for CD44, CD73 and CD90, and negative for CD31 and CD45. Also, they could be induced to differentiate into osteoblasts and adipocytes *in vitro*. Urokinase pretreatment is an optimal strategy to isolate MSCs from poorly aspirated and clotted human bone marrow samples.

INTRODUCTION

Mesenchymal stromal cells (MSCs) are a kind of adult stem cells characterized by their hematopoiesis-supporting and immune regulatory activities, and have been clinically trialed in the treatment of various kinds of diseases including graft-versus-host disease, musculoskeletal defects, ischemic disorders, and neurological diseases^[1-3]. Though MSCs are low in immunogenicity and allogeneic transplantation has been widely used, autologous MSCs still remain an ideal option in some cases, such as in the repair of bone and cartilage defects. And in these settings, bone marrow is usually aspirated from the patients though adipose tissue might be another choice for MSC isolation^[4]. In some cases, however, bone marrow samples are poorly aspirated and clotted promptly after the procedure, especially when the patients are in a hypercoagulable state^[5-7]. This usually leads to the decrease of MSC output or even failure to culture-expand MSCs. To solve this practical problem, we have developed an easily-handled method to isolate MSCs from human marrow

clots.

MATERIALS AND METHODS

Marrow sample collection and treatment

Heparinized bone marrow samples were aspirated from seven healthy adult donors after informed consent in accordance to the Ethical Guidelines for Research Involving Human Subjects or Human Tissue from General Hospital of Air Force. Nucleated cells were counted by trypan blue exclusion assay and the samples were diluted with PBS to a concentration of 2×10^6 or 2×10^7 /mL. The samples were then treated as depicted in Figure 1. Briefly, one sample was divided into 12 aliquots containing 2×10^6 nucleated cells and 12 aliquots containing 2×10^7 nucleated cells. To mimic coagulation, eight aliquots of each group were treated with thrombin (Sigma) at a final concentration of 1 U/mL and maintained at 37 °C for 1 h. The thrombin-treated and untreated samples were stored at 4 °C for 0 (subgroup 0 h), 8 (subgroup 8 h) and 16 h (subgroup 16 h) for further treatment. Each subgroup contained 3 thrombin-treated samples and one un-coagulated sample. The three clotted samples were either untreated, mechanically minced into pieces or treated with urokinase. For urokinase treatment, urokinase (Urokinase for injection, Lizon Pharmaceutical Factory, Zhuhai, Guangdong) was added into the samples at a final concentration of 50000 U/mL and maintained at 37 °C with a horizontal rotation of 120 rpm for 20 min. All the samples were further treated with NH₄Cl buffer to lyse the contaminated red blood cells, washed twice in PBS, and suspended in alpha-MEM containing 10% fetal bovine serum from selected lots (Stemcell Co. Canada)^[8]. The cells were used in the experiments described below.

Colony-forming unit-fibroblast assay

The samples which contained 2×10^6 nucleated cells each and stored at different times were separately seeded into culture dishes with a diameter of 100 mm. The culture was maintained for 12 d. The medium was then removed, and the cells were washed twice with PBS. Wright-Giemsa staining was performed to reveal the colonies that were more than 0.5 mm in diameter. The number of colonies was calculated with the software of Quantity One 4.4 as described previously^[9].

Cell passage culture

When the confluence of the attached cells cultured from un-clotted samples reached to around 80%, the cells from all groups were harvested by trypsin digestion, counted and re-seeded into culture dishes at a density around 6000 cells/cm². When the cell attachment from the control samples reached around 80%, the cells from all the counterpart groups were detached, the cell numbers were counted and the cells were plated for passage culture. The cells at passage 2 were also collected for phenotype analysis and *in vitro*

Figure 1 Study design. Bone marrow samples from 7 healthy volunteers were aliquoted and treated by different protocols. The cells were plated for passage culture or CFU-F assay. CFU-F: Colony-forming unit-fibroblast.

differentiation assay as reported previously^[9,10]. Colony-forming unit-fibroblast (CFU-F) was stained with Giemsa solution and counted as routinely described^[9].

Flow cytometry

The attached cells from passage culture were detached by trypsin digestion, washed in PBS and reacted with PE-conjugated monoclonal antibodies (BD, United States) against human CD31 (endothelial cell marker), CD45 (hematopoietic cell marker), CD73 (positive on mesenchymal cell lineage) and CD90 (stem cell marker) for 30 min in dark at room temperature. The cells were washed twice in PBS and at least 10000 events were collected with FACSCalibur (BD, United States). The data were analyzed with WinMdi 2.9 software after the targeted events were gated according to the cell size and granularity.

Differentiation assays

For *in vitro* osteogenic differentiation, the attached cells for passage culture were digested with 0.05% trypsin, washed in PBS, and seeded into 24-well plates at a density of 5000 cells per well. The cells were allowed to attach overnight and then exposed to 0.1 $\mu\text{mol/L}$ dexamethasone, 50 $\mu\text{mol/L}$ ascorbic acid 2-phosphate, and 10 mmol/L β -glycerophosphate as previously described with a little modification^[10,11]. After 12 d,

cellular activity of alkaline phosphatase (ALP) was revealed with ALP immunohistochemistry kit (Sigma, United States) following the manufacture's protocol.

For adipogenic differentiation, the cells were seeded a 24-well plate at a density of 10000 cells per well. Inductive agents containing 1 $\mu\text{mol/L}$ dexamethasone, 0.5 mmol/L isobutylmethylxanthine (IBMX, Sigma, United States), and 100 $\mu\text{mol/L}$ indomethacin (IDM, Sigma, United States) were supplemented. The culture was maintained for 7 d and intracellular lipid droplets were revealed by Oil-Red staining^[9-11].

Statistical analysis

The data were expressed as mean values incorporating the standard deviation. Statistical significance was analyzed by Student's *t* test. A *P*-value less than 0.05 was considered significant. The statistical analysis has been reviewed by Dr. Qing-Yi Zhang from Beijing Institute of Basic Medicine.

RESULTS

Urokinase treatment could release MSCs from clotted marrow samples

To establish a ready-use method to isolate MSCs from clots of human bone marrow aspirates, heparinized marrow samples were aliquoted according to the nucleated cell numbers and treated with thrombin to coagulate the samples. Then, the clots were treated with urokinase digestion, mechanically minced or untreated. The cells were plated to allow MSCs to attach and expand. The numbers of CFU-F and the attached cells were counted separately.

As expected, bone marrow coagulation did affect the output of MSCs. The numbers of CFU-F were greatly decreased from clotted samples compared with those from un-clotted samples (Figure 2A). However, the average CFU-F number of urokinase-treated samples ($16.85 \pm 11.77/10^6$) was comparable to that of un-coagulated control samples ($20.22 \pm 10.65/10^6$, $P = 0.293$), which was significantly higher than those of mechanically-cut clots ($6.5 \pm 5.32/10^6$, $P < 0.01$) and untreated clots ($1.95 \pm 1.86/10^6$, $P < 0.01$). Statistical analysis showed that the CFU-F numbers decreased after samples were stored for 8 h, and those were greatly decreased after the samples were stored for further 8 h compared with those from the same groups. However, the CUF-F numbers of control and urokinase-treated clots from stored samples were higher than those in the stored samples of the other two groups (Figure 2A).

Consistent with the results above, as shown in Figure 2B, the numbers of the attached cells at passage 0 were higher in control (average: $38.86 \pm 17.4 \times 10^4$, $n = 7$) and urokinase-treated clots ($38.57 \pm 16.78 \times 10^4$, $n = 7$) than those of mechanically-cut clots ($18.57 \pm 13.69 \times 10^4$, $n = 7$, $P = 0.016$ compared with control) and untreated clots ($13.14 \pm 8.39 \times 10^4$, $n =$

Figure 2 Colony-forming unit-fibroblast and mesenchymal stromal cell numbers of different groups. A: CFU-F numbers per 10⁶ nucleated cells from seven bone marrow samples; B-D: Bone marrow samples were diluted and split into 12 aliquots containing 10⁷ nucleated cells. The attached cells at passage 0 (B: × 10⁴), passage 1 (C: × 10⁵) and passage 2 (D: × 10⁵) were counted and summed up. The average and standard errors are shown. CFU-F: Colony-forming unit-fibroblast.

7, $P = 0.002$ compared with control). These differences were also observed when cell counting was performed at passage 1 and 2 (Figure 2C and D). The results further confirm the advantages of urokinase treatment on bone marrow coagulated clots.

The attached cells were MSCs *per se*

Marrow samples were treated by different protocols and the nucleated cells were cultured in media traditionally for MSC expansion after the contaminated red cells were lysed in NH₄Cl. After 72 h, cells attached to the plastic were observed and colonies were evident after 12 d of culture. As shown in Figure 3, the attached cells appeared in all of the four groups and were fibroblast-like in morphology, suggestive of the features of the cells as MSCs.

To further confirm that the attached cells from differently treated bone marrow samples were MSCs *per se*, some of the surface markers on several kinds of fibroblast-like cells were analyzed with flow cytometry. The results showed that the cells from the four groups were homogeneously negative for CD31 and CD45, proving that the cells were devoid of endothelial and hematopoietic cells, two cell types that are commonly observed when bone marrow cells are cultured (Figure

4). Meanwhile, the cells were positive for CD73, a mesenchymal marker^[12], and for CD90, a pan-marker for stem cells including MSCs^[13].

Furthermore, when the attached cells were exposed to specific inductive conditions, they became ALP-positive and intracellular lipid droplets were observed (Figure 5). The results prove that the cells had the capacity to differentiate into osteoblasts and adipocytes. The fibroblast-like in morphology, the expression of unique surface markers and the differentiation capacity support the conclusion that the attached cells were MSCs *per se*^[14].

DISCUSSION

Bone marrow sample coagulation is a common phenomenon in clinical practice and, it is indeed a problematic issue to isolate MSCs from the samples. To overcome this problem and establish an easily handled method, urokinase was used in this study to dissolve the clots and subsequently, the contaminant red blood cells in the pre-treated bone marrow samples were lysed with ammonium chloride, and the nucleated cells were seeded. The procedures described here seem practical in isolating MSCs from the bone marrow clots

Figure 3 Representative morphological features of the colonies and the attached cells. Bone marrow samples were treated by different protocols and the cells were maintained for 12 d. Colonies of fibroblast-like cells were stained with Wright-Gimsa solution and observed under a microscope with a lower (A) and a higher magnification field (B). as the treated cells could form CFU-F and the attached cells had the capacity to differentiate osteoblasts and adipoblasts.

CFU-F is a well-recognized surrogate for MSCs^[15-18]. The numbers of CFU-F in urokinase-treated clots were

comparable to those in uncoagulated controls at three time points, suggesting that urokinase treatment could optimally release MSCs in the clots. Urokinase is not only able to dissolve the coagulated clots but also could migrate MSCs from the potentially existed undissolved

Figure 4 Surface marker analysis of the attached cells by flow cytometry. The attached cells at passage 2 were collected for flow cytometric analysis. The antigenic markers are indicated. UK: Urokinase-treated clots; CUT: Mechanically-cut clots; CLOT: Untreated clots. The results are representative of 7 individual experiments.

small ones^[19], resulting in the “liberation” of MSCs from the dense fibrin arrangement. Further, it is interesting that the numbers of CFU-F decreased sharply when the samples, pre-coagulated or uncoagulated, were stored at 4 °C for 8 or 16 h. It has been proven that prolonged storage time does decrease the viable cell numbers in bone marrow aspirates^[20], which is also observed in this study. Meanwhile, the temperature is also an important issue for preservation of marrow samples. It is clear that

room temperature is an optimal condition for marrow sample storage when the sample is designed to be used shortly afterwards^[21]. Therefore, it is recommended that human bone marrow samples be used as soon as possible or be stored at room temperature when necessary.

The results above suggest that urokinase pretreatment is an optimal strategy to culture MSCs when human bone marrow are poorly aspirated and clotted.

Urokinase might not only dissolve the coagulated clots but also mobilize MSCs wrapped in the fibrin structure^[19]. Previous data have also shown that urokinase might affect the migration and differentiation^[19,22]. However, urokinase treatment described in this protocol needs only four hours and the potential ligation of urokinase to the receptor on MSCs is transient. The differentiation properties of MSCs might be unaffected. Therefore, urokinase treatment should be a practical method to release MSCs in the coagulated clots.

COMMENTS

Background

Bone marrow is a commonly used origin for the isolation of mesenchymal stem cells (MSCs); however, in some cases, marrow samples are poorly collected and clotted promptly after aspiration, leading to the decrease of MSC output or even failure to culture-expand MSCs.

Research frontiers

MSCs are adult stem cells with the capacities to differentiate several connective tissues, support hematopoiesis, promote angiogenesis, and regulate immune reactions. Therefore, several hundreds of clinical trials with MSCs are on-going and MSCs have officially approved to treat ischemic diseases and immune-associated disorders.

Innovations and breakthroughs

In this study, the authors found that urokinase treatment could release MSCs from clotted marrow samples and maintain the number of colony-forming units compared with the uncoagulated control. The isolated MSCs exhibited fibroblast in morphology, expressed the specific markers and could be induced to osteoblast and adipoblast.

Applications

Coagulation of human bone marrow samples is a common problem in practice. The study strongly suggests urokinase digestion is a good method to treat the clots to isolate MSCs in this setting.

Terminology

Mesenchymal stromal cells: MSCs are adult stem cells characterized by their hematopoiesis-supporting, angiogenesis-promoting and immune regulatory activities, and have been officially approved by several countries to treat various kinds of diseases including graft-versus-host disease, musculoskeletal defects and ischemic heart disorders. Colony-forming unit-fibroblast: Colony-forming unit (CFU) is a unit commonly used to estimate the number of viable targeted cells in a sample. CFU-fibroblast (CFU-F) expresses the frequency of cells in a sample that can form colonies consisting of fibroblasts or fibroblast-like cells after culture for several days. The visual appearance of a colony in a cell culture requires significant growth, and when counting colonies it is uncertain if the colony arose from one cell or a group of cells. Expressing results as colony-forming units reflects this uncertainty. CFU-F is a well-recognized surrogate for MSCs and used to evaluate the potential proportion of MSCs in a sample. Urokinase: Urokinase is a serine protease that was originally isolated from human urine. The primary physiological substrate of urokinase is plasminogen. Clinically, urokinase is used in the treatment of deep venous thrombosis, pulmonary embolism, and myocardial infarction.

Peer-review

This is a well-designed study that clearly shows that urokinase-treated samples provides a superior method for obtaining useable mesenchymal stem cells. The methods of this study were sound and the conclusions followed logically from the data obtained. The study has significant relevance for stem cell therapies.

World Journal of Stem Cells
Volume 7 Number 9 October 26, 2015

ABOUT COVER

Editorial Board Member of *World Journal of Stem Cells*, Gui-Rong Li, PhD, Departments of Medicine and Physiology, University of Hong Kong, Hong Kong, China

AIM AND SCOPE

World Journal of Stem Cells (*World J Stem Cells*, *WJSC*, online ISSN 1948-0210, DOI: 10.4252), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJSC covers topics concerning all aspects of stem cells: embryonic, neural, hematopoietic, mesenchymal, tissue-specific, and cancer stem cells; the stem cell niche, stem cell genomics and proteomics, and stem cell techniques and their application in clinical trials.

We encourage authors to submit their manuscripts to *WJSC*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

INDEXING/ ABSTRACTING

World Journal of Stem Cells is now indexed in PubMed Central, PubMed, Digital Object Identifier, and Directory of Open Access Journals.

Abstract

Normal and abnormal hematopoiesis is working as a complex adaptive system. From this perspective, the development and the behavior of hematopoietic cell lineages appear as a balance between normal and abnormal hematopoiesis in the setting of a functioning or malfunctioning microenvironment under the control

of the immune system and the influence of hereditary and environmental events.

Key words: Acute leukemia; Complex adaptive system; Stem cells; Hematopoiesis; Treatment

Core tip: Complex adaptive systems are self-organizing systems involved everywhere. In bone marrow, cell lineages are working as a complex adaptive system. While the standard leukemia stem cell theory postulates that rare stem cells with self-renewal capacities are able to give rise to partially differentiated progenies, leukemia appears as a breakdown of the existing biological order under the influence of genetic and environmental factors, more than only the presence of abnormal cells.

Thomas X. Understanding leukemic hematopoiesis as a complex adaptive system. *World J Stem Cells* 2015; 7(9): 1145-1149
Available from: URL: <http://www.wjgnet.com/1948-0210/full/v7/i9/1145.htm> DOI: <http://dx.doi.org/10.4252/wjsc.v7.i9.1145>

Complex adaptive systems are self-organizing systems involved everywhere in all disciplines^[1]. They have in common the emergence of self-organization on the macro-scale from micro-scale interactions of the agents contributing to the system. Complex adaptive systems share common traits of which: (1) simple rules of interaction potentially leading to self-organization when a group of individuals achieve a certain size; (2) the complexity is only at a macro level, individuals are ignorant of the overall organization since simple rules regulate local interactions between individuals and their environment; (3) local self-organization fails to emerge; and (4) interactions between agents or agents and their

Figure 1 Normal and pathologic hematopoiesis as complex adaptive system.

environment form negative feedback loops leading to adapted responses, maintaining the complexity of the system. Although hematopoiesis is classically regarded as a linear process, stem cell processes and cell lineages that arise from them, are working within the framework of an adaptive complex network^[2,3]. Bone marrow cells share many of the above defining characteristics. They only respond to local signals and interactions through feedback loops, have no action on the entire organism and can work independently of the whole hematopoietic system.

Despite intensive studies and analyses to complete the picture, malignant hemopathies did not always behave as expected. It is apparent that pathologic hematopoiesis (like normal hematopoiesis) is working according to a very different set of rules to cause and effect than those commonly admitted. Complexity theory, which has emerged in all disciplines and can be also considered for hematopoiesis, is based on relationships, emergence, patterns and iterations (Figure 1). All cells present in the hematopoietic system should be considered as involved in that system. All interactions and connections between those cells are not predictable and not planned. A pattern will emerge from cell interactions, will feedback on the hematopoietic system and will inform the interactions of the various agents leading to the establishment of a new balance.

Our understanding of the pathogenesis of acute leukemia has evolved over the years. Leukemic hematopoiesis appears to retain some semblance of its normal counterpart, and also works as a complex adaptive system. Actually, the first one derives from the second one, and both normal and abnormal systems can coexist at variable functional, qualitative, and quantitative intensities under the influence of inner and outer factors (Figure 2). Most systems are not unique, but are within other systems and participate to those bigger systems. In the standard leukemia stem cell theory, rare stem cells with self-renewal capacities

Figure 2 Factors influencing interactions between normal and abnormal hematopoiesis.

can give rise to partially differentiated progenies which will constitute the bulk of leukemia^[4,5]. However, this view of leukemia hematopoiesis reveals only dominant pathways and do not take into account the alternate pathways representative of a complex adaptive system. It is based on linear relationships which imply precise solutions. Actually, a hierarchy of command and control does not exist. Nothing is planned or managed. The hematopoietic system is continually self-organizing to find the best fit with the microenvironment. Cells interact through the process of emergence and feedback apparently at random with non-linear relationships and only approximate solutions. Patterns emerge from these interactions and will influence the behaviour of these cells within the system and the hematopoietic system itself.

The ways in which the cells interact to one another is critical to the survival of hematopoietic cell lineages. Patterns are formed from these connections as well as the feedback. Connections between the cells appear generally more important than the cells themselves. The bulk leukemia cells are supposed to possess limited proliferative potential and to have few capacities for initiating or maintaining the disease. Eradicating these cells is therefore not enough to cure the disease, while drug-resistant leukemia stem cells will re-populate the bone marrow and cause leukemia relapse^[6,7]. The potential emerging patterns are numerous, even if the rules governing the overall function of the system remain quite simple. The total number of mutations potentially found in leukemia cells is quite large. However, few mutations commonly occur in coding regions and are relevant to disease pathogenesis. Any leukemic cell has relatively few of these recurring mutations^[8,9]. Small changes in an initial condition can have significant effects. In a hematopoietic stem cell, clonal expansion starts with the occurrence of an "initiating" mutation. Such a mutation might be a translocation or a coding sequence mutation. Within the expanding clone, new

mutations can occur, completing the transformation process. Different sub-clones may develop within this founding clone. The situation may also evolve under the influence of disease evolution. New mutations may randomly occur as a matter of time. They can also occur as a result of the treatment mutagenic potential. Clonal evolution is common at the time of relapse and occurs through the acquisition of new mutations, either in the dominant primitive clone or in a subclone of the founder clone^[10]. Therapy itself can contribute to the acquisition of therapy-resistant mutations. A dominant sub-clone may evolve, possibly because of varying sensitivities to therapy or the influence of therapy on the microenvironment and on residual normal hematopoiesis^[10].

Other factors may influence the balance between normal and abnormal hematopoiesis.

Hematopoietic cells are part of their microenvironment. Cell populations present in the bone marrow niche are able to regulate stem cells. Leukemia stem cells depend on the same signals as their normal counterpart^[11]. In response to infection or bone marrow stress, the cellular composition of the microenvironment and therefore the production of cytokines are able to change fundamentally^[12]. Hematopoietic cells will have to adapt and to respond to all changes susceptible to occur in this environment to ensure the best fit. They will also modify their microenvironment by causing inflammation and by inducing an adaptive and innate immune response in the bone marrow. Furthermore, as the environment has already changed they will need to change again as a constant process. Leukemia-specific effector T cells infiltrating bone marrow may potentially target leukemia stem cells and participate to their eradication. However, mechanisms that evolved to protect normal hematopoietic stem cells and to regulate demand-adapted responses can protect leukemia stem cells against an attack from the immune system and favor their progression. Quiescence warrants the genetic integrity of stem cells as frequent chromosomal replications may introduce oncogenic DNA mutations and also protect stem cells from uncontrolled proliferation. Hematopoietic stem cells can undergo asymmetrical division. This non-exhaustive proliferation capacity can be initiated by all stress situations, of which infections and cytotoxic chemotherapy, and respond to signals from immune cells^[13]. Self-renewing hematopoietic stem cells persist for long periods of time, allowing the accumulation of genetic damage and malignant transformation. They can therefore serve as the cell-of-origin for leukemia stem cells^[14]. However, more mature progenitor cell types can serve as leukemia-initiating cells in some cases^[15]. Although not excluding a hierarchical model, this sustains the stochastic model hypothesis. Here, every malignant cell, given that it enters a permissive situation, has the ability to self-renew and to recapitulate the disease phenotype^[16].

During leukemogenesis, leukemia stem cells can "hijack" the niche and the signaling molecules from

normal hematopoietic cells. Molecular changes in the bone marrow niche contribute to leukemia development. In the niche, leukemia stem cells may be more therapy resistant and may therefore potentially provide important cellular markers of clinically relevant minimal residual disease^[17]. Immune cells are involved in the regulation of hematopoietic stem cell homeostasis and emergency hematopoiesis^[18]. CD4⁺ T cells are particularly important in maintaining hematopoietic stem cell function^[19]. T regulators represent one-third of all CD4⁺ T cells in the bone marrow. They provide an immune-privileged niche, protecting hematopoietic stem cells from immune destruction^[20]. Monocytes and macrophages are also important cells serving as regulators of hematopoietic stem cell egress from the bone marrow^[21]. The immune system interacts with hematopoietic stem cells *via* direct cell-cell interactions and *via* soluble factors. Leukemic cells express can interact with T cells through the molecular repertoire of major histocompatibility molecules and co-stimulatory ligands. Cytotoxic T lymphocytes directed against leukemia antigens have been detected^[22]. However, an activated immune system can also contribute to the leukemia progression by CD27 signaling on leukemia stem cells.

Hematopoietic stem cells are not spared by the aging process, in which DNA damage, telomerase shortening, oxidative stress, and poor homing efficiency have been reported. This could explain some of the differences between childhood and adult leukemias. Such genetic and epigenetic damage together with decreased immune system efficacy, vulnerability of older patients with a decreased function of various organs, and environmental factors can result in the development of malignant hemopathies in elderly patients^[23,24]. Furthermore, two obvious contributory factors are the dominant determinant of the country-to-country variability of leukemia incidence: heredity and environment.

Hematopoiesis permanently fluctuates between equilibrium and chaos. In a state of equilibrium, the hematopoietic system will slowly fail because its internal dynamics is not able to allow enough responses to its microenvironment. Similarly, a system in chaos will also fail, but that is because it will cease to function as a system. The most productive state always remains at the edge of chaos. This situation is the one that generates a maximum of variety and creativity, and a maximum of new possibilities for the evolution of the system. Leukemia is a disease of chaos, a breakdown of the existing biological order within the bone marrow, more than only the presence of abnormal cells. The disorder derives directly from malfunctioning of the controls that are normally present. We are still far from being able to understand with any precision how any single human leukemia arises. The process of leukemia formation is a complex one of multiple steps involving multiple alterations of cells and their physiologic control mechanisms. These steps may occur rapidly and

Figure 3 Hematopoiesis between equilibrium and chaos.

therefore may not be “rate-limiting”, while others may require more time to complete. Multistep leukemia progression can be depicted as a form of Darwinian evolution. Darwinian evolution involves expansions of cells that are endowed with advantageous genotypes and thus phenotypes. Recent whole genome and exome sequencing studies have begun to illustrate the extent of molecular heterogeneity in acute leukemia. The biologic behavior of leukemia cells is the sum of all the acquired genetic changes. Leukemia stem cells, rather than the bulk leukemia cell population, may be the objects of genetic alteration and clonal selection. The clonal descendants of the “favourable” mutated cell dominate by the cells that lack this mutation, resulting in a clonal expansion.

The development and the behavior of hematopoietic cell lineages appear therefore as a balance between normal and abnormal hematopoiesis in the setting of a functioning or malfunctioning microenvironment under the control of the immune system and the influence of hereditary and environmental events. Multiple equilibrium states may exist. Having leukemia cells does not mean having leukemia. All states seem possible, either stable or transitory, going from normal and functional hematopoiesis to the presence of abnormal cells easily controlled by the immune system, or to pre-leukemic stages without any consequences on normal hematopoiesis, or pre-leukemic stages with inhibition of normal cell lineages without major expansion of abnormal cells, or to the development of an abnormal clone without major infiltrative and proliferative abilities, or to the development of an aggressive leukemia clone taking absolute control of the bone marrow leading to an overt disease. The number of events necessary to affect the equilibrium depends on its stability. In this setting, massive events are required to modify a stable state, while a less stable equilibrium will be changed by minor events. The system, that will emerge, will be the one that will be better than its competitors. Then, the system will trade off increased efficiency every time in favor of greater effectiveness. The strength of a system is proportional to the variety within the system.

Contradictions are used by the hematopoietic cells, as by all complex adaptive systems. They are required to create new possibilities to co-evolve with their microenvironment (Figure 3).

Better understanding pathologic hematopoiesis as a complex adaptive system should have consequences in a therapeutic point of view and should modify our vision to consider disease control. Current therapeutic successes using aggressive treatment approaches, such as intensive chemotherapy or stem cell transplantation, have been conceived based upon the hierarchical concept of hematopoiesis with a “black or white” initial response to therapy and long-term survival defining “cure”, relying on a definitively fixed organization of hematopoiesis. Instead of this traditional reductionist approach, a moving status with a permanent adapting condition of hematopoietic cells according to inner and outer factors as suggested in a complex adaptive system is probably more realistic and could represent the common rule. Indeed, in real life, the concept of morphologic complete remission appears not anymore as an absolute requisite for therapeutic decision-making. The development of more accurate techniques to evaluate residual disease and a better knowledge of intra-cellular mechanisms leading to the introduction of targeted therapies should help the change our way to conceive leukemia therapy. Novel therapeutics should authorize more individualized therapeutic approaches. As it has already been the case in chronic leukemias since the introduction of tyrosine kinase inhibitors, a concept of acute leukemia therapy moving to an effective control of the disease compatible with a normal life instead of a supposed “complete” eradication of malignant cells seems a more accurate and more realistic goal.

Abstract

Pluripotency of embryonic stem cells (ESCs) and induced pluripotent stem cells is regulated by a well characterized gene transcription circuitry. The circuitry is assembled by ESC specific transcription factors, signal transducing molecules and epigenetic regulators. Growing understanding of stem-like cells, albeit of more complex phenotypes, present in tumors (cancer stem cells), provides a common conceptual and research framework for basic and applied stem cell biology. In this review, we highlight current results on biomarkers, gene signatures, signaling pathways and epigenetic regulators that are common in embryonic and cancer stem cells. We discuss their role in determining the cell phenotype and finally, their potential use to design next generation biological and pharmaceutical approaches for regenerative medicine and cancer therapies.

INTRODUCTION

Embryonic stem cells (ESCs) have two unique properties, self-renewal and pluripotency^[1]. Mouse ESCs (mESCs) are isolated from day 3.5 blastocyst and possess ground state pluripotency whereas human ESCs (hESCs) are isolated from late blastocyst and correspond to the epiblast stem cells of the mouse^[2,3]. The pluripotency of ESCs is determined by the concerted action of signaling pathways that respond to external stimuli, intrinsically expressed transcription factors and complexes that govern the epigenetic state. The extended transcriptional network of ESCs is centered on the triad of master regulators of pluripotency Oct4, Sox2 and Nanog^[4]. In the last decade the introduction in somatic cells of transcription factors (Oct4, Sox2, Klf4, c-Myc), microRNAs and small molecules allowed the generation of induced pluripotent stem (iPS) cells^[5]. Due to their ability to give rise to any type of differentiated cells and tissues, both ES and iPS cells offer many opportunities for modeling human diseases and development of regenerative medicine^[6].

ESCs and tumor cells share many common properties exemplified by rapid proliferation, similar metabolic requirements and inhibition of differentiation. Pluripotent ESCs have inherent tumorigenic potential and they generate benign tumors and teratomas when injected in immunodeficient mice^[7]. Reprogramming of somatic cells into pluripotency by oncogenes like Myc and Klf4 suggest a strong link between pluripotency and tumorigenicity^[8,9]. Currently, growing experimental evidence has revealed that tumors contain a variable number of cells that have self-renewal and partial differentiation capacities^[10-12]. Because these cells share these properties with the adult tissue stem cells from which they are likely derived they were termed cancer stem cells (CSCs)^[10-12]. The procedures of somatic cell reprogramming and CSC establishment are both dependent on transitions between epithelial and mesenchymal states (EMT/MET)^[13,14]. In addition, CSCs from epithelial tumors also exhibit ESC-like signatures^[15,16] that include the oncogene c-Myc and factors important for pluripotency such as Sox2, Dnmt1, Cbx3 and HDAC1^[16].

The CSC model^[10-12] ultimately links Cancer with Stem cell biology and provides a common framework that is proposed to account for all the properties of stem cells, regardless of their early or late developmental origin in normal or pathological states. In this review, we analyze common regulatory mechanisms of embryonic

and CSCs focusing on biomarkers, signaling pathways, transcription factors and epigenetic complexes. This information can elucidate the risks stemming from the tumorigenic potential of pluripotent ESC and iPS cells used in tissue regeneration therapies. Additionally, knowledge about their stem cell properties is valuable for the eradication of CSCs that are responsible for therapy resistance, tumor invasion and metastasis.

GENERAL PROPERTIES AND MARKERS FOR EMBRYONIC/PLURIPOTENT AND CSC

Three types of markers for the identification of either ESCs or CSCs are utilized: cell surface molecules, signaling pathway markers and transcription factors^[17]. However, cell surface molecules are mostly used as biomarkers since they can be assessed on intact living cells.

ESC biomarkers

All pluripotent stem cells express on their surface glycan epitopes that show species-specific and differentiation stage-specific expression, the stage specific embryonic antigens (SSEA-1, 3 and 4). SSEA-1 (CD15/Lewis x) is expressed on mESCs and embryonic carcinoma cells (ECCs) but is absent from hESCs^[18,19]. Upon mESC differentiation SSEA-1 expression decreases whereas SSEA-4 expression is induced. Undifferentiated hESCs express SSEA-3/4 but following differentiation they are both silenced and SSEA-1 is induced^[20-22] (Table 1).

Human ESC, embryonic carcinoma and germ tumors are characterized by the expression of tumor rejection antigens (TRA-1-60 and TRA-1-81). These are proteoglycan epitopes that reside on the 200 kDa form of podocalyxin (SC-podocalyxin)^[23,24]. Because they are not expressed on somatic cells, TRAs are useful markers for the isolation of human iPS cells during reprogramming^[25].

Cluster of differentiation antigens (CDs) are membrane proteins that function in diverse processes such as cell adhesion, communication and differentiation. Various family members are expressed in mESCs, hESCs and ECCs. Their expression usually changes following differentiation^[26]. CD324 (E-cadherin), CD31 (PECAM-1), CD24, CD90 (Thy-1), CD9, CD59, CD133 and CD326 (EpCAM) are present on the membrane of ESCs and ECCs although their expression levels can vary depending on the cell line and culture conditions^[17]. Among CDs the epithelial marker CD326 (EpCAM) is the more closely correlated with the undifferentiated state and is rapidly lost upon differentiation^[27] (Table 1). Interestingly, some of the above CDs are also used as CSC markers, as will be discussed below.

Among these markers of stemness, Cripto-1 (CR1, TDGF-1) represents an important component of a critical core pathway that is used by ESCs (Table

Table 1 Biomarkers of pluripotency in mouse and human embryonic stem cells

Biomarker	Role in mESC	Role in hESC
Oct4	Pluripotency ^[200]	Pluripotency ^[4]
Sox2	Pluripotency ^[215]	Pluripotency ^[4]
Nanog	Pluripotency ^[227]	Pluripotency ^[4]
Klf4	Pluripotency ^[253,255]	Pluripotency ^[253]
c-Myc	Pluripotency ^[190]	Pluripotency ^[190]
SSEA1/CD15	Pluripotency ^[118,19]	Not expressed
SSEA 3, 4	Not expressed	Pluripotency ^[20,22]
TRA-1-68	Not expressed	Pluripotency ^[24]
TRA-1-81	Not expressed	Pluripotency ^[24]
Cripto-1	Pluripotency ^[28,474]	Pluripotency ^[28,474]

hESC: Human embryonic stem cell; mESCs: Mouse embryonic stem cells; SSEA: Stage specific embryonic antigens; TRA: Tumor rejection antigens.

1). This growth factor acts during embryogenesis as a TGF- β ligand, co-receptor and as an oncogene. Moreover, Cripto-1 is involved in PI3K/Akt and MAPK pathways in a SMAD-independent manner and it enhances the Wnt and Notch pathways acting as a chaperone for low-density lipoprotein receptor-related protein 5 (LRP5) and Notch respectively^[28]. Cripto-1 is crucial for early embryonic development and is expressed in both mouse and human ESCs resulting in maintenance of stem cell pluripotency. Additionally, Cripto-1 regulates ESC fate choices by repressing the neural and enhancing the cardiomyocytic differentiation^[29]. Recently, it was shown that Cripto-1 performs an essential role in the etiology and progression of several types of human tumors, where it is expressed in a CSC subpopulation and facilitates epithelial-mesenchymal transition (EMT)^[28]. Intracellular transcription factors such as Oct4, Sox2, Nanog, Klf4 that are specifically expressed in undifferentiated stem cells are also important biomarkers. Their importance for pluripotency is examined in detail below.

CSC biomarkers in solid tumors

Breast cancer was the first type of solid tumor where CSCs were identified. Cells exhibiting the EPCAM⁺ ESA⁺CD44⁺CD24^{-/low}Lin⁻ phenotype were able to propagate breast tumors when injected even in a low concentration into the mammary fat pad of immunodeficient mice^[30]. Further studies identified a subpopulation of CD44⁺CD24⁻ cells expressing Aldehyde dehydrogenase (ALDH) capable of propagating tumor, by injection of as little as 20 cells in immunodeficient mice^[31]. CD44 is a cell membrane protein that binds hyaluronan (HA) and has a role in cell-cell and cell-extracellular matrix (ECM) interactions. Studies have implicated CD44 in breast cancer cell adhesion, migration, invasion and metastasis^[32]. Additionally, it protects cells from apoptosis which is an important characteristic of CSCs^[33]. HA-CD44 interaction promotes multiple cascades, activating gene transcription of stem cell-related factors in many different tumors, such as ovarian, breast, head and

neck cancer^[33]. Like CD44, CD24 is a widely expressed glycosylated cellular adhesion protein. Low expression of CD24 in breast CSCs was shown to enhance their growth ability and metastatic potential, through a chemokine receptor CXCR4 response^[34]. Additional surface markers for breast CSCs are: CD13, also a marker for brain and colon CSCs, α 6-integrin, CD61, CD29 and CD49.

The ALDH family of enzymes catalyzes the oxidation of aldehydes into carboxylic acids in a NADP⁺ dependent manner^[35]. ALDHs play a crucial role in retinoic acid biosynthesis, metabolism of cyclophosphamides and clearing toxic byproducts of reactive oxygen species^[36]. High ALDH activity was measured in human adult hematopoietic and breast stem cells, murine neural stem cells, as well as leukemia, breast, colon, head and neck CSCs^[35]. Emerging evidence supports the significance of ALDH as a biomarker for adult and CSCs of different origin, including pancreatic, prostate, ovarian, lung, head and neck squamous cell carcinoma^[37].

The first evidence for the existence of CSCs in brain tumors was provided by Singh *et al.*^[38]. Brain CSCs express the cell surface marker CD133 and lack the expression of neural differentiation markers. CD133 is a transmembrane glycoprotein expressed in mouse and human ESCs, as well as in different types of adult stem/progenitor cells, including hematopoietic and neural stem cells, endothelial precursors, mesenchymal progenitors, kidney, mammary glands and pancreatic, colorectal, testis, prostate, ovarian, lung and melanoma CSCs^[39]. The exact function of this protein remains unknown, but it was proposed to act as an organizer of the cell membrane topology^[40]. Limitations on the exclusive use of CD133 as a brain CSC marker arise from a study by Beier *et al.*^[41] who have reported that CD133 negative cells from glioblastoma sphere cultures are able to propagate tumors in immunodeficient mice. Moreover, CD133 expression was shown to depend on culture conditions and hypoxia levels. Additional markers shared by normal and cancer brain stem cells are nestin, Sox2, Musashi-1 and Bmi-1^[42]. Several studies have indicated that multidrug resistance transporters (MDR) such as ATP binding cassette (ABC) transporters and breast cancer resistance protein (BCRP/ABCG2) increase drug efflux from the cells^[43,44].

Stage-specific embryonic antigen 1 (SSEA1), also known as CD15, is a well characterized marker of undifferentiated mouse and differentiated human ESCs. It was first identified in neural embryonic progenitors and represents a putative brain CSC marker. SSEA1 expression correlates with increased cell proliferation, decreased differentiation and apoptosis^[45]. CD15⁺ cells exhibit high tumorigenicity. Another potential brain CSC marker is Nestin, an intermediate filament protein that was first identified as a neural stem cell marker^[46]. It is expressed in many different brain tumors and is involved in stemness, cell growth, invasion and migration^[47]. Finally, brain, like other CSCs

from breast and lung are resistant to chemotherapy and radiotherapy because of the expression of MDR1 transporter on their cell surface^[48].

Colorectal CSCs also express CD133^[49] and the surface molecule Epithelial Specific Antigen (ESA/EpCAM), while lacking expression of intestinal differentiation markers such as cytokeratin 20 (CK20). EpCAM is an epithelial adhesion molecule involved in proliferation, differentiation, migration and signaling^[50,51]. Another adhesion protein, CD166, was proposed as a biomarker in colorectal CSCs^[51]. CD166 is present in a wide variety of normal tissues, as well as in different cancers including breast, lung, prostate and melanoma^[52]. CD166 is used as a positive prognostic marker for survival in colorectal cancer despite the contradictory studies regarding its timeframe of expression during tumorigenesis. Other recently identified potential markers include CD24, CD29 and Lgr5. CD29 (β 1-integrin), a transmembrane receptor for extracellular proteins activates signaling cascades responsible for proliferation, differentiation, migration, survival or death^[53]. Finally, Leucine-rich repeat-containing G protein coupled receptor 5 (Lgr5), a receptor for R-spondins is characterized by a large extracellular and seven transmembrane domains. It binds R-spondin proteins which activate Wnt/ β -catenin signaling as a Wnt pathway co-receptor^[54,55]. Lgr5, a Wnt pathway target itself, is expressed in various stem cell types. High Lgr5 expression levels are associated with high vimentin and low miR-200c expression followed by increased invasiveness and lymph node metastasis^[56].

Pancreatic CSCs are characterized as CD44⁺CD24⁺-EpCAM⁺^[57], like CSCs from other solid tumors, such as ovarian cancer^[46]. On the contrary, breast CSCs exhibit low CD24 expression. Tyrosine kinase c-Met and CD133 have emerged as additional pancreatic CSC markers^[58,59]. Indeed, solely CD133⁺ cells, were shown to induce tumor formation in high frequency^[59]. Moreover, concomitant expression of CXCR4 promotes metastasis and represents a useful target for antitumor drugs^[59,60].

Prostate CSCs are characterized by high expression of CD44 and CD133, as well as the existence of ALDH1A1 and ABCG2 transporter on their cell surface, which confer chemoresistance. A2 β 1 integrin was also proposed as a prostate CSC marker, in addition to the lack of differentiation markers, such as PSA^[61].

Ovarian CSC markers are CD133, CD44 and CD24^[62]. Additional markers are EpCAM, ALDH1 and CD117 or c-kit proto-oncogene^[62]. The c-KIT receptor is activated by autophosphorylation upon stem cell factor (SCF) binding and is involved in cell proliferation, apoptosis, differentiation and adhesion^[46]. Moreover, CD117 was associated with chemotherapy resistance^[63]. Finally, other molecules that are significant for ovarian CSCs are MyD88 for chemoresistance, Lin28 and Oct4 for cancer stemness and dedifferentiation^[35].

Melanoma CSCs were recently found to be positive for CD20, CD133 and the ABC transporters, ABCG2 and

ABCB5^[64]. Additional markers are CD133 and CD166^[64]. CD133⁺ melanoma cells, which overexpress CD166 and nestin, exhibit tumor-propagating ability and high expression levels of genes responsible for tumor initiation and metastasis^[65]. CD271, which was proven to be important for maintenance of stem-like properties and tumorigenicity of melanoma cells^[66] is considered as the most convincing biomarker for melanoma CSCs. In addition, CXCR6 is implicated in their asymmetric division^[67] and Oct4 that is induced upon hypoxia is capable of promoting melanoma cell dedifferentiation into CSCs^[68].

Lung CSCs express CD133 as well as CD24, CD34, CD44, CD87 and ALDH1^[35,69]. CD133⁺ cells show increased expression of Oct4 protein and the ABCG2 transporter^[70]. Finally, Bmi-1 which is expressed in human small cell lung cancers could be applied as a potential lung CSC marker due to its role in self-renewal^[71].

Hepatocellular CSCs express CD133^[72]. CD133⁺ cells exhibited increased expression of Oct4, Notch, Wnt/ β -catenin, Hedgehog and Bmi-1, genes implicated in self-renewal, pluripotency, proliferation and differentiation^[73]. EpCAM, CD90 (Thy-1), CD44, CD13, ALDH1, ABCG2, CD117 and AFP represent additional hepatic CSC markers^[74].

The head and neck squamous cell carcinoma share the same biomarkers as most of the above described CSCs, including CD44, CD133, ABCG2, ALDH1, c-Met, Bmi-1 and Lgr5^[75-77].

In conclusion, putative CSCs have been characterized and enriched from many types of solid tumors using various cell surface markers. These CSC biomarkers offer important biological diagnostic and therapeutic tools (Table 2).

CONVERGENCE OF SIGNALING PATHWAYS IN EMBRYONIC AND CSC

Pluripotency of ESCs is regulated by core transcription factors as well as key signaling pathways, including LIF/Stat3 in the case of mESCs, Wnt, Hedgehog, Notch, FGF and TGF- β for both mESCs and hESCs^[78]. One hallmark of CSCs is their self-renewal capacity driven by developmental pathways^[13,79,80]. Below, we will outline the common signaling mechanisms in self-renewal, differentiation and pluripotency of mES, hES and CS cells in solid tumors.

Jak/Stat signaling

Binding of cytokines to their cognate receptors induces the activation of Jak kinases and the phosphorylation, dimerization and nuclear shuttling of signal transducers and activators of transcription (STATs). The Jak/Stat signaling pathway is activated by the cytokine LIF (leukemia inhibitory factor) in mESCs and is required for their self-renewal and pluripotency^[81]. In contrast, LIF does not support the pluripotency of human ESC.

Table 2 Biomarkers of cancer stem cells

Cancer type	Biomarkers
Breast	CD44 ^[32,33] ALDH ^[31,35] EpCAM ^[30] CD13 ^[35] A6-integrin ^[35] CD61 ^[35] CD29 ^[35] CD49 ^[35] ABCG2 ^[43,44] Nanog ^[204] Klf4 ^[263,264]

Numerous studies have shown the ability of STAT3 to promote tumorigenesis when it is aberrantly activated^[82]. Most importantly Stat3 has been recently shown to regulate the survival and proliferation of colon^[83] prostate^[84] and breast^[85] CSCs.

Wnt/β-catenin signaling

The Wnt/β-catenin branch of Wnt signaling-also referred to as the “canonical” Wnt-pathway- is important for proper embryonic development and adult tissue homeostasis. There are more than 30 extracellular Wnt-ligands, which bind to the receptor complex Frizzled and LRP5/6 (member of the LDL receptor family)^[86]. In the absence of Wnt signals, the scaffolding proteins Axin and adenomatous polyposis coli (APC) anchor the intracellular signaling protein β-catenin to a “destruction” complex involving Glycogen-activated kinase-3 (GSK-3). Wnt ligand-receptor binding initiates a series of events resulting in inhibition of the destruction complex and β-catenin cytoplasmic accumulation^[87]. Its concentration-dependent nuclear translocation and interaction with the T-cell factor/lymphocyte enhancer binding factor (Tcf/Lef) family leads to transcription of proliferative genes such as c-Myc and cyclinD1^[88,89].

