We demonstrated Que ameliorates oxidative stress-induced senescence of NPMSCs and delays the progression of IDD. Que may be a potential agent for the treatment of IDD.

ACKNOWLEDGEMENTS

We also thank Figdraw for the assistance in drawing graphical abstract.

Abstract

BACKGROUND

Local mesenchymal stem cell (MSC) therapy for complex perianal fistulas (PFs) has shown considerable promise. But, the long-term safety and efficacy of MSC therapy in complex PFs remain unknown.

AIM

To explore the long-term effectiveness and safety of local MSC therapy for complex PFs.

METHODS

Sources included the PubMed, EMBASE, and Cochrane Library databases. A standard meta-analysis was performed using RevMan 5.3.

RESULTS

After screening, 6 studies met the inclusion criteria. MSC therapy was associated with an improved long-term healing rate (HR) compared with the control condition [odds ratio (OR) = 2.13; 95% confidence interval (95%CI): 1.34 to 3.38; P = 0.001]. Compared with fibrin glue (FG) therapy alone, MSC plus FG therapy was associated with an improved long-term HR (OR = 2.30; 95%CI: 1.21 to 4.36; P = 0.01). When magnetic resonance imaging was used to evaluate fistula healing, MSC therapy was found to achieve a higher long-term HR than the control treatment (OR = 2.79; 95%CI: 1.37 to 5.67; P = 0.005). There were no significant differences in long-term safety (OR = 0.77; 95%CI: 0.27 to 2.24; P = 0.64).

CONCLUSION

Our study indicated that local MSC therapy promotes long-term and sustained healing of complex PFs and that this method is safe.

Key Words: Complex perianal fistula; Mesenchymal stem cells; Long-term evaluation; Meta-analysis

Core Tip: The long-term safety and efficacy of mesenchymal stem cell (MSC) therapy for complex perianal fistulas (PFs) remain unknown. So, we explored the long-term effectiveness and safety of local MSC therapy for complex PFs. We found that MSC treatment is a safe and effective method that can significantly improve the long-term healing of complex PFs, and this method confers no risk of MSC-related adverse events.

INTRODUCTION

A perianal fistula (PF) is an epithelialized tract that connects the luminal surface of the anal canal or rectum with the perianal or perineal skin. It affects approximately 2 in 10000 people and represents a difficult therapeutic challenge and a source of physical and psychological morbidity with a long-term risk of proctectomy[1]. The most severe form is complex PF, which is difficult to manage, as it has a high rate of recurrence and may cause sphincter damage and fecal incontinence. Complex PF is defined as cases with more muscle involvement or anterior fistulas in female patients, as well as recurrent fistulas, suprasphincteric fistulas, extrasphincteric fistulas, horseshoe fistulas, fistulas associated with irritable bowel disease, transsphincteric fistulas that involve greater than 30% of the external sphincter and fistulas associated with preexisting fecal incontinence, inflammatory bowel disease, radiation, malignancy, or chronic diarrhea. PFs are also a probable consequence of Crohn's disease (CD) since as many as 26% of CD patients eventually develop a PF within 20 years after diagnosis[2,3]. Complex PFs in patients with CD have a high recurrence rate and cause a vast range of complications that significantly reduce quality of life (QoL)[4]. In addition, there is a risk of developing a neoplasm in the PF area related to the complexity and perianal disease duration[5]. The results of one study showed that complex PFs may lead to anal cancer in approximately 28% of patients within 20 years after diagnosis[6]. Complex PF is a chronic, recurrent immune-mediated disease with a variety of treatment options. Its exact pathogenesis is unknown. The key long-term therapeutic goals for the treatment of complex PF are to: (1) Resolve fistula discharge; (2) achieve fistula healing; (3) prevent fistula recurrence; (4) maintain fecal continence; (5) avoid long-term diversion (protectomy with stoma), and hence; and (6) improve and maintain QoL for patients. Although current treatments for PFs include a range of medical and surgical options, managing this condition is difficult. Patients with complex PFs tend to have poor treatment outcomes or experience frequent relapses, and most interventions are ineffective in providing long-term healing[7-10]. Immunomodulators can have serious side effects. Additionally, there is a risk of opportunistic infection associated with the use of biological treatments. In more severe cases of complex PF, fecal incontinence can occur, furthering morbidity. Complex PF is often not permanently cured by surgery, leading to multiple procedures and complications such as fecal incontinence. Therefore, there is a need for an effective therapy that provides long-term healing of complex PFs without the risk of fecal incontinence.

In recent years, local injection of mesenchymal stem cells (MSCs) has shown notable promising results in the treatment of PFs[11]. MSCs are a heterogeneous subset of stromal stem cells. They can be isolated from a wide variety of tissues and expanded *in vitro* to obtain large quantities. MSCs are characterized by multilineage differentiation and powerful immunomodulatory effects and are able to mitigate inflammatory states. Complex PF is thought to arise from an epithelial defect, which may be caused by ongoing inflammation. Current treatments cannot maintain long-term healing of the disease. Possible alternative treatments include cell therapy, especially MSC therapy. Local administration is the most performed approach to deliver MSCs. After being delivered directly to fistula tracts, MSCs induce peripheral tolerance and migrate to injured tissues, where they can inhibit the release of proinflammatory cytokines and promote the survival of damaged cells. Consequently, MSCs are capable of repairing damaged tissues and promoting tissue healing, which can lead to long-term fistula healing, significantly improving patients' quality of life. An increasing number of studies have indicated that local MSC therapy is safe and efficacious for complex PFs. In 2020, to evaluate whether local MSC therapy for complex PFs is effective and safe, we conducted a meta-analysis. That study, with a follow-up of 8 wk to 2 years, showed that local MSC therapy for complex PFs was safe and feasible. However, the efficacy and safety evaluation period of the study was short and middle term[12]. Therefore, the long-term efficacy of MSC therapy is unclear. To date, an increasing number of studies have aimed to perform long-term evaluations of MSC therapy for PFs. Thus, based on a previous study[12], this study aimed to explore the long-term effectiveness and safety of MSC therapy for complex PFs (48 wk to 4 years of follow-up after MSC therapy).

MATERIALS AND METHODS

Data source and search strategies

This meta-analysis followed the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines[13]. In August 2022, a search was performed in the PubMed, EMBASE and Cochrane Library databases for clinical studies written in English regarding local MSC treatment in patients with complex PFs. The following search terms were used: "Mesenchymal stem cell'', "mesenchymal stromal cell", "complex perianal fistula", "perianal fistula", "complex perianal Crohn's disease", "Crohn's perianal fistula", "perianal Crohn's disease", "Crohn's disease", "perianal fistulizing Crohn's disease", "cryptoglandular perianal fistula", and "long-term". We also checked the reference lists of the screened full-text studies to identify other potentially eligible trials.

Study selection

Two authors independently assessed studies for inclusion by screening titles and abstracts. The inclusion criteria were: (1) Studies of human subjects; (2) randomized clinical trials (RCTs) and retrospective studies or cohort studies of patients with complex PFs treated with local injection(s) of autologous or allogeneic MSCs from any source; (3) local injection of MSCs or MSCs combined with fibrin glue (FG) for complex PFs; and (4) assessment of the efficacy and/or safety of MSC therapy at least 48 wk after treatment.

Data extraction and quality assessment

A customized data extraction form was used by two authors to extract data. These authors extracted study data features including: (1) Study characteristics (first author, publication year); (2) MSC origin; (3) definition of fistula healing [clinical and/or magnetic resonance imaging (MRI)]; (4) study outcomes; (5) dosage and modalities of intervention administration; (6) adverse events (AEs); and (7) concomitant treatment (anti-TNF). Table 1 lists the basic characteristics of the 6 identified studies. Quality assessment was performed using Review Manager (version 5.3) according to the recommendations from the Cochrane Collaboration. The bias risk assessment tool recommended by Cochrane was used to assess the quality of all enrolled studies. Each item of studies was judged as having a high, low or unclear risk of bias.

Statistical analysis

Based on the included studies, odds ratios (ORs) and corresponding 95% confidence intervals (95%CIs) were calculated to compare the MSC groups and control groups. Heterogeneity was quantified using the I^2 statistic. If the I^2 value was ≤ 50%, heterogeneity was considered low, and we employed a fixed-effect model. If the I^2 value was > 50%, heterogeneity was considered high, and we employed a random-effect model. All statistical analyses were performed using Review Manager (version 5.3). A value of $P < 0.05$ was considered statistically significant.

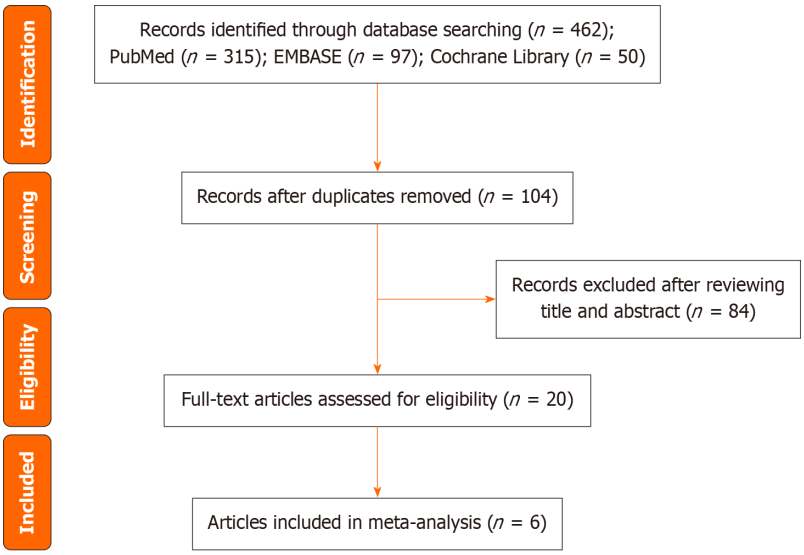
RESULTS

Literature search and quality assessment

The literature search process is illustrated in Figure 1. Using this search strategy, we identified 462 references related to local MSC treatment for complex PF, of which 358 duplicate articles were removed. After reading the titles and abstracts, we identified 20 articles for full-text review. Ultimately, after all criteria were applied, 6 articles were included in the meta-analysis[14-19]. A summary of the risk of bias in the included articles is presented in Figure 2.

Long-term efficacy of MSCs in complex PF (48 wk to 4 years of follow-up after MSC therapy)

Our meta-analysis included 6 studies that assessed the long-term efficacy of post-MSC treatment. The pooled analysis showed that MSC therapy was associated with an improved long-term healing rate (HR) compared with the control condition (OR = 2.13; 95%CI: 1.34 to 3.38; $P = 0.001$) (Figure 3). The benefit was sustained for at least 48 wk of follow-up after MSC therapy.



Long-term efficacy of MSCs for complex PF (MSCs + FG vs FG alone)

Cell therapy strategies using MSCs carried in FG have shown promising results in regenerative medicine. FG is a natural polymer involved in the coagulation process. In regenerative medicine, FG can be used as a delivery system for drugs, biomolecules, growth factors and cells. FG also provides a temporary structure that favors angiogenesis, extracellular matrix deposition and cell-matrix interactions and it also FG maintains the local and paracrine functions of MSCs, providing tissue regeneration through less invasive clinical procedures. The biological properties of FG as a growth environment for MSCs have been reported in several studies[20]. Now, local FG combined with MSCs therapy is still a relatively new treatment and has not yet gained popularity. So, the need for the local FG combined with MSCs therapy remains unknown. In our meta-analysis, three studies were included that reported local FG combined with MSCs therapy for PF[14,15,17], with low heterogeneity between the studies ($I^2 = 0\%$). In a fixed-effects model, MSCs plus FG had more long-term efficacy for fistula healing than FG alone (OR = 2.30; 95%CI: 1.21 to 4.36; $P = 0.01$) (Figure 4). So, we think local FG combined with MSCs therapy have synergistic effect on PF.

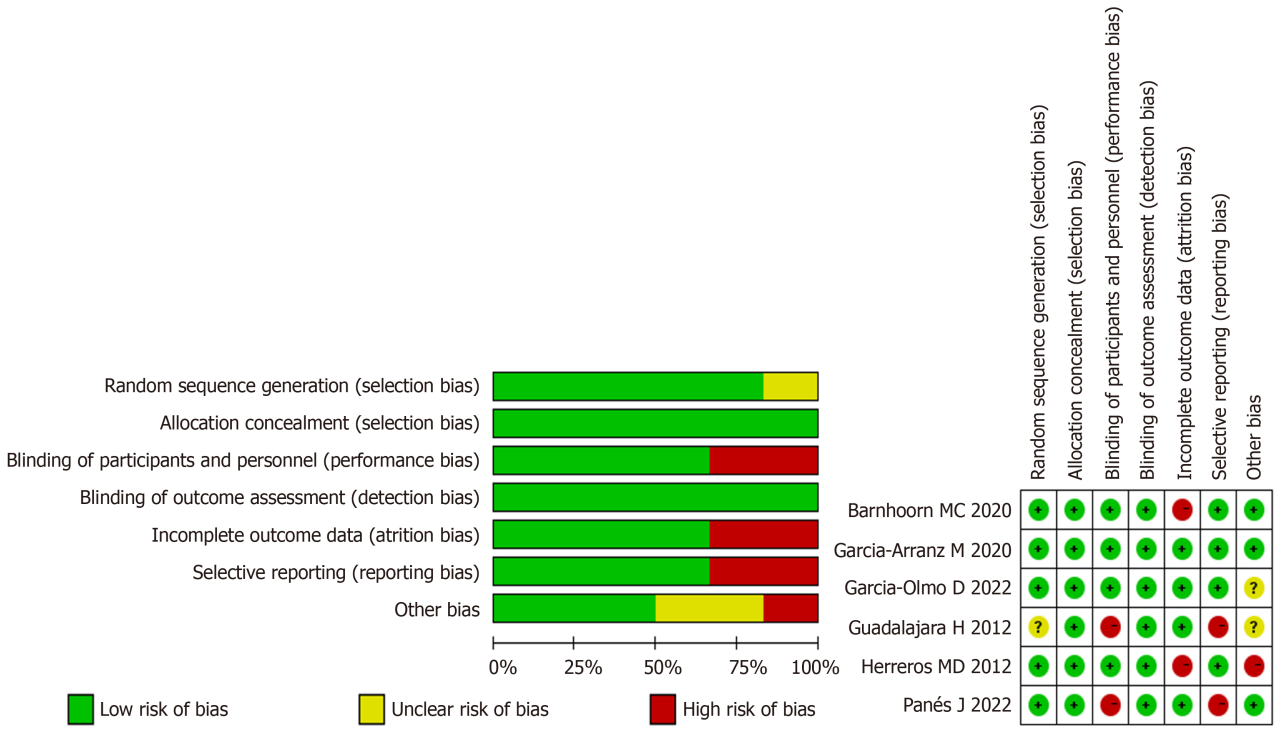
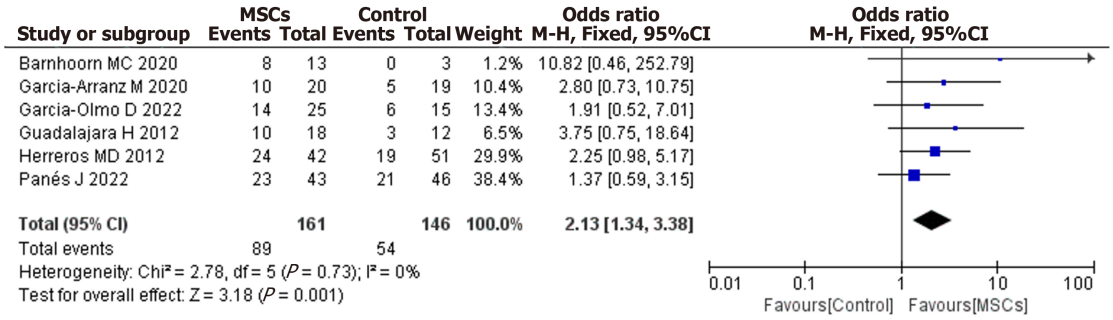
MRI as the standard for evaluating fistula healing



In our meta-analysis, MRI was used to evaluate fistula healing in 3 studies. The pooled analysis showed that MSC therapy was associated with improved long-term HR (OR = 2.79; 95%CI: 1.37 to 5.67; P = 0.005) (Figure 5).

Long-term safety

Only two studies[16,19] in this review assessed the long-term safety of MSC treatment for complex PF. The pooled results demonstrated that MSC treatment did not increase the risk of any long-term adverse or serious AEs (OR = 0.77; 95%CI: 0.27 to 2.24; P = 0.64) (Figure 6). No serious AEs related to MSC therapy were found.



DISCUSSION

During the past decade, cell therapy-based treatments have been developed to manage several digestive tract diseases, including PF[21,22]. Previous research has shown that MSCs have a variety of mechanisms that promote wound healing. These cells also lack substantial immunogenicity and are thus suitable for use across human leukocyte antigen (HLA)

barriers[23,24]. An increasing number of studies have shown that MSC therapy is a safe and efficacious option for the short-term closure of PFs. However, maintaining continuous long-term fistula closure is also very important. A recurrent fistula is considered more difficult to treat surgically than the original fistula. Recently, an increasing number of studies have aimed to perform long-term follow-up of patients undergoing MSC administration to treat complex PFs. However,

there has been no meta-analysis to comprehensively evaluate the long-term effectiveness and safety of MSC treatment. Therefore, this study aimed to find a treatment to maintain long-term PF healing and to provide a basis for clinical application.

To our knowledge, this is the first meta-analysis to evaluate the long-term safety and efficacy of local MSC therapy for complex PFs. Findings from our study show that MSC therapy promotes sustained healing of complex PFs and that this therapy alone or combined with FG treatment can promote the long-term healing of complex PFs (OR = 2.13; 95%CI: 1.34 to 3.38; P = 0.001). The benefit over the control was sustained for at least 48 wk after local injection of MSCs. In our study, the timepoint for the assessment of fistula healing fluctuated greatly (48 wk-4 years), and all included studies showed good long-term healing of fistulas post-MSC treatment. Therefore, we believe that fistula healing persisted after MSC treatment. Barnhoorn *et al*[17] also reported that in addition to high fistula closure rates, MSC-treated patients had a higher QoL after therapy than at baseline. Some studies have also shown that in patients receiving MSC transplantation, the PF closure rate is significantly higher and the time to closure significantly shorter than that with anti-TNF drugs and fistulotomy, and MSC transplantation yields a decreased frequency of recurrence of the disease[25-27]. Therefore, these data confirm that MSC therapy promotes the long-term healing of complex PFs and significantly improves the QoL of patients. In the future, in evaluating MSC therapy for PF, it might be useful to consider work productivity and lifestyle restrictions.

Cell therapy strategies using MSCs carried in FG have shown promising results in regenerative medicine. MSCs have angiogenic, anti-apoptotic and immunomodulatory properties. FG provides a temporary structure that favors angiogenesis, extracellular matrix deposition and cell-matrix interactions. Additionally, FG maintains the local and paracrine functions of MSCs, providing tissue regeneration through less invasive clinical procedures[28]. The use of FG has been found to be uniformly safe, with minimal adverse effects, an early return to normal activity, and no negative impact on continence. One study showed that FG had a short-term effectiveness in the treatment of PF. At week 8 of the study, more than one-third of patients had healed fistulas, and half showed clinical improvement. Most of the patients in clinical remission at week 8 maintained clinical remission at week 16[29]. There was also a study indicating that FG was effective over the long term for the treatment of PF, and nearly 2 years after the use of FG to treat PF, over half of the patients showed clinical signs of remission[30]. Therefore, in association with MSCs, the use of FG has shown promising results in the field of regenerative medicine[31]. However, there is a lack of long-term success data on the combination of FG and other treatments for complex PF. In our study, MSCs plus FG had more long-term efficacy for fistula healing than FG alone (OR = 2.30; 95%CI: 1.21 to 4.36; P = 0.01). Therefore, we believe that the stimulation of the cellular adhesion and growth action of FG and the differentiation ability of MSCs may have a synergistic effect on the healing of fistulas. In our study, all patients received cleaning surgery before MSC treatment. Deep curettage had a positive effect on fistula closure in both groups (MSC recipients and controls). However, Garcia-Arranz *et al*[16] observed an increased number of long-term recurrences among control participants. Therefore, we speculate that the inflammatory focus persists, explaining why "deep curettage" may not provide a lasting resolution. In this scenario, MSCs and their anti-inflammatory and immunomodulatory effects can promote long-term healing.

Questions persist regarding the safety of MSC treatment for PF. Although MSC therapy has not raised any major safety concerns thus far in clinical trials, it is important to evaluate the safety of cell therapy in the long term. Our study

provides evidence that MSC therapy has a good long-term safety profile as a treatment for complex PF (OR = 0.77; 95%CI: 0.27 to 2.24; P = 0.64). In our study, the surgical management was fistula tract curettage and internal opening closure before MSC therapy. Notably, this is a minimally invasive surgery (involving perioperative antibiotic use, anesthesia, antisepsis, internal fistula orifice location, de-epithelization of the fistula tract, cleaning of the cavities and fistula tracts, closure of the internal opening, stem cell handling and resuspension, and cell injection) and does not produce fecal incontinence[32]. In contrast, anti-TNF therapies used for the treatment of PFs are associated with an increased risk of opportunistic infections, and surgical procedures often result in fecal incontinence. Tumorigenicity and ectopic tissue formation are the main concerns with the use of MSCs, and the risk of these SAEs is especially high during long-term MSC treatment. To date, MSCs have not been reported to cause tumors. Nevertheless, neoplasm development may become apparent only after longer follow-up periods. In another study conducted by our group, no neoplasm development was reported over the longest follow-up period of approximately 4 years[17]. To further confirm that neoplasms are not a concern with MSC treatment, biopsies taken from the fistula region were examined in that study. However, publication of these results is still pending, and we can continue the follow-up. While MSCs have not been shown to cause tumors in existing studies, long-term follow-up should be carried out to investigate the risk of cancer development. In the future, more long-term safety data are needed to fully assess the safety aspects of local MSC treatment.

Studies included in our meta-analysis used variable definitions of fistula healing. We believe that defining a healed fistula as complete re-epithelialization of external openings is not objective or accurate, as it does not account for the inside of the entire fistula. To evaluate the efficacy of MSC treatment, we should use more accurate methods for evaluating the inside of the entire fistula. MRI is the reference standard and cornerstone of fistula imaging. It demonstrates high sensitivity and specificity for the number and location of fistula tracts, detecting complexities frequently missed on clinical examination alone[33]. Therefore, MRI plays a crucial role in the evaluation, detection and follow-up of complex PFs[34]. In our meta-analysis, 3 RCTs based fistula healing on a combination of clinical examination and MRI imaging. The results showed that the MSC group had a higher HR than the control group (OR = 2.79; 95%CI: 1.37 to 5.67; P = 0.005). The absence of MRI examinations in some of the included studies at the end of the long-term follow-up is a limitation of this meta-analysis. In the future, if possible, blood should be drawn for standard measurements, and serum should be used to comprehensively evaluate the long-term healing of MSC therapy.

In this study, we aimed to evaluate the long-term efficacy and safety of MSC therapy through a meta-analysis. However, there are some unresolved questions. In the current clinical research, there are two ways to inject stem cells: (1) Systemic (mainly intravenous) injection; and (2) local injection. In our study, all patients received local MSC treatment. We speculate that for localized digestive tract diseases, local application and delivery seems more logical because side effects can be minimized and the cells are kept in direct contact with the at-risk tissue. Therefore, local MSC therapy seems to be a more promising treatment approach for further research. In our study, all eligible patients received a fixed dose of MSCs (one-time local injection or a second dose). Unfortunately, not all of the studies have compared various doses of MSCs or the benefit of repeat injections after the initial treatment. Most patients in our study received two doses of MSCs. Some studies have indicated a relationship between cell dose—or even the number of doses and efficacy[35,36]. In addition, all eligible patients with complex PFs may have branches with multiple tracks involving an extensive area that cannot always be adequately treated with a fixed dose of cells. Perhaps the cell dosage is related to the length of the fistula tracts and cavities. Due to the limitations of studies, it is difficult to provide recommendations on the optimal dose. In future research, we should pay attention to these unresolved questions (such as MSC origin, dosage and modality of intervention) to ensure that PF patients receive optimal treatment.

Our meta-analysis is the first to evaluate the long-term efficacy and safety of MSCs for PF treatment. Inevitably, this article has some limitations: (1) The studies used MSCs of different origins (adipose tissue and bone marrow from autologous as well as allogeneic sources); (2) some included studies defined the healed fistula as re-epithelialization of the external opening of the fistula. This may cause our results to be overestimated; (3) all patients underwent surgical procedures such as deep curettage. This may be beneficial to the short-term clinical remission of the fistulas. However, whether deep curettage will benefit long-term healing remains uncertain; (4) the follow-up period of the included studies varied significantly. Indeed, some of the studies lacked long-term follow-up data. In the future, we need more patients to enter the extended follow-up period so that the long-term safety and efficacy of MSCs can be assessed; and (5) the number of included studies and the sample size were limited, and extrapolation of the meta-analysis results was limited to some extent. So, our study was limited by its multiple centers and heterogeneity in the study inclusion criteria, mesenchymal stem cell origin, dose and frequency of delivery, and definition and time point of fistula healing. In the future, more patients must be evaluated in long-term follow-ups to optimize the efficacy and safety of MSCs for PF treatment.

CONCLUSION

In summary, MSC treatment is a safe and effective method that can significantly improve the long-term healing of complex PFs, and this method confers no risk of MSC-related AEs.

ARTICLE HIGHLIGHTS

Research background

An increasing number of studies have indicated that local mesenchymal stem cell (MSC) therapy is safe and efficacious for complex perianal fistulas (PFs). But, the long-term efficacy of MSC therapy is unclear. To date, an increasing number of studies have aimed to perform long-term evaluations of MSC therapy for PFs.

Research motivation

Local MSC therapy for PFs has shown considerable promise. But, the long-term safety and efficacy of MSC therapy in complex PFs is unknown.

Research objectives

To explore the long-term effectiveness and safety of MSC therapy for complex PFs.

Research methods

PubMed, EMBASE and Cochrane Library databases were searched that reported the long-term evaluation of local MSC therapy for complex PFs. The effectiveness and safety data analysis were conducted using RevMan5.3.

Research results

After screening, 6 studies met the inclusion criteria. MSC therapy was associated with an improved long-term healing rate (HR) compared with the control condition [odds ratio (OR) = 2.13; 95% confidence interval (95%CI): 1.34 to 3.38; P = 0.001]. Compared with fibrin glue (FG) therapy alone, MSC plus FG therapy was associated with an improved long-term HR (OR = 2.30; 95%CI: 1.21 to 4.36; P = 0.01). When magnetic resonance imaging was used to evaluate fistula healing, MSC therapy was found to achieve a higher long-term HR than the control treatment (OR = 2.79; 95%CI: 1.37 to 5.67; P = 0.005). There were no significant differences in long-term safety (OR = 0.77; 95%CI: 0.27 to 2.24; P = 0.64).

Research conclusions

Our study indicated that local MSC therapy promotes long-term and sustained healing of complex PFs and that this method is safe.

Research perspectives

In complex PFs treatment, local MSC therapy should be paid more attention to. Considering that this small number may not be enough to represent the whole complex PFs population, In the future, to improve on the quality of research, future studies should be carefully designed and reported.

ABOUT COVER

Editorial Board Member of *World Journal of Stem Cells*, Khawaja Husnain Haider, PhD, Professor, Department of Basic Sciences, Sulaiman Al-Rajhi University (SRU), Al-Qaseem 52726, Saudi Arabia. kh.haider@gmail.com

AIMS AND SCOPE

The primary aim of *World Journal of Stem Cells* (*WJSC*, *World J Stem Cells*) is to provide scholars and readers from various fields of stem cells with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJSC* publishes articles reporting research results obtained in the field of stem cell biology and regenerative medicine, related to the wide range of stem cells including embryonic stem cells, germline stem cells, tissue-specific stem cells, adult stem cells, mesenchymal stromal cells, induced pluripotent stem cells, embryonal carcinoma stem cells, hemangioblasts, lymphoid progenitor cells, *etc*.

INDEXING/ABSTRACTING

The *WJSC* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Journal Citation Reports/Science Edition, PubMed, PubMed Central, Scopus, Biological Abstracts, BIOSIS Previews, Reference Citation Analysis, China National Knowledge Infrastructure, China Science and Technology Journal Database, and Superstar Journals Database. The 2023 Edition of Journal Citation Reports® cites the 2022 impact factor (IF) for *WJSC* as 4.1; IF without journal self cites: 3.9; 5-year IF: 4.5; Journal Citation Indicator: 0.53; Ranking: 15 among 29 journals in cell and tissue engineering; Quartile category: Q3; Ranking: 99 among 191 journals in cell biology; and Quartile category: Q3. The *WJSC*'s CiteScore for 2022 is 8.0 and Scopus CiteScore rank 2022: Histology is 9/57; Genetics is 68/325; Genetics (clinical) is 19/90; Molecular Biology is 119/380; Cell Biology is 95/274.

Abstract

BACKGROUND

Mesenchymal stem cells (MSCs) have been used in liver transplantation and have certain effects in alleviating liver ischemia-reperfusion injury (IRI) and regulating immune rejection. However, some studies have indicated that the effects of MSCs are not very significant. Therefore, approaches that enable MSCs to exert significant and stable therapeutic effects are worth further study.

AIM

To enhance the therapeutic potential of human menstrual blood-derived stromal cells (MenSCs) in the mouse liver ischemia-reperfusion (I/R) model *via* interferon-γ (IFN-γ) priming.

METHODS

Apoptosis was analyzed by flow cytometry to evaluate the safety of IFN-γ priming, and indoleamine 2,3-dioxygenase (IDO) levels were measured by quantitative real-time reverse transcription polymerase chain reaction, western blotting, and ELISA to evaluate the efficacy of IFN-γ priming. *In vivo*, the liver I/R model was established in male C57/BL mice, hematoxylin and eosin and TUNEL staining was performed and serum liver enzyme levels were measured to assess the degree of liver injury, and regulatory T cell (Treg) numbers in spleens were determined by flow cytometry to assess immune tolerance potential. Metabolomics analysis was conducted to elucidate the potential mechanism underlying the regulatory effects of primed MenSCs. *In vitro*, we established a hypoxia/reoxygenation (H/R) model and analyzed apoptosis by flow cytometry to investigate the mechanism through which primed MenSCs inhibit apoptosis. Transmission electron microscopy, western blotting, and immunofluorescence were used to analyze autophagy levels.

RESULTS

IFN-γ-primed MenSCs secreted higher levels of IDO, attenuated liver injury, and increased Treg numbers in the mouse spleens to greater degrees than untreated MenSCs. Metabolomics and autophagy analyses proved that primed MenSCs more strongly induced autophagy in the mouse livers. In the H/R model, autophagy inhibitors increased the level of H/R-induced apoptosis, indicating that autophagy exerted protective effects. In addition, primed MenSCs decreased the level of H/R-induced apoptosis *via* IDO and autophagy. Further rescue experiments proved that IDO enhanced the protective autophagy by inhibiting the mammalian target of rapamycin (mTOR) pathway and activating the AMPK pathway.

CONCLUSION

IFN-γ-primed MenSCs exerted better therapeutic effects in the liver I/R model by secreting higher IDO levels. MenSCs and IDO activated the AMPK-mTOR-autophagy axis to reduce IRI, and IDO increased Treg numbers in the spleen and enhanced the MenSC-mediated induction of immune tolerance. Our study suggests that IFN-γ-primed MenSCs may be a novel and superior MSC product for liver transplantation in the future.

Core Tip: In this study, we identified a suitable interferon-γ (IFN-γ) priming strategy for menstrual blood-derived stromal cells (MenSCs) in the liver ischemia-reperfusion (I/R) model and proved that primed MenSCs could significantly increase the number of regulatory cells in the spleen by secreting higher levels of indoleamine 2,3- dioxygenase (IDO) and thereby exhibited better immunoregulatory potential. Besides, through metabolomics and related molecular biology experiments, we found that IDO could reduce ischemia-reperfusion injury *via* the AMPK-mammalian target of rapamycin-autophagy axis. Our study suggests that IFN-γ-primed MenSCs may be a novel and superior mesenchymal stem cell product for liver transplantation in the future.

INTRODUCTION

Liver transplantation is the only therapeutic option that is available to patients with terminal liver failure. Both liver ischemia-reperfusion injury (IRI), which occurs during surgery, and immune rejection, which occurs after surgery, affect the results of liver transplantation[1]. Therefore, there is an urgent need to develop effective strategies for treating IRI and immune rejection.

Mesenchymal stem cells (MSCs) have been used in liver transplantation and have shown certain therapeutic effects[2-4]. For example, MSCs alleviated hepatocellular apoptosis in a mouse liver ischemia-reperfusion (I/R) model *via* PINK1-dependent mitophagy[5]. In a clinical study, the percentage of regulatory T cells (Tregs) and the ratio of Tregs to T helper 17 (Th17) cells, which can be used as indicators of immune tolerance potential, were significantly increased in liver transplant recipients 4 wk after MSC infusion[6]. However, the results of another clinical study showed that the infusion of MSCs into liver transplant recipients before surgery was safe, but only mild changes in the peripheral blood immunoregulatory T cell numbers and natural killer cell numbers were observed in these patients[7]. In addition, the administration of immunosuppressive agents with MSCs showed no synergistic effect compared with the administration of immunosuppressive agents alone in a rat liver transplant study[8]. Therefore, approaches that enable MSCs to exert

more significant protective effects in reducing IRI and inducing immune tolerance in liver transplantation deserve further study.

Priming can induce an anti-inflammatory state in MSCs, causing them to secrete more bioactive molecules and improving their therapeutic effects[9,10]. Interferon (IFN)-γ-primed MSCs have been shown to have more stable and stronger abilities to regulate immune responses and prevent damage in many disease models[11-13]. Priming with IFN-γ increases the mRNA expression of Toll-like receptor 3 and the secretion of immunosuppressive molecules, such as indoleamine 2,3-dioxygenase (IDO), interleukin (IL)-10, hepatocyte growth factor, and kynurenine[14]. IDO, an enzyme involved in tryptophan metabolism, has been widely reported to regulate T-cell immunity, specifically by promoting the differentiation of Tregs, inhibiting Th17 cells, and promoting immune tolerance and immune escape[15,16]. Additionally, compared with control conditions, IFN-γ priming significantly induces IDO expression, enhances the immunoregulatory effect of MSCs on T cells, increases Treg differentiation, and promotes immune tolerance[17].

Menstrual blood-derived stromal cells (MenSCs) have been studied in several clinical and preclinical trials, and their safety and immunomodulatory properties have been fully demonstrated[18-20]. In addition, MenSCs can be collected in a manner that is painless, noninvasive, convenient, and inexpensive, thus, their use in cell-based therapy has high clinical and economic value. In this study, we hypothesized that IFN-γ-primed MenSCs could secrete higher levels of IDO to better induce immune tolerance in a mouse liver I/R model. However, whether priming with IFN-γ affects the viability of MenSCs themselves is unclear. Moreover, whether IFN-γ-primed MenSCs, which represent a new type of modified MSC product, can better mitigate liver injury in the liver I/R model has not been clarified. Therefore, it is worthwhile to further study appropriate priming strategies and whether primed MenSCs can exert better therapeutic effects in the liver I/R model.

MATERIALS AND METHODS

MenSCs

MenSCs were provided by the Innovative Precision Medicine Group (IPM, Hangzhou, China) and cultured as described in our previous study[2-4]. Briefly, the cells were cultured in α-minimum essential medium (Thermo Fisher Scientific, United States) supplemented with 10% foetal bovine serum (FBS) (Thermo Fisher Scientific, United States) and 1% penicillin-streptomycin solution (Thermo Fisher Scientific, United States) in an incubator at 37 °C with 5% CO_2. When the cells reached 80%-90% confluence, they were subcultured with 0.25% trypsin-EDTA (Thermo Fisher Scientific) and passaged 5-8 times before being used in experiments. MenSCs were identified based on their surface marker expression and differentiation potential.