Many members of the Wnt signaling pathway are implicated in stem-cell proliferation and activity. In mESCs, Wnt promotes self-renewal^[90]. Studies using small-molecule inhibitors have highlighted GSK-3 as a critical regulator of pluripotency for both mouse and human ESCs^[91]. β-catenin is dispensable for mESC maintenance, however, in its absence, the positive effect of GSK3 inhibition on self-renewal is abolished^[92] and β-catenin mutant mice display embryonic neural progenitor defects^[93]. Double mutants of GSK3 and β-catenin promote exit from pluripotency and

induction of neuroectoderm differentiation^[94]. From the mechanistic point of view, accumulating evidence indicates that the key pathway effector Tcf3 is acting as a repressor of Oct3/4, Sox2 and Nanog, whereas β -catenin inhibits this repression by converting Tcf3 into activator^[95]. Additionally, active β -catenin interacts with Oct4 and enhances its activity in a Tcf-3 independent manner^[96]. In hESCs, there is an ongoing debate about the contribution of Wnt signaling in self-renewal or differentiation^[91,97]. Long-term inhibition of Wnt did not affect survival of hESCs, whereas activation of Wnt signaling resulted in activation of mesoderm differentiation. In fact, differential activity of Wnt signaling associates with distinct lineage-specific differentiation potential of hESCs^[98].

Wnt signaling also regulates the activity of somatic SCs including those in the skin, blood, brain and the mammary gland, whereas aberrant signaling results in neoplasia^[94]. Mutations in key mediators of the Wnt pathway have been observed in approximately 90% of all colon cancers^[78]. Wnt activity was found to be enhanced in the CD133⁺ stem-like cell population of colorectal cancer and in Lgr5⁺ (a Wnt family member) intestinal crypt stem cells, which were identified as the origin of adenocarcinomas^[94,99]. Following transplantation in a mouse model for lineage tracing, Lgr5⁺ cells expand clonally repopulating all other adenomas^[100]. Myofibroblast-secreted factors were linked through β -catenin-dependent transcription to colon CSC clonogenicity and were shown to restore the CSC phenotype in more differentiated tumor cells, both *in vitro* and *in vivo*^[101]. These findings indicate a Wnt-dependent role of the tumor microenvironment in colon carcinogenesis.

Wnt is also involved in mammary gland tumorigenesis, since Wnt signaling expands mammary gland stem cells in early tumorigenic lesions of MMTV-Wnt1 transgenic mice^[102]. The mammary gland CSCs pool is sustained through recruitment of Wnt ligands by periostin, a component of the extracellular matrix of fibroblasts. Infiltrating tumor cells induce its expression in the stroma of secondary organs, such as lung, to allow colonization. Inhibition of its function prevents metastasis^[103].

Finally, although the role of Wnt in brain CSCs is still unclear, autocrine activation of Wnt/ β -catenin signaling by the orphan nuclear receptor Tlx, that induces glioma formation when overexpressed, was shown to enhance the proliferation of murine neural stem cells^[104]. Moreover, a recent study linked low oxygen levels in the hippocampus with neurogenesis through HIF-1 α enhanced Wnt signaling^[105]. Interestingly, brain tumor formation is promoted by hypoxia^[94] and HIFs were identified as key players in stemness and malignancy maintenance of colon cancer cells^[106].

Hedgehog and Notch signaling

Hedgehog (Hh) signaling is implicated in many developmental processes, such as in proliferation

and cell-fate specification of neural stem and neural crest stem cells. In lack of Hh pathway activity, many target genes like the Hh receptor Patched (PTC) and the Gli family of transcription factors are actively repressed. Secreted Hh-transmembrane PTC binding results in releasing PTC-repression on Smoothed (SMO), a G-protein-coupled receptor that activates downstream intracellular components^[107]. Despite the presence of functional pathway components, SHh (Sonic Hedgehog) ligand appears to be dispensable for maintaining pluripotency and promoting proliferation of undifferentiated hESCs. However, addition of exogenous SHh to embryoid bodies generated by hESCs promotes differentiation towards neuroectodermal^[108]. On the contrary, SHh was reported to stimulate mESC proliferation through the concerted effect of activated Gli1, increased intracellular Ca²⁺ levels, PKC (protein kinase C) and epidermal growth factor receptor (EGFR) activation^[109].

In adults the Hh pathway is mainly inactive, but it has been reported to participate in tissue maintenance and repair. Its deregulated activity has been linked to cancer development, however little is known about its role in CSCs^[110]. Hh signaling downstream effectors Gli1/2 and Bmi-1, a transcriptional repressor of the polycomb group and central regulator of self-renewal in normal stem cells, were recently shown to control proliferation and pluripotency of breast CSCs and normal human mammary stem/progenitor cells^[111]. Active Hh signaling has also been identified in glioblastoma CSCs. Inhibition of the pathway by chemical molecules or siRNAs leads to loss of their tumorigenic potential^[112,113]. Hh signaling is furthermore preferentially activated in colon carcinoma CSCs derived from primary clinical specimens, whereas its hindrance negatively regulates cancer cell proliferation and induced apoptosis of colon CSCs^[114]. Finally, a number of recent studies have implicated Hh signaling in EMT and metastasis, for example in pancreatic cancer cell lines inhibition of Hh results in EMT-inhibition and blocks metastasis^[115].

Notch signaling is a crucial regulator of cell to cell communication during embryogenesis, cellular proliferation, differentiation, and apoptosis^[79]. The Notch pathway consists of a membrane-tethered receptor (Notch 1-4), that undergoes proteolytic cleavage by ADAM-type metalloproteases and γ -secretase upon ligand binding (membrane-associated Delta-like, Jagged in mammals). Following cleavage, the released intracellular Notch domain shuttles to the nucleus to form a transcriptional complex with recombining binding protein suppressor of hairless (RBPJ, also known as CBF1) and mastermind-like proteins, ultimately activating genes of the hairy and enhancer of split-related family^[78,79].

Despite the presence of functional pathway components during early embryonic development, Notch signaling is dispensable for the maintenance of hESC or mESC pluripotency and constitutively activated Notch does not alter the stem cell phenotype^[116-118].

Inhibition of pathway components by siRNAs or by a chemical compound against γ -secretase activity (GSI) interfered with hESC proliferation without driving their differentiation^[119]. However, a number of studies indicate a decisive role for Notch in ESC fate determination. Activated Notch signaling was shown to promote neural commitment of both hESCs and mESCs^[117]. In undifferentiated hESCs it is required to form the progeny of all three embryonic germ layers except for trophoblast cells^[120]. In mESCs, there appears to be no *in vivo* requirement for the Notch pathway, until after all three germ layers have formed^[121].

Notch signaling is important for tissue maintenance in many organs, including the skin, blood, intestine, liver, kidney, central nervous system, bone and muscle^[121]. It promotes the maintenance of the neural, myogenic and intestinal stem cell pool in both *Drosophila* and mouse^[122].

Deregulation of Notch has been reported in several cancer types and is progressively linked to CSC self-renewal^[78]. Notch pathway components are characterized by higher expression level in pancreatic CSCs. Their inhibition using either GSI or Hes1 shRNA reduced CSC numbers and tumorsphere formation. Conversely, Notch activation increased pancreatic CSC self-renewal. *In vivo* treatment of orthotopic pancreatic tumors in NOD/SCID mice with GSI blocked tumor proliferation and reduced the CSC population^[123]. Notch signaling is also activated and plays a crucial role in promoting CSC survival, proliferation and tumor initiation (but not progression) in colon cancer. An antibody against Notch ligand DLL4 inhibited tumor growth in a xenograft mouse model^[124,125].

In medulloblastoma, increased Notch and Hh signaling have been linked to the maintenance of a stem-like cell population. Pharmacological depletion of Notch signaling inhibits medulloblastoma growth in mouse xenografts^[126]. In this context, Notch was proposed to interact with Hh signaling to promote oncogenesis^[127]. Additional pathway interactions were found in human breast epithelial cells, where oncogenic conversion is driven by increased Wnt signaling *via* Notch-dependent mechanism^[128]. Deregulation of Notch signaling is an early event in pre-invasive ductal carcinomas. Reduced mammosphere forming efficiency of *in situ* ductal carcinoma in the presence of Notch inhibitors suggested that Notch regulates breast CSC self-renewal^[129]. In normal breast tissue, Notch1 was proposed to regulate progenitor-to-luminal differentiation, whereas Notch4 stem-to-progenitor cell transitions. Interestingly, inhibition of Notch4 and, to a lesser extent, Notch1 signaling results in decrease of the stem-like cell population and of tumorsphere formation in primary breast cancer samples and cell lines and in limited tumor formation *in vivo*^[130]. Furthermore, Notch4 (but not Notch1) activation inhibits mammary epithelial cell differentiation and promotes mammary carcinogenesis in mice^[80,131].

TGF- β signaling

The TGF- β pathway plays a major role in development. Depending on the downstream effector molecules, it can be classified into the Smad1/5/8, the Smad2/3 and the Tab/Tak pathways. Secreted TGF- β ligands bind to the extracellular domain of Ser/Thr kinase type I and type II TGF- β trans-membrane receptors (TGF- β R) thereby phosphorylating and activating latent cytoplasmic SMAD transcription factors^[132]. Among 42 known ligands in humans, bone morphogenetic proteins (BMPs) and growth differentiating factors bind type I receptors (GDFs) activate Smad1/5. Activin and Nodal trigger phosphorylation of Smad2/3 through TGF- β R I/II. Activated Smads form a higher-order protein complex with Smad4, which then translocates to the nucleus to modify gene transcription. Inhibitory cytoplasmic Smad6/7, as well as molecules secreted by neighboring cells like Lefty, further increase the regulatory complexity of the pathway^[78].

During embryonic development cell fate determination, such as mesoderm and primitive streak formation in the mouse, as well as neural induction and mesoderm specification in *Xenopus* are affected by the TGF- β pathway^[133]. Both the Smad1/5/8 and the Smad2/3 branches are involved in ESC pluripotency/differentiation. Activin/Nodal/Smad2/3 signaling is important for sustaining self-renewal and pluripotency of mouse and human ESCs^[134-136], whereas BMP/Smad1/5/8 signaling promotes self-renewal in mESCs^[137,138] and differentiation in hESCs^[139-141]. The partly divergent signaling outcomes observed in mouse vs human ESCs are most likely due to the different developmental stages from which they are derived, hESCs being more similar to mouse epiblast stem cells (EpiSCs)^[3,142].

In mESC culture, concerted BMP/LIF signaling sustains pluripotency through the induction of inhibitor of differentiation (Id) proteins, and by inhibiting two major differentiation pathways, namely extracellular receptor kinase (ERK) and p38 mitogen-activated protein kinase (MAPK) at the same time^[137,138,143]. Furthermore, it was recently reported that mESC self-renewal is endogenously activated by autocrine loops of Activin/Nodal^[135].

In hESC culture, Activin A, which is secreted by mouse embryonic fibroblast feeder layers, suppresses BMP signaling and hESC differentiation, while stimulating the expression of pluripotency factors (e.g., NANOG, OCT4, FGF2/8, NODAL)^[144,145]. Nodal is secreted by hESCs themselves, reinforcing their pluripotent state by an autocrine mechanism. A regulatory loop is formed by simultaneous secretion of the Nodal inhibitor Lefty. Upon differentiation Nodal expression is rapidly down-regulated^[134,136,146]. Pluripotency is further sustained by downstream pathway effectors Smad2/3 which bind to and trans-activate Nanog expression in undifferentiated hESCs^[147,148]. Smad2/3 phosphorylation levels decrease upon early hESC differentiation^[134]. Smad3 alone was

also shown to form a complex with Oct4 and directly regulate many Oct4 targets^[149]. On the contrary, SMAD1/5 phosphorylation levels increase upon hESC differentiation^[134,150], a finding consistent with the ability of BMP4 to initiate differentiation to trophoblasts *in vitro*^[139].

The TGF- β pathway is also involved in EMT during embryonic morphogenesis. Interestingly, some epithelial cells acquire thereby self-renewing characteristics reminiscent of stem cells^[151]. In carcinomas, EMT can lead to metastasis and high-grade malignancy^[152].

TGF- β signaling plays a complex, context-dependent and tissue-specific role in cancer development and CSC proliferation. While inhibiting the onset of carcinogenesis the pathway may promote invasion and metastasis at later disease stages^[153].

Skin epithelia lacking TGF- β II exhibiting enhanced integrin/focal adhesion kinase (FAK) signaling were prone to age-dependent squamous cell carcinoma development^[154]. Moreover, tumor regression occurred in cancer cells lacking integrin/FAK signaling^[155]. CSCs isolated from the tumor/stromal interface of TGF- β II null squamous carcinoma formed less differentiated, highly aggressive and metastatic skin cancers. Interestingly, FAK depletion counterbalanced the TGF- β II-null phenotype^[156]. These data support an important role for TGF- β in counterbalancing the integrin/FAK-dependent tumorigenic effects in squamous cell carcinoma by down-regulating CSC proliferation and expansion^[133].

Breast cancer cells respond to TGF- β by exhibiting stem-like properties. A recent study revealed that chemotherapy relapse of triple-negative breast cancer (TNBC) might involve expansion of CSCs caused by activated TGF- β and IL-8 signaling in The resistant CSCs are prone to TGF- β pathway inhibitors^[157].

In malignant gliomas, TGF- β signaling also appears to exert agonistic effects on tumorigenesis through the Nodal/Activin branch of the pathway, increasing self-renewal of glioma stem cells (GSCs) by enhancing LIF/STAT signaling^[158]. Furthermore, TGF- β -Sox4-Sox2 signaling appears to be important for the maintenance of stemness of GSCs^[159]. On the other hand, the activation of the BMP branch of the pathway by BMP4, initiated neural differentiation and blocked tumor growth in a mouse xenograft model^[160]. In addition, epigenetically silenced BMP signaling was proposed to desensitize glioblastoma stem-like cells to normal differentiation cues and to promote their proliferation^[161].

The differential CSC responses to TGF- β cues underlie a serious dilemma over the clinical use of TGF- β agonists/antagonists^[133].

Fibroblast growth factor signaling

Most fibroblast growth factor ligands (FGF1-22) function in a classical autocrine or paracrine manner. Ligand-receptor binding results in autophosphorylation and dimerization of the intracellular region of a tyrosine kinase trans-membrane receptor (FGFR1-4)^[162]. The signal is further relayed through four main pathways:

RAS-RAF-MAPK (ERK), PLC γ -PKC, PI3K-AKT and JAK/STAT. Emerging evidence suggests that FGFRs also traffic to the nucleus, activating entirely different downstream molecules^[163].

Mutations of FGF pathway components result in pre-implantation lethality of the early mouse embryo^[162]. Autocrine FGF-induced ERK1/2 signaling is dispensable for mESC pluripotency but requisite for their differentiation into neural and mesendodermal lineages^[164,165]. Ying *et al.*^[166] further suggested that addition of LIF and BMP to culture media promotes mESC self-renewal solely by compensating for the pro-differentiation effects of FGF4. mESCs are comprised of heterogeneous populations. Cells primed for differentiation towards the primitive endoderm express FGF5 and Brachyury. FGF4 signaling on the other hand additionally maintains the primed state towards germ layer differentiation^[162,167].

In stark contrast to mESCs, hESCs require exogenous FGF2 to sustain self-renewal and the capacity to give rise to somatic lineages^[168,169]. The combined use of FGF2 and Activin is the most effective in maintaining hESCs and EpiSCs self-renewal. Recent studies suggest that spontaneous extra-embryonic differentiation, to which both hESCs and EpiSCs are prone, may be blocked by FGF^[3,162]. FGF2 seems to influence the pluripotent state of hESCs on several levels. It activates NANOG expression in cooperation with Activin signaling through SMAD2/3^[147] and synergizes with Noggin to repress trophoblast-inducing BMP signaling^[140,170]. FGF/ERK signaling leads to phosphorylation of c-Myc, c-Jun and c-Fos. Its inhibition leads to a decrease in the expression of core pluripotency factors Nanog, and Oct4^[171-173]. Interestingly, ERK and GSK-3 inhibition have successfully supported the reprogramming procedure for the generation of human iPS cells^[174]. Furthermore, conversion of hESCs to an mESC-like phenotype was achieved by the concerted action of ERK and p38 inhibitors with LIF^[175]. A number of recent studies raise the possibility of differential and sometimes opposing functions of FGF in hESCs, depending on the downstream effector signaling cascades^[172,176].

Exogenous FGF2 is also required for growth and maintenance of CSCs isolated from different human carcinomas (*e.g.*, brain, breast) in tumorspheres, but the mechanisms of FGF action remain to be elucidated^[177,178]. A recent study revealed that the expansion of a functional breast CSC pool in response to estrogens is induced through a paracrine FGF/FGFR/Tbx3 signaling cascade, which is also functional in epithelial stem cells from the normal mammary gland^[179]. Guthridge and colleagues transformed NIH3T3 cells with FGF4 and found out, that HSP-90, p63, LAMP-1 and CyclinD1 were massively activated^[180]. The obtained results suggest a link between FGF4, CSC expansion and tumorigenesis^[181]. Indeed, Cyclin D1 is considered to be a marker for cancer onset and progression, while in stratified epithelial tissues p63 is thought to regulate stem cell characteristics^[182,183].

In conclusion, emerging evidence indicates a complex crosstalk between signaling pathways in development, adult tissue homeostasis and cancer. A better understanding of the pathway interplay and how it controls the biology of ESCs, SCs and CSCs will be essential for the advance of regenerative medicine and for developing effective cancer therapies.

COMMON TRANSCRIPTIONAL REGULATORS OF EMBRYONIC/PLURIPOTENT AND CSC

Regulatory networks in pluripotency

Transcription factors Oct3/4 (Pou5f1), Sox2 and Nanog constitute the “core pluripotency network” that regulates pluripotency of both mouse and human ESCs. They bind synergistically to their own promoter/enhancer elements establishing an auto-regulatory circuit^[4,184]. This master pluripotency network, including additional factors such as Sall4, Klf4, and Stat3 binds to and regulates the expression of two distinct groups of genes in ESCs: genes related to self-renewal (active) and genes related to differentiation (silenced)^[185]. The latter group of genes is co-occupied by the epigenetic silencing complexes Polycomb (PRC1 and PRC2)^[186]. A second important multi-protein complex is centered on the oncoprotein Myc (Myc network). Both networks are mutually regulating each other and interact physically and functionally with chromatin remodeling and modification complexes^[187,188]. The Myc complex binds near the transcription start site (TSS), whereas the core pluripotency complex binds to upstream promoters and enhancers^[189-191]. The master pluripotency factors (Oct4, Sox2, Nanog) form super-enhancers, clusters of enhancer elements that recruit Mediator and determine cell identity^[192,193].

Oct4, Sox2, Klf4 and Myc were the initial factors with the potential to reprogram somatic cells into pluripotency^[188,194]. The individual role of these factors in pluripotent and CSCs will be examined below. Oct4 in ESCs and CSCs Oct4 belongs to the POU family of homeodomain proteins and is encoded by the *Pou5f1* gene. Its expression has been identified in undifferentiated ESCs, embryonic carcinoma cells (ECCs), pluripotent epiblast and embryonic germ cells (EGCs)^[195-197]. Nichols *et al.*^[198] reported that Oct4 expression is essential for the maintenance of ESC properties. They showed that Oct4-deficient embryos did not form a pluripotent inner cell mass and differentiated to trophoblast^[199]. Moreover, inhibition of Oct4 in mESCs led to the upregulation of trophoblast genes (*Cdx2*), while its overexpression caused differentiation into primitive endoderm and mesoderm^[200]. Under serum free culture conditions Oct4 overexpression in ESCs promoted neuroectoderm formation and subsequent neuronal differentiation^[201]. Oct4 cooperates with Sox2 to regulate the expression level of genes important for self-renewal and pluripotent

phenotype of ESCs (e.g., Nanog). On the other hand, when the Oct4 or Sox17 expression levels increased, Sox2 was replaced by Sox17 and targeted genes that trigger the endodermal expression program^[202]. These results indicated that the precise levels of Oct4 determined the ESC fate and that Oct4 is a master player in sustaining stem cell self-renewal.

Numerous studies have indicated that Oct4 plays a crucial role in tumorigenesis and tumor metastasis. It was shown to be upregulated in many human cancers such as bladder, seminoma, prostate and breast cancer^[15,203-206]. Hu *et al.*^[207] reported that in murine lung carcinoma cells and human breast cancer MCF7 cells, ablation of Oct4 expression leads to apoptosis of CSC-like cells through the Oct4/Tcl1/Akt1 pathway and inhibition of tumor growth. Another study confirmed that the reduction of Oct4 in lung cancer cells blocked the clonogenicity and tumor invasion^[70]. Chiou *et al.*^[208] enriched oral CSCs by sphere formation and concluded that these cells highly expressed Oct4 and had similar characteristics of stem cells and malignant tumors. A year later, Rentala *et al.*^[209] reported that the expression of Oct4 in prostate CSCs maintained their stem cells properties. Moreover, it has been revealed that ectopic expression of Oct4 into normal primary breast epithelial preparations generated cell lines which form triple-negative breast carcinomas in nude mice^[210]. Recently, Wang *et al.*^[211] demonstrated that cervical cancer cells expressed higher Oct4 levels than normal cervix cells. They proposed that Oct4 promotes tumor formation *in vivo* and inhibits apoptosis by the activation of miR-125b expression^[211]. In addition, Oct4 has been suggested to regulate stemness of head and neck squamous carcinoma CSCs. The overexpression of Oct4 activated Cyclin E leading to tumor growth and tumor invasion through slug expression^[212].

Sox2 in ESCs and CSCs

Sox2 is a member of the Sox (SRY-related HMG box) family that consists of transcription factors with a single high-mobility group box DNA-binding domain and also belongs to the SOXB1 subgroup^[213]. Sox2 is expressed in the inner cell mass (ICM) and extraembryonic ectoderm of pre-implantation blastocysts^[214]. Sox2 deficient blastocysts could not form a pluripotent ICM. Moreover, Sox2-deficient mESCs differentiated primarily into trophoblast, while the Oct4 overexpression rescued the pluripotency of Sox2-null mESCs^[215]. As a result, Sox2 is critical for the maintenance of Oct4 expression and hence the stem cells' properties. Furthermore, Masui *et al.*^[215] identified a synergistic function of Sox2 and Oct4 for the activation of Oct-Sox enhancers, leading to the regulation of various pluripotency genes, including Nanog, Oct4 and Sox2. Overexpression of Sox2 in ESCs led to their differentiation^[216,217]. This effect was due to the repression of pluripotency genes *Sox2*, *Oct4*, *Nanog*, *Fgf4* and *Utf1*^[216] and the induction of neuroectoderm, mesoderm and trophoblast^[217].

To date, many reports have demonstrated the

involvement of Sox2 in cancer biology and especially in CSCs. Sox2 is critical for osteosarcoma cell self-renewal and antagonizes the pro-differentiation Wnt pathway which can also affect negatively the expression of Sox2^[218]. In addition, it is implicated in the promotion of cell migration and invasion in ovarian cancer, through regulating fibronectin 1^[219]. Studies in gastric cancer showed that inhibition of Sox2 results in reduction of spheres formation and in increase of apoptotic sphere cells^[220]. The contribution of Sox2 in pancreatic CSCs was suggested by the fact that it regulates stemness *via* the control of genes of G1/S transition and EMT^[221]. In prostate CSCs, the inhibition of EGFR signaling led to the decrease of Sox2 expression and self-renewal of prostate CSCs. Moreover, knockdown of Sox2 reduces the ability of prostate CSCs to grow under anchorage-independent conditions^[222]. Similar findings have been extracted from non-small cell lung cancer studies. Singh and colleagues inhibited the expression of Sox2 and noticed a 2.5-fold reduction in sphere formation^[223]. Additionally, EGFR/Src/Akt signaling influenced Sox2 protein expression, due to the decreased levels of Sox2 during the EGFR or SRC inhibition^[223]. In melanoma CSCs, Sox2 is highly expressed and interact with Hedgehog-GLI (HH-GLI) signaling^[224]. In more detail, Santini *et al.*^[224] showed that knockdown of Sox2 decreases the melanoma sphere formation and self-renewal of melanoma CSCs. Two HH-GLI signaling transcription factors, GLI1 and GLI2, have the ability to bind the proximal promoter of Sox2 and thus the HH-GLI signaling regulates Sox2. Finally, Favaro *et al.*^[225] proved that Sox2 is required for CSC maintenance in a high-grade oligodendroglioma mouse model.

Nanog in ESCs and CSCs

Nanog is the third member of the core pluripotency network in undifferentiated ESCs^[226-228]. It is a homeodomain containing transcription factor, which was discovered through a functional screening for pluripotency factors which allowed the maintenance of ESC properties, in the absence of the LIF-STAT3 pathway^[227,228]. Chambers *et al.*^[228] also added that Nanog expression is high in Oct4-null embryos, whereas its overexpression does not counteract the differentiation program of ESCs prompted by Oct4 deletion. In the absence of Nanog, embryos do not form a pluripotent ICM^[227,229], although Nanog-null mESCs can be established^[227,228]. Intriguingly, these Nanog-deficient mESCs although disposed to differentiation, could still be maintained in the undifferentiated state^[227,228]. In 2005, Hyslop *et al.*^[230] showed that Nanog down-regulation in human ESCs promotes differentiation towards extraembryonic lineage, as shown by the upregulation of endodermal- and trophoblastic-characteristic genes. This suggests a pivotal role for Nanog in the maintenance of pluripotency in human embryonic development. Oct4/Sox2 heterodimers bind to the octamer/Sox elements within the Nanog proximal promoter and regulate

Nanog expression in ESCs^[231]. Moreover, Nanog, Oct4 and Sox2 cooperate with signaling pathways mediators resulting in delivering signals directly to the genes regulated by the core factors^[191]. Sites co-occupied by the three core regulators generally have enhancer activity, while the transcription of the respective genes requires the recruitment of at least one of the trio^[191].

Nanog expression was investigated in several types of cancer, including lung, breast, oral, kidney, gastric, cervix, brain, ovarian and prostate cancer^[232-237]. In particular, high expression levels of Nanog are related to a poor prognosis for ovarian serous carcinoma, colorectal, and breast cancer patients^[238-240]. In oral squamous cell and lung adenocarcinoma, Nanog and Oct4 high levels were linked to advanced cancer stage and shorter patient survival^[208,234]. Several groups demonstrated that Nanog expression is much higher in CSCs than in non-stem cancer cells in many types of cancer^[233,241-246]. In colorectal cancer, Nanog-positive CSCs constitute approximately 2% of the total cancer cell population^[241]. In addition, a direct connection between the surface markers of CSC and Nanog has not been clarified yet, but there are many studies which demonstrated that cancer cells expressing these markers would have higher levels of pluripotency genes^[247]. For instance, CD133⁻ or CD44⁻ cancer cells express significant lower levels of Nanog compared to CD133⁺ or CD44⁺ cells, respectively^[248,249]. Moreover, functional studies in various cancer types showed that Nanog induces CSC-like characteristics. Jeter *et al.*^[242] demonstrated that NANOGP8 overexpression in prostate cancer increased clonogenicity and tumor regenerative ability^[247]. Nanog activation leads a small population of colorectal cancer cells to acquire a stem-cell like phenotype^[247]. Furthermore, Han *et al.*^[250] proved that Nanog binds to Cyclin D1 promoter region and regulates proliferation and cell cycle of breast cancer cells^[247,250]. Recently, Siu *et al.*^[251] reported that increased expression of Nanog in ovarian cancer controls cell proliferation, migration and invasion through E-cadherin and FoxJ1 deregulation^[247,251]. These results propose that Nanog may constitute a CSC marker and play a vital role in cancer progression^[251].

Klf4 in ESCs and CSCs

Following the identification of KLF4 as a critical transcription factor for reprogramming, more attention was given to its actions. Klf4 belongs to the Kruppel-like transcription factor family and has a central role in cell cycle regulation, somatic cell reprogramming and pluripotency^[194,252-254]. Klf4 is highly expressed in mESCs and its expression decreases strongly upon differentiation^[255]. The inhibition of Klf4, using RNAi, leads to the differentiation of ESCs^[252,254], while Klf4 ectopic expression postpones differentiation, enhances the expression of Oct4 and promotes self-renewal^[256]. Klf4, in conjunction with Oct4 and Sox2 drives the expression of Lefty1^[257] and Nanog^[258]. In addition, the expression of Klf4 is regulated by STAT3 and Nanog^[252].

being a direct target of both transcription factors^[252,259]. In a recent report, Aksoy *et al.*^[260] described that Klf4 reduction induces differentiation towards visceral and definitive endoderm, concluding that Klf4 inhibits endoderm differentiation in mESCs.

It is not surprising that Klf4 plays a key role in maintaining CSC populations. It is known that telomerase activity is sustained by Klf4 *via* telomerase reverse transcriptase in both CSCs and hESCs, suggesting that Klf4 is important for the long-term proliferative potential of these cells^[261]. Moreover, Hoffmeyer *et al.*^[262] reported that β -catenin regulates Tert expression *via* the interaction with Klf4, supporting a connection between stem cells and oncogenesis. In 2011, Yu *et al.*^[263] reported for the first time that Klf4 is crucial in maintaining breast CSCs and inducing cell migration and invasion. Klf4 is expressed at high levels in CSC populations in mouse primary mammary tumor and human breast cancer cell lines. The inhibition of Klf4 in MCF-7 and MDA-MB-231 decreases the ability of breast CSCs to self-renew and form mammospheres and tumors *in vivo*^[264]. On the other hand, it was shown that Klf4 suppresses metastasis in MDA-MB-231 cells by maintaining the expression of E-cadherin and inhibiting EMT^[265]. Klf4 is highly expressed in colorectal CSCs and its knockdown leads to the decrease of spheres formation, migration, invasion and EMT. These results prove the essential role of Klf4 for maintaining colorectal CSCs^[266]. Furthermore, Wellner *et al.*^[267] reported that Klf4 is induced by ZEB1 through the repression of stemness inhibitor miR-203, and controls/enhances pancreatic and colorectal cancer cells ability to initiate tumor development. Moreover, repression of Klf4 by miR-7 inhibits metastasis of human breast CSCs in nude mice^[268] whereas inhibition of Klf4 by mir-152 suppresses the generation of glioblastoma SCs^[269].

These results propose that Klf4 has important roles not only in stem cell self-renewal and cell motility, but also in CSC and carcinoma cell invasion and metastasis.

Myc in ESCs and CSCs

Myc family which includes three important members - c-Myc, N-Myc and L-Myc - acts as an essential regulator in cell growth, proliferation, differentiation and apoptosis and it is thought to be crucial for stem cell pluripotency and proliferation^[270-272]. Myc is directly regulated by LIF/STAT3 signaling and its constitutive activity renders ESC self-renewal independent of LIF. In contrast, the overexpression of Myc dominant negative form induces differentiation^[273]. Although the individual inactivation of c-Myc and N-Myc has no effect on pluripotency, their simultaneous deletion destabilizes the pluripotent state leading to primitive endoderm and mesoderm differentiation^[274]. Moreover, the overexpression of either c-Myc or N-Myc restore pluripotency of ESCs^[274], supporting the idea that c-Myc and N-Myc perform redundant roles in maintaining pluripotent stem cell identity. Recently, Chappell *et al.*^[275] showed that Myc represses MAPK signaling and results in inhibiting

differentiation.

Several genome-wide analyses have been performed in order to determine how Myc regulates ESC pluripotency. These studies showed that Myc binds to and possibly regulates the transcription of at least 8000 genes in ESCs^[191,276-278]. The Myc-centered complex in ESCs is binding to the TSS and includes also E2F Max and NuA4 HAT complex^[189].

Myc deregulation and elevation have been observed in a wide range of human malignancies, associated with aggressive and poorly differentiated tumors^[279]. It is well-known that Myc is involved in the regulation of 15% of genes in the human genome^[280] and regulates important pro-tumorigenic factors including KRAS and AKT, and tumor-suppressors PTEN and p53^[281,282]. Some reports also showed that Myc-centered protein interaction networks in ESCs are enriched in some cancers, especially in the CSCs, conferring metastatic potential and poor outcome^[16,183]. These findings suggest that the Myc network is responsible for the similarities between ESCs and cancer cells. Wang *et al.*^[283] determined that glioma CSCs expressed high levels of Myc, which is crucial for growth, proliferation and survival. Furthermore, glioma CSCs with low levels of Myc did not generate neurospheres *in vitro* or tumors after xenotransplantation in the brains of immunodeficient mice^[283]. Salcido *et al.*^[284] found that Myc is expressed at high levels in CSC population of small-cell lung cancer. Additionally, it has been demonstrated that Myc expression is significantly upregulated in tumor spheres formed by rhabdomyosarcoma cell lines^[285]. In a recent study, it has been indicated that silencing of Myc using promoter targeting siRNA, decreased prostate CSC maintenance and tumorigenicity and induced senescence in the prostate CSC subpopulation^[286]. The clarification of the role of Myc in hepatic CSCs biology came from Akita work in 2014. They revealed a direct link between c-Myc expression levels and CSC properties and they have further mechanistically demonstrated that c-Myc modulates the hepatic CSC phenotype in a p53-dependent manner^[287].

Collectively the result of accumulating research suggests that ESCs and CSCs share critical transcription factors (Table 3). It is clear that pluripotency factors Oct4, Nanog, Sox2, Klf4 and Myc play a crucial role in cancer development and contribute to cancer treatment. However, further investigation of their role in determining the CSC phenotypes, will provide the exact regulatory mechanisms and possibly new regulatory factors relating to tumorigenesis and metastasis.

COMMON EPIGENETIC REGULATORS IN ESCS AND CSC

Cell epigenetic state has been recognized as an important factor in diverse developmental and differentiation processes *via* global or gene specific regulatory mechanisms. Genome wide analyses and

knockout studies provide new information about the role of epigenetic processes in self-renewal and cancer initiation and permit the development of "epigenetic" therapy as a cancer treatment option^[288,289].

This part of the review highlights our current view of the most important common epigenetic regulators associated with DNA methylation, histone modifications as well as long-non coding RNAs and miRNAs in ESCs and CSCs, their significance in normal development and their deregulation in tumorigenesis.

DNA methylation regulators in ESCs and CSCs

DNA methylation is generated by DNA methyltransferases (DNMTs), enzymes that add methyl groups on cytosines. The most studied members of the mammalian DNMT family include DNMT1, DNMT3a and DNMT3b. DNMT1 is thought to be responsible for the replicative maintenance of the DNA methylation, while DNMT3A and DNMT3B function as *de novo* methyltransferases^[290]. Nevertheless, recent evidence shows that DNMT1 may also be required for *de novo* DNA methylation^[291] and that DNMT3a and DNMT3b can also participate in the maintenance of the DNA methylome^[292]. These findings emphasize the need to clarify the exact role of each DNMT and their potential crosstalk.

Restriction enzyme digestion-mediated and Methylation DNA Immunoprecipitation-ChIP (MeDIP-ChIP) analyses of global DNA methylation show that the DNA methylation levels are reduced in mouse ESC compared to the somatic cells and that methylations on promoter regions lie primarily outside of CpG islands^[293-295]. A methylation analysis of CpGs by Bibikova *et al.*^[296]

reported that the methylation levels of over 370 genes in 14 hESC lines were lower than those of mESCs^[294].

Two groups, Lister *et al.*^[297] and Laurent *et al.*^[298] have compared the methylation maps of hESCs and human fibroblast cell lines and observed significantly higher levels of non-CpG methylation present in hESCs that may be due to differences in methylation regulatory mechanisms between un- and differentiated cell types. Laurent *et al.*^[298] observed that CpA methylation was the most frequent type of non-CpG methylation in hESCs, and that this modification was lost upon differentiation. Non-CpG methylation is also present in mESCs and is reduced from 8% to 4.3%, six days after induction of differentiation^[299]. This non-CpG methylation is more abundant within gene bodies than promoter regions and is catalyzed by DNMT3a and DNMT3b requiring also the presence of DNMT3L^[300]. Methylation profiles of iPS cells are highly similar to the ones of ESC, showing that this is a unique characteristic of pluripotent cells^[297,301]. However its functional role remains unclear.

Deletion of Dnmt1 or 3b in mice results in embryonic lethality^[302], while Dnmt3a^{-/-} mice die within 4 wk after birth showing that these enzymes are essential for normal development^[303]. DNMT1 overexpressing ESCs when injected in blastocysts resulted in embryonic lethality, resembling the effect of DNMT1 deficiency^[304]. DNMT1, DNMT3a and DNMT3b are expressed in hESCs^[305]. Mouse knockout experiments have shown that deletion of DNMTs does not affect ESCs self-renewal but deregulates cell specification, suggesting that global methylation may be dispensable for the undifferentiated state but is critical for differentiation. More specifically, DNMT1^{-/-} EBs contain a large number of Oct4 positive pluripotent cells indicating that methylation is required for proper cell differentiation^[293]. In Dnmt3a^{-/-} Dnmt3b^{-/-} mouse ESCs, only 0.6% of CpGs are demethylated^[293], suggesting that these molecules have limited contribution on global DNA methylation. Furthermore, Pawlak *et al.*^[306] showed that Dnmt3a and Dnmt3b are dispensable for nuclear reprogramming.

Although many observations implied the reversibility of DNA methylation, only recently were identified the TET (ten eleven translocation) enzymes that actively demethylate DNA. The mammalian TET family has three members, TET1, TET2 and TET3 that catalyze 5mC oxidation and generate the 5mC derivatives 5hmC, 5fC or 5caC (5-hydroxymethylcytosine, 5-formylcytosine, 5-carboxylcytosine)^[307-310]. 5hmC is the first intermediate toward DNA demethylation and its variable amounts in different cells and tissues implies a distinct regulatory role^[311]. Recent reports, studying the genomic distribution of 5hmC in mouse and human ESCs, provide evidence that this modification may function as a specific epigenetic mark in gene expression regulation^[312-314].

The expression levels of TET1 and 2 are high in undifferentiated ESCs and decline upon differentiation, in parallel with an increase of TET3^[315]. Further studies have shown that TET1 adds 5hmC on promoter regions and TSSs whereas TET2 activity is detected

in the coding regions^[316]. TET1 activity in ESCs is associated with the demethylation and expression of pluripotency related genes as well as repression of Polycomb targeted developmental regulators^[317]. Moreover, TET proteins were found to participate in various gene expression regulatory complexes *via* interaction with Sin3A co-repressor^[318], Polycomb Repressing Complex 2 (PRC2)^[317] and the O-linked N-acetylglucosaminetransferase, (Ogt)^[319,320].

Although earlier studies have suggested a role for TET1 and TET2 in ESC self-renewal^[321], it was recently clarified that these enzymes are in fact required for proper differentiation of ESCs^[322]. TET1 and TET2 are regulated by the Oct4-Sox2 complex in ESCs and TET1 knock down promotes the differentiation toward endoderm/mesoderm and trophoblast pathways^[315]. A Tet1/2/3 triple knock-out mouse ESC line was unable to generate embryoid bodies, teratomas and could not give rise to healthy chimeras^[322].

A current model proposes that the accumulation of epigenetic and/or genetic changes in a normal adult stem cell generates eventually a heterogeneous tumor population that contains a subset of "CSCs" that are responsible for its long term maintenance^[323]. Regardless of the hierarchical or stochastic nature of the CSCs, studying their epigenome is of paramount importance both for understanding the origin and evolution of cancer as well as applying novel epigenetic therapies. As a result, a growing number of studies has recently been directed in the elucidation of common or distinct epigenetic mechanisms that govern the self-renewal program of ESCs and CSCs.

Cancer epigenome exhibits global DNA hypomethylation and specific promoter hypermethylation^[324,325]. DNA hypomethylation promotes cancer development by increasing genomic instability and activating growth-promoting genes such as R-Ras^[326]. On the contrary site-specific hypermethylation favors oncogenesis by repressing tumor suppressor genes, other genes encoding transcription and DNA repair factors as well as PRC target genes^[327,328]. The above studies provide compelling evidence for deregulated DNA methylation in cancer but do not address distinct cell subpopulations. In this line, Yasuda *et al.*^[329] studied 10 tumor suppressor genes (TSGs) in bulk and CSC enriched MCF7 breast cancer cells based on their ability to form tumor-spheres and found lower DNA methylation levels and H3K27m3 marks in the latter population. Ikegaki *et al.*^[330] proved that epigenetic modifiers can affect the expression of stemness genes and contribute to the establishment of CSCs. They showed that short-term treatment of Neuroblastoma cell lines with the DNA methylation inhibitor 5-aza-2'-deoxycytidine (5AdC) and/or the histone deacetylase inhibitor 4-phenylbutyrate, enhances their CSC phenotype^[330].

The expression levels of DNMTs are elevated in several cancer types^[331-333]. DNMT3b has been shown to play a crucial role in *de novo* hypermethylation of promoter CpG islands. In line with the role of DNMTs in

cancer development, sustained overexpression of the murine *dnmt1* gene in NIH3T3 cells results in cellular transformation^[334]. Conversely, reduction of DNMT1 by an antisense DNMT-RNA reversed the transformed phenotype of the Y1 tumor cell line^[335].

Morita *et al.*^[336] compared colorectal HCT116 WT and its *dnmt1* knockout derivative and showed that the latter has reduced stem cell markers and contained less CSCs, as assessed by tumor formation following xenotransplantation. Again no difference in DNMT3a and DNMT3b was detected^[336]. The importance of DNMT1 in CSC self-renewal was further confirmed by Trowbridge *et al.*^[337] using MLL-AF9 induced mouse leukemia. Additionally, a recent paper about the lyotropic reagent chloroquine reports that it can eliminate CSCs in a TNBC population through reduction of DNMT1 and Jak2 expression^[338]. The above studies demonstrate the role of DNMT1 in the maintenance of the CSC properties and *in vivo* tumorigenicity.

Concerning the effects of DNA demethylase, 5hmC levels are decreased in a broad range of cancer cells^[339]. TET1 has been found as a fusion partner of MLL in a subset of patients with acute myeloid leukemia^[340,341]. TET2 has been reported as one of the most frequently mutated genes in hematopoietic cancer types, but many mutations appear in sites that don't affect its enzymatic activity^[342]. In agreement with this, it was recently found that enzymatically inactive TET1, acting as a transcriptional co-activator for Hif1a, is required for EMT^[343]. Additionally, work by Song *et al.*^[344] has shown that TET2 is involved in breast cancer stemness and metastases due to the silencing of miR-200.

Investigating the methylation signature of CSCs permits identification of modifiers that can target their stemness properties, leading to increased tumor sensitivity to chemotherapy. Current DNMT inhibitors used in cancer therapy, such as Decitabine (5'-aza-2' deoxycytidine) act through incorporation into DNA therefore causing adverse side effects^[345]. Less hazardous alternatives include use of small molecule inhibitors such as SGI-1027^[346] and dietary phytochemicals^[342].

Chromatin modifiers in ESCs and CSCs

It is the complex interplay of DNA methylation with the posttranslational modifications of the histone tails that determines the transcriptional activity of a particular locus^[347]. The effect of histone modifications on diverse cellular functions, has caused intense interest in studying the chromatin modifying enzymes. These epigenetic modifiers include a variety of factors, such as histone methyltransferases (HMTs), demethylases (HDMs), acetyltransferases (HATs) and deacetylases (HDACs)^[348,349]. All the above mentioned factors participate in the regulation of chromatin structure that in turn governs gene transcription.

ESCs are characterized by permissive chromatin structure and consequently higher transcriptional activity compared to differentiated cells. Generally,

histone marks associated with active transcription are more abundant in ESCs and become reduced upon differentiation^[350,351], whereas repressive marks appear in higher levels in differentiated cells. Another interesting feature most commonly found in ESCs are bivalent domains, which are defined by the presence of the active H3K4me3 mark alongside the repressive H3K27me3 mark and is believed to hold genes in a "transcription-ready" state^[352,353]. However a recent study by Denissov *et al.*^[354] challenges the prevailing view by showing that not all bivalently marked genes in mESCs lose their differentiation responsiveness upon loss of H3K4me3. Thus, the role of bivalency and its association with pluripotency remains an open question.

Self-renewal in ESCs necessitates the action of chromatin repressive complexes in order to inhibit expression of differentiation-promoting genes. The best studied silencers of differentiation pathways in pluripotent cells are the PcG proteins, which are organized into two multiprotein complexes PRC1 and PRC2^[355]. PRCs are highly expressed in ESCs and bind mainly to CpG-rich promoters of developmentally regulated genes^[186,356].

The PRC2 complex has three core protein subunits: The enhancer of zeste homology (EZH2) component that catalyzes di- and trimethylation of H3k27, Embryonic ectoderm development (Eed) and suppressor of zeste (Suz12). PRC2 triggers gene silencing by recruiting PRC1, histone deacetylases and DNA methyltransferases^[357]. The PRC1 complex composition is highly variable and the canonical complexes include CBX (polycomb), polycomb group factor (PCGF), human polyhomeotic homolog (HPH) and RING, the E3-ligase that catalyzes the monoubiquitination of histone H2A on lysine 119^[358].

Depletion of PRC2 results in embryonic lethality in mice^[359], while mESCs lacking Eed, Suz12 or Ezh2 show loss of H3K27me2/3, retention of self-renewal capacity and *in vitro* differentiation defects^[360-363]. On the contrary, inactivation of PRC1 in mice leads to deficiencies concerning later developmental stages^[364]. RING1b (subunit of PRC1 complex) deficient mESCs show a slight deregulation of some genes and loss of differentiation potential^[365], whereas mESCs double mutated for Ring1a/Ring1b lose also the ability to self-renew^[366]. In summary, PcG proteins seem to be required for proper ESC cell fate transition but not for their self-renewal. More information is required about their partners to fully understand their regulatory role in ESCs^[367]. Moreover, it was shown that PRC1 and PRC2 can occupy distinct genomic sites and act independently^[368].

The maintenance of the expression program that determines pluripotency requires the presence of both repressive and activatory chromatin modifiers. A complex that counteracts the repressing effect of Polycomb is the Trithorax/MLL^[369]. Trithorax group (TrxG) complex contains a histone K4 tri-methyltransferase

(Set1a/b, MLL1-4), a subunit that recognizes the H3K4me3 mark, tryptophan-aspartate repeat protein 5 (WDR5), absent-small-homeotic-2-like (Ash2L), retinoblastoma-binding protein 5 (RbBP5) and dumpy-30 (DPY-30)^[369,370].

Both activating H3K4me3 and repressive H3K27me3 and H3K9me3 marks are removed by histone demethylases belonging to the Jumonji domain-containing protein family (Jmjd)^[371]. Jmjd proteins connect ESC core transcriptional network with chromatin modulation. More specifically, Jmjd2c participates in stem cell maintenance by reversing H3K9me3 marks at the Nanog promoter, consequently protecting it from silencing, whereas *Jmjd1a/2c* gene expression is positively regulated by Oct4^[372]. The diverse role of Jmjds is underlined by Pasini *et al.*^[362], who reported the involvement of JARID2 in the recruitment of PRC2 by differentiation-related genes in ES cells.

Another chromatin modifier called LSD1/KDM1 factor, is a histone demethylase that suppresses gene expression by removing methylation groups from H3K4. LSD1 has been found to colocalize with NuRD at the enhancer of pluripotency genes and down-regulates their expression upon differentiation^[373]. Finally, Suv39H1, Suv39H2 and G9a methylases, generate H3K9me3 repressive mark important in ESCs^[374].

Histone acetyltransferases (HATs) and the equivalent histone deacetylases (HDACs) constitute another critical category of chromatin modifiers acting as co-activators or co-repressors respectively^[375]. Although deacetylation is associated with gene silencing, ChIP-sequencing studies show that HDACs also colocalize with acetyltransferases at transcriptionally active loci, probably to reset acetylation levels after gene activation^[376].

HDAC1 and HDAC2, the most studied HDACs in ESCs, have been shown to be dispensable for mESCs self-renewal^[377]. However, HDAC1 knockout- ESCs show differentiation defects. HDAC1 and HDAC2 are usually part of large complexes with repressive action like NuRD, CoREST and Sin3^[378]. Alteration of the histone acetylation pattern interferes with stem cell pluripotency and differentiation^[376] as well as reprogramming^[379]. Most importantly inhibitors of HDACs are used as facilitators of reprogramming^[380]. Noteworthy, NuRD complex, which couples chromatin remodeling capacity and histone deacetylation activity^[381], has been shown to act as negative regulator of pluripotency associated genes by fine tuning their expression levels and sensitizing cells to differentiation stimuli^[382]. The distinct repression targets of PRCs and NuRD may explain why reprogramming efficiency is increased by overexpression of PRCs components^[383], but depletion of NuRD proteins^[384].

Finally, small molecule drugs targeting histone demethylases or DNA demethylases are also valuable tools for reprogramming since they can substitute for transcription factors^[385].

The information related to chromatin modifiers

in ESCs has facilitated the elucidation of their role in tumorigenesis. In addition to DNA hypo-methylation, reduced histone acetylation but enhanced histone methylation is an epigenetic feature characteristic of cancer cells^[386,387].

Polycomb HMT proteins are commonly upregulated in cancer^[388]. EZH2, the best studied PcG protein has been found to promote tumor growth by inhibiting pro-differentiation pathways and enhancing cell cycle progression^[389]. Furthermore HDMs, which reverse the action of HMTs, like LSD1, have also been implicated in oncogenesis^[390]. Increased HDAC activity usually characterizes cancer cells^[391]. Resetting normal acetylation levels through treatment with HDAC inhibitors (HDACi) has lowered tumorigenicity, suggesting HDACs as attractive targets for cancer epigenetic therapy^[392].

The role of chromatin regulators in CSCs has recently started to be under study with Polycomb Group (PcGs) proteins to be in the spotlight. EZH2 proved to be essential for the maintenance of breast and pancreatic CSCs^[393]. Intriguingly, EZH2 promotes NFκB signaling in ER-negative breast cancer cells^[243], that in turn has been shown to contribute to the generation of CSCs through a positive feedback loop involving IL6^[394]. In previous studies, silencing of EZH2 in glioblastoma CSCs significantly delayed intracranial tumor formation, demonstrating the necessity for EZH2 in CSC-driven tumorigenesis^[395], whereas treatment of prostate cancer cells with the PRC2 inhibitor DZnep (3-Deazaneplanocin A) inhibited CSC spheroid formation and decreased CSC frequency^[396]. Furthermore, EZH2 seems to contribute to the stemness phenotype of Ewing tumors by suppressing endothelial and neuroectodermal differentiation^[397]. Gupta *et al.*^[398] developed a model of phenotypic transitions to study stochasticity in regulating cell-state equilibrium in cancer cells and EZH2 was used as one of the main phenotypic markers for the CSC population.

Increasing number of studies implicate BMI-1, another PcG member, in cancer stemness. Its expression has been found elevated in many CSC populations such as in salivary adenoid cystic carcinoma^[399], prostate^[400], esophageal^[401], head and neck^[402], cervical^[403], colorectal^[404], laryngeal^[405] and ovarian^[406] CSCs. In addition it has been reported that depletion of Suz12 - a component of PRC2 complex - results in the blockade of mammospheres formation^[407] and increased apoptosis in colon CSCs^[408]. These findings highlight Suz12, as an essential regulator of CSCs.

Downregulation of the histone methyltransferase MLL1 reduces CSC self-renewal and tumorigenicity suggesting a role in CSCs^[409]. Additionally, HDMs like LSD1 are crucial for the biology of CSCs too. Wang *et al.*^[410] proved that inhibition of LSD1 inhibits the proliferation of pluripotent cancer cells but not that of normal somatic or non-pluripotent cancer cells. Except for histone methylation, histone acetylation is also essential for CSCs as a recent study showed that inhibition of HDACs limits the population of CSCs of

head and neck cancer^[411].

In conclusion, epigenetic regulators such as members of the Polycomb and Trithorax complexes, histone demethylases and histone deacetylases are essential for ESC pluripotency and at the same time can promote cancer stemness (Table 3). DNA methyltransferases are indispensable for both cell types and have been already reported as important targets for iPS generation and cancer chemotherapies (Table 3). Finally, DNA demethylases (TET 1, 2, 3) are critical targets for iPS generation, whereas their functions in CSCs await further clarification (Table 3).

MicroRNAs in ESCs and CSCs

The crucial role of microRNAs in mouse and human ESCs has been identified using Dicer and DGCR8 knockout mice. Dicer deletion resulted in embryonic lethality in mice^[412], while DGCR8-deficient mouse ESCs retained self-renewal capacity^[413].

Among the first families of microRNAs identified, miR-290-295 (miR-371 family, human homologous) and miR-302-367 clusters, which include the majority of miRNAs in mouse and human ESCs. Common characteristics of the two clusters is the promoter binding of the core pluripotency transcription factors (Oct4, Sox2 and Nanog)^[414] and the decrease of their expression during differentiation^[415]. Reintroduction of these miRNAs into Dicer1-knockout^[416] and DGCR8-knockout^[413] mice rescued proliferation and normal ESC self-renewal, respectively. It was found that these two clusters maintain the self-renewal by targeting retinoblastoma like 2 (Rb12), a repressor of DNA methyltransferases (Dnmt3a and Dnmt3b). The latter methylates CpG islands and epigenetically silences Oct4^[416,417]. In addition, these miRNAs were shown to regulate the G1/S transition of the ESC cell cycle, by repressing directly or indirectly the expression of the G1/S transition inhibitors (p21, Lats2, Rb1, Rb12 and Rb11)^[418,419].

Other miRNAs acting on the hESC cell cycle were studied by Qi *et al.*^[420], showed that miR-195 and miR-372 promote the transition of G2/M and G1/S, by suppressing the G2/M checkpoint kinase WEE1 and CDKN1A respectively^[420]. Furthermore, miR-92a and 92b were identified to target the *CDKN1C* gene and CDKN2B (known as p57), promoting in this way the G1/S transition^[421].

Beside their function in maintaining pluripotency, miRNAs play important role in the differentiation of ESCs. Tay *et al.*^[422,423] demonstrated that miR-134, miR-296 and miR-470 bind to the coding regions of Oct4, Sox2 and Nanog and suppress their expression and thus the self-renewal state. Similarly, miR-200c, miR-203 and miR-183 target Sox2 and Klf4^[267], while miR-145 was shown to repress human OCT4, Sox2 and KLF4 by binding to their 3'UTR, suggesting its role to regulate pluripotency^[424]. In another study, induction of differentiation caused the increase of miR-21 expression levels revealing its crucial role in stem cell

differentiation by targeting Nanog, Sox2 and Oct4^[425]. Moreover, the expression of miR-22 was also detected in high levels during ESC differentiation^[426]. Landgraf *et al.*^[427] demonstrated that miR-26a, miR-99b, miR-193, miR-199a-5p, and miR-218 are able to suppress the self-renewal of ESCs but the mechanism remains unclear. Another example of miRNAs that regulate the differentiation of ESCs is the miR-125 and miR-181 clusters^[428]. A recent study showed that miR-125 and miR-181 families suppress Cbx7, the primary Polycomb ortholog of the PRC1 complex, in undifferentiated ESCs. Their overexpression leads to the differentiation of ESCs via regulation of Cbx7^[428]. Furthermore, it was found that miR-34a, miR-100, and miR-137 are required for the differentiation of ESCs, and that they function in part by targeting Sirt1, Smarca5 and Jarid1b mRNAs^[429].

Let-7 is another miRNA family which has been widely involved in the establishment of the differentiated cell fate. Melton *et al.*^[430] identified that silencing of pluripotency and self-renewal of ESCs can be caused by the introduction of let-7 into DGCR8-knockout ESCs. In addition, let-7 binds to 3'UTR, inhibits expression of several stemness factors (c-Myc, Sall4n, Lin28) and induces ESCs differentiation^[430]. Interestingly, Lin28 forms a negative feedback loop with let-7, resulting from its blocking function during let-7 biogenesis at the Dicer processing step^[431,432]. Let-7 can also target the G1/S transition activators (cdc25a, cdk6, cyclinD1 and cyclinD2) that increase susceptibility of G1 phase cells to pro-differentiation signals and promote differentiation of ESCs^[431,432].

MiRNAs also play important roles in regulating CSC properties such as cell cycle exit and pluripotency, pro-survival and antistress mechanisms, EMT, migration and invasion, which contribute to tumor metastatic potential.

Because of the early discovery and better understanding of breast CSCs, miRNA studies are more advanced in this cancer type^[433]. Let-7 regulates the properties of CSCs and its overexpression results in the reduction of mammosphere and tumor formation, metastasis and cell proliferation. Moreover, let-7 diminishes the expression of HMAG2, c-Myc, and RAS and controls CSC properties^[434]. Another miRNA that is repressed in breast CSCs is miR-30. The inhibition of miR-30 induces metastasis and self-renewal of breast CSCs^[435] and the transfection of both let-7 and miR-30, causes a more complete reduction of mammospheres formation and CSC abilities in breast CSCs^[435].

Iliopoulos *et al.*^[436] showed the importance of an inflammatory positive feedback loop involving NF-κB, Lin28, let-7 and Il6 in the epigenetic maintenance of the cell transformation state following Src oncogenes activation. The same group using miRNA profiling defined a set of 22 miRNAs that are differentially expressed in normal vs CSCs that included the let-7 and the miR-200 families^[407]. Interestingly, Shimono *et al.*^[437] also identified that miR-200 cluster is down-regulated in breast CSCs and miR-200c reduces the

tumor formation. In addition, members of this family have the ability to regulate the breast CSC properties by repressing the BMI-1^[437] and a subunit of a polycomb repressor complex, SUZ12^[407]. Furthermore, several studies showed that miR-200 family and miR-205 modulate EMT, which is crucial for metastasis and tumor invasion. It was found that the expression of these miRNAs is decreased in cells undergoing TGF-beta induced EMT and their overexpression inhibits the EMT process. These miRNAs modulate the expression of EMT activators, ZEB1 and ZEB2, causing the inhibition of EMT program^[438]. In contrast, ZEB1 and ZEB2 activate EMT by forming a double negative feedback loop with the miR-200 family, resulting from their binding to promoter regions of miR-200 family members^[439]. As previously mentioned, miR-22 directly suppresses the expression of the TET family members (TET1-3), which are implicated in the demethylation of miR-200 promoter. In other words, miR-22 inhibits the activity of miR-200 cluster and promotes EMT and metastasis^[344]. Polytaichou *et al.*^[440] identified that miR-15/16, miR-103/107, miR-145, miR-335, and miR-128b inhibit breast CSC function and growth by directly inhibiting the expression of Suz12, Bmi1, Zeb1, Zeb2, and Klf4.

MiR-9/9*, miR-17 and miR-106b are the mostly represented miRNAs in the CSC population in glioblastoma. It was demonstrated that knocking down of miR-9 and miR-17 causes a reduction of neurosphere formation^[441]. Another study showed that miR-128 reduces glioma cell proliferation *in vitro* and glioma xenograft growth *in vivo*^[442]. Furthermore, miR-128 overexpression modulates the properties of glioma^[443] and prostate CSCs^[400] by inhibiting BMI-1. Li *et al.*^[444] examined the role of miR-34a in brain tumor cells and human gliomas and they demonstrated that miR-34a causes cell cycle arrest, apoptosis or xenograft tumor repression, regulating the glioblastoma CSCs. In CD133⁺ CSCs of glioblastoma, miR-145 causes the inhibition of tumor formation as well as the reduction of CSC properties by targeting Sox2 and OCT4^[445]. miRNA expression profiles of glioblastoma stem cells and non-stem cells revealed that miR-451 is downregulated in the glioma CSCs. Transfection with the above miR leads to the inhibition of tumor growth of glioma CSCs and neurospheres formation^[446]. Another miRNA which is important for CSCs of brain tumors is miR-199b-5p. It was shown that miR-199b-5p blocks Notch signaling and inhibits the self-renewal capacity of medulloblastoma cells by targeting HES-1, a transcription factor of the Notch signaling pathway^[447].

Using prostate CSCs, Liu *et al.*^[448] performed miRNAs expression profiling and found that miR-34a, let-7b, miR-106a and miR-141 are downregulated whereas miR-301 and miR-452 are increased. They also showed that overexpression of miR-34a inhibits prostate CSC metastasis by targeting CD44, while knocking-down of miR-34a promotes tumor migration and development^[448]. MiR-320 was also investigated for

its role in prostate CSCs. Hsieh *et al.*^[449] illustrated that β -catenin is directly targeted by miR-320. Moreover, gene expression profile of miR-320-overexpressing prostate cancer cells revealed a diminished expression of both the genes involved in the Wnt/ β -catenin pathway and the markers of CSCs^[449].

As mentioned before, miR-34a does not play pivotal role only in glioma and prostate CSCs, but also in pancreatic and gastric CSCs^[450,451]. Overexpression of miR-34a in these two cancer types reduces sphere formation and tumor regeneration^[450,451]. Bu *et al.*^[452] reported that miR-34a inhibits colon CSC self-renewal and suppresses tumor formation. Particularly, miR-34a targets Notch-1 resulting in inhibition of Notch signaling which is frequently crucial in colorectal cancer^[452].

LncRNAs in ESCs and CSCs

A number of studies investigated the role of lncRNAs in self-renewal and differentiation of mouse and human ESCs. By performing genome-wide screening, Sheik Mohamed *et al.*^[453] identified four lncRNAs residing proximally to the genomic binding sites of Oct4 and Nanog. Two of them, the AK028326 and the AK141205 have been shown to be the direct targets of Oct4 and Nanog, while their overexpression or inhibition resulted in dramatic changes in the mRNA expression levels of the two core transcription factors, revealing their involvement in the regulatory network^[453]. Chakraborty *et al.*^[454] introduced a new technique combining knock-down and localization analysis of noncoding RNAs (c-KLAN) to study lncRNAs. By inhibiting Panct-1, a non-coding transcript, the amounts of Oct4 and Nanog mRNA were decreased, whereas the expression of differentiation markers increased (Gata6, Fgf5, and T-Brachyury)^[454]. To further examine the role of lncRNAs in ESCs, Wang *et al.*^[418] demonstrated the lncRNA-RoR function as a critical regulator of self-renewal and differentiation in hESCs. lncRNA-RoR prevents the suppression of Oct4, Sox2 and Nanog by miRNAs (miR-145) and forms a feedback loop with the core transcription factors and microRNAs^[418].

Concerning hESCs, the lncRNA_N1 lncRNA_N2 and lncRNA_N3 are important regulators of neuronal differentiation fate^[455].

LncRNAs have also been investigated in cancer. Their role is not well understood in CSCs, but recent studies have correlated some lncRNAs with CSC activity, based on their ability to promote metastasis^[103]. Gutschner *et al.*^[456] developed a metastasis-associated lung adenocarcinoma transcript 1 (MALAT1) knockout model in human lung tumor cells, which confirmed the role of MALAT1 as a biomarker for lung cancer metastasis and revealed its ability to regulate genes associated with lung cancer metastasis^[456]. Furthermore, MALAT1 was implicated in cervical cancer by regulating gene expression (caspase-3, -8, Bax, Bcl-2, BclxL), while in a more recent study it was shown that MALAT1 promotes cell migration and proliferation of cervical

cancer cells^[457,458]. HOTAIR is another lncRNA which has been widely studied for its role in cancer. Gupta *et al.*^[459] demonstrated that HOTAIR is a strong metastasis and tumor invasiveness biomarker in primary breast tumors. This function is due to the recruitment of PRC2 that silences metastasis suppressor genes^[459]. Moreover, other studies suggest that HOTAIR is a potential biomarker for the existence of lymph node metastasis in hepatocellular carcinoma (HCCs)^[460]. As discussed earlier, lncRNA-RoR is an important ESC self-renewal regulator. Recently, it has been shown that its expression was negatively regulated by the NRF2 transcription factor in mammary stem cells^[461]. In particular, the inhibition of NRF2 led to an increase of both mammosphere formation in breast cancer cells and lncRNA-RoR levels supporting an involvement of lncRNA-RoR in tumorigenicity^[461].

To summarize, the above studies demonstrate an essential role of ncRNAs in stemness of ESCs and CSCs (Table 3). A better understanding of ncRNA biology will ultimately provide further insights into the molecular mechanisms of tumorigenesis and lead to the development of new therapeutic strategies against cancer.

DISCUSSION

In recent years there is a tremendous expansion of research focused on the biology of stem cells. As understanding of the differences and similarities of stem cells of various normal or abnormal developmental origins increases, so is the appreciation of their great complexity. In this review we have presented an overall comparison between embryonic and CSCs in terms of biomarkers (Tables 1 and 2), signaling pathways (Figure 1, Table 3), transcriptional and epigenetic regulators (Table 3).

Cell surface markers are very important for the characterization and separation of stem cells. Pluripotent (ES, iPS) cell markers are very useful for fast and effective enrichment when undifferentiated cells are required (positive selection). In addition, such markers are valuable in order to eliminate the pluripotent cells from their differentiated descendants (negative selection) before transplantation. Concerning cancer, a small proportion of cells that bears stem cell features - CSCs - are endowed with self-renewal and differentiation capacity and enhanced tumorigenicity. These cells are refractive to conventional therapies. In line with the above, promising therapies can be based on targeting CSC *via* their specific surface markers, as it has been shown in experimental models and clinical trials. An obvious disadvantage of such an approach is that while various markers are currently reported to mark or enrich for CSCs, no exclusive CSC markers are so far available to ensure high cell specificity of targeting. Table 2 shows combinations of markers that are used in order to identify CSCs from various cancer types. Among them, the major category are cell adhesion or

communication molecules CD44, Esa/EpCAM, CD166, CD129 and receptor-associated proteins such as Lgr5, c-met, c-kit. The enzymatic activity of ALDH can be a useful tool for separating CSCs, however a detailed identification of the active isoforms that are expressed in various cancer types is required^[462]. Most importantly, some ALDH isoforms can have functional roles in CSCs since they are directly involved in retinoic acid signaling and stemness. Another category of various CSC markers are the ABC transporters (Table 2) that actually render CSCs resistant to therapies. A recent promising method for CSC isolation is based on measurement of the intrinsic auto-fluorescence of epithelial CSCs due to the accumulation of riboflavin in cytoplasmic complexes containing ABCG2 transporters^[463]. Some CSC markers are also common with those of ESCs such as CD133, SSEA1, EpCAM and the pluripotency transcription factors Oct4, Sox2 and Nanog. Brescia *et al.*^[464] have demonstrated that silencing CD133 expression in human GBM neurospheres disrupts the self-renewal and tumorigenic properties of the neurosphere cells, indicating that CD133 could potentially be used as a therapeutic target in these tumors. Transcription factors regulating pluripotency could be particularly useful as biomarkers since they are not expressed in tissue stem cells. However, pluripotency factors are intimately cross-regulated and difficult to assess unless convenient assays are used. The importance of these common markers in tumor aggression and metastasis awaits further investigation.

Cell differentiation during embryonic development and cell transformation that leads to oncogenesis share common signaling pathways, suggesting that deregulation of embryonic signaling pathways in adult tissues might result in tumor progression by transforming adult stem and progenitor cells. Many signaling pathways are involved in the stemness of both pluripotent (ES/iPS) and CSCs (Figure 1, Table 2). Wnt, TGF/BMP and FGF are important regulators of ESC self-renewal and differentiation and are able to enhance the CSC population. On the other hand, Hedgehog and Notch pathways have great importance for CSCs and only marginal role in ESCs. Chemical inhibitors of the Wnt, Notch and Hh pathways have been proven valuable in combating CSC populations from diverse solid tumors^[79]. Agents that regulate Wnt signaling such as the CBP/ β -catenin antagonist ICG-001, that forces β -catenin to bind p300 instead of CBP, are tested in pre-clinical trials for the eradication of CSC^[464]. Gamma-secretase inhibitors are able to block the Notch signaling pathway resulting in inhibition of CSC proliferation and tumor regression^[79]. Cyclopamine and synthetic small molecules that antagonize Hh pathway are used alone or in combination with conventional antitumor agents for the inhibition of pancreatic and glioblastoma CSCs^[465].

Additional research on the regulation of normal stem cell response to external stimuli will offer alternative therapeutic means for cancer treatment.

Figure 1 Core signaling pathways in embryonic stem cells and cancer stem cells. A: Mouse ESCs require concerted LIF/BMP signaling to sustain self-renewal and pluripotency, whereas hESC pluripotency depends on the activity of the TGF- β and the FGF pathway. Wnt signaling is important for pluripotency in both species; B: Wnt, Hedgehog, Notch and FGF signaling pathways are associated with CSC self-renewal, while BMP signaling is implicated in CSC differentiation. The TGF- β /Activin/Nodal pathway has a controversial role in CSCs depending on cancer type. ESCs: Embryonic stem cells; CSCs: Cancer stem cells; hESC: Human ESCs; APC: Adenomatous polyposis coli; Dsh: Dishevelled; FGF: Fibroblast growth factor; GSK3: Glycogen synthase kinase 3; JAK: Janus-family tyrosine kinase; LRP: Lipoprotein receptor-related protein; PKC: Protein kinase C; SUFU: Suppressor of fused homolog; TCF/LEF: Tcell factor/Lymphocyte enhancer binding factor.

Emerging evidence suggests that ESCs and CSCs may depend on common critical transcription factors (Table 3). In addition to the Myc oncogene that orchestrates a complex on its own (Myc-complex), CSCs also express members of the ESC core pluripotency complex such as Oct4, Sox2 and Nanog^[466]. Although Oct4, Sox2 and Nanog expression positively correlates with the development of CSCs, the role of Klf4 is highly context-dependent^[467]. While it promotes the self-renewal of various CSCs, it can inhibit EMT signaling pathway^[260,265] and attenuate lung and liver metastases^[468]. Pluripotency transcriptional factors may provide advantageous targets for the elimination of CSCs. For this purpose it would be important to characterize their regulatory circuits in CSCs to the same precision as it was previously attained in ESCs. This knowledge may provide novel approaches for combating cancer^[247,469].

In addition to transcription factors, critical regulators of gene expression in embryonic and CSCs are non-coding RNAs (ncRNAs). Interestingly, ncRNAs, which are important for ESC pluripotency such as lncRNA-RoR, miR-145, miR-200, miR-34a and let-7, can affect the generation of CSCs (Table 3). Accumulating evidence indicates that individual miRNAs and lncRNAs behave as tumor suppressors or oncogenes. Among them, the miR-200 family in combination with the TGF- β signaling are major determinants of the EMT transition that correlates tightly with the appearance of CSCs^[433,434]. Therefore, further investigation of their function in ESCs and CSCs may lead to clinical applications of non-coding RNAs in cancer diagnosis, treatment, and prognosis.

Epigenetic alterations are very important for the inheritance of the cellular phenotype properties. By governing chromatin state transitions and gene expression regulation, epigenetic processes have a crucial role in cell differentiation and tumorigenesis. Most importantly differentiated cancerous cells are driven into stemness *via* a profound epigenetic reprogramming that sustains the malignant phenotype^[470,471]. Although there is already accumulating information regarding epigenetic alterations and therapeutic use of epigenetic modifiers in cancer, less is known about their role in CSCs. Muñoz *et al.*^[471] recently reviewed the role of epigenetic effectors (such as DNMT, EzH2, BMI1 and MLL1) in leukemia and solid tumors and proposed that epigenetic targeting of CSCs may contribute to therapy. The advent of somatic cell reprogramming to pluripotency (iPS) offered a new way to test the effect of extreme epigenetic changes in tumor cells. Can cancer cells be reprogrammed to pluripotency and then induced to differentiate? Although not abundant, recent results in this area suggest a cancer context dependent response to the iPS process^[472]. In those cases, pluripotency was able to dominate over the cancerous phenotype leading to "normalization" although the neoplastic identity reappeared when cancer iPS cells were coaxed to differentiate to their lineage of origin^[472]. Thus reprogramming could offer a new way to track the history of tumor progression.

In conclusion, studies in the fields of stem cells, iPS and CSCs provide strong evidence of cross-complementing benefits. Insight of the tumorigenic properties of stem cells and their differentiated descendants is required before their use in cell replacement therapies^[473]. Understanding the biology and gene circuits shared by both normal stem cells and CSCs, is important for efficient cancer treatment. Cancer heterogeneity is contributed by both clonal and CSC components that are responsible for tumor aggressiveness, invasion and resistance to therapies. An emerging concept in cancer biology is that primary tumors may be composed of evolving and variable clones, each containing biologically distinct stem cells. As cell line models suffer from limited preservation of heterogeneity and newer models of patient derived xenografts are much more labor intensive and costly, alternative, *ex vivo* cancer models are important. As a result, use of the iPS approach may be useful. The hypothesis of normalizing cancer cells by epigenetic reprogramming has been recently under testing but its limits are not defined yet. Mixed initial results may reflect the heterogeneity of the experimental systems utilized, and various oncogenic and genome aberrations that may not be reversed by pluripotency. However, this is a new promising area that may generate diverse iPS-cancer clones from primary tumors. Thus even if the iPS process cannot "cure" cancer, it may provide, as with other human diseases, novel experimental models for studying cancer biology and drug discovery.

Abstract

Traditional therapies against cancer, chemo- and radio-therapy, have multiple limitations that lead to treatment failure and cancer recurrence. These limitations are related to systemic and local toxicity, while treatment failure and cancer relapse are due to drug resistance and self-renewal, properties of a small population of tumor cells called cancer stem cells (CSCs). These cells are involved in cancer initiation, maintenance, metastasis and recurrence. Therefore, in order to develop efficient treatments that can induce a long-lasting clinical response preventing tumor relapse it is important to develop drugs that can specifically target and eliminate CSCs. Recent identification of surface markers and understanding of molecular feature associated with CSC phenotype helped with the design of effective treatments. In this review we discuss targeting surface biomarkers, signaling pathways that regulate CSCs self-renewal and differentiation, drug-efflux pumps involved in apoptosis resistance, microenvironmental signals that sustain CSCs growth, manipulation of miRNA expression, and induction of CSCs apoptosis and differentiation, with specific aim to hamper CSCs regeneration and cancer relapse. Some of these agents are under evaluation in preclinical and clinical studies, most of them for using in combination with traditional therapies. The combined therapy using conventional anticancer drugs with CSCs-targeting agents, may offer a promising strategy for management and eradication of different types of cancers.

Core tip: Cancer stem cells (CSCs) play important roles in tumor formation, metastasis and cancer relapse. In this article, we review the literature on the recent progress in developing anti-cancer stem cell strategies based on improved understanding of CSCs properties and molecular features. These novel therapeutic systems are designed with the aim of eradicating CSCs, by targeting surface specific markers and altering signaling pathways or mechanisms involved in CSCs maintenance and drug resistance, and also to disturb microenvironmental signals that sustain CSCs growth, with specific aim of impede CSCs regeneration and cancer relapse.

INTRODUCTION

Tumor progression is explained by two models: The clonal (stochastic) evolution model and cancer stem cell model. The first one sustain that all transformed cell within a tumor have carcinogenic potential, with unlimited proliferation capacity, and the disease healing requires as therapy the elimination of all tumor cells^[1,2]. This hypothesis is supported by several studies demonstrating that a large number of cancer cells sustain tumor growth when are transplanted into histocompatible mice and the relevant results in this area depends on the xenotransplantation model used. Thereby, modifying xenotransplantation assay conditions can increase the detection of all tumorigenic cells^[3,4]. The second cancer evolution model sustain that tumors evolve from a small population of cells with self-renewal ability and high resistance to chemotherapy and radiotherapy. These cells were called CSCs or cancer initiating cells, due to their capacity to auto-regenerate, proliferate and induce tumor formation. Among their properties, resistance to standard oncology treatments is responsible for ineffectiveness of traditional cancer therapies and lead to tumor recurrence and metastasis^[5].

The CSCs model gained wide acceptance over the last years, based on continuous observations. Recent data suggests that CSCs might evolve from normal stem cells, progenitors or more differentiated cells

with whom they share many resemblance like: Self-renewing, differentiation to progenitor cells, expression of surface markers, common signaling pathways and a close association with microenvironment^[2].

There are two hypothesis regarding CSCs formation: (1) transformation of normal stem cells or progenitor cells into CSCs, process that occurs through multiple gene mutations as result of genetic and epigenetic instability^[6]; and (2) tumor cells progressively acquire stem cell properties through reversal of ontogeny based on oncogene-induced plasticity^[7].

Several studies suggest that epithelial-mesenchymal transition (EMT) process characterized by the repression of epithelial markers (*e.g.*, E-cadherin) and up-regulation of mesenchymal markers (*e.g.*, vimentin, fibronectin and N-cadherin) can also generates cells with stem-like properties^[8]. Mani *et al*^[9] using immortalized human mammary epithelial cells demonstrated that EMT induction results in the enrichment of cells with stem-like properties, an increased expression of stem-cell markers and an increased capacity of cells to form mammospheres. Gupta *et al*^[10] showed that E-cadherin inhibition and EMT induction, respectively leads to an increase number of CSCs in breast cancer cell populations, characterized by an increased resistance to chemotherapy.

CSCs were first described in acute myeloid leukemia, in which a population of CD34⁺CD38⁻ was noticed to possess stem cells capacities of proliferation, self-renewal and differentiation, and to reconstitute a heterogeneous cell population in nonobese diabetic/severe combined immunodeficiency mice^[11]. Later, CSCs were identified in various solid tumors including glioma^[12], as well as breast^[13], head and neck^[14], lung^[15], pancreatic^[16], liver^[17], stomach^[18], colon cancer^[19], *etc.*

Current review presents basic information about CSCs and discusses targeted therapeutic strategies developed for cancer eradication.

CSC: DEFINITION, CHARACTERISTICS, MARKERS

CSCs are auto-regenerating cells, able to proliferate and differentiate through symmetrical and asymmetrical cell divisions, with tumorigenic potential and specific surface markers useful for CSC identification and isolation. Additionally, several other properties like sphere forming capacity in serum-free medium or soft agar, dye exclusion ability based on over-expression of drug-efflux pumps (ATP binding cassette or multidrug resistance transporters), enzymatic activity of aldehyde dehydrogenase 1, are used to identify CSCs. However, the most important property of CSCs can be verified only by *in vivo* assay: Tumorigenicity in animal model, maintained even after serial transplantation.

The surface markers for CSCs vary according to

Table 1 Cell surface antigens present on cancer stem cells

Cancer type	Surface antigens	Ref.
Leukemia	CD34 ⁺ CD38 ⁺ CD47 ⁺ CCL-1 ⁺ CD96 ⁺ TIM3 ⁺ CD32 ⁺ CD25 ⁺	[11,20-24]
Brain	CD133 ⁺	[12]
Head and neck	CD44 ⁺ CD24 ⁺	[14]
Breast	ESA ⁺ CD44 ⁺ CD24 ⁺	[13,16]
Pancreatic	ESA ⁺ CD44 ⁺ CD24 ⁺	[13,40]
Lung	CD133 ⁺ CD44 ⁺	[15]
Liver	ESA ⁺ CD133 ⁺ CD90 ⁺ CD44 ⁺ CD24 ⁺	[17]
Gastric	CD44 ⁺	[18,38]
Colorectal	ESA ⁺ CD133 ⁺ CD166 ⁺ CD44 ⁺ CD24 ⁺	[19,26]

tumor type. Main surface markers for CSCs from solid tissue are CD133, CD44 and CD24. To these, several other more specific markers might be added, according to tumor tissue origin (Table 1). Thus, the phenotype epithelial specific antigen (ESA⁺) together with CD44⁺-CD24⁺ was described in pancreatic CSCs^[16], while ESA⁺CD44⁺CD24^{low} was the phenotype identified in breast CSCs^[13]. For liver CSCs the following combination ESA⁺CD133⁺CD90⁺CD44⁺CD24⁺ was proposed^[17]. For hematological malignancy CD34 and CD38 are main surface antigens^[11]. Subsequently novel markers have been found to be highly expressed on leukemia stem cells than normal hematopoietic stem cells. These include CD47^[20], C-type lectin-like molecule-1 (CLL-1)^[21], CD96^[22], TIM3^[23], CD32 and CD25^[24].

Although recent studies have contributed to a better understanding of CSCs surface molecules, the picture is not complete. It is often observed that CSCs do not express the same markers, or that normal cells also express these surface antigens. Therefore, it is not possible yet to certainly isolate CSCs, but only to identify a CSCs-enriched population. Consequently, identification of CSCs must be based on additional functional assays such as the ability to form spheres in serum-free medium and to initiate tumor growth after serial transplantation in immunocompromised animal models, based on their self-renewal capacity. However, these assays also have limitations due to microenvironment. Thus, the *in vitro* assay may not detect quiescent stem cells that are not capable to develop spheres due to lack of additional extrinsic signals needed for their activation. Moreover, in this type of assay there is a selection pressure imposed by specific culture conditions in presence of exogenous growth factors. Serial transplantation as well might have limitations, since considerable number of cells is required to induce tumor growth *in vivo*, due to insertion in a foreign microenvironment deficient in specific signals for survival and development^[25].

Therefore, to specifically address CSCs in further experiments, it is necessary to sort cells based on surface markers and subsequently to assess their functional abilities by *in vitro* and *in vivo* specific assays.

THERAPIES TARGETING CANCER STEM CELLS

Traditional therapies against cancer, chemo- and radiotherapy, have multiple limitations that result in treatment failure and cancer recurrence. These limitations are related to systemic and local toxicity because the agents are not selective enough and may affect also healthy tissue. An additional restriction is drug resistance due to CSCs specific properties like: Slow rate of division, high expression of drug-efflux pumps, high capacity for DNA repairing, and also to microenvironment characteristics: hypoxia and acidosis. Therefore, targeting CSCs became essential in treating cancer and preventing tumor relapse.

Recently, multiple strategies have been conceived with the specific aim of destroying CSCs and their niche. These include targeting specific surface markers, modulation of signaling pathways, adjustment of the microenvironment signals, inhibiting of drug-efflux pumps, manipulation of miRNA expression, induction of CSCs apoptosis and differentiation. A summary of these therapeutic strategies is presented in the Figure 1. At the moment, some of them are successfully used in clinic, mainly in combination with traditional therapies, and others are still under evaluation.

Targeting surface markers

The surface markers used for identification and isolation of CSCs are also important targets for therapy. Immunotherapy that involves antibodies targeting CSCs specific markers is often used as an adjunct to chemotherapy, radiotherapy and surgery. The most important CSCs associated markers together with strategies for targeting them are mentioned below.

CD133 (prominin-1) is a cell surface glycoprotein widely expressed on CSCs in solid tumors such as glioma^[12], lung^[15], liver^[17] and, colorectal cancer^[19,26]. Cancers with large CD133 subpopulation have a drug resistant phenotype and poor prognosis. For this reason, several strategies for anti-CD133 therapy have been generated. The polymeric nanoparticles loaded with paclitaxel (CD133NPs) targeting CD133 were tested on colorectal adenocarcinoma Caco-2 cells and proved to efficiently decrease the cell number and colonies formed. On the other hand, in xenograft model, the CD133NPs improved therapeutic efficacy compared to free paclitaxel treatment^[27]. Another anti-CD133 antibody constructed through the fusion with pseudomonas exotoxin 38, inhibited the progression of tumor growth after multiple intraperitoneal injections of drug over a period of 4-6 wk in xenografted mice with ovarian cancer. The elimination of CD133⁺ ovarian cancer cells resulted in long-term disease free tumor survivors^[28]. These studies suggest that anti-CD133 therapy might be associated with drug delivery, forming antibody-drug conjugates that enhance the effect on

Figure 1 Therapies targeting cancer stem cells. Numerous therapies aiming to eradicate cancer stem cells have been developed during last year's. Here we highlighted most common seven approaches: targeting surface biomarkers, signaling pathways that regulate cancer stem cells (CSCs) self-renewal and differentiation, drug-efflux pumps involved in apoptosis resistance, microenvironmental signals that sustain CSCs growth, manipulation of miRNA expression, and induction of CSCs apoptosis and differentiation, with specific aim of hamper CSCs regeneration and cancer relapse. ATRA: All trans retinoic acid; HDACI: Histone deacetylase inhibitors; PI3K: Phosphatidylinositol 3-kinase; NF-κB: Nuclear factor kappa B; TRAIL: Tumor necrosis factor-related apoptosis-inducing ligand.

CD133⁺ CSCs and eliminate them. Anti-CD133⁺ cell therapy was also tested on sarcoma CSCs, reducing proliferative capacity and resulting in decreased sarcoma tumor-initiating ability^[29]. Similar results were obtained for pancreatic and hepatic CSCs^[30,31].

However CD133 expression is not restricted to CSCs. Shmelkov *et al.*^[32] demonstrated that both CD133⁺ and CD133-metastatic colon cancer cells can initiate tumors. Also, Beier *et al.*^[33] demonstrated that CD133⁺ and CD133-glioblastoma cancer cells meet stem cell criteria, but they might reflect two biologically distinctive glioblastoma subtypes. The authors concluded that primary glioblastomas might develop either from different cells of origin or from related cell types that further acquired different molecular alterations.

CD44 is a transmembrane protein that mediates cell to cell adhesion and cell to extracellular matrix interactions, being a receptor for hyaluronic acid, selectin, collagen, osteopontin, fibronectin and laminin^[34]. CD44 is involved in cell proliferation, survival, migration, differentiation, apoptosis, self-renewal, niche preparation, epithelial-mesenchymal transition, and resistance

to apoptosis^[35,36]. It was found overexpressed in many tumor cells: breast^[13], bladder^[37], gastric^[38], prostate^[39], pancreas^[40], ovar^[41], colorectal^[26,42], hepatocellular^[43], head and neck^[44], acute myeloid leukemia (AML) CSCs^[45], etc. Targeting CD44 with monoclonal antibodies appears as a good strategy to eliminate CSCs. Treatment with anti-human CD44 monoclonal antibody can induce myeloid differentiation in patient-derived AML blasts, inhibits homing to the microenvironmental niche and alters stem cell fate^[46]. Marangoni *et al.*^[47] used an anti-human CD44 monoclonal antibody in combination with doxorubicin and cyclophosphamide to prevent relapse of aggressive breast cancer. Moreover, a mouse IgG1 anti-human CD44 receptor that inhibits CD44-STAT3 signaling pathways was used on human pancreatic cancer stem-like cells or MiaPaCa-2 cells and was found to decrease *in vitro* tumor sphere formation of CSCs, inhibiting pancreatic tumor growth, metastasis and tumor recurrence in xenografted nude mice^[48]. Similar results were obtained in colorectal, lung, bladder, larynx and breast cancers^[49,50].

CD47 is a transmembrane protein, receptor for

thrombospondin family members and for signal regulatory protein alpha (SIRP α)^[51]. It was found widely expressed on AML CSCs^[20] and almost all human solid tumor cells^[51,52]. Two anti-CD47 mAbs such as B6H12.2 and B6H12 were developed as strategy for cancer therapy. In a xenograft mouse model, B6H12.2 antibodies prevented the engraftment of human AML cancers stem cells and completely eradicated them^[20]. Administration of B6H12.2 prevented and inhibited growth of tumors derived from glioblastoma, ovarian, breast, colon, bladder cancer^[52], human non-Hodgkin lymphoma^[53], acute lymphoblastic leukemia^[54] and multiple myeloma CSCs^[55]. B6H12, a fully humanized anti-CD47, effectively inhibits aggressive leiomyosarcoma growth and metastasis in xenograft mice model^[56].

Other antibodies approved by FDA for the treatment of solid and haematological tumours, *e.g.*, rituximab (anti-CD20), cetuximab (anti-EGFR), trastuzumab (anti-HER2), bevacizumab (anti-VEGF-A), ipilimumab (anti-CTLA-4), pembrolizumab (anti-PD-1) are currently used in immunotherapy against tumor cells^[57].

Targeting signal cascades

One of the mechanisms by which CSCs manage to avoid or to survive cancer treatments seems to be represented by signals generated within the tumor microenvironment, due to dysregulation of signaling pathway networks^[58]. Like normal stem cells, CSCs use signaling pathways that are essential for self-renewal, proliferation and differentiation in order to preserve stem cell properties but the final result is carcinogenesis. Many studies have focused on signaling pathways dysregulation in CSCs attempting to find new strategy for cancer therapy; this line of research is promising mainly because many cancers present up- or down-regulation of the same signaling cascades. In this regard, CSCs can be identified by surface markers but also by the signals they send in tumor microenvironment^[59]. The major signaling pathways involved in the regulation of self-renewal and differentiation of normal and cancer stem cells are Notch, Hedgehog, Wnt/ β -catenin, NF- κ B, phosphatidylinositol 3-kinase (PI3K)/Akt, PTEN; sustained by aberrant activation of these pathways, CSCs have the capacity to initiate cancer and promote recurrence after the surgical removal of tumor^[60].

Notch signaling cascade is one major pathway involved in numerous critical cellular processes, including stem cell maintenance, progenitor cell proliferation and differentiation, and determination of cell fate during embryonic development^[61,62]. Notch signaling involvement in carcinogenesis and tumor progression seems to depend on tissue/cell-type. Thereby, Notch signaling was identified as oncogenic due to an increased activation in T-cell acute lymphoblastic leukemia, medulloblastoma, colorectal cancer, non-small cell lung carcinoma, hepatocellular carcinoma, melanoma, and breast cancer while in myeloid malignancies, head and neck squamous cell carcinoma, Notch displays tumor

suppressor functions^[63,64]. Notch signaling pathway comprises four Notch receptors (Notch 1, Notch 2, Notch 3 and Notch 4) and five ligands (Delta-like 1, Delta-like 3, Delta-like 4, Jagged 1 and Jagged 2); depending on the cellular type, many studies have been focused on activation or inhibition of these proteins^[65,66]. *In vitro* and *in vivo* studies showed that human lung cancer lines presented an overexpression of Notch3; downregulation of Notch signaling, using a specific inhibitor was associated with decrease of tumor cell proliferation, induction of apoptosis, and inhibition of *in vivo* growth. Notch3 was also found to be overexpressed in resected human lung cancers and was associated with poor overall survival^[67,68]. Moreover, activation of Notch4 and Notch1 was noted breast CSCs, and inhibition of these receptors, especially Notch4, leads to decreased activity of breast CSCs *in vitro*, and reduced tumor development *in vivo*^[69]. In hepatocellular carcinoma, inhibition of Notch signaling pathway also reduced the invasion of tumor cells by downregulation of matrix metalloproteinase-2 and -9 and vascular endothelial growth factor^[70]. In colorectal cancers, Notch1 signaling seems to have a dual role; it can increase the tumor progression but also counteracts β -catenin signaling whose activation is an important factor in human colorectal carcinogenesis^[71]. Many studies reported an overexpression of Notch signaling proteins in head and neck squamous cell carcinoma, sustaining a pro-oncogenic role of this signaling but recent exome sequencing analyses reported loss-of-function mutations in the *Notch1* gene in a significant proportion of patients with this malignancy^[72].

Notch signaling inhibitors tested in clinical trials include inhibitors of γ -secretase complex involved in Notch activation and antibodies against DLL-4 and Notch-1, -2 or -3 receptors^[43]. Results for phase 1 clinical trial using BMS-906024, one of these γ -secretase inhibitors, for patients with relapsed T-cell acute lymphoblastic leukemia showed at least 50% reduction in BM blasts in 8 of the 25 patients (32%)^[73].