Flow cytometry was performed to detect the surface markers of MenSCs. The cells were collected, washed twice with staining buffer (BD, Biosciences, San Jose, CA), and incubated with antibodies against CD29, CD34, CD45, CD73, CD90, CD105, CD117, and human leukocyte antigen-DR (HLA-DR) (PE, BD, Biosciences, San Jose, United States) at 4 °C for 30 min in the dark. Negative controls (NCs) were established with the corresponding isotype control antibodies. A flow cytometer (ACEA Biosciences, CA, United States) was used to analyze all the cells.

Osteogenic, adipogenic, and chondrogenic differentiation was induced to evaluate the multi-differentiation potential of the cells. Briefly, approximately 5 × 10^5 MenSCs were cultured in 6-well plates for 3-4 wk with osteogenic differentiation medium (Cyagen Biosciences, United States) or adipogenic differentiation medium (Cyagen Biosciences, United States) in an incubator at 37 °C with 5% CO_2 to promote osteogenic or adipogenic differentiation, respectively; the medium was changed every 1-3 d according to the instructions. After fixation with 4% formaldehyde, the cells were incubated with Alizarin Red or Oil Red O solution for 30 min to label calcium or neutral lipids, respectively. Chondrogenic differentiation was performed in a 15 mL centrifuge tube. Approximately 5 × 10^5 MenSCs were centrifuged and cultured with 1 mL of human MSC chondrogenic differentiation medium (Cyagen Biosciences, United States) in an incubator at 37 °C with 5% CO_2 for 3-4 wk; the medium was changed every 2-3 d according to the instructions. After fixation with 4% formaldehyde, the pelleted cells were embedded in paraffin, cut into 4 mm sections, and stained with Alcian blue solution to label cartilage.

Priming of MenSCs and IDO quantification

IFN-γ (Miltenyi Biotec Inc., Auburn, CA, United States) at a concentration of 100 or 200 ng/mL was used to prim MenSCs for 24, 48, or 72 h. After the cells were collected, RNA or protein was extracted to measure IDO expression by quantitative real-time reverse transcription polymerase chain reaction (qRT-PCR) or western blotting assays, respectively, as described below. Additionally, the supernatants were collected to evaluate the release of IDO using a Human IDO ELISA Kit (Sangon Biotech, Shanghai, China).

Establishment of the mouse liver I/R model and animal grouping

Six- to eight-week-old male C57BL/6J mice (Slac Laboratory Animal Corporation, Shanghai, China) were housed in a specific pathogen-free room (23 ± 2 °C, 12 h light/12 h dark cycle, and 50% humidity) at the Laboratory Animal Center of Zhejiang University with plenty of food and water for two weeks prior to experimentation. All the procedures used for the animal experiments, the number of animals, and the ethics of the animal housing environment were performed according to the 3Rs rule and approved by the Experimental Animal Center of Zhejiang University, and the ethical approval number is ZJU20210299.

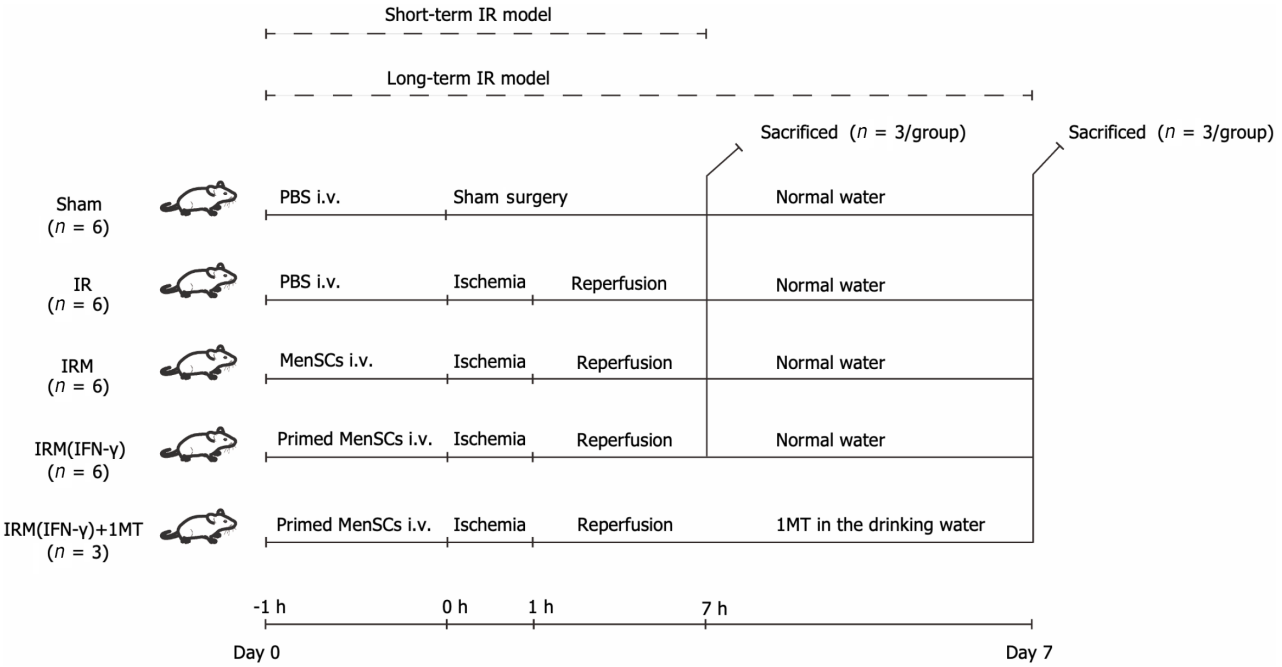
Anesthesia: Before all the surgical procedures, 1% pentobarbital sodium (100 μL/10 g intraperitoneal injection) was used to anesthetize the mice (weight 20-23 g)[5]. Surgical procedure: All the mice received a ventral midline incision. Hepatic arteries, portal veins, and bile ducts were clipped with an atraumatic vascular clip to interrupt 70% of the blood supply to the liver. After 1 h of ischemia, the atraumatic vascular clamps were removed to terminate the ischemia; the wounds were sutured layer by layer, and erythromycin ointment was applied to prevent infection. The mice were resuscitated on a 37 °C blanket to maintain their body temperature. Group design: The sample size (total n = 27, and n = 3/group), grouping, and animal experiment schedule were decided based on a similar study published previously[2] and can be found in Figure 1. To establish the short-term I/R model, the mice were randomly divided into the sham group, IR group, IRM group, and IRM (IFN-γ) group (n = 3/group). The model mice in the IR, IRM, and IRM (IFN-γ) groups were administered 100 μL of phosphate buffered saline (PBS) or MenSCs (10^6/100 μL intravenous injection) or IFN-γ-primed MenSCs (10^6/100 μL intravenous injection) 1 h before the surgery. The mice in the sham group received only a ventral midline incision and were sutured after injection of PBS. After 6 h of reperfusion, the mice were euthanized in a classic, quick, and painless manner (150 mg/kg pentobarbital sodium, intraperitoneal injection), and tissue samples were collected for further investigation.

To establish the long-term I/R model, the mice were randomly divided into the sham group, IR group, IRM group, IRM (IFN-γ) group, and IRM (IFN-γ) + 1-methyl-D-tryptophan (1MT) group (n = 3/group). The treatment plan was similar to that used for the short-term model, with the exception that 1MT (2 mg/mL; MCE, New Orleans, LA, United States) was added to the drinking water of the mice in the IRM (IFN-γ) + 1MT group, and the mice in this group had continuous access to this supplemented water starting from the day of the surgery (day 0) until the seventh day (day 7). The mice in the other groups were given normal water without 1MT. All the long-term I/R model mice were euthanized (150 mg/kg pentobarbital sodium, intraperitoneal injection) on day 7 for tissue collection.

Assessment of liver injury

The serum alanine aminotransferase (ALT) and aspartate aminotransferase (AST) levels were measured using the ALT Kit and AST Kit (Nanjing Jiancheng Bioengineering Institute, Nanjing, China), respectively, to assess the liver injury. Liver injury was also assessed by hematoxylin and eosin staining. Sections were examined under a microscope, and Suzuki's injury criteria (Supplementary Table 1) were utilized to determine the histological damage score by a researcher who was blinded to the group of the immunohistochemistry sections.

qRT-PCR



To confirm the effects on the transcriptome, RNA was extracted from cells using the RNA Extraction Kit (TaKaRa, Beijing, China). Prime Script TMRT Master Mix and TB Green Premix Ex Taq Bulk (TaKaRa, Beijing, China) were used for qRT-PCR. First, Buffer RL was added to the cells to lyse them, and the lysis solution was transferred to a gDNA Eraser Spin Column to remove impurities and gDNA. Then, 70% ethanol was added to the filtrate, and the mixture was moved to an RNA spin column to capture the RNA. Then, the RNA spin column was cleaned with Buffer RWA and Buffer RWB. The RNA solution was obtained by eluting the RNA with RNase-free dH_2O. Then, we mixed an appropriate amount of RNA with 5 × A solution and RNase-free dH_2O to a final volume of 10 μL, and reverse transcription was performed to obtain cDNA. Then, the TB Green mix (12.5 μL), forward PCR primer (10 μM × 0.5 μL, Supplementary Table 2), reverse PCR primer (10 μM × 0.5 μL, Supplementary Table 2), DNA template (2 μL), and 9.5 μL ddH_2O were mixed in a final volume of 25 μL. The qRT-PCR conditions were as follows: 95 °C for 30 s ; 40 cycles of 95 °C for 5 s and 60 °C for 30 s for 2 step PCR; and 95 °C for 15 s, 60 °C for 30 s, and 95 °C for 15 s for dissociation. The melting curves were determined, and the cycle threshold (CT) values of the β-actin (ACTB) transcripts were used to normalize the CT values of the IDO transcripts. The qRT-PCR data were analyzed using the ΔΔCT method.

Western blotting

Liver tissues and cells were lysed with a moderate amount of lysis buffer, which was composed of radioimmunoprecipitation assay buffer (RIPA Lysis Buffer, 10 ×, Merck KGaA, Darmstadt, Germany), a protease and phosphatase inhibitor cocktail for mammalian cell and tissue extracts (Beyotime, Shang Hai, China) and ddH_2O, on ice for 30-60 min. Equal amounts of proteins were subjected to 12% or 8% SDS polyacrylamide gel electrophoresis and then transferred to polyvinylidene difluoride membranes (Millipore, Billerica, MA, United States). The membranes were incubated with 5% nonfat milk for 1 h and then with the primary antibodies overnight at 4 °C; the primary antibodies included antibodies against IDO (16630, Cell Signaling Technology, United States), LC3 (12741, Cell Signaling Technology, United States), AMPKα (total) (5831, Cell Signaling Technology, United States), p-AMPKα (50081, Cell Signaling Technology, United States), mammalian target of rapamycin (mTOR) (total) (2983, Cell Signaling Technology, United States), p-mTOR (5536, Cell Signaling Technology, United States), and β-actin (ACTB) (8227, Abcam, United States). The membranes were then washed three times with Tris-buffered saline with Tween 20 (TBST) and incubated with the secondary antibody [anti-rabbit immunoglobulin G (IgG), Sigma, United States or anti-mouse IgG, Sigma, United States] for 1 h at room temperature. The membranes were washed three times with TBST and visualized by enhanced chemiluminescence with a Fluor Chem Systems imager (Bio-Rad, CA, United States). The intensities of the bands were determined using ImageJ software.

Transmission electron microscopy

Liver samples were cut into 1-mm^3 pieces and fixed with 2.5% glutaraldehyde overnight at 4 °C. After fixation and dehydration, all the samples were stained with osmic acid and uranyl acetate. Then, we used an ultramicrotome to slice the samples and obtain ultrathin sections. All the samples were imaged with a transmission electron microscope (Talos

Figure 1 Animal experiment grouping and timeline. Detailed descriptions are provided in the Materials and Methods. In brief, we established short-term and long-term liver ischemia-reperfusion mouse models to explore the therapeutic potential of menstrual blood-derived stromal cells (MenSCs) and primed MenSCs. MenSCs: Menstrual blood-derived stromal cells; IFN-γ: Interferon-γ; 1MT: 1-methyl-D-tryptophan; IR: Ischemia-reperfusion; IRM: Combination treated with ischemia-reperfusion and menstrual blood-derived stromal cells; IRM (IFN-γ): Combination treated with ischemia-reperfusion and interferon-γ-primed menstrual blood-derived stromal cells; PBS: Phosphate buffered saline; i.v.: Intravenous injection.

L120C, Thermo Fisher, Carlsbad, CA, United States) to confirm and monitor autophagy, and the number of autophagic vacuoles in each cell was quantified.

Establishment of the hypoxia/reoxygenation model in L02 cells and grouping

Under normoxic conditions, the L02 cells (FuHeng Biology, Shanghai, China) were cultured in 1640 complete medium (RPMI 1640 medium supplemented with 10% FBS and 1% penicillin-streptomycin) in a typical incubator at 37 °C with 5% CO_2. To simulate liver IRI, the L02 cells were subjected to hypoxia/reoxygenation (H/R). Briefly, after 6 h of culture in FBS-free 1640 medium in a 2.5 L sealed culture tank (MGC, Tokyo, Japan) under hypoxic conditions, the cells were transferred to atypical incubator for 4 h to allow reoxygenation. The hypoxic conditions in the sealed culture tank (94% N_2, 5% CO_2, and 1% O_2) were maintained by AnaeroPack-Anaero-5% (MGC, Tokyo, Japan).

Group design: The cells that were cultured under normal oxygen conditions were divided into the NC group, 3-methyladenine (3MA) group, 1MT group, MenSCs group, and MenSC (IFN-γ) group. The cells that were cultured under H/R conditions were divided into the HR group, HR + 3MA group, HR + 1MT group, HRM group, HRM (IFN-γ) group, HRM (IFN-γ) + 3MA group, and HRM (IFN-γ) + 1MT group.

The NC group consisted of cells cultured in 1640 complete medium without any other treatment. The cells in the 3MA group and 1MT group were cultured in 1640 complete medium with 10 mmol/L 3MA (an autophagy inhibitor, MCE, New Orleans, LA, United States) or 1 mmol/L 1MT (an IDO inhibitor, MCE, New Orleans, LA, United States). The cells in the MenSCs group and MenSC (IFN-γ) group were cocultured with MenSCs or MenSC (IFN-γ), respectively, in 1640 complete medium using a coculture chamber as described previously. The HR group, HR + 3MA group, HR + 1MT group, HRM group, and HRM (IFN-γ) group, were subjected to treatments that were similar to those used in the experiments conducted under normal oxygen conditions, but H/R treatment was added. In addition to the HRM (IFN-γ) treatment, the cells in the HRM (IFN-γ) + 3MA group and HRM (IFN-γ) + 1MT group received 3MA and 1MT in the medium, respectively.

Quantitative GFP-LC3 analysis

L02 cells in every group were transfected with pCMV-GFP-LC3 (Beyotime, Shang Hai, China) for 24 h before treatment. We used a confocal laser scanning microscope (Olympus Corporation, Japan) to detect fluorescence emission. Intense punctate GFP-LC3 aggregates in the nucleus and cytoplasm were considered to indicate autophagy, whereas diffuse distribution of GFP-LC3 was considered to indicate non-autophagic conditions. We counted the number of intense punctate GFP-LC3 aggregates in each cell to indicate the number of autophagosomes.

Treg analysis

The mononuclear cells in the spleen were harvested by gradient centrifugation using Ficoll 1.084 (Cytiva, Logan, UT, United States). FACS was performed with 3 fluorochrome-conjugated antibodies: Anti-CD4 monoclonal antibody (APC,

17-0041-83, eBioscience, CA, United States), anti-CD25 monoclonal antibody (PE, 12-0251-82, eBioscience, CA, United States), and anti-FOXP3monoclonal antibody (FITC, 11-5773-82, eBioscience, CA, United States). Nuclear permeabilization was performed with a FoxP3/transformation factor permeabilization buffer (00-5523-00, eBioscience, CA, United States) before the anti-FoxP3 antibody was added to the cells for incubation. Cell fluorescence was evaluated using a flow cytometer (ACEA Biosciences, CA, United States). The percentage of $CD4^+$ $CD25^+$ cells among all mononuclear cells and the percentage of $FoxP3^+$ cells among the $CD4^+CD25^+$ cells were recorded, and the product of these percentages was used to represent the percentage of Tregs among all mononuclear cells.

Statistical analysis

The metabolomics data were analyzed using the free online Majorbio choice platform (cloud.majorbio.com). Other data were analyzed using Prism version 5.0 (GraphPad, United States). The data are shown as the means ± SDs or means ± SEMs. One-way ANOVA was used for comparisons of three or more groups. A P value of <0.05 was considered to indicate a significant difference ($^aP < 0.05$, $^bP < 0.01$, $^cP < 0.001$, and $^dP < 0.0001$), and P values ≥ 0.05 were considered to indicate no significant difference (NS).

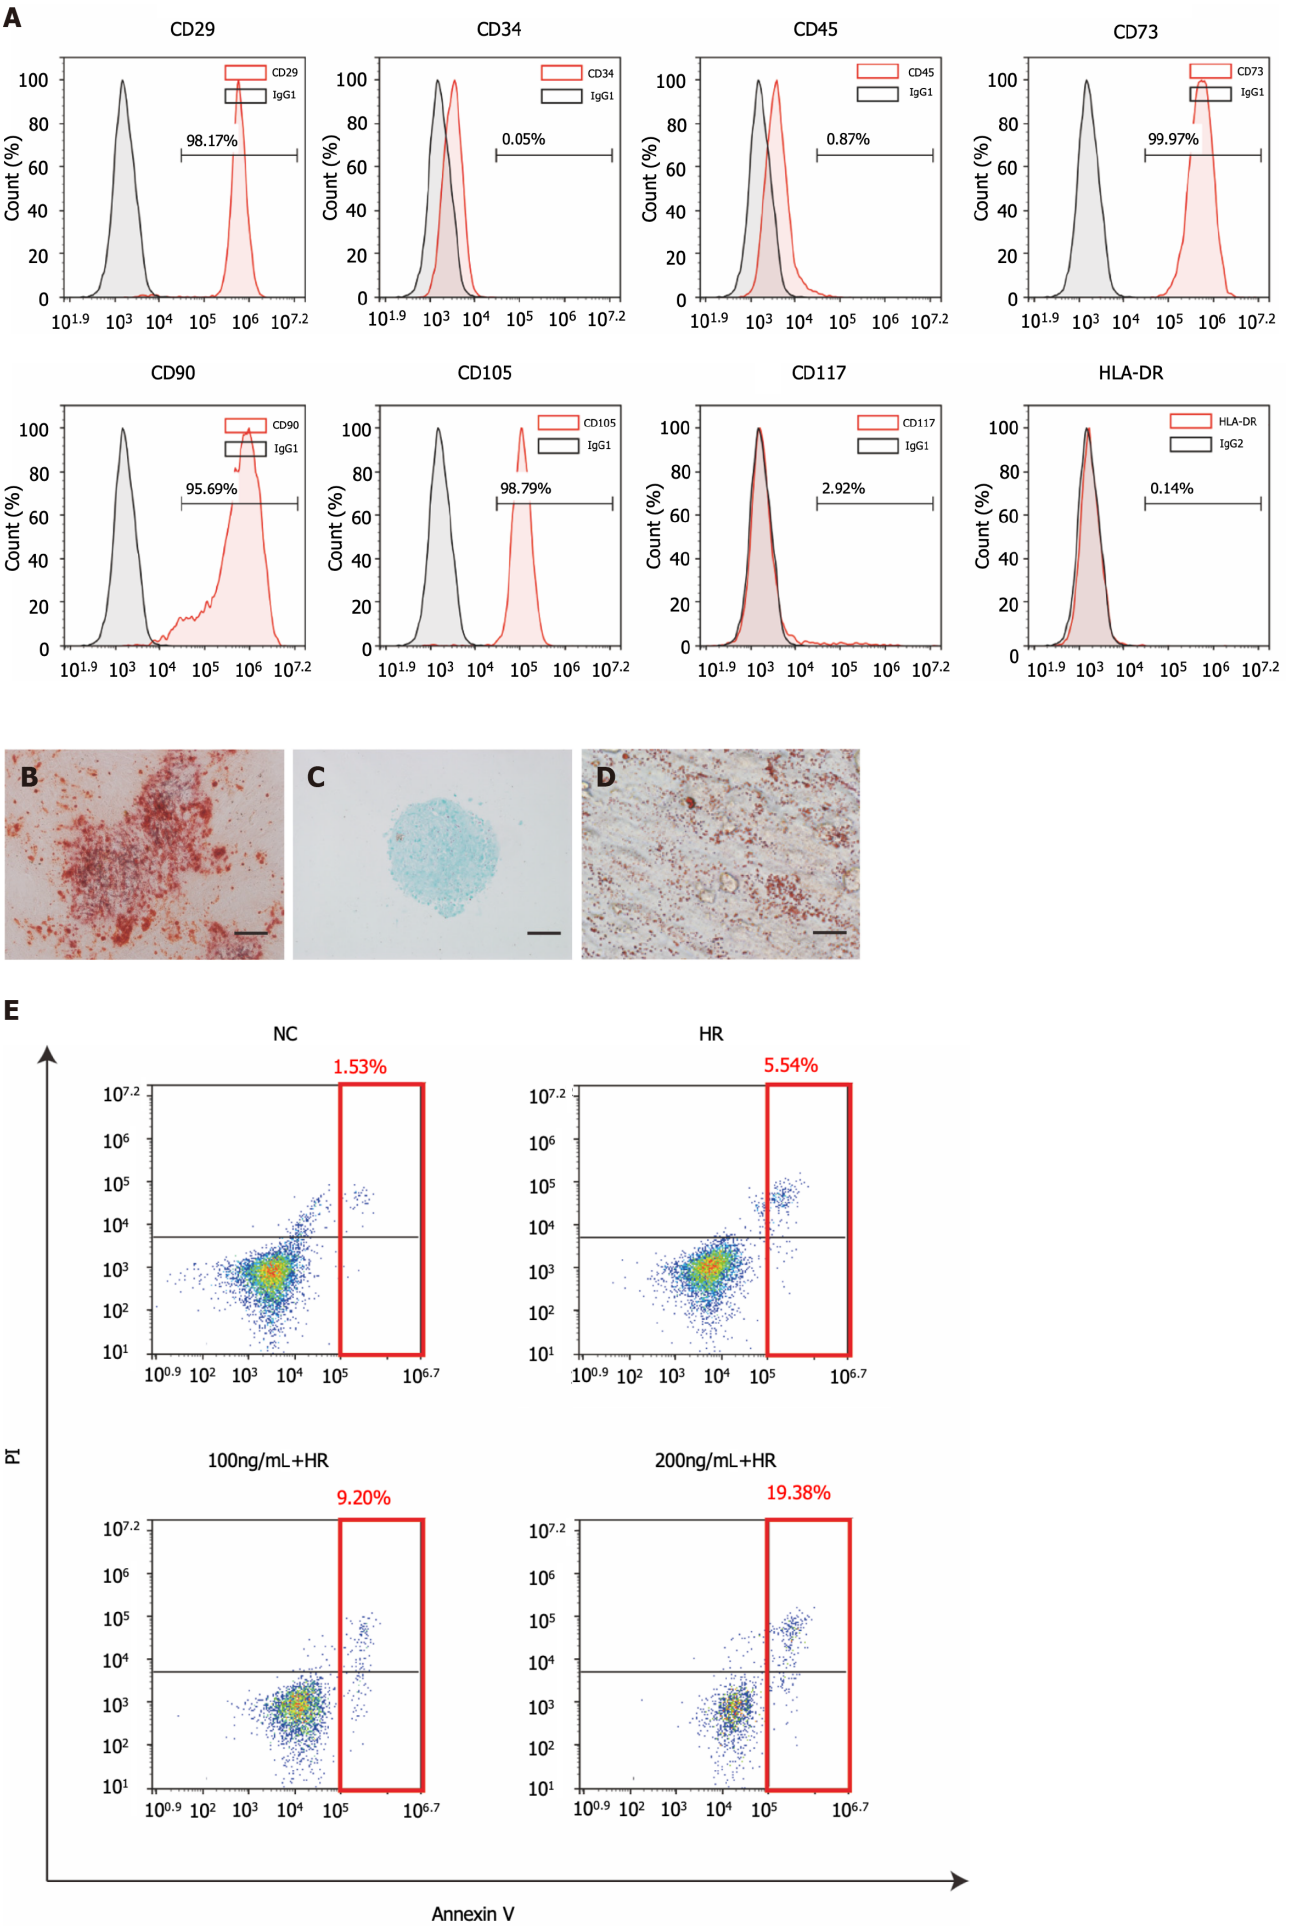
RESULTS

Characterization of MenSCs

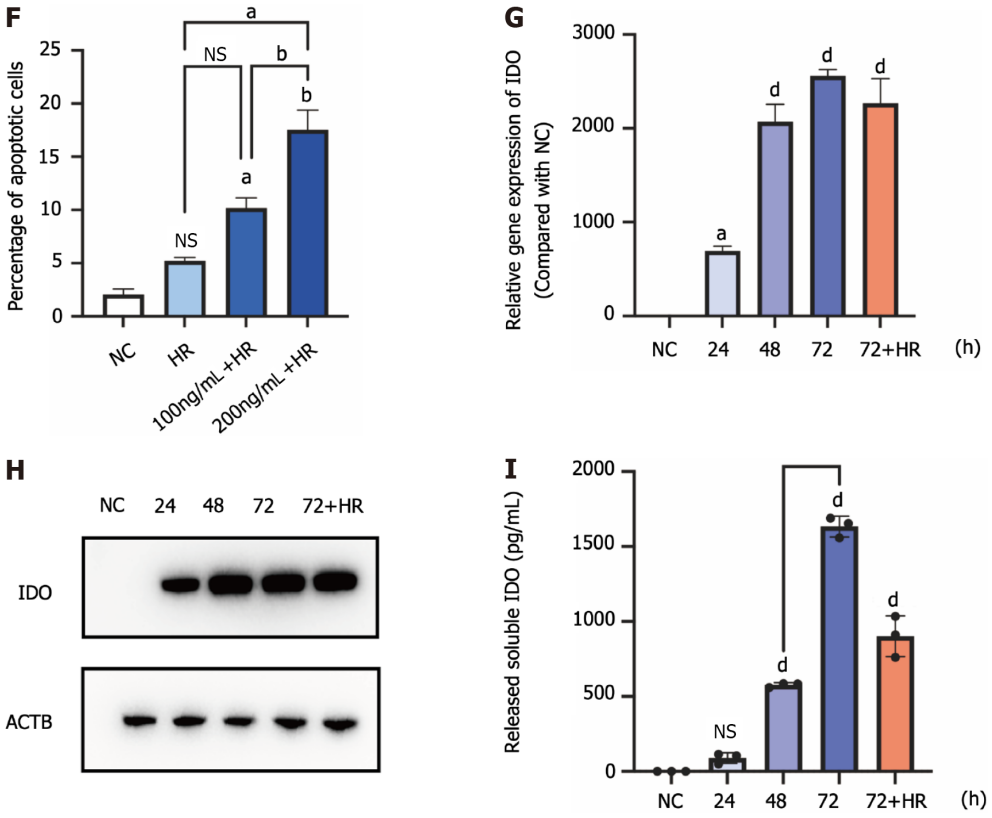
Primary MenSCs were cultured and exhibited adherent growth after approximately 24 h, and obvious cell proliferation was observed as soon as the cells became round and fusiform. According to a phenotypic analysis, MenSCs expressed CD29, CD73, CD90, and CD105, but they did not express CD45, CD80, CD117, or HLA-DR (Figure 2A). Specific staining showed that MenSCs could undergo osteogenic, chondrogenic, and adipogenic lineage differentiation (Figures 2B-D). The MenSCs that were used in this study met the International Society for Cellular Therapy criteria for the definition of multipotent MSCs[21].

MenSC priming with IFN-γ

In this study, we hypothesized that IFN-γ-primed MenSCs could secrete higher levels of IDO to induce stronger immune tolerance in a liver I/R model. Therefore, to determine the appropriate priming strategy, we evaluated the safety and efficacy of priming by measuring the degree of cell apoptosis and the levels of IDO, respectively.



MenSCs were treated with 100 ng/mL IFN-γ (low concentration) or 200 ng/mL IFN-γ (high concentration) to determine the appropriate concentration for treatment. To accurately mimic the environment in which MenSCs perform their biological functions, we exposed MenSCs to H/R 72 h after priming[14,18]. Then, the cells were stained with Annexin V and propidium iodide (PI), and the proportions of apoptotic MenSCs in the different treatment groups were analyzed by flow cytometry. We found that H/R slightly increased stem cell apoptosis, but the difference was not significant (Figures 2E and F). Moreover, MenSCs that were primed with low and high IFN-γ concentrations were less resistant to H/R-induced apoptosis, and the overall proportions of apoptotic cells reached approximately 10% and 17%, respectively (Figures 2E and F). To maintain a relatively good state of MenSCs after intervention, we used the lower concentration of 100 ng/mL to prim MenSCs in the subsequent experiments.



As previously mentioned, IDO secreted by MSCs plays a key role in the regulation of T cells, and this metabolite can induce the differentiation of Tregs and thus promote immune tolerance[15,16]. Therefore, we used the IDO levels as an indicator to evaluate the efficacy of priming. The mRNA and protein levels of IDO in MenSCs were measured by qRT-PCR and western blotting, respectively, and the concentrations of IDO that were secreted by MenSCs were measured by ELISA. These results showed that the expression of IDO in MenSCs was upregulated 24 h after IFN-γ priming and reached a high level at 72 h. In addition, IDO continued to be expressed at a high level in MenSCs under H/R treatment conditions after the removal of IFN-γ (Figures 2G and H). Measurement of the IDO levels by ELISA showed that IDO was gradually secreted into the cell culture medium after priming, and when IFN-γ was removed after 72 h of priming, a considerable amount of IDO continued to be secreted by MenSCs under H/R treatment conditions (Figure 2I).

These results indicated that MenSCs could be maintained in a relatively good cell state when exposed to H/R after treatment with a low concentration of IFN-γ. Additionally, IFN-γ priming for 72 h promoted the expression and continuous secretion of IDO by MenSCs. Therefore, we chose 100 ng/mL IFN-γ for 72 h as the strategy for priming MenSCs to ensure that priming would be safe and effective.

IFN-γ-primed MenSCs attenuated liver IRI in the mouse short-term I/R model

The grouping and timeline of the animal experiments are shown in Figure 1. We administered MenSCs and IFN-γ-primed MenSCs (primed MenSCs) to short-term I/R model mice to explore their therapeutic potential. We found that the mice in the IR group showed significant hepatocyte injury after 6 h of reperfusion; this injury manifested as vacuole formation, increased inflammatory cell infiltration, disordered hepatic lobules, and tissue necrosis (Figure 3A), and these effects were accompanied by elevated serum levels of AST and ALT, which are indicators of liver function (Figures 3E and F), and relatively high Suzuki's injury scores (Figure 3B). However, the administration of MenSCs and primed MenSCs resulted in decreased ALT and AST levels, ameliorated IRI, and decreased Suzuki's injury scores (Figures 3A, B, E and F). Additionally, caspase-3 and TUNEL staining of liver tissue sections were performed to observe apoptosis. We reached the same conclusion, namely, that both MenSCs and IFN-primed MenSCs could attenuate I/R-induced hepatocyte apoptosis (Figures 3C and D). Moreover, these results also showed that primed MenSCs exerted a better therapeutic effect than

untreated MenSCs (Figures 3A-F).

IFN-γ-primed MenSCs reduced hepatocellular damage and increased the Treg numbers in the mouse long-term I/R model

As IFN-γ-primed MenSCs could exert a better therapeutic effect in the short-term model, we used 7 d of reperfusion after I/R to establish a long-term model in order to further explore the long-term effects of primed MenSCs, particularly their potential to induce immune tolerance.

We found that after 7 d of ischemia, the liver tissues of the mice showed obvious edema, a large cavity, and necrosis, and these conditions resulted in high Suzuki's injury scores. However, MenSCs and particularly IFN-γ-primed MenSCs significantly inhibited these changes (Figures 4A and B). Additionally, we determined the Treg numbers in the spleen to assess the immune tolerance of the mice. To determine the number of Tregs, we analyzed the percentage of cells that were positive for CD4, CD25, and Foxp3. Tregs accounted for approximately 1% of the total lymphocyte population in the sham and IR groups, and primed MenSCs increased the percentage of Tregs in the lymphocyte population to a great extent (Figures 4C and D). However, although untreated MenSCs also increased the percentage of Tregs, no significant difference was found compared with the sham group (Figures 4C and D). To verify the correlation between the stronger immunomodulatory ability of primed MenSCs and IDO, we added 1MT to the drinking water of some mice and found that 1MT clearly reversed the increase in the percentage of Tregs in the spleen and inhibited the protective effect of primed MenSCs on the liver (Figures 4A-D).

These results indicated that after 7 d of reperfusion, IFN-γ-primed MenSCs exerted a stronger and more stable effect on reducing liver injury and increasing the percentage of Tregs in the spleen compared with untreated MenSCs. These stronger therapeutic effects were closely associated with IDO.

MenSCs: Menstrual blood-derived stromal cells; IFN-γ: Interferon-γ; IR: Ischemia-reperfusion; IRM: Combination treated with ischemia-reperfusion and menstrual blood-derived stromal cells; IRM (IFN-γ): Combination treated with ischemia-reperfusion and interferon-γ-primed menstrual blood-derived stromal cells; HE: Hematoxylin and eosin; TUNEL: Terminal deoxynucleotidyl transferase-mediated dUTP-biotin Nick End Labeling; ALT: Alanine aminotransferase; AST: Aspartate aminotransferase.

IFN-γ-primed MenSCs promoted autophagy in mouse livers

As described above, we verified that the more significant immunomodulatory effect of primed MenSCs was indeed related to IDO. Strikingly, the more significant effect of primed MenSCs in alleviating liver injury was also associated with IDO. To explore the specific mechanism through which primed MenSCs ameliorate IRI, metabolomics sequencing of mouse liver samples from the short-term model was performed.