Recently was reported the development of an antibody OMP-59R5 (tarextumab) which alone or together with chemotherapeutic agents can inhibit Notch2 and Notch3 function. The antitumor effect of OMP-59R5 was observed on xenograft tumors representing different types of epithelial cancers like breast, small-cell lung, ovarian, and pancreatic; and was associated with down-regulation of Notch target genes in tumor cells and with suppression of Notch3, HeyL, and Rgs5, expression in tumor stroma^[74].

Hedgehog is another pathway that plays an important role in stem cells maintenance and embryonic development, being involved in various cellular processes such as proliferation and differentiation; this cascade was also aberrant activated in several human tumors, including glioblastoma, breast cancer, pancreatic adenocarcinoma, multiple myeloma and chronic myeloid leukemia^[75,76]. Furthermore, Hedgehog signaling

contributes to development and maintenance of CSCs and acquisition of epithelial-to-mesenchymal transition, highlighting the involvement of Hedgehog cascade in cancer cell invasion, metastasis, chemotherapeutic resistance and tumor recurrence^[77]. Canonical Hedgehog signaling involves three ligands: Sonic (SHH), Indian (IHH), and Desert (DHH) with different expression depending on cell type; SHH is widely expressed, mostly during embryogenesis, IHH is found in hematopoietic cells, bone, and cartilage, while DHH is expressed in the peripheral nervous system and testes. Hedgehog signaling implies Hedgehog ligands binding to Patched receptor, Smoothened activation, and activation of transcriptional effectors that belong to the GLI family^[78,79]. Aberrant activation of Hedgehog signaling may be due to gene mutations, resulting in ligand-independent pathway activation, or by interaction with other molecular signaling pathways, such as Ras/Raf/MEK/Erk, PI3K/Akt/mTOR, and Notch. Thus, there are many studies sustaining that the combination therapies targeting more than one signaling pathway improves antitumor efficacy and survival in animal models^[80]. There are also several preclinical studies showing that in several cancers, Hedgehog signaling inhibition using specific inhibitors of Smoothened leads to the blocking of drug resistance, relapse, and metastasis. In basal cell carcinoma and medulloblastoma patients, Smoothened inhibitors such as vismodegib, BMS-833923, saridegib (IPI-926), sonidegib/erismodegib (LDE225), PF-04449913, LY2940680, LEQ 506, and TAK-441 were used as monotherapy with promising results^[81]. A recent study reported a significant negative association between GLI1 and GLI2 expression and overall survival, and also an increase of DHH plasma levels in acute myeloid leukemia patients. By *in vitro* and *in vivo* experiments the authors demonstrated that GLI1/2 inhibition induces apoptosis, and reduces proliferation, and colony formation in acute myeloid leukemia cells, and also increases the survival in murine models^[82]. Another study focused on biliary tract cancer showed that inhibition of Hedgehog and mTOR signaling pathways with rapamycin and vismodegib specific inhibitors results in decrease of Nanog and Oct-4 expressions and also in decrease of CSCs and ALDH-positive cells proliferation^[83]. In pancreatic cancer, the combination of focal radiation with Hedgehog inhibitors reduces lymph node metastasis, sustaining the involvement of this signaling pathway in carcinogenesis^[84].

Wnt/ β -catenin signaling pathway is one of the most deregulated pathways in many cancers, including leukemia, colon, breast and skin cancers. For instance, in human colon carcinoma, mutations in adenomatous polyposis coli (APC) result in aberrant activation of Wnt signaling and induce transformation of epithelial cells^[60]. There are also studies that support the involvement of Wnt signaling in self-renewal and maintenance of stem cells and CSCs, in several tissues like skin, intestine and

mammary gland^[85]. A minor subpopulation of breast tumor-initiating cells associated with drug resistance was identified in human breast cancer; *in vitro* and *in vivo* study showed that suppression of Wnt signaling inhibited sphere- and colony-formation of primary breast tumor cells and blocked tumor growth in murine models^[86].

Wnt/ β -catenin signaling pathway includes Wnt ligands, Frizzled receptors and a complex, composed of APC, Axin1, Glycogen synthase kinase 3- β , and CK1 (casein kinase 1) which stabilizes β -catenin^[87]. Wnt/ β -catenin inhibitors include small-molecule inhibitors (e.g., nonsteroidal anti-inflammatory drugs and natural compounds: aspirin, indomethacin, vitamins A and D derivatives) and biologic inhibitors (monoclonal antibodies, small interfering RNAs and recombinant proteins)^[2].

OMP-54F28 is an example of Wnt signaling inhibitor with interesting results in clinical trials, in several advanced solid tumors, such as ovarian, pancreatic and hepatocellular cancers^[88]. OMP-18R5 - an antibody targeting several Frizzled receptors - reduces tumor cell proliferation and tumor-initiating cell number in lung, breast, colon, and pancreatic tumors^[89]. *In vitro* study on lung CSCs showed that β -catenin nuclear transfer inhibitor PP significantly decreased colony formation and downregulated pluripotent stem cell signaling pathway, being a promising therapeutic approach in lung adenocarcinoma patients^[90]. The studies performed until now showed that Wnt inhibitors and modulators can eliminate drug-resistant CSCs and tumor-initiating cells but more studies are needed regarding the safety of this therapeutic approach, given the essential role of Wnt signaling in tissue homeostasis and repair^[91].

PI3K/Akt/mTOR signaling pathway is an important cascade of phosphorylation reactions, comprising several key molecules involved in carcinogenesis processes: PI3K - presents activating mutations in several human cancers; Akt - overexpression/activation of this protein kinase is associated with tumor metastasis and invasion; mTOR - protein kinase critical for cancer cell growth, cell proliferation, survival and angiogenesis^[59].

Many studies suggest the involvement of this signaling pathway in maintaining CSCs features. In breast cancer, inhibition of PI3K or Akt activity reduced generation and growth of CD44/CD24 mammospheres, leading to stem cell/mesenchymal phenotype loss and recovery of epithelial-like markers^[92]. In prostate cancer, PI3K/Akt/mTOR pathway deregulation is associated with CSCs quiescence and maintenance; moreover, prostate CSCs seem to present resistance to selective mTOR inhibitors^[93]. Another study showed that combination between PI3K/mTOR inhibitor (BEZ235) and radiotherapy increased radiosensitivity and apoptosis, and also reduced CSCs marker expressions in prostate cancer radioresistant cell lines^[94]. In endometrial tumors, PTEN/PI3K/Akt/mTOR pathway aberrant activation by miRNAs is a common event,

being involved in epithelial-mesenchymal transition and CSC maintenance^[95].

PTEN (phosphatase and tensin homolog) is a tumor suppressor and an inhibitor of PI3K and ERK activities, being one of the most inactivated tumor suppressor genes in cancers; many tumors present loss of PTEN function by mutations, deletions, transcriptional silencing, or protein instability affecting important cell processes such as survival, proliferation, energy metabolism and cellular architecture. Loss of PTEN activity was also linked to CSC development and proliferation in several cancers, including prostate, lung, intestinal, and pancreatic cancer^[95]. Moreover, PTEN loss and Akt activation lead to increase activity of β -catenin in hematopoietic stem cells while Notch signaling activation results in reduced PTEN expression in human T-cell acute lymphoblastic leukemia^[96].

Nuclear factor kappa B (NF- κ B) is a transcription factor constitutively activated in several tumors, being also associated with self-renewal and expansion of CSCs^[97]. NF- κ B interacts with many apoptosis-related proteins, including Bcl-xL, Bcl-2, survivin, cellular inhibitors of apoptosis (cIAPs), TRAF and cell cycle regulatory components, and NF- κ B aberrant expression was related to cancer development and progression, chemoresistance, chronic inflammation and autoimmune diseases^[60].

In hepatocellular carcinoma cell lines, one of the most activated signaling pathways is NF- κ B cascade; NF- κ B inhibition using SN50, suppressed tumor cell growth and the authors suggested that targeting NF- κ B signaling might specifically inhibit CSCs populations and it could be considered a new therapeutic strategy for hepatocellular carcinoma patients with poor prognosis^[97]. Pancreatic ductal adenocarcinoma characterized by a pronounced hypoxic tumor microenvironment presents epithelial-mesenchymal transition and stem-like features related to NF- κ B signaling activation. An *in vitro* study demonstrated that inhibition of NF- κ B with triptolide can reverse epithelial-mesenchymal transition and reduced migration, self-renewal activity, stem cell-related signaling^[98]. NF- κ B signaling is also considered an important therapeutic target in breast cancer; HER2-NF- κ B-HER2 pro-survival pathway seems to be activated in breast CSCs upon radiation therapy^[99].

Numerous studies have focused on identifying the molecular mechanisms and signaling pathways characteristic for CSCs, in solid and hematological malignancies. Notch, Hedgehog, Wnt/ β -catenin, NF- κ B, PI3K/Akt, and PTEN cascades present aberrant activation in cancers and they have been associated with high proliferative and metastatic capacity, self-renewal and differentiation of CSCs and also multi-drug resistance, being considered attractive targets for CSCs specific eradication. However, more studies are required to demonstrate the safety of these targeted therapies, considering the crucial role of these signaling pathways for normal stem cell maintenance^[97].

Targeting microenvironment

The tumor microenvironment provides necessary signals for CSCs maintenance, regulation of self-renewal and homeostatic processes such as angiogenesis, hypoxia and weakly acidic pH.

Interaction between CSCs and tumor stroma is ensured by CXCL12-CXCR4 axis. CXCL12 [also called stromal-derived factor-1 (SDF-1)] is a chemokine that binds its receptor CXCR4 and it is involved in migration, invasion and survival of normal and malignant cells^[100]. CXCR4 is highly expressed on several stem cells mainly haematopoietic, but also on endothelial, neural and embryonic stem cells, facilitating their response to gradients of CXCL12 produced in case of tissue damage and hypoxia. On the other hand, CXCL12 ligand has a constitutive expression on stromal cells in many tissues. It has an increased level in bone marrow, lymph nodes, lung and liver, and a low level in small intestine, skin skeletal muscle^[101].

Many studies have emphasized that under physiological conditions CXCL12-CXCR4 axis plays a crucial role in processes like normal development, tissue regeneration and repair. With respect to tumor growth, it was shown that CXCL12-CXCR4 axis ensures a close contact between cells and tumor stroma and consequently activates various signals related to cell growth, metastasis and chemoresistance^[102]. In human breast cancer CXCL12 generated by stromal fibroblasts exerts two types of effects on tumor growth: an endocrine effect by promoting angiogenesis *via* recruiting endothelial progenitor cells into the tumor mass, as well as a paracrine effect by acting directly on tumor cells through CXCR4^[103].

The important roles of CXCL12-CXCR4 axis in cancer led to an intense research for developing drugs that inhibit signaling through this axis. A series of inhibitors have been investigated, targeting either CXCR4 or CXCL12. Among CXCR4 inhibitors, AMD3100, also known as plerixafor, induces the rapid mobilization of hematopoietic stem and progenitor cells into the blood in mice and humans^[104], inhibits growth of intracranial glioblastoma and medulloblastoma xenografts by increasing apoptosis and decreasing the proliferation of tumor cells^[105], and can reduce the intraperitoneal dissemination of epithelial ovarian cancer^[106]. On the other hand, in a recent study it was shown that treatment with the AMD3100 diminished metastatic growth, but it didn't affect significantly the frequency of metastases or overall survival in a murine model of metastatic human non-small cell lung cancer^[107].

CTCE-9908 is another CXCR4 antagonist that proved to be effective in reducing both tumor growth and metastasis in xenograft mouse models of inflammatory breast cancer^[108] and also in an orthotopic model of esophageal carcinoma^[109]. A recent study highlighted the role of CTCE-9908 in decreasing the tumor invasivity and angiogenesis in prostate cancer^[110].

One of the most studied CXCL12 inhibitor is NOX-A12

that seems to suppress CXCL12-induced chemotaxis of chronic lymphocytic leukemia cells and to cause chemosensitization^[111]. In addition, Liu *et al.*^[112] observed that this compound had the potential to improve tumor response in glioblastoma multiforme animal model after irradiation.

CXCL12-CXCR4 axis can also promote angiogenesis. Liang *et al.*^[113] have shown that CXCR4 induces an increased expression of vascular-endothelial growth factor (VEGF) at both the mRNA and protein levels through the activation of PI3K/Akt pathway.

Tumor angiogenesis is another mechanism promoted by microenvironment that has been related with CSCs survival and tumor growth, since targeting VEGF can lead to normalization of the vasculature, decrease in tumor growth and disruption of the CSCs niche^[60,114]. Inhibitors against the VEGF/VEGFR-system are already in clinical use. Among the approved drugs that target VEGF/VEGFR-system are bevacizumab, anti-VEGF blocking antibody, and pazopanib, sorafenib and sunitinib, VEGFR-2 pathway inhibitors. Moreover, a series of compounds are tested in clinical trials or they are just in experimental phase^[115]. From those, fruquintinib (HMPL-013), a small molecule inhibitor very potent and highly selective against VEGFR family, is currently in phase II clinical studies^[115].

Another feature of the tumor microenvironment is hypoxia that is regulated by inducible transcription factors HIF-1 and HIF-2. Many studies correlated tumor hypoxia with tumor growth, cancer progression, metastasis, resistance to chemo- and radiotherapy. Therefore targeting HIF activity might represent an effective method of inhibit tumor metastasis and improve the outcome of chemo- and radiotherapy^[116,117].

In breast cancer, inhibition HIF activity in BrCa cells by using RNA interference or digoxin treatment prevent primary tumor growth and also reduce breast cancer dissemination in lungs by down-regulating the expression of angiopoietin-like 4 (ANGPTL4) and L1 cell adhesion molecule (L1CAM) 21860410. In a recent study, Gillespie *et al.*^[118] investigated the inhibition of HIF-1 α by using small interfering RNA in an orthotopic mouse model for glioblastoma. *In vivo* treatment reduced tumor growth and increased survival.

Another important therapeutic target can be represented by acidic extracellular pH, a major feature of tumor tissue that is the result of cancer cells increased metabolic activity and of the poor vascular perfusion of tumors^[119,120]. As it was shown in previous studies, tumor acidity can offer a selective advantage of cancer cells over the normal tissues and contribute to drug resistance^[119,121].

The acidity of tumor environment can be managed either by using delivery drugs that have specificity for acid environment, or can be reversed directly with systemic buffers or indirectly by using inhibitors for pH-regulatory pathways like carbonic anhydrase IX (CAIX).

Developing compounds that are tumoral acidic pH-

responsive is a dynamic area of research; liposomes, micelles, polymers and inorganic nanoparticles have been tested for anticancer therapy^[122]. An improved drug-delivery method is to encapsulate drugs into silica matrices like camptothecin and doxorubicin^[122,123].

Sodium bicarbonate is one of the systemic buffers that can be used to alkalinize the microenvironment. In intraductal tumors it have been shown that sodium bicarbonate can prevent or slow down the transition from in situ to invasive cancer^[124].

One approach, more captivating is to regulate cellular pH with drugs that inhibit CAIX, a hypoxia and HIF-1-inducible protein, overexpressed in many cancers. Data from phase III clinical trial suggest that CAIX score can be also used as statistically prognostic biomarker for survival in patients with high-risk nonmetastatic renal cell carcinoma (ccRCC)^[125].

Targeting the tumor microenvironment might affect communication with stroma and self-regulating process, the vasculature as the main nutrients supply, and essential features like oxygen level and acidity needed by CSCs, all these being fundamentals for CSCs maintenance. However these strategies are not specific enough and might affect also normal stem cells and their stroma. Consequently, a more particular approach is needed that addresses only tumor stroma.

Targeting ATP-binding cassette transporters

The ability to isolate and characterize CSCs from different tumors facilitated a more specific investigation of the therapeutic possibilities based on another distinctive feature of the CSCs, chemoresistance^[126]. CSCs identification by augmented efflux of Hoechst 33342 dye through ATP-binding cassette (ABC) transporters (defined as side population, SP cells) in flow cytometry analysis, proved to be very useful in isolating hematopoietic stem cells, and a variety of CSCs from solid tumors, including ovarian, breast, colon and hepatic cancers^[127-131]. Aberrant expression of ABC transporters is a major mechanism of chemoresistance in cancers cells, including cancer CSCs^[132] but may be generated by other mechanisms involved directly or indirectly in the process, from transcription to protein expression. All the mechanisms involved in ABC transporter modulation might be potential targets for overcoming chemoresistance in CSCs.

ABC transporter proteins are members of the ABC superfamily that have as most important physiologic role prevention of the accumulation of xenobiotics and toxic compounds in normal cells. These efflux pumps consist of a single or multiple sets of transmembrane domains and nucleotide binding domains. Nucleotide binding domains hydrolyze ATP giving power for the efflux while a variety of structurally unrelated substrates, including drugs, sugars, proteins, and metabolites are "pumped-out" through the transmembrane domains.

Among the numerous members of the ABC-transporters described to date, only few were well docu-

mented to be expressed in human CSCs: Multidrug resistance 1 (MDR1) or P-glycoprotein (Pgp)/ABCB1, multidrug resistance protein 1 (MRP1)/ABCC1, and breast cancer resistance protein (BCRP)/ABCG2/MXR/ABCP. These proteins differ in structure and in substrate specificity. MDR1 is a protein that confers cross-resistance to many antitumor agents, including anthracyclines, mitoxantrone, epipodophyllotoxins, and taxanes. ABCC1 is structurally similar to ABCB1 but shares only 15% amino acid sequence identity; it also generates resistance to anthracyclines, mitoxantrone, and epipodophyllotoxins but differs from MDR1 in the level of resistance to taxanes. BCRP also confers resistance to mitoxantrone, but anthracyclines resistance was found to depend on mutations at the codon 482^[133].

The new concept of targeting ABC transporters considers inhibitors as "CSC sensitizing agents". Clinical studies have attempted to overcome drug resistance by combination therapies in which a cytotoxic drug was given along with an ABC-transporter inhibitor. However, ABCB1 inhibitors have shown very limited effectiveness in clinical trials despite the debate on the fact that the clinical trials on the first generation of inhibitors have not been targeting CSCs but only the reduction of the tumors that express a particular drug transporter (usually ABCB1). If the stem cells are considered the principal culprits of drug resistance, the efficacy of ABC inhibitors would be better evaluated monitoring the relapse instead of tumor size reduction^[134]. However, ABC inhibitors would be most effective if are combined with an anticancer agent that specifically targets the stem cells.

Three generations of ABC transporter blockers were investigated until now and the fourth generation, based on natural compounds, is under development^[135].

First generation of inhibitor drugs were already in use for different conditions and also were able to block MDR1 (ABCB1), such as calcium channel inhibitors like verapamil, immuno-suppressants like cyclosporin A, anti-arrhythmics and neuroleptics like quinidine, reserpine, and yohimbine, and antiestrogens like tamoxifen and toremifene. The efficacy of these drugs was limited by their toxicity, which urged the development of drugs with less important side effects as first generation compounds.

Second generation of MDR1 modulators like R-verapamil, elacridar (GF120918), dofequidar (MS-209), valspodar (PSC833), biricodar (INCEL, VX-710), or timcodar (VX-853) were derived from first generation P-gp modulators. Although second generation modulators are less toxic than first generation modulators, they still induce important side effects due to non-selective inhibition of multiple cell ABC transporters and unpredictable pharmacokinetic interactions^[136].

Third generation modulators such as Zosuquidar (LY335979), oc144093 (ONT-093), laniquidar (R101933), and tariquidar (XR-9576), which are more selective inhibitors of ABCB1, ABCC1, ABCG2, are still in different phases of investigation as CSCs sensitizing

agents.

Although the expression of ABC transporters could render CSCs resistant to drugs, it is not the unique cause of resistance by ABC proteins, as multiple levels of regulation between transcription and protein expression might be susceptible to modifications. Future trends of drug development should consider such levels of regulation of ABC transporters that might be speculated in cancer therapy. One such direction should evaluate, for example, the potential of using miRNAs targeting specific RNA that results in its degradation. MiR-328, miR 519c, miR-520h, miR-487a, miR-181a are only few of the miRNAs reported to be involved in ABC transporter regulation.

Recently, was observed that the presence of side population (SP) cells in tumors is highly dependent on the driving genetic alterations of the tumor. For example, hepatic tumors driven by Myc, but not Akt and RAS, had a significant number of SP cells that show the same properties as chemoresistant tumor-initiating CSCs. These studies show that even the common mechanisms of chemoresistance may change under genomic alterations conditions that are very frequent in cancer. There are increasing evidence that small-molecule tyrosine kinase inhibitors (TKIs), such as AST1306, lapatinib, linsitinib, masitinib, motesanib, nilotinib, telatinib and WHI-P154, can inhibit ABC transporters, suggesting that these TKI might have also a direct effect on ABC proteins inhibitors^[137]. Effect of Akt, PI3K and mTOR inhibitors on ABC transporters trafficking and/or expression has been well documented^[138]. Particularly, LY294002, a derivative of quercetin, is able to inhibit PI3Ks, mTOR and ABCG2 and has been recently proposed as a new candidate to target efficiently ABCG2-expressing CSCs that depend on Akt signaling for survival. ABCG2 expression and the SP might be regulated by PTEN through the PI3K/Akt pathway, which was proposed as a potentially effective strategy for targeting CSCs^[139].

Using nanomedicines as delivery vehicles can enhance the therapeutic response in resistant tumors by bypassing efflux pumps or by increasing the concentration of drugs in CSCs at a given time point^[140].

Simultaneous targeting of genomic alterations that are responsible for different types of cancer and resistance phenotypes together with new strategies of delivery and retention of the drugs inside the CSCs, will allow the development of more selective therapy.

Manipulation of miRNA expression

MicroRNAs (miRs) are small non-coding RNAs (20 to 24 nucleotides in length) that negatively regulate post-transcription by binding to the 3'UTR of target messenger RNA, having a broad range of effects over self-renewal, differentiation and division of cells^[141]. MiRNA are involved not only in maintaining normal cell functions, but also might modify several signaling pathways that could transform stem cells into cancer stem cells. Aberrant expression of miRNA in cancer

stem cells was noted by many studies. MiRNAs differentially regulate the key properties of CSCs, including cell-cycle exit and differentiation, prosurvival and antistress mechanisms and EMT, migration and invasion, which increase tumor initiation and metastatic potential^[142]. They can act either as oncogenes or tumor suppressors.

Targeting oncogenic miRNAs can be achieved by antisense oligonucleotide inhibition. Studies have shown that miR-21 has been found to be frequently up-regulated in different CSCs^[143]. Thus, knockdown of miR-21 inhibits cell proliferation, migration and tumor growth in breast cancers^[144,145], ovarian^[146], and lung cancer^[147].

Several studies have exposed the potential of miRNA based therapeutics as a novel strategy towards cancer stem cells. MiR-34 is a target of tumor suppressor gene *p53* and is down-regulated in many cancers^[148]. Liu *et al.*^[149] showed that miR-34a, was underexpressed in CD44⁺ prostate cancer cells and increased expression of miR-34a in CD44⁺ prostate cancer cells inhibited clonogenic expansion, tumor regeneration, and metastasis. Moreover, Shi *et al.*^[150] demonstrated that transfection of synthetic miR-34a in CD44⁺ non-small cell lung cancer cell lines inhibited clonogenic expansion, and tumor regeneration *in vivo*. Consistently, forced expression of miR-124 and miR-137 in human derived glioblastoma stem cells leads to loss of their self-renewal and oncogenic capacity, leaving normal stem and precursor cells unharmed^[151].

Abnormal miRNA expressions lead to the initiation, development, and progression of cancer. Thus, miRNA based therapy that can correct abnormal transcripts at CSCs level show great potential for cancer cure.

Induction of CSCs apoptosis

Apoptosis is a critical mechanism that mediates death and survival through a complex signaling mechanism. Escape from this system is the precondition for cancer initiating cells. Usually, the apoptotic mechanisms are impaired during cancer development and progression.

Induction of apoptosis in CSC holds great promise for cancer therapy. Therefore, many compounds have been developed to target intrinsic and extrinsic apoptotic pathways. For example, activating of the death receptors [CD95 and trimeric human tumor necrosis factor-related apoptosis-inducing ligand (TRAIL)], part of extrinsic apoptotic pathway, leads to caspase-8 activation. Once activated, caspase-8 either directly cleaves and activates effector caspase-3 or, alternatively, processes Bid into the active fragment tBid, which translocates to mitochondrial membranes to initiate mitochondrial outer membrane permeabilization^[152]. Treatment with TRAIL in combination with various anticancer agents was reported to be effective in removing cancer stem cells. Thus, co-treatment with cisplatin was described to be very efficient in reducing triple negative breast cancer stem cells through inhibition of Wnt signaling

and increasing of apoptosis^[153]. Likewise, combined treatment with TRAIL and cytarabine or daunorubicin, has been shown to suppress the growth of acute myeloid progenitors^[154]. Furthermore, TRAIL in addition to Bortezomib, a proteasome inhibitor, was recently shown trigger apoptosis in glioblastoma stem cells^[155]. Moreover, mesenchymal stem cells (MSC) engineered to express TRAIL through transduction with a lentiviral vector, were used to activate apoptosis in of squamous and lung cancer stem cell population. Experiments were done by injecting TRAIL-secreting MSC subcutaneously into nude mice that hold tumors. Results showed that MSC migrate and localized near the cancer site and inhibited tumor growth through apoptosis induction^[156].

Another target in inducing CSCs death might be NF- κ B, a transcription factor linked to the control of apoptosis signaling. Mainly, NF- κ B inhibits apoptosis and promotes cell proliferation, inflammation, tumor promotion, angiogenesis and metastasis^[157-159]. In breast cancer, pharmacological inhibition of NF- κ B with small-molecules like parthenolide, pyrrolidinedithiocarbamate and its analog diethyldithiocarbamate preferentially target breast cancer stem cells. These results underline that NF- κ B activity is critical to maintain the survival of tumor-initiating cancer stem cells^[160]. Moreover, inhibition of NF- κ B by the proteasome inhibitor MG-132 together with the anticancer drug idarubicin induced apoptosis preferentially in the leukemic stem cells population but considerably less in normal hematopoietic stem cells^[161].

Targeting CSC population by reactivation of apoptosis programs has been shown in preclinical studies to offer the possibility to eradicate cancers. Future challenges should include the increasing of specificity and efficiency in targeting cancer stem cells and avoid toxicity of normal tissue stem cells.

Induction of CSCs differentiation

Traditional anti-cancer therapies successfully manage differentiated cancer cells but did not affect CSCs. This observation leads to another method to restrain cancer progression, induction of CSCs differentiation that became favored over self-renewal programs, diminishing CSC population. Many studies are currently in progress proposing various differentiation agents like: retinoic acid, histone deacetylase inhibitors, miRNAs, tyrosine-kinase and signaling pathways inhibitors.

Retinoic acid and its analogs (ATRA) are currently used to treat acute promyelocytic leukemia. Retinoic acid regulates several chromatin remodeling factors due to its interaction with retinoid receptors^[162]. Campos *et al.*^[163] demonstrated that ATRA induced differentiation of glioma CSCs, and showed that the anti-tumor effect is present both *in vitro* and *in vivo* experiments. Moreover, Ginestier *et al.*^[164] showed that modulation of retinoid signaling may promote self-renewal or induce differentiation of breast CSCs, and suggested that ATRA may be considered as targeted therapy for breast CSC

population.

Other agents that can affect cancer stem cell differentiation are histone deacetylase inhibitors (HDACI). To date, HDACI are used as differentiation therapy in several hematologic malignancies. Recently, this type of therapy was proposed for breast CSCs^[165] and head and neck CSCs^[166]. In the first study HDACI (abexinostat) induced CSC differentiation. Moreover, in the second study, HDACI (suberoylanilide hydroxamic acid and trichostatin A) altered the CSCs phenotype and also induced cell cycle arrest and apoptosis.

Petrelli *et al.*^[167] showed that miR-100 favors breast CSCs differentiation, converting a basal like phenotype into luminal. It induces the expression of a functional estrogen receptor and renders basal-like BrCSCs responsive to hormonal therapy. Vaz *et al.*^[168] suggest that pancreatic differentiation 2 (PD2) is a novel CSC maintenance protein, loss of which renders the CSCs more susceptible to drug-induced cell death. Knockdown of PD2 protein in CSCs decreased cell viability, enhanced apoptosis and diminish expression of CD133 and MDR2. Dong *et al.*^[169] demonstrated that long-term culture of glioblastoma cancer stem cells with imatinib mesylate, a tyrosine-kinase inhibitor, induced cell differentiation, confirmed by decreased expression of stem cell markers, CD133, Oct-3/4, nestin, and Bmi1, and increased expression of GFAP (astrocyte marker) and class III β -tubulin isotype (Tuj1, neuron marker), associated with reduced ability to form aggregates and colonies *in vitro* and tumorigenicity *in vivo*. Another strategy targeting signaling pathways in order to induce CSCs differentiation is directed against hyperactivated Akt/mTOR and the inhibited wild-type p53 pathways in glioma CSCs. Daniele *et al.*^[170] uses two inhibitors (FC85 and ISA27) that blocked proliferation and promoted the differentiation of GSCs by reducing Akt/mTOR signalling and reactivating p53 functionality.

Inducing CSC differentiation combined with CSC-targeted therapies and traditional therapies may bring real benefits in depleting cancer cells by increasing the efficacy.

CONCLUSION

In this review we have summarized recent advances in identification of CSCs molecular markers that might become targets for developing new therapies, aiming to hamper CSCs regeneration and cancer relapse. These novel therapeutic strategies are designed to target directly CSCs or to interrupt signals from the microenvironment that regulate important properties like self-renewal, differentiation and apoptosis resistance.

All these alternative therapies are very promising, but some of them not specific and might affect also healthy tissue since CSCs niche is similar and close to normal stem cell niche that can also be affected by compounds. There are also many ways by which CSCs could evade treatment. They reside in an area of low

oxygen and vascularity, preventing efficient delivery of the drugs.

Future challenges should include the increasing of specificity and efficiency in targeting CSCs, avoiding toxicity of normal tissue stem cells, and also new strategies of delivery and retention of the drugs inside the CSCs. These new therapies should increase the efficacy of existing drugs against aggressive cancers, and thus should prevent tumor relapse and enhance patient survival.

Volume 7 Number 10 November 26, 2015

ABOUT COVER

Editorial Board Member of *World Journal of Stem Cells*, Soren Paludan Sheikh, MD, PhD, Professor, Department of Biochemistry, Pharmacology and Genetics, Odense University Hospital, University of Southern Denmark, 5000 Odense C, Denmark

AIM AND SCOPE

World Journal of Stem Cells (*World J Stem Cells*, *WJSC*, online ISSN 1948-0210, DOI: 10.4252), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJSC covers topics concerning all aspects of stem cells: embryonic, neural, hematopoietic, mesenchymal, tissue-specific, and cancer stem cells; the stem cell niche, stem cell genomics and proteomics, and stem cell techniques and their application in clinical trials.

We encourage authors to submit their manuscripts to *WJSC*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

INDEXING/ ABSTRACTING

World Journal of Stem Cells is now indexed in PubMed Central, PubMed, Digital Object Identifier, and Directory of Open Access Journals.

Abstract

The identification of an ideal cell source for tissue

regeneration remains a challenge in the stem cell field. The ability of progeny cells to differentiate into other cell types is important for the processes of tissue reconstruction and tissue engineering and has clinical, biochemical or molecular implications. The adaptation of stem cells from adipose tissue for use in regenerative medicine has created a new role for adipocytes. Mature adipocytes can easily be isolated from adipose cell suspensions and allowed to dedifferentiate into lipid-free multipotent cells, referred to as dedifferentiated fat (DFAT) cells. Compared to other adult stem cells, the DFAT cells have unique advantages in their abundance, ease of isolation and homogeneity. Under proper condition *in vitro* and *in vivo*, the DFAT cells have exhibited adipogenic, osteogenic, chondrogenic, cardiomyogenic, angiogenic, myogenic, and neurogenic potentials. In this review, we first discuss the phenomena of dedifferentiation and transdifferentiation of cells, and then dedifferentiation of adipocytes in particular. Understanding the dedifferentiation process itself may contribute to our knowledge of normal growth processes, as well as mechanisms of disease. Second, we highlight new developments in DFAT cell culture and summarize the current understanding of DFAT cell properties. The unique features of DFAT cells are promising for clinical applications such as tissue regeneration.

Key words: Adipocytes; Dedifferentiated fat cells; Adult stem cells; Pluripotent stem cells; Differentiation

© **The Author(s) 2015.** Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: Multipotent dedifferentiated fat (DFAT) cells provide evidence of plasticity in adipocytes. The newly established DFAT cells exhibit vigorous proliferation and multipotent abilities with advantages over other adult stem cells. Modified culture methods reduce the risk of contamination by cells from the stromal vascular fraction to a minimum. In *in vitro* and/or *in vivo* experiments have revealed adipogenic, osteogenic, chondrogenic,

myogenic, angiogenic and neurogenic potentials in DFAT cells. Moreover, the DFAT cells express embryonic stem cell markers and are similar to induced pluripotent stem cells in certain physiological aspects. Based on the abundance, ease of preparation, homogeneity, and multi-lineage potential, the DFAT cells are uniquely suited for regenerative medicine.

Jumabay M, Boström KI. Dedifferentiated fat cells: A cell source for regenerative medicine. *World J Stem Cells* 2015; 7(10): 1202-1214 Available from: URL: <http://www.wjgnet.com/1948-0210/full/v7/i10/1202.htm> DOI: <http://dx.doi.org/10.4252/wjsc.v7.i10.1202>

INTRODUCTION

Adipose tissue is well known to house the largest energy reserve in the body. However, adipose tissue is more than just a simple storage depot. Adipocytes secrete hormones, growth factors and cytokines, such as leptin and tumor necrosis factor- α , as well as proteins related to immunological and vascular functions^[1-3]. Through this network of endocrine, paracrine, and autocrine signals, adipose tissue participate in energy homeostasis and is a global regulator of energy metabolism. Normal adipocyte function is also important for host defense and reproduction, and dysfunction may contribute to the development of pathological states such as insulin resistance^[4,5]. Interestingly, recent research indicates that mature adipocytes can be eliminated by dedifferentiation^[6-9]. With the advancement of tissue culture techniques it has been shown that mature adipocytes are able to dedifferentiate into progenitor cells, referred to as dedifferentiated fat (DFAT) cells. The DFAT cells are multipotent, and are able to redifferentiate into a variety of cell lineages^[10,11]. The DFAT cells may serve as an alternative source of adult multipotent cells, with significant potential for use in tissue engineering and regenerative medicine. In this review, we focus on the recent literature addressing dedifferentiation of mature adipocytes as well as the isolation, characterization, and multipotency of DFAT cells.

DEDIFFERENTIATION, TRANSDIFFERENTIATION, AND STEM CELLS

The ultimate goal of regenerative medicine is to restore structure and function of damaged tissues and organs. To successfully support new tissue development, three regenerative processes are essential: dedifferentiation, transdifferentiation, and reprogramming of cells. These are all involved in the transition of adipocytes to DFAT cells, which may be an appropriate model for enhancing our understanding of these phenomena.

Cellular dedifferentiation is considered a regression

of a cell from a highly specialized state to a simpler state that confers pluripotency, giving rise to undifferentiated progenitor cells. Transdifferentiation implies a process where one mature somatic cell transitions to another mature somatic cell. The induction of pluripotency in somatic cells is referred to as reprogramming. Stem cells are by definition able to self-renew, remain in an undifferentiated state, and differentiate along multiple cell lineages. Progenitor cells, on the other hand, exhibit less capacity for self-renewal and differentiate along one or a few lineages.

Dedifferentiation

Dedifferentiation is the basis of tissue regeneration. The first evidence of dedifferentiation during regeneration was found in plants^[12,13], where it is a common process during secondary growth and wound healing. However, in mammals, the capacity to regenerate subsequent to dedifferentiation is limited. For example, myotubes in newts are able to dedifferentiate and proliferate *in vivo*^[14], but this has not been shown for mouse myotubes. The *MYOD* and *MYOG* (myogenin) genes have been shown to be essential for myotube dedifferentiation. When mouse myotubes were treated with extracts from regenerating limbs of newts, *MYOD* and *MYOG* were downregulated, which allowed the myotubes to dedifferentiate and proliferate^[15]. Fortunately, recent studies have demonstrated that dedifferentiation can also occur in defined situations in many cell types in human tissue^[16,17].

Dedifferentiation and cell division are important intermediate processes in the process of switching phenotype, although they do not appear to be obligatory in all cases. Studies on the role of retinoblastoma protein (RB) and RB-like 2 showed that dedifferentiation of mature cardiomyocytes facilitated cardiomyocyte proliferation in cardiac hypertrophy^[18]. Furthermore, inhibition of the p38 mitogen-activated protein kinase induced mammalian cardiomyocytes to dedifferentiate, which may be essential for cardiomyocyte regeneration^[19,20]. However, other experimental data suggest that dedifferentiation may not be required for cardiomyocyte proliferation^[21]. It has also been observed that proliferation promoted by neuregulin, an essential extracellular ligand of the epidermal growth factor receptor during cardiomyocyte development, causes cardiomyocytes to reenter the cell cycle^[22,23]. Alternatively, dedifferentiation may cause cellular plasticity to emerge and allow rerouting of cells into different cell lineages. This could lead to intermediary transdifferentiation of the cell, and result in a progressive conversion into another terminally differentiated cell. Furthermore, dedifferentiation occurs during rare pathological events, which have been found in osteosarcoma, chondrosarcoma, and epithelial-myoeptithelial carcinoma in humans^[24-26]. A population-based study and a 20-year survey on soft tissue sarcoma also included cases of dedifferentiated liposarcoma^[27].

During normal cellular development, cellular dedif-

ferentiation has been shown to relate to the regenerating cells entering the cell cycle^[28]. Prolonged stress, injury, or activation of oncogenic pathways may trigger conversion of a “dedifferentiated” cell into a diseased cell, thereby opening the door for pathological changes. Hypoxia is believed to be the main factor driving the emergence of DFAT cells from adipocytes, as well as dedifferentiation of chondrocytes and smooth muscle cells^[29,30]. However, more studies are needed to fully evaluate the connection between hypoxia and dedifferentiation.

Specific injuries or manipulations stimulate cellular dedifferentiation^[31]. Cells lose their maturity and become susceptible to lineage modification. Dedifferentiation might occur, resulting in loss of cell function while the cells remain as undefined or resting cells as long as the insult persists. Thus, dedifferentiation would be a transition step prior to adopting a new identity, which would be distinguished by the reemergence of factors that redirect cell fate. Alternatively, dedifferentiation may be seen as an adaption to stressful stimuli, causing the cell to cease normal activity, thereby prohibiting progression toward cellular dysfunction, which in extreme cases could end in cell death. Thus, it is possible that specific changes in the intrinsic, environmental, or hormonal milieu might stimulate cells such as adipocytes to withdraw from the cell cycle, undergo dedifferentiation and acquire stem cell characteristics. Understanding the details of the dedifferentiation process would enhance our knowledge of normal regeneration.

Reprogramming

Mature cells acquire stem cell features by undergoing dedifferentiation prior to the acquisition of a new cell fate. The newly undifferentiated stem cells are primed to respond to specific cues and differentiate into a variety of cell lineages. Reprogramming can be attained through cell fusion with embryonic stem cells (ESC), somatic cell nuclear transfer, exposure to stem cell extracts, or induction of pluripotency by defined factors generating what are referred to as induced pluripotent stem cells (iPSCs). During the reprogramming, an erasure and remodeling of epigenetic marks occur including DNA methylation and modification of histone and chromatin structures^[32]. A major challenge in the field of iPSCs is to convert mature cells into pluripotent cells resembling ESC for use in transplantation therapies. The reprogramming of the somatic cells is induced by the transfer of pluripotent factors, many of which are oncogenes. It has also been suggested that iPSCs might be the product of dedifferentiation of somatic cells following oncogenic insult^[33,34]. To address the fear of tumorigenicity in iPSCs, a study recently showed that overexpression of core transcription factor genes or its activators support the maintenance of the cell type-specific transcriptional profile, thus inhibiting alterations in the expression of genes required for iPSC induction^[35]. The stable nature of gene signatures limits

dedifferentiation and promotes the cell type-specific transcriptional profiles.

Transdifferentiation

A normal, fully differentiated cell can either change its identity to a new cell type, referred to as transdifferentiation, or lose its functionality and revert to an immature state referred to as dedifferentiation. The transition to a new phenotype may occur directly or through dedifferentiation triggered by genetic factors or environmental cues. Intermediary transdifferentiation has been shown to occur when acinar cells undergo dedifferentiation into duct-like cells with exocrine as well as endocrine potentials^[36]. Another type of scenario is the conversion of phenotype without a detectable intermediate step, which is referred to as direct reprogramming. It is possible that dedifferentiated cells retrace normal development toward a different, sometimes closely related, cell lineage after reaching the progenitor state.

Different interventions, including naturally occurring events and experimental manipulations, might result in transdifferentiation of cells in unfamiliar compartments. Dedifferentiation is described as the entrance to such transdifferentiation. A recent study demonstrated that cultures of purified hepatic oval stem cells are capable of transdifferentiation into functional endocrine cells^[37]. It has also been reported that increased expression of CAAT/enhancer-binding protein (C/EBP) α and C/EBP β in differentiated islet β cells leads to reprogramming into macrophages without DNA methylation^[38]. Another example is fibroblasts that have transdifferentiated into cardiomyocytes after transfer of the transcription factors GATA4, MEF2C, and TBX5^[39].

The concept that terminally differentiated cells retain intrinsic plasticity increases the number of cell sources that could be used for tissue regeneration in cases of injury or disease. The generation of DFAT cells is an example of reemergence of plasticity in adipocytes, resulting in the ability to transdifferentiate into alternate cell types and to serve as a model for dedifferentiation and transdifferentiation.

DFAT cells and mesenchymal stem cells

The goal of tissue engineering is to repair and regenerate damaged organs with the help of stem cells, biomaterials, and cytokines. However, the limited availability of human stem cells that are able to differentiate along multiple lineages has hampered the progress and slowed the development of these treatments. While ESCs inherently exhibit nearly unlimited differentiation potential *in vitro* and *in vivo*, their use is constrained by scientific concerns regarding safety and efficacy, as well as by ethical, legal, and political concerns. An alternative approach is to use stem cells derived from adult tissues, which would circumvent most of these concerns.

Multipotent stem cells have been defined as a special kind of cells with a unique capacity to self-renew

indefinitely, which implies that the stem cells can be extensively expanded *ex vivo*. Human mesenchymal stem cells (MSCs) were initially derived from bone marrow, but have now been isolated from most types of tissue^[40], including the brain, dermis, periosteum, skeletal muscle, synovium, trabecular bone, vasculature, and adipose tissue, which is the most abundant and accessible source of adult stem cells^[41-43]. MSCs express cell surface markers like cluster of differentiation (CD)10, CD29, CD44, CD73, CD90, CD105, CD117 and STRO-1, but are negative for the hematopoietic lineage markers CD14, CD34, CD45 and HLA-DR. Identification of adipose-derived stem cells (ASCs) suggests that a pool of stem cells exists within the adult adipose tissue. The ASCs are derived from the adipose stroma vascular fraction (SVF), which includes all cells in adipose tissue except the white adipocytes. The ASCs are similar to MSCs in their expression of MSC markers, but lack expression of hematopoietic lineage markers and the endothelial markers CD31 and von Willebrand factor (vWF)^[43,44]. Studies have also identified a periendothelial pericyte-like subpopulation of ASCs, possibly due to the inclusion of vascular elements in the SVF. These cells express CD34, as well as mesenchymal, pericytic, and smooth muscle markers, including chondroitin sulfate proteoglycan (NG2), CD140a, and CD140b^[45], but are negative for CD31, CD45 and CD144. However CD34 and CD104b did not co-localize in these cells, suggesting that CD34+/CD31- cells in the adipose vasculature are not pericytes^[46].

The DFAT cells initially lack expression of CD34, CD31, CD146, CD45, and pericyte markers, distinguishing them from ASCs derived from the SVF^[6-9] (see below for further characterization of DFAT cells). Interestingly, lineage tracing in mice suggest that part of the stromal cells may be derived from adipocytes *in vivo*^[47], suggesting that ASCs and DFAT cells in part have the same precursor cells. The DFAT cells, however, constitute a more homogeneous cell population than the ASCs, further supporting a role of the mature adipocyte fraction as a source of stem cells^[48-50].

DFAT cells and iPSCs

Three major types of pluripotent stem cells have so far been identified, ESCs, iPSCs from reprogrammed adult somatic cells^[51], and multilineage-differentiating stress-enduring cells, referred to as Muse cells, isolated from mesenchymal human tissues^[52]. The Muse cells are considered MSCs, capable of forming cell clusters and expressing a set of genes associated with pluripotency.

All three cell types have factors that limit their use. Ethical concerns make the ESCs controversial, and heterologous transplantation of ESCs may produce immune rejection in the recipient. Transplantation of both ESCs and iPSCs run the risk of producing teratomas in the recipient because of their uncontrolled capacity of proliferation and differentiation. The paucity of Muse cells has so far been a limitation for their widespread

use. Other limitations to the use of iPSCs are derived from the fact that reprogramming genes have been introduced and remain with low efficiency expression in the host cells. One of the ways to overcome this problem is to achieve efficient transgene-free reprogramming using Sendai virus^[53]. Sendai virus remain in the cytoplasm and do not have the ability to integrate into the host genome. Most commonly, virus clearance is achieved by clonal propagation of primary colonies leading to isolation of sub-clones free of the viral genome. However, about 10% of the cells still have the virus after 10 passages^[54]. Although human is not the natural host for Sendai virus, and the virus is non-pathogenic to humans, the potential mucosal exposure to the virus remains a concern. Therefore, identification and development of new sources of pluripotent adult stem cells remain important.