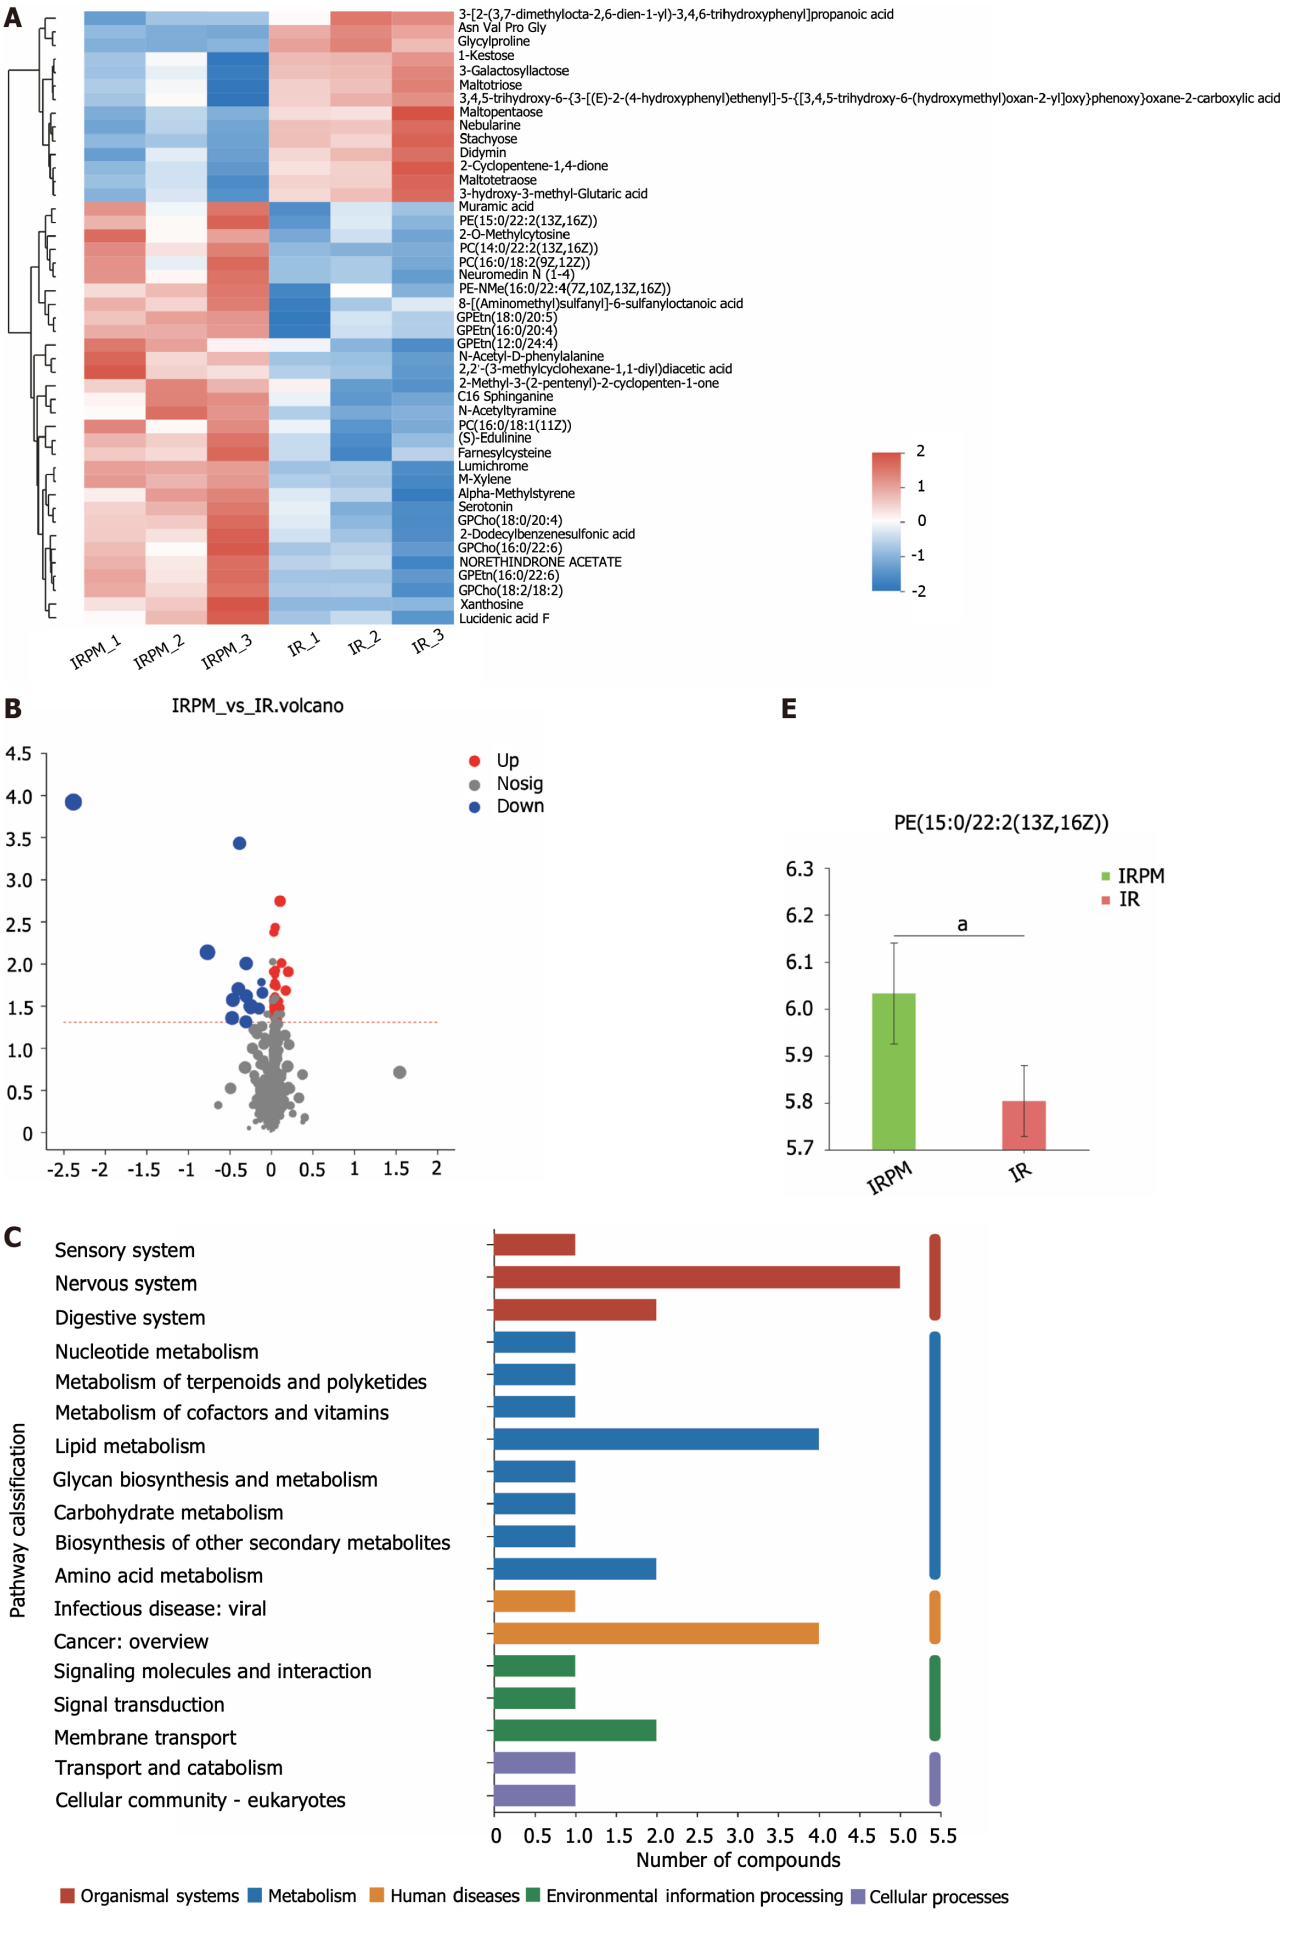
Figure 4 Interferon-γ-primed menstrual blood-derived stromal cells reduced hepatocellular damage and increased the Treg numbers in the mouse long-term ischemia-reperfusion model. A: Representative images of histological liver sections stained with hematoxylin and eosin were obtained (hematoxylin and eosin staining, magnification 200×, images in the second row are partial magnifications of regions indicated by the red box); B: The degree of liver injury in each group was determined according to Suzuki's injury score. The data are expressed as the means ± SEMs (n = 3-5/group); C: The numbers of CD4, CD25, and FoxP3 positive cells (regulatory T cells) in the spleen were determined by flow cytometry to estimate the ability of primed menstrual blood-derived stromal cells to induce immune tolerance; D: The percentages of Tregs are expressed as the means ± SEMs (n = 3/group). $^{a}P < 0.05$, $^{b}P < 0.01$, $^{c}P < 0.001$, $^{d}P < 0.0001$. NS represents not statistically significant. All P values were obtained by one-way ANOVA. MenSCs: Menstrual blood-derived stromal cells; IFN-γ: Interferon-γ; 1MT: 1-methyl-D-tryptophan; IR: Ischemia-reperfusion; IRM: Combination treated with ischemia-reperfusion and menstrual blood-derived stromal cells; IRM (IFN-γ): Combination treated with ischemia-reperfusion and interferon-γ-primed menstrual blood-derived stromal cells; HE: Hematoxylin and eosin; Treg: Regulatory T cell.

PCA and PLS-DA of samples from the two groups were performed to evaluate the degree of aggregation and dispersion of samples within a single group as well as between different groups, and the results indicated that the data could be used for subsequent analysis (Supplementary Figures 1A-D). A statistical heatmap of 45 metabolites that differed between the IR group and IRPM group [IRM (IFN-γ) group] was generated, and the results are also shown in the form of a volcano plot (Figures 5A and B). Kyoto Encyclopedia of Genes and Genomes (KEGG) annotation of the differential metabolites revealed that the differential metabolites are involved in a variety of biological processes, mainly including lipid metabolism, amino acid metabolism, signaling molecule transduction, and membrane transport (Figure 5C). To further elucidate the main biological functions of the differential metabolites, we performed KEGG pathway enrichment analysis of these differential metabolites, and the results showed that the differential metabolites were mainly enriched in autophagy (Figure 5D). Relative quantification of the level of the differential metabolite phosphatidyl ethanolamine (PE), which is related to autophagy, showed that treatment with IFN-γ-primed MenSCs increased the levels of PE in the livers (Figure 5E). The main role of PE in autophagy is mediating the formation of the autophagy membrane marker LC3II from LC3I. A higher PE level is related to a higher level of autophagy[22-25]. Therefore, we hypothesized that primed MenSCs may increase the level of autophagy in mouse liver tissues.

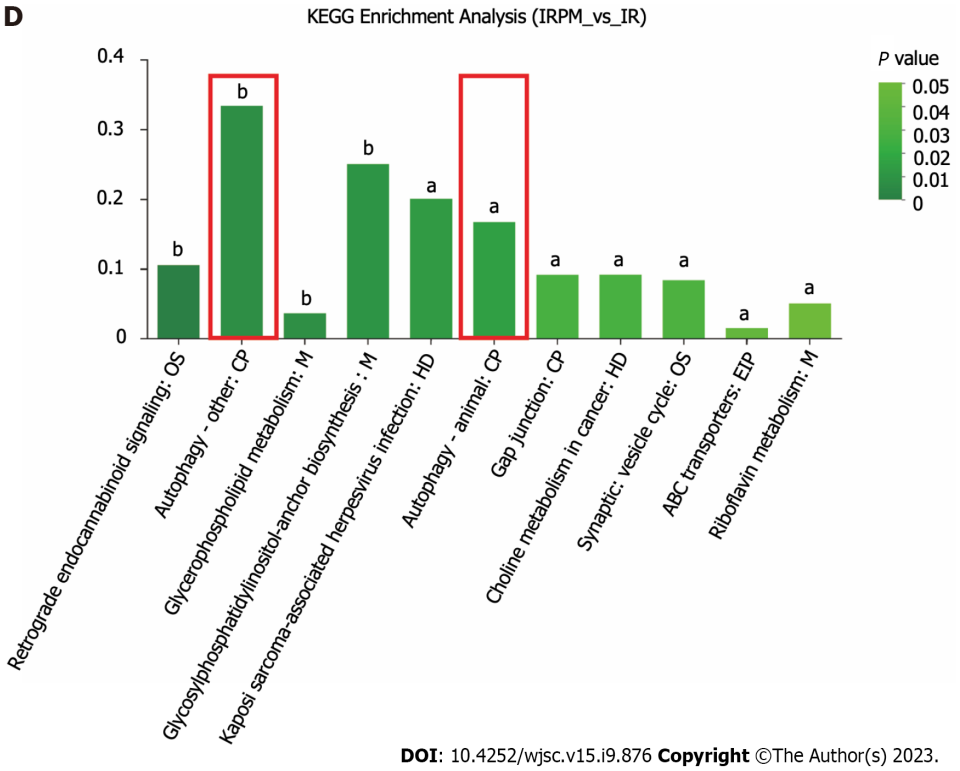
To further verify this hypothesis, we observed the autophagic bodies in mouse liver cells by transmission electron microscopy (TEM) and measured the expression of autophagy-related proteins in liver tissues by western blotting to evaluate the autophagy levels. MenSCs, and primed MenSCs increased the number of autophagosomes in liver tissues, and the increase was most obvious in the IRM (IFN-γ) group (Figures 6A and B). Consistent with the TEM results, LC3II expression was increased after I/R, suggesting that I/R could increase the level of autophagy in hepatocytes (Figures 6C and D). Moreover, the autophagic flux was amplified by MenSCs and particularly by primed MenSCs (Figures 6C and D). Additionally, we observed the changes in the AMPK pathway and the mTOR pathway, which are two classical pathways that are upstream of autophagy, and we found that I/R could promote AMPK phosphorylation and inhibit mTOR phosphorylation; in other words, I/R could activate the AMPK pathway and inhibit the mTOR pathway (Figures 6C and D). Moreover, most of these effects were enhanced by MenSCs and particularly primed MenSCs (Figures 6C and D).

In conclusion, we demonstrated that primed MenSCs amplified I/R-induced autophagy in the mouse livers through metabolome sequencing analysis and molecular biology experiments. However, the relationship between the enhanced autophagy and IDO and whether autophagy is related to the therapeutic effect of MenSCs in alleviating IRI still need to be further clarified.

IFN-γ-primed MenSCs decreased H/R-induced hepatocyte apoptosis via autophagy and IDO



To further investigate the relationship among the therapeutic effect of primed MenSCs, IDO, and enhanced autophagy, we established an *in vitro* H/R model in L02 cells with the corresponding treatment conditions.



First, we exposed L02 cells to H/R for different times to determine an approximately appropriate H/R time. Autophagy-related protein levels were measured by western blotting. The AMPK pathway activation that was caused by hypoxia gradually decreased with increases in the reoxygenation time, and primed MenSCs delayed this process (Supplementary Figure 2A). In addition, we observed that autophagy-related protein expression changed in a time-dependent manner in the mouse model (Supplementary Figure 2B). To allow significant comparisons, we selected 6 h of hypoxia and 4 h of reoxygenation as the H/R conditions.

Apoptotic cells were identified by PI/Annexin V staining, and flow cytometry was performed to analyze cells that were exposed to different treatments. Cells in the upper right corner represent late apoptotic cells, cells in the lower right corner represent early apoptotic cells, and the sum of these two populations represents the overall level of apoptosis. We treated LO2 cells with 3MA (an autophagy inhibitor), 1MT (an IDO inhibitor), MenSCs, and primed MenSCs under normoxic conditions. These treatments alone did not significantly affect apoptosis under normoxic conditions (Figures 7A and B). After H/R, significant L02 cell apoptosis was observed, and the total apoptotic cell proportion accounted for approximately 14.89% of the overall cell population. After treatment of the cells with 3MA to inhibit autophagy under H/R conditions, the total apoptotic cell proportion accounted for approximately 45.06% of the overall cell population (Figures 7A and B). This finding indicated that H/R induced L02 cell apoptosis, and inhibition of autophagy significantly increased H/R-induced apoptosis. In addition, we also observed that the proportion of apoptotic cells was significantly reduced after coculture with MenSCs and particularly with primed MenSCs under H/R conditions, and this result indicated that stem cells can protect L02 cells from H/R-induced apoptosis (Figures 7A and B). A comparison of the HRM (IFN-γ) and HRM (IFN-γ) + 3MA groups revealed that the protective effect of primed MenSCs was significantly reduced when autophagy was inhibited (Figures 7A and B). This finding indicated that primed MenSCs may protect L02 cells against H/R by enhancing autophagy. In addition, a comparison of the HRM (IFN-γ) and HRM (IFN-γ) + 1MT groups showed that inhibition of IDO by 1MT also inhibited the protective effect of primed MenSCs (Figures 7A and B). These results indicated that autophagy reduced H/R-induced apoptosis and that the more powerful protective effect of IFN-γ-primed MenSCs was closely associated with autophagy and IDO.

IDO secreted by primed MenSCs enhanced autophagy by inhibiting the mTOR pathway and activating the AMPK pathway

As mentioned above, primed MenSCs attenuated H/R-induced apoptosis *via* IDO and autophagy. To further investigate whether IDO is related to autophagy, we used 1MT to inhibit IDO and observed changes in autophagy. L02 cells were transfected with pCMV-GFP-LC3, exposed to the indicated treatments and then observed under a fluorescence microscope. We counted the number of intense punctate GFP-LC3 aggregates in each cell to assess autophagy. The results showed that H/R increased the level and aggregation of GFP-LC3 in cells, and this phenomenon was amplified by MenSCs and particularly by primed MenSCs (Figures 8A and B). In addition, the effect of primed MenSCs on GFP-LC3

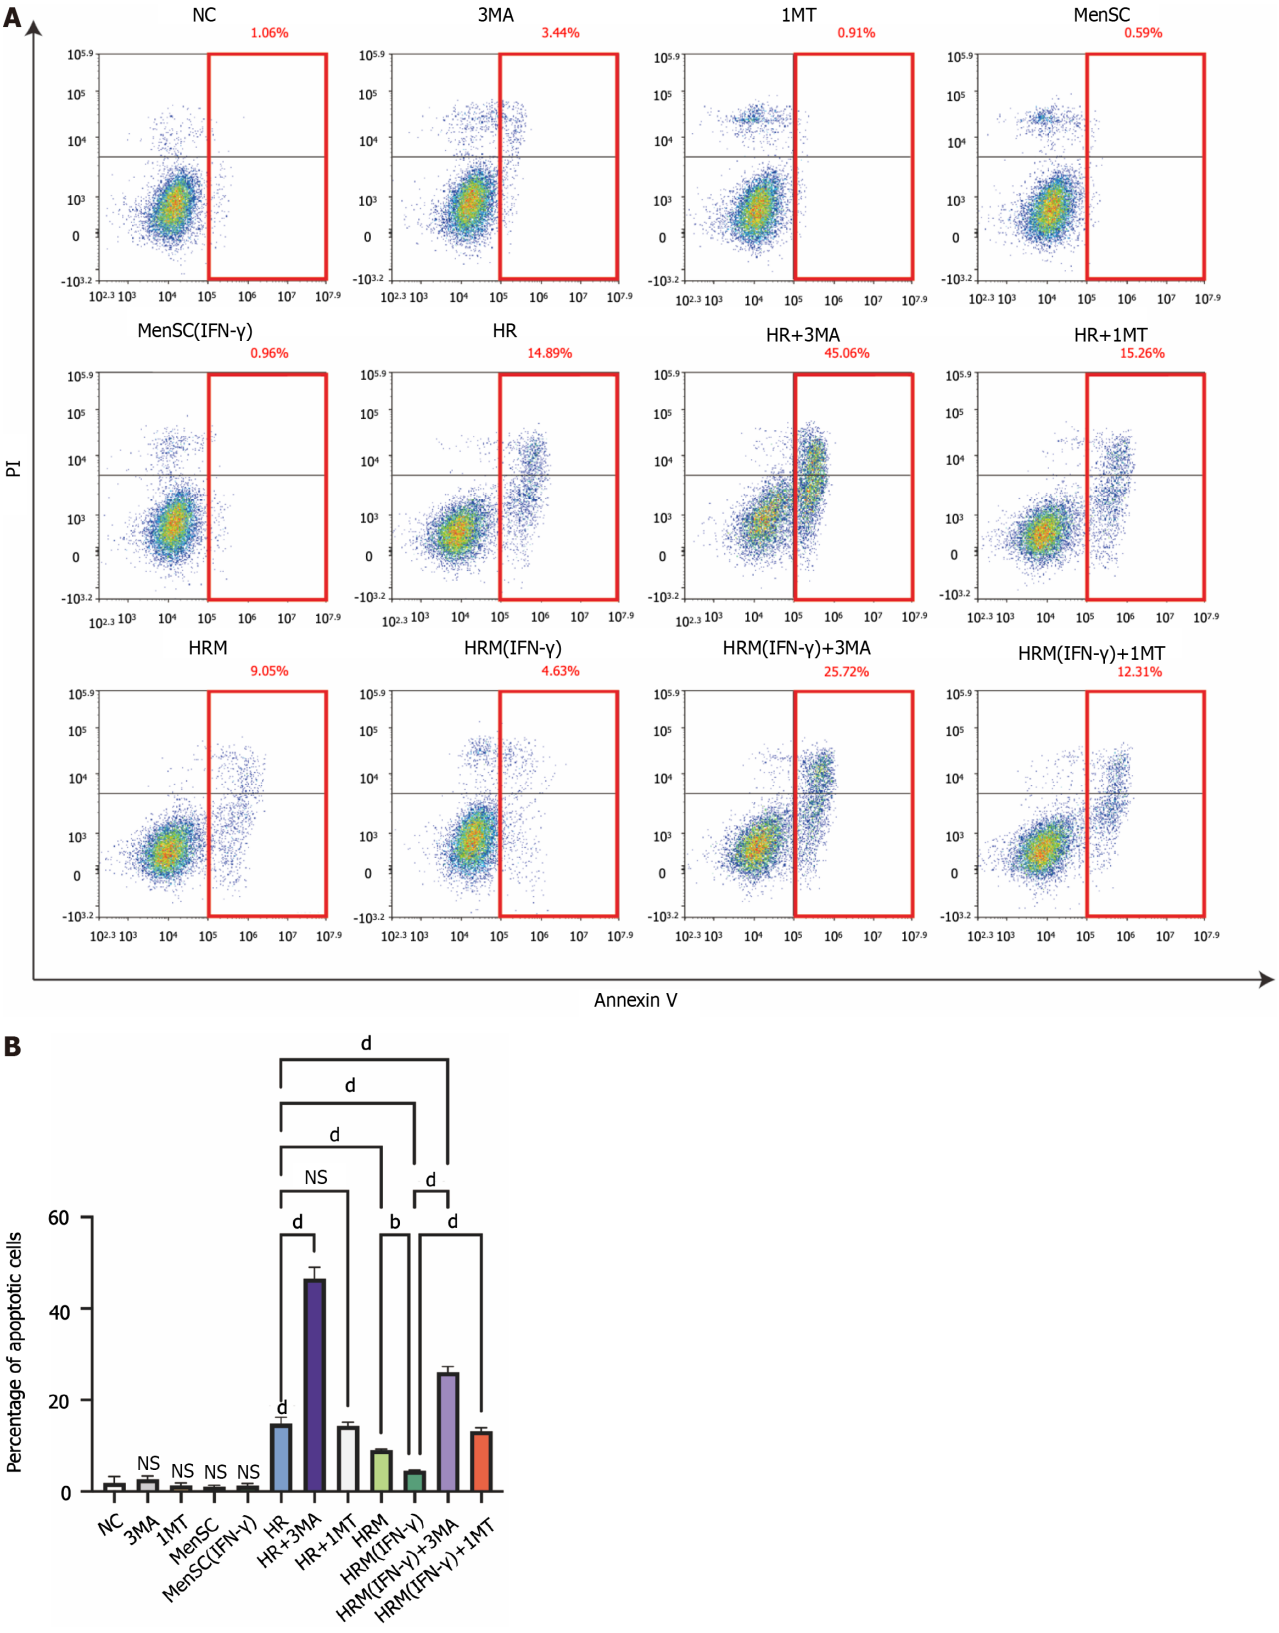
punctate aggregation was reversed by 1MT, which suggested that IDO was related to the promotion of autophagy (Figures 8A and B). Then, we measured the changes in autophagy-related protein expression by western blotting to further explore how IDO affects autophagy. The results showed that H/R could inhibit the mTOR pathway, activate the AMPK pathway, and increase autophagy, and these effects were enhanced by MenSCs and particularly by primed MenSCs (Figures 8C and D); furthermore, the enhanced effect of primed MenSCs on autophagy was reversed by the IDO inhibitor 1MT (Figures 8C and D). These results indicated that IDO secreted by primed MenSCs enhanced autophagy by inhibiting the mTOR pathway and activating the AMPK pathway.

DISCUSSION



In this study, we found that IDO secreted by IFN-γ-primed MenSCs enhanced the therapeutic effect of MenSCs in the mouse liver I/R model, and the related mechanisms are shown in Figure 9. However, some studies have indicated that the combination of IFN-γ and tumor necrosis factor-alpha (TNF-α) could more efficiently promote the secretion of IDO by MSCs[12]. Although our study showed that priming with 100 ng/mL IFN-γ for 72 h was sufficient to initiate IDO secretion by MenSCs, priming with multiple inflammatory factors to generate better and more functional MenSCs still has a very high experimental value. However, considering that the high concentration of IFN-γ decreased the tolerance of MenSCs to H/R-induced injury (Figures 2E and F), we hypothesized that the priming of MenSCs with multiple inflammatory cytokines may cause more severe damage. Consequently, the side effects of these inflammatory cytokines on MSCs need to be further investigated *in vitro* and *in vivo*.

In addition to priming MSCs with some inflammatory factors, such as transforming growth factor-β, IL-17, TNF-α, and IFN-γ, to promote the secretion of immune regulatory cytokines[26-28], MSCs could also be modified by gene editing to overexpress some immune regulatory factors and thus enhance their therapeutic effects. In one study, MSCs that overexpressed IDO were more effective in alleviating injury in dilated cardiomyopathy in mice and further enhanced the responses of Tregs and Th2 cells[29]. Therefore, subsequent studies may examine the differences in safety, efficacy, and cost between these two approaches to identify the more suitable method of MSC modification.

To date, 79 clinical trials involving the use of MSCs to prevent or treat graft-*versus*-host disease (GVHD) have been conducted[30]. Most of the studies demonstrated the safety and efficacy of MSCs, but some studies showed that MSCs did not exert the desired protective effect; differences in the immunomodulatory effects of MSCs may be related to the origin and the dose of MSCs that were used. One study compared the therapeutic potential of MSCs from different origins in a mouse GVHD model and found that bone marrow-derived MSCs (BM-MSCs) induced a rapid proinflammatory response before exerting immunosuppressive effects and that BM-MSCs were less capable of inducing Treg differentiation than umbilical cord blood-derived MSCs (UC-MSCs)[31]. Therefore, differences in the origin of MSCs might be a reason why some MSCs did not exert the expected effects in some studies[7,8]. It has also been suggested that subsequent studies on MSCs may focus on the differences in the therapeutic potential of MSCs that are derived from different sources. Moreover, another study showed that a double dose of UC-MSCs exerted a better therapeutic effect than a single dose of UC-MSCs in a rat dilated cardiomyopathy model[29]. Consequently, in addition to improving MSCs, selecting the right MSC source and the right MSC dose is also crucial for research.

Figure 9 Schematic depiction of the mechanism. Ischemia-reperfusion injury (IRI) and immune rejection are two important factors that affect the prognosis of liver transplantation. After priming menstrual blood-derived stromal cells (MenSCs) with interferon-γ, the MenSCs secreted high levels of indoleamine 2,3-dioxygenase (IDO). On the one hand, MenSCs and IDO enhanced the AMPK-mammalian target of rapamycin-autophagy axis to reduce IRI; on the other hand, IDO promoted the differentiation of lymphocytes into Tregs to reduce immune rejection. IRI: Ischemia-reperfusion injury; MenSCs: Menstrual blood-derived stromal cells; IFN-γ: Interferon-γ; IDO: Indoleamine 2,3-dioxygenase; AMPK: AMP-activated protein kinase signaling pathway; mTOR: Mammalian target of rapamycin signaling pathway; Tregs: Regulatory T cells.

This study found that IDO secreted by IFN-γ-primed MenSCs was found to activate the AMPK pathway and inhibited the mTOR pathway, which resulted in inducing of protective autophagy in hepatocytes. However, the specific mechanism through which IDO activates the AMPK pathway or inhibits the mTOR pathway remains unclear. IDO is a metabolic enzyme that can promote tryptophan metabolism and produce kynurenine. Some studies have shown that IFN-γ priming and IDO overexpression can promote tryptophan depletion and kynurenine accumulation, and these phenomena induce autophagy in cervical cancer cells and promote phagocytosis by macrophages[32]. Studies have also shown that a protective autophagic response and amino acid metabolism, which are driven by IFN-γ-mediated induction of IDO enzyme activity, could inhibit antibody-mediated inflammatory kidney injury in a mouse model of nephrotoxic serum nephritis[33]. Another study showed that glucose metabolism is also related to the T cell inhibition caused by MSCs and IDO[34]. In this study, we found that primed MenSCs increased the relative expression of the autophagy-related metabolite PE in mouse livers, and corresponding experiments proved that primed MenSCs indeed promoted autophagy through IDO; however, we did not conduct targeted metabolomics analyses to quantify the absolute expression of PE. In addition, how IDO causes changes in the levels of PE are unclear. Therefore, further study is needed to determine how IDO triggers autophagy. Notably, tryptophan catabolism by IDO could alter inflammatory responses and favor T-cell tolerance in cancer[35,36]. Although there is no evidence showing that MSCs can promote tumor growth and our previous study showed that MSCs can inhibit the growth of hepatocellular carcinoma through epigenetic regulation[37], the use of primed MSCs in cancer patients may still be controversial.

In addition, because IDO secreted by MSCs could increase the Tregs to induce immune tolerance, as has been observed in several studies[14,17], we paid more attention to the potential of primed MenSCs to reduce liver IRI in this study, and only used the number of Tregs as an indicator to evaluate the MSC-induced - immune tolerance potential. Therefore, although primed MenSCs significantly increased the numbers of Tregs, it is still necessary to verify whether the increased Tregs could alleviate IRI[38] or better induce immune tolerance in the liver transplantation model. Besides, recent studies have shown that macrophage activation and neutrophil infiltration also play important roles in liver IRI[39,40], and the regulation of MSCs to different types of immune cells deserves further study.

Notably, untreated MenSCs could also activate the AMPK pathway, inhibit the mTOR pathway and enhance autophagy in the I/R or H/R models; however, untreated MenSCs secreted little IDO (Figures 2G-I). This finding indicates that the effect of MenSCs in enhancing autophagy is not entirely dependent on IDO and may be related to other mechanisms. How stem cells enhance autophagy in recipient cells is still worth further study.

CONCLUSION

IFN-γ-primed MenSCs could exert a better therapeutic effect in a liver I/R model than untreated MenSCs by secreting higher levels of IDO. On the one hand, MenSCs and IDO enhanced the AMPK-mTOR-autophagy axis to reduce IRI; on the other hand, IDO increased the Treg numbers in the spleen and enhanced the ability of MenSCs to induce immune tolerance. Our study suggests that IFN-γ-primed MenSCs may be a novel and improved MSC product for liver transplantation in the future.

ARTICLE HIGHLIGHTS

Research background

Ischemia-reperfusion injury (IRI) and immune rejection are two important factors that affect the prognosis of liver transplantation. Mesenchymal stem cells (MSCs) have been used in liver transplantation and showed certain beneficial effects.

Research motivation

Some studies have indicated that the effects of MSCs are not very significant. Therefore, there is an urgent to find a new way to make MSCs exert better therapeutic effect.

Research objectives

In this study, we attempted to enhance the therapeutic potential of human menstrual blood-derived stromal cells (MenSCs) in a mouse liver ischemia-reperfusion (I/R) model through interferon-γ (IFN-γ) priming strategies and explore the specific mechanisms.

Research methods

After determining the appropriate priming strategies, we applied MenSCs and primed MenSCs in the short-term and long-term mouse liver I/R models, and compared their therapeutic effects. In order to further explore the specific mechanism, we performed a metabolomic analysis of mouse liver samples.

Research results

IFN-γ-primed MenSCs secreted higher levels of indoleamine 2,3-dioxygenase (IDO), attenuated liver injury, and increased regulatory T cell (Treg) numbers in the mouse spleens to greater degrees than untreated MenSCs. Metabolomics and autophagy analyses proved that primed MenSCs more strongly induced protective autophagy in the mouse livers. Further experiments proved that IDO enhanced the protective autophagy by inhibiting the mammalian target of rapamycin (mTOR) pathway and activating the AMPK pathway.

Research conclusions

IFN-γ-primed MenSCs exerted better therapeutic effects in the liver I/R model through secreting higher IDO levels. IDO, on the one hand, increased Treg numbers in the spleen; on the other hand, activated the AMPK-mTOR-autophagy axis to reduce IRI.

Research perspectives

Our study suggests that IFN-γ-primed MenSCs may be a novel and superior MSC product for liver transplantation in the future, and the specific mechanism of how MSCs or IDO enhance autophagy in recipient cells is still worth further study.

Abstract

BACKGROUND

Heart failure (HF) is a global health problem characterized by impaired heart function. Cardiac remodeling and cell death contribute to the development of HF. Although treatments such as digoxin and angiotensin receptor blocker drugs have been used, their effectiveness in reducing mortality is uncertain. Researchers are exploring the use of adipose-derived mesenchymal stem cell (ADMSC) exosomes (Exos) as a potential therapy for HF. These vesicles, secreted by cells, may aid in tissue repair and regulation of inflammation and immune responses. However, further investigation is needed to understand the specific role of these vesicles in HF treatment.

AIM

To investigate the mechanism of extracellular vesicles produced by ADMSC s in the treatment of HF.

METHODS

Exogenous surface markers of ADMSCs were found, and ADMSCs were cultured.

RESULTS

The identification of surface markers showed that the surface markers CD44 and CD29 of adipose-derived stem cells (ADSCs) were well expressed, while the surface markers CD45 and CD34 of ADSCs were negative, so the cultured cells were considered ADSCs. Western blotting detected the Exo surface marker protein, which expressed CD63 protein but did not express calnexin protein, indicating that ADSC-derived Exos were successfully extracted.

CONCLUSION

The secretion of MSCs from adipose tissue can increase ATP levels, block cardiomyocyte apoptosis, and enhance the heart function of animals susceptible to HF. The inhibition of Bax, caspase-3 and p53 protein expression may be related to

this process.

Key Words: Adipose-derived mesenchymal stem cell exosomes; Heart failure; Cardiomyocyte apoptosis

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Our study highlights the potential of mesenchymal stem cell exosomes (Exos) from adipose tissue as a promising therapy for heart failure (HF). Administration of adipose-derived mesenchymal stem cell Exos improved cardiac function, evidenced by increased ATP content and enhanced parameters like ejection fraction, fractional shortening, and stroke volume. Furthermore, adipose-derived stem cells (ADSCs)-Exo reduced serum levels of b-type natriuretic peptide and atrial natriuretic peptide, associated with HF progression, and exhibited anti-apoptotic effects by regulating pro- and anti-apoptotic proteins in cardiac tissue. These findings suggest that ADSCs-Exo could prevent cardiomyocyte death and inhibit HF progression.

INTRODUCTION

Heart failure (HF), which is mainly caused by impaired ventricular diastolic or systolic function, is characterized by arterial ischemia or venous congestion. As the final stage of many diseases, HF is a significant public health issue that needs to be addressed globally[1,2]. Numerous studies have found that HF develops and is directly correlated with cardiac remodeling, while cardiomyocyte apoptosis is an important factor leading to myocardial remodeling[3,4]. Although the clinical treatment of HF has been effective in recent years, the prognosis for patients is generally dismal, and hospitalization and fatality rates are still high. We review recent progress in the diagnosis and treatment of chronic HF. Digoxin has been used clinically for more than 200 years and is an essential drug in the treatment of chronic HF. However, the results of the DIG study confirmed that digoxin did not reduce or increase mortality compared with that of the placebo but was superior to placebo in reducing hospitalization rates for HF. In recent years, with the accumulation of ELITEII, OPTIMAAL and VALIANT studies, especially the results of recent CHARM trials, the role of angiotensin receptor blocker drugs in the treatment of HF has been improved. In particular, there is clear evidence that candesartan and valsartan reduce mortality and disability. The recently published HEAAL study showed that losartan 150 mg daily (high-dose group) was more effective than losartan 50 mg daily (low-dose group) in the treatment of HF. Therefore, it is difficult to explore the pathogenesis of HF and find an effective treatment for HF. Mesenchymal stem cells (MSCs) comprise cells with a wide range of differentiation potential and include MSCs from adipose tissue, umbilical cord, bone marrow, and other sources[5]. Because adipose tissue is more abundant than other MSCs and benefits from simple access and consumption, it has been widely studied by an increasing number of scholars[6,7]. However, adipose-derived MSCs (ADMSCs) have relatively high requirements during storage and transportation, which causes the survival rate of these cells during transplantation to significantly decline. Therefore, the clinical use of adipose-derived stem cells (ADSCs) has certain limitations. Exosomes (Exos) are lipid bilayer vesicles secreted by cells with a diameter of 30-200 nm. In addition to being secreted into cells, these Exos can also be stored for a long time in any environment at 4 °C and easily transported. The discovery of Exos provides a new direction for the clinical use of ADSCs[8,9]. All cells secrete Exos in both normal and pathological states. Exos are mainly involved in intercellular communication and regulate a series of physiological processes in target cells. Exos from different cell types have different functions. Some studies have found that ADSC Exos have the functions of tissue repair and regeneration, inflammation inhibition and immune regulation. However, the effect of ADSC Exos on HF has not been confirmed. The goal of this research is to investigate how ADMSC Exos work to treat HF.