DFAT cells have been shown to express ESC markers including the POU homeodomain protein Oct4, sex determining region Y-box 2 (SOX2), myelocytomatosis oncogene (*c-Myc*), and the homeobox protein Nanog, which are key factors in maintaining pluripotency^[55]. In addition, high alkaline phosphatase and telomerase activity further support similarities between DFAT cells and undifferentiated pluripotent stem cells. However, the expression of pluripotency markers decrease significantly in DFAT cells that have been cultured for longer than 2 wk. It is possible that the early expression of pluripotency markers in DFAT cells was missed in previous investigations where specific lineages were studied, causing the pluripotency in DFAT cells to be overlooked. Several investigators have also reported low levels of expression of pluripotency markers in human ASCs^[56-58], and other studies have revealed similar degrees of pluripotency in DFAT cells and iPSCs^[59,60].

The DFAT cells are unlike the iPSCs, in which simultaneous overexpression of the transcription factors Oct4, SOX2, *c-Myc*, and the Kruppel-like factor 4 leads to the generation of a pluripotent, ESC-like state in fibroblasts. After derivation from adipocytes, pluripotency emerges transiently of DFAT cells with expression of the same transcription factors as in iPSCs, as well as low levels of Nanog, stage-specific embryonic antigen (SSEA)-3, and CD105^[59]. The DFAT cells are able to differentiate into cells representative of the three germ layers, with no evidence of teratoma after injection of human DFAT cells in immunodeficient mice^[59]. It was recently shown that mature porcine adipocytes, in response to dedifferentiation, downregulate many genes important for lipid metabolism and upregulate genes involved in cell proliferation, cell morphology and regulation of cell differentiation^[53]. By this process, the dedifferentiated adipocytes achieved the appropriate DNA methylation status, underwent gene-reprogramming, and gained stem cell properties. Thus, the available data support that dedifferentiated adipocytes have the molecular signature of a reprogrammed cell similar to pluripotent stem cells.

ADIPOCYTE AND DFAT CELL ISOLATION, AND CHARACTERIZATION

Isolation and dedifferentiation of mature adipocytes

Large lipid accumulations make the white adipocytes naturally buoyant and therefore difficult to culture. This technical difficulty has in part made their *in vitro* characteristics inaccessible for study. Additionally, they have been considered to be in the terminal stages of differentiation and lacking proliferative activity, further decreasing the interest in their *in vitro* and *in vivo* behavior on a cellular level. It is more than five decades since Rodbell^[61] first succeeded in separating unilocular adipocytes from mature white fat tissue using collagenase treatment. Since then, most biochemical studies of adipocytes have made use of such dispersed cells. However, mature adipocytes do not attach to the bottom of tissue culture plates, but rather float to the surface of any given culture medium. To overcome this issue, Sugihara *et al.*^[9,62] proposed to use using ceiling culture as a way of culturing adipocytes. Most adipocytes lose their intracellular lipid and buoyancy with time *in vitro*. Ultimately, the cells have lost all lipids, appear fibroblastic, and proliferate to confluence. *In vivo*, tissue expanders were placed within the inguinal fat pad of rats^[63]. Expanded fat pads were then autotransplanted to a distant location. Histologic analysis demonstrated that the tissue-expanded fat pads had lost over half their original volume, and the adipocytes had become elongated, fibroblast-like cells. These changes were attributed to the mechanical forces of the expander but may represent adipocyte dedifferentiation. Interestingly, after these same "atrophied" fat pads were transplanted as autografts, they regained their previous volume, suggesting adipocyte redifferentiation. This supports the concept of an adipocyte equilibrium in which dedifferentiated adipocytes may withstand ischemic insult better than differentiated adipocytes.

In the last decade, several studies have explored the plasticity of mature adipocytes and introduced to them to the stem cell field. Adipocyte dedifferentiation is readily seen *in vitro*. Matsumoto *et al.*^[6] showed that adipocytes containing two nuclei were occasionally detected in adipocytes before they were placed in ceiling culture, but were frequently seen after 3 d of culture. Such binuclear adipocytes were always positive for BrdU in both nuclei, suggesting that the cells had entered S-phase and the nuclei had divided. The authors also performed time-lapse fluorescence microscopy, which revealed that fibroblast-like cells were indeed generated from lipid-filled adipocytes with single nuclei through asymmetric division^[6,64]. Another similar study demonstrated isolation of stem cells with characteristics of immature neural crest cells through asymmetric cell division in cultured human hair follicles *in vitro*^[65]. Asymmetric cell division permits a single mother cell to generate daughter cells that are distinct in size, shape, function and fate. The generation of two progeny with different

fates requires a highly regulated molecular program. In general, disruption of asymmetric cell division leads to the creation of two progeny that retain stem cell characteristics, but with reduced ability to achieve full differentiation^[66-69]. As far as we have observed, the emergence of DFAT cells from mature adipocytes occurs *via* two phenomena; mature adipocytes lose their lipid content and acquire a fibroblast-like shape, and asymmetric cell division of mature adipocytes into one lipid-filled adipocyte and another small daughter cells without lipid (Figure 1). Subsequently, the cells undergo dedifferentiation without the use of inducing agents, resulting in proliferative DFAT cells.

Recent studies exploring DFAT cells describe specific purification steps to ensure, to the extent possible, the purity of the initial preparation of mature adipocytes. Indeed, the purity of the primary adipocytes is essential in the preparation of DFAT cells, as to avoid the possibility of floating adipocytes "dragging" contaminating cells with them^[70]. Recently, we proposed a new method to prepare DFAT cells, using insert culture (Figure 2)^[59]. In this method, DFAT cells are generated from lipid-filled mature adipocytes isolated from small pieces of subcutaneous adipose tissue or human fresh lipoaspirate, washed repeatedly with phosphate-buffered saline until the washes are clear^[6,59,62]. Approximately 1 g of adipose tissue is minced and digested in 0.1% (w/v) collagenase solution (Collagenase type I) at 37 °C for 1 h with gentle agitation. After filtration through nylon filters (core size 100 µm) and centrifugation at 135 g for 3 min, the floating top layer of adipocytes is collected. The adipocytes are then washed repeatedly (usually three times) in Dulbecco's Modified Eagle Medium supplemented with 20% fetal bovine serum before further use. Adipocytes intended for DFAT cell generation are floated on top of medium in culture dishes or plastic tubes to let remaining non-adipocytes detach and sink to the bottom and be discarded after centrifugation. Adipocytes from the top creamy layer (30-50 µL) are subsequently transferred to 6-well plates fitted with 70 µm-filters and incubated for 5 d in culture medium. DFAT cells derived from the adipocytes sink through the filters and attach to the bottom of the dishes. The filters with remains of the adipocytes are removed after 5 d (Figure 2). This method of preparing DFAT cells does not include attachment of the adipocytes to plastic surfaces or ceiling culture, as previously described^[6-8,62,71]. In addition, this method allows the separation of the DFAT cells from the adipocytes as soon as they sink through the filter and attach to the bottom of the dish. This reduces the influence of adipocyte remnants on the surface of the medium on the characteristics of the nascent DFAT cells. We regularly collect up to 10000 DFAT cells during 5 d of collection. The inclusion of these additional steps not only enhances the purity of DFAT cells, but significantly increases the early expression of pluripotency markers

Figure 1 Dedifferentiation of adipocytes. Mature adipocytes lose their lipid content and acquire a fibroblast-like shape. Mature adipocytes also divide asymmetrically into one lipid-filled adipocyte and small daughter cells without lipid. The new lipid-free cells are referred to as DFAT cells. DFAT: Dedifferentiated fat.

previously described^[59].

Characterization of DFAT cells

Most studies on the DFAT cells have concluded that they are a largely homogeneous cell population with an immunophenotype similar to those of ASCs and other MSCs^[72,73]. Human ASCs are relatively heterogeneous and carry hematopoietic-associated markers such as CD11a, CD14, CD45, CD86 and HLA-DR, and low levels of the MSCs-associated markers CD13, CD29, CD34, CD44, CD63, CD73, CD90 and CD166^[73,74]. On the other hand, the DFAT cells are positive for CD13, CD29, CD44, CD90, CD105, CD9, CD166 and CD54, and negative for CD14, CD31, CD34, CD45, CD66b, CD106, CD117, CD133, CD146, CD271, CD309, HLA-DR and alpha-smooth muscle cell actin^[1,50,75]. Both ASCs and DFAT cells express HLA-A, -B and -C, which suggests that both cell types have allogeneic transplantation potential. In addition, we detected that 7.1% of the human DFAT cells expressed SSEA-3, and that most of the human DFAT cells expressed CD105, whereas mouse DFAT cells expressed Sca-1^[59]. This expression was maintained for multiple passages. However, the expression of stem cell markers in human DFAT cells varies with the donor's age, culture conditions, and the degree of differentiation.

DIFFERENTIATION POTENTIAL OF DFAT CELLS

DFAT cells have emerged as a potential cell source for regenerative medicine because of their transdifferentiation capability and similarity to ASCs and bone marrow MSCs^[75-77]. Multiple studies have demonstrated differentiation of DFAT cells into multiple lineages including adipogenic, osteogenic, chondrogenic, myogenic, angiogenic and neurogenic lineages (Figure 3). To monitor the fate of DFAT cells, investigators have used DFAT cells prepared from the adipose tissue of GFP-transgenic mice for transplantation into wild type mice^[64,78], or adipocyte protein 2-Cre^{+/+}; LacZ ROSA (R26R)^{+/+} double transgenic mice^[79]. Human DFAT cells used for injection of immunodeficient mice were traced by anti-human mitochondria staining^[59]. However, the potential need to maintain a specific cell identity once the DFAT cells have achieved a desired phenotype, or the methodology to do so, has not been assessed thus far.

Adipogenesis

Soft tissue reconstruction is an important aspect of tissue engineering, and adipose grafts are needed for minimally invasive injectable therapies in order to

Figure 2 Schematic drawing of dedifferentiated fat cell preparation using preincubation and filters. Isolated adipocytes are incubated for 24 h in culture medium, before transfer to a new dish with filter, where the adipocytes remain for five days before the filter is removed. DFAT cells are allowed to sink through the filter to the bottom of the dish. The adipocytes and filter insert are then removed, and the new DFAT cells are cultured by regular methods. ASCs: Adipose-derived stem cells; DFAT: Dedifferentiated fat.

restore soft tissue volume. The most important features of adipose tissue as a cell source might be its relative expendability and the ease with which large quantities can be obtained with minimal risk. Correctly prepared adipocytes could therefore be a useful alternative for tissue augmentation, such as breast surgery with allogeneic material or tissue flap surgery.

Previous studies have confirmed that mature adipocytes easily redifferentiate into adipocytes^[6,7,11]. We demonstrated that mouse DFAT cells spontaneously underwent adipogenic differentiation without special treatment, whereas human DFAT cells required adipogenic induction^[51]. Another study showed that although DFAT cells expressed lower levels of lipoprotein lipase, leptin, and glucose transporter 4 compared to mature adipocytes, they still expressed important adipogenic markers such as peroxisome proliferator-activated receptor gamma (PPAR γ), C/EBP α , C/EBP β , C/EBP δ , and sterol regulatory element-binding protein-1c^[6,80]. In addition, the DFAT cells have been shown to have adipogenic capacity *in vivo*. Direct injection of DFAT cell into the subcutaneous portion over sternum of mice resulted in fat pad formation after 3 wk without the use of chemical induction^[7,81]. Furthermore, it was found that that PPAR γ and C/EBP α mRNA levels were higher in DFAT cells derived from intramuscular adipose tissue rather than visceral adipose tissue in pigs, suggesting a more active adipogenesis in intramuscular DFAT cells, as compared to visceral DFAT cells^[82]. It implies that DFAT cells from the same donor may differ in rates of redifferentiation and expression of molecular markers depending on the depot of origin.

Osteogenesis and chondrogenesis

DFAT cells can be derived from small amounts of subcutaneous adipose tissue regardless of the age of the donors, and may be useful in cell-based therapies for a

variety of diseases commonly affecting elderly subjects, including metabolic bone disorders and osteoporosis. An earlier study found that the transcription factors RUNX2 and SP7, secreted phosphoprotein 1, bone Gla protein, parathyroid hormone 1 receptor and SOX9 were expressed in DFAT cells, suggesting osteogenic and chondrogenic potentials^[6]. Osteogenic differentiation was stimulated by the addition of dexamethasone, β -glycerophosphate and L-ascorbic acid-2-phosphate to the culture medium. It was also stimulated by the addition of retinoic acid, an analogue of retinol that interacts with bone morphogenetic proteins (BMPs) to limit adipogenesis and promote osteogenesis^[83]. Chondrogenic induction, however, was facilitated by the addition of L-ascorbic acid-2-phosphate, proline, pyruvate, and transforming growth factor β 3. Appropriate mineralization of the cells was confirmed by alkaline phosphate, Alizarin Red S and von Kossa staining, whereas chondrocyte differentiation was confirmed by Alcian Blue staining. An experiment using implantation of DFAT cells in combination with collagen-based scaffolds further showed the ability of the cells to undergo osteochondrogenesis *in vivo*^[84]. Another study proposed DFAT cells as a cell source for periodontal regeneration, after the cells promoted osteogenic differentiation in co-cultures with periodontal ligament stem cells^[85]. Furthermore, the ability of human DFAT cells from the buccal fat pad to undergo osteoblastic differentiation appears to be higher than that of ASCs from the same fat depot^[86]. Thus, the DFAT cells may be attractive as a cell source for tissue engineering in bone disorders such as nonunion fractures and osteoporosis.

Myogenesis

Myocytes are generally divided into three categories: skeletal, cardiac and smooth muscle cells, which differ in their cellular characteristics and behaviors.

Figure 3 Schematic drawing of differentiation in dedifferentiated fat cells. The DFAT cells are able to differentiate into multiple lineages, including adipogenic, osteogenic, chondrogenic, myogenic, angiogenic and neurogenic lineages. Potential for differentiation into hepatocytes, lung cells, intestine cells and hematopoietic cells has not been reported. DFAT: Dedifferentiated fat.

Myogenesis is a multi-stage process resulting in the formation of muscular cells and tissue. It involves myoblast proliferation, secretion of fibronectin into the extracellular matrix, alignment of the myoblasts into multi-nucleated myotubes, and cell fusion^[87]. The two muscle-specific transcription factors Myf5 and MyoD are known to actively regulate these processes. Treatment with 5-azacytidine (Aza-C), a demethylating agent, led to induction of MyoD and Myogenin in DFAT cells and the formation of multinucleated cells with expression of myosin heavy chain, even though Myf5 was not expressed after induction^[88]. Another study found that DFAT cells underwent smooth muscle cell differentiation and contributed to the regeneration of bladder smooth muscle^[78]. It also was shown that DFAT cell transplantation promoted the recovery of the sphincter muscle and improved the urethral sphincter contractility

in a rat vaginal distension model^[89]. Our previous study demonstrated that DFAT cells were able to differentiate into cardiomyocytes *in vitro*, and injection of DFAT cells into ischemic rat hearts induced neovascularization and supported rehabilitation of the cardiac tissue^[64]. Although pluripotent stem cells have exhibited spontaneous cardiomyocyte differentiation, both *in vitro* and *in vivo*, none of the adult stem cell models studied thus far have spontaneously undergone cardiomyocyte differentiation *in vitro*, except for the DFAT cells^[8,90]. Other adult stem cell models have required either co-culture with isolated cardiomyocytes or treatment with methylation inhibitors and histone deacetylase inhibitors. However, mouse DFAT cells spontaneously differentiated into functional cardiomyocytes without specific induction or genetic treatment^[59]. Human DFAT cells, on the other hand, did not undergo spontaneous

cardiomyocyte differentiation, although they expressed cardiomyocyte markers after cardiogenic induction^[59]. Thus, cardiomyogenic differentiation differs between mice and human DFAT cells, a difference that could be explored to uncover pathways active in spontaneous cardiomyogenesis.

Angiogenesis

Blood vessels consist of an interior lining of endothelial cells surrounded by perivascular support provided by smooth muscle cells or pericytes. Human DFAT cells without induction have been shown to express low levels of endothelial cell or progenitor markers in culture such as the vWF, CD31 or CD34^[6,10,11], and to be stimulated to undergo endothelial differentiation by treatment with BMP4 and BMP9^[10]. They also differentiated into endothelial cells in established *in vitro* and *in vivo* models of angiogenesis^[91-93]. DFAT cells cultured in Matrigel® form tube-like structures that are stable for weeks and stain for endothelial markers, including CD31 and VE-cadherin^[10]. Some researchers have proposed the tube-like structures to be a result of the perivascular nature of DFAT cells, as suggested by the expression of the pericyte-related markers CD140b and NG2^[74]. Similarly, MSCs within adult mesenchymal tissues may differentiate into pericytes without induction by growth factors^[94,95]. In our experiments we initially did not detect pericyte markers in DFAT cells even though they appeared later during culture. Moreover, in Matrigel®, the human DFAT cells differentiated into cells that expressed either endothelial markers or α -smooth muscle actin, which suggests that the cells undergo differentiation into multiple cell types (unpublished observations). It is possible that interactions between endothelial cells and support cells, also derived from the DFAT cells, strengthen the tube structures and promote cell maturity. Thus, the DFAT cells are able to differentiate into endothelial cells *in vitro*, and participate in neovascularization *in vivo*.

Neurogenic and other lineages

Treatments of peripheral or central nerve injuries are still suboptimal despite significant advances in neuroscience and microsurgery. The standard treatment of autologous nerve grafting is unsatisfactory because of morbidity and loss of function at the donor site. Neural progenitor cells such as ESCs and neural stem cells derived from the adult central nervous system may provide new prospects although logistical, ethical, and immunological factors are likely to limit potential applications. However, recent studies have revealed differentiation of ASCs into early neural progenitors, which has generated interest in the field of regenerative medicine. Hsueh *et al.*^[96] observed that, when seeded on a chitosan-coated surface, human ASCs form spheres containing up to 19.5% nestin positive cells. Ahmadi *et al.*^[97] further reported that, after culture in serum-free medium, 51% nestin-positive cells could be generated from human ASCs. However, Zuk *et al.*^[43]

found that nestin was expressed in multiple cell types, including myogenic, endothelial, and hepatic cells, indicating that nestin expression alone is not suitable for the identification of neural cells, especially without functional analysis. Some studies suggest that adipose tissue stem cells are able to induce neurite outgrowth *in vitro*, as well as tissue-specific commitment to neural cell lineages and expression of the tropomyosin receptor kinase A neurotrophin receptor *in vivo*^[98,99]. Most recently, a study demonstrated that ASCs differentiated into astrocytes, oligodendrocytes, and functional neurons, which were able to generate tetrodotoxin-sensitive sodium currents^[100]. DFAT cells, prepared in parallel with ASCs, also had neurogenic potential and expressed neurotrophic factors such as brain-derived neurotrophic factor and glial cell line-derived neurotrophic factor. After transplantation, the DFAT cells supported functional recovery from spinal cord injury (SCI)-induced motor dysfunction in rats^[101]. Furthermore, the DFAT cells promoted remyelination and inhibited glial scar formation in SCI mice, possibly through cell-autonomous as well as cell-non-autonomous effects^[102]. It is possible that the neurotrophic factors secreted from the grafted DFAT cells contribute to the functional recovery. Further characterization of the capacity of DFAT cells to undergo neurogenesis, with particular focus on neurophysiologic and neurochemical signal transduction properties, is needed.

Even though hematopoietic lineage differentiation has not yet been reported in DFAT cells, studies comparing porcine-derived mature adipocytes and DFAT cells suggest that such potential exists^[60,103]. Upregulation of genes related to multiple lineages occurred during the dedifferentiation, including those related to hematopoietic cell differentiation.

Overall, DFAT cells appear to constitute an excellent source of cells for tissue engineering. However, the mechanisms of dedifferentiation, and whether it occurs under physiological or pathological conditions *in vivo*, need further exploration. In addition, culture conditions for the maintenance of stem cell characteristics, as well as induction of specific lineages, need development. DFAT cells can also be prepared to match the individual patient, thus allowing for replacement therapies using autologous transplantation. Although no human trial has ever been reported on DFAT cells, it should not deter us from anticipating their clinical application, with focus on tissue regeneration.

CONCLUSION

Multipotent DFAT cells provide evidence of plasticity in adipocytes. The recently characterized DFAT cell model exhibit robust proliferation and multipotency potential giving them an advantage over other adult stem cell models. Compared to bone marrow derived stem cells, white adipose tissue is mostly located subcutaneously and their abundance is generally guaranteed. Further-

more, access to mature adipocytes is obtained through less invasive methods such as liposuction, which have less physical and psychological effects on the donor. Compared to ASCs, DFAT cells comprise a more homogeneous population of cells. Modified culture methods reduce the risk of contamination by cells from the stromal vascular fraction to a minimum. *In vitro* and/or *in vivo* experiments have revealed adipogenic, osteogenic, chondrogenic, myogenic, angiogenic and neurogenic differentiation potentials in DFAT cells. Moreover, the DFAT cells express ESC markers and are similar to iPS cells in certain physiological aspects. Based on the abundance, ease of preparation, homogeneity, and multi-lineage potential, the DFAT cells are uniquely suited for regenerative medicine.

Abstract

AIM: To evaluate adhesion, proliferation and differentiation of human dental pulp stem cells (hDPSCs) on four commercially available scaffold biomaterials.

METHODS: hDPSCs were isolated from human dental pulp tissues of extracted wisdom teeth and established in stem cell growth medium. hDPSCs at passage 3-5 were seeded on four commercially available scaffold biomaterials, SureOss (Allograft), Cerabone (Xenograft), PLLA (Synthetic), and OSTEON II Collagen (Composite), for 7 and 14 d in osteogenic medium. Cell adhesion and morphology to the scaffolds were evaluated by scanning electron microscopy (SEM). Cell proliferation and differentiation into osteogenic lineage were evaluated using DNA counting and alkaline phosphatase (ALP) activity assay, respectively.

RESULTS: All scaffold biomaterials except SureOss (Allograft) supported hDPSC adhesion, proliferation and differentiation. hDPSCs seeded on PLLA (Synthetic) scaffold showed the highest cell proliferation and attachment as indicated with both SEM and DNA counting assay. Evaluating the osteogenic differentiation capability of hDPSCs on different scaffold biomaterials with ALP activity assay showed high level of ALP activity on cells cultured on PLLA (Synthetic) and OSTEON II

Collagen (Composite) scaffolds. SEM micrographs also showed that in the presence of Cerabone (Xenograft) and OSTEON II Collagen (Composite) scaffolds, the hDPSCs demonstrated the fibroblastic phenotype with several cytoplasmic extension, while the cells on PLLA scaffold showed the osteoblastic-like morphology, round-like shape.

CONCLUSION: PLLA scaffold supports adhesion, proliferation and osteogenic differentiation of hDPSCs. Hence, it may be useful in combination with hDPSCs for cell-based reconstructive therapy.

Core tip: Recently, the plasticity of postnatal stem cells from dental origin including human dental pulp stem cells (hDPSCs) has been suggested. Their osteogenic potential makes them valuable for craniofacial bone regeneration. hDPSCs can be easily isolated from dental medical wastes, extracted teeth, and expanded *ex vivo*. Combination of numerous postnatal stem cells and three-dimensional scaffold biomaterials has been used in bone tissue engineering. Selection of an ideal scaffold biomaterial is a challenging part of reconstructive surgeries. Current study aims to evaluate behavior of hDPSCs including adhesion, proliferation, morphology and differentiation on four different scaffold biomaterials. Our finding indicates that PLLA (Synthetic) scaffold supports adhesion, proliferation and osteogenic differentiation of hDPSCs. Therefore, it can be useful for the purpose of craniofacial tissue engineering.

INTRODUCTION

Non-healing craniofacial defects occur frequently due to various factors such as trauma, infection, tumor, and congenital deformities^[1,2]. The treatment of large bone defects has been posed a challenge for reconstructive surgeons. The conventional treatment approach for treatment of craniofacial bone defects is harvesting and transplanting autogenous cancellous bone graft, particularly from ilia crest^[3]. However, the surgical procedures are invasive and it usually associated with donor site morbidities and limited availability^[4,5]. Another approach is utilization of allogeneic bone which is also limited by the risk of immunogenicity or disease transmission^[6].

The concept of harvesting adult stem cells (ASCs) in combination with appropriate three-dimensional (3D) scaffolds have been proposed as a promising alternative approach in reconstructive surgery^[7-12].

ASCs have been isolated from various tissues. In dental clinic teeth are often need to be extracted in order to avoid further complications including orthodontic treatments. Human dental pulp has been harvested from extracted teeth and shown to contain multilineage population of progenitor/stem cells, dental pulp stem cells (hDPSCs)^[13,14]. The differentiation capability of hDPSCs towards the osteoblast lineage and their accessibility and ease of *ex-vivo* expansion make them suitable cell source to be considered for repair of skeletal defects^[15,16].

Bone formation from hDPSCs is required a 3D structure provided by scaffolds. An ideal scaffold should provide an appropriate environment for cellular attachment, growth, and differentiation. A wide range of scaffold biomaterials have been developed for variety of applications in tissue engineering^[17]. Scaffolds can be categorized as following groups: (1) Allograft; (2) Xenograft; (3) Synthetic; and (4) Composite biomaterials. In order to select a suitable scaffold for craniofacial engineering, it is necessary to evaluate the cell-scaffold interactions *in vitro*. Current study is aimed to investigate hDPSCs behavior including cell adhesion, attachment, and differentiation on four commercially available scaffolds from given groups.

MATERIALS AND METHODS

hDPSC culture

hDPSC cultures are established from dental pulp tissues isolated from extracted teeth of healthy volunteer adults (aged 18-30) as previously described^[14]. Briefly, pulp tissues are gently separated from the crown and root and then digested in a solution of 0.075% collagenase type I (Sigma-Aldrich, St. Louis, Missouri, United States) for 1 h at 37 °C. hDPSCs are established by growing the primary cell suspension in stem cell growth medium containing DMEM-HG (Invitrogen, Grand Island, NY, United States), 10% FBS (Invitrogen, Grand Island, NY, United States) and 100 units/mL penicillin 100 mg/mL streptomycin (Invitrogen, Grand Island, NY, United States) in T-25 flasks overnight at 37°C and 5% CO₂, and non-adherent cells were removed by medium change. The remaining cells were cultured until they reached 80%-90% confluency. Cells were trypsinized using 0.05% Trypsin-EDTA (Invitrogen, Grand Island, NY, United States) and passaged at a ratio of 1:3 until the desired passages were reached. Passage 3-5 were used for subsequent experiments.

Scaffolds and cell seeding

Four commercially available bone-graft substitutes were studied. SureOss (HansGBR Biomaterial, Seoul, South Korea) is a freeze dried cortical bone allograft. It is a granular biomaterial with the particle size of 200-850

µm. Cerabone (Biotiss Biomaterial, Zossen, Germany) is a xenograft derived from the mineral phase of bovine bone. It is a granular biomaterial with the particle size of 0.5-1.0 mm. PLLA is a synthetic biomaterial. OSTEON II Collagen (Dentium, Gyeonggi, South Korea) is a composite biomaterials contains HA:β-TCP = 30:70 and natural type I collagen. It has particle size of 0.2-0.5 mm.

Approximately 100 mg of given biomaterial scaffolds were placed into 96-well plates. hDPSCs were seeded onto the scaffolds at a cell density of 10^4 cells/well in osteogenic medium (Invitrogen, Grand Island, NY, United States). The cells - scaffold constructs were maintained at 37 °C in a humidified 5% CO₂ atmosphere for 7 and 14 d.

Cell adhesion

hDPSCs adhesion on following scaffolds were assessed using scanning electron microscopy (SEM). Seven days after cell seeding, samples were fixed with 2.5% glutaraldehyde (MerckKGaA, Darmstadt, Germany) solution for 30 min. Specimens were then post-fixed with 1% Osmium tetroxide (Sigma-Aldrich, St. Louis, Missouri, United States). After cell fixation, the specimens were subsequently dehydrated by ascending grades of alcohol (25%, 50%, 75%, 96%, and 100% ethanol) for 15 min each step. The specimens were then allowed to dry in air. After complete drying, they were sputtered with gold and analyzed using a SEM imaging (Hitachi, Tokyo, Japan).

Cell proliferation

To determine the proliferation of hDPSCs on following scaffolds, DNA counting assay were performed using QIAamp® DNA Mini Kit, according to the manufacturer's description (Qiagen, Valencia, CA, United States). Briefly, cells at days 7 and 14 were harvested using 0.05% Trypsin-EDTA (Invitrogen, Grand Island, NY, United States). Then, cell pellets were collected by centrifugation and re-suspended in phosphate-buffered saline (PBS). DNA was collected with QIAam spin column. The amount of DNA (ng/mL) was measured using Nanodrop (Thermo Scientific, Waltham, MA, United States).

Cell differentiation

Osteogenic differentiation of hDPSCs on scaffold were evaluated at days 7 and 14 after cell seeding using alkaline phosphatase (ALP) activity assay. The cell-scaffold constructs were rinsed with PBS and homogenized in lysis buffer (pH 7.5, 10 mmol/L Tris-HCl, 1 mmol/L MgCl₂, and 0.05% Triton X-100). The resulting mixture was then centrifuged at 12000 rpm for 10 min at 4 °C. The cell lysate was mixed with *p* nitrophenol phosphate substrate solution (Sigma aldrich, St. Louis, Missouri, United States) and alkaline buffer solution (Sigma aldrich, St. Louis, Missouri, United States). After incubation at 37 °C for 15 min, the above mixture

was added to 0.5 N NaOH to stop the reaction and the absorbance at 405 nm was measured using ELIZA reader (BioTek, Winooski, VT, United States).

Statistical analysis

All quantitative data were expressed as mean ± SE. Analysis of variance and Post hoc tests was conducted for multiple comparisons. A *P* value less than 0.05 were considered to be significant.

RESULTS

Evaluation of hDPSC morphology and adhesion

The suitability of the 3D structure of scaffolds for cell seeding was assessed by observing cell morphology and adhesion using SEM imaging. SEM microphotographs after 7 d confirmed the adherence of hDPSCs in all biomaterial scaffolds (Figure 1-D) except SureOss (Allograft) (Figure 1A). Marked cell aggregation was observed on PLLA scaffold (Synthetic) (Figure 1D-F). hDPSCs were covered almost the entire PLLA scaffold surface. In contrast, fewer cells were aggregated on the surface of Cerabone (Xenograft) and OSTEON II Collagen (Composite) scaffolds (Figure 1B and C). The adherent hDPSCs on Cerabone (Xenograft) and OSTEON II Collagen (Composite) scaffolds demonstrated fibroblastic morphology with several cytoplasmic extension (Figure 1-F). The osteoblastic-like morphology, round-like shape, was observed on cells attached on PLLA (Synthetic) scaffold (Figure 1B, C, G and H).

Evaluation of hDPSC proliferation

The proliferation of hDPSCs on different scaffold biomaterials were monitored and quantified after 7 and 14 d culturing of the cells by means of DNA counting assay (Figure 2). DNA counting assay confirmed the SEM results. The amount of DNA was highest on PLLA group at both time points (Figure 2A and B).

Evaluation of hDPSC differentiation

The osteogenic differentiation capability of hDPSCs on different scaffold biomaterials was compared using ALP activity assay. The results are presented in Figure 3A and B. At day 14 both cells cultured on PLLA (Synthetic) and OSTEON II Collagen (Composite) scaffolds showed high level of ALP activity compared to cells on Cerabone (Xenograft). No significant difference observed between osteogenic activity of hDPSCs on OSTEN II Collagen and PLLA group (Figure 3B).

DISCUSSION

An ideal scaffold should interact with cells, support cell attachment and proliferation, and stimulate tissue regeneration. In current study, we investigated the hDPSC activity and growth behavior on four different 3D scaffold biomaterials. The scaffold biomaterials used

Figure 1 Scanning electron microscopy microphotographs of human dental pulp stem cells attachment and morphology on four different scaffolds. A: SureOss (Allograft); B: Cerabone (Xenograft); C: OSTEON II Collagen (Composite); D: PLLA (Synthetic); E and F: PLLA at lower magnification; G and H: Cerabone at lower magnification. Note that cells were covered almost the entire scaffold surface of PLLA (D-F). Also note that attached cells on PLLA surface showed fibroblastic morphology (D-F), whereas cells on Cerabone and OSTEON II Collagen demonstrated osteoblastic phenotype (B, C, G, H).

in this study are already commercially available for clinical applications. However, comparing their efficiency to provide structural support for hDPSCs is essential. hDPSCs has been selected for our observation, since

their clinical application seems feasible. Harvesting and isolating these progenitor population are relatively easy and a sufficient number of the cells can be provided in two weeks^[14,15]. In addition, since dental pulp stem

Figure 2 The quantitative analysis of human dental pulp stem cells proliferation by DNA counting assay after 7 (A) and 14 (B) d. Note that the highest amount of DNA was observed on PLLA group at both time points.

cells are derived from neural crest, different origin from mesoderm-derived bone marrow stem cells, they may be considered better candidate for repair of damages in neural crest-derived tissues including periodontium and craniofacial defects^[15,18].

We have shown that all scaffold biomaterials except SureOss (Allograft) support hDPSC adhesion, proliferation and differentiation. Among them, the highest cell proliferation was observed in the presence of PLLA, as it confirmed with both SEM and DNA counting assay. SEM showed almost all surface of PLLA scaffold was covered by adhering cells. PLLA is one of the few synthetic degradable polymers which approved by the Food and Drug Administration for clinical application^[19] and has been used extensively in reconstructive surgery in combination with mesenchymal stem cells (MSCs)^[20-22]. In our study, we have shown that MSCs derived from dental pulp tissues also are attached, proliferated, within PLLA scaffold.

In addition, SEM examination showed that cell morphology differs clearly between scaffolds. In the presence of Cerabone (Xenograft) and OSTEON II Collagen (Composite) scaffolds, the hDPSCs demonstrated the fibroblastic phenotype, which is the typical MSC morphology^[23]. However, the cells on PLLA (Synthetic) scaffold showed the round-like shape which is the typical osteoblastic phenotype^[24], indicating that PLLA scaffold not only can improve cell adhesion and growth, but also upregulate the osteoblastic phenotype.

Evaluating hDPSCs adhesion, proliferation and differentiation of HA/ β -TCP in composition with collagen, we have shown that despite the increase in ALP

Figure 3 The assessment of osteogenic differentiation of human dental pulp stem cells by alkaline phosphatase activity assay after 7 (A) and 14 (B) d. ALP activity was highest on PLLA and OSTEON II Collagen groups at day 14. Note that no significant difference was observed between PLLA and OSTEON II Collagen. Also, note that different letters are indicated significant difference at $P \leq 0.05$. ALP: Alkaline phosphatase.

activity, the cellular attachment and proliferation was lower compared to PLLA scaffold. Phosphate Ceramics including HA and β -TCP have been described as an osteoinductive materials for many years^[25-27]. Despite their similarity to mineral component of human bone, their major drawbacks including their high resorption rate and low mechanical strength^[28] hampers their applications in clinics. The combination of these materials and collagen has been reported in various studies to reinforce their mechanical strength and decrease resorption rate^[29-31]. Moreover, several studies have been used both collagen and HA in combination with other scaffold biomaterial in order to mimic the natural environment of the bone^[32]. Akkouch *et al.*^[32], showed increased osteogenic capability of hDPSCs cultured on composite scaffold made of HA, collagen and poly (L-lactide-co- ϵ -caprolactone) (PLCL). However, there have been controversies among the literature regarding the beneficial effects of these phosphate ceramics on cellular attachment and proliferation. Study of Pereira-Junior *et al.*^[33], showed the slow growth of MSCs in the presence of HA granule. Similar study on MSCs seeded on β -TCP has shown the slow bone formation *in vivo*^[34]. In contrast, study of Kasten *et al.*^[35], showed that HA ceramics supported the cellular attachment and differentiation. Ling *et al.*^[36], compared the attachment, proliferation and osteogenic differentiation of DPSCs on composite scaffold containing HA, collagen and poly

(L-lactide) (PLA) with β -TCP. They demonstrated that although DPSCs had more mineralization on β -TCP, cell attachment and proliferation were higher in composite scaffold of HA, collagen and PLA.

Present study was designed to evaluate these bone substitute materials in response to MSCs derived from dental pulp. However, the result of this study needs to be confirmed *in vivo*, where the interaction of cell-scaffold with host environment is an essential factor.

Our findings indicate that PLLA (Synthetic) scaffold supports adhesion, proliferation and osteogenic differentiation of hDPSCs. Therefore, it can be useful for the purpose of craniofacial tissue engineering.

COMMENTS

Background

The treatment of large non-healing craniofacial defects has been posed a challenge for reconstructive surgeries. The conventional treatment approach for treatment of craniofacial bone defects is usually associated with donor site morbidities and limited availability. The concept of harvesting adult stem cells (ASCs) in combination with appropriate three-dimensional (3D) scaffolds have been proposed as a promising alternative approach in reconstructive surgery. Human dental pulp stem cells (hDPSCs) can be easily isolated from dental medical wastes, extracted teeth, and expanded *ex vivo*. Their osteogenic capability makes them appropriate source of ASCs. Bone formation from hDPSCs is required a 3D structure provided by scaffolds which should provide an appropriate environment for cellular attachment, growth, and differentiation.

Research frontiers

A wide range of scaffold biomaterials have been developed for variety of applications in tissue engineering. Scaffolds can be categorized as following groups: (1) Allograft; (2) Xenograft; (3) Synthetic; and (4) Composite biomaterials. In order to select a suitable scaffold for craniofacial engineering, it is necessary to evaluate the cell-scaffold interactions *in vitro*. Current study is aimed to investigate hDPSCs behavior including cell adhesion, attachment, and differentiation on four commercially available scaffolds from given groups.

Innovations and breakthroughs

The authors' findings indicate that PLLA (Synthetic) scaffold supports adhesion, proliferation and osteogenic differentiation of hDPSCs.

Application

DPSCs in combination with PLLA scaffold can be useful for the purpose of craniofacial tissue engineering.

Terminology

A scaffold is an artificial designed biomaterial which mimics extra cellular matrix and it is support cellular attachment, proliferation and differentiation.

Peer-review

The study is well designed and results are clear and support the conclusions.

ABOUT COVER

Editorial Board Member of *World Journal of Stem Cells*, Basem M Abdallah, Associate Professor, Medical Biotechnology Center, Department of Molecular Endocrinology, Southern Denmark University, DK-5000 Odense C, Denmark

AIM AND SCOPE

World Journal of Stem Cells (*World J Stem Cells*, *WJSC*, online ISSN 1948-0210, DOI: 10.4252), is a peer-reviewed open access academic journal that aims to guide clinical practice and improve diagnostic and therapeutic skills of clinicians.

WJSC covers topics concerning all aspects of stem cells: embryonic, neural, hematopoietic, mesenchymal, tissue-specific, and cancer stem cells; the stem cell niche, stem cell genomics and proteomics, and stem cell techniques and their application in clinical trials.

We encourage authors to submit their manuscripts to *WJSC*. We will give priority to manuscripts that are supported by major national and international foundations and those that are of great basic and clinical significance.

INDEXING/ ABSTRACTING

World Journal of Stem Cells is now indexed in PubMed Central, PubMed, Digital Object Identifier, and Directory of Open Access Journals.

Abstract

Testicular germ cell cancer (TGCC) is rare form of malignant disease that occurs mostly in young man between age 15 and 40. The worldwide incidence of TGCC is 1.5 per 100000 man with the highest rates in North Europe. After discovery of cisplatin cure rates of TGCC are very favorable between 90%-95% and unlike most solid tumors, cure rate for metastatic TGCC is around 80%. Metastatic TGCC is usually treated with 3-4 cycles of bleomycin, etoposide, cisplatin chemotherapy with or without retroperitoneal surgery and cure rates with this approach are between 41% in poor risk group and 92% in good risk group of patients. Cure rates are lower in relapsed and refractory patients and many of them will die from the disease if not cured with first line chemotherapy. High dose chemotherapy (HDCT) approach was used for the first time during the 1980s. Progress in hematology allowed the possibility to keep autologous haematopoietic stem cells alive *ex-vivo* at very low temperatures and use them to repopulate the bone marrow after sub-lethal dose of intensive myeloablative chemotherapy. Despite the fact that there is no positive randomized study to prove HDCT concept, cure rates in relapsed TGCC are higher after high dose therapy than in historical controls in studies with conventional treatment. Here we review clinical studies in HDCT for TGCC, possibilities of mobilising sufficient number of stem cells and future directions in the treatment of this disease.

Key words: High dose chemotherapy; Germ-cell cancer; Stem cell transplantation; Plerixafor

Core tip: High dose chemotherapy with autologous haematopoietic stem cell transplantation is effective option in treating relapsed metastatic germ-cell cancer. We reviewed this topic in regard of clinical studies, optimal mobilising and conditioning regimens, with special review on plerixafor in this indication. We also analysed risk adapted approach in those patients and future directions in field.

High dose chemotherapy with stem cell support in the treatment of testicular cancer. *World J Stem Cells* 2015; 7(11): 1222-1232 Available from: URL: <http://www.wjgnet.com/1948-0210/full/v7/i11/1222.htm> DOI: <http://dx.doi.org/10.4252/wjsc.v7.i11.1222>

INTRODUCTION

Testicular germ cell cancer (TGCC) is a rare form of malignant disease that occurs mostly in young man between age 15 and 40. The worldwide incidence of TGCC is 1.5 per 100000 man with the highest rates in Northern Europe^[1]. One half of all TGCC are seminomas and other half are non-seminomas. The majority of TGCC arise from the gonads while around 5% arise from extragonadal sites in the body's mid-line: retroperitoneum, mediastinum or brain^[2]. After discovery of cisplatin TGCC cure rates have become very favorable ranging between 90%-95% and unlike most solid tumors, cure rate for metastatic TGCC is around 80%^[1,2]. Metastatic TGCC is usually treated with 3-4 cycles of bleomycin, etoposide, cisplatin (BEP) chemotherapy with or without retroperitoneal surgery and cure rates with this approach are between 41% in poor risk group and 92% in favourable risk group of patients^[3] (Table 1). Cure rates are lower in relapsed and refractory patients and many of them will die from the disease if not cured with first line chemotherapy^[3]. High dose chemotherapy (HDCT) approach was first used during the 1980s. Progress in hematology allowed the possibility to keep autologous haematopoietic stem cells alive *ex-vivo* in very low temperatures and using them to repopulate the bone marrow after sub-lethal dose of intensive myeloablative chemotherapy^[4].

RATIONALE FOR HIGH DOSE CHEMOTHERAPY

Resistance to chemotherapy is a major problem in the treatment of patients with malignant diseases. Large number of studies are directed towards finding and overcoming resistance mechanisms. One of the simplest and most logical way is to increase the dose of cytotoxic drugs^[5]. The evidence that higher doses

Table 1 Prognostic criteria for metastatic germ cell tumors^[3]

	Good prognosis group	Intermediate prognosis group	Poor prognosis group
Seminoma	90% of cases 5 yr PFS 82% 5 yr OS 86% All of the following criteria: Any primary site No non-pulmonary visceral metastases Normal AFP Any hCG Any LDH	10% of cases 5 yr PFS 67% 5 yr OS 72% Any of the following criteria: Any primary site Non-pulmonary visceral metastases Normal AFP Any hCG Any LDH	-
Non-seminoma	56% of cases 5 yr PFS 89% 5 yr OS 92% All of the following criteria: Testis/ retroperitoneal primary Non non-pulmonary visceral metastases AFP < 1000 ng/mL hCG < 5000 IU/L (1000 ng/mL) LDH < 1.5 × ULN	28% of cases 5 yr PFS 75% 5 yr OS 80% Testis/ retroperitoneal primary Non non-pulmonary visceral metastases AFP 1000-10000 ng/mL hCG 5000-50000 IU/L (1000 ng/mL) LDH 1.5-10 × ULN	28% of cases 5 yr PFS 75% 5 yr OS 80% Any of the following criteria: Mediastinal primary Non-pulmonary visceral metastases AFP > 10000 ng/mL hCG > 50000 IU/L (1000 ng/mL) LDH > 10 × ULN

AFP: Alpha-fetoprotein; hCG: Human chorionic gonadotrophin; LDH: Lactate dehydrogenase; PFS: Progression free survival; OS: Overall survival.

of cytotoxic drug kill more malignant cells has been well known for decades. Back in 1964, Skipper *et al*^[6] demonstrated that the curve showing the dose dependency of the treatments with cytotoxic drugs is very steep, indicating that even a small increase of the cytotoxic drug dose will kill more malignant cells. Also, this curve for cytotoxic drugs, unlike the curves from other drugs, has no plateau, which means that a constant increase of the dose of cytotoxic drugs leads to a steady increase in numbers of destroyed malignant cells^[6]. During the 1980s, Frei *et al*^[7] showed a dose-dependent killing of malignant cells in AKR and L1210 cell lines. Frei *et al*^[8] demonstrated the same on MCF7 breast cancer cells treated with alkylating agents BCNU, melphalan and nitrogen mustard. However, it was not possible to administer the 5 to 10-fold higher dose of chemotherapy *in vivo* due to the high toxicity and virtually lethal toxicity on bone marrow. Therefore, the researchers started to scrutinize bone marrow transplantation as a method for overcoming this high toxicity after chemotherapy^[9]. Afterwards, numerous studies of high dose chemotherapy and autologous stem cell transplantation in a large number of solid tumor cases were completed, however, this form of treatment

has remained standard practice only for TGCC^[10-13].

CLINICAL TRIALS WITH HDCT TGCC

As already mentioned, the majority of patients with metastatic TGCC are cured with standard chemotherapy: 3-4 cycles of BEP protocols^[3]. However, in patients with a poor prognosis, cure rate is below 50%. In these patients, and in patients with relapsed testicular cancer, unsatisfactory performance standard chemotherapy has directed researchers to search for new forms of treatment. The rationale of using high dose chemotherapy in chemo-sensitive cancer lead on investigators to start clinical trials with high dose chemotherapy and stem cell support^[3,14].

HDCT AS THE INITIAL TREATMENT IN PATIENTS WITH POOR PROGNOSIS

The initial studies of high dose chemotherapy for patients with poor prognosis in the first line setting were completed in the nineties. Motzer *et al.*^[15,16] from Memorial Sloan-Kettering Cancer Center in phase II studies demonstrated slightly better response to HDCT compared to a historical control with the standard dose chemotherapy (SDCT). In a study from 1993, 15 of 27 patients (56%) achieved a complete remission, 46% were free of disease, and 57% alive after a median of 31.2-mo follow-up^[15]. In another study by the same authors 30 patients were treated, 16 with etoposide, ifosfamide, cisplatin (VIP) chemotherapy, while 14 patients after VIP therapy, received HDCT, combination carboplatin, etoposide, cyclophosphamide (CEC). Patients selected for HDCT included those in whom tumour markers did not normalise after two cycles of chemotherapy. After a median follow-up of 30 mo, 15 (50%) patients remained progression-free. Patients treated with marker-dependent, early-intervention HDCT experienced longer survival^[16]. Bokemeyer *et al.*^[17] published in 1999 a match-paired multivariate analysis which compared the outcomes of patients with poor prognosis metastatic TGCC treated sequentially with standard VIP protocol and HDCT in a multicentric study including patients from German group studies and patients treated in two studies from Indiana University, with BEP or VIP conventional chemotherapy. High dose chemotherapy group included 147 patients, while 309 patients were in the SDCT group. Patients treated with HDCT had a longer progression free survival (PFS) 75% vs 59% ($P = 0.0056$) and a longer overall survival (OS) 82% vs 71% ($P = 0.0184$)^[17]. After that, Schmoll *et al.*^[18] from German Testicular Cancer Study Group (GTCSG) published a phase I/IIa study where they treated poor prognosis TGCC patients with a VIP-escalated protocol. After one cycle of standard VIP protocol, they applied dose escalated VIP with autologous stem cell transplantation, three to four cycles. Five-year PFS in this group of patients was 68%,

which is longer than the historical control with SDCT. After the advent of paclitaxel, and proven effectiveness of this drug in cisplatin-resistant TGCC, GTCSG announced the study of addition of a paclitaxel to dose-escalated VIP protocol^[19]. Addition of paclitaxel to high dose-VIP (HD-VIP) protocol resulted in higher response rate of 79%, and five-year PFS and OS of 64.1% and 75.2% respectively.

The only completed randomized phase III study is the one of Motzer *et al.*^[20]. This study included 219 untreated patients with metastatic TGCC intermediate and poor prognosis. One group of patients was treated with standard therapy, four cycles of BEP, while the experimental group received two cycles of BEP and afterwards two cycles high dose CEC (HD-CEC) protocol. Proportion of one year complete remission was not different in the two groups of patients (52% PEB + HD-CEC vs 48% BEP, $P = 0.53$). Benefit of a high dose chemotherapy, in this clinical trial, was observed only in those patients with unsatisfactory tumor markers decline. The study concludes that there is no benefit of adding a HDCT in this group of patients. Two other studies have started the third phase, but due to poor recruiting of patients they are not fully completed^[21-23]. The analysis of the included patients from high dose chemotherapy did not show the expected benefit in first-line treatment of metastatic TGCC with a poor prognosis. A review of studies of the first line is given in Table 2.

HDCT IN SECOND-LINE THERAPY

Therapeutic options of SDCT in patients with relapsed/refractory testicular cancer can achieve long-term remission of 25% of the cases with vinblastine, etoposide, ifosfamide (VeIP) protocol^[24], to about 65% of patients treated with paclitaxel, ifosfamide, cisplatin (TIP)^[25]. Considering the chemosensitivity of TGCC and relative modest results of conventional chemotherapy protocols, a large number of researchers have designed a variety of studies which applied HDCT with the support of haematopoietic autologous stem cell transplantation (Table 3).

Rodenhuis *et al.*^[26] have demonstrated a 54% PFS after a median follow-up of 37 mo in a phase II study on 35 patients. In this study they used two cycles of a HDCT after the induction with conventional chemotherapy. Similar design study was published in 2000^[27]. Two cycles of intensification were used and the results were almost the same as in the previous study. The same year, Motzer *et al.*^[28] demonstrated overall survival of 54% after a median of nearly three years of follow-up. They used the induction regimen with paclitaxel and ifosfamide, and three cycles of high dose protocol carboplatin/etoposide (TI-CE). A slightly worse result was achieved in the study by Rick *et al.*^[29] which included only one cycle of high dose protocol after the induction with three cycles of TIP. Three-year survival in this study was 30%. The explanation for the slightly

worse result in this study could be the application of only one cycle of high dose protocol.

The only prospective, randomized phase III study by Pico *et al*^[30] compared four cycles of conventional chemotherapy VeIP or VIP with three cycles of SDCT with the addition of one cycle of high dose carboplatin/etoposide (HD-CE) protocol. This study included a total of 263 patients. It did not demonstrate the superiority of the addition of one cycle of HDCT. Based on that study and study by Rick *et al*^[29], it was concluded that one cycle of HDCT was not sufficient to achieve better results in treatment compared to conventional chemotherapy, so further studies had two or even three cycles of HDCT.

The study which probably had the greatest impact on the practice of treating relapsed TGCC and utilization of HDCT was that by Einhorn *et al*^[31].

One hundred and eighty-four patients were retrospectively analysed, and 135 of 184 patients received two cycles of HD-CE protocol in the first relapse, while the other 49 were treated in second and subsequent relapses with the same protocol. After a median follow-up of four years, progression free survival in patients treated in the first relapse was 70%. Lorch *et al*^[32] compared one cycle of high dose therapy with three cycles of HD-CE. After long-term follow-up PFS was 49% vs 39% in favor of the sequential approach while overall survival did not differ between these two groups.

Table 4 High dose chemotherapy for third or subsequent lines, refractory/absolute refractory

Ref.	Type of study	Number of patients	Setting	Protocol	OS (%)	PFS (%)	Median follow-up (mo)
Vaena <i>et al</i> ^[38]	Retrospective	80	Second and subsequent lines, refractory	HD-CE × 2	40 (2 yr)	32 (2 yr)	24
Lotz <i>et al</i> ^[39]	Prospective	45	Second and subsequent lines, refractory/absolute refractory	Epi-Tax × 2 + HD Thio-Tax × 1 + HD-ICE × 2	23.5 (3 yr)	23.5 (3 yr)	36

Popovic <i>et al</i> ^[42]	Prospective	8	Fourth or fifth line, refractory	Epi-Tax × 2-3 + HD-CE × 1-2	Median 11 mo	NR	NR

Epi-Tax: Epirubicin, paclitaxel; HD: High dose; HD-CE: High dose carboplatin, etoposide; HDCT: High dose chemotherapy; HD-ICE: High dose ifosfamide, carboplatin, etoposide; NR: Not reported; OS: Overall survival; PFS: Progression free survival; SDCT: Standard-dose chemotherapy; Thio-Tax: Thiotepa, paclitaxel; TI: Paclitaxel, ifosfamide.

Feldman *et al*^[33] demonstrated in a prospective study of 107 patients a five-year PFS of 48% using the TI-CE protocol with three cycles of high dose chemotherapy.

A multicenter retrospective analysis of 1984 patients by Lorch *et al*^[34] compared the standard and high dose chemotherapy in patients with metastatic TGCC after progression on first-line chemotherapy. Patients were divided into five prognostic groups according to previously established criteria: Very low risk, low risk, intermediate risk, high and very high risk^[35]. Total of 1594 patients had all the data necessary for analysis, 773 of which received conventional chemotherapy, while 821 patients received HDCT. Two-year PFS and five-year OS was longer in the group with HDCT: 49.6% vs 27.8% (HR = 0.44; $P < 0.001$), 53.2% vs 40.8% (HR = 0.65; $P < 0.001$). This difference was seen in all prognostic groups except in low-risk group^[34].

Selle *et al*^[36] in the study TAXIF II demonstrated efficiency of a complex protocol which included several high dose cycles of paclitaxel, thiotepa, ifosfamide, carboplatin and etoposide, after induction with a combination of paclitaxel/epirubicin. The median PFS was 22 mo and OS was 32 mo. Two-year PFS was 50%, with Kaplan-Meier curve that showed a plateau at that value, and two-year OS of 66%^[36]. German Testicular Cancer Study Group retrospectively analyzed 143 patients and compared the HDCT ($n = 95$) with CDCT ($n = 48$). They showed a significantly longer median PFS 8 mo vs 42 mo ($P < 0.001$) with HDCT, but this difference was not seen when they analyzed overall survival^[37].

HDCT FOR REFRACTORY AND HEAVILY PRETREATED PATIENTS

Patients who progressed during standard cisplatin based chemotherapy have the worst prognosis. This group of patients also includes those who have not been cured after two lines cisplatin protocol. For this group of patients there have been several studies that, despite the very poor prognostic characteristics, showed some benefit from HDCT (Table 4).

Vaena *et al*^[38] retrospectively analyzed the results of HDCT in platinum-refractory patients. Two-year PFS was 32%, while two-year OS was 40%. Lotz *et al*^[39] applied a different concept in refractory patients. In TAXIF study they prospectively treated 45 patients with absolutely refractory metastatic TGCC. After mobilization therapy with paclitaxel/epirubicin, they gave two cycles of high dose ifosfamide, carboplatin, etoposide (ICE) protocol. Three-year PFS and OS were 23.5%^[39]. Kondagunta *et al*^[40] prospectively treated 47 refractory patients with high dose chemotherapy. After a median of 40 mo of observation the PFS was 51%. The Study by Einhorn *et al*^[31] treated 49 patients with HDCT in third and subsequent lines of chemotherapy. Time to disease progression and OS in these patients was 45% and 55% respectively. In patients with third and subsequent lines of therapy, Lorch *et al*^[41] reached five-year OS of 17% at five-year PFS 27%. In a pilot study, we have treated 8 heavily pretreated patients with HDCT. We used a modified TAXIF protocol^[39]. All patients had previously received four lines of different therapies. The median OS was 11 mo, with no long-term survival^[42,43].

HDCT FOR EXTRAGONADAL GCC

Extragenital GCC tumors occur most often in retroperitoneum and mediastinum and have worse prognosis compared to TGCC^[2]. Several studies with high dose chemotherapy administration has addressed this subgroup of patients (Table 5). Bokemeyer *et al*^[44] have treated patients with primary mediastinal germ cell tumors (PMNSGCT) initially with high dose chemotherapy. They included 28 patients and achieved 56% and 64% PFS and OS, respectively. Banna *et al*^[45] also used HDCT in the first line of treatment PMNSGCT and reached a three-year OS 41%. Rosti *et al*^[46] retrospectively analyzed 22 patients who had primary extragonadal non-seminomatous germ cell tumor (EGNSGCT) and received HDCT. Five-year survival in this group of patients was 75%. Hartmann *et al*^[47] and De Giorgi *et al*^[48] in two studies published in 1999 showed retrospective results of a treatment of

Table 5 High dose chemotherapy for extragonadal germ cell cancer

Ref.	Type of study	Number of patients	Setting	Protocol	OS (%)	PFS (%)	Median follow-up (mo)
Bokemeyer <i>et al</i> ^[44]	Phase I/II, prospective	28	PMNSGCT, first line	VIPx 1 + HD-VIP × 3	64 (5 yr)	56 (5 yr)	43

EGCT: Extragonadal germ cell tumor; EGNSGCT: Extragonadal non-seminomatous germ cell tumor; HD: High dose; HD-CEC: High dose carboplatin, etoposide, cyclophosphamide; HDCT: High dose chemotherapy; HD-ICE: High dose ifosfamide, carboplatin, etoposide; NR: Not reported; OS: Overall survival; PFS: Progression-free survival; PMNSGCT: Primary mediastinal non-seminomatous germ cell tumor.

Table 6 International Germ Cell Cancer Collaborative Group-2 prognostic criteria for relapsed germ cell cancer patients

Parameter	Score points			
	0	1	2	3
Primary site	Gonadal	Extragenadal	-	Mediastinal non-seminoma
Prior response	CR/PRm-	PRm+/SD	PD	-
PFI, mo	> 3	≥ 3	-	-
AFP salvage	Normal	≤ 1000	> 1000	-
HCG salvage	≤ 1000	> 1000	-	-
LBB	No	Yes	-	-
Score sum (0-10)				
Regroup into categories: (0) = 0; (1 or 2) = 1; (3 or 4) = 2; (5 or more) = 3				
Add histology points: Seminoma = -1; Non-seminoma or mixed = 1				
Final prognostic score: -1 = Very low risk; 0 = Low risk; 1 = Intermediate risk; 2 = High risk; 3 = Very high risk				

AFP: Alpha-fetoprotein; CR: Complete remission; HCG: Human chorionic gonadotrophin; LBB: Liver, brain, bone; PD: Progressive disease; PFI: Progression free interval; PRm-: Partial remission, markers negative; PRm+: Partial remission, markers positive; SD: Stable disease.

EGNSGCT after progression on first-line therapy. Results were rather modest with 12%-14% long term survival.

RISK ADAPTED APPROACH FOR USING HDCT

The first prognostic score related to the outcome of a HDCT was developed Beyer *et al*^[49]. They have analyzed a series of 310 patients treated with HDCT in four centers in Europe and the United States and by multivariate analysis of prognostic factors determined the data which had influenced the outcome. Progressive disease before HDCT, primary mediastinal localization, refractory or absolute refractory disease to cisplatin therapy and the value of human chorionic gonadotropin (HCG) over 1000 were independent factors for failure-free survival (FFS) after HDCT. These parameters separated patients into groups with good, intermediate and poor prognosis. Patients with good, intermediate

and poor prognosis had 51% FFS after HDCT, 27%, and 5% ($P < 0.001$) respectively. The International Prognostic Factors Study Group (Table 6) analyzed data of 1984 patients with TGCC, who have progressed after at least three cycles of cisplatin based chemotherapy. Patients' data were collected from 38 centers worldwide and 1594 patients had sufficient data for analysis. Patients were treated with SDCT or HDCT based on carboplatin. Factors that influenced the outcome were: Site of primary tumor, previous response to therapy, progression free survival on previously applied therapy, alpha-fetoprotein and HCG above 1000 and the presence of metastases in the liver, bone and/or bone^[35].

Based on these factors, patients were divided into five categories: Very low risk with a two-year PFS of 72%, low risk with PFS 51%, medium risk with 40%, high risk with 26% and very high risk with 6%. This is followed by the already mentioned retrospective analysis by Lorch *et al*^[34] which showed benefits in all prognostic categories, except in the low risk group. Given that the benefit was demonstrated even in the category of very low risk, there is a question in which prognostic groups, in patients with relapsed GCC, HDCT should be applied and which groups should receive conventional chemotherapy. Opinions differ greatly, and certain groups of authors believe that high dose chemotherapy should be applied in all patients with relapsed GCC, while some groups believe that patients with a low risk should be treated with the conventional chemotherapy in the second line, and HDCT should be applied in patients with medium and higher risk as well as in those with a low risk who relapse after second-line of conventional chemotherapy^[50]. Our position is closer to the second opinion.

STEM CELLS MOBILISATION AND OPTIMAL PROTOCOL OF CONDITIONING

Collection of sufficient numbers of hematopoietic stem cells is a key step in the further implementation of

Figure 1 Randomized phase III trial of initial salvage chemotherapy for patients with germ cell tumors study (TIGER study) design^[62]. PD: Progressive disease; GCT: Germ cell tumors; HDCT: High dose chemotherapy; G-CSF: Granulocyte colony-stimulating factor.

a HDCT, and the possibility of treating patient with multiple cycles of HDCT. Combination of chemotherapy with granulocyte growth factor (G-CSF) is a standard for the mobilization of hematopoietic stem cells. However, in heavily pretreated patients, this method of mobilization is not enough to collect a sufficient number of stem cells. In our cohort of heavily pretreated patients median collected hematopoietic stem cells was 3.6×10^6 cells/kg of BW. Consequently, it was not possible for us to apply tandem transplantation in some patients^[43]. Some other authors as well conclude that the mobilization with chemotherapy + G-CSF was inadequate for obtaining a sufficient number of stem cells, especially in cases of highly pretreated patients^[4,51-53].

Plerixafor is the CXCR4 receptor antagonists which separate hematopoietic stem cells from bone marrow stroma and can lead to better mobilization of these cells into peripheral blood^[54]. After the positive outcome in poor-mobilisers with lymphoma and multiple myeloma increased enthusiasm for using plerixafor to mobilize hematopoietic stem cells in patients with TGCC. The four

smaller cohorts and three case studies^[52-60] showed the efficiency of plerixafor in heavily pretreated patients with TGCC. Worel *et al.*^[55] showed the efficiency of plerixafor in 33 patients with non-hematologic diseases, of which 11 were metastatic GCC. A total of 28 (85%) patients gathered a sufficient number of stem cells. Kobold *et al.*^[57] showed a series of 6 patients who had previously received chemotherapy for 3.5 lines metastatic GCC and were not able to mobilize a sufficient number of stem cells for transplantation. After the use of plerixafor, five of these six patients mobilized an adequate number of cells for a minimum one transplant. Kosmas *et al.*^[52], in a pilot study, showed stem cells mobilization in pretreated patients with GCC, in which 7 out of 10 patients could yield an adequate number of hematopoietic stem cells for transplantation. The remaining three, poor-mobilisers, have amassed an adequate number of stem cells after applying plerixafor. In all these publications, engraftment of stem cells obtained after the mobilization with plerixafor was adequate.

Despite attempts with different drugs that would

supplement carboplatin, such as thiotepa and ifosfamide, panelists of the third European consensus conference on the treatment of GCC, agreed that a combination of carboplatin and etoposide is a standard high dose protocol^[50].

FUTURE DIRECTIONS

Although HDCT is considered standard treatment option for relapsed GCC in most major cancer centers, there are still no level IA evidence for applying HDCT in the current recommendations for the treatment of GCC^[2,3,61]. The reason for this is the series of negative results of the randomized phase III studies by Motzer *et al.*^[20] in the first line, and Pico *et al.*^[30] in metastatic relapsed GCC, therefore TIGER (randomized phase III trial of initial salvage chemotherapy for patients with germ cell tumors) has been initiated^[62]. The study design is shown in Figure 1. The plan is to include 390 patients, a group of which will receive four cycles of TIP protocol, while the second group will receive TI-CE protocol with three cycles of a HDCT. The hypothesis is that the overall survival of patients should be 13% higher after the treatment with the HDCT.

The second concept is target therapy in addition to the treatment of relapsed GCC, for conventional, as well as for high dose chemotherapy. Vascular endothelial growth factor over-expression is an independent factor of poor prognosis for non-seminomatous germ cell tumor (NSGCT), especially for teratoma NSGCT which is the most refractory to chemotherapy^[4]. Voigt *et al.*^[63] showed a case of successful treatment of patients absolutely refractory to cisplatin with bevacizumab and HD-ICE protocol. At the last ASCO meeting, Nieto *et al.*^[64] presented a phase II study for the first and the second relapse of intermediate and high risk metastatic GCC. They combined bevacizumab with tandem HDCT. In the first cycle of HDCT they combined bevacizumab with gemcitabine, docetaxel, melphalan and carboplatin, while in the second cycle they combined bevacizumab with HD-ICE protocol. One-year and 2 year-OS were 72% and 65% respectively^[64]. In addition to these studies, there is an ongoing study TAXIF III, of the French group, with the addition of bevacizumab to HD-ICE protocol^[65]. Approximately 70% of embryonic GCT express CD30 receptor on cell surface^[66]. Brentuximab-vedotin is an anti-CD30 conjugated to a monoclonal antibody that has shown significant results in the treatment of Hodgkin's and peripheral T-cell lymphomas^[67]. The Italian group has started a phase II clinical study of efficiency brentuximab vedotin in refractory CD30-positive metastatic testicular cancer^[68].

CONCLUSION

Although there are no randomized phase III trials that support HDCT as an effective treatment option for patients with metastatic GCT, the majority of centres use this type of therapy in patients with intermediate

and high risk according International Germ Cell Cancer Collaborative Group-2 score^[35]. TIGER study might give a definitive answer whether HDCT should be a standard treatment for these patients, and a better understanding of tumor biology, detection of markers of resistance to cisplatin, as well as if adding target therapy such as bevacizumab should improve the treatment of GCT, especially in the group of patients with a poor prognosis.

Abstract

With the advent of safer and more efficient gene transfer methods, gene therapy has become a viable solution for many inherited and acquired disorders. Hematopoietic stem cells (HSCs) are a prime cell compartment for gene therapy aimed at correcting blood-based disorders, as well as those amenable to metabolic outcomes that can effect cross-correction. While some resounding clinical successes have recently been demonstrated, ample room remains to increase the therapeutic output from HSC-directed gene therapy. *In vivo* amplification of therapeutic cells is one avenue to achieve enhanced gene product delivery. To date, attempts have been made to provide HSCs with resistance to cytotoxic drugs, to include drug-inducible growth modules specific to HSCs, and to increase the engraftment potential of transduced HSCs. This review aims to summarize amplification strategies that have been developed and tested and to discuss their advantages along with barriers faced towards their clinical adaptation. In addition, next-generation strategies to circumvent current limitations of specific amplification schemas are discussed.

Key words: Gene therapy; Hematopoietic stem cells; *In vivo* selection; Chemical Inducer of Dimerization; Chemo-selection; Lentivirus

Core tip: Though hematopoietic stem cell (HSC)-directed gene therapy is becoming a viable therapy for many disorders, optimization of clinical output needs improvement. One approach to circumvent lower efficiencies of gene transfer and/or engraftment is to apply *in vivo* amplification strategies. Here we review

various modules that have been developed and tested to mediate amplification of HSCs after gene transfer.

INTRODUCTION

Hematopoietic stem cells (HSCs) are long-term, multipotent, self-renewing cells that reside in specialized bone marrow (BM) niches and are capable of generating and repopulating the entire spectrum of blood and lymphoid cells^[1,2]. Due to these unique properties, HSCs are targets for therapy for a number of hematological malignancies and many inherited blood disorders including β -thalassemia, sickle cell anemia, chronic granulomatous disease, and severe combined immunodeficiencies (SCID-X1 and ADA-SCID) among others^[3-8]. Additionally, HSC transplants have been used in attempt to correct other monogenic deficiencies, such as the mucopolysaccharidoses and Gaucher disease^[9-11].

There are still numerous drawbacks of allogeneic transplantation despite its clinical utility. Often, HSCs are collected from the patient's sibling, parents, or a matched donor. HLA-identical donors can be difficult to find and there are risks involved with the use of HLA-haploidentical or non-identical donors including rejection or poor engraftment of HSCs along with the occurrence of graft-versus-host disease (GVHD). Conditioning is also necessary for engraftment of HSCs, which can increase the risk of infections^[12-14]. As a consequence, HSC allo-transplantation is still considered a fairly risky intervention and is applied with caution in the clinic.

Gene therapy targeting patient-derived HSCs is a viable solution for some monogenic diseases^[15] (Figure 1A). Autologous transplantation has been well studied and detailed clinical protocols are available for this procedure^[3]. Additionally, autologous transplantation does not have a risk of GVHD associated with it and immune reconstitution after ablation occurs in a shorter period of time^[16,17]. Gene transfer into HSCs has been traditionally achieved by stable transduction of target cells using replication-incompetent retroviruses^[15]. There the expression of transgenes can be driven by constitutive or tissue-specific promoters, giving a range of control over the intended therapeutic intervention. Next-generation strategies are also being developed to correct original nucleotide mutations with the use of gene-editing technologies, such as TALENs and CRISPR-Cas9, though these remain to be optimized for clinical application^[18-20].

Over 2000 clinical gene therapy trials have been conducted to date^[4,15,21,22]. Most earlier trials employed

onco-retroviral vectors, which have shown to be clinically disadvantageous because of their tendency to integrate close to genes that are important for cell growth and proliferation, enhancing their expression and increasing the likelihood of developing leukemias^[4,15,23-25]. So far it appears that this genotoxicity and tendency towards insertional mutagenesis has been diminished with the introduction of HIV-1-derived, replication-incompetent, and self-inactivating lentiviral vectors (LVs), which do not show preferential integration near genes involved in cell growth and/or proliferation^[4,26-30].

There are other caveats to using HSCs as target cells for gene therapy that are a result of their unique biology. HSCs can be more difficult to transduce than some other cell types, partially owing to the difficulty of culturing them *ex vivo*. Longer-term culturing ensures that the cells will differentiate. Transduction also requires transient activation of the cell cycle, especially with onco-retroviral-based vectors since their downstream integration requires a breakdown of the nuclear membrane. As a consequence of *ex vivo* manipulation and cell-cycle activation, transduced HSCs often have lower engraftment potential and reduced longevity once engrafted. These additional limitations have also been partially addressed with the use of LVs, which need shorter transduction times and do not require target cells to be fully cycling^[31-35].

In spite of the progress made in HSC gene therapy with the implementation of recombinant LVs, there is ample room for additional improvements to increase therapeutic efficacy. Many active fields of research are geared towards optimizing gene therapy for HSCs. Efforts are under way to hone GMP-grade LV production to subsequently allow modulation of multiplicities of infection at a clinical level, whilst reducing the cost of gene therapy^[36,37]. Improvements are also being made to protocols for *ex vivo* handling and culture of HSCs with studies demonstrating enhanced transduction with shorter culture times and less activation, which have resulted from better understanding of the biology of HSCs and their BM microenvironments^[4,38,39]. In addition, in-depth studies of HSC biology have identified molecular targets for drugs that allow more efficient and safer mobilization of patient stem cells^[40-42]. The gene therapy field has also sought out methods to provide extrinsic selective pressure for transduced cells, though clear clinical utility of any system has yet to be demonstrated, especially in the context of reconstitutive HSC-directed gene therapy.

Reconstitution of deficient gene products in some inherited blood diseases leads to innate positive selective pressure *in vivo* for mature cells derived from transduced progenitor cells, especially when the gene product is necessary for the development or function of those cells. For example, reconstitution of the common gamma chain (γ /CD132) in SCID-X1 allows immune cells to develop normally, thus progeny cells are derived from successfully transduced HSCs almost exclusively^[17,43-45]. Selectivity for donor-derived late-stage

Figure 1 General outline of *ex vivo* hematopoietic stem cell gene therapy and pre-selection methods. A: CD34⁺ cells are enriched by CliniMACS after apheresis of peripheral blood of patients following mobilization. These cells are then briefly activated *ex vivo* and can be modified, commonly by viral transduction, to express a desired therapeutic protein. Cells are then assessed for quality control metrics and engrafted into patients following ablation; B: Pre-selection of transduced cells. Cells can be engineered to express an inert surface marker that can be used to immuno-enrich for the transduced population prior to engraftment. This strategy can increase the chances of hematopoietic reconstitution from the transduced population. Alternatively, cells can be given resistance to cytotoxic drugs. Pre-treatment of the cells *ex vivo* with drugs can kill off the non-transduced population. *Ex vivo* treatment allows the use of drugs that would normally not be efficacious in the bone marrow environment at a tolerable dose.

erythrocytes has also been observed in β -thalassemia patients that have received allo-transplantations; and a similar trend has been observed with gene therapy in mouse models of the disorder^[7,46,47]. HSC gene therapy may therefore become routine clinical practice some day for patients suffering from such hematological disorders that do not have matched donors, considering the innate advantage of such reconstituted cells.

There is also great potential of HSC-directed gene therapy for the treatment of non-hematological, monogenic enzyme deficiencies, such as those that lead to lysosomal storage disorders (LSDs) and other metabolic indications. In most cases, functional enzymes expressed after gene transfer into LSD patient cells have the potential to be secreted and subsequently taken up by other cells that do not have the transgene, a process termed metabolic cooperativity or "cross-correction". This occurrence has been demonstrated for a number of LSDs including Gaucher, Farber, and Fabry diseases^[48-51]. The current standard of care for many LSDs, enzyme replacement therapy (ERT), is actually a corollary of this phenomenon. HSC-directed gene therapy presents numerous putative advantages over conventional ERT, including sustained and continuous secretion of therapeutic enzyme by ubiquitously circulating cells, improvements in patient lifestyle by reducing the need for biweekly enzyme infusions, and overall cost savings. It is necessary to tailor HSC gene therapy for individual patients, however, which is incongruous with many current industrial business models, highlighting the necessity of shifting industrial focus from general to

personalized therapeutics.

Our laboratory is currently pursuing first-in-man HSC-based gene therapy for Fabry disease and is concomitantly demonstrating the utility of gene therapy for amelioration of Farber disease. However, in these cases, as with many such target disorders, expression of the functional gene product imparts no innate growth advantages to transduced cells. Vector-encoded transgenes alone or in tandem that allow extrinsic selective pressure to be applied *in vivo*, leading to an increased percentage of vector-transduced cells over background could therefore be highly beneficial in the context of HSC gene therapy for LSDs and many other monogenic deficiencies. Additionally, application of positive selective pressure could result in cell populations that have higher transgene expression, resulting in an increased therapeutic benefit.

In this review, we aim to summarize the various strategies that have been employed to date in attempts to increase vector-transduced HSC numbers, thereby increasing the efficacy of HSC-targeted gene therapy. In addition, we will discuss putative next-generation strategies aimed at addressing current shortcomings of applying selective positive pressure on transduced HSCs.

EX VIVO PRE-SELECTION STRATEGIES

Resistance to cytotoxic drugs

Selection of genetically modified cells is a compilation of laboratory techniques commonly applied to acquire

polyclonal cell lines after gene transfer. To achieve this, target cells are engineered to express proteins that confer resistance to drugs or proteins that allow selection by immune-affinity methods such as fluorescence- and magnetic-activated cell sorting (FACS and MACS, respectively)^[52,53] (Figure 1B). Ideally, proteins expressed for enrichment should have low or no endogenous expression in target cells, and should have no effect on the biology of the transduced cells or their progeny. Traditionally, xenogenic enzymes have been used to confer cells with resistance to pan-toxic drugs in this context. For example, neomycin and hygromycin phosphotransferases (NeoR and HygR) derived from bacteria are commonly used to provide protection against neomycin and hygromycin B, respectively^[54,55]. As such, first attempts at conferring resistance to cells for engraftment were made with these enzymes. However, the use of xenogenic enzymes in clinical protocols has been limited by their tendency to be highly immunogenic once such modified cells are engrafted^[56-58]. To address this, mutants of various endogenous enzymes have been used to confer resistance to other cytotoxic drugs. These enzymes are discussed in the section below in the context of *in vivo* selection. However, most drugs require prolonged *ex vivo* culture to effectively enrich for the gene-modified population. Prolonged *ex vivo* handling of HSCs reduces their usefulness post-selection due to a loss of “stemness” and engraftment potential^[31]. Thus, drug-mediated *ex vivo* pre-selection may not be ideal in current iterations for clinical purposes.

Cell-surface marking for immuno-enrichment

Transduced HSCs can also be enriched *ex vivo* with the use of cell-surface markers. Selectable cell-surface markers that have been studied for HSC marking and pre-selection include truncated forms of the human low-affinity nerve growth factor receptor (Δ LNGFR)^[59-62], the heat stable antigen (HSA/CD24)^[48,50,63,64], the human lymphocyte antigen T1 (CD5)^[65,66], and the human interleukin-2 receptor alpha chain (IL-2R α /huCD25)^[67]. In mouse allograft experiments, long-term engraftment of transduced and FACS-enriched BM cells along with hematopoietic cell marking has been demonstrated using CD24^[64] and CD5^[66] as selectable markers. However, it must be noted that those experiments did not include a control in which no pre-selection was applied prior to engraftment. This makes it difficult to unequivocally assess the contribution of pre-selection to the engraftment and repopulating ability of transduced cells.

Despite positive results in pre-clinical settings with the use of FACS for enrichment, it has more detrimental effects on cell survival, viability, and function than MACS, even though FACS can lead to higher purity^[68]. It is also difficult to physically and/or temporally achieve enrichment of large numbers of clinically-applicable cells by FACS. As such, MACS and analogous schemas are preferred for enrichment prior to engraftment in patients. Over 90% purity has been achieved with

MACS enrichment of Δ LNGFR-marked HSCs *in vitro*^[60] and similarly marked lymphocytes in clinical trials^[69-71]. In an allograft experiment with a mouse model of Fabry disease, BM mononuclear cells were transduced with a therapeutic vector capable of co-expressing α -galactosidase A and huCD25^[67]. Pre-selection of transduced cells by MACS led to a long-term increase of huCD25-marked peripheral blood mononuclear cells when compared to controls. Therapeutic benefit of pre-selection was demonstrated by a higher α -galactosidase A activity in plasma and most organs. Additionally, the utility of pre-selection in long-term HSC marking has been demonstrated in some cases by secondary transplant experiments^[64,67].

Since pre-selection strategies reduce the size of the transduced cell population^[60], however, their application to HSC gene therapy can be critically limited if there are difficulties in collecting large numbers of patient HSCs. *Ex vivo* expansion of HSCs is currently not a viable solution in order to compensate for reduced cell numbers since over-activation can have detrimental effects on their “stemness” and engraftment potential^[31]. In addition, pre-selection increases time of *ex vivo* manipulation, which increases costs and risks of contamination. It is therefore difficult to obtain a post-selection yield high enough to exert a therapeutic effect. Nevertheless, these studies demonstrate the benefit of enriching transduced cells *ex vivo* and that clinical translation may be augmented by higher yields of HSCs during their acquisition.

***IN VIVO* CHEMO-SELECTION STRATEGIES**

Various proteins have been shown to grant variable degrees of chemoprotection in the context of cancer therapy, such as ATP-binding cassette, sub-family B, member 1 (ABCB1), dihydrofolate reductase (DHFR), and *O*⁶-alkylguanine DNA alkyltransferase (MGMT). Overexpression of these proteins in HSCs has been pursued with the aim of protecting the hematopoietic compartment from the severe toxicity of many cytotoxic drugs used in cancer chemotherapy^[72].

Pan-resistance to chemotherapeutic agents using ABCB1

ABCB1 [also known as multidrug resistance protein 1 (MDR1); or P-glycoprotein 1 (P-gp1)] is a cell membrane transporter with broad specificity that pumps foreign compounds out of the cell and is also involved in lipid translocation^[73,74]. ABCB1 mediates chemoresistance in cancer cells in which its expression is upregulated^[75]. Overexpression of ABCB1 in murine BM was shown to confer protection to many chemotherapeutic agents such as vinblastin, doxorubicin, daunomycin, taxol, vincristine, etoposide, actinomycin D, colchicine, and paclitaxel^[76,77]. Early studies with mouse allografts showed *in vivo* selection of hematopoietic cells derived

from *ABCB1*-overexpressing HSCs, but it is unclear whether selection occurred at the stem cell level^[78,79]. Later studies demonstrated successful selection of human HSC-derived cells in the BM of murine xenograft models^[80,81]. In contrast to these outcomes, early autograft experiments in large animals and clinical trials demonstrated rather disappointing results. In a canine model, high toxicity was documented despite long-term *ABCB1*⁺-peripheral blood cell enrichment in the only surviving animal^[82]. In a study involving non-human primates, there was low initial *ABCB1* cell marking, drug-induced neutropenia, and no significant increase of neutrophil counts after drug treatment^[83]. In clinical trials, selection after drug treatment has been low and predominantly transient, albeit with little or no toxicity^[84-87]. The inefficacy of *ABCB1*-mediated selection may have been due to insufficient expression of the transgene in hematopoietic cells^[88]. Onco-retrovirally-mediated expression of *ABCB1* was found to be unstable due to cryptic splice sites within the cDNA^[89]. This issue was resolved by introducing a silent mutation that inactivates that splice site, which subsequently increased expression of onco-retrovirally-delivered *ABCB1*^[90,91]. Nevertheless, the robustness of this system must be reliably demonstrated in large animal models before it can be considered a feasible strategy to enrich HSCs after transplant for clinical gene therapy in patients.

Antifolate resistance using mutant DHFR

DHFR catalyzes the reduction of dihydrofolate to tetrahydrofolate, a precursor required for the *de novo* synthesis of purines and some amino acids. Antifolate drugs such as methotrexate (MTX) and trimetrexate (TMTX) inhibit DHFR activity, thus blocking cell proliferation and promoting apoptosis in dividing cells. HSCs and myeloid progenitor cells, however, can employ nucleotide salvage mechanisms to escape antifolate toxicity^[92]. In order to overcome this, the nucleoside transport inhibitor nitrobenzylthioinosine 5'-monophosphate (NBTI/NBMPP-P) has been used in combination with MTX or TMTX^[92]. Transplanted HSCs have been engineered to over-express mutant forms of DHFR, such as DHFR^{L22Y}, that are resistant to antifolate agents^[93]. *In vivo* enrichment of transduced HSCs in murine allogeneic transplants has been demonstrated^[94,95]. However, translation of this method into large animal models has been rather discouraging. In a study in rhesus macaques that used a recombinant onco-retrovirus to deliver DHFR^{L22Y}, enrichment of cells derived from the transduced graft was only transient, indicating poor selection at the HSC level^[96]. To address this problem, enrichment of CD34⁺ progenitor cells in a xenograft transplant of human embryonic stem cells (hESCs) into mice has been demonstrated, though this enrichment was only modest and no clinically established methods to transplant hESCs exist^[97]. High toxicity and lethality has been documented in antifolate-mediated selection studies in dogs and rhesus macaques^[96,98]. Additionally, antifolate

toxicities are well documented when such compounds are indicated for treatment of cancer patients^[99-102]. These toxicities and the lack of positive evidence suggest that DHFR-mediated *in vivo* selection may not be useful for HSC gene therapy targeting monogenic diseases. Instead, it may be better suited to prevent graft rejection after HSC transplants, because antifolates would spare highly-proliferating T lymphocytes arising from transduced donor HSCs while eliminating alloreactive recipient T cells as shown recently *in vitro*^[103] and in a canine model^[104].

Selectivity using O⁶BG-resistant MGMT

MGMT repairs DNA damage by removing adducts from the O⁶ position of guanine, and thus confers resistance to the cytotoxic effects of alkylating agents such as dacarbazine, temozolomide (TMZ), procarbazine, and nitrosoureas such as 1,3-bis-(2-chloroethyl)-1-nitrosourea (BCNU)^[105,106]. MGMT is expressed at very low levels in the BM^[107,108]. MGMT overexpression was attempted in murine^[105,109,110] and human^[105] HSCs to confer BCNU resistance. A modest increase in resistance to BCNU was achieved in murine progenitors, both *in vitro* and *in vivo*^[105,109,110]. Human HSCs, however, had poor resistance *in vitro*^[111]. In order to sensitize the HSC compartment to alkylating drugs to achieve better *in vivo* selection, BCNU or TMZ have been co-administered with O⁶-benzylguanine (O⁶BG), a pseudosubstrate that irreversibly inactivates endogenous MGMT^[112]. O⁶BG-resistant mutants MGMT^{P140K} and MGMT^{G156A} have also been studied^[113]. The former is more commonly used in selection strategies, despite having a modest reduction in its DNA-repair activity compared to the wild-type enzyme^[113]. Indeed, MGMT^{P140K} has been shown to mediate selection of transduced HSCs in murine and canine allograft and autograft models^[114-117], and in murine xenograft models with human HSCs^[30,118,119]. However, high dose administration of BCNU and/or TMZ has been shown to cause toxicity^[120-122]. For example, selection experiments have shown up to 75% mortality in mice treated with TMZ^[120] or BCNU^[121], and 88% mortality in rhesus macaques treated with TMZ^[122].

Optimization of drug dosing by co-administering high doses of O⁶BG with low doses of BCNU or TMZ has partially ameliorated the cytotoxic effects of the alkylating drugs and allowed better engraftment of HSCs transduced at low MOIs^[121,123,124]. The improvements in survival are thought to be a result of lowering the threshold of MGMT expression required for resistance, which allows partial fulfillment of conditions expected in clinical trials. This dose-adjusted protocol has conferred successful chemoprotection of the hematopoietic compartment in a canine^[125] and a nonhuman primate model^[126], with no significant toxicity reported in the former. Despite survival of the macaques in the latter study, administration of chemoselective agents led to substantial peripheral blood cell depletion and enrichment of different blood lineages was highly variable^[126]. In the same study, use of a multi-

cistronic vector to co-express C46, which is an anti-HIV transgene, MGMT^{P140K}, and enhanced green fluorescent protein (eGFP) resulted in lower selective potential^[126]. From a translational point of view, the risk-to-benefit ratio is currently not in favor of implementation of such chemoselective strategies though further adjustments to drug regimens can be done.

In the context of gene therapy for murine models of β -thalassemia^[123], hemophilia A^[124], and hemophilia B^[127], amelioration of the disease phenotype has been enhanced with the use of bicistronic LVs encoding the therapeutic gene and an MGMT^{P140K}-based selection module. Additionally, increased expression of the therapeutic gene after drug selection in secondary^[123,124] and tertiary^[127] recipients of serial BMT demonstrated enrichment at the HSC level. MGMT-mediated enrichment of eGFP⁺ BM and peripheral blood cells has also been demonstrated in a murine model^[128]. Despite these promising results, there are still no reports of successful MGMT-mediated selection following gene therapy in large animals that we are aware of, wherein HSC selection may be less efficient because of their lower replication rates^[129]. However, autologous MGMT^{P140K}-transduced HSC transplants have been attempted in MGMT^{hi}, TMZ-resistant glioblastoma patients^[130]. Drug selection resulted in no significant extra-medullary toxicity and all three participants surpassed the median survival (12 mo) for glioblastoma patients with unmethylated MGMT-promoter status. Despite these promising results in the context of chemoprotection of the hematopoietic compartment during glioblastoma treatment^[130], it must be noted that gene-modified circulating blood cells were depleted from the patients with termination of treatment. As such, repeat administration of chemotherapy may be required for the use of this system for amplification of transduced HSCs for gene therapy.

Hypoxanthine-guanine phosphoribosyltransferase inactivation for 6-thioguanine resistance

While the strategies described above rely on the overexpression of a protein that confers chemoprotection to transduced cells, down-regulating endogenous enzymes necessary to activate cytotoxic drugs can achieve analogous outcomes. Hypoxanthine-guanine phosphoribosyltransferase (HPRT) is an enzyme involved in the purine nucleotide salvage pathway. HPRT can catalyze the addition of ribose 5-phosphate to the purine analog 6-thioguanine (6TG) to generate thioguanosine monophosphate (thio-GMP)^[131]. Thio-GMP is then converted into thiodeoxyguanosine triphosphate (thio-dGTP), which can be incorporated into DNA inducing futile mismatch repair and consequent apoptosis. It has been shown that BM cells of HPRT-deficient mice are resistant to 6TG treatment^[132]. Transplantation of HPRT-deficient BM into wild-type HPRT mice under 6TG selection resulted in good engraftment and long-term hematopoietic reconstitution in primary and secondary recipients^[133]. Furthermore, transduction of murine hematopoietic progenitor cells with a LV

encoding a short-hairpin RNA (shRNA) that targets HPRT can confer resistance to 6TG *in vitro*^[134]. The same knockdown strategy has shown effective enrichment in murine allograft models^[135] and human HSC xenograft models^[136]. This approach has some advantages over other drug selection methods described above. 6TG can be used for both pre-conditioning and chemoselection, and the shRNA sequence is very short, which makes it easier to include in a dual-gene vector. Also, ample information about 6TG dosage and toxicity is available because it has been used in the clinic for decades^[137]. A recent study suggests, however, that this method may be limited to enrichment of committed progenitor cells, which would decrease long-term efficacy with single-dosing regimens^[136]. Also, hereditary HPRT deficiency is the cause of Lesch-Nyhan syndrome, which has been associated with megaloblastic anemia^[138]. Therefore, it is necessary to carefully assess long-term consequences of HPRT deficiency in the hematopoietic lineage, especially in large animal models. Nevertheless, selective induction of an enzyme deficiency, as demonstrated by virally-induced HPRT knockdowns, may be a powerful method of introducing selective pressure following gene therapy.

ENGINEERED INDUCIBLE GROWTH AND SELECTION MODULES

Cytotoxic chemical inducers of dimerization

Discoveries relating to functional consequences of forcing proteins such as receptor tyrosine kinases into proximity with each other have allowed the use of protein engineering to confer specific biological characteristics to a subset of modified cells with exposure to various stimuli. For example, chemical inducers of dimerization (CIDs) are synthetic compounds that can be used to induce dimerization of proteins that are expressed as fusions to CID-binding domains (CBDs). With the use of CBDs, cell-fates can be made dependent upon the addition of CIDs (Figure 2A). One of the first examples of such a system utilized FK1012, a synthetic dimer of the immunosuppressant FK506 (Tacrolimus)^[139]. Proteins that can modulate cell biology, including proliferation^[140] and apoptosis^[141], have been engineered from growth factor receptors and the FK506 binding domain from FK506-binding protein (FKBP12). However, FK1012 retains the ability to bind endogenous FKBP12^[139]. This is undesirable from a clinical point of view because endogenous FKBP12 could sequester the drug, preventing its intended effect. In addition, FK1012 administration could affect the normal physiological role of FKBP12^[142-145]. As a result, the use of these systems has been limited, though thorough clinical evaluation of the drug has yet to be completed. However, amplification protocols can be envisioned wherein the underlying toxicities of FK1012, which are expected to be similar to FK506, are exploited. Future systems can be developed using other cytotoxic agents with their respective binding targets as CBDs fused to survival or growth signaling

Figure 2 Summary of next-generation amplification modules. A: Fusion proteins comprised of chemical inducer of dimerizations (CBDs) such as FKBP12 (WT CBD) or F36V (Mut CBD) and receptors involved in hematopoietic stem cells (HSC) growth, proliferation, and survival. Activation of signaling by CIDs allows expansion of the transduced population. The use of cytotoxic CIDs (CID^{TOX}) can allow simultaneous depletion of the non-transduced population. FK1012 is a putative cytotoxic CID-binding domain. Examples of inert or neutral CIDs (CID^{NEU}) include AP20187 and AP1903; B: Controlled overexpression of HSC homing and adhesion molecules can increase the potential for therapeutic cells to survive and can promote long-term engraftment. Examples of such molecules include but are not limited to CXCR4, VLA4, and Tie2. Their corresponding ligands (SDF-1, VCAM-1, and Ang-1, respectively) are usually expressed on osteoblasts, osteoclasts, MSCs, and other cells that make up the bone marrow stroma; C: Downstream effectors of key signaling pathways involved in maintaining HSC phenotypes that are down-regulated during *ex vivo* handling of CD34⁺ cells can be reconstituted to prevent stem cell exhaustion and to increase long-term engraftment of transduced cells. HoxB4 is an example of a transcription factor that is activated in response to Wnt signaling and is key to maintenance of the stem phenotype of HSCs.

factors^[146]. Careful dosing can allow for simultaneous depletion of non-transduced cells and expansion of the transduced population (Figure 2A). Such studies have yet to be performed in clinically-relevant settings. Conversely, the application of such current systems remains risky as the continuous use of cytotoxic agents in general can have detrimental effects on patient quality of life. A potential solution is to aim for selective pressure to be applied to more mature cells, where dose reduction can be envisioned whilst clinical benefit is still achieved.