MATERIALS AND METHODS

Animal experiment

The license number for Jinan Pengyue Experimental Animal Breeding Co., LTD sale's of the rats used in this investigation was SCXK (Lu) 2019-0003. There were 30 rats with a body weight of 180-220 g Wistar and 20 C57 mice, all of which were male specific pathogen-free (SPF) grade. All the experimental animals were kept in the SPF animal room, drinking water freely and providing animal feed according to the standard. The room temperature was controlled at 20 °C to 26 °C, and the humidity was controlled at 50%-60%, ensuring that the indoor environment was controlled at 12 h/12 h alternating day and night.

Reagents and instruments

Mouse adipose stem cell complete medium (Suzhou Saiye Biotechnology Co., LTD.); antibodies against Bcl-2, Bax, and caspase-3 (Cell Signaling Technology, United States); hematoxylin staining and eosin staining (Beijing Yili Fine Chemicals Co., LTD.); ELISA kit (Wuhan Fien Biotechnology Co., LTD.); polyvinylidene fluoride (PVDF) transfer membrane (Millipore, United States); goat anti-rabbit IgG antibody that was HRP-labeled (Shanghai Biyuntian Biotechnology Co., LTD.); IE33 heart color exclusive Opo ultrasound instrument (Philips, Netherlands); RM2245 microtome and DW4-B biological microscope (Leica, Germany).

Extraction and culture of ADSCs

Ten C57 mice were sacrificed in a sterile environment, and the subcutaneous adipose tissue of the mice was taken and cut into pieces until the tissue was erosive and placed in a centrifuge tube. Then, 0.5% collagenase type I was added to the centrifuge tube, and the centrifuge tube was digested for 45 min in the dark. After that, an equal volume of α-MEM medium was added to the centrifuge tube to terminate digestion. The mixture in the centrifuge tube was filtered through a 200-mesh sterile steel sieve, and the filter was collected and centrifuged at 15000 r/min for 5 min. The supernatant was thrown away, and an equal volume of red blood cell lysate was added to the centrifuge tube to lyse the cells. After 5 min, the cells were centrifuged again, and then α-MEM complete medium was added to the centrifuge tube to obtain the cell suspension, which was completely spread in the culture dish. After 24 h, the cells began to grow adherent, and all the nonadherent cells were removed. Under a microscope, the cell morphology was observed, and the cell surface expression markers CD29, CD44, CD34 and CD45 were detected by a cell loss analyzer.

Extraction and identification of Exos derived from ADSCs

Fourth-generation ADSCs with a fusion degree of 80% were used, and serum-free MEM was used instead of complete medium. Cell supernatant was collected after 48 h of culture. The cells received the same amount of Exo extraction reagent and were cultured overnight at 4 °C. Then, the cells were placed into a centrifuge tube and centrifuged at 15000 r/min for 30 min to separate the Exos. The morphology of the Exos was identified by transmission electron microscopy, and the protein expression related to the Exos was determined by western blotting.

Grouping and model preparation

Thirty Wistar rats received 7 d of adapted feeding. Using a random number system, the rats were divided into groups that were not given any instructions. (Control group), HF rat model group (HF group), and HF rat model treated with ADSC-derived Exo intervention group (ADSCS-Exo group). Each group included ten rats. Except for the control group, the other rats were intraperitoneally injected with 0.8 mg/kg doxorubicin solution at a dose of 3 mg/kg in the first three weeks and 2 mg/kg in the second 3 wk. For six weeks, the control group of rats received weekly intraperitoneal injections of the same volume of NaCl solution. After the intervention, the cardiac function indices of the rats in each group were measured. The establishment of the rat model of HF was demonstrated by a left ejection fraction (LVEF) of 45%. Rats in the ADSC-Exo group were injected with 100 μL of ADSC-derived Exos suspension at a concentration of 0.2 mg/mL through the tail vein, and identical doses of phosphate buffered saline (PBS) solution were injected into the tail veins of the rats in the control and HF groups. Rats in each group were injected once every 2 d for two consecutive times.

Determination of cardiac function indices

After the drug intervention, the rats in each group were fasted for 12 h and allowed to drink water freely. The rats were fixed in the supine position after receiving an intraperitoneal injection of 20% urethane to induce anesthesia. By using color Doppler echocardiography, cardiac function markers, such as left ventricular ejection fraction, were found. Three consecutive cardiac cycles were used to test each group's LVEF, left ventricular fractional shortening (LVFS), and stroke volume (SV), with the average value being used.

Serum b-type natriuretic peptide and atrial natriuretic peptide levels were measured

The abdominal aortas of rats in each group were sampled for 5 mL of blood. After standing for 2 h at 3000 rpm and 4 °C, the blood samples were centrifuged for 10 min. According to the directions on the ELISA kit, serum b-type natriuretic peptide (BNP) was found. According to the directions on the ELISA kit, BNP and atrial natriuretic peptide (ANP) serum levels were discovered.

The pathological changes in myocardial histopathology were detected by hematoxylin and eosin staining

The rats in each group were killed by cutting the neck and chest to remove the blood stains on the surface of the heart disease. After placing the heart in ice, all tissues except the left ventricular myocardial tissue were removed. Dry filter paper was used to cut part of the left ventricular apex group. After dehydration, the heart was fixed in 4% paraformaldehyde solution, made transparent, and embedded in paraffin sections with a thickness of 4 μm. Hematoxylin and eosin (HE) staining, neutral resin and biopsy tissue were used to observe each group of sections under the microscope to find any abnormal myocardial changes.

Flow cytometry was used to detect cardiomyocyte apoptosis

By using a mechanical process, a single-cell suspension was created. Put AGAR in 200 stainless steel net, cut up the myocardial tissue in 2 net, rub while washed with PBS solution, after being fully knead, collected in AGAR suspension again through 300 mesh sieve, collected after cell suspension in centrifuge tube, in a speed of 2000 r centrifugal 5 min per

minute, suck out and discard the supernatant, collected after the cells. The cells were resuspended with PBS solution at 4 °C, then placed in the centrifuge tube again under the same conditions as above, washed and adjusted the cell density to 1 × 10^5/ mL. The cells were resuspended in 300 μL binding buffer, and after that, the cells were gently mixed with 5 L of Annexin V-FITC. The cells were cultured at room temperature for fifteen minutes, and then 5 μL PI and 200 μL binding buffer were added. To determine which group of cardiomyocytes had undergone apoptosis, the centrifuge tube was placed into a flow cytometer.

Comparison of ATP content in myocardial tissue of rats in each group

One hundred milligrams of rat myocardial tissue was taken, 500 μL of perchloric acid was added, and at room temperature for fifteen minutes, 200 μL of supernatant was taken, and 120 μL of 1 mol/L sodium hydroxide (NaOH) was added. Following a 5-min, 5000 r/min, 4 °C centrifugation, ATP content in rat myocardial tissue was detected by high performance liquid chromatography.

Western blotting was used to detect the protein expression of Bcl-2, Bax, caspase-3 and p53 in myocardial tissue

Fifty milligrams of myocardial tissue from each rat was lysed on ice until tissue homogenization was performed by centrifugation. The DAB technique was used to determine the protein content in the supernatant. The concentrations of the concentration and separation gel were 5% and 8%, respectively. The sample protein was added to the gel well, and the membrane was transferred after electrophoresis for 10 min. After 2 h of incubation, 5% blocking solution was added to the sample, after which it was activated and transported to the PVDF membrane, and the PVDF membrane was blocked for one hour. Overnight, the primary Bcl-2, Bax, caspase-3, and p53 antibodies were added. HRP-labeled secondary antibodies were added and incubated for another 2 h. The PVDF membrane was detected by ECL and imaged.

Statistical methods

SPSS 26.0 software was utilized for the statistical evaluation. The mean and standard deviation of the data were written as (mean ± SD). One-way analysis of variance was used to compare the groups. The LSD-*t* test was used for homogeneity of variance, and the nonhomogeneity of variance was corrected using the *t* test. At $P < 0.05$, statistics were deemed significant.

RESULTS

Morphological changes of ADSCs

ADSCs began to grow adherent after 24 h of primary culture, and the cell fusion rate was 80% at 5-7 d. The size of cells in the first generation was inconsistent, and the morphology was mostly spindle, round and polygon. At the fourth passage, the morphology of ADSCs gradually changed to a long spindle shape, which was similar to that of fibroblasts and arranged in a spiral shape, and the nuclei became significantly larger (Figure 1).

Identification of ADSC surface markers

The ADSC surface markers CD44 and CD29 were positively expressed, and the expression rates were 99.4% and 94.8%, respectively. The ADSC surface markers CD45 and CD34 were negative, with expression rates of 0.026% and 0.213%, respectively. Thus, the cultured cells were ADSCs (Figure 2).

Morphology and protein identification of ADSC-derived Exos

The Exos were spotted using transmission electron microscopy to have a round shape and an unbroken cell membrane (Figure 3A). Western blot detection of Exo surface marker protein showed that CD63 protein was expressed, but Calnexin protein was not expressed, indicating that ADSC-derived Exos were successfully extracted (Figure 3B).

Comparison of cardiac function in each group

Rats in the HF group had considerably lower LVEF, LVFS, and SV values than those in the control group ($P < 0.05$). The LVEF, LVFS, and SV of rats in the ADSCS-EXO group were significantly greater than those in the HF group ($P < 0.05$) (Table 1).

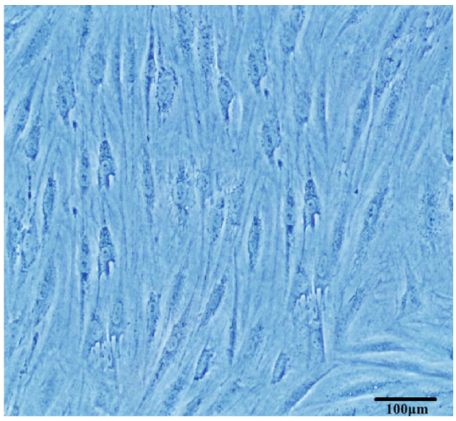
Comparison of BNP and ANP levels in the serum of rats in each group

BNP levels in serum were significantly higher in the HF group of rats and ANP compared to those in the control group ($P < 0.05$). Rats in the ADSCS-Exo group had significantly lower serum levels of BNP and ANP than the HF group ($P < 0.05$) (Table 2).

Comparison of myocardial histopathological changes in each group

The control group cardiomyocytes had a distinct, orderly, and closely packed structure. There was no degeneration or necrosis of the cells and no edema or congestion in the interstitium. The configuration of the cardiomyocytes in the HF group was noticeably different from that of the control group, with obvious swelling, cell degeneration or even necrosis, myocardial fiber breakage, and obvious interstitial edema. In contrast to the HF group, the myocardial tissue of the ADSCS-Exo group was greatly enhanced, with loose arrangement of cardiomyocytes, reduced swelling and necrotic cells (Figure 4).

Table 1 Comparison of left ejection fraction, left ventricular fractional shortening and stroke volume in each group (mean ± SD, %)



Group	*n*	LVEF	LVFS	SV
Control group	10	83.26 ± 3.41	50.01 ± 2.63	0.27 ± 0.03
HF group	10	40.16 ± 2.37[a]	28.65 ± 1.84[a]	0.13 ± 0.02[a]
ADSCs - exobiology group	10	70.85 ± 2.86[a,b]	40.27 ± 2.16[a,b]	0.22 ± 0.03[a,b]
F value		580.8	229.2	68.64
P value		< 0.0001	< 0.0001	< 0.0001

[a]*P* < 0.05, compared to control group.
[b]*P* < 0.05, compared with heart failure group.
ADSC: Adipose-derived stem cells; HF: Heart failure; LVEF: Left ejection fraction; LVFS: Left ventricular fractional shortening; SV: Stroke volume.

Table 2 Comparison b-type natriuretic peptide of and atrial natriuretic peptide contents in serum of rats in each group (mean ± SD, pg/mL)

Group	*n*	BNP	ANP
Control group	10	153.62 ± 10.42	123.46 ± 8.11
HF group	10	518.37 ± 15.91[a]	326.54 ± 11.42[a]
ADSCs - exobiology group	10	225.43 ± 13.65[a,b]	151.27 ± 9.34[a,b]
F value		2044	1283
P value		< 0.0001	< 0.0001

[a]*P* < 0.05, compared to control group.
[b]*P* < 0.05, compared with heart failure group.
ADSC: Adipose-derived stem cells; HF: Heart failure; BNP: B-type natriuretic peptide; ANP: Atrial natriuretic peptide.

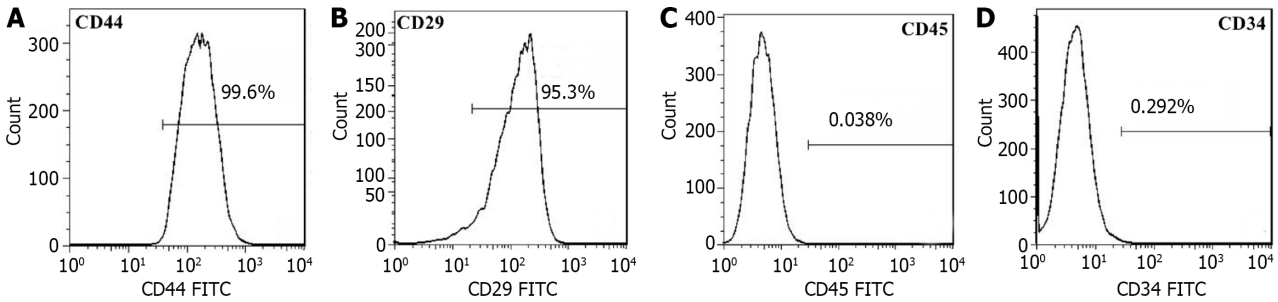

Figure 1 Morphology of adipose-derived stem cells at passage 4 (× 100).

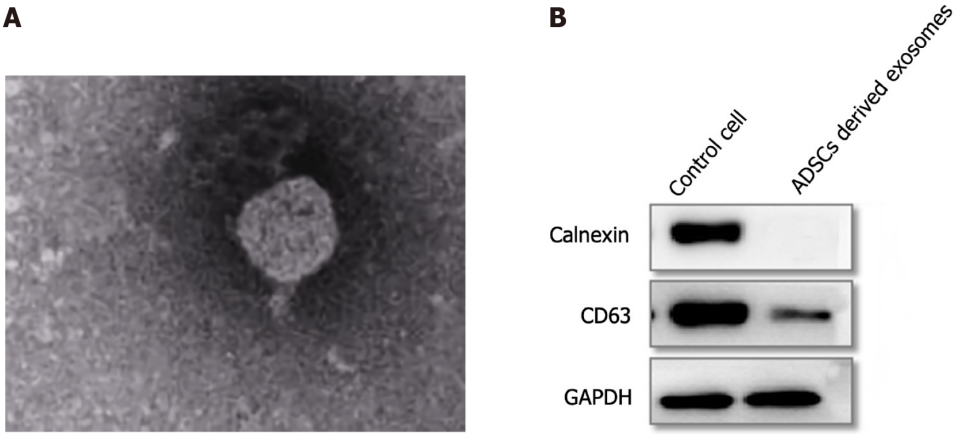
Comparison of cardiomyocyte apoptosis rate in each group

The rate of cardiomyocyte apoptosis in the HF group was much greater than that in the control group ($P < 0.05$). The cardiomyocyte apoptosis rate of the ADSC-Exo group was much lower than that of the HF group ($P < 0.05$) (Figure 5).



Comparison of ATP content in myocardial tissue of rats in each group

Rats in the HF group had considerably lower myocardial ATP content than those in the control group ($P < 0.05$). Rats in the ADSCS-Exo group had considerably more ATP in their cardiac tissue than the HF group ($P < 0.05$) (Figure 6).

ADSC: Adipose-derived stem cell.

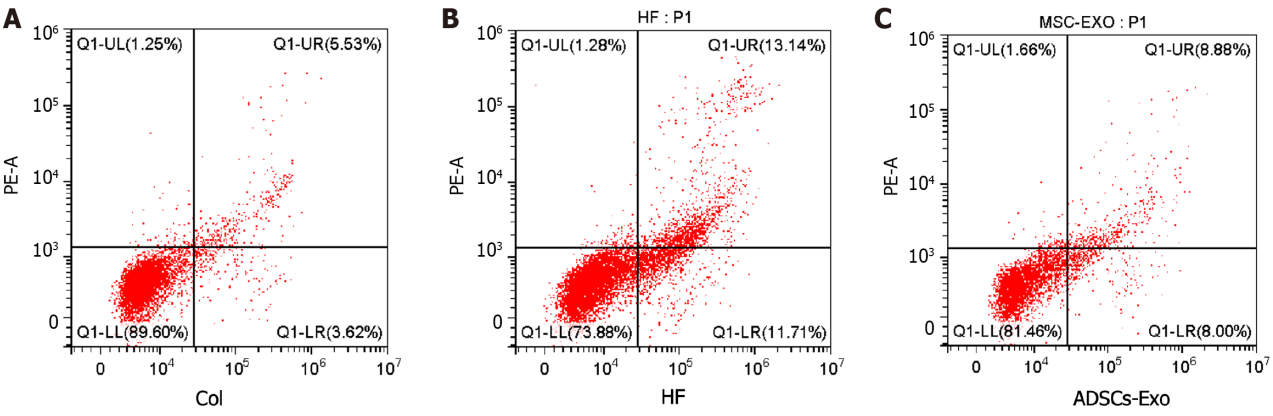
Comparison of protein expression of Bcl-2, Bax, caspase-3 and p53 in myocardial tissue of rats in each group

Bcl-2 protein expression was considerably decreased relative to the control group in the HF group, and the HF group's Bax, caspase-3, and expression levels of the p53 protein were much greater than those of the control group. p53, caspase-3, and Bax protein levels were all substantially lower in the HF group than in the control group, while Bcl-2 protein expression was substantially greater in the ADSC-Exo group than in the HF group ($P < 0.05$) (Figure 7).

DISCUSSION



Current research suggests that HF is a chronic, naturally progressing condition[10]. HF is a disease with a pathogenesis induced by aberrant neuroendocrine system activation, which results in ventricular remodeling and cardiomyocyte death. When cardiomyocyte apoptosis occurs, the myocardium will not only maintain myocardial function due to a large amount of cell loss but also lead to myocardial failure and gradual deterioration when the number of cardiomyocytes is lost, thus forming a vicious cycle of pathological processes[11]. Therefore, by enhancing pump performance, prevention of cardiomyocyte apoptosis can successfully lower the incidence of myocardial remodeling and ease the onset and development of HF. Doxorubicin is a common anthracycline in clinical practice. Doxorubicin has been used to treat a variety of tumors, but its use is limited due to its dose-dependent and delayed cardiotoxicity[12]. Doxorubicin can often cause irreversible damage to the heart, including HF[13]. Doxorubicin was injected intraperitoneally to create a rat HF model for this investigation. LVEF < 45% was detected by cardiac color Doppler ultrasound, demonstrating the establishment of the rat model of cardiac failure. Current research on the molecular mechanism by which doxorubicin causes myocardial damage shows that doxorubicin can interact with DNA and inhibit protein synthesis-induced myocardial cell apoptosis, but there is currently no effective treatment for HF caused by adriamycin; thus, exploring new drugs for HF is a hotspot in current clinical studies[14].

ADSCs can grow rapidly in culture medium without excessive nutrient requirements, have strong proliferation and passage ability and are relatively stable in the genetic process, with multiple differentiation potential. Currently, it has been clinically found that ADSCs can purify ADSC-derived Exos in the supernatant of ADSC culture in either hypoxic or normoxic environments, and the diameter of the Exos is significantly larger than that of previously reported Exos[15].

Numerous studies have found that Exos derived from ADSCs can promote vascular regeneration, wound healing, scar repair, and nerve regeneration and regulate immunity, the inflammatory response and tumor growth[16]. Some scholars have found that through the study of a myocardial ischemia model[17], ASC-derived Exos can inhibit cardiomyocyte apoptosis and alleviate myocardial structural remodeling. In this study, the surface markers of ADSC-Exos were identified, and Exos may be effectively extracted from adipose-derived mesenchymal cells and adipose tissue. After injecting ADSC-Exos into HF rats, it was found that the LVEF, LVFS and SV of rat heart function indices were significantly increased, suggesting that ADSC-Exos could alleviate cardiac function in rats with HF. Sun *et al*[18] discovered that Exos from MSCs generated from adipose tissue may treat old HF rats, and the mechanism may be due to miR-423-mediated control of 5p in the PI3K/Akt signaling pathway.

ANP is mainly synthesized by the atrium, where it is stored and secreted. ANP levels are frequently elevated in a number of illnesses, including HF, coronary heart disease, and chronic pulmonary obstruction, and elevated concentrations suggest poor prognosis. The findings of this investigation demonstrated that rats in the HF group had considerably higher serum levels of BNP and ANP, and serum BNP and ANP concentrations of rats after ADSCS-Exo intervention were significantly decreased, suggesting that by reducing the serum concentrations of BNP and ANP in HF-prone rats, ADSCS-Exo can enhance cardiac function. Chen and Li[19] showed that rats with HF have significantly higher serum levels of ANP and BNP, which can improve the cardiac function of patients by reducing the levels of ANP and BNP. The heart needs energy metabolism to sustain its typical physiological processes and energy needs because the most

direct source of energy for cellular functions is ATP. Some researchers have found that compared that of normal people, ATP in HF patients is significantly reduced by 30%-40%[20]. The findings of this investigation demonstrated that ADSC-Exos can enhance the amount of ATP in HF rat cardiac tissue, demonstrating that when HF occurs, ADSC-Exos can increase the amount of ATP in myocardial tissue and then maintain the energy required for normal myocardial activity by improving the dysfunction of mitochondrial energy metabolism. These results were consistent with the above studies.

The transition from compensatory to decompensatory HF is marked by cardiomyocyte apoptosis, which can be controlled by numerous genes associated with apoptosis, including the pro- and apoptotic protein Bcl-2. Bcl-2 protein family members that have received much research are Bcl-2 and Bax. The Bcl-2 to Bax ratio is highly associated with cell survival or death. By preserving mitochondrial integrity, cytochrome C cannot be released when Bcl-2 is present. By decreasing mitochondrial membrane potential, Bax can cause the release of cytochrome C and certain apoptotic precursors into the cytoplasm, and cytochrome C can form apoptotic bodies by activating APAF-1 and caspase-9. Cytochrome C can induce apoptosis by activating caspase-3 and caspase-7. P53 is a pro-apoptotic transcription factor that can mediate the induction of cardiomyocyte apoptosis and accelerate the progression of HF. When HF occurs, DNA is damaged in cardiomyocytes, and p53 protein is activated, which can accelerate the development of HF by inducing cardiomyocyte apoptosis by upregulating the competitive binding of Bax protein to Bcl-2 and lowering the Bcl-2 to Bax ratio by downregulating the expression of Bcl-2. The results of this study showed that ADSC-Exos could inhibit the expression of Bax, caspase-3 and p53 proteins in cardiac tissue and thereby improve cardiac function by inhibiting cardiomyocyte apoptosis. Sun *et al*[21] demonstrated that ADSC-Exo treatment can boost the production of the protein Bcl-2 while decreasing the presence of Bax and caspase-3 in cardiomyocytes and upregulate the ratio of Bcl-2/Bax to inhibit cardiomyocyte apoptosis, enhancing heart function in rats suffering from cardiomyocyte apoptosis.

CONCLUSION

In conclusion, our findings suggest that MSC Exos derived from adipose tissue have the potential to improve heart health in rats with HF. This finding is supported by the observed increase in ATP content and improvement in cardiac function parameters, such as LVEF, LVFS, and SV. In addition, the administration of ADSC-Exos was associated with a significant reduction in serum BNP and ANP levels, indicating a potential cardioprotective effect. Furthermore, ADSC-Exo treatment suppressed the expression of proteins involved in apoptosis, including Bax, caspase-3, and p53, while promoting the expression of the anti-apoptotic protein Bcl-2 in cardiac tissue.

These findings imply that ADSC-Exos may prevent cardiomyocyte death and inhibit the progression of HF. The ability of ADSC-Exos to modulate key factors involved in cell survival and apoptosis suggests their potential therapeutic application for treating HF. However, further research is needed to fully understand the underlying mechanisms and to optimize the dosage and administration protocol. Nevertheless, this study provides valuable insights into the potential use of ADSC-Exos as a novel therapeutic strategy for HF.

ARTICLE HIGHLIGHTS

Research background

This paper discusses the significant public health issue of heart failure (HF) and the limited efficacy of current treatment options. It explores the use of digoxin and angiotensin receptor blockers in HF treatment, with conflicting results regarding mortality reduction. The paper introduces mesenchymal stem cells (MSCs), specifically adipose-derived MSCs (ADMSCs), as a potential solution. However, storage and transportation requirements limit their clinical use. Exosomes (Exos), lipid bilayer vesicles secreted by cells, are proposed as an alternative. These Exos can be stored and transported easily and have shown potential in tissue repair, inflammation inhibition, and immune regulation. The aim of the research is to investigate the use of ADMSC Exos for treating HF.

Research motivation

The research motivation of the paper is to address the global public health issue of HF and the limitations of current treatment options. The authors aim to explore the potential of ADMSC Exos as a novel therapy for HF. By investigating the effects of these Exos on heart function, the researchers seek to provide insights into new diagnostic and treatment strategies for chronic HF.

Research objectives

The research objectives of the paper are to review the current state of diagnosis and treatment for chronic HF, explore the potential use of ADMSC Exos as a therapy, investigate the limitations of ADMSCs for clinical use, examine the functions of MSC Exos, and evaluate their effectiveness in treating HF. The ultimate goal is to contribute to the development of more effective diagnostic and treatment strategies for HF.

Research methods

The exogenous surface markers of adipose derived MSCs were found and adipose derived MSCs were cultured.

Research results

The identification of surface markers showed that the surface markers CD44 and CD29 of adipose-derived stem cells (ADSCs) were well expressed, while the surface markers CD45 and CD34 of ADSCs were negative, so the cultured cells were ADSCs. Western blotting detected the Exo surface marker protein, which expressed CD63 protein but did not express calnexin protein, indicating that ADSCs derived Exos were successfully extracted.

Research conclusions

The secretion of MSCs from adipose tissue can increase ATP level, block cardiomyocyte apoptosis, and enhance the heart function of animals susceptible to HF. The inhibition of Bax, caspase-3 and p53 protein expression may be related to this process.

Research perspectives

Current research suggests that HF is a chronic condition caused by neuroendocrine system activation, leading to ventricular remodeling and cardiomyocyte death. Preventing cardiomyocyte apoptosis is crucial in managing HF. Doxorubicin, a chemotherapy drug, can cause heart damage. ADSC Exos have shown potential in promoting heart regeneration and immune regulation. They can inhibit cardiomyocyte apoptosis, alleviate structural remodeling, and improve cardiac function. ADSC Exos may achieve these effects through the PI3K/Akt signaling pathway. Elevated levels of atrial natriuretic peptide (ANP) are associated with HF, and ADSC Exos can reduce ANP and b-type natriuretic peptide concentrations, improving cardiac function. ADSC Exos can also increase ATP content in cardiac tissue to maintain normal myocardial activity. They inhibit the expression of apoptotic proteins while promoting anti-apoptotic protein expression, thus improving cardiac function. Overall, ADSC Exos have therapeutic potential for HF, but further research is needed.

Abstract

BACKGROUND

Acute lung injury (ALI) and its final severe stage, acute respiratory distress syndrome, are associated with high morbidity and mortality rates in patients due to the lack of effective specific treatments. Gut microbiota homeostasis, including that in ALI, is important for human health. Evidence suggests that the gut microbiota improves lung injury through the lung-gut axis. Human umbilical cord mesenchymal cells (HUC-MSCs) have attractive prospects for ALI treatment. This study hypothesized that HUC-MSCs improve ALI *via* the lung-gut microflora.

AIM

To explore the effects of HUC-MSCs on lipopolysaccharide (LPS)-induced ALI in mice and the involvement of the lung-gut axis in this process.

METHODS

C57BL/6 mice were randomly divided into four groups (18 rats per group): Sham, sham + HUC-MSCs, LPS, and LPS + HUC-MSCs. ALI was induced in mice by intraperitoneal injections of LPS (10 mg/kg). After 6 h, mice were intervened with 0.5 mL phosphate buffered saline (PBS) containing 1 × 10^6 HUC-MSCs by intraperitoneal injections. For the negative control, 100 mL 0.9% NaCl and 0.5 mL PBS were used. Bronchoalveolar lavage fluid (BALF) was obtained from anesthetized mice, and their blood, lungs, ileum, and feces were obtained by an aseptic technique following CO_2 euthanasia. Wright's staining, enzyme-linked immunosorbent assay, hematoxylin-eosin staining, Evans blue dye leakage assay,

immunohistochemistry, fluorescence *in situ* hybridization, western blot, 16S rDNA sequencing, and non-targeted metabolomics were used to observe the effect of HUC-MSCs on ALI mice, and the involvement of the lung-gut axis in this process was explored. One-way analysis of variance with post-hoc Tukey's test, independent-sample Student's *t*-test, Wilcoxon rank-sum test, and Pearson correlation analysis were used for statistical analyses.

RESULTS

HUC-MSCs were observed to improve pulmonary edema and lung and ileal injury, and decrease mononuclear cell and neutrophil counts, protein concentrations in BALF and inflammatory cytokine levels in the serum, lung, and ileum of ALI mice. Especially, HUC-MSCs decreased Evans blue concentration and Toll-like receptor 4, myeloid differentiation factor 88, p-nuclear factor kappa-B (NF-κB)/NF-κB, and p-inhibitor α of NF-κB (p-IκBα)/IκBα expression levels in the lung, and raised the pulmonary vascular endothelial-cadherin, zonula occludens-1 (ZO-1), and occludin levels and ileal ZO-1, claudin-1, and occludin expression levels. HUC-MSCs improved gut and BALF microbial homeostases. The number of pathogenic bacteria decreased in the BALF of ALI mice treated with HUC-MSCs. Concurrently, the abundances of *Oscillospira* and *Coprococcus* in the feces of HUS-MSC-treated ALI mice were significantly increased. In addition, *Lactobacillus*, *Bacteroides*, and *unidentified_Rikenellaceae* genera appeared in both feces and BALF. Moreover, this study performed metabolomic analysis on the lung tissue and identified five upregulated metabolites and 11 downregulated metabolites in the LPS + MSC group compared to the LPS group, which were related to the purine metabolism and the taste transduction signaling pathways. Therefore, an intrinsic link between lung metabolite levels and BALF flora homeostasis was established.

CONCLUSION

This study suggests that HUM-MSCs attenuate ALI by redefining the gut and lung microbiota.

Key Words: Acute lung injury; Human umbilical cord mesenchymal cells; Lipopolysaccharide; Microflora; Untargeted metabolomics; Toll-like receptor 4/nuclear factor kappa-B signaling pathway

Core Tip: The results of this study suggest that human umbilical cord mesenchymal cells (HUC-MSCs) inhibit the inflammatory cytokine expression levels in serum and the lung of mice with acute lung injury (ALI), which may be achieved by redefining the gut and lung microbiota. This study not only provides a scientific basis for the pathophysiological mechanisms and clinical application of HUC-MSCs, but it also provides new ideas for the development of therapeutic strategies for ALI.

INTRODUCTION

Acute lung injury (ALI), whose final severe stage is defined as acute respiratory distress syndrome (ARDS), is caused by various pathogenic factors, including acute pneumonia, sepsis, severe trauma, and acute pancreatitis[1]. It is primarily characterized by pulmonary edema and acute inflammation[2], and has high morbidity and mortality rates in patients due to the lack of effective patient-specific treatments[3]. Therefore, ALI has received much attention from the academic community, and significant developments have been made in understanding its pathophysiological mechanisms; however, clinically available treatments for ALI are still limited[4]. Lipopolysaccharide (LPS), a common pathogenic factor associated with ALI, is the main constituent of the Gram-negative bacterial cell wall[5]. A previous study found that LPS induced lung tissue damage and increased the expression of inflammatory factors in the bronchoalveolar lavage fluid (BALF)[6]. Animal models of LPS-induced lung injury are commonly used to study ALI[7]. Interestingly, LPS-induced ALI mice have a gut microbiota imbalance, and improvement in gut microbiota homeostasis can ameliorate lung inflammation of ALI mice and inhibit Toll-like receptor 4 (TLR4)/nuclear factor kappa-B (NF-κB) signaling in the lungs [8], suggesting the possible involvement of the intestinal microbiota in ALI.

A prospective observational cohort study focused on the relationship between lung microbiota and ALI and found that BALF microbiota can predict clinical outcomes in critically ill patients, especially the enrichment of gut-associated bacteria in BALF[9]. There is increasing evidence that the effects of host-microorganism interactions extend well beyond the local environment and influence the responses of peripheral tissues[7]. Homeostasis of the gut microbiota is important for human health, including its modulatory effects on ALI[10]. A study, based on 16S rRNA amplicon and metagenomic sequencing, found that the composition of the gut microbiota has a significant impact on wasting and death

in mice with ALI, suggesting the importance of the lung-gut microbiota crosstalk in lung injury[11]. Moreover, the depletion of gut microbes using an antibiotic cocktail improves lung injury and decreases interleukin (IL)-6 levels in the BALF of ALI mice[12]. A clinical cohort study found that the gut microbiome composition in patients with coronavirus disease 2019 (COVID-19), a respiratory illness, was significantly altered compared with that in non-COVID-19 individuals, irrespective of whether patients had received medication, and that the gut microbiome composition was correlated with disease severity[13]. Additionally, intestinal diseases alter the composition of the pulmonary microbiota and their metabolites[14]. Therefore, changes in the abundance and composition of the gut microbiota may be key to improving ALI *via* the lung-gut microflora. Recently, the impact of gut microbiota homeostasis on lung diseases has come into focus.

Mesenchymal stem cells (MSCs) are multipotent cells that can differentiate into various specialized cell types, including osteoblasts, chondrocytes, and adipocytes[15]. They originate from the mesoderm and are widely derived from adult stem cells with multi-differentiation potential, and can be isolated from a variety of tissues, such as the bone marrow, umbilical cord, amniotic membrane, adipose tissue, and skeletal muscle[16]. In addition, they have been shown to have beneficial effects in ALI[17]. Human umbilical cord mesenchymal cells (HUC-MSCs) have gained popularity in stem cell research and applications because of their specific advantages, including easy availability, abundance, lack of tumorigenicity, and ethical compliance[18]. Ahn *et al*[19] found that HUC-MSCs improved chronic lung disease and bronchopulmonary dysplasia in premature infants, without any transplantation-related adverse outcomes. Additionally, HUC-MSCs improved lung injury and inhibited the pro-inflammatory cytokine levels in the lungs of LPS-induced ALI mice[20]. HUC-MSC treatment ameliorated lung inflammation and fibrosis in bleomycin-induced pulmonary fibrosis mice[21]. Furthermore, researchers have reported that intraperitoneal infusions of HUC-MSCs improve colitis by reshaping the diversification of the gut microbiota[22]. Additionally, the gut microbiota of pulmonary hypertension mice was reversed by MSC treatment[23]. Studies on the HUC-MSC treatment of inflammation-related diseases are developing rapidly; however, their mechanisms of action are poorly understood. Therefore, by analyzing the lung-gut microbiota and lung metabolomics, this study aimed to explore the mechanisms underlying the amelioration of ALI by HUC-MSCs to provide a scientific basis for the clinical application of HUC-MSCs and a direction for the development of therapeutic strategies for ALI/ARDS.

MATERIALS AND METHODS

Animals and cells

A total of 72 6-8-wk-old male C57BL/6 mice were purchased from Beijing Vital River Laboratory Animal Technology Co., Ltd. (Beijing, China) and housed in a standard specific pathogen-free environment. The mice were isolated and allowed to adapt for one week. All procedures involving animals were approved and supervised by the Animal Experimentation Ethics Committee of Zhejiang Eyong Pharmaceutical Research and Development Center. Mycoplasma free HUC-MSCs (HUM-iCell-e009) were purchased from iCell Bioscience Inc. (Shanghai, China) and cultured in a specialized medium (PriMed-iCELL-012; iCell Bioscience, China) containing supplements at 37 °C in a 5% CO_2 incubator. The purity of HUC-MSCs was assessed by flow cytometry and was typically greater than 90%. Cell identification was performed by iCell Bioscience Inc.