Neutral CIDs

Reverse-engineering of proteins and drugs that bind to them have led to numerous other CIDs and their respective CBDs. Progress in understanding the modularity of protein signaling has yielded numerous opportunities to generate CBD-signaling domain fusions. From a gene therapy perspective, ideal CIDs are those that would have little to no effect on any cells other than the transduced population. Ideal CBDs should also have no effect on the biology of transduced cells without the presence of a CID. As well, engineered polypeptides with CBDs should be derived from endogenous proteins where possible to minimize the potential immunogenicity of the fusions. In addition, unexpected effects of CID-induced dimerization of CBD fusion proteins should not occur in cells derived from transduced HSCs. "Bump and

hole" engineering of FK1012 and FKBP12 has yielded derivative CIDs such as AP20187 (B/B homodimerizer; Takara) and AP1903 (Rimiducid; Bellicum)^[147]. Such CIDs are chemically modified to prevent them from binding the original CBD. The derivative CBDs, such as FKBP12^{F36V} (F36V) for AP20187 and AP1903, have mutations that confer ability to bind the engineered CIDs^[147] (Figure 2A). These modifications allow such CID-CBD systems to be acceptable for use in gene therapy, as outlined above.

Amplification of HSCs using neutral CIDs

Multiple studies have been performed in cell, mouse, and canine models that utilize AP20187 and protein receptors fused to F36V^[148-154]. Our lab has previously shown the utility of a kinase insert domain receptor (KDR/CD309)-F36V fusion to control cell-fate in an AP20187 dependent manner, and we characterized the molecular mechanisms that are induced as a consequence of KDR dimerization in TF1 cells^[150]. The utility of this system has yet to be demonstrated in an animal model of HSC engraftment. The characterization of HSC cells and their signaling components have yielded other targets for F36V fusion and CID-mediated control of cell fate, such as c-Kit (SCF receptor)^[155], and c-Mpl (thrombopoietin receptor)^[149,152,156] (Figure 2A). It must be noted that these signaling components are not fully

unique to the HSC compartment and subsequent risk of unwanted proliferation can exist. That said, restricted expression of CBD-receptor fusions using HSC-specific promoters in gene transfer vehicles could reduce effects on non-target cells.

A long-term study in canines using an engineered thrombopoietin receptor, Mpl-F36V, has demonstrated the utility of intermittent use of AP20187 and AP1903 administration over the course of a number of years with no effect on the normal physiology of the dogs and no effect on the HSC compartment without drug administration^[152]. However, this study only involved long-term monitoring of two dogs and did not test the utility of such a system in a reconstitutive gene therapy context. Studies in healthy human volunteers (see below) may need to be conducted to unravel the effects of long-term administration of AP20187 in order to inform the FDA prior to administration in patients.

Unlike AP20187, AP1903 has gained more momentum with respect to its translation into the clinic. It induces dimerization through the same CBD as AP20187, extending the utility of studies that use F36V fusions^[150-156]. Most importantly, a phase I clinical trial in which a single infusion of AP1903 was administered to 28 healthy volunteers at a range of doses has already been conducted^[157]. No relevant adverse effects were observed at any of the doses. Furthermore, donor T cells that are genetically modified with a CID-inducible caspase-9 (iCasp9) suicide system have been administered to leukemia patients to enhance immune reconstitution in recipients of allogeneic HSC transplants^[158,159]. A single dose of AP1903 was sufficient to ameliorate the GVHD. T cell counts were reduced in as little as 30 min after drug administration followed by resolution of GVHD symptoms in 24 h. Further administration of AP1903 is being tested in patients receiving cell products that have been gene modified with iCasp9 (www.bellicum.com). The dosing for these patients has been informed by the pharmacokinetics observed in healthy volunteers^[157]. Long-term follow-up of patients from one study has been published with up to 4-year occurrence-free survival of patients receiving iCasp9-modified T cells and AP1903^[160]. However, it must be noted that repeated administration of the drug and associated safety profiles have not been published to the best of our knowledge. This is mainly because single-administration of the drug resolved symptoms in the studies conducted thus far and eliminated the need for further intervention^[158,159]. Additionally, no information about biodistribution and pharmacogenomics of AP1903 in humans is available - that we are aware of. As such, the drug is still considered experimental and there is no prior knowledge about its efficacy in the bone marrow niche other than that which has been observed in animal models^[152,161]. Further studies conducted in healthy volunteers to assess a full set of biological parameters can boost the clinical development of enrichment modules relevant to HSC-directed gene therapy.

Engineering alternative amplification modules

While FDA approval and consequential routine administration of existing CIDs in patients may be achievable in the future, there is value in stepping away from sole confinement to FKBP12-derived systems. Multiple other technologies exist that utilize either compounds known to be benign along with reverse engineered signaling domains or compounds and their respective binding domains derived from other species. For example, a recently demonstrated degron-system that uses an auxin-inducible domain derived from plants^[162] could be engineered to enhance Wnt signaling in HSCs by targeting axin degradation in an auxin analog-dependent manner^[163]. Mouse studies have shown no effect of this analog on normal physiology^[164]. In addition, reverse engineering of G-protein-coupled receptors (GPCRs) have led to the development of a variety of Designer Receptors Activated by Designer Drugs (DREADDs)^[165]. One DREADD has been designed to mediate chemotaxis of monocytes and neutrophils in a drug-dependent manner and highly promising results have been demonstrated *in vivo*^[166]. This DREADD is activated in response to Clozapine-N-oxide (CNO), a benign metabolite of the clinically-approved anti-psychotic agent, Clozapine^[167]. With our growing understanding of protein modularity, it is not difficult to envision the development of a similar DREADD that potentially activates HSC-specific survival and proliferative signals. Development of systems that utilize compounds with known pharmacokinetics and biodistribution that can be fast-tracked for FDA approval can provide a significant boost to *in vivo* enrichment strategies for HSC-directed gene therapy.

MODULES TO ENHANCE ENGRAFTMENT OF THE TRANSDUCED HSC SUB-POPULATION

HSCs are housed in specialized compartments in the BM. They use cell surface receptors and ligands to anchor themselves in their niche and to modulate signals for long-term survival and self-renewal^[4,168]. Roles of multiple signaling pathways have been elucidated; as well, cell surface proteins that can demarcate HSCs as single cells that can stably engraft and that are capable of reconstituting the entire hematopoietic system have been uncovered^[169]. It is therefore not difficult to envision novel clinical roles for these cell surface proteins. For example, plerixafor (Mozobil, Sanofi) is a drug that was developed to disrupt the interaction of C-X-C chemokine receptor type 4 (CXCR4, fusin) and C-X-C motif chemokine 12 (CXCL12, or SDF-1)^[170]. Greater numbers of CD34⁺ cells can be acquired with administration of plerixafor over the traditional mobilization strategy that uses granulocyte-colony stimulating factor^[171,172]. Recently, experiments have shown the potential of another drug, Bortezomib (Velcade, PS-341), in HSC mobilization *via* disruption of very late antigen 4 and

vascular cell adhesion molecules (VCAM-1) in mice^[173].

Enhancement of engraftment can also be envisioned using information resulting from such aforementioned studies. Specifically, interactions that can be disrupted for HSC mobilization can also be used to increase engraftment potential. To this effect, studies have shown stage-specific roles for CXCR4 in BM homing and survival of engrafted HSCs^[174,175] (Figure 2B). In addition, the benefit of virally-mediated CXCR4 transgene expression for HSC engraftment into a humanized mouse model has been shown with *ex vivo*-cultured human CD34⁺ cells^[176,177]. Concerns of long-term side effects of CXCR4 expression, such as diminished repopulating potential of the transduced cells and off-target expression in non-HSCs, still remain. For example, high CXCR4 expression is associated with worse prognosis in acute myeloid leukemia, amongst other cancers^[178,179]. Developments in transient cDNA introduction, conditional control of transcription, and/or robust, tissue-specific control of expression may minimize these concerns, though they remain to be tested. Should such technologies be developed in a clinically-relevant manner, multiple other cell surface targets for enhancing HSC homing, survival, and "stemness" could be utilized, such as Tie2, VLA4, and c-Kit^[168,180-182] (Figure 2B). Other methods relying on expression of downstream components of survival and self-renewal signaling such as homeobox protein Hox-B4 (HoxB4) can also be envisioned to be employed in a controlled manner^[183] (Figure 2C). Though introduction of transgenes may provide the ultimate solution to these challenges, other groups are focusing on development of small molecules and co-injection protocols as alternative methods; such as co-injection of BM-derived mesenchymal stem cells^[184-186].

LINEAGE-SPECIFIC ENRICHMENT

As discussed previously, it can be conceptually difficult to target therapeutic HSCs for *in vivo* amplification due to the unique microenvironment in the BM niche in which they reside and because of their inherently quiescent nature. Whilst it is generally agreed that the most clinical benefit can be obtained by targeting long-term precursor cells, it is not conclusively proven to be so. Examples of gene therapy that result in enrichment of cells derived from transduced HSCs, such as in SCID-X1 and β -thalassemia, provide proof-of-concept for the clinical utility of targeting a subset of the mature hematopoietic compartment for selection^[7,17,43-47]. Application of enrichment strategies in such a manner can overcome many of the hurdles of attempting to enrich the original HSC engraftment, such as bioavailability of the compounds used for enrichment and toxicities towards the core center of hematopoiesis. In addition, targeting mature cells, and more importantly, excluding the HSC compartment, reduces the chances of long-term complications in patients that have already gone through a risky intervention and reduces the likelihood of sporadic malignant disease arising from alterations

in "stem-like" progenitor cells. One conceptual disadvantage of such a targeted system is the lack of persistence of selection, since mature hematopoietic cells will be replaced over time. Enrichment protocols can be developed, however, that utilize either drug dosing that has little or no toxicity in normal cells, or compounds that specifically act on cells that arise from transduced HSCs. As such, continuous administration of the respective agent can provide for prolonged enrichment with minimal or no side effects.

IMPDH2 mutants for MMF resistance in T/B cell progeny

Inosine monophosphate dehydrogenase 2 (IMPDH2) is the rate-limiting enzyme involved in the *de novo* biosynthesis of guanosine monophosphate (GMP)^[187]. While most cells in the body have a salvage pathway, T cell activation and proliferation as well as B cell maturation are highly dependent upon this biosynthetic pathway^[188,189]. Mycophenolic acid (MPA) is a potent, non-competitive, reversible inhibitor of IMPDH2^[190-192]. Its prodrug, Mycophenolate Mofetil (MMF, Roche), is routinely used in the clinic as an immunosuppressant to control GVHD amongst other indications^[193]. Mutants of IMPDH2 that have diminished binding affinity for MPA have been described^[194,195]. The most potent amongst these is the combination of T333I and S351Y (IMPDH2^{IV}). The utility of this double mutant has been demonstrated in the context of donor T cell selection, both *in vitro* and in mouse models using primary human T cells^[196,197]. It should be noted that the total lymphocyte count in these experiments was dramatically lowered with MMF treatment, reducing the benefit of such a system with respect to T cell gene therapy^[197]. The dosage of drug used in that study, however, was considerably higher than that used to treat patients for GVHD. The effect of low-dose MMF treatment on engrafted cells expressing IMPDH2^{IV} has yet to be shown. In addition, it has been demonstrated that there is no biological effect of constitutive expression of this mutant enzyme on HSC differentiation^[194]. Therefore, use of such an enrichment strategy could exclude HSCs and all hematopoietic progeny other than T and B cells from being affected. That said, previous work has only described the use of IMPDH2^{IV} for application in T cell-related disorders, such as HIV treatment and prevention of GVHD^[194,197]. To our knowledge, *in vivo* use of this enrichment module in HSC gene therapy has not yet been demonstrated.

CID-dependent enrichment of gene modified progeny

Numerous examples exist of receptor-CBD fusions that can provide a proliferative advantage to subsets of mature cells. Most recently, an erythropoietin receptor (EpoR)-F36V fusion has been developed for use in facilitating AP20187-dependent erythropoiesis^[198]. The fusion is engineered with the minimal components of EpoR required for dimerization-induced signaling along with a myristoylation signal. The fusion is expressed under the control of an erythrocyte-specific promoter. The goal of that study was to design a system to

replace the necessity of recombinant Epo administration in anemic patients. The authors have successfully demonstrated CID-dependent erythropoiesis *in vivo* in a mouse model^[198]. Though this group has not shown the utility of their system in the context of HSC gene therapy, it can be postulated that it would be applicable for enhancement of treatment for disorders that affect erythropoiesis. It must be noted that such systems are hindered to date in their clinical translation due to their use of clinically-unavailable CIDs. Future studies utilizing clinically-available compounds and a variety of lineage specific growth signals are anticipated.

DISCUSSION

Safety of LV-mediated gene therapy

With the initial implementation of recombinant onco-retroviruses in gene therapy strategies, an emergent obstacle to be considered when genetically modifying long-term, stem-like cells is the potential for the development of malignancy^[4,15,23-25]. As discussed above, LVs greatly diminish the likelihood of integration near known oncogenes or tumor suppressors^[4,26-30]. However, multiple other mechanisms that can lead to gross cellular aberrations or changes in function of cells derived from transduced HSCs are still of concern. Though improbable, integrative modification of gene loci can lead to alternative splicing of putative oncogenes, or to the insertional inactivation of tumor suppressors^[199,200]. Additionally, a comprehensive understanding of oncogenesis has yet to be achieved in all its different forms, especially within the complex network of cells in the hematopoietic system. As such, continuation of long-term studies investigating the effects of transplanting patients with transduced HSCs is a necessity, especially with new knowledge being acquired regarding the functional importance of intergenic "junk" DNA.

One strategy to circumvent putative side effects of HSC gene therapy is to include suicide modules (or "cell-fate control" systems) in the transfer vector. Suicide modules refer to elements of therapeutic vectors that are capable of inducing specific cell-death of transgenically modified cells. This is especially important when considering the inclusion of amplification modules, which have not been thoroughly tested in patients. These systems can be designed to induce cell death by providing a surface target for antibodies, by inclusion of an inducible component that activates the apoptotic pathway, or by being able to activate a normally non-toxic prodrug. For example, there are multiple CID-based systems that bring together components of the apoptotic-signaling pathway^[158,159,201-203]. One of these, iCasp9, is currently being tested in patients receiving haploidentical donor T cell infusions amongst other indications, as discussed previously, though the CIDs being used have yet to acquire FDA approval^[158,159]. Additionally, such systems have been tested for their ability to eliminate autologous HSC engraftments in rhesus macaques^[204].

The ability to conditionally activate prodrugs has been a useful tool in molecular biology to induce killing of subsets of cells, though many of the enzymes used are derived from other species. For example, thymidine kinase (tk), derived from the herpes simplex virus (HSV-tk), can be used to render cells sensitive to the drug ganciclovir, a commonly employed laboratory technique^[205]. HSV-tk has been used to ameliorate GVHD in patients receiving allogeneic transplants and in anti-tumor suicide gene therapy^[71,206-209]. However, use of this system is limited by concerns of immunogenicity of non-human proteins that can cause elimination of otherwise useful cells^[56,57]. Additionally, ganciclovir and acyclovir are commonly prescribed for viral infections following engraftment, and use of HSV-tk can lead to unintended elimination of transduced cells^[210]. Our lab has developed a fusion protein comprised of the extracellular and transmembrane components of LNGFR (CD271) along with an engineered variant of human thymidylate kinase^[211]. This module combines the advantages of being able to overexpress a cell surface marker for tracking transduced HSCs and their progeny, since CD271 expression is absent in circulating blood cells, and the ability to activate azidothymidine to a toxic form.

Stem cell exhaustion and clonal selection

One of the principal advantages of *in vivo* selection is the potential for an increase in therapeutic benefit from an initially lower number of transduced repopulating cells. Yet, proliferative stress on few selected HSCs can occur, resulting in a gross negative, long-term impact on HSC proliferation and lineage differentiation. This is termed "stem cell exhaustion" and can eventually lead to BM failure in recipients. Such concerns have been studied in mice^[212] and dogs^[213] that underwent serial MGMT^{P140K}-expressing HSC transplantation under prolonged O⁶BG/BCNU treatment. Importantly, these studies revealed no apparent impairment in HSC repopulation, proliferation, or differentiation, suggesting that stem cell exhaustion may not be an issue, at least in the context of that mode of chemoselection. Further studies in long-lived, clinically-relevant models need to be conducted, however, especially in the context of HSC gene therapy, to demonstrate lack of long-term exhaustion within primary autologous recipients. *Ex vivo* selection may also be achievable without stem cell exhaustion with the co-expression of factors that maintain HSC "stemness", such as HoxB4^[183].

In vivo drug selection can also exacerbate clonal dominance, a phenomenon readily observed with the use of recombinant onco-retroviruses. Amplification strategies could augment the proliferative advantage of cells with proviral integration sites in or near proto-oncogenes, risking the development of hematopoietic malignancies. For example, analysis of tertiary MGMT-transduced BM recipients showed only 17 unique retroviral integration sites (RIS) following chemoselection^[212]. Most RIS in that study were in or near

genes involved in important cell regulatory processes, such as cell growth, cell development, and/or cell differentiation. However, this observation may be an artifact of the use of derivatives of murine stem cell retrovirus. In contrast, studies in canines and humanized mice that utilized recombinant LVs, and a mouse allograft study utilizing a foamy viral vector, showed no observable evidence of clonal dominance following chemoselection^[30,213,214]. Taken together, current data suggests that stem cell exhaustion and clonal dominance are unlikely to occur with amplification strategies, especially with the use of recombinant LVs. Nevertheless, a persistent concern remains when considering HSC gene therapy in patients. As such, an excellent strategy to address issues surrounding *in vivo* amplification of transduced HSCs is to apply enrichment to mature hematopoietic cells, as discussed previously. However, more studies need to be conducted to demonstrate clinical efficacy and safety of amplification of mature cells subsequent to HSC gene therapy.

Future considerations

Many of the enrichment strategies that have been suggested or tested for use in gene therapy applications are designed to be expressed in a constitutively “on” manner. While this may increase the potency of the given strategy, unexpected secondary effects on normal physiology may occur. Therefore, conditional expression cassettes for clinical use should be developed in order to minimize unwanted expression of amplification modules. This is paramount when considering the use of highly engineered or trans-species proteins, which can, over time, elicit immune responses against target cells. In addition, to avoid similar issues at a genomic level, use of innate promoters, such as that derived from the elongation factor 1- α locus (EF1 α), in contrast to virally-derived promoters, such as that derived from cytomegalovirus (CMV), should be considered for clinical application^[215].

Greater focus in the gene therapy field is placed upon the improvement of gene delivery methods and, in the context of HSC gene therapy, efforts are being made to increase the efficacy of various aspects of HSC acquisition, engraftment, and patient care. However, there is limited research to develop next-generation strategies for other aspects of HSC gene therapy that can improve clinical efficacy of this treatment modality. Clinically-feasible strategies need to be developed that allow for selection or enrichment of transduced, therapeutic HSCs after engraftment. In addition, strategies that use other target cell types, such as MSCs, should also be considered for tandem gene therapeutics, to increase the efficiency of correction mediated by HSC gene therapy. More specifically, enrichment strategies that utilize clinically-approved compounds with known pharmacokinetics and pharmacodynamics, such as MMF, need to be developed. Such systems have the potential to be employed in the clinic more quickly and can allow for

repeated administrations or continuous low dosing for long-term benefit. Dose adjustments can also be safely made to compensate for variability in patient pharmacogenomics. The development of modules that allow resistance to drugs used for the treatment of benign hematopoietic hyperplasias can encompass many of the aforementioned advantages.

Abstract

The establishment of multipotent pancreas progenitors (MPP) should have a significant impact not only on the ontology of the pancreas, but also for the translational research of glucose-responding endocrine β -cells. Deficiency of the latter may lead to the pandemic type 1 or type 2 diabetes mellitus, a metabolic disorder. An ideal treatment of which would potentially be the replacement of destroyed or failed β -cells, by restoring function of endogenous pancreatic endocrine cells or by transplantation of donor islets or *in vitro* generated insulin-secreting cells. Thus, considerable research efforts have been devoted to identify MPP candidates in the pre- and post-natal pancreas for the endogenous neogenesis or regeneration of endocrine insulin-secreting cells. In order to advance this inconclusive but critical field, we here review the emerging concepts, recent literature and newest developments of potential MPP and propose measures that would assist its forward progression.

Key words: Multipotent pancreas progenitors; Regeneration; Self-renewal; Clonogenesis; Differentiation

Core tip: Diabetes mellitus is a pandemic health problem that currently affects approximately 400 million people worldwide and its incidence is increasing by 2%-3% per year. At present, insulin deficiency in diabetes is treated by exogenous insulin given as either multiple daily injections or continuous subcutaneous infusion (pump), which is associated with acute, potentially life-threatening metabolic disturbances as well as chronic, vascular complications with significant morbidity and mortality. The ultimate solution would therefore be regenerative therapies by which lost β -cells in disease processes could be restored/replaced by surrogate insulin-secreting cells including those derived from multipotent pancreas progenitors.

INTRODUCTION

In contrast to what we would expect, modern humans encounter unprecedented health challenges, including the pandemic diabetes mellitus (DM), which is a major metabolic disorder worldwide with a progressively climbing incidence. This disease currently affects 387 million individuals, with one dying in every 7 s due to severe complications (<http://www.idf.org/diabetesatlas>). Among them, approximately 10% suffer from type 1 DM (T1DM), due to the absolute lack of glucose-responding β -cells destroyed by the patient's own immune system. Provided autodestruction of β -cells is under control, a permanent replacement approach may therefore be an ideal solution for T1DM, through regeneration *in situ* of endogenous β -cells, or by the replacement with donated glucose-responding islets, or of *in vitro* produced insulin-secreting β -cells from stem cell sources such as pluripotent stem cells (PSCs). The other 90% diabetic subjects are currently affected by type 2 DM (T2DM), resulting from the inability to react to insulin regulation by key metabolic tissues, the inability to regulate the generation of glucose from the liver and the dysfunction of endocrine β -cells^[1]. The latter is typically believed to be caused by the increase of β -cell death^[2]. Recently, accumulating evidence has suggested that β -cell dysfunction in T2DM is also caused by the dedifferentiation of glucose-regulating β -cells^[3,4]. Thus, the ability to restore function of failed endocrine cells would provide a novel redifferentiative treatment for T2DM. In order to develop regenerative medicine therapies to T1DM and T2DM, the interest to both stem cells and progenitors in the pancreas has recently been progressively increased.

In general, the concept of multipotent progenitors is exchangeable with that of stem cells. The latter are usually used to define undifferentiated primitive cells that have the capacity for self-renewal themselves as well as of differentiation into terminal functional cells. For example embryonic stem cells (ESC) and induced pluripotent stem cells (iPSC, both together known as PSC) are able to produce all types of 210 cells that build up the body. Debatably, progenitors with multipotency are stem cells. Progenitors could be multipotent, oligopotent or unipotent based on their developmental potentials. Multipotent progenitors/stem cells are of fundamental importance to normal physiology and to regeneration during disease/injury repair. Multipotent pancreas progenitors (MPP) would be a rare subset present in developing and adult pancreas, and have a capacity for regeneration when required, even though

their location and origin have not yet been completely established and are still controversial. In this article, we will summarize knowledge on the candidate MPP along the natural route of endocrine pancreas development and in three functional components of the pancreas. We will also propose future research perspectives on the potential MPP.

CLASSICAL EMBRYOLOGY

The pancreas is an important digestive and endocrine organ originating from the endoderm of posterior foregut. The latter along the other two germ layers is derived from the inner cell mass and would develop into the pancreas primordia when a localized area of thickened columnar epithelia along the dorsal and ventral posterior foregut appears. The columnar endodermal layer evaginates into the neighboring mesenchymal tissues of mesoderm origin and gives rise to the dorsal and ventral buds of the pancreas, respectively. Whilst continuously proliferating and branching, two buds gradually fuse together due to the gut rotation movement. Subsequently, the primordial pancreas continues to expand, transform and, finally, differentiate into the mature organ. The mature pancreas is composed of the acinar compartment that secretes digestive enzymes and fluid, that are drained into the intestinal lumen by the pancreatic ducts and, the endocrine pancreas that secretes hormones (glucagon, insulin, somatostatin, ghrelin or pancreatic polypeptide) responsible for maintaining normal glucose metabolism.

The key developmental events in the human pancreas are different from what we know about from developing pancreas in mice^[5]. For instance, human dorsal bud is detectable at 26 d post conception (dpc), which is an equivalent age of embryonic day (E)9.5 in mouse embryos. The cellular developmental sequences in humans also differ from that in mice. Although they are not visible until 52 dpc, approximately 2 wk later than the equivalent stage at which they can be detected in mice, insulin-positive β -cells in humans appear precedent, unlike that in mice, to glucagon-positive α -cells at 8-10 wk of gestation^[6]. All islet cells are detectable at the end of the first trimester in humans^[6], but at later stages (E17.5) in mice^[7]. Finally, the dynamics of gene expression during embryonic development and in pathophysiological conditions also differ between the two species^[8]. Readers are referred to more reviews of human pancreas development elsewhere^[9-12].

POTENTIAL MPP ALONG THE DEVELOPMENT OF ENDOCRINE PANCREAS

Remarkably, PSC can be guided to differentiate into definitive endoderm (DE)-like progenitors *ex vivo* by applying knowledge of *in vivo* developmental mechanisms (Figure 1). For example, this has been achieved

Figure 1 Multiple fate selections allow the development of the pancreas islet lineages. Committed from one of three germ layers (the ectoderm, mesoderm and endoderm) during gastrulation, the definitive endodermal cells (DE) are marked by the expression of Sox17 (the Sry-related HMG box transcription factor 17) and foxhead homeobox 2a (Foxa2). Along the anterior-posterior axis the DE is divided into foregut (giving rise to the lung, thyroid and esophagus), posterior foregut (PF), marked by the expression of the transcription factor hepatocyte nuclear factor 4a (Hnf4a) and hindgut (committing the intestine and colon). *In vitro*, retinoic acid would direct the DE cells to PF cells. Largely to the liver and duodenum, a fraction of the PF cells give rise to pancreatic progenitors (PP, marked by the expression of the transcription factor Pdx1). Mostly to the exocrine and ductal tissues, the PP commits to progenitors of the endocrine islet lineages [IP, marked by the expression of Neurog3, as well as neural differentiation 1 (NeuroD), insulinoma associated 1 (IA1), Islet 1 (Isl1), paired box factor 6 (Pax6) and Rfx6]. The IP then differentiates into at least five types of islet cells [α , β , δ (somatostatin), pancreatic polypeptide (PP) and ϵ (ghrelin)].

in culture by supplementing with a pharmacological level of activin A, a growth factor (GF) of the superfamily of the transforming GF β . Furthermore, human PSC-derived self-renewable DE-like cells have been reported to expand under the stimuli of four GFs^[13]. These DE-like endodermal progenitors have proliferated over 24 passages with an astonishing increase in cell numbers. To establish their reliability and utility in developmental biology, drug screening and regenerative medicine, PSC-derived DE-like cells should be biologically and transcriptomically compared to embryo-derived DE cells. Although further research is required, these endodermal progenitors may indeed function as pre-MPP in addition to possessing an incredible capacity for expansion.

Sox9-expressing MPP

Cystic epithelial colonies expressing E-cadherin first were generated by our group (Figure 2). After dissociation, fetal pancreatic cells produced cystic colonies containing β -cells in the presence of the basement membrane glycoprotein laminin 1, 1, 1 and a bone morphogenetic protein^[14,15]. Interestingly, spherical but not cystic colonies are generated in the presence of epidermal GF^[16], suggesting these GFs play different roles during development. We have not investigated whether all or only some fractions of cystoid epithelial cells stochastically commits to different lineages, though it seems possible that these cystic colonies originated from multipotent progenitors that are Sox9⁺ (see below).

Sox genes encode versatile regulators of stem/progenitor cell fate^[17], belonging to members of transcription factor family that contain the Sry (sex deter-

mining region Y) box-related high-mobility group. Sox9 for example critically regulates the development of multiple embryonic organs including the pancreas. This pivotal transcription factor is first detectable at E10.5 in the dorsal and ventral pancreases^[18] and at E13.5, Sox9-expressing progenitors (Figure 3) develop into the exocrine and endocrine lineages in the pancreas^[19]. However, by E16.5 the expression of Sox9 is progressively restricted to pancreatic ductal cells^[19]. Genetic tracing studies reveal that Sox9 is also expressed in organs of other posterior foregut origin such as the liver, the bile duct and the duodenum. For example, it is present in bile ductal cells adjacent to the portal vein from E16.5. Sox9 also is broadly detectable in the intestinal epithelia at E13.5 but confined to the crypt region from E18.5^[19]. Thus All Sox9-expressing cells in the posterior foregut region could be MPP. Supportive to these analyses, Sox9-expressing (Sox9⁺) multipotent progenitors purified from E11.5 Sox9-eGFP embryos generate expandable cystoid colonies that contain hormone-expressing cells in a laminin 1, 1, 1-enriched Matrigel-coated culture condition^[20].

Sox9⁺CD133⁺ ductal cells generates duct-like "ring/dense" colonies (1/5) in the culture of the Matrigel-containing methylcellulose-based semisolid medium. With the addition of the roof plate-specific spondin 1, a Wnt agonist, these ring/dense colony-forming cells can be serially dissociated and replated in the presence of Matrigel with an expansion of more than 100000-fold^[21]. In a laminin-containing hydrogel, the Sox9⁺CD133⁺ (cluster differentiation 133) cells are able to give rise to acinar/endocrine colonies^[21]. Further investigations

Figure 2 Cystic colony formation from dissociated fetal mouse pancreas cells. A: Phase contrast image showing that BMP-6 promotes colony formation. Open arrows indicate colonies $\leq 30 \mu\text{m}$; B: Immunocytochemical analyses: a: Proinsulin staining. Fixed colonies were stained with proinsulin antibody (brown); b: Activin A antagonizes colony formation; c, d: Insulin staining. Histological sections of harvested colonies were stained with anti-insulin antibody (brown). Adapted and modified from ref.^[14].

are needed to ascertain whether Sox9⁺CD133⁺ cells are identical to, or distinct from, the colony-forming Lgr5 [leucine-rich repeat-containing G-protein coupled receptor 5, also known as GPR49 or GPR67 (G-protein coupled receptor 49 or 67)]-expressing cells described below. However, Sox9-positive ductal and centroacinar cells are unable to produce β -cells in a few experiments for regeneration or trans differentiation, such as with cerulean-induced acute pancreatitis, an *in vitro* culture experiment, pancreatic duct ligation (PDL), partial pancreatectomy and a streptozotocin-induced diabetic model^[19,22]. Originated from the posterior foregut endoderm, a human bile duct progenitor population known as “biliary tree-derived cells”^[23] may have a MPP potential and give rise to islet lineages. However, the purified population, molecular profile and detailed developmental potential of these “tree-derived cells” require further investigations.

Pdx1-expressing MPP

A cluster of unique cells in the thickened DE epithelium along the dorsal and ventral surfaces of the posterior

foregut in E9.0-9.5 mouse embryos expresses the homeobox gene named Pdx1 (pancreas and duodenum transcription factor 1). The latter encodes a parahox homeobox-containing factor, critical for the establishment of primitive pancreas^[24] as well as the maintenance of functional β -cells^[25,26].

Studies have demonstrated that Pdx1-expressing (Pdx1⁺) progenitors are MPP because they give rise to acinar, ductal and islet tissues of the pancreas^[27]. Genetic lineage tracing studies revealed that these MPP reside in the termini of the tree-like branching ducts in the developing pancreas that also express the acinar transcription factor known as Ptf1a and the exocrine cell marker known as Cpa1^[28]. The Pdx1⁺ cells are capable of taking up the thymidine analogue bromodeoxyuridine (BrdU) and incorporating the latter into their genome during mitosis^[29], revealing that these cells are proliferative.

Using developmental biological knowledge, PSC have been manipulated to generate Pdx1⁺ cells that have been expanded for 16-fold co-cultured with pancreas-derived mesenchymal cells^[30]. To verify the proliferation

Figure 3 Cystic colonies generated from Sox9-tagged cells. A: Embryonic Sox9⁺ progenitors in the pancreas capable of generating cystic colonies; a: Sox9 is expressed in most ductal progenitors in E11.5 mouse pancreas; b: Cystic colonies are formed from purified Sox9-eGFP⁺ progenitors in E11.5 mouse pancreas; B: Purified Sox9⁺ cells in adult mouse pancreas capable of generating cystic colonies under a phase contrast (a) or a fluorescence microscope (b). Adapted and modified from [20,21].

of Pdx1⁺ cells, independent confirmation of this report will be required. We also need to ascertain whether these PSC-derived Pdx1⁺ cells share all or partial characteristics of embryonic pancreatic progenitors, because *Pdx1* is also expressed in extra-pancreatic tissues including other endoderm-derived non-pancreas organs [31].

In developing human pancreas, numerous PDX1⁺ progenitors are present between 8 and 21 wk of gestation [32,33]. These PDX1⁺ progenitors are frequently expressed SOX9 and highly proliferative [34], supporting the notion that pancreatic progenitors are committed from SOX9⁺ multipotent progenitors. The progressive increase of PDX1⁺ cells that co-express insulin or somatostatin is observed in this period of gestation [32]. Further research is required to investigate whether the PDX1⁺ progenitor pool is established by its self-renewal or by direct differentiation of the posterior foregut progenitors or both.

Strategies for proliferation, self-renewal and differentiation of pancreatic progenitors will be of importance in developmental biology and regenerative medicine. Interestingly, reserpine and tetrabenazine that inhibit the vesicular monoamine transporter-2 are shown to direct PSC-derived Pdx1⁺ cells to produce cells that express neurogenin 3 (*Neurog3*, also known as *Ngn3*) [35], a DNA-binding protein, belonging to the transcription factor family of the basic helix-loop-helix category. However, as a positive control, Pdx1⁺ progenitors purified from embryonic pancreas would have been tested with these two molecules to examine their capacity and efficiency to give rise to islet progenitors. Furthermore, caution needs to be exercised for the use of genetic lineage tracing in PSC differentiation *in vitro* because temporospatial cues are essential for the success of *in vivo* lineage tracing studies (see review by [36]). To enrich PSC-derived genuine pancreatic progenitors for further expansion and differentiation, identification of their specific markers would be highly valuable.

***Neurog3*-expressing pancreatic endocrine progenitors**

Approximately in E9.5 mouse embryos, within the

thickened posterior foregut DE epithelium there is a small cluster of cells that express a high level of the *Neurog3*, an endocrine determinant [27,37,38]. The cells that express *Neurog3* highly are the progenitors of endocrine pancreas as they develop into all islet lineage cells *in vivo*. Several studies verify the critical role of *Neurog3* in the ontogenesis of endocrine pancreas: Islet cells are not observed in *Neurog3* targeted mouse pancreas [37]; genetic tracing demonstrates that *Neurog3*⁺ progenitors differentiate into all five types of islet cells [27]; isolated adult *Neurog3*⁺ cells reappeared after PDL can, after inoculation into an embryonic pancreas *ex vivo*, give rise to five types of endocrine cells [38]. Nevertheless, a few *Neurog3*⁺ cells are observed to coexpress insulin in the dual fluorescence-tagged developing mouse pancreas [39]. Another laboratory reported that PDL allows the activation of *Neurog3* expression but the *Neurog3*-expressing cells are not able to complete the entire β -cell regeneration program [22]. Furthermore a recent study found that β -cell mass and insulin content are totally unchanged after PDL-induced injury [40], unresponsive to the conclusion of an active β -cell regeneration. The reason for these inconsistencies is unknown and future investigation is warranted to confirm or refute the conclusion.

Whereas the expression of mouse *Neurog3* mRNA in the developing pancreas plateaus approximately E15.5 [41] (approximately week 9 of gestation in humans), that of human *NEUROG3* is low prior to 9 wk, but increases sharply onward and remains very high until 17 wk [33]. Furthermore some cells coexpress both *NEUROG3* and insulin in the embryonic pancreas from 10 to 21 wk [32]. Although earlier studies showed that *Neurog3*⁺ cells could proliferate [42,43], clonal assays by "mosaic analysis with double marker" (MADM) have confirmed that *Neurog3*⁺ cells are quiescent and commit to only one cell type of the endocrine pancreas [44]. A recent study consistently demonstrated that the activation of *Neurog3* itself inhibits cell division by the activation of cyclin-dependent kinase inhibitor 1a [45]. The inconsistencies between the previous and recent reports require future research to reconcile. Again, it is formally

possible that PSC-derived Neurog3-expressing cells are not completely bona fide islet progenitors as Neurog3 is expressed in endoderm-derived non-pancreas organs.

Insulin⁺ multipotent progenitors

Embryonic insulin-expressing cells may be endocrine progenitors in the pancreas as they can give rise to other islet cell types in addition to β -cells at least during development^[46]. By employing fluorescence-tagged tracing strategies, multipotent progenitors that are insulin⁺ (arguably to be MPP) in the pancreatic tissues are believed to be originated from the Pdx1⁺ progenitors, instead from the ectoderm-derived neural crest. These MPP-like cells express several islet progenitor markers and are able to differentiate into all endocrine cells *in vivo*. The MPP express a low concentration of insulin and low copies or complete lack of glucose transporter-2, clearly different from functional mature β -cells^[47]. Nevertheless, studies have demonstrated that the expression of insulin gene is activated in Pdx1⁺ MPP, *via* Neurog3⁺ precursors to adult β -cells^[48,49], thus future investigation is needed to establish what stages at which insulin⁺ MPP are present: The embryonic, fetal and/or adult endocrine pancreas.

Human insulin⁺ multipotent progenitors have also been described with a similar developmental potential to the mouse ones. These cells, isolated from either mice or humans, could, after transplantation into diabetic mice, develop into functional cells to ameliorate hyperglycemia. Surprisingly, however, these insulin⁺ multipotent progenitors also gave rise to neural lineage cells *in vivo*^[47].

Ghrelin (ϵ)-expressing progenitors?

Ghrelin-expressing ϵ -cells are the fifth cell type in the endocrine pancreas and are first discovered in the stomach. Ghrelin is a polypeptide hormone composed of 28-amino acid residuals and known to negatively regulate insulin secretion from mouse, rat and human islets^[50]. Now it is well established that pancreatic ϵ -cells are detectable in mid-gestation in mice and humans and their number plateaus during the perinatal period^[51]. However, there are a substantial number of ϵ -cells in only human but not mouse and rat adult islets^[51], raising the possibility that ϵ -cells could participate in the regulation of glucose homeostasis.

Deletion of the *Arx* gene, encoding an α -cell transcription factor, drastically reduces the number of ϵ -cells^[52]. In contrast, knockout of *Nkx2.2*, *Pax4* or *Pax6* significantly increases the number of these cells at the expense of reducing other pancreatic endocrine cell types^[53,54]. Intriguingly, genetic studies of lineage tracing demonstrated that ϵ -cells give rise to α , PP and, to a lesser extent, β -cells in adult mouse pancreas^[55], suggesting that these cells have a unusual plasticity for trans differentiation towards, and may even be progenitors of, other islet cells. However, whether ϵ -cells would act as MPP of functional islets remains to be established.

Can islet β -cells behave like unipotent “progenitors”?

Functional duplication of insulin-secreting β -cells is first described by Dor *et al.*^[56] by using RIP (rat insulin promoter)-driving genetic lineage tracing. They revealed that mouse β -cells in the endocrine pancreas could be reproduced by RIP-expressing cells under the physiological condition or after partial pancreatectomy. This report however did not preclude the presence of and the role of MPP by assuming that all RIP-expressing cells are functional β -cells. Similarly, in a transgenic model using the RIP to govern diphtheria toxin expression resulted in 70%-80% β -cell apoptosis, disrupted architecture of endocrine pancreas and eventually in the development of diabetes. Withdrawing the expression of diphtheria resulted in a significant recovery of β -cell mass, islet architecture and of normoglycemia^[57]. Further analysis revealed that a subset of 20%-30% surviving “ β ”-cells played a major role in the β -cell regeneration and recovery of euglycemia^[57]. These studies suggest that islet β -cells are indeed facultative unipotent progenitor cells.

In the sophisticated double transgenic MADM (designated RIP-CreER; Rosa26^{GR}/Rosa26^{RG}) mouse pancreas, each RIP-expressing clone is made up of only 5 cells after one month of chase, slightly increasing to 8 cells by two months^[58]. The clusters that express RIP have been viewed as supportive evidence of regeneration of functional cells, but this should be treated with caution as discussed hereafter. A further study with a reductionist approach on the gene *Hnf4a* (hepatocyte nuclear factor 4a) suggested that the β -cell regeneration may be associated with the signaling cascade of the Ras/Erk pathway^[59] and even be modulated by cell cycle regulators such as cyclin D2^[60]. Collectively, it is critical to establish and identify the well-known RIP-expressing cells either in self-duplication or in dedifferentiation both *in situ* and *ex vivo*, as the latter may be a key MPP candidate for a T1DM replacement solution.

Furthermore, lineage tracing labeled with a thymidine analogue showed that β -cells are produced within an islet by rare self-renewable cells that have a long duplication-refractory time. Under stress conditions such as during pregnancy or after partial pancreatectomy, the number of self-renewable cells is dramatically elevated^[61]. However the molecular nature of these rare cells and the replication-refractory length have not been established. Future studies should characterize their molecular identity and reveal whether these self-renewable replicating cells are fully functional. Due to the ethical barrier and technical difficulties, similar studies are not possible to be undertaken to label human endocrine pancreas *in vivo*, but a similar research should be repeated with larger mammals.

The above described investigations of β -cell self-renewal as a regenerative mechanism have drawn considerable interest in last several years, due to its promise as a way to increase β -cell mass for the treatment of diabetes. However, these studies have not excluded

whether the insulin transcript (as controlled, for instance, by the RIP transgene) is only expressed in functional β -cells. There is increasing evidence suggesting that is not the case. First, the expression of insulin gene is detectable in the Pdx1^+ progenitors, dramatically increasing in Neurog3^+ precursors and peaking in mature islet β -cells^[48,49]. Second, the demonstration of insulin⁺ multipotent progenitors^[47] precludes insulin as an exclusive marker of functional β -cells. Third, insulin protein has been detectable in some mouse and human islet precursors as described above.

Taken together, the expression of insulin gene is clearly not exclusive for functional β -cells. It is formally possible β -cell populations in adults are maintained not only by the self-replication of functional glucose-regulating cells but also by the self-duplication and development of MPP. In order to demonstrate that MPP are indeed present in the adult endocrine pancreas, their clonogenesis must be established with isolated single cell MPP candidates *ex vivo*, with data generated from the intermediary stages of the clonogenesis, and with demonstrable ability to give rise to at least non- β endocrine cells *in vivo*.

MPP PRESENT IN THREE TYPES OF PANCREAS TISSUES

Accumulating evidence generated in *ex vivo* studies has suggested that MPP are present in three major tissues of the pancreas: The pancreatic ductal^[62-64], acinar and islet compartments^[65,66]. For instance, the application of flow cytometry has identified a potential MPP population in the mouse pancreas both in development and in adults^[67]. These candidates are characterized by the exhibition of the receptor c-met for hepatocyte GF, without the presence of hematopoietic lineage markers including CD45, c-Kit (stem cell factor receptor), Flk-1 and TER119. The purified population is able to give rise to several types of pancreatic cells *ex vivo* and generate pancreatic endocrine and exocrine cells *in situ* after transplantation^[67]. Nevertheless, the spatial localization and the molecular natures of these c-met positive cells are completely unknown and the clonogenesis has not been established at the single cell level.

MPP likely present in the ductal epithelium

Many studies suggest that MPP are present in the ductal epithelium. Bonner-Weir *et al.*^[68] first reported that human ductal epithelial cells in adult pancreas are able to differentiate into islet-like clusters containing insulin-secreting β -cells. Ramiya *et al.*^[63] showed that insulin-secreting islet-like clusters generated *in vitro* from mouse MPP are capable of ameliorating diabetes after being grafted under the kidney capsule. In cultures of human "pancreatic ductal cell aggregates" after isolation of the islets for transplantation, cells with fibroblast-like morphology appear known as pancreatic "mesenchymal stem cells (MSC)". These cells were

passed over 12 times and expressed an array of markers of bone marrow MSC such as CD13, CD29, CD44, CD49f (also known as α_6 integrin subunit), CD54, CD90 (also known as Thy1) and CD105. The pancreatic MSC are shown to be able to give rise to cross-germ layer cells such as endoderm-originated non-pancreas lineages^[69]. Utilizing culture protocols suitable for producing the neurospheres of ectoderm origin, ductal cells from mouse pancreas are shown to give rise to neurosphere-like clusters that subsequently give rise to a few types of endocrine cells, such as insulin-secreting β cells^[66]. Nevertheless, the exact nature of the special cells has not been established. A major limitation of the forementioned reports is the use of unenriched/unpurified cell preparations in addition to not demonstrating single-cell self-renewability.