Animal model of ALI

The random number method was used to divide mice into four groups, namely, sham, sham + MSCs, LPS, and LPS + MSCs groups, with 18 mice in each group. The 36 randomly selected mice were intraperitoneally injected with 100 mL of LPS (10 mg/kg) to induce ALI[7], and sham mice were administered 100 mL of 0.9% NaCl as controls. After 6 h, half of the ALI mice and half of the sham mice were given 0.5 mL of phosphate buffered saline (PBS) containing HUC-MSCs (1×10^6 cells/mL) by intraperitoneal injections[24], and the other half of the ALI mice and sham mice were given 0.5 mL of 0.9% NaCl. The mice were reared under standard laboratory conditions. The experiments were carried out by expert technicians who were blinded to the animal grouping.

Sample preparation

Three days after HUC-MSC intervention in ALI mice, BALF was obtained after the mice were anesthetized with isoflurane as reported by Wu *et al*[24]. Briefly, the trachea was flushed five times with PBS *via* a 20-gauge catheter, and all liquids were collected. Subsequently, all mice were euthanized with CO_2, and the blood, lungs, ileum, and feces were obtained using aseptic techniques. The lungs (one lung was evenly divided into four) from three mice in each group were taken, weighed, and then baked in an oven at 80 °C for 48 h to determine the dry weight to calculate the ratio of wet lung weight to dry lung weight (W/D weight ratio) as reported by Li *et al*[25]. In addition, a part of the remaining lung and ileum were made into paraffin blocks separately, and the other were stored at 80 °C for further analysis. The BALF was divided into two parts for inflammation cytokine detection and 16S rDNA sequencing, respectively.

Detection of immune cells and inflammatory cytokines

The protein concentration in the BALF was measured using the BCA assay (Beyotime, China). Additionally, the cells in BALF were precipitated and resuspended, and mononuclear cells and neutrophils were counted after Wright's staining. The levels of tumor necrosis factor (TNF)-α (ml002095-1, Enzyme-linked, China), IL-1β (ml063132-1, Enzyme-linked, China), and IL-6 (ml002293-1, Enzyme-linked, China) in the serum, lungs, and ileum were measured by enzyme-linked

Table 1 Information of antibodies used in this study

Antibody	Dilution ratio	Manufacturer	Country	Cat. No.
VE-cadherin antibody	1:2000	Affinity	United States	AF6265
ZO-1 antibody	1:5000	Proteintech	United States	21773-1-AP
Occludin antibody	1:1000	Affinity	United States	DF7504
TLR4 antibody	1:2000	Affinity	United States	AF7017
Myd88 antibody	1:1000	Affinity	United States	AF5195

β-actin antibody	1:10000	Affinity	United States	AF7018

VE: Vascular endothelia; ZO-1: Zonula occludens-1; TLR4: Toll-like receptor; Myd88: Myeloid differentiation factor 88; NF-κB: Nuclear factor kappa-B; IκB α: Inhibitor α of nuclear factor kappa-B; HRP: Horse radish peroxidase.

immuno sorbent assay (ELISA) according to the manufacturer's instructions.

Histopathological observation

Hematoxylin-eosin (H&E) staining was performed to observe the histopathology of the lungs and ileum. Briefly, the lungs and ileum were fixed in 10% formalin. The tissues were then placed in paraffin and sectioned, and sections were stained with H&E. The injury of lungs and ileum were scored in a blinded fashion as previously reported[26,27].

Measurement of alveolar-capillary permeability

Three mice were randomly selected from each group for the Evans blue dye leakage assay to explore the function of the lung tissue endothelial barrier as previously reported[28]. This assay was performed using 25 mg/kg of 0.5% blue dye (Sigma, United States) injected into mice *via* the tail vein 2 h before isoflurane anesthesia. After the heart of the anesthetized mice was exposed, the left ventricle was intubated and flushed with 4% normal saline. Subsequently, the mice were euthanized using CO_2. Lungs were homogenized in 2 mL PBS and treated with formamide (Sigma, United States) at 60 °C for 24 h. Finally, the concentration of Evans blue dye in the lung tissue was determined at 620 nm using a microplate reader (CMaxPlus, Molecular Devices, United States).

Immunohistochemistry

Immunohistochemistry (IHC) was performed as described by Peng *et al*[29]. Paraffin sections of lung tissue were deparaffinized, permeabilized, and blocked. The sections were then incubated at 4 °C overnight with anti-TLR4 antibody (1:100 dilution; Affinity, United States). After washing with PBS, the slides were incubated with goat anti-rabbit IgG HRP (Abcam, United States) at 37 °C for 30 min. The slides were washed again, mounted with DAPI (Vector Laboratories, Burlingame, CA), and examined using an E100 fluorescence microscope (Nikon, Japan).

Fluorescence in situ hybridization

Fluorescence *in situ* hybridization (FISH) was performed on slides of ileum and lung tissues as previously described[30], using a pan-bacteria FITC-labeled probe (EUB338) and an RNA FISH kit (Genepharma, China). After DAPI staining, the slides were visualized under an inverted fluorescence microscope (Ts2-FL; Nikon, Japan). Images were acquired using Micro-Manager and analyzed using ImageJ/FIJI software (National Institutes of Health, United States, version 1.53c).

Western blot analysis

The antibodies used for western blot (WB) are shown in Table 1. The lung and ileum tissues were homogenized in a lysis solution for the extraction of proteins. After centrifugation and supernatant collection, the samples were uniformly concentrated and denatured. Briefly, sodium dodecyl sulfate-gel electrophoresis and membrane transfer were performed for 20 μg protein per group as reported by Li *et al*[3]. The membranes were incubated with primary antibodies overnight and then with secondary antibodies for 1 h. Finally, the membranes were subjected to chemiluminescence reactions and protein levels were measured by enhanced chemiluminescence. ImageJ/FIJI software was used for semiquantitative analysis.

16S rDNA sequencing

High-throughput 16S rDNA sequencing was performed to analyze the gut and pulmonary microflora by BioDeep Co., Ltd (Suzhou, China). A sequencing library was prepared using the TruSeq Nano DNA LT Library Prep Kit of Illumina. A NovaSeq6000 system (PE250, Illumina, United States) was used for sequencing as reported by Yi *et al*[31]. Then the QIIME2 DADA2 and OmicStudio platforms[32] were used to analyze the data.

Metabolomics for lung tissue

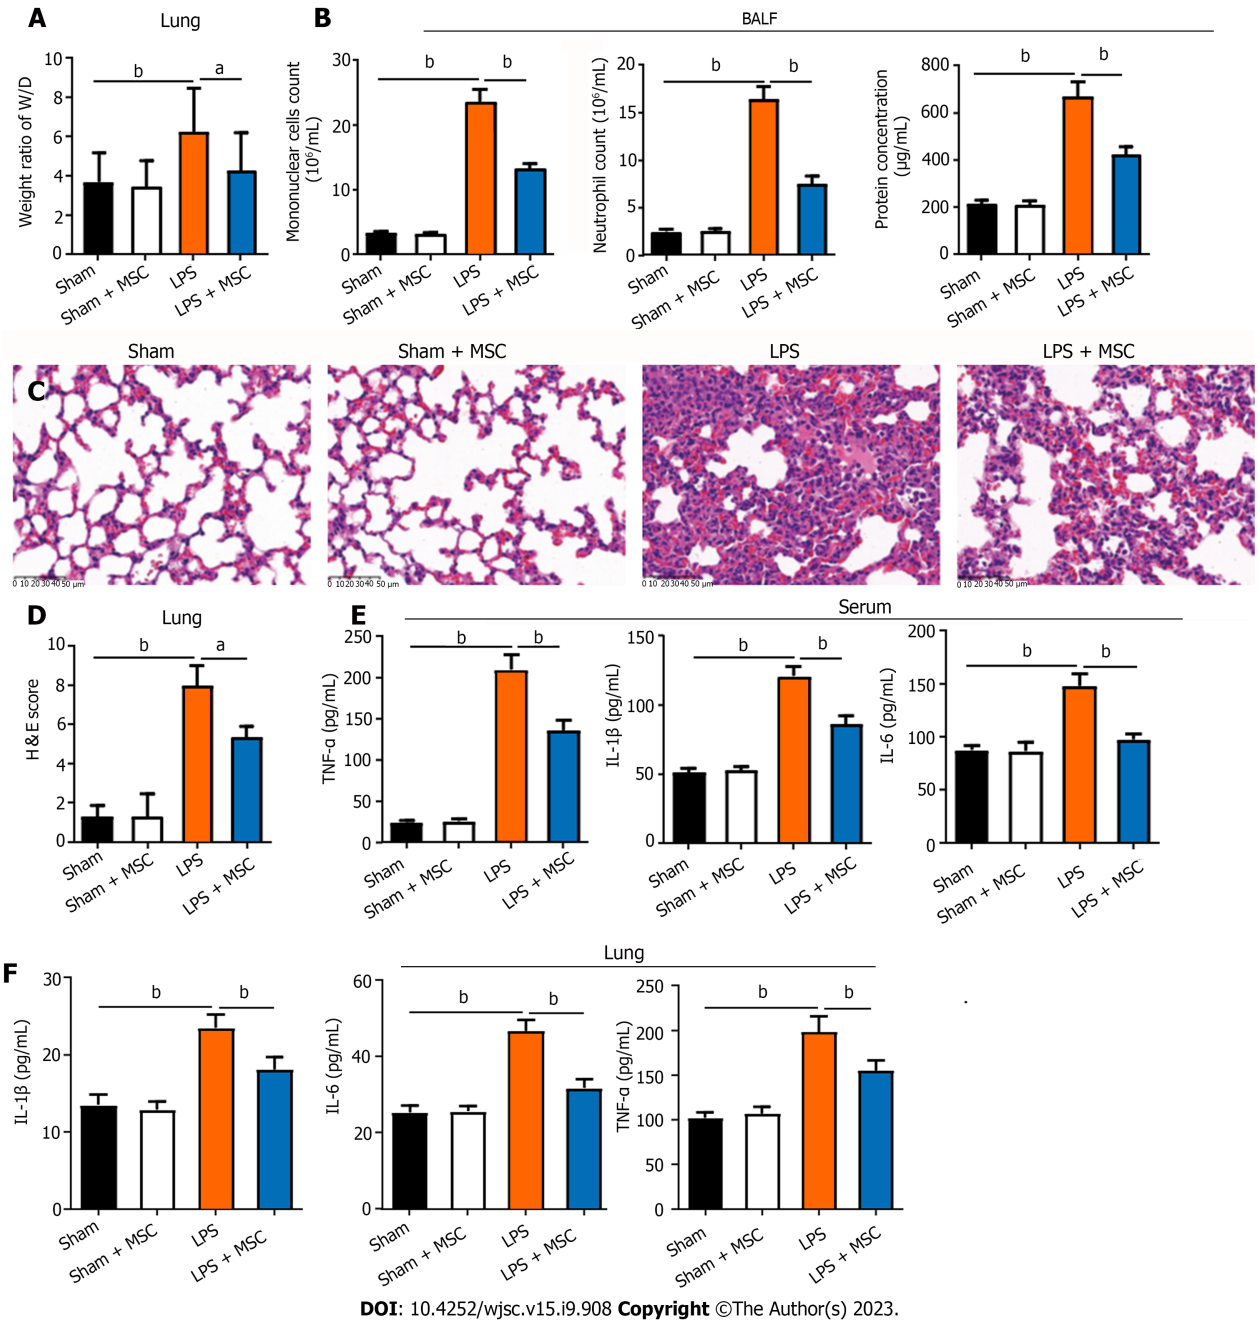
The non-targeted metabolomics approach was performed by PANOMIX Biomedical Tech Co., Ltd. (Suzhou, China). The samples were treated with 75% methanol-chloroform (9:1) and 25% water for sonication and centrifugation to extract the metabolites. The samples (2 μL) were analyzed by liquid chromatography-mass spectrum (MS) detection with the Vanquish UHPLC System (Thermo, United States). Additionally, an Orbitrap Exploris mass spectrometer (Thermo, United States) was used for mass spectrometry analysis. After data acquisition, the Proteowizard package (v3.0.8789) and the R xcms package were used to preprocess the data. Metabolites were identified on the public databases such as the Human Metabolome Database[33], MassBank (https://massbank.eu/MassBank/), Lipid Maps (https://Lipidmaps.org/), mzCloud (https://www.mzcloud.org/), Kyoto Encyclopedia of Genes and Genomes (KEGG)[34], and self-building repository, and Orthogonal Projections to Latent Structures Discriminant Analysis (OPLS-DA) analysis was performed to screen the differential metabolites.

Statistical analysis

Statistical analyses were performed using SPSS (version 16.0; IBM, Armonk, NY, United States). Data from multiple *in vivo* experiments were analyzed using one-way analysis of variance (ANOVA) with a post-hoc Tukey test. The independent-samples Student's *t*-test was used for comparison between the two groups. The Wilcoxon rank-sum test was conducted to explore the microflora with a significant difference in abundance. Pearson's correlation analysis was used to explore the intrinsic associations. Additionally, the Variable Importance for the Projection (VIP) of OPLS-DA was used to screen for metabolites with biomarker potential (VIP > 1). Two-way Orthogonal Partial Least Squares (O2PLS) analysis was used to explore the links between BALF microbiota and lung metabolism. The threshold for significance was $P < 0.05$ for all tests.

RESULTS

HUC-MSC treatment alleviates lung injury and inflammation in ALI mice



This study used LPS to induce ALI in mice and then collected their lungs and BALF to explore the ameliorating effect of HUC-MSCs on ALI by H&E staining and ELISA. ALI mice had a higher lung W/D weight ratio and more mononuclear cells and neutrophils than sham mice ($P < 0.01$), whereas HUC-MSC treatment on ALI mice decreased the lung W/D weight ratio ($P < 0.05$), mononuclear cell and neutrophil counts, and protein concentration ($P < 0.01$) (Figures 1A and B). Additionally, compared to sham mice, the lung of ALI mice had markedly thickened alveolar septa with significant inflammatory cell infiltration; however, HUC-MSC treatment alleviated the degree of alveolar septal thickening and inflammatory cell infiltration in ALI mice (Figure 1C). Likewise, the score of lung injury in the LPS group was higher than those in the sham ($P < 0.01$) and LPS + MSC groups ($P < 0.05$) (Figure 1D). Moreover, ALI mice had significantly increased levels of TNF-α, IL-1β, and IL-6 in their serum and lung tissues ($P < 0.01$) (Figures 1E and F). In particular, the above-mentioned inflammatory factor levels were decreased in the ALI mice treated with HUC-MSCs ($P < 0.01$) (Figures 1E and F).

HUC-MSC treatment improves endothelial barrier function and integrity in the lungs of ALI mice

In addition, this study observed the endothelial barrier function and integrity of the lungs using Evans blue, WB, and IHC assays. As shown in Figure 2A, ALI mice had a higher concentration of Evans blue dye in the lungs than the sham mice, and HUC-MSC treatment reduced Evans blue concentration in the lungs of ALI mice ($P < 0.01$). In particular, the levels of endothelial barrier-associated proteins, such as vascular endothelial (VE)-cadherin, zonula occludens-1 (ZO-1), and occludin, were markedly decreased in ALI mice ($P < 0.05$ or $P < 0.01$); however, HUC-MSC treatment reversed the expression levels of these proteins ($P < 0.01$) (Figures 2B-D). In addition, this study explored the signal intensity of the TLR4/myeloid differentiation factor 88 (Myd88)/NF-κB signaling pathway. The TLR4, Myd88, p-NF-κB/NF-κB, and p-inhibitor α of NF-κB (p-IκBα)/IκBα expression levels in the lung were all increased in ALI mice compared to the sham mice ($P < 0.01$); however, in ALI mice treated with HUC-MSCs, the expression levels of these proteins were decreased ($P < 0.05$ or $P < 0.01$) (Figures 2E-I). Similarly, TLR4 detected by IHC had a strong positive expression in the lungs of ALI mice, whereas HUC-MSC treatment attenuated the positive expression of TLR4 ($P < 0.05$ or $P < 0.01$) (Figures 2J and K).

HUC-MSC treatment improves injury, endothelial barrier integrity, and bacterial translocation in the ileum of ALI mice

Studies have reported not only lung function injury but also intestinal dysfunction in ALI[17]. Therefore, the ileum was examined using H&E staining, ELISA, WB, and FISH. The ileal tissue of ALI mice had shorter and ruptured villi with significant inflammatory cell infiltration compared to sham mice, whereas these ileal injuries in ALI mice treated with HUC-MSCs were improved ($P < 0.05$ or $P < 0.01$) (Figure 3A). In addition, LPS treatment on mice markedly increased the ileal TNF-α, IL-1β, and IL-6 levels ($P < 0.01$), whereas HUC-MSC treatment inhibited them ($P < 0.01$) (Figure 3B). The suppressed expression of endothelial barrier-associated proteins, including claudin, ZO-1, and occludin by LPS was

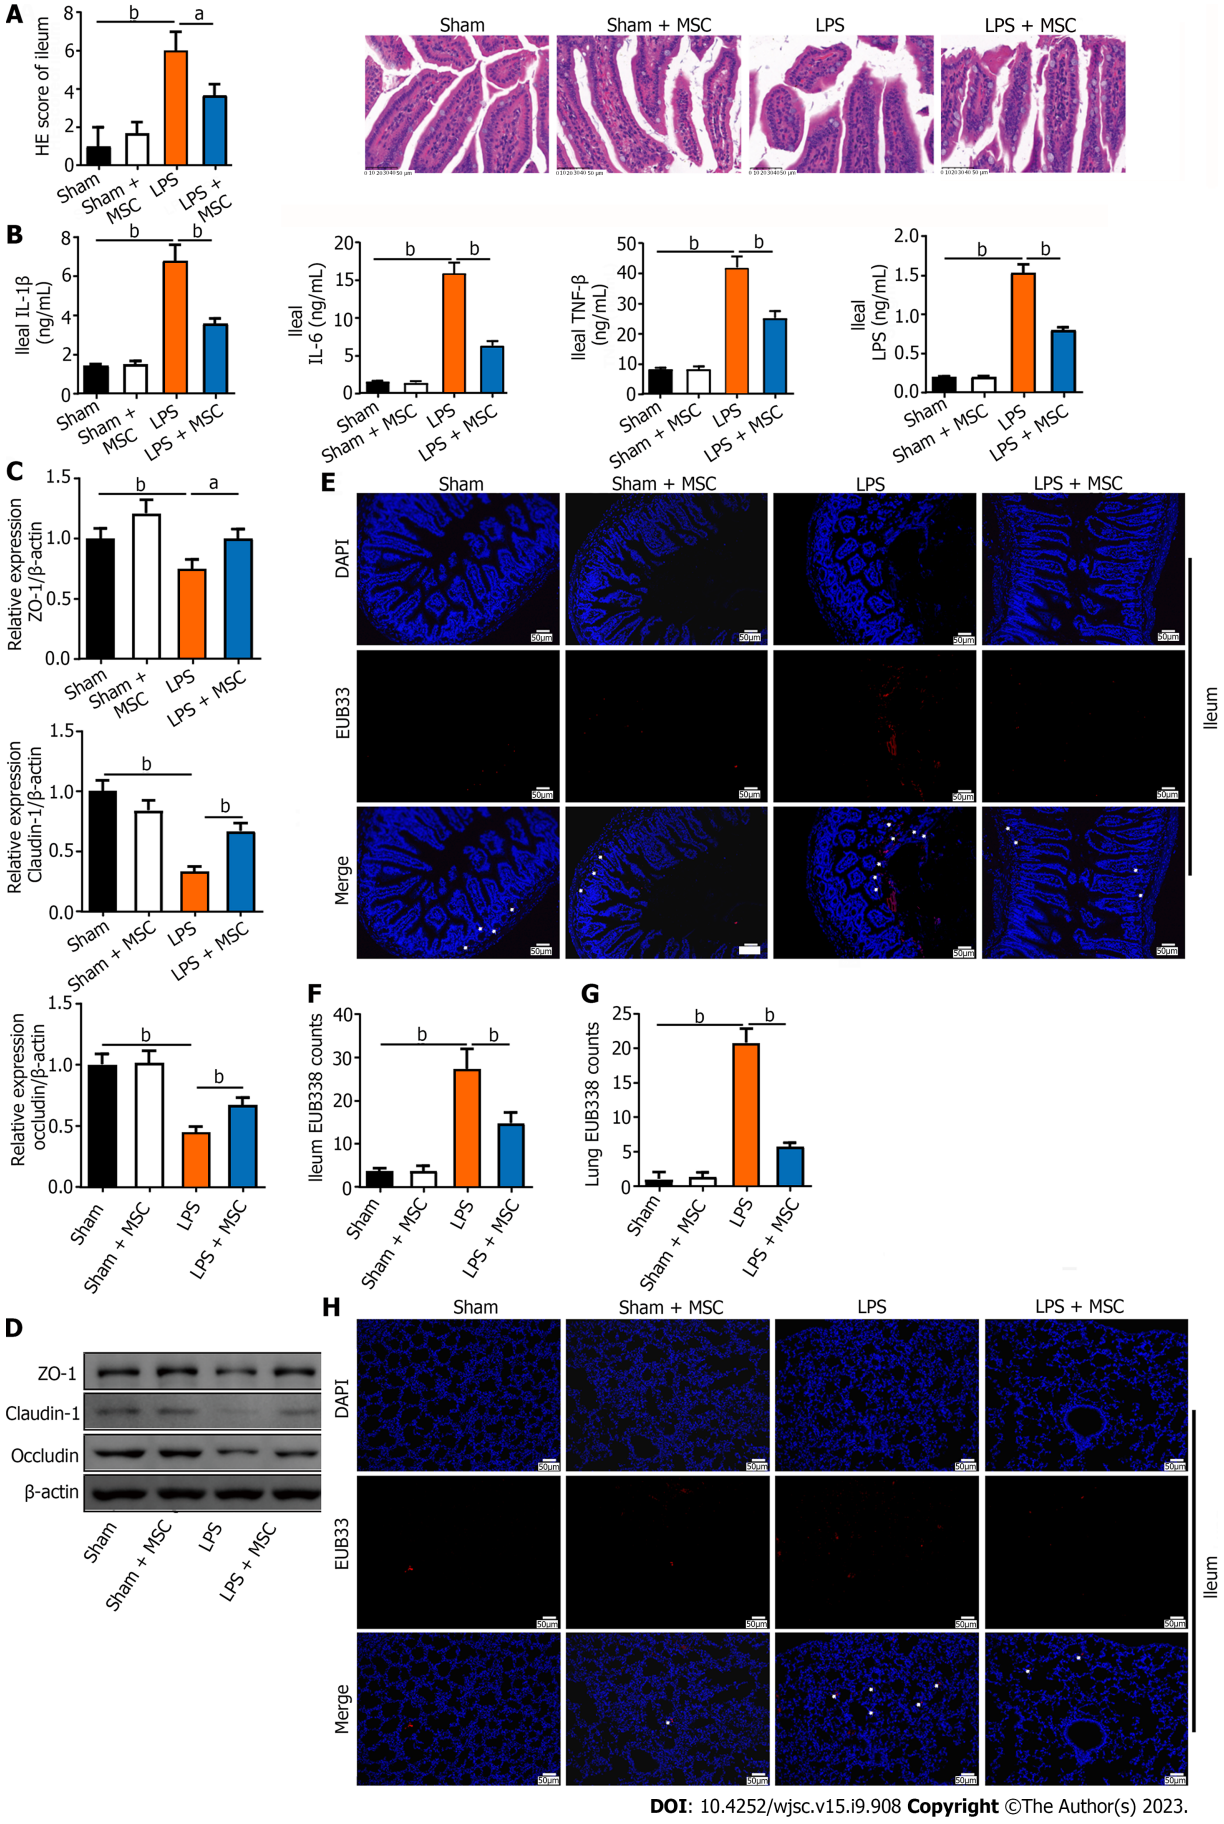
Figure 1 Human umbilical cord mesenchymal stem cells attenuate lipopolysaccharide-induced lung injury and inflammation in acute lung injury mice. A: In acute lung injury (ALI) mice, the wet-to-dry (W/D) weight ratio of the lung was higher than that of human umbilical cord mesenchymal stem cell (HUC-MSC)-treated ALI mice (n = 3); B: ALI mice had more mononuclear cells and neutrophils, and higher protein concentration in bronchoalveolar lavage fluid (BALF) than sham mice, while HUC-MSC treatment decreased these parameters (n = 12); C: Representative images of hematoxylin-eosin (H&E)-stained lung tissues (× 400, scale = 50 μm); D: Lung histopathological damage in mice (H&E staining; n = 3); E: Serum tumor necrosis factor (TNF)-α, interleukin (IL)-1β, IL-6, and lipopolysaccharide levels were higher in ALI mice and HUC-MSC treatment decreased their levels (n = 12); F: TNF-α, IL-1β, and IL-6 levels in the lungs of ALI mice were hugely increased than those in sham mice, while HUC-MSC treatment in ALI mice decreased them (n = 12). $^{a}P < 0.05$, $^{b}P < 0.01$. LPS: Lipopolysaccharide; MSC: Mesenchymal stem cell; BALF: Bronchoalveolar lavage fluid; H&E: Hematoxylin-eosin; IL: Interleukin; TNF: Tumor necrosis factor.

enhanced by HUC-MSC treatment in ALI mice ($P < 0.05$) (Figures 3C and D). Furthermore, the EUB338 counts of the ileum epithelium and lungs in ALI mice were measured to observe the lung translocation of gut bacteria, and it was found that they were increased in ALI mice, whereas HUC-MSC treatment reduced them ($P < 0.01$) (Figures 3E-H).



HUC-MSC treatment attenuates ALI via regulating lung-gut microbiota homeostasis

16S rDNA sequencing was used to explore the effect of the lung and gut microbiota on the HUC-MSC-mediated amelioration of ALI. BALF and fecal samples were collected for 16S rDNA sequencing. After homogenizing the sequencing depth of each group, 48 BALF and fecal samples from the four groups were identified at the genus level, with an average of 48.25 units in each group. Figures 4A and B shows the top 20 flora with the highest average abundance at the genus level. The Shannon and Simpson indices of alpha diversity reflect richness and community evenness,

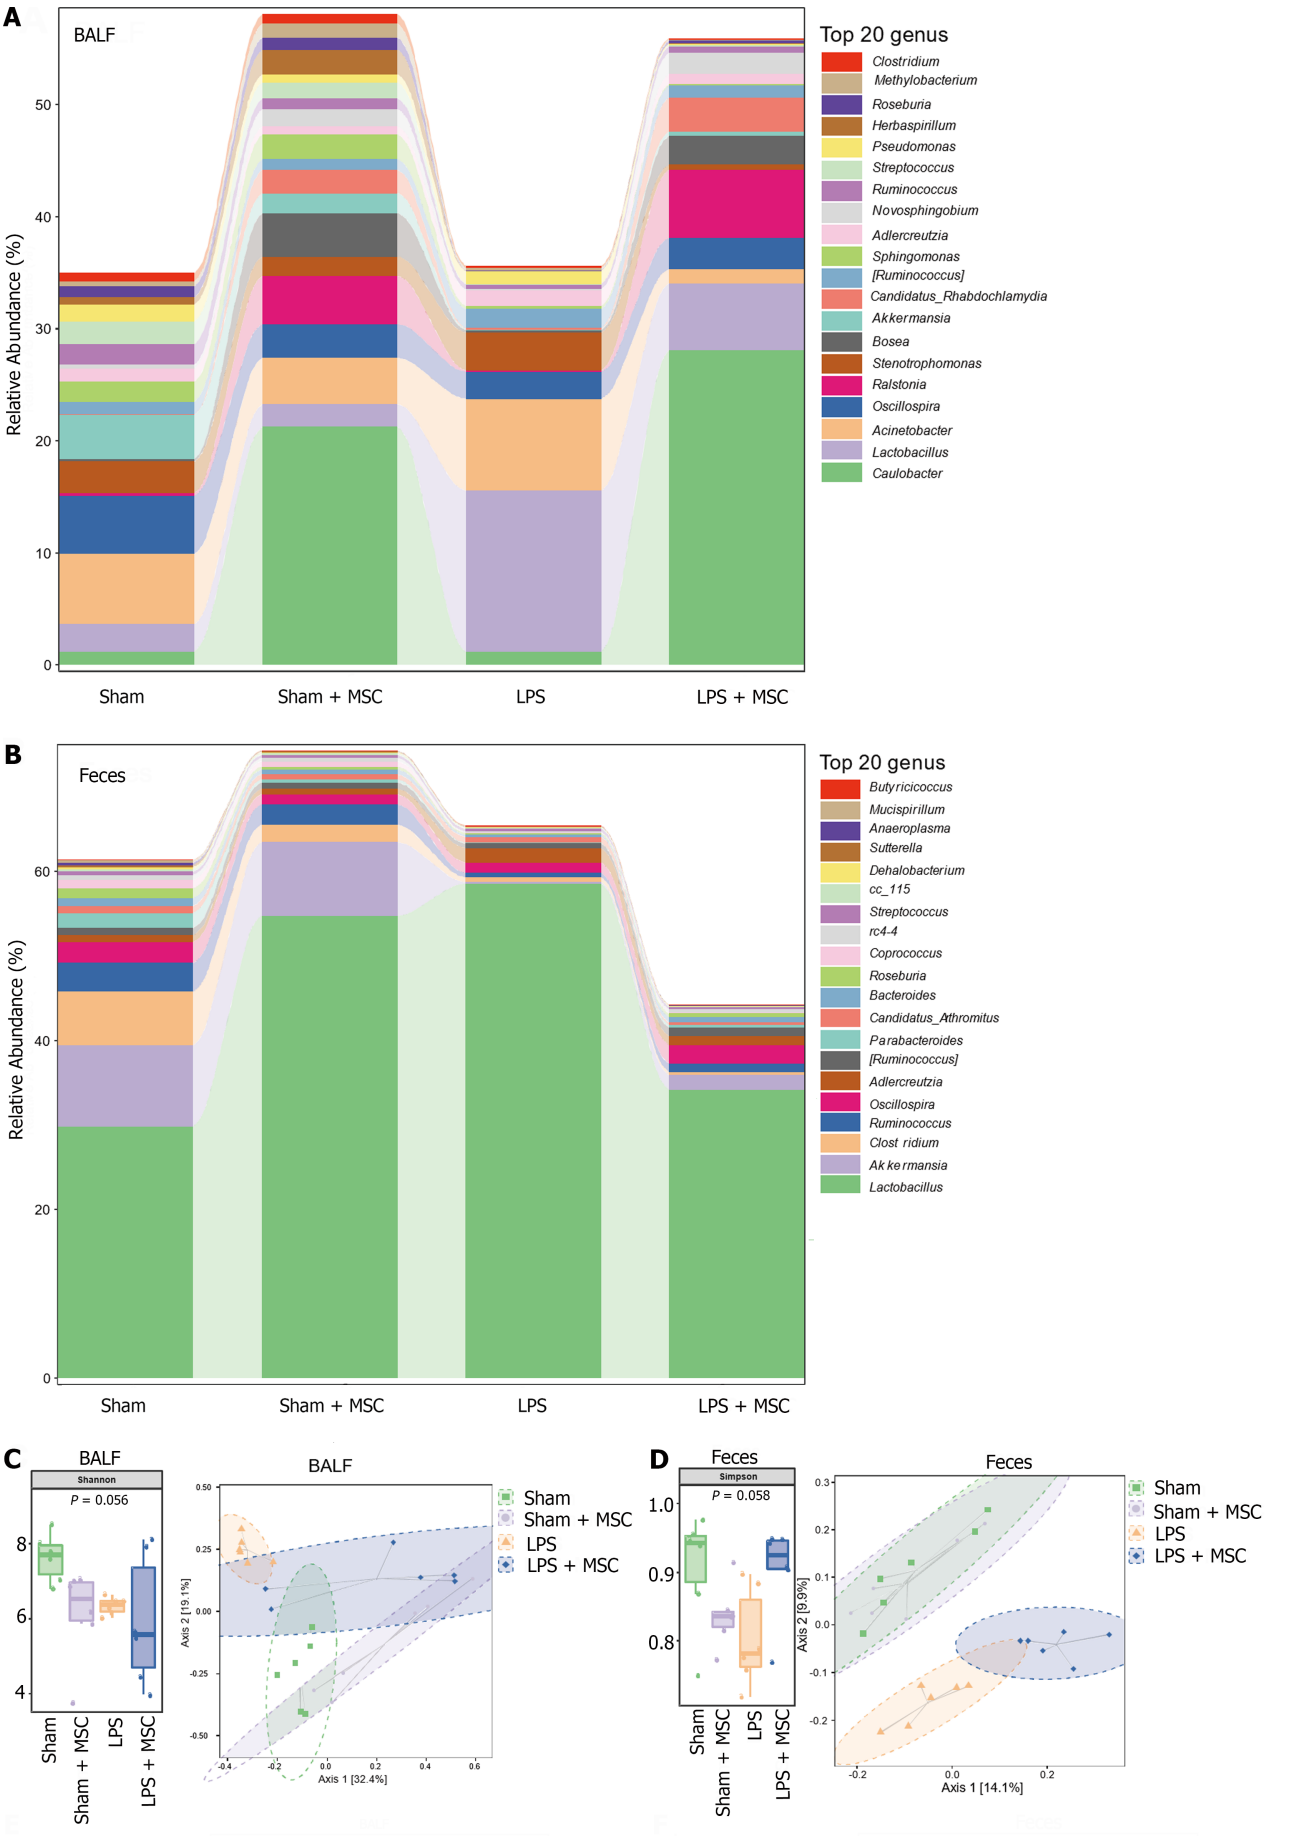
Figure 3 Human umbilical cord mesenchymal stem cells improve histopathology, inflammation, and endothelial barrier integrity of the

ileum in acute lung injury mice. A: Ileum tissue injury in acute lung injury (ALI) mice was observed after hematoxylin-eosin staining. ALI mice had severe ileum tissue injury while human umbilical cord mesenchymal stem cell (HUC-MSC) treatment improved such injury (n = 3); B: Tumor necrosis factor (TNF)-α, interleukin (IL)-1β, IL-6, and lipopolysaccharide (LPS) levels in the ileum were measured by ELISA (n = 12), and ALI mice had higher levels of TNF-α, IL-1β, IL-6, and LPS compared to sham mice, while HUC-MSC treatment decreased the levels of these factors; C: Zonula occludens-1 (ZO-1), claudin-1, and occludin levels were measured to observe the integrity of the ileum barrier (n = 3); D: Representative western blot bands of ZO-1, claudin-1, and occludin; E-H: Bacterial translocation was determined by fluorescence *in situ* hybridization, and the EUB338 counts in the ileum epithelium and lung per field were quantified (n = 3). $^{a}P < 0.05$, $^{b}P < 0.01$. MSC: Mesenchymal stem cell; LPS: Lipopolysaccharide; ZO-1: Zonula occludens-1; HE: Hematoxylin-eosin; IL: Interleukin; TNF: Tumor necrosis factor.

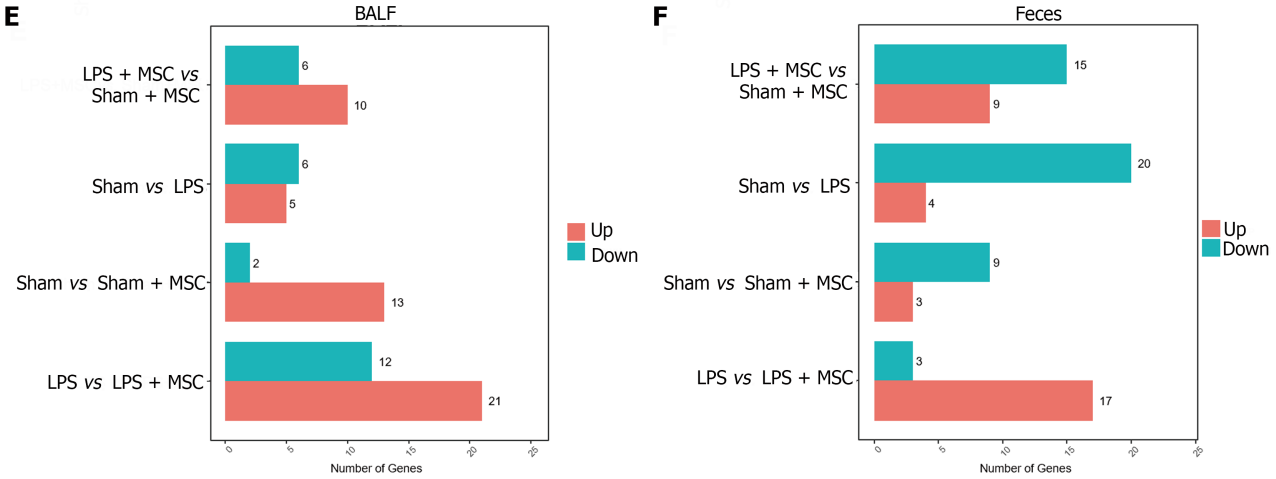
respectively. According to the Kruskal-Wallis rank-sum test, the Shannon index showed no significant differences among the groups (P = 0.056) (Figure 4C). Additionally, the Bray-Curtis distance of beta diversity reflects microbial diversity between groups and was analyzed by principal coordinates analysis, which revealed that the projection distance of the LPS + MSC group on the coordinate axis was closer to that of the negative control group than that of the LPS group (Figure 4C). Similarly, the Simpson index showed no significant differences among the groups (P = 0.058), and the projection distance of the gut microflora was closer to that of the negative control group than to that of the LPS group (Figure 4D).

Subsequently, the Wilcoxon rank-sum test was performed to explore the microflora with a significant difference in abundance (marked microflorae) (Figures 4E and F). In particular, there were 21 microflorae with upregulated abundance and 12 microflorae with downregulated abundance in the BALF of mice in the LPS + MSC group compared to the LPS group ($P < 0.05$) (Figure 4E), and 17 microflorae with upregulated abundance and 3 microflorae with downregulated abundance in feces ($P < 0.05$) (Figure 4F). The 33 marked microflorae with the largest upregulation or downregulation of operational taxonomic units in the BALF of ALI mice with/without HUC-MSC treatment are shown in Figure 5A, and 20 marked microflorae in feces are shown in Figure 5B. *Rhizobiales* had the largest log2 fold change (FC) in the BALF of mice in the LPS + MSC group compared to the LPS group [log2(FC) = 9.3264, P = 0.0284], and *Elizabethkingia* had the lowest log2FC in the BALF of mice in the LPS + MSC group compared to that of the LPS group [log2(FC) = -5.1799, P = 0.028] (Figure 5A). In fecal samples, the log2FC of *unclassified_Bacteroidales* was the highest in the marked microflorae of the LPS + MSC group compared to that of the LPS group [log2(FC) = 4.7549, P = 0.027], and that of the unidentified_F16 was the lowest [log2(FC) = -4.6328, P = 0.012] (Figure 5B).

Furthermore, the Pearson's correlation analysis was used to analyze the correlation between marked microflorae of the gut and lungs, and most of the bacteria in the BALF and feces had a strong or extremely strong correlation (Figure 6). The *Desulfovibrio* genus in feces was positively correlated with *Stenotrophomonas* in BALF ($P < 0.05$) (Supplementary Table 1).



HUC-MSC treatment regulates metabolic profile of lung tissue in ALI mice



The base peak chromatograms in the positive and negative modes of the four groups showed similar trends, suggesting good repeatability and reliable results (Figure 7A). Additionally, Partial Least Squares-Discriminant Analysis (PLS-DA) was used to distinguish metabolite differences between groups in the positive/negative mode. In particular, all blue Q2 positions in the permutation test chart were lower than the original points on the far right, suggesting that the PLS-DA models were valid (Figures 7B and C). In the positive mode, MS analysis identified a total of 1206 common biomarkers between the sham and LPS + MSC groups, 362 between the LPS and sham + MSC groups, 347 between the LPS and sham groups, 343 between the LPS + MSC and LPS groups, and 181 between the sham + MSC and sham groups (Figure 7D). In the negative mode, this study identified 905 common biomarkers between the sham and LPS + MSC groups, 476 between the LPS and sham + MSC groups, 225 between the LPS and sham groups, 112 between the LPS + MSC and LPS groups, and 139 between the sham + MSC and sham groups (Figure 7E).

Subsequently, precise screening of the metabolic profiles by MS/MS was performed to eliminate false positives. This study identified four upregulated metabolites (3-succinoylpyridine, nicotinamide ribotide, aldosterone, and phenylacetic acid) and one downregulated metabolite (lithocholic acid) in the sham + MSC group compared to the sham group. In addition, KEGG enrichment analysis suggested that these differential metabolites might participate in nicotinate and nicotinamide metabolism, aldosterone-regulated sodium reabsorption, and aldosterone synthesis and secretion pathways (Figures 8A-C). Additionally, 12 markedly upregulated metabolites (hydroxyindole, xanthine, and N-acetyl-L-aspartic acid, *etc.*) and 20 markedly downregulated metabolites (prostaglandin E2, argininosuccinic acid, and guanine, *etc.*) were identified in the LPS group compared to the sham group, and these metabolites were predicted to be potentially involved in alanine, aspartate, and glutamate metabolism, oxidative phosphorylation, the cAMP signaling pathway, and so on (Figures 8A, D and E). In particular, five upregulated metabolites (anabasine, IMP, lidocaine, salicylic acid, and propionylcarnitine) and 11 downregulated metabolites (N-acetylleucine, guanosine, guanine, *etc.*) were identified in the LPS + MSC group compared to the LPS group (Figures 8A and F). They were related to purine metabolism and the taste signaling transduction pathways ($P < 0.001$) (Figure 8G).

Significant correlations between microbes in BALF and metabolites in lung tissue

To explore the role of HUC-MSCs in regulating the microflora of the lung-gut axis to improve ALI, we performed an O2PLS correlation analysis on the expression of microflora in BALF and the expression of metabolites in the lungs to determine the microflora involved in the improvement of ALI by HUC-MSCs and their impact on metabolism. In Figure 9A, the top 25 bacteria and top 25 metabolites are shown with large absolute joint loading values, suggesting that they have a large weight in the improvement of ALI following HUC-MSC treatment. Subsequently, these flora and metabolites were analyzed using correlation analysis (Supplementary Table 1). Significantly related bacteria and metabolites were screened based on $P < 0.05$. Figure 4 Microflora homeostasis in bronchoalveolar lavage fluid and feces of acute lung injury mice (*n* = 6). A and B: Relative abundance of top 20 genera of microflora in bronchoalveolar lavage fluid (BALF) and feces; C and D: The within-sample richness and evenness (alpha diversity) were statistically analyzed by Shannon index, Simpson index, and the bray-Curtis based principal coordinates analysis of similarity coefficients in the BALF and feces of different groups (beta diversity); E and F: The Wilcoxon rank sum test was used to explore microflorae with a significant difference in abundance on OmicShare Tools. The number of differential microflorae in lipopolysaccharide (LPS) + mesenchymal stem cells (MSCs) group *vs* sham + MSC group, sham group *vs* LPS group, sham group *vs* sham + MSC group, and LPS group *vs* LPS + MSCs group is presented. The length of the red bar indicates the number of up-regulated microflorae and the length of the blue-green bar indicates the number of down-regulated microflorae. LPS: Lipopolysaccharide; MSC: Mesenchymal stem cell; BALF: Bronchoalveolar lavage fluid.

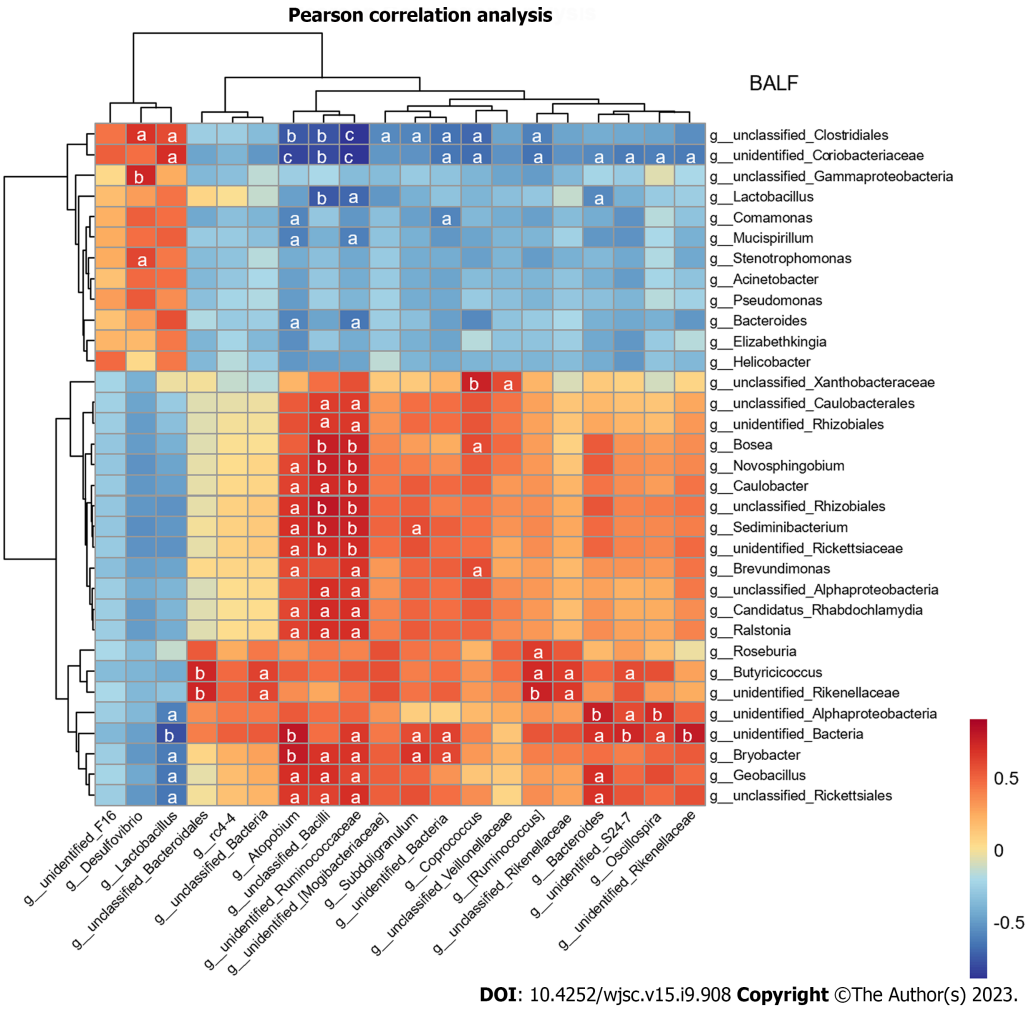
is shown in Figure 9B. Additionally, metabolites with a large role in the improvement of ALI by HUC-MSC treatment were subjected to KEGG enrichment analysis and were found to be mainly involved in the signaling pathways of drug metabolism-other enzymes, tyrosine metabolism, autophagy-animal, and endocytosis (Figure 9C).

DISCUSSION

MSCs have emerged as a promising therapeutic strategy for inflammatory diseases, owing to their low immunogenicity, ability to stabilize immunity, and ability to ameliorate inflammatory responses[35]. Moreover, HUC-MSCs not only ameliorate acute and chronic pneumonia, but also enteritis[36,37]. This study found that HUC-MSCs improved pulmonary edema, alleviated pathological damage to the lungs and ileum, and inhibited the levels of inflammatory cells in the BALF and inflammatory factors in the serum, BALF, lungs, and ileum. Furthermore, HUC-MSC treatment of ALI mice improved endothelial barrier integrity in the lungs and ileum. Endothelial permeability is regulated by intercellular junctions including adherens junctions and tight junctions, which are composed of cell junction proteins including occludin, claudin 1, VE-cadherin, *etc*[38]. Claudin-1 in the ileum and VE-cadherin, ZO-1, and occludin in the lung and ileum play key roles in maintaining vascular integrity. This decrease indicated endothelial barrier disruption in the lungs and ileum. In this study, HUC-MSC treatment of ALI mice advanced lung VE-cadherin, ZO-1, and occludin expression signal intensity and upregulated claudin-1, ZO-1, and occludin expression levels in the ileum. Collectively, treatment of ALI mice with HUC-MSCs ameliorates lung and ileal barrier integrity.



Inflammatory factors and cells promote ALI injury. A study reported that TNF-α could promote M1 macrophage activation which has pro-inflammatory effects in sepsis-related ALI[39]. Neutrophil overactivation promotes the development of inflammation and injury in ALI[40]. Microvascular endothelial barrier dysfunction, the main pathophysiological feature of ARDS/ALI, induces capillary leakage and edema, which further intensifies inflammatory injury, thus causing high morbidity and mortality[41]. Botros and colleagues reported that stabilizing the endothelial barrier during inflammation alleviated inflammatory responses, edema, and lung injury in mice with ALI[42]. Interestingly, the inhibition of the TLR4 signaling pathways is related to the integrity of the pulmonary endothelial barrier. One study found that TLR4 knockdown decreased the sensitivity to particulate matter-induced pulmonary edema in ALI mice and increased the signal expression intensity of VE-cadherin[43]. Furthermore, MSC treatment in paraquat-induced ALI rats downregulated the TLR4 and NF-κB protein levels in the lungs[44]. Besides, LPS facilitates TLR4 activation to recruit MyD88 and thereby activates NF-κB to promote the production of pro-inflammatory factors such as TNF-α and IL-6[45]. Similarly, this study reported the inhibitory effect of HUC-MSCs on TLR4, Myd88, and NF-κB in the lungs of LPS-induced ALI mice, which suggests that HUC-MSCs may mitigate microvascular endothelial barrier dysfunction and inflammation in ALI *via* the TLR4/Myd88/NF-κB signaling pathway.

There is a correlation between microbiota levels and lung diseases[46]. By analyzing the 16S rDNA of microflora in BALF, we observed a decrease in some pathogenic bacteria. For example, the *Stenotrophomonas* genus was decreased in the BALF of mice in the LPS + MSC group. One study has reported that *Stenotrophomonas* maltophilia is commonly found

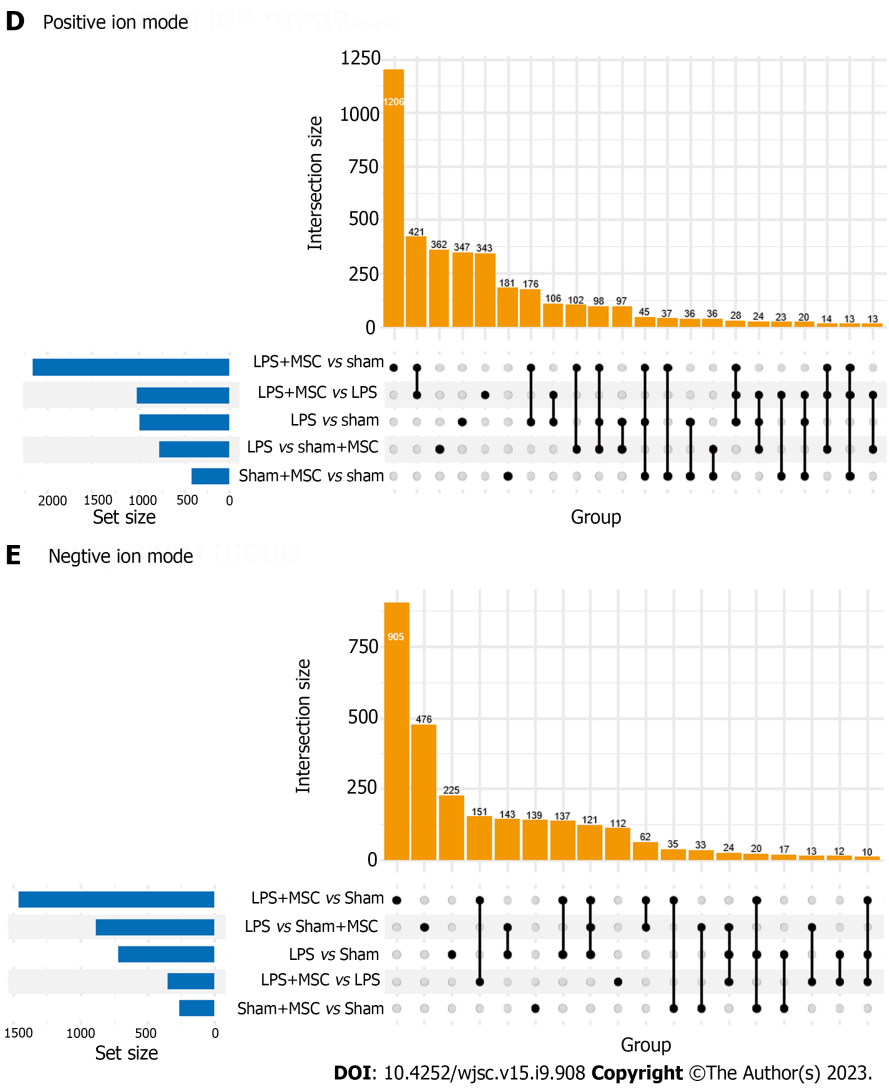
in respiratory tract infections[47]. Additionally, the *Comamonas* genus is an important opportunistic pathogen in human [48]. The genus *Elizabethkingia* has recently emerged as the cause of life-threatening infections in humans, most commonly causing meningitis[49]. *Acinetobacter Baumannii* infections have also been linked to ventilator-associated pneumonia[50]. These findings suggest that HUC-MSCs ameliorate ALI by inhibiting the abundance of pathogenic bacteria. Additionally, by analyzing the microflora in the feces, *Oscillospira* and *Coprococcus* genus abundance in the LPS + MSC group was increased. *Oscillospira*, a common genus of gut bacteria, positively correlates with gut microbiota diversity[51]. Moreover, butyrate, a product of the *Coprococcus* genus, is thought to be able to participate in anti-inflammatory processes[52]. Thus, *Oscillospira* and *Coprococcus* may be involved in the restorative effects of HUC-MSC treatment on gut microflora homeostasis. Additionally, some bacteria have contradictory roles in various diseases. The *Mucispirillum* genus is associated with Crohn's disease-like colitis in immunodeficient mice and is linked to health promotion in immunocompetent hosts[53]. In this study, the improvements in ALI may have been correlated with the abundance of microflora.



Correlation analysis of the gut and lung microflora noticed that the *Desulfovibrio* genus was positively correlated with *Stenotrophomonas*. The *Desulfovibrio* genus is a candidate microbe that induces weight loss of mice with ALI and is directly related to survival[11]. This study not only noted bacteria that strongly correlated with the downregulation of pathogenic bacterial abundance in BALF but also those that were present in both the gut and lungs. *Lactobacillus, Bacteroides,* and *unidentified_Rikenellaceae* genera appeared in the feces and BALF. Moreover, the *Bacteroides* in feces were significantly related to *Lactobacillus* in the BALF. Significant changes in their abundance may be associated with the mechanism of the lung-gut axis. Although the *Lactobacillus* genus is a beneficial flora most of the time in colitis[54], *Lactobacillus rhamnosus* GG treatment in patients with severe pneumonia does not improve the clinical outcomes[55], suggesting that changes in the abundance of *Lactobacillus* may be a consequence of the improvement of ALI by HUM-MSCs and could be used as biomarkers. *Lactobacillus, Bacteroides,* and *unidentified_Rikenellaceae* genera are potential biomarkers for evaluating the treatment efficacy of HUC-MSCs.

Moreover, lung tissue metabolomics was performed in this study, and the composition of metabolites was different in sham mice and ALI mice; HUM-MSC treatment in ALI mice changed the lung metabolite composition. The results of the metabolomic analysis suggest that HUM-MSC treatment alters the bile secretion pathway. Bile and its nuclear receptor farnesoid X are involved in inflammatory liver and bowel diseases[56]. In addition, this study verified the correlation

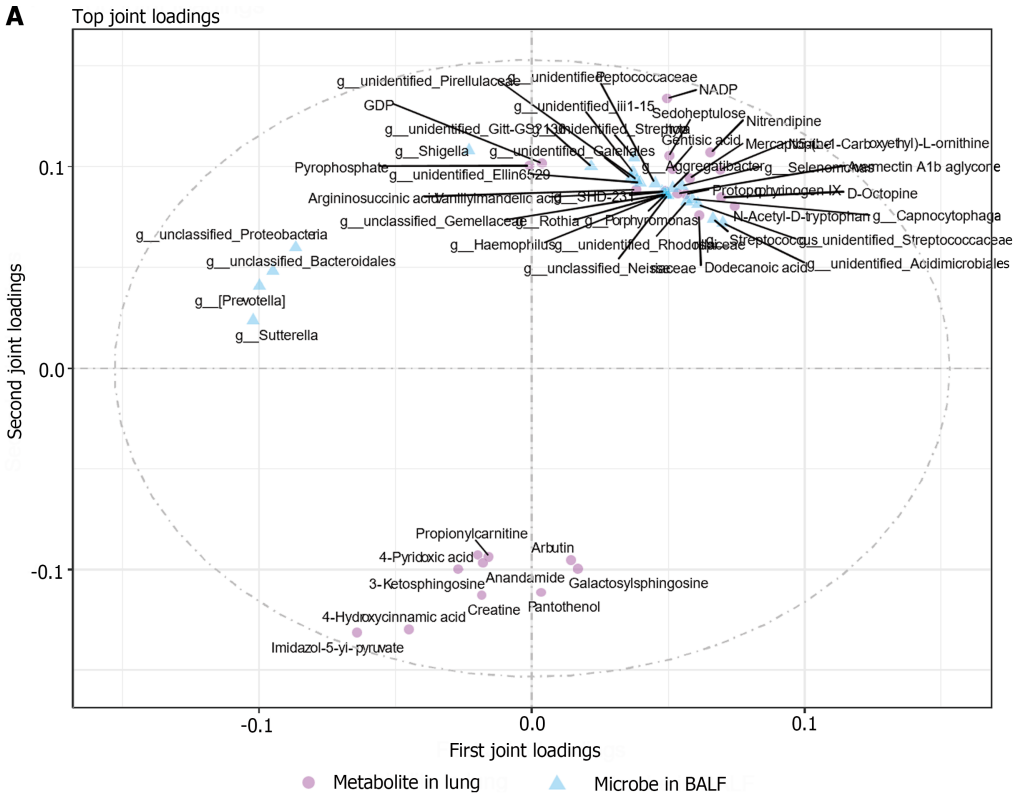
between the BALF microflora and lung tissue metabolites using the O2PLS method. *Haemophilus* has a pivotal role in improving ALI mice by HUC-MSCs. One study reported that non-typeable *Haemophilus influenzae* induces neutrophilic inflammation in severe asthma[57]. Moreover, Yue *et al*[58] found that autophagy can combat the inflammation caused by *Haemophilus parasuis*, acting as a cellular defense mechanism. Similarly, KEGG enrichment results of the high-impact metabolites predicted by O2PLS suggested that autophagy-related pathways may play a critical role in HUC-MSC treatment in ALI mice. The exploration of lung metabolites contributes to the biological mechanism and biomarker discovery of HUM-MSCs treatment in ALI.

Naturally, this study only examined the correlation between microarray and metabolomics in the lung and gut and cannot have conclusive evidence to confirm that the lung-gut axis microbiota is a crucial factor behind the ability of HUC-MSCs to improve ALI. Animal and clinical studies are necessary to validate the role of gut and lung microorganisms in the improvement of ALI by HUC-MSCs. As depicted in Figure 10, this research showcases the crucial involvement of the lung-intestinal axis in safeguarding the lungs and intestines of ALI rats treated with HUC-MSCs, highlighting the interconnectedness of the lung-intestinal microbiota and metabolites.

CONCLUSION



This study showed that HUM-MSC treatment of ALI improved the edema, tissue injury, and endothelial barrier function of the lung; upregulated the VE-cadherin, ZO-1, and occludin levels in the lung; and inhibited the inflammatory cytokine expression levels in the serum and lung. Moreover, HUM-MSC treatment of ALI attenuated the expression of the TLR4/Myd88/NF-κB signaling pathway in the lung tissue. In addition, HUM-MSC treatment of ALI mice improved ileal histopathological damage, reduced the levels of inflammatory factors, promoted ZO-1, claudin-1, and occludin protein

expression, and decreased EUB338 counts in the lung and ileum. In particular, this study found that the gut and lung microflora and metabolites were significantly different between ALI mice untreated and treated with HUM-MSCs. There was a correlation between the abundances of the gut and lung microflora. *Lactobacillus*, *Bacteroides*, and *unidentifiedden-tified_Rikenellaceae* genera are potential biomarkers for evaluating the treatment efficacy of HUC-MSCs. Additionally, this study contributes to the biological mechanism and biomarker discovery of HUM-MSC treatment of ALI by the combined

analysis of lung tissue metabolomics and microbiota, providing a scientific basis for the biological mechanism and clinical application of HUC-MSCs and new ideas for the development of therapeutic strategies for ALI.

ARTICLE HIGHLIGHTS

Research background

Acute lung injury (ALI) has high morbidity and mortality rates and needs effective treatment. Research has found that the gut microbiota improves lung injury through the lung-gut axis. Human umbilical cord mesenchymal cells (HUC-MSCs) can improve ALI.

Research motivation

Although HUC-MSCs can improve ALI, their biological mechanism of action is not yet clear.

Research objectives

To explore changes in the microbiota in the lung-gut axis and the relationship with HUC-MSC treatment.

Research methods

C57BL/6 mice were used to establish an ALI animal model by intraperitoneal injections of lipopolysaccharide. Wright's staining, ELISA, hematoxylin-eosin staining, Evans blue dye leakage assay, immunohistochemistry, fluorescence *in situ* hybridization, and western blot were used to observe the improvement of ALI mice by HUC-MSCs. High-throughput 16S rDNA sequencing was used to observe the microbiota homeostases in the lung-gut axis. The non-targeted metabolomics was used to explore changes in lung tissue metabolites.

Research results

HUC-MSCs ameliorated histopathological damage in the lung and ileum of ALI mice. HUC-MSC treatment improved inflammation, endothelial barrier integrity, and bacterial translocation in the lungs and ileum of ALI mice. HUC-MSCs regulated lung-gut microbiota homeostasis. HUC-MSC treatment regulated the metabolic profile in the lung and ileum of ALI mice.

Research conclusions

This study shows the improvement of changes in the lung and ileum of ALI mice by HUC-MSCs, and suggests a correlation between HUM-MSC-improved ALI and gut and lung microbiota homeostases.

Research perspectives

This study explores the biological mechanism of HUC-MSCs in improving ALI from the perspective of the correlation between the microbiota in the lung-gut axis and lung tissue metabolites, providing a research basis for HUC-MSC treatment.

Abstract

BACKGROUND

Umbilical cord (UC) mesenchymal stem cell (MSC) transplantation is a potential therapeutic intervention for atherosclerotic vascular disease. Integrin beta 3 (ITGB3) promotes cell migration in several cell types. However, whether ITGB-modified MSCs can migrate to plaque sites *in vivo* and play an anti-atherosclerotic role remains unclear.

AIM

To investigate whether ITGB3-overexpressing MSCs ($MSCs^{ITGB3}$) would exhibit improved homing efficacy in atherosclerosis.

METHODS

UC MSCs were isolated and expanded. Lentiviral vectors encoding ITGB3 or green fluorescent protein (GFP) as control were transfected into MSCs. Sixty male apolipoprotein $E^{-/-}$ mice were acquired from Beijing Vital River Lab Animal Technology Co., Ltd and fed with a high-fat diet (HFD) for 12 wk to induce the formation of atherosclerotic lesions. These HFD-fed mice were randomly separated into three clusters. GFP-labeled MSCs ($MSCs^{GFP}$) or $MSCs^{ITGB3}$ were transplanted into the mice intravenously *via* the tail vein. Immunofluorescence staining, Oil red O staining, histological analyses, western blotting, enzyme-linked immunosorbent assay, and quantitative real-time polymerase chain

reaction were used for the analyses.

RESULTS

ITGB3 modified MSCs successfully differentiated into the "osteocyte" and "adipocyte" phenotypes and were characterized by positive expression (> 91.3%) of CD29, CD73, and CD105 and negative expression (< 1.35%) of CD34 and Human Leukocyte Antigen-DR. In a transwell assay, $MSCs^{ITGB3}$ showed significantly faster migration than $MSCs^{GFP}$. ITGB3 overexpression had no effects on MSC viability, differentiation, and secretion. Immunofluorescence staining revealed that ITGB3 overexpression substantially enhanced the homing of MSCs to plaque sites. Oil red O staining and histological analyses further confirmed the therapeutic effects of $MSCs^{ITGB3}$, significantly reducing the plaque area. Enzyme-linked immunosorbent assay and quantitative real-time polymerase chain reaction revealed that MSC^{ITGB3} transplantation considerably decreased the inflammatory response in pathological tissues by improving the dynamic equilibrium of pro- and anti-inflammatory cytokines.

CONCLUSION

These results showed that ITGB3 overexpression enhanced the MSC homing ability, providing a potential approach for MSC delivery to plaque sites, thereby optimizing their therapeutic effects.

Core Tip: Mesenchymal stem cell (MSC) transplantation is considered a new treatment for atherosclerosis. However, research regarding homing of MSCs to atherosclerotic lesions is insufficient. Here, we transplanted integrin beta 3 (ITGB3)-overexpressing MSCs into a mouse model of atherosclerosis. ITGB3-overexpressing MSCs were more greatly accumulated in atherosclerotic plaques. These MSCs prevented plaque progression by shifting the local cytokine profile. The use of ITGB3-overexpressing MSCs may be a novel tool to treat atherosclerosis.

INTRODUCTION

Atherosclerosis is a serious public health problem and the most commonly diagnosed cardiovascular disease in the general population[1]. Implementing early detection of atherosclerosis[2] with systemic pharmacological treatments[3] and percutaneous coronary intervention[4] has contributed to substantial progress in the treatment of atherosclerosis-related diseases[5,6]. Despite medical improvements, the incidence of atherosclerosis-related diseases remains high[7]. Atherosclerotic plaques are still associated with high mortality rates in patients with high-risk or visible advanced plaque disease. Therefore, more studies are needed to discover and explore effective molecules and targets for treatments.

Mesenchymal stem cell (MSC) transplantation accomplished improvements in experimental studies of atherosclerosis [8-11]. MSCs have the ability to secrete many cytokines that mitigate vascular inflammation and regulate the local microenvironment owing to the effects of their secreted anti-inflammatory factors within the vascular plaque[12-14]. However, some limitations preclude the translation of stem cell therapy into clinical applications[15,16], such as stem cells accurately homing to plaques. To determine this, we need to understand the specific mechanisms that underlie the migration and adhesion of MSCs under physiological and pathological conditions. Some studies have attempted to genetically decorate MSCs with specific receptors required for efficient homing. For example, Shahror *et al*[17] found that overexpression of fibroblast growth factor 21 considerably increased MSC migration to and adhesion in the injured brain tissue. Moreover, overexpression of C-X-C chemokine receptor 5 (CXCR5) increased the migratory capability of MSCs toward CXCL13, which changed most substantially in animal models of contact allergy, accompanied by decreases in inflammatory cellular infiltration and reduced levels of pro-inflammatory cytokine production[18]. It is well established that damaged tissues release specific types of cytokines and chemokines. Therefore, elucidating the interrelationships between tissue-specific chemokines and matching receptors on MSCs could offer novel ways of promoting homing and treatment effects of these cells.

The integrin family of receptors, a major family of migration-promoting receptors, plays an important role in the crosstalk between cells and their surroundings[19,20]. Arg-Gly-Asp (RGD) site-containing proteins and corresponding integrin receptors constitute the primary recognition system for cell adhesion[21,22]. Many inflammatory cytokines, such as intercellular cell adhesion molecule-1 (ICAM-1), osteopontin (OPN), and vascular cell adhesion molecule-1 (VCAM-1), contain an RGD motif in their structure[23,24]. The primary sequence of integrin beta 3 (ITGB3), a well-preserved region in all integrin beta subunits, has been called the RGD crosslinking region[25]. Based on this information, we genetically

modified MSCs using *ex vivo* lentiviral transduction to overexpress ITGB3. In the current study, we first demonstrated that ITGB3-overexpressing MSCs ($MSCs^{ITGB3}$) showed enhanced chemotaxis toward plaque tissues *in vivo* and inflammatory cells *in vitro*. Compared with green fluorescent protein (GFP)-labeled MSCs ($MSCs^{GFP}$), $MSCs^{ITGB3}$ reduced the formation of atherosclerotic plaques in homozygous apolipoprotein-E $(ApoE)^{-/-}$ mice, suggesting that ITGB3 enhances homing of modified stem cells to plaque tissue, thereby promoting their therapeutic efficacy in the $ApoE^{-/-}$ mouse model of atherosclerosis.

MATERIALS AND METHODS

Isolation of human umbilical cord MSCs

Human umbilical cord (UC) samples were collected from three healthy donors. All the donors provided written informed consent. MSCs were isolated and cultured from the UCs as reported previously[26]. Briefly, the UC tissue was collected from healthy pregnant women undergoing labor. After removing the UC tissue's arteries and veins, the remaining Wharton's jelly was cut into small pieces for patch cultures. The tissue fragments were cultured at 37 °C and 5% CO_2 in mesenchymal stem cell medium (MSC medium; Sciencell, Carlsbad, CA, United States) containing 5% fetal bovine serum (FBS), stem cell growth supplements, penicillin, and streptomycin. After 10-15 d, fibroblast-like MSCs migrated out of the tissue patches. The studies involving pregnant participants were reviewed and approved by The Ethical Committee of The Second Hospital of Hebei Medical University (approval number: 2021-R496).

Raw264.7, vascular smooth muscle cell, and primary microvascular endothelial cell cultures

The murine macrophage cell line Raw264.7 was purchased from the Cell Resource Center of Shanghai Institutes for Biological Sciences, the Chinese Academy of Science (Shanghai, China). Vascular smooth muscle cells were isolated from mouse aortas and cultured in low-glucose Dulbecco's modified Eagle's medium containing 10% FBS. Lung primary microvascular endothelial cells were obtained from the lungs of 4-week-old C57 mice through two series of immunoselection with CD31- and CD102-conjugated magnetic beads using a previously described procedure[27] and subsequently cultured in endothelial cell medium containing 5% FBS and endothelial cell growth supplements.

Lentiviral vector construction and transduction

Lentiviral vector (LV) encoding ITGB3 and GFP as control were generated and packaged by Hanbio Biosciences (Shanghai, China). All LVs were used for MSC transfection with an infection multiplicity of 30-40. MSCs were plated at a density of 3-5 × 10^5 cells/cm^2 in each six-well plate, depending on the subsequent use. When MSCs reached 40%-50% confluence, the transfection was performed in the presence of polybrene (Cyagen Biosciences, Santa Clara, CA, United States). Following transfection for 72 h, the transfection effectiveness of the virus was checked through fluorescent staining.

AS model induction and MSC delivery

$ApoE^{-/-}$ mice (7–8-week-old) were acquired from Beijing Vital River Lab Animal Technology Co., Ltd (Beijing, China). Sixty male $ApoE^{-/-}$ mice were housed in Hebei Medical University and fed with standard chow and drinking water for 1 wk to adapt to the new surroundings. Then, all animals were fed a high-fat diet (HFD) for 12 wk to induce the formation of atherosclerotic lesions. These HFD-fed mice were randomly separated into three clusters and received the following treatment: (1) HFD mice (n = 20) were injected 200 μL of phosphate-buffered saline (PBS) into the caudal vein every week from week 9, four times in total; (2) MSC^{GFP} mice (n = 20) receiving 200 μL of PBS containing 1 × 10^6 $MSCs^{GFP}$ intravenously through the tail vein every week from week 9; and (3) MSC^{ITGB3} mice (n = 20) receiving 200 μL of PBS containing 1 × 10^6 $MSCs^{ITGB3}$ intravenously through the tail vein every week from week 9. The animals were euthanized after 12 wk of HFD, the aorta and aortic sinus were collected, and histological samples were processed for subsequent atherosclerosis assessment. At the same time, blood samples were collected to determine lipid levels. All animal procedures complied with the Guide for the Care and Use of Experimental Laboratory Animals and were approved by the Animal Care Committee of The Second Hospital of Hebei Medical University (No. 2021-R496).