Furthermore, numerous CK19^+ ductal cells and islet cells are detected after PDL^[38]. The lineage relationship between the ductal cells and islet cells has further been addressed using the genetic lineage tracing of the Cre-loxP system. Using the system, the Cre governs the promoter activity of carbonic anhydrase II gene, encoding a marker of adult ductal epithelia and controls the removal of the stop sequence (Rosa-loxP-stop-loxP-lacZ) in the reporter Rosa26 (R26R) mice. This resulted in Cre-driving β -galactosidase expression in ductal epithelia. After 28 d in normal or PDL pancreas, the activity of β -galactosidase is detectable in numerous ductal epithelia, localized acinar tissue and in up to 40% islet cells^[70,71]. These data have been viewed as further evidence that the ductal cells expressing carbonic anhydrase II are able to regenerate mouse endocrine cells. It remains unclear, nevertheless, how many cells that express carbonic anhydrase II have this regenerative capacity, how many potential MPP are present or whether a trans differentiation process also takes place.

Nevertheless, once an exon of the ductal epithelial marker gene *Tcf2* (T cell factor 2, also known as Hnf1b, hepatocyte nuclear factor 1b) is exchanged with the transgene containing Cre, the lineage tracing has demonstrated that the Tcf2^+ cells in the postnatal duct cannot develop into endocrine cells in both normal and PDL pancreas^[72]. However, a complicating factor in this report is that one allele of *Tcf2* was non-functional, leading to reducing by half the transcription of *Tcf2*. As heterozygous *Tcf2* mutant does not support pancreas development in mice and humans^[73,74], inactivation of one allele of *Tcf2* in the lineage tracing studies may have led to haploinsufficiency and affected the differentiation of potential MPP into functional islet cells.

Fbw7 (F-box and WD-40 domain protein 7), an ubiquitin ligase, is expressed in embryonic and adult ductal epithelial cells. Deletion of this gene stabilizes the heavily ubiquitinated *Neurog3*, and reprograms the ductal cells to α , β and somatostatin-producing δ -cells^[75]. This study suggests that pancreatic ductal cells are a latent MPP and Fbw7 is a critical cell-fate

regulator. Nevertheless, this report did not describe whether all or a small fraction of the ductal cells express Fbw7 and what the frequency of the reprogramming event is; both are critical to assess whether this might become a viable strategy to regenerate islet cells by suppressing the Fbw7 signaling. A fundamental assay on reprogrammed cells to ameliorate diabetes has also not been reported.

Interestingly, PDL robustly activates the Wnt signaling pathway and allows the regenerating ducts to express Lgr5^[76], a Wnt target which marks actively dividing stem cells such as those present in the intestine^[77]. Purified ductal Lgr5-expressing cells are also responsive to spondin 1 and form clonal 3D pancreatic organoids within the gel-forming Matrigel that generate ductal as well as endocrine lineages upon transplantation^[76].

MPP likely present in acinar tissue of the pancreas

In the clinic with experimental transplantation of donated islets from the cadaver's pancreas, the acinar cells are normally un-used. The discovery of a scientific and practical value for the acinar cells has hence drawn considerable attention. Cotransplantation with pancreatic cells from fetal mice under the kidney capsule in the immunocompromised mice, the acinar cells are reported to give rise to islet cells with undetectable β -cell division or cell fusion^[78]. The results imply that MPP or progenitor cells might be present in the acinar tissue of human adult pancreas. Moreover, the Cre-loxP lineage tracing analysis showed that acinar cells expressing amylase and elastase gave rise to insulin-producing cells in a rotating culture system^[79]. Nevertheless, a self-renewable assay at the single-cell level and its intermediate steps need to be demonstrated. Additionally, these studies have not excluded the possibility that some pancreatic acinar cells might have trans differentiated into surrogate insulin-expressing cells^[80,81]. This likelihood was supported by a previous study that showed that mouse acinar cells could be directly re-programmed *in vivo* to β -like cells by forced expression of three DNA-binding genes, namely, *Pdx1*, *Neurog3* as well as *MafA*^[82]. In addition, as the acinar cells from cadavers^[78] were not isolated by FACS, residual ductal or even islet cells present in the system may have compromised their conclusion. Supporting this view, a lineage tracing study *in vivo* did not provide evidence that the mouse acinar cells would give rise to insulin-secreting β -cells after 70%-80% pancreatectomy^[83]. Thus these inconsistencies remain to be addressed more carefully.

MPP likely present in the endocrine pancreas

A large body of evidence suggests that the islets of Langerhans harbor the MPP. The potential MPP are nestin⁺ and hormone⁻ present in both rat and human islets. These nestin⁺ cells are reported to expand in culture for approximately 8 mo and differentiate into cells that exhibit markers of liver (α -fetoprotein) and pancreas lineages (including amylase, CK19, PDX1, glucagon, insulin and neural-specific cell adhesion

molecule). These nestin⁺ MPP candidates may thus have been involved in the generation of new pancreatic islet cells^[65], potentially modulated by the incretin hormone GLP1, a processed product from the polypeptide pro-glucagon^[84]. It, however, remains unclear whether these nestin⁺ cells are either islet or duct-originated multipotent progenitors that transform into neurosphere-like structures as well as differentiated into β -like cells of the endocrine pancreas^[66], or the outgrown fibroblast-like cells that expand readily and differentiate *in vitro* into aggregates of non-typical hormone-expressing endocrine cells^[85]. Human endocrine cells transduced with a RIP-controlling transgene dedifferentiated into fibroblast-like cells that proliferate up to 16 population doublings without detectable insulin expression^[86]. Nevertheless, *in vivo* Nestin⁺ cells are mostly present in non-endodermal-derived compartments^[87,88]. Governed by their promoters, Pdx1- and RIP-expressing cells have not committed significantly *ex vivo* to the observed cells with fibroblast-like morphology^[89]. These discrepancies require clarifications in the future studies.

CONCLUSION

The presence of MPP remains to be conclusively established. Future development of the field needs to: establish essential criteria for MPP; screen and select cell surface antigens that can be used to generate antibodies for purification of candidate MPP and establish a simple, effective and robust *in vitro* assays and *in vivo* experimental protocols for the examination of the multipotency and lineage commitments of isolated MPP candidates.

The following minimal criteria have to be satisfied: (1) enriched or purified cell population by FACS or other technologies should form colonies at the single cell level; (2) single cells after purification should be studied *ex vivo* with their self-renewability; (3) colony cells would be able to differentiate *in vitro* into multiple functional cellular lineages; and (4) the clonogenic cells post transplanted into a recipient should be able to give rise *in vivo* to different terminally differentiated lineages. Thus, embryonic mouse Sox9⁺ multipotent progenitors and probably adult Sox9⁺ ductal cells satisfy some but not all criteria of MPP. Research into MPP would therefore be highly valuable for two reasons. First, MPP differentiation and trans differentiation of non- β -cell types in the pancreas may provide an important source for surrogate β -cells. Second, as there is a significant difference in regeneration capability of islets from mice, rats to humans, we should not extrapolate directly from rodent regenerative data to humans.

Future MPP research should apply integrated approaches, different from many previous *in situ* or *ex vivo* studies that did not target defined cell populations. Application of flow cytometry and cell surface markers would allow the separation of interested subsets for demonstrating *in vitro* the capacity of self-duplication, clonogenesis and differentiation. The latest technologies

such as single-cell RNA-seq, single-cell genomics and single-cell epigenomics^[90-92] should be applied to examine their developmental dynamics, differentiation pathways, gene interactions and genetic heterogeneity, and along with genetic studies to characterize their growth pattern, biological potential and lineage commitment *in vivo*. Lastly cross-sector, cross-institutional and global collaborations as well as the involvement of the biotechnological and drug companies will eventually deepen our understanding of MPP that assists the establishment of a platform towards a regenerative therapy for both T1DM and T2DM.

Abstract

AIM: To investigate the effect of secreted frizzled-related proteins (sFRPs) on CXC chemokine expression in human mesenchymal stem cells (hMSCs).

METHODS: CXC chemokines such as CXCL5 and CXCL8 are induced in hMSCs during differentiation with osteogenic differentiation medium (OGM) and may be involved in angiogenic stimulation during bone repair. hMSCs were treated with conditioned medium (CM) from L-cells expressing non-canonical Wnt5a protein, or with control CM from wild type L-cells, or directly with sFRPs for up to 10 d in culture. mRNA expression levels of both CXCL5 and CXCL8 were quantitated by real-time reverse transcriptase-polymerase chain reaction and secreted protein levels of these proteins determined by ELISA. Dose- (0-500 ng/mL) and time-response curves were generated for treatment with sFRP1. Signal transduction pathways were explored by western blot analysis with pan- or phosphorylation-specific antibodies, through use of specific pathway inhibitors, and through use of siRNAs targeting specific frizzled receptors (Fzd)-2 and 5 or the

receptor tyrosine kinase-like orphan receptor-2 (RoR2) prior to treatment with sFRPs.

RESULTS: CM from L-cells expressing Wnt5a, a non-canonical Wnt, stimulated an increase in CXCL5 mRNA expression and protein secretion in comparison to control L-cell CM. sFRP1, which should inhibit both canonical and non-canonical Wnt signaling, surprisingly enhanced the expression of CXCL5 at 7 and 10 d. Dickkopf1, an inhibitor of canonical Wnt signaling prevented the sFRP-stimulated induction of CXCL5 and actually inhibited basal levels of CXCL5 expression at 7 but not at 10 d post treatment. In addition, all four sFRPs isoforms induced CXCL8 expression in a dose- and time-dependent manner with maximum expression at 7 d with treatment at 150 ng/mL. The largest increases in CXCL5 expression were seen from stimulation with sFRP1 or sFRP2. Analysis of mitogen-activated protein kinase signaling pathways in the presence of OGM showed sFRP1-induced phosphorylation of extracellular signal-regulated kinase (ERK) (p44/42) maximally at 5 min after sFRP1 addition, earlier than that found in OGM alone. Addition of a phospholipase C (PLC) inhibitor also prevented sFRP-stimulated increases in CXCL8 mRNA. siRNA technology targeting the Fzd-2 and 5 and the non-canonical Fzd co-receptor RoR2 also significantly decreased sFRP1/2-stimulated CXCL8 mRNA levels.

CONCLUSION: CXC chemokine expression in hMSCs is controlled in part by sFRPs signaling through non-canonical Wnt involving Fzd2/5 and the ERK and PLC pathways.

Core tip: Chemokines have multiple functions during bone formation and fracture repair. The ELR⁺ chemokines classically have a role in blood vessel formation and were found to be stimulated by the non-canonical Wnt5a protein and also by soluble frizzled-related proteins (sFRPs) that are known inhibitors of both canonical and non-canonical Wnt signaling. This stimulation was mediated *via* the p44/42 extracellular signal-regulated kinase and phospholipase C pathways signaling through the non-canonical frizzled receptors 2 and 5. This is a newly identified role for the sFRPs in stimulation of ELR⁺ chemokines which may be involved in blood vessel formation during wound repair.

INTRODUCTION

Bone fracture repair proceeds through a series of sequential steps including an inflammatory phase resulting in recruitment and differentiation of mesenchymal stem cells (MSCs) into osteoblasts, restoration of blood supply, subsequent soft (cartilaginous, in the case of endochondral repair) and hard (bone, in both endochondral and intramembranous) callus formation, and ultimately remodeling of the new woven bone into lamellar bone. During the initial inflammatory stage, neutrophils, macrophages, and lymphocytes migrate to the wound, fight infectious organisms, scavenge tissue debris, and begin the process of granulation tissue formation^[1]. Cytokines, chemokines, and growth factors released from these cells are necessary to initiate bone repair in the adult. The pro-inflammatory cytokine, tumor necrosis factor- α (TNF- α) is critical in both long bone fracture as well as intramembranous bone repair^[2,3]. TNF- α can highly induce members of the CXC chemokine family *via* NF- κ B signaling in osteoblasts^[4]. CXC chemokines can be grouped as to whether or not they contain a Glu-Leu-Arg (ELR) motif. ELR⁺ CXC chemokines, such as CXCL8 (IL-8), are present during the inflammatory phase to serve as chemoattractants for neutrophils^[5,6] and exhibit angiogenic activity^[7-9]. Chemokines without the ELR sequence are anti-angiogenic^[9].

Human MSCs (hMSCs) express CXCL8 mRNA^[10-12] and it has been reported that TNF- α can prime hMSCs to upregulate production of several CXC chemokines (highest upregulation with CXCL5 and CXCL8) and induce hMSC migration^[13]. In humans, CXCL8 is a ligand for both CXC receptor 1 (CXCR1) and CXCR2 whereas CXCL5 interacts solely with CXCR2. Angiogenesis in response to CXCL8 has only been associated with CXCR2 signaling^[14-16]. We previously demonstrated that CXCL8 expression can be stimulated with dexamethasone treatment during osteoblastic differentiation^[17] and by low extracellular pH^[18] in hMSCs. We also demonstrated that secreted CXC chemokines induced angiogenic tube formation of a human microvascular endothelial cell line (HMEC-1)^[17] consistent with *in vitro* angiogenesis.

The mouse CXC receptor (mCXCR) is functionally related to hCXCR2^[19]. Mice lacking the mCXCR (mCXCR2^{-/-}) have been described^[20] and some healing^[21] and bone^[22-24] defects have been reported. A second murine CXCR (mCXCR1) has also been identified; although, it has no discernable defect phenotype when inactivated (Jackson Laboratory Stock #005820). We have shown by DEXA and micro computerized tomography analysis that the mCXCR2^{-/-} mice (Jackson Laboratory Stock #002724) have an osteopenic phenotype with decreased trabecular bone volume, number, and thickness without any changes in bone formation and resorption indices^[25]. However, bone quality was affected as femurs had reduced stiffness and a lower ultimate load breaking point^[25]. There was

also a reduction in the blood vessel density in the newly repaired bone in a cranial defect model^[25]. During bone regeneration, ingrowth of blood vessels is required for endochondral bone formation^[1]. These results suggest a potential coupling of mMSC differentiation, bone formation, and angiogenesis in response to mCXCR signaling.

The Wnt family of secreted glycoproteins is involved in differentiation of an assortment of tissues^[26]. Wnts signal through specific seven transmembrane spanning G-protein coupled frizzled (Fzd) receptors *via* both canonical β -catenin signaling, and non-canonical Wnt/calcium and Wnt/planar cell polarity pathways^[27,28]. The highly conserved and redundant nature of the Wnt/Fzd system (19 Wnts and 10 Fzd in humans) only adds to the complexity of this system and confusion as to its role in osteogenesis.

The canonical pathway is characterized by Wnt binding to both Fzd and LRP5/LRP6 co-receptors resulting in activation of Disheveled (Dsh) which inhibits glycogen synthase kinase β (GSK3 β) phosphorylation. In the absence of Wnt binding, GSK3 β phosphorylation ultimately results in β -catenin degradation, preventing its nuclear translocation for activation of target genes. In murine models, evidence suggests that canonical Wnt/ β -catenin signaling is necessary for lineage commitment of pluripotent MSCs to osteochondroprogenitor cells, then to osteoprogenitor cells, and for differentiation to mature osteoblasts while suppressing both chondrogenesis and adipogenesis^[29,30]. However, in hMSC models, β -catenin and canonical Wnt3a can negatively regulate the differentiation of MSCs into the skeletal precursor cells that precede the appearance of the osteochondroprogenitor cells^[31-35]. Additionally, de Boer *et al.*^[36] reported a dose-response relationship in which lower levels of β -catenin stimulated hMSC proliferation while blocking adipogenesis; whereas, higher levels induced expression of alkaline phosphatase. The authors thus concluded that canonical Wnt/ β -catenin signaling could initiate osteogenic differentiation in the human system^[36].

Signal transduction through the non-canonical or β -catenin-independent Wnt pathways has also been shown to inhibit adipogenesis and chondrogenesis in MSC models and to stimulate osteogenesis^[33,37-40] mediated through activation of phospholipase C (PLC), and then through activation of the calcium-calmodulin kinase, nuclear factor of activated T-cells (NFAT), and protein kinase C (PKC) pathways or through the mitogen-activated protein kinase (MAPK) and RhoA pathways. Non-canonical Wnt signaling through traditional canonical Wnt ligands, Wnt3a and Wnt7b, and the non-canonical Wnt ligand, Wnt4, can also lead to osteogenic differentiation in both murine and human MSCs models through the activation of PKC and/or MAPK pathways^[33,41,42]. Levels of non-canonical Wnt5a are increased in the inflammatory environment during early fracture healing^[43] and non-canonical signaling (Wnt4 and Wnt5a) can affect the transition from

proliferative osteoprogenitors to mature osteogenic cells^[44,45]. However, as with canonical signaling, there are conflicting reports as to whether non-canonical Wnt5a can induce osteogenesis^[30,33].

Wnt antagonists which include secreted frizzled related proteins (sFRPs), that can inhibit both canonical and non-canonical Wnt signaling^[46], or the canonical Wnt/ β -catenin Dickkopf (Dkk) inhibitors may also contribute to osteoblast differentiation and mineralization^[30,38,47]. sFRP1 knock-out mice exhibit increased trabecular bone mass due to reduced osteoblast and osteocyte apoptosis^[48] suggesting that Wnt signaling is involved in bone formation. Additionally, long bone fracture healing is enhanced in sFRP knockout mice through canonical Wnt signaling as a consequence of MSCs directed to differentiate into osteoblasts rather than towards cartilage^[49]. However, high sFRP1 levels expressed early in fracture repair in this model would suggest that both canonical and non-canonical Wnt signaling are inhibited in early callus formation. Wnt5a/5b expression was decreased in the sFRP1 knockouts; although, contrary to conventional thought, canonical Wnt7a and Wnt1 were elevated^[49]. There have been other reports of sFRPs enhancing rather than inhibiting Wnt activity^[50] through mechanisms which may involve: (1) sFRP-Wnt binding to each other and facilitating transport and binding of Wnts to Fzd receptors on distant cells; or (2) binding to both Wnt molecules and Fzd receptors simultaneously to activate downstream Fzd signaling^[51]. Many repair processes are stimulated by sFRP2-Wnt interactions including the enhancement of vascular density during granulation tissue formation^[52]; inhibition of cardiomyocyte apoptosis during cardiac repair^[53]; establishment of MSC-endothelial and smooth muscle contacts to stabilize new blood vessel formation^[54]; and stimulation of angiogenesis by sFRP1 (FzIA) independent of VEGF, bFGF2, or angiopoietin1^[55].

A key observation made by several laboratories is that canonical Wnt/ β -catenin signaling may be important in osteoblastogenesis through the cooperation of Wnt signaling with other known osteogenic factors such as BMP-2 and BMP-4^[47,56]. Thus taken together, canonical Wnt/ β -catenin signaling appears to be involved in determining a specific tissue fate of MSCs. However, further effects of Wnt signaling (both canonical and non-canonical) on osteogenic differentiation is dependent on several factors including: The species from which the MSCs are derived, the specific Wnt (and Fzd receptors) expressed, the stage of osteogenic differentiation, the amount of β -catenin available to translocate to the cell nucleus, and other biologically active molecules (*e.g.*, growth factors) present in the MSC's microenvironment^[30,57]. These other factors could include the ELR⁺ CXC chemokines which are also elevated in the inflammatory phase of healing and which have been shown to be stimulated by non-canonical Wnt5a^[58,59]. In this article, we report the observation that sFRP treatment of hMSCs leads to an increased expression of ELR⁺ CXCL5 and CXCL8 which may serve

to attract MSCs to the wound or to couple angiogenesis to osteogenesis in the early phase of bone repair.

MATERIALS AND METHODS

Cell culture

hMSCs, growth supplements, and basal medium were purchased from LonzaWalkersville, Inc. (Walkersville, MD). hMSCs from several donors were used: 19 years old male (Lonza Lot #6F4393; race unknown); 20 years old Caucasian male (Lot #0000351482); 27 years old Black male (Lot #0000318006). Cells were grown in complete medium (HMSCGM) at 37 °C under 95% air/5% CO₂ atmosphere and subcultured once a week at 60%-70% confluence.

For osteoblastic differentiation, hMSCs were treated every 3-4 d with osteogenic medium (OGM) consisting of complete growth medium with 50 mmol/L ascorbic acid-2-phosphate, 10 mmol/L β-glycerophosphate, and 10⁻⁷ mol/L dexamethasone (Sigma-Aldrich, St. Louis, MO).

Cells (passage 2-7) were plated at 5000-10000 cell/cm² in HMSCGM and allowed to adhere for 4 h prior to exposure to OGM ($n \geq 3$ for all experiments). Differentiation toward the osteoblastic lineage was monitored by detection of mRNA levels of the reporter gene alkaline phosphatase or by Alizarin Red staining for calcium at 28 d as previously described^[17]. Qiagen RNeasy Miniprep columns (Qiagen, Inc., Valencia, CA) were used to isolate RNA at the specified time-points. In some experiments exogenous sFRPs (varying concentration from 0-500 ng/mL; PeproTech Inc., Rocky Hill, NJ), Dkk1 (50 ng/mL, PeproTech), and L-cell or Wnt5a-conditioned medium (CM) (1:1 mixture with

HMSCGM) were added as needed. The PLC signal transduction inhibitor (U73122) and control (U73343) were used at 10 μmol/L (Calbiochem, San Diego, CA). Effects of siRNA inhibition of receptors were determined by transfection of hMSCs with siRNA (150 ng/mL) using the HiPerFect transfection reagent (Qiagen) followed by treatment of the cells with sFRPs for 48 h before gene expression analysis. siRNA were purchased from Qiagen and the nucleotide sequences indicated in Table 1. A scrambled oligonucleotide siRNA was used as a negative control.

Quantitative reverse transcriptase-polymerase chain reaction

Relative mRNA levels of various genes were determined by real-time RT-PCR using the Opticon Continuous Fluorescence System (Bio-Rad Laboratories, Inc., Hercules, CA) and the SYBR Green RT-PCR kit (Qiagen). Primers used for RT-PCR are indicated in Table 2.

PCR reactions were performed in triplicate. Reactions consisted of reverse transcription at 50 °C (30 min), inactivation at 95 °C (15 min); followed by 50 cycles of denaturing at 94 °C (15 s), annealing at 60 °C (30 s), and extension at 72 °C (30 s). Gene expression changes were calculated and normalized to 18S ribosomal levels and the reference time point using the 2^{-ΔΔC(T)} method^[60].

ELISA analysis

Secreted CXCL5 protein levels were determined with the human CXCL5/ENA-78 DuoSet (R and D Systems, Minneapolis, MN) after concentration of supernatants with microcon centrifugal filters (EMD Millipore Inc, Billerica, MA). Culture supernatant samples were compared to CXCL5 standard curves and were run in duplicate.

Western blot analysis

Cells were plated in 35 mm dishes and treated with OGM medium (7 d). sFRP1 (150 ng/mL) was added and cell lysates isolated at indicated time points in PhosphoSafe Extraction Reagent (EMD Chemicals, Gibbstown, NJ). Proteins were separated (SDS-PAGE), transferred to polyvinylidenedifluoride membrane, and probed with ERK-specific pan or phospho-antibodies (Cell Signaling Technology, Danvers, MA). Immunoreactive proteins were detected using the ECL kit (GE Healthcare Bio-sciences, Piscataway, NJ) and levels quantitated using AlphaView Software (ProteinSimple, San Jose,

Figure 1 CXCL5 chemokine induction in human mesenchymal stem cells treated with osteogenic medium or non-canonical Wnt5a. A: CXCL5 mRNA levels are induced at 7 d in complete osteogenic medium or medium containing 0.1 $\mu\text{mol/L}$ dexamethasone. Conditioned medium containing non-canonical Wnt5a induces (B) mRNA expression and (C) protein secretion. All values are mean $\pm$ SD. ^a $P < 0.05$; ^b $P < 0.01$ vs HMSCGM-treated group. HMSCGM: Human mesenchymal stem cell growth medium; DEX: Dexamethasone; OGM: Osteogenic medium; L-cell: Conditioned medium from L-cells; Wnt5a: Conditioned medium from L-cells expressing Wnt5a.

CA).

Statistical analysis

Data values are reported as mean $\pm$ SD. Statistical analysis (1-way ANOVA with the Bonferroni method for multiple comparisons between pairs or non-parametric Mann-Whitney *t* test) was performed using GraphPad Prism software. Differences from negative controls were considered to be statistically significant at the $P < 0.05$ level.

RESULTS

We had previously demonstrated that mRNA and protein for CXCL8 (IL-8) and CXCL1 (GRO α)^[17] were

induced in hMSCs exposed to osteogenic differentiation medium (OGM) containing ascorbate-2-phosphate, β -glycerophosphate, and dexamethasone. To see if another angiogenic CXC chemokine, CXCL5 (ENA-78), was also induced by osteogenic differentiation, RNA from hMSCs treated with OGM was analyzed for CXCL5 expression levels. OGM treatment for 7 d stimulated CXCL5 mRNA levels approximately 8-fold ($P < 0.01$; Figure 1A). Dexamethasone alone (0.1 $\mu\text{mol/L}$) in the presence of proliferating medium (HMSCGM) increased CXCL5 mRNA by 5.5-fold ($P < 0.01$).

Non-canonical Wnt signaling has also been associated with osteogenic differentiation of hMSCs^[32,61]. Since osteogenic differentiation using OGM or dexamethasone alone resulted in CXCL5 mRNA expression, we then explored if treatment of hMSC cells with non-canonical Wnt5a protein was able to stimulate the expression of CXCL5. hMSC cells were treated for 7 d with CM from L-cells overexpressing Wnt5a protein or control L-cell CM. CM containing Wnt5a induced the expression of CXCL5 mRNA 3-fold ($P < 0.05$) compared to the lack of stimulation of CXCL5 in both non-osteogenic medium (HMSCGM medium) or control L-cell medium (Figure 1B). CXCL5 protein secretion was also increased 1.5-fold ($P < 0.05$) above controls (Figure 1C).

We next sought to inhibit all Wnt signaling, both canonical and non-canonical Wnt signaling, using sFRPs. Surprisingly and unexpectedly, sFRP1 increased CXCL5 mRNA levels 3-fold ($P < 0.01$) at 7 d and approximately 8-fold ($P < 0.01$) at 10 d of culture in HMSCGM medium (Figure 2A). To see if canonical Wnt signaling inhibition was responsible for the unexpected stimulation of CXCL5, hMSCs were treated with Dkk1 which binds to the low density lipoprotein receptor related protein 6 (LRP6) to inhibit canonical signaling. Unlike sFRP-1, Dkk1 addition did not induce an increase in CXCL5 levels at 7 or 10 d and in fact significantly inhibited basal mRNA expression levels more than 50% ($P < 0.01$) at 7 d (Figure 2A). To see if the effect of sFRP1 on CXCL5 was unique amongst the other sFRP family members, sFRPs 2, 3, or 4 was each added separately to the medium (150 ng/mL) for 7 d and levels of CXCL5 protein secreted into the medium determined. All four sFRPs added independently significantly stimulated CXCL5 protein secretion 3-4-fold ($P < 0.01$) over unstimulated vehicle control (Figure 2B).

We next tested if CXCL8 mRNA levels are also stimulated by sFRP1 treatment. sFRP1 treatment increased CXCL8 mRNA levels in a dose-dependent manner (Figure 2C). Maximum stimulation of CXCL8 mRNA expression (approximately 5-fold) was observed at a concentration of 150 ng/mL sFRP1 ($P < 0.05$). A time-course study of CXCL8 mRNA expression stimulated by sFRP1 (150 ng/mL) showed maximal expression levels ($P < 0.05$) between 5 and 7 d of culture (Figure 2D).

In an effort to explore the mechanism of the sFRP1-stimulated increase in both CXCL5 and CXCL8 expres-

Figure 2 Secreted frizzled-related protein-stimulated expression of CXCL5 and CXCL8 in human mesenchymal stem cells. A: sFRP1, an inhibitor of canonical and non-canonical Wnt signaling, induces expression of CXCL5 mRNA. Dkk1, an inhibitor of canonical Wnt signaling does not induce CXCL5; B: All four of the sFRPs stimulated CXCL5 protein secretion as determined by ELISA analysis of cell supernatants. sFRP1 induces expression of CXCL8 mRNA in a dose- (C) and time- (D) dependent manner with maximum expression at 150 ng/mL and 7 d post-treatment. All values are mean $\pm$ SD. $^aP < 0.05$; $^bP < 0.01$ vs HMSCGM-treated group (A, B), vs untreated (C), or 3-d CXCL8 mRNA levels (D). HMSCGM: Human mesenchymal stem cell growth medium; sFRP: Secreted frizzled-related protein; Dkk1: Dickkopf-related protein 1.

Figure 3 Phosphorylated state of mitogen-activated protein kinase p44/42 extracellular-signal-regulated kinases in response to secreted frizzled-related protein 1 stimulation. Western Blot time-course analysis of pan and phosphorylated states of the MAPK p44/42 ERK proteins (A); The ratio of phospho/pan p44/42 ERK reaches a maximum at 5 min in the presence of OGM and sFRP1 (B); whereas, in OGM alone the maximal ratio level is not reached until 10 min post stimulation (representative experiment). sFRP1: Secreted frizzled-related protein 1; MAPK: Mitogen-activated protein kinase; ERK: Extracellular-signal-regulated kinases; OGM: Osteogenic medium.

ssion, we characterized the phosphorylated state of the extracellular signal-regulated kinase (ERK) p44/42, a member of the MAPK pathway, since it has been previously reported that CXC ligand expression can be increased *via* MAPK activation^[62-66]. p44/42 was shown to be phosphorylated maximally at 5 min in the presence of OGM and sFRP1, whereas maximal p44/42 phosphorylation occurred at 10 min in OGM alone (Figure 3).

To see if other G-protein coupled signaling mechanisms could be involved in sFRP stimulation of CXCL8 mRNA expression, the PLC inhibitor, U73122, was added (10 μ mol/L) to the HMSCGM medium and CXCL8 mRNA levels determined after 3 d of sFRP treatment. Both sFRP1 and sFRP2 in the presence of the inactive isomer, U73343, enhanced CXCL8 mRNA by approximately 3 to 5 fold ($P < 0.05$). However, U73122 prevented the increase in both sFRP1- and sFRP2-stimulated CXCL8 mRNA levels returning them back to HMSCGM control levels (Figure 4).

Since Fzd receptors are G-protein coupled seven transmembrane receptors, it was further investigated if the sFRP stimulation of CXCL8 could be through interactions with specific frizzled receptors. Fzd2 and Fzd5 have been associated with non-canonical Wnt signaling^[67,68]; whereas, Fzd7 is associated with canonical signaling^[69]. sFRP1, 2 and 3 all stimulated CXCL8 mRNA levels in the presence of a scrambled

Figure 4 Modulation of secreted frizzled-related protein-stimulated induction of CXCL8 mRNA. sFRP1/2-stimulated CXCL8 mRNA expression is suppressed in the presence of the PLC inhibitor U73122 suggesting that signaling is *via* the Wnt/calcium non-canonical pathway (values are mean $\pm$ SD). ^a $P < 0.05$ vs HMSCGM-treated levels. sFRP1/2: Secreted frizzled-related protein 1/2; PLC: Phospholipase C.

siControl siRNA (7 to 10-fold for sFRP1 and sFRP2; 3-fold for sFRP3). In the presence of siRNA to Fzd2 and 5, the sFRP-stimulation was almost entirely inhibited back to baseline levels ($P < 0.05$; Figure 5A and B). siRNA to Fzl7 did not have any effect on sFRP1 or sFRP2 induction of CXCL8 mRNA (data not shown). The receptor tyrosine kinase-like orphan receptor-2 (RoR2) has been shown to be either a stand-alone receptor or co-receptor with Fzd in non-canonical Wnt signaling^[70,71]. siRNA directed against RoR2 inhibited sFRP1-stimulated CXCL8 mRNA expression by approximately 65% but did not have an effect on sFRP2-stimulated CXCL8 mRNA expression (Figure 5C).

DISCUSSION

sFRPs have been traditionally thought to act as Wnt signaling antagonists by binding to Wnt molecules and preventing them from binding to Fzd receptors thus inhibiting signal initiation^[72]. Interaction of Wnts with Fzd receptors has been hypothesized to occur *via* interaction with the extracellular cysteine-rich domains (CRDs) found in Fzd receptors. sFRPs also contain N-terminal CRDs, but without the transmembrane domain characteristic of Fzd receptors^[73], and it has been demonstrated that sFRP interaction with Wnts occurs through binding within this CRD^[74,75]. Additionally, Bafico *et al.*^[75] found that at least one sFRP could also bind to a selected Fzd (e.g., Fzd6) and hypothesized that heteromeric complex of Fzd and sFRPs would render Fzd receptors nonfunctional.

However, there has been emerging evidence that sFRPs may not only function as Wnt antagonists or anti-morphogens but also serve as molecules that promote differentiation of specific tissues. It has been suggested that sFRPs may aid in Wnt protein distribution and signaling within tissues. Wnt proteins interact with heparin sulfate proteoglycans thereby limiting diffusion

Figure 5 Effect of siRNA directed to frizzled receptors or receptor tyrosine kinase-like orphan receptor-2 on secreted frizzled-related protein-stimulated CXCL8 mRNA levels. sFRP-stimulated CXCL8 mRNA expression is inhibited in the presence of siRNAs directed toward non-canonical (A) Fzd2 and (B) Fzd5 or (C) the non-canonical Frizzled co-receptor RoR2. All values are mean $\pm$ SD. ^a $P < 0.05$ vs untreated siControl levels for each graph. sFRP1-3: Secreted frizzled-related protein 1-3; siFzd2/5: siRNA to the non-canonical frizzled receptor 2/5; RoR2: Receptor tyrosine kinase-like orphan receptor-2; siRoR2: siRNA to RoR2; siControl: Scrambled control siRNA.

of the Wnt proteins within tissues. sFRPs may compete with this binding, enabling the Wnt-sFRP "transport" complexes that are formed to diffuse along a more extended gradient allowing for longer range Wnt signaling within the tissue^[76] thereby aiding in tissue generation or differentiation. In one mouse model system, MSCs engineered to overexpress protein kinase B (also known as Akt) produce high levels of sFRP2 which can effectively limit cardiac muscle infarct size through the inhibition of cardiomyocyte apoptosis^[53].

The increased sFRP2 led to increased levels of nuclear β -catenin thus enhancing canonical Wnt signaling and increased transcription of anti-apoptotic genes such as Birc1b and to a lesser extent Bcl2.

Others have reported links between non-canonical Wnt signaling and sFRP-mediated differentiation processes. Chung *et al.*^[77] reported that sFRP3 could increase osteoblast differentiation in the mouse pre-osteoblastic cell line, MC3T3-E1, by increasing alkaline phosphatase, osteocalcin, and promoting mineralization of MC3T3-E1 cultures. Endostatin, which promotes degradation of β -catenin independent of GSK3 β , did not abrogate sFRP3-stimulated osteogenic differentiation suggesting that non-canonical Wnt signaling may be involved in the sFRP3 effect. Esteve *et al.*^[78] also reported that chick sFRP1 enhanced retinal differentiation by increasing the generation of retinal ganglion and photoreceptor cells independent of cell proliferation. This group noted that canonical Wnt- β -catenin signaling was not involved in this process; although, they did find that phosphorylation of GSK3 β down-regulated its activity while promoting retinal cell differentiation. The authors were unclear if non-canonical Wnt signaling was involved in the sFRP1 findings at that time. In a subsequent communication, this group reported that chick sFRP1 binds to Fzd2 to stimulate axonal outgrowth from retinal neurons^[79]. Furthermore, the action of sFRP1 on the retinal ganglion cells was dependent on cAMP and cGMP in a pertussis toxin-sensitive manner suggesting that sFRP1 acted as an agonist for Fzd2 non-canonical Wnt signaling.

Several reports have shown that sFRPs were involved in stimulating angiogenesis through canonical Wnt signaling but independent of VEGF signaling^[54,55,80]. In studies utilizing MRL/MpJ mice, which have enhanced regenerative capacity, it was found that MRL/MpJ bone marrow MSCs showed decreased expression of cyclin D1, Sox2, and Axin2, which are target genes of canonical Wnt signaling. Concomitantly, sFRP2 and sFRP4 expression was found to be significantly up-regulated^[52] in these cells. It was also reported that sFRP2 overexpression in mouse MSCs that were then injected into the cardiac peri-infarct area reduced infarct size and improved cardiac function similar to that seen when MRL/MpJ MSCs were injected. Of note, vascularization of granulation tissue was also enhanced by sFRP2 overexpression. This was also reported in another MRL/MpJ MSC engraftment wound healing model^[52] whereby sFRP2 overexpression in mouse MSCs increased levels of several angiogenic factors including FGF2 receptor, PDGF receptor beta, VEGF, and angiopoietins among others. While the authors concluded that the increased sFRP2 inhibited canonical Wnt signaling which may be related to the increased angiogenesis, non-canonical Wnt signaling was not examined. Furthermore, the expression of ELR⁺ CXC chemokines that are also angiogenic was not assessed.

There are a number of steps that occur in new blood vessel formation, several of which have been linked to sFRP1 signaling, including endothelial cell

(EC) spreading, proliferation and migration, vascular channel formation, and blood vessel stabilization. sFRP1 has been shown to enhance angiogenesis in a chick chorioallantoic membrane model of angiogenesis and to increase blood vessel density in a tumor implantation model^[55]. EC spreading was hypothesized to be a result of an interaction of sFRP1 with Fzd4 and Fzd7 thereby blocking Fzd activity and has also been shown to be independent of canonical Wnt- β -catenin signaling; although, this process still involving GSK3 β upstream of Rac 1 signaling^[80]. sFRP1 has also been shown to stimulate EC migration and chemotaxis *in vitro*, increase EC branching in capillary structures when cultured on Matrigel, and inhibit EC apoptosis^[55]. EC and vascular smooth muscle cell proliferation are also inhibited as evidenced by slower entry into S-phase as well as decreased expression of the cell cycle components cyclin D1 and cdk4^[81]. This latter inhibition of vascular cell proliferation appeared to be dependent on inhibition of canonical Wnt- β -catenin signaling but not MAPK signaling through ERK1/2. Vessel maturation and stabilization of EC channels by pericytes or MSCs were also enhanced by sFRP1 stimulated cell-cell interactions between MSCs and ECs or smooth muscle cells in a GSK3 β -dependent manner. Interestingly, sFRP1 increased α -smooth muscle actin expression in MSCs suggesting differentiation of MSCs to pericytes which are involved with blood vessel stabilization. Furthermore, the localization of β -catenin at cell-cell junctions rather than intranuclear locations could further support a non-canonical Wnt signaling mechanism. Others have also reported that sFRP2 can also stimulate EC migration and tube formation as well as inhibit hypoxia-induced EC apoptosis through a non-canonical Wnt-calcium pathway involving an increase in NFATc3 nuclear translocation^[82,83].

The mechanism of how sFRPs stimulate angiogenesis is currently unknown. sFRP1, which did not induce expression of the known angiogenic factors VEGF or FGF2, did increase expression of PDGF-BB which is involved in postnatal blood vessel maturation^[84]. Expression of other angiogenic factors such as the ELR⁺ CXC chemokines could potentially be the result of sFRP1 actions. Indeed we are the first to report here that sFRPs are able to induce the ELR⁺ CXC chemokines CXCL5 and CXCL8 in hMSCs. Rauner *et al.*^[85] has shown that human bone marrow MSCs stimulated with pro-inflammatory factors (lipopolysaccharide or TNF- α) resulted in Wnt5a and Ror2 increases in mRNA and protein. The expression of the ELR⁺ CXC chemokines, CXCL1, CXCL2, and CXCL5, was also increased with Wnt5a treatment of these hMSCs. Additionally the CC chemokines, CCL2, CCL5, CCL7, and CCL19 were also upregulated, although, to a lesser extent than the CXC chemokines CXCL1 and CXCL5. Albers *et al.*^[59] also reported that Fzd9 knockout mice demonstrated an osteopenic phenotype caused by decreased bone formation which was unrelated to canonical Wnt signaling^[59]. The presumed non-canonical Wnt regulation

of bone mass in Fzd9-deficient mice was also shown to have significantly decreased CXCL5 expression. In these studies, treatment of wild type osteoblasts with Wnt5a showed a 12-fold increase in CXCL5 mRNA. In a fracture repair model in Fzd9-deficient mice, protein expression of CXCL5 and CCL2 in the healing callus was diminished in comparison to wild-type, and overall new bone in the Fzd9 knockout mice was reduced^[86]. Most recently, Zhao *et al.*^[87] reported that in human dental pulp cells, non-canonical Wnt5a significantly induced CXCL8, CCL2, and CCL5 mRNA and protein expression, as well as increasing CXCL1 mRNA expression. CXCL5 expression was not tested in response to Wnt5a stimulation in this model.

The signaling mechanism(s) responsible for sFRPs induction of ELR⁺ CXC chemokine expression are unknown. Our results suggest that ELR⁺ CXC chemokine stimulation by sFRPs in human bone marrow-derived MSCs is *via* non-canonical Wnt signaling. MAPK, specifically though ERK1/2, and PLC pathways appear to play a role in sFRP stimulation of the ELR⁺ CXC chemokines. PLC signaling can be upstream of MAPK/ERK^[88] and perhaps the non-canonical Wnt-calcium pathway is involved. Our findings that inhibition of sFRP-induced ELR⁺ CXC chemokine expression by PLC as well as demonstration of ERK phosphorylation upon sFRP stimulation of MSCs are consistent with potential sFRP signaling thru serpentine G protein-coupled receptors such as the Fzd receptors. Furthermore, our data demonstrating prevention of sFRP1-stimulated CXCL8 mRNA induction with siRNA-directed inhibition of the non-canonical Fzd2 and Fzd5 are also consistent with a role of sFRP-Fzd receptor interaction in ELR⁺ CXC chemokine genesis. How RoR2 either acting as a co-receptor with non-canonical Fzd receptors or independently fits in to the regulation of ELR⁺ chemokine expression is currently unknown. Since these angiogenic chemokines are expressed during the inflammatory phase of wound healing, these chemokines could contribute to several aspects of bone repair including attraction of additional MSCs to the site for differentiation or attraction of endothelial cells for generation of vascularized granulation tissue and stimulation of angiogenesis as we had previously demonstrated^[17]. Thus, in addition to regulation of Wnt signaling as inhibitory substances, our study adds to a growing body of knowledge on the stimulatory functions of sFRPs. Specifically, a novel function of sFRPs in stimulating angiogenic chemokines can be envisioned that may aid in wound and bone repair.

COMMENTS

Background

Mesenchymal stem cells (MSCs) have the capability to differentiate into several cell types including adipocytes, chondrocytes, and osteoblasts and thus have high potential as treatment for repairing bone defects. This process requires the interaction of various growth factors, chemokines, and signaling pathways resulting in the necessary inflammatory, angiogenic, and osteogenic stages of bone repair.

Research frontiers

Although much attention has been placed on the role of the major angiogenesis proteins (vascular endothelial growth factor and fibroblast growth factors) and the Wnt system in bone repair, not much research has been conducted on the role of the ELR⁺ chemokines in this process. These chemokines also have important functions in inflammation and blood vessel formation and have been shown to be stimulated by non-canonical Wnt signaling and during osteogenic differentiation of MSCs.

Innovations and breakthroughs

In this report, the authors demonstrate that treatment of human MSC (hMSC) with the soluble frizzled-related proteins (sFRPs), which should inhibit both canonical and non-canonical Wnt signaling, actually stimulates the expression of the angiogenic CXC ELR⁺ chemokines CXCL5 and CXCL8. CXC ELR⁺ chemokine stimulation was mediated through the non-canonical frizzled receptors 2 (Fzd2) and Fzd5 Wnt receptors and the RoR2 co-receptor. This adds to the data suggesting non-canonical Wnt control of several bone formation processes through expression of the ELR⁺ chemokines and identifies a potential new role for the sFRPs in coupling ELR⁺ chemokine angiogenesis to bone repair.

Applications

Many recent reports have focused on the use of native or genetically engineered MSCs as a treatment to speed up or enhance the quality and mineralization of bone in wound and bone defect models. The ability of the sFRPs to stimulate ELR⁺ CXC chemokines detailed in this study may suggest another avenue for manipulation of bone formation pathways and may eventually lead to a therapeutic treatment to hasten bone healing and return bone strength back to pre-injury levels.

Terminology

MSCs: Multipotent stromal cells that can be differentiated into several cell types including cartilage (chondrocytes), bone (osteoblasts), fat (adipocytes) and muscle (myocytes); ELR⁺ CXC chemokines: Family of small cytokines secreted by cells and containing a Cys-X-Cys domain. CXC chemokines can be further divided into those with or without a Glu-Leu-Arg (ELR⁺) motif. ELR⁺ CXC chemokines are angiogenic. ELR⁻ CXC chemokines are angiostatic. Wnt signaling: family of signaling molecules (Wnts) and Fzds that are important in many developmental pathways including cell fate, proliferation, and differentiation; sFRPs: Family of proteins that inhibit Wnt signaling by acting as soluble, decoy receptors preventing Wnt binding to Fzds.

Peer-review

The paper found that CXC chemokine expression in hMSC is controlled in part by sFRPs signalling through non-canonical Wnt involving Fzd2/5 and the ERK and PLC pathways. The results are interesting.