Echocardiographic assessment

At the end of week 12, 10 mice were gas-anesthetized *via* a facemask and kept on a minimal dose of isoflurane (1.0%-2.0%). The mice were placed in a supine position and maintained spontaneous breathing with isoflurane insufflation throughout the echocardiographic assessment. Echocardiographic data were recorded by a VisualSonics Vevo2100 Imaging System (Fujifilm Visual Sonics Inc., Tokyo, Japan) with an EZ-SA800 Single Animal System (E-Z Systems Inc., Bethlehem, PA, United States). Ascending aorta functions were evaluated from the parasternal view of the long axis. The diameter of the systolic aorta was measured at the peak anterior movement point of the ascending aorta, and the diameter of the diastolic aorta was measured using a Q-wave (end-diastolic) echocardiogram. The average diameter measurements of five consecutive heart cycles were selected for data analysis. Meanwhile, left ventricle function and heart chamber dimensions were also evaluated, including the left ventricular ejection fraction (EF) and left ventricular fractional shortening (FS), using accompanying software. The data were recorded and analyzed.

Murine aortic tissue culture

Murine aortic rings were cultured as described previously[28]. Briefly, after 12 wk of HFD, external organs and tissues

were removed. Then, the whole aortic vessel was separated from the adipose and surrounding tissue. The aorta was divided into 2-4 mm rings and cultured in low-glucose Dulbecco's modified Eagle's medium supplemented with 5% FBS. Aortic rings were maintained at 37 °C in 5% CO_2 for 24 h for further experiments.

Hematoxylin and eosin staining, Masson's trichrome staining, and oil red O staining

The aortic arch and aortic valve were harvested after 12 wk of HFD. The animals were euthanized, and the left ventricles were cannulated and injected with PBS containing heparin. Thereafter, the aortic arch and aortic valve were separated, embedded in optimal cutting temperature compound, shortly frozen in liquid nitrogen, and sliced. Subsequently, hematoxylin and eosin (HE) staining was performed to assess plaque size. The cross-sectional areas of the plaque were measured with Image-Pro Plus (IPP) 6.0 software (Media Cybernetics Corp., Rockville, MD, United States). Collagen depositions were assessed using Masson's trichrome staining. Average values were determined from at least three sections in each sample.

For oil red O (ORO) staining, the fixed whole aorta was incubated with 0.3% ORO solution (Sigma-Aldrich, St Louis, MO, United States) for 20 min and, then, washed with 60% isopropanol. Frozen aortic arch and aortic valve sections were incubated with ORO for 5 min, washed with PBS, and counterstained with hematoxylin. The atherosclerotic lesions were photographed using a light microscope (Carl Zeiss, Jena, Germany) and quantified using IPP 6.0 software.

Cell viability assay

The effects of LV transfection on MSC viability were evaluated using cell counting kit 8 (CCK-8) assays as described previously[29]. Briefly, MSCs, $MSCs^{ITGB3}$, and $MSCs^{GFP}$ were seeded into 96-well plates at a density of 1×10^4 cells/well, respectively. After 24 h, CCK-8 was added to each well and incubated at 37 °C for 1 h. The absorbance was measured at 450 nm using a VersaMax (Ocean Springs, MI, United States) microplate scanner.

Chemotaxis assays

Chemotaxis assays were operated in 24-well transmembrane chambers with 8-μm pore filters. To test the ability of stem cells to migrate toward defined chemokines, Raw264.7, vascular smooth muscle cells, and primary microvascular endothelial cells were separately seeded into the lower chamber (1×10^5 cells/well). After achieving confluence, serum-free cells were stimulated with tumor necrosis factor-α (TNF-α, 20 ng/mL) for 24 h. Then MSCs, $MSCs^{GFP}$, and $MSCs^{ITGB3}$ were respectively plated into the upper chamber at 2×10^4 cells/well. After incubation for 24 h, the upper layer of cells was removed, and the lower layer was stained with crystal violet.

For the vascular atherosclerotic plaque, mice were sacrificed after week 12. Aortic rings were separately cultured for 24 h in Dulbecco's modified Eagle's medium with 5% FBS. Next, MSCs, $MSCs^{GFP}$, and $MSCs^{ITGB3}$ were respectively plated into the upper chamber at 2×10^4 cells/well. The medium for re-suspending MSCs matched the medium in the lower chamber. After incubation for 24 h, non-migrated cells were removed from the upper surface, and the cells that had migrated across the membrane to the lower surface were fixed with 4% paraformaldehyde and stained with crystal violet. For each membrane, five fields of view were imaged and analyzed. Each experiment was repeated at least three times, and the number of migrated cells was expressed as the mean ± standard error of the mean (SEM) of total cell counts per field.

RNA extraction and quantitative real-time polymerase chain reaction

Total RNA of cells or tissue samples was extracted using TRIzol reagent, according to the manufacturer's protocol. cDNA was synthesized using the M-MLV First Strand Kit. Quantitative real-time polymerase chain reaction (qRT-PCR) using SYBR Green qPCR SuperMix were performed using an ABI 7500. qRT-PCR analyses were repeated at least three times. The qRT-PCR data were standardized to β-actin expression, using the $2^{-\Delta\Delta Ct}$ method. The primers used are listed in Supplementary Table 1. The average threshold cycle for each gene was determined from at least three independent experiments.

Western blot analysis

Cell or tissue lysates were extracted with lysis buffer. Equal amounts of protein were separated by 10% sodium dodecyl-sulfate polyacrylamide gel electrophoresis and transferred to a polyvinylidene fluoride membrane. The membranes were blocked with 5% bovine serum albumin for 1 h at room temperature, incubated with specific antibodies against VCAM-1, ICAM-1, OPN, and GAPDH at 4 °C overnight, and, then, incubated with horseradish peroxidase-conjugated anti-mouse or anti-rabbit immunoglobulin G for 1 h at room temperature. Antigen-antibody complexes were assessed using the GE ImageQuant™ LAS 4000 detection system (GE Healthcare Inc., Chicago, IL, United States). The protein bands of interest were quantified with IPP 6.0 software.

Statistical analyses

Data analysis was performed with GraphPad Prism 8 software (GraphPad Software, Inc., San Diego, CA, United States). Data are displayed as mean ± SEMs, and each independent experiment was repeated three times. The statistical significance of differences between two groups was determined using the unpaired Student's t-test, and comparisons of more than two groups were performed using a one-way analysis of variance. For all statistical comparisons, significance was considered at $P < 0.05$.

RESULTS

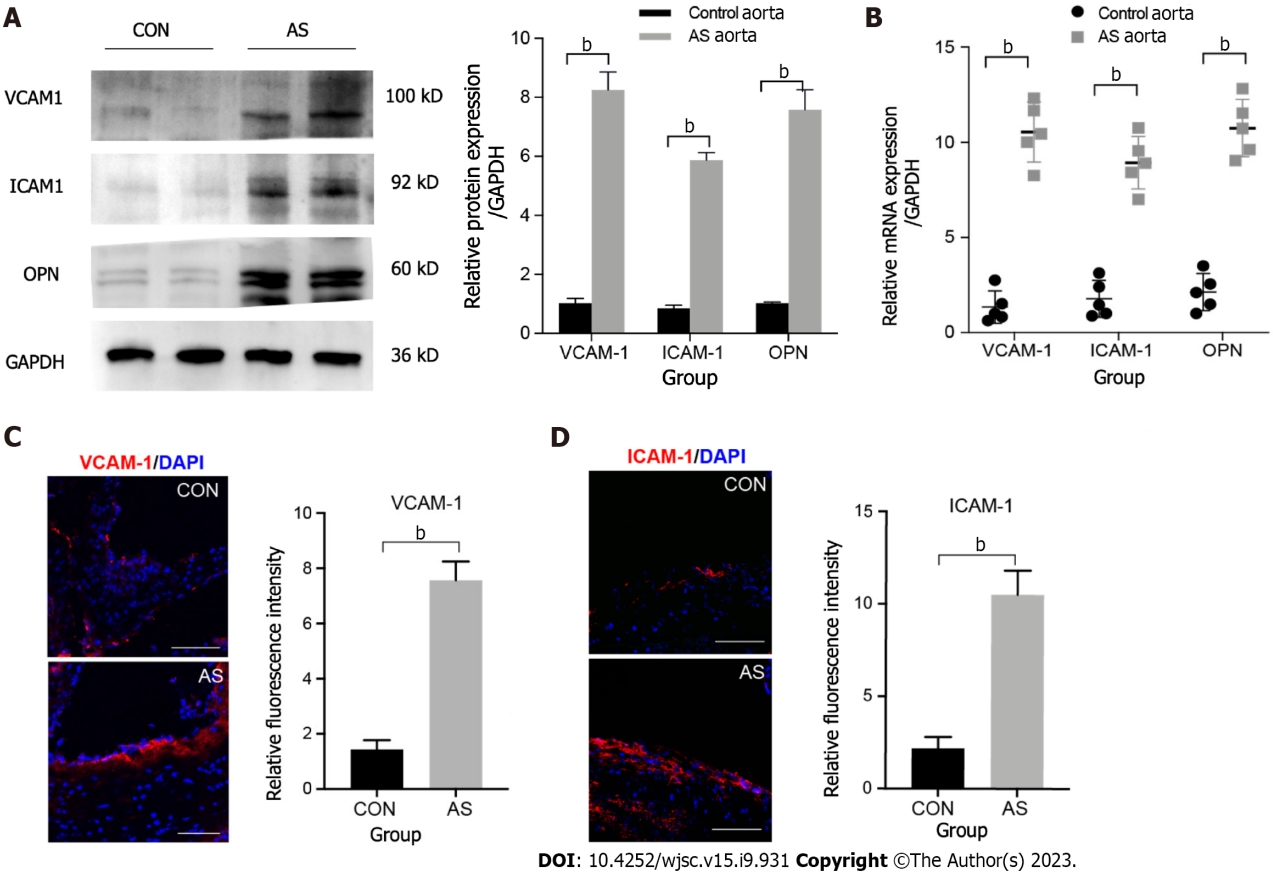
Inflammatory factors containing the RGD motif are highly upregulated in atherosclerotic vessels

Atherosclerosis is a chronic inflammatory disease of the arteries with high expression of adherence molecules. We tested the expression of VCAM-1, ICAM-1, and OPN because studies have shown that they contain the RGD motif that can bind to the ITGB3 receptor[19,20,30]. Our results demonstrated that the protein expression levels of VCAM-1, ICAM-1, and OPN were six to eight times higher in atherosclerotic than in control blood vessels (Figure 1A). Similarly, qRT-PCR and immunofluorescence staining also confirmed that the three adhesion factors considerably increased at sites of inflammation (Figure 1B–D).

The ITGB3 receptor is scarcely expressed on human UC-derived MSCs, and ITGB3 overexpression by MSCs does not affect other MSC characteristics

Inflammatory factors that are highly expressed at plaque sites and matching receptors expressed on the surface of MSCs play an important role in guiding stem cells. Thus, we analyzed the expression of the ITGB3 receptor using western blot, qRT-PCR, and fluorescence staining methods. First, human MSCs at the third passage had very low expression of the ITGB3 receptor at the protein and mRNA levels (Figure 2A and B). Second, immunofluorescence staining confirmed that MSCs barely expressed the ITGB3 receptor (Figure 2C and D). To further determine whether overexpression of ITGB3 receptor in MSCs can promote their homing capability toward plaque tissues, MSCs were transfected with LVs encoding ITGB3 and GFP ($MSCs^{ITGB3}$ for short) or GFP ($MSCs^{GFP}$ for short). We found that both $MSCs^{ITGB3}$ and $MSCs^{GFP}$ highly expressed GFP, confirming the stable expression of the GFP reporter gene (Figure 2C). In contrast to $MSCs^{GFP}$ and MSCs, $MSCs^{ITGB3}$ showed substantially stronger expression of ITGB3 at the protein, mRNA, and fluorescence staining levels (Figure 2A–D). Moreover, ITGB3 overexpression did not affect stem cell viability according to CCK8 analyses (Figure 2E). To further verify whether transfection of ITGB3 affects the differentiation properties of MSCs, we observed several typical stem cell markers using flow cytometry and qRT-PCR analyses. The results showed that in $MSCs^{ITGB3}$, MSC-specific markers (CD73, CD105, and CD29), but not hemopoietic stem cell antigens (CD34 and human leukocyte antigen-DR), were highly expressed (Figure 2F and G). The differentiation of $MSCs^{ITGB3}$ into adipocytes and osteoblasts was separately evaluated using ORO and Alizarin red staining (Figure 2H and I). Moreover, marker genes in induced adipocytes and osteoblasts were verified through qRT-PCR (Figure 2J and K). These findings confirmed that transfected MSCs still have stem cell properties.

ITGB3 enhances MSC migration toward inflammatory sites in vitro and in vivo



ITGB3 is vital for cell migration, adhesion, and invasion[20-22,31]. Therefore, we next checked whether $MSCs^{ITGB3}$ could promote MSC migration *in vitro* and *in vivo*. The *in vitro* cell chemotaxis assay showed that in the presence of TNF-α, $MSCs^{ITGB3}$ displayed a significantly increased migration toward the bottom chamber, especially if it contained macrophages (Figure 3A and B). However, in the absence of TNF-α, all cells showed similar, very low, nonspecific migration toward the lower, cell-containing chamber (Figure 3A and B). We also performed transwell-based chemotaxis assays using atherosclerotic aorta samples *in vitro* (Figure 3C and D). $MSCs^{ITGB3}$ had the highest migratory activity, indicating that the atherosclerotic plaque secreted inflammatory factors which were chemoattractants for $MSCs^{ITGB3}$, but not for $MSCs^{GFP}$ (Figure 3C and D). Next, we observed whether MSCs migrate to plaque sites *in vivo* following intravenous infusion. $MSCs^{ITGB3}$ and $MSCs^{GFP}$ were injected into HFD mice through the tail vein every week from weeks 9 to 12. The aortas were collected from each group at the end of week 12 for in situ fluorescence staining. The results showed that $MSCs^{ITGB3}$ were highly aggregated at sites of inflammation, whereas $MSCs^{GFP}$ had less positive staining at such sites (Figure 3E and F). Meanwhile, the qRT-PCR results also revealed that there was a higher GFP expression in the MSC^{ITGB3} group when compared to the GFP expression in the $MSCs^{GFP}$ group (Figure 3G). However, there were negligible MSCs in the myocardium, and no difference between the two groups was observed (Supplementary Figure 1). These data suggested that ITGB3 overexpression promoted the targeted migration of MSCs to plaque sites *in vivo*, possibly by targeting inflammatory factors containing the RGD structure.

$MSCs^{ITGB3}$ reduce the progression of atherosclerotic plaques in $ApoE^{-/-}$ mice fed an HFD

To explore the effects of $MSCs^{ITGB3}$ on the progression of atherosclerosis, the whole aorta, aortic root, and aortic arch were stained with 0.5% ORO, and the stained areas were quantified to determine the atherosclerotic plaque area. The stained area in the aorta was substantially decreased in the MSC^{ITGB3} group when compared with that of the HFD and MSC^{GFP} groups (Figure 4A and B). The stained areas in the aortic root and aortic arch decreased in the MSC^{ITGB3} group compared with the corresponding in the HFD and MSC^{GFP} groups (Figure 4C). HE and Masson's trichrome staining analyses of sections taken from the aortic root and aortic arch demonstrated that $MSCs^{ITGB3}$ inhibited aortic plaque formation and collagen deposition more effectively than $MSCs^{GFP}$ (Figure 4D and E). Aortic stiffness is the earliest detectable evidence of changes in arterial wall function. Echocardiographic results showed that both systolic and diastolic diameters were considerably increased while the vessel wall thickness was decreased in the MSC^{ITGB3} group (Figure 4F). However, left ventricular EF and FS were not different among the three groups (Supplementary Figure 2). The number of macrophages in atherosclerotic plaques at the aortic arch was determined by F4/80 staining. The F4/80 staining-positive areas were notably reduced in the MSC^{ITGB3} group compared with the HFD group (Figure 4G).

$MSCs^{ITGB3}$ do not alter the biochemical parameters of $ApoE^{-/-}$ mice fed an HFD

To evaluate the effects of $MSCs^{ITGB3}$ on biochemical features *in vivo*, we recorded changes in mouse body weight and

measured blood lipid concentrations. The results showed that the body weight did not vary among the three groups during the experiment (Supplementary Figure 3A). Plasma lipid analyses, including those measuring total cholesterol, high-density lipoprotein cholesterol, triglyceride, and low-density lipoprotein cholesterol levels, were performed on terminal blood samples obtained by cardiac puncture but showed no statistical differences among the HFD, MSC^{GFP}, and MSC^{ITGB3} groups (Supplementary Figure 3B). These results suggest that intravenous injection of stem cells did not interfere with lipid metabolism in mice receiving an HFD.

MSCs^{ITGB3} modulate cytokine expression in the AS mouse model

The levels of inflammatory factors are positively correlated with the degree of inflammation in atherosclerosis. Cytokines play a pivotal role in chronic inflammatory diseases[31]. They affect the expression of adherence molecules, permeability of endothelial cell, as well as proliferation and migration of inherent cells in blood vessels, all of which are associated with atherosclerosis. Interleukin (IL)-1β, an established driver of atherosclerotic disease[32], is involved in the entire process of atherosclerotic lesion progression[33]. Advanced atherosclerotic plaques can be alleviated and stabilized through IL-1β inhibition. After observing that MSC^{ITGB3} treatment can reduce the plaque area, we further investigated whether MSC^{ITGB3} infusion can decrease the levels of pro-inflammatory factors or increase the levels of anti-inflammatory factors in the serum and aorta tissue. Our results showed that pro-inflammatory factors, including TNF-α, IL-1β, and IL-6, showed a significant downward trend in mice who had received MSC^{ITGB3} or MSC^{GFP} treatment. However, the treatment effect of MSCs^{ITGB3} was more pronounced than that of MSCs^{GFP}. Likewise, mice receiving MSCs^{ITGB3} or MSCs^{GFP} showed significantly increased levels of anti-inflammatory factors, such as IL-4, IL-10, and tumor necrosis factor-stimulated gene-6 in the serum and aorta tissue (Figure 5). These results indicate that MSC^{ITGB3} treatment primarily reduces pathological inflammatory responses by improving the balance between secreted pro- and anti-inflammatory factors.

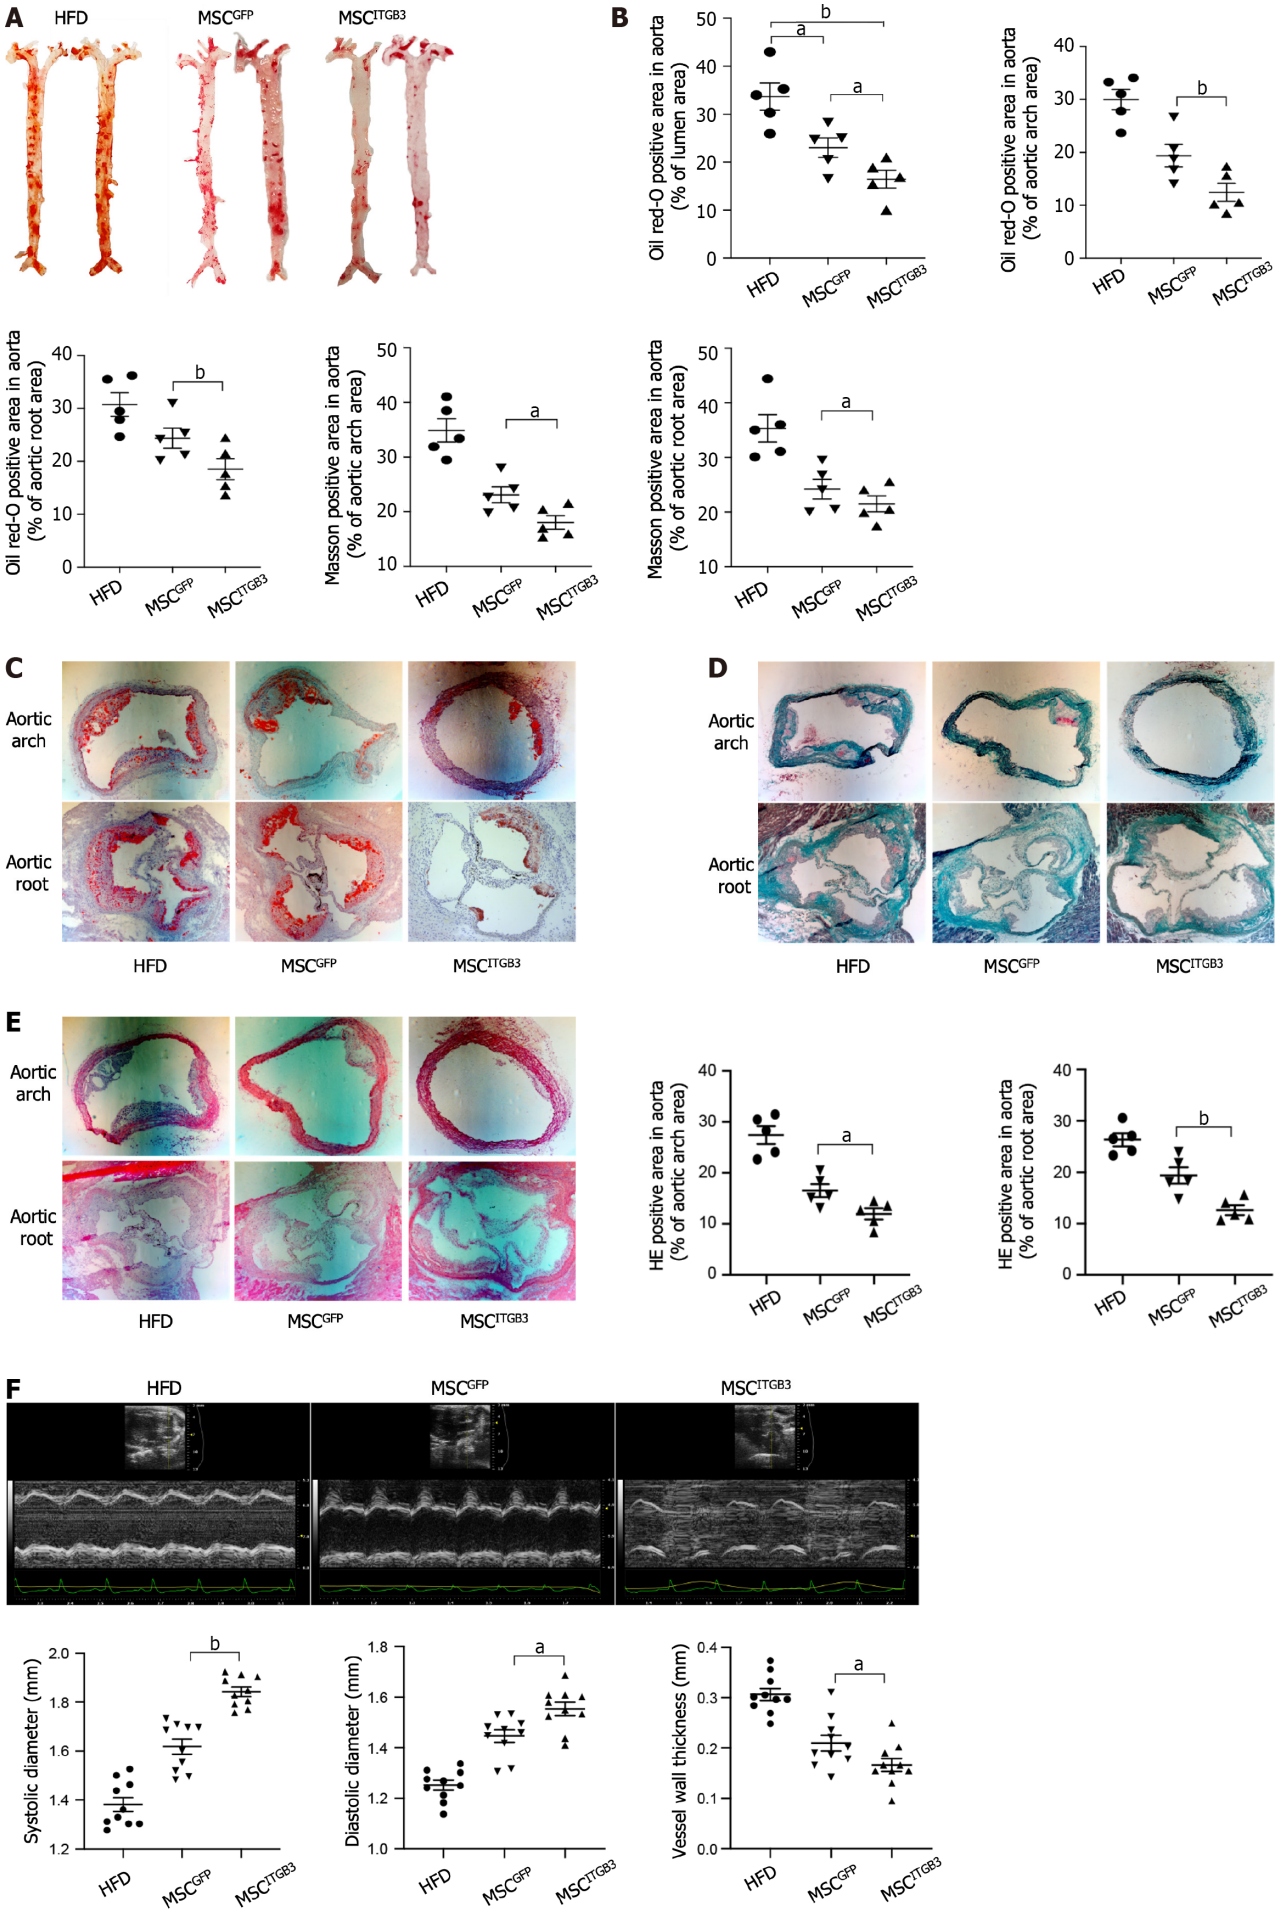
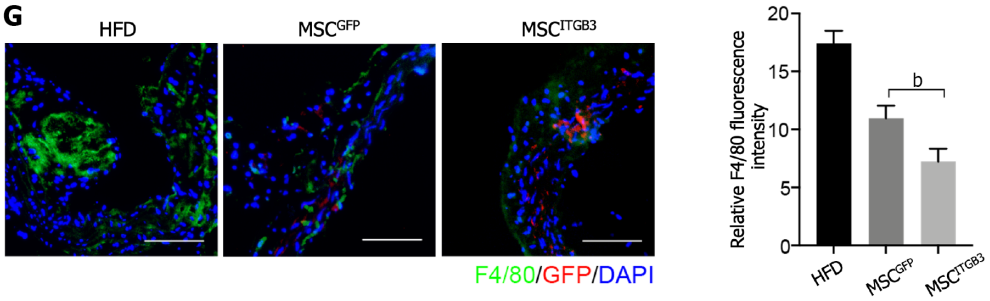
DISCUSSION

In this study, adhesion molecules containing the RGD motif were highly expressed in an atherosclerosis model, and transfection of ITGB3 into MSCs improved their targeting capability. As expected, intravenous injection of MSCs^{ITGB3} substantially reduced atherosclerotic plaque in the ApoE$^{-/-}$ HFD mouse model.



Owing to their adaptive immunomodulatory properties and superior secretory potential, MSCs have attracted extensive attention in the treatment of atherosclerotic diseases[8,14]. The route of MSC administration is critical for their therapeutic efficiency, and systemic delivery *via* intravenous infusion is the primary approach for many cell therapies. However, several problems occur with this approach, and one of the major hurdles is insufficient cell engraftment into the damaged tissue[34]. It is well known that the therapeutic level of MSCs mainly depends on intercellular interactions and their regulation by the local microenvironment. Therefore, the therapeutic effect of intravenously injected MSCs may be closely related to their localization. It is predicted that the effectiveness of cell therapy can be improved by increasing local recruitment, further promoting tissue repair. However, methods to increase intercellular interactions that promote local engraftment of MSCs remain unclear.



Integrins, as transmembrane receptors, mediate cell connections by integrating Ig superfamily counterreceptors (ICAM-1 and VCAM-1) on adjacent cells[20]. Adhesion molecules and integrin receptors have been identified to facilitate cell migration toward target organs and adhesion in target tissues. Therefore, intravenous injection of MSCs^{ITGB3} may

provide a new approach to improve stem cell homing. Previous studies have also verified that MSCs with altered chemokine receptors, such as CXCR5[18], integrin α4[35], and CCR5 and CXCR6[36], significantly increased cell motion to lesion sites and enhanced the therapeutic effect of MSCs. MSC homing to a target organ requires the proper integration of interactions of chemokines secreted by injured tissue and adhesion molecules with matching receptors on MSCs. Therefore, determining disease-specific ligand expression profiles will provide the precise signal necessary for MSC homing. In our study, we elucidated that the ITGB3/RGD motif axis is a specific regulator for MSC homing in atherosclerosis. Adhesion molecules containing the RGD motif, such as VCAM-1, ICAM-1, and OPN, are highly expressed in atherosclerotic plaque and are involved in a variety of immune functions, including T cell activation, migration, and extravasation[37]. High VCAM-1 and ICAM-1 expression levels have also been reported in the inflamed tissue, including vascular plaque[38]. We found that the RGD structure acts as an important feature of the plaque tissue that chemoattracts the migration of MSCs^{ITGB3} to lesions *in vivo*. Moreover, our findings demonstrated that the ITGB3-RGD motif axis is the atherosclerosis-specific regulator for MSC homing. Factors containing RGD structures can be observed in various inflammatory tissues, including the site of atherosclerotic lesions[39]. However, the expression of ITGB3 was almost absent on the surface of MSCs. Thus, MSCs^{ITGB3} may serve as a disease-specific therapeutic tool to improve MSC homing when treating atherosclerosis. MSC transplantation and homing appear to improve atherosclerosis *via* different mechanisms. There is a substantial amount of evidence indicating that transplanted MSCs primarily promote local microenvironmental improvement through their paracrine secretory effects[40-42]. The anti-inflammatory cytokines secreted by MSCs can reduce inflammation and modulate immune response while enhancing normal cell survival and differentiation[9,11]. It has also been documented that the anti-inflammatory properties of MSCs are primarily mediated by extracellular vesicles (EVs)[8,43]. Various disease models, such as those involving endothelial cell senescence[44], autoimmune diseases[45], arterial stiffness and hypertension[46], and lung injury[47], have demonstrated that EVs derived from MSCs can mitigate cell death, prevent apoptosis, and enhance recovery. In this regard, as a result of the continuous release of EVs in the vicinity of the damage site, transplantation of MSCs overexpressing ITGB3 with improved migratory capability could play a more effective role in treating atherosclerotic disease.

A previous study found that ITGB3 stimulated the progression of human pancreatic ductal adenocarcinoma *via* activation of the STAT3 pathway[48]. Furthermore, ITGB3 promoted cell senescence and profibrotic changes through p53 signaling activation and secretion of transforming growth factor beta in cultured tubular cells[49]. However, these studies have not examined the specific effect of ITGB3 overexpression on MSC migration and homing *in vivo*. Further research is necessary to elucidate the underlying mechanisms of how overexpression of ITGB3 intensifies homing abilities of MSCs.

This study has certain limitations. First, the MSCs^{ITGB3} were generated by lentiviral infection. As lentiviral vectors can randomly integrate into the genome resulting in deleterious mutations, their therapeutic application in humans is limited by an inherent risk of tumorigenesis. Second, other suitable methods are needed to increase the expression of ITGB3. Third, the current experiment did not specifically investigate the survival time of MSCs^{ITGB3} *in vivo*. The next step will be to trace the target location and lifespan of MSCs^{ITGB3} through *in vivo* imaging technology.

CONCLUSION

Collectively, we genetically modified MSCs *in vitro* and found that ITGB3 overexpression substantially upregulated MSC migration, aggregation in plaque sites, and immunomodulatory properties of MSCs *in vivo*. Although the therapeutic potential of modified MSCs in atherosclerosis has not yet been translated into clinical practice, our work improves our

understanding of the adhesion molecule–integrin receptor axis, as well as of stem cell features, and may provide novel insights into the rapid and targeted delivery of MSCs to disease sites, thereby optimizing their therapeutic effects.

ARTICLE HIGHLIGHTS

Research background

Umbilical cord mesenchymal stem cell (MSC) transplantation is a potential therapeutic intervention for atherosclerotic vascular disease. Integrin beta 3 (ITGB3) promotes cell migration in several cell types. However, whether ITGB3-modified MSCs can migrate to plaque sites *in vivo* and play an anti-atherosclerotic role remains unclear.

Research motivation

Atherosclerosis is a serious public health problem and more treatment options are needed to explore and identify effective molecules and targets.

Research objectives

The objective of our study was to evaluate the chemotaxis ability of ITGB3-overexpressing MSCs toward inflammatory cells *in vitro* and plaque tissues *in vivo,* promoting their therapeutic efficacy in the atherosclerosis mouse model.

Research methods

Umbilical cord MSCs were isolated and expanded. Lentiviral vectors encoding ITGB3 or green fluorescent protein (GFP) as control were transfected into MSCs. Male apolipoprotein $E^{-/-}$ mice were fed with a high-fat diet (HFD) for 12 wk to induce the formation of atherosclerotic lesions. The HFD-fed mice were randomly separated into three clusters. GFP-labeled MSCs ($MSCs^{GFP}$) or $MSCs^{ITGB3}$ were transplanted into the mice intravenously *via* the tail vein. Immunofluorescence staining, Oil red O staining, histological analyses, western blotting, enzyme-linked immunosorbent assay, and quantitative real-time polymerase chain reaction were used for the analyses. Statistical evaluation between two groups was determined using the unpaired Student's t-test, and comparisons of more than two groups were performed using a one-way analysis of variance.

Research results

$MSCs^{ITGB3}$ successfully differentiated into the "osteocyte" and "adipocyte" phenotypes and were characterized by positive expression (> 91.3%) of CD29, CD73, and CD105 and negative expression (< 1.35%) of CD34 and human leukocyte antigen-DR. $MSCs^{ITGB3}$ showed significantly faster migration than $MSCs^{GFP}$. ITGB3 overexpression had no effects on MSC viability, differentiation, and secretion. Immunofluorescence staining revealed that ITGB3 overexpression substantially enhanced the homing of MSCs to plaque sites. Oil red O staining and histological analyses further confirmed the therapeutic effects of $MSCs^{ITGB3}$, significantly reducing the plaque area. Enzyme-linked immunosorbent assay and quantitative real-time polymerase chain reaction revealed that MSC^{ITGB3} transplantation considerably decreased the inflammatory response in pathological tissues by improving the dynamic equilibrium of pro- and anti-inflammatory cytokines.

Research conclusions

The study demonstrated that ITGB3 overexpression enhanced the MSC homing ability, providing a potential approach for MSC delivery to plaque sites, thereby optimizing their therapeutic effects.

Research perspectives

The ITGB3-modified MSCs can migrate the plaque sites and play an anti-inflammation role, which may be an effective strategy to treat vascular atherosclerotic related diseases.

Abstract

BACKGROUND

Rapid wound healing remains a pressing clinical challenge, necessitating studies to hasten this process. A promising approach involves the utilization of human umbilical cord mesenchymal stem cells (hUC-MSCs) derived exosomes. The hypothesis of this study was that these exosomes, when loaded onto a gelatin sponge, a common hemostatic material, would enhance hemostasis and accelerate wound healing.

AIM

To investigate the hemostatic and wound healing efficacy of gelatin sponges loaded with hUC-MSCs-derived exosomes.

METHODS

Ultracentrifugation was used to extract exosomes from hUC-MSCs. Nanoparticle tracking analysis (NTA), transmission electron microscopy (TEM), and western blot techniques were used to validate the exosomes. *In vitro* experiments were performed using L929 cells to evaluate the cytotoxicity of the exosomes and their impact on cell growth and survival. New Zealand rabbits were used for skin irritation experiments to assess whether they caused adverse skin reactions. Hemolysis test was conducted using a 2% rabbit red blood cell suspension to detect whether they caused hemolysis. Moreover, *in vivo* experiments were carried out by implanting a gelatin sponge loaded with exosomes subcutaneously in Sprague-Dawley (SD) rats to perform biocompatibility tests. In addition, coagulation index test was conducted to evaluate their impact on blood coagulation. Meanwhile, SD rat liver defect hemostasis model and full-thickness skin defect model were used to study whether the gelatin sponge loaded with exosomes effectively stopped bleeding and promoted wound healing.

RESULTS

The NTA, TEM, and western blot experimental results confirmed that exosomes

were successfully isolated from hUC-MSCs. The gelatin sponge loaded with exosomes did not exhibit significant cell toxicity, skin irritation, or hemolysis, and they demonstrated good compatibility in SD rats. Additionally, the effectiveness of the gelatin sponge loaded with exosomes in hemostasis and wound healing was validated. The results of the coagulation index experiment indicated that the gelatin sponge loaded with exosomes had significantly better coagulation effect compared to the regular gelatin sponge, and they showed excellent hemostatic performance in a liver defect hemostasis model. Finally, the full-thickness skin defect healing experiment results showed significant improvement in the healing process of wounds treated with the gelatin sponge loaded with exosomes compared to other groups.

CONCLUSION

Collectively, the gelatin sponge loaded with hUC-MSCs-derived exosomes is safe and efficacious for promoting hemostasis and accelerating wound healing, warranting further clinical application.

Key Words: Human umbilical cord mesenchymal stem cells; Exosomes; Gelatin sponge; Safety; Hemostasis; Wound healing

Core Tip: In this study, we loaded exosomes derived from human umbilical cord mesenchymal stem cells onto a gelatin sponge, a common hemostatic substance in clinics, to stop bleeding and promote wound healing. The fabricated material appears relatively safe, provides better hemostatic activity than gelatin sponge alone, and promotes good wound healing.

INTRODUCTION

In recent years, biomaterials have increasingly been used in clinical practice. Notably, gelatin sponges have been widely used in various surgical procedures owing to their excellent characteristics. Gelatin sponges are highly accessible, cheap, and easy to use, allowing use as a dry material or impregnated with saline or thrombin prior to use. Furthermore, gelatin sponges exhibit a robust absorption capacity and can absorb approximately 40 times their own weight of water or liquid and expand to 200% of their original volume, thus increasing the local platelet concentration[1]. Moreover, the expanded gelatin particles help limit blood flow and provide a packing effect in the limited space, thereby promoting the formation of blood clots during wound healing.

Gelatin sponges were first used in neurosurgery in the 1940s and have since been widely used in various surgical procedures. In recent years, many new applications have been developed for absorbable gelatin sponges. Wang *et al*[2] have fabricated an Au/Ag gelatin sponge by adding Au/Ag to the gelatin matrix, which improved its antibacterial performance. Yang *et al*[3] have used a cocktail of ropivacaine, dexamethasone, and vitamin B12 to impregnate a gelatin sponge for promoting leg pain relief and functional recovery after percutaneous endoscopic lumbar discectomy. Notably, Jogo *et al*[4] have loaded gelatin sponge particles with 5% ethanolamine oleate iopamidol and used the mixture to examine the effect of retrograde occlusion of veins in gastric varices. Incorporating colloidal Ag into gelatin sponges was beneficial in promoting bone healing in infected skull defects[5]. Accordingly, gelatin sponges can be used to promote wound healing and combined with various drugs or substances to improve their therapeutic effects.

Mesenchymal stem cells (MSCs) have been shown to markedly improve wound closure, angiogenesis, and wound healing. However, stem cell therapy is complex, expensive, and time-consuming. Recent studies have demonstrated the effectiveness of stem cell-derived exosomes in treating wounds. Exosomes are emerging as a new mode of intercellular communication. Additionally, exosomes play an important role in wound repair[6]. Exosomes are membrane-derived vesicles interacting with target receptor cells, enabling inter cellular communication[7]. Growing evidence suggests that exosomes are crucial in coagulation, intercellular signaling, and waste metabolism[8]. The biological characteristics of exosomes derived from MSCs are similar to those of umbilical cord (UC)-MSCs, making them valuable for tissue repair.

Recently, an increasing number of studies have explored the combined application of exosomes and biological materials. Wang *et al*[9] have fabricated an injectable, viscous, heat-sensitive, multifunctional polysaccharide-based wound dressing capable of sustained exosomes release to accelerate wound healing by stimulating the angiogenic process of the wound tissue. Tao *et al*[10] have combined exosomes released by synovial MSCs overexpressing miR-126-3p with chitosan, demonstrating that this strategy could be used to treat skin wounds. Xu *et al*[11] have assembled exosomes on chitosan/silk hydrogel sponges based on platelet-rich plasma to examine wound healing in a diabetic rat model, revealing their capacity to promote wound healing during diabetes. Furthermore, Nooshabadi *et al*[12] have employed an exosome-loaded chitosan hydrogel to study wound healing and dermal reconstruction in mice. The authors found that the exosome-loaded chitosan hydrogel exhibited a wound closure capacity of approximately 83.6% and a high degree of

re-epithelization[12]. Based on the above literature, novel dressings made by combining exosomes and a variety of biological materials afford better effects than conventional dressings.

In the present study, we loaded a common clinically used gelatin sponge with exosomes to synthesize a novel gelatin sponge with improved characteristics. The safety and effectiveness of the improved gelatin sponge in hemostasis and promotion of healing were studied both *in vivo* and *in vitro*. The findings will provide novel avenues for further research on the potential applications of human UC MSCs (hUC-MSCs)-derived exosomes in tissue repair. Furthermore, our study provided evidence for the feasibility of using a bioscaffold synthesized by combining exosomes and biological materials simply and non-invasively to stop bleeding and promote wound healing, thereby supporting the further use of exosomes for clinical applications.

MATERIALS AND METHODS

Statement of animal treatment

All animals were obtained from Changsha Tianqin Biotechnology Co., Ltd. (Changsha, China) and were housed under ordinary conditions. The animals were maintained under a 12-h light/12-h dark cycle at stable temperature (22-26 °C) and humidity (50%-70%). They were given free access to food and water throughout the study period.

Extraction and characterization of exosomes derived from hUC-MSCs

hUC-MSCs were purchased from Guangxi TaiMeiRenSheng Biotechnology Co. Ltd. Fourth-passage cells at logarithmic phase were inoculated in T175 air-permeable cell culture flasks with a dedicated medium (HUXUC-90011, Cyagen). The cells were cultured at 37 °C in an incubator containing 5% CO_2. When the adherent cells reached a confluence of 80%-90%, the used cell medium was discarded and replaced with a serum-free medium. After 48 h, cells were centrifuged and cell supernatants were collected. Exosomes in the cell supernatants were extracted by ultracentrifugation. Impurities in the cell supernatants were removed by centrifugation at 300 × *g* for 10 min, followed by the removal of dead cells by centrifugation at 2000 × *g* for 20 min; then, cell debris was removed by centrifugation at 10000 × *g* for 30 min. Subsequently, cell supernatants were filtered using a 0.22 μM membrane filter and centrifuged in an ultracentrifuge (Beckman, America) for 120 min at 120000 × *g*, and the supernatants were discarded. The precipitated exosomes were re-suspended in phosphate buffered saline (PBS) and centrifuged again for 120 min at 120000 × *g*, and the exosomes precipitate were finally re-suspended in filtered PBS. All centrifugations were performed at 4 °C.

Exosomes were identified using a nanoparticle tracking analyzer (ZetaView, Particle Metrix, Germany), which was used to measure their concentration and particle size. A transmission electron microscope (HT-7700, Hitachi High-tech Company) was used to observe the shape and size of exosomes. Western blot was used to detect the surface marker proteins, CD9, Tsg101, and Calnexin, in exosomes. The protein concentration of hUC-MSCs-derived exosomes was determined using a BCA protein quantitation kit (Zoman, Biotechnology, ZD301). After adding the required proportion of loading buffer, the sample was heated at 95 °C for protein denaturation. Protein from each sample was separated on a sodium dodecyl sulfate-polyacrylamide gel and then transferred to polyvinylidene fluoride membranes. After blocking with 5% skim milk for 2 h, the membranes were incubated overnight with anti-CD9 (20597-1-AP, Proteintech), anti-Tsg101 (28283-1-AP, Proteintech), and anti-Calnexin (10427-2-AP, Proteintech) antibodies. Subsequently, the secondary antibody (SA00001-2, Proteintech) was added, followed by incubation for 1.5 h. Band visualization was achieved using a chemiluminescence kit (P0018FM, Beyotime, China) and observed on a chemiluminescent imaging system (MiniChemi 610, Sagecreation, China).

Characterization of gelatin sponge loaded with hUC-MSCs derived-exosomes

An absorbable gelatin sponge was purchased from Jiangxi Xiangen Medical Technology Development Co., Ltd. It was sliced into appropriate sizes, and immersed in the exosome solution mixed with trehalose, to ensure that the gelatin sponge fully absorbed the exosomes. Subsequently, the loaded gelatin sponge was freeze-dried and characterized *via* scanning electron microscopy.

Cell viability assay

The effect of the hUC-MSCs-derived exosomes on mouse epithelioid fibroblasts (L929) was evaluated using the CCK-8 assay. Briefly, L929 cells were inoculated into 96-well plates and divided into control, sponge extract, and exosome groups. The cell density was adjusted to 10000 cells/well and then incubated at 37 °C in a 5% CO_2 incubator for 12 h. Subsequently, the medium in the exosome group was adjusted to ensure that each well contained 6 × 10^6 particles of exosomes and then incubated at 37 °C under 5% CO_2 for a further 6 h. After 6 h, 10 μL of CCK-8 reagent was added to all groups, followed by incubation in the dark for 1 h. Finally, the absorbance of each well was measured at 450 nm using a microplate reader.

Hemolysis assay

Briefly, 5 mL of fresh blood from New Zealand rabbits was stirred in one direction with a glass rod, followed by fibrin removal; then, 20 mL of normal saline was added. The mixture was mixed well and centrifuged at 2000 rpm for 10 min. The supernatant was discarded, normal saline was added, and the process was repeated 3-4 times until the supernatant was clear. Finally, the supernatant was discarded, and 1 mL of fresh blood was added to 49 mL of normal saline to obtain a 2% rabbit red blood cell suspension for subsequent use. The assay was divided into negative control, positive control,

sponge, and exosome-loaded sponge groups. Subsequently, 500 μL of the 2% rabbit red blood cell suspension was added to each group, and an equal volume of liquid was added (normal saline was added to the negative control group, and Triton X-100 with a mass fraction of 0.5% was added to the positive control group. Gelatin sponge extract at a concentration of 10 mg/mL was added to the sponge group, and gelatin sponge extract with 1×10^9 exosomes was added to the exosome-loaded sponge group). Then, the solutions were mixed evenly and incubated at 37 °C for 3 h. The samples were then centrifuged at 3000 rpm for 3 min. The optical density (OD) of the supernatant was measured at a wavelength of 545 nm, and the hemolysis rate was calculated by photography. The hemolysis rate was calculated as $(OD_{sam} - OD_{neg})/(OD_{pos} - OD_{neg}) \times 100\%$ (1)[13].

Skin irritation test

The skin irritation test was performed using three New Zealand rabbits. The hair on their backs was carefully removed. Four specific areas on their skin were identified and treated with different fluids. They were blank group without any articles, NaCl group with 0.9%NaCl solution, sponge group with 10 mg/mL sponge extract, and exosome group with 5×10^8 exosomes solution. The application was repeated every 24 h until absorption was complete. The rabbits were closely monitored to assess any changes in their skin condition, such as redness, swelling, inflammation, or other related symptoms. After 72 h, skin samples were harvested from treated sites for histopathological examination to observe any signs of inflammation in the skin tissue.

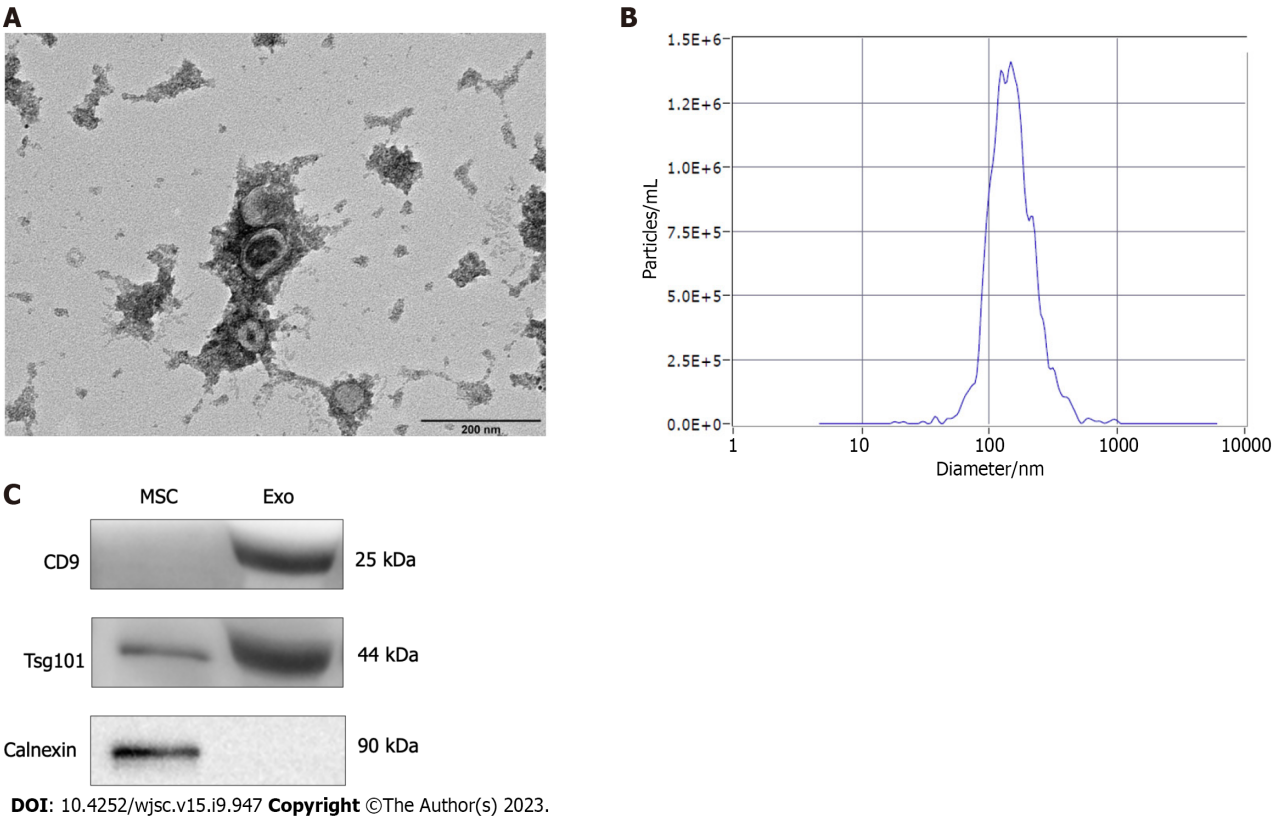
Histocompatibility assay

Eighteen male Sprague-Dawley (SD) rats were divided into blank control, sponge, and exosome-loaded sponge groups. After anesthesia with 10% chloral hydrate, the hair on their back was removed, the subcutaneous bags were excised, and 1 cm × 1 cm × 0.5 cm of either gelatin sponges or gelatin sponges loaded with exosomes were implanted into them, while the blank control group was not implanted with any gelatin sponge. The adjacent skin was collected for pathological analysis on day 7 and 14, respectively, to evaluate the *in vivo* biocompatibility of the gelatin sponges.

Whole blood coagulation index test

The gelatin sponges were cut into 1 cm × 1 cm × 0.5 cm sections, and preheated in an oven at 37 °C for 5 min. In the sponge and exosome groups, the gelatin sponges were infiltrated with 100 μL of normal saline and 100 μL of exosome solution containing 5×10^8 exosomes, respectively. Next, 100 μL of rat whole blood was added to each gelatin sponge in both groups for adequate absorption, followed by 10 μL of 0.2 M calcium chloride solution, and incubated at 37 °C for 15 min. Subsequently, 25 mL of deionized water was used to rinse blood from the gelatin sponge surface without coagulation. Finally, the absorbance (Abs1) of the washed liquid was measured at 540 nm by using a microplate reader. For the blank control (Abs0), 100 μL of whole blood was added to 25 mL of deionized water, and the blood coagulation index (BCI) was calculated using the formula: $BCI\ (\%) = Abs1/Abs0 \times 100\%$ (2).

Hemostatic assay using rat liver defect hemostasis model



The hemostatic capacity of the exosome-loaded gelatin sponge was evaluated using a rat liver defect hemostasis model [14]. Twelve SD rats were divided into sponge and exosome-loaded sponge groups (n = 6 rats/group), with an equal distribution of male and female rats. After anesthesia induction with 10% chloral hydrate, an abdominal incision was made to expose the liver, and the tissue fluid around the liver was carefully removed using a dry cotton ball to prevent inaccurate blood weight measurements. The liver was placed on a pre-weighed filter paper, and a 0.5 cm long and 0.2 cm deep wound was created on the liver using a scalpel. The gelatin sponge loaded with exosomes was immediately placed at the bleeding site and bleeding was observed. After the bleeding stopped completely, the bleeding time was recorded, and the blood-absorbed filter paper was weighed. The weight difference between the front and rear of the filter paper was considered as the weight of blood loss from the rat liver.

Effect of exosomes-loaded gelatin sponge on healing of skin full-thickness defect model

Eighteen male SD rats (220-280 g) were randomly divided into control, sponge, and exosome-loaded sponge groups. After anesthesia induction with 10% chloral hydrate, the hair on the back of rats was removed, and a full-thickness skin defect wound (approximately 1.5 cm × 1.5 cm) was created on their backs. Photographs were taken to record the original area, and the wound was covered with either a gelatin sponge or an exosome-loaded gelatin sponge, and wrapped with a transparent dressing; the control group received only a transparent dressing. On day 7 and 14 post the procedure, the gauze was opened to observe and record wound healing. All wounds were photographed, the area was analyzed using Image J software (National Institutes of Health, Bethesda, MD), and skin samples around the wounds were collected and fixed with 4% paraformaldehyde for pathological analysis.

Masson staining and immunohistochemistry

Masson's trichrome staining was used to determine collagen content and wound maturity. Image J software was used to analyze the areas of interest. The collagen content was quantified. Ki67 was used to evaluate local whole-cell proliferation and CD31 staining was used to evaluate angiogenesis. Sections were incubated with antibodies against Ki67 (1:600, #AF0198, Affinity) or CD31 (1:1000, Cat No.28083-1-AP, Proteintech). Subsequently, the secondary antibody was added (2118D1104, Beijing Zhongshan Jinqiao Biotechnology Co., Ltd.). Six randomly selected areas were imaged using an inverted microscope for each specimen, and the number of Ki67- and CD31- positive cells/positive blood vessels was detected using image J software.

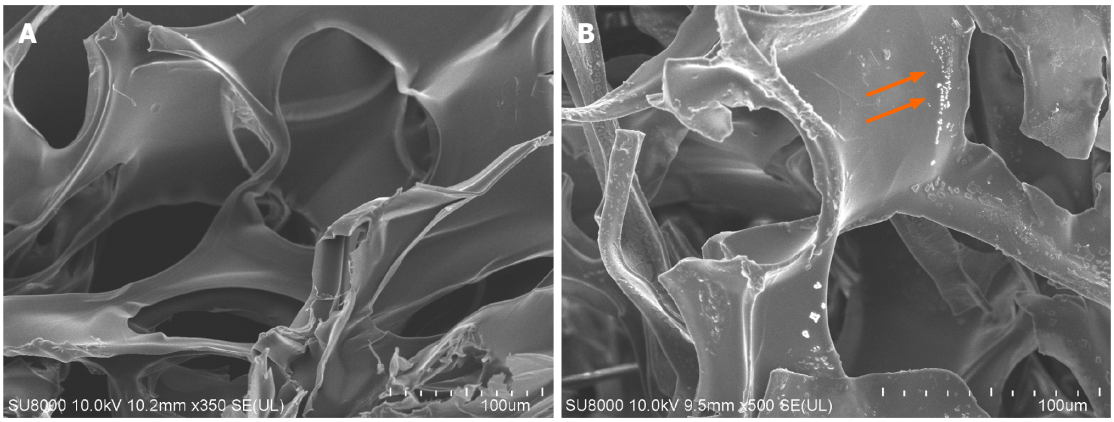
Figure 1 Characterization of human umbilical cord mesenchymal stem cell-derived exosomes. A: Morphology of the exosomes assessed by transmission electron microscopy. Scale bar = 200 nm; B: Grain size of the exosomes; C: Surface protein markers of exosomes. MSC: Mesenchymal stem cell; Exo: Exosome.

Statistical analysis

SPSS 26.0 (IBM Corp., Armonk, NY, United States) and GraphPad Prism 8.0 (GraphPad Software Inc.; San Diego, CA, United States) were used for statistical analyses. Paired or unpaired *t*-tests were used for comparisons between two groups, and one-way analysis of variance (ANOVA) was used for comparisons among three or more groups. $P < 0.05$ was considered statistically significant.

RESULTS

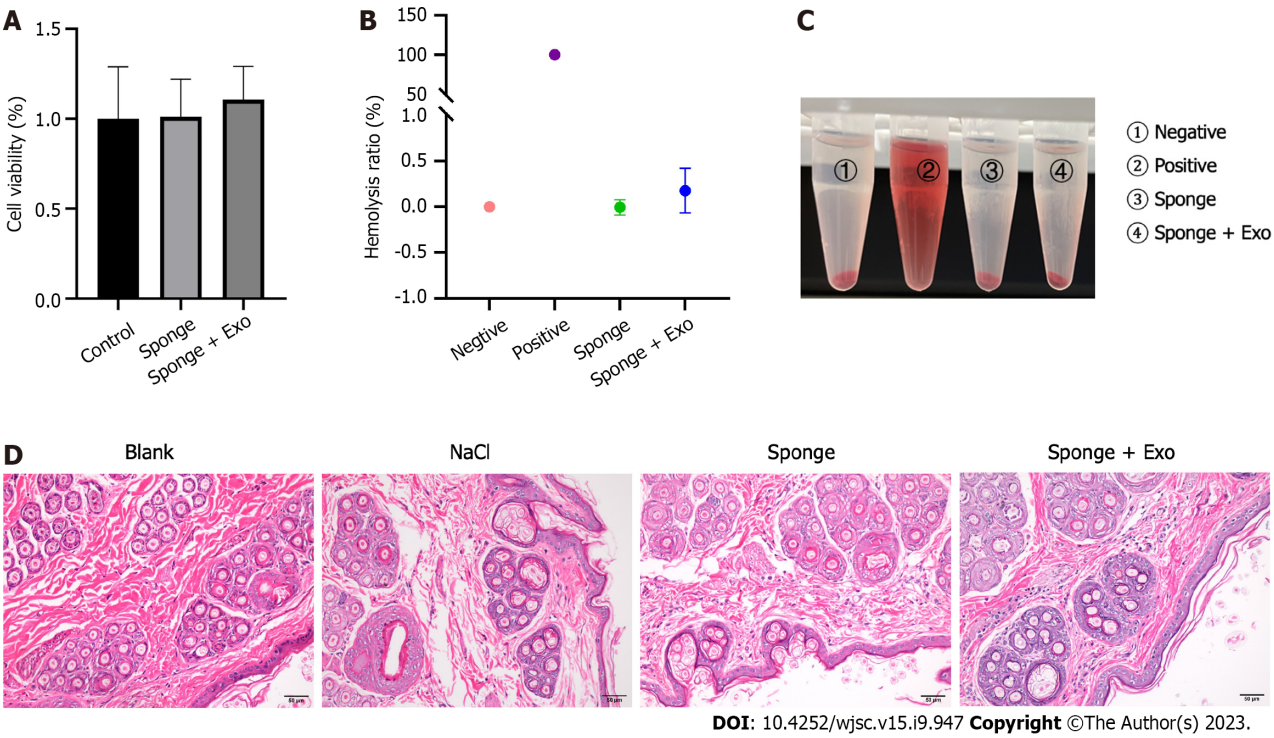
Identification of exosomes



We successfully isolated exosomes from hUC-MSCs by ultracentrifugation. After successful separation, the morphology of the exosomes was observed by using TEM, and a typical cup-shaped structure was observed (Figure 1A). The exosome concentration and particle size were measured using a nano-particle size analyzer. The average exosome particle size was 144.7 nm, consistent with the particle size of exosomes (30-150 nm) (Figure 1B). Western blot results showed that the extracted exosomes successfully expressed the surface marker proteins CD9 and Tsg101, but not Calnexin (Figure 1C).

Characterization of gelatin sponge loaded with exosomes

The exosomes on the gelatin sponge were detected *via* scanning electron microscopy. The gelatin sponge with exosomes was coarser than the sponge without exosomes, and exosome particles could be observed (Figures 2A and B).



Cytotoxicity and biocompatibility of gelatin sponge loaded with exosomes

The gelatin sponge loaded with exosomes did not induce significant toxicity toward L929 cells as the cells remained viable following exposure to them (Figure 3A). Moreover, the hemolytic assay showed that no hemolysis was observed with the naked eye using the gelatin sponge loaded with exosomes (Figure 3C). Measuring the OD value of the solution and calculating the hemolysis rate, we found that the hemolysis rates of the gelatin sponge and exosome-loaded gelatin sponge in whole blood were -0.01% and 0.18%, respectively, which were within the permissible range for biological materials (less than 5%), indicating that the exosome-loaded gelatin sponge was safe for use (Figure 3B). All experimental rabbits had an intact epidermis, with normal sebaceous glands, hair follicles, and hair structures; there were no notable pathological changes, such as inflammatory cell infiltration, tissue congestion, and edema (Figure 3D).

A: Cell viability of gelatin sponge loaded with exosomes; B and C: Hemolysis ratio of gelatin sponge loaded with exosomes; D: Representative diagram of pathological condition of rabbit skin after stimulation with exosome and sponge extract. Scale bar = 50 μm. Exo: Exosome.

To investigate the *in vivo* biocompatibility of gelatin sponge loaded with exosomes, we implanted the gelatin sponge into the dorsal subcutaneous space of SD rats, and observed the condition of the implant on day 7 and day 14 (Figures 4A and B). A portion of the gelatin sponge was retained in the body on day 7 and day 14; however, the gelatin sponge on day 14 was obviously smaller than that on day 7, indicating that the gelatin sponge could be degraded in the body. Adjacent skin tissue samples were collected for pathological analysis. After 7 and 14 d of implantation, there was no obvious inflammatory response around the tissue, and no obvious tissue fibrosis or necrosis was observed (Figure 4C), indicating that the gelatin sponge loaded with exosomes showed good biocompatibility.

Hemostatic effect of gelatin sponge loaded with exosomes

We evaluated the clotting ability of gelatin sponge and gelatin sponge loaded with exosomes. Our findings showed that the BCI values of the gelatin sponge and exosome-loaded gelatin sponge groups were 45.63% and 31.47%, respectively, indicating that both groups had significant clotting ability, and the clotting ability of the exosome-loaded gelatin sponge was significantly higher than that of the gelatin sponge group (Figure 5A).

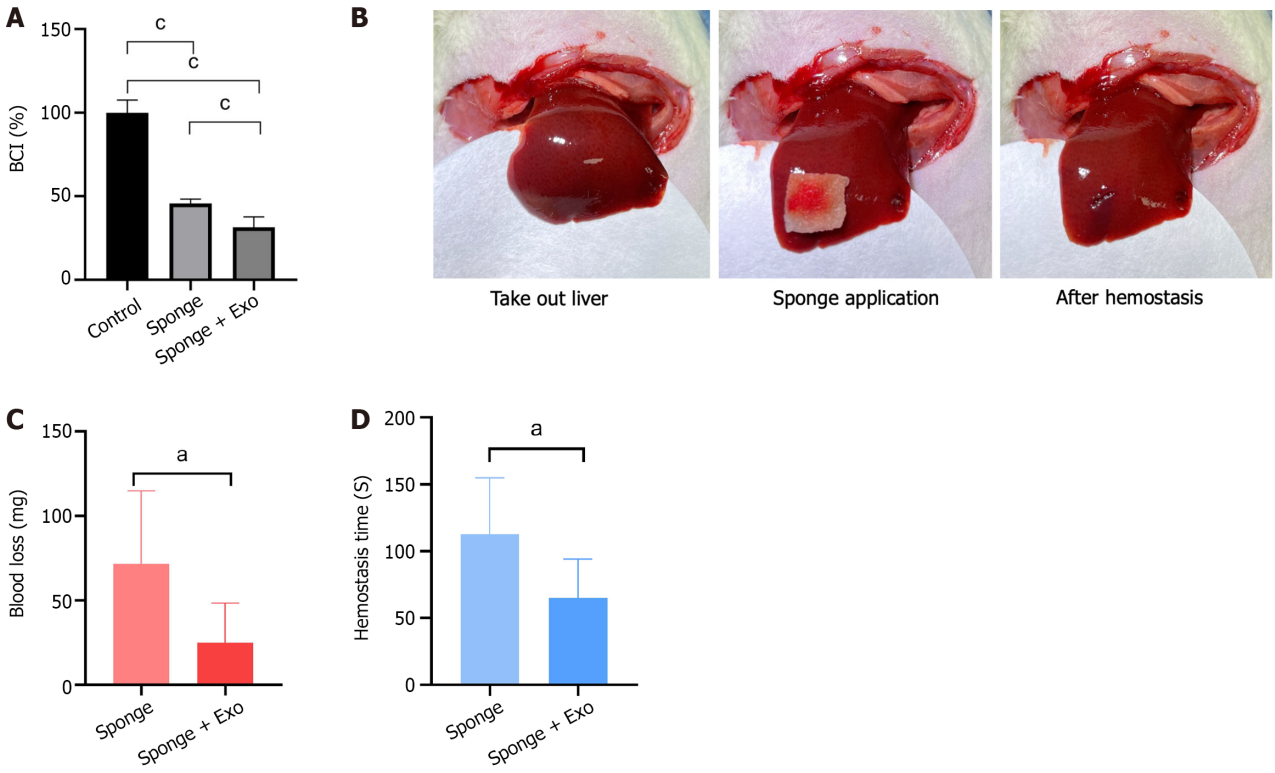
Figure 4 Biocompatibility of gelatin sponge loaded with exosomes. A and B: The size of the gelatin sponge remaining on day 7 and day 14; C: Hematoxylin and eosin staining of the adjacent skin tissues in the dorsal subcutaneous space of SD rats after 7 and 14 d of implantation. Scale bar = 100 μm. Exo: Exosome.



After establishing a liver defect model, we covered the wound with a gelatin sponge and recorded blood loss and hemostasis time. The blood loss and hemostasis time of the gelatin sponge group loaded with exosomes were significantly lower than those of the gelatin sponge group, indicating that the gelatin sponge loaded with exosomes had a better hemostatic effect than the conventional gelatin sponge (Figures 5B-D).

Effect of gelatin sponge loaded with exosomes in promoting wound healing

After establishing a rat full-thickness skin defect model, the wound was covered with a gelatin sponge, and the gauze was opened on day 7 and day 14 post the procedure to observe and record the wound healing status. The wound size of all groups decreased with time. Moreover, the wound size of the gelatin sponge group loaded with exosomes was smaller than that of the other two groups, indicating that the gelatin sponge loaded with exosomes promoted wound healing better than the conventional gelatin sponge (Figures 6A and B). Histopathological results showed that on day 14, the gelatin sponge loaded with exosomes group demonstrated better regeneration of hair follicles and sebaceous glands than the other two groups (Figure 6C).

Masson's trichrome staining was performed on the skin adjacent to the wound to evaluate the formation and distribution of collagen, which is important for promoting wound healing. Microscopic observations showed that collagen fibers in the skin of all three groups were relatively few on day 7. However, on day 14, the collagen fibers in the skin of the three groups gradually increased along with gradual healing of the wound (Figure 7A). Statistical analysis showed that the collagen fibers in the exosome-loaded gelatin sponge group were significantly higher than those in the other two groups on day 14; on day 7, the collagen fibers in the gelatin sponge and exosome-loaded gelatin sponge groups were significantly higher than those in the control group (Figure 7B). These findings suggested that the exosome-loaded gelatin sponge promoted wound healing by promoting collagen fiber synthesis.

To explore the possible mechanism of action of gelatin sponges loaded with exosomes, we employed immunohistochemical techniques to evaluate angiogenesis and cell proliferation in the granulation tissue. To evaluate angiogenesis, we stained the skin near the wound for CD31. On day 7 and day 14, the number of CD31-positive blood vessels in the exosome-loaded gelatin sponge group was significantly higher than that in the control group; on day 14, this number was significantly higher than that in the gelatin sponge group (Figures 7C and D). Subsequently, we detected the proliferation of whole cells of granulation tissue in the skin near the wound and found that the proportion of Ki67-positive cells in the exosome-loaded gelatin sponge group was significantly higher than that in the control and gelatin sponge groups on day 7 and day 14. However, there was no statistically significant difference in the proportion of Ki67-positive cells between the gelatin sponge and control groups (Figures 7E and F). These results indicated that the gelatin sponge loaded with exosomes could promote cell proliferation and angiogenesis, thereby accelerating wound healing.

DISCUSSION

Wound healing presents an important challenge for both clinicians and patients. Poor wound healing can negatively impact the patient's quality of life and exacerbate pain, stress, and depression[15,16]. Therefore, methods that effectively promote wound healing are particularly important. Several studies have demonstrated that MSCs accelerate wound closure by promoting skin cell migration, angiogenesis, epithelization, and granulation tissue formation. However, the clinical application of MSCs faces ethical issues, and there is a lack of long-term follow-up evidence regarding their safety. Therefore, alternative cell-free therapies are required. With the emergence of the paracrine hypothesis, the therapeutic applications of exosomes have become more extensive. Exosomes exhibit functions similar to MSCs[17]. Given their immunogenicity, compared with that of MSCs, exosomes can be considered a good alternative[18]. Recently, an increasing number of studies have shown that stem cell-derived exosomes contain mRNA, microRNAs, growth factors, and various other proteins, and potentially participate in processes such as hemostasis, angiogenesis, and wound healing[19,20]. For example, exosomes derived from hUC-MSCs containing miR-21, miR-23a, miR-125b, and miR-145 inhibit fibroblast proliferation and reduce scar formation during wound healing[21].

In the current study, we proposed a new method for loading exosomes into gelatin sponges to achieve wound healing. Our analyses showed that exosome-loaded gelatin sponge was safe and reliable for use. *In vivo* and *in vitro* experiments showed that exosome-loaded gelatin sponge exhibited a good hemostatic effect and promoted the formation of wound granulation tissue, collagen deposition, and angiogenesis, thereby promoting wound healing. Although several studies have shown that exosomes are well-tolerated in animal models, their clinical safety needs to be verified. Considering the goal of exosome-loaded gelatin sponges for clinical application, the safety of exosome-loaded gelatin sponges was verified in this study. We confirmed that the exosome-loaded gelatin sponge was safe for use, as determined by hemolysis, skin irritation, and histocompatibility experiments, consistent with the results of Sun *et al*[22]. These findings provide further evidence for the clinical application of exosomes.

Healing of skin injuries is a complex process that mainly includes four stages: Hemostasis, inflammation, proliferation, and remodeling[23]. The first stage involves hemostasis and clot formation to prevent blood loss. The second stage is the inflammatory stage, which includes coagulation, phagocytosis, removal of foreign bodies, and recruitment of growth factors and anti-inflammatory cells to injury site. The third stage involves proliferation, including fibrous proliferation, angiogenesis, and cell migration. Finally, fibroblasts continue to secrete collagen during the remodeling phase[24,25]. Type I collagen replaces type III collagen at the wound site. Subsequently, scar formation occurs *via* apoptosis.

In this study, we conducted *in vitro* and *in vivo* experiments to verify the potential role of a gelatin sponge loaded with exosomes in coagulation and hemostasis. We found that the coagulation index of the gelatin sponge loaded with exosomes was significantly lower than that of the control group and the gelatin sponge group, thereby suggesting that the gelatin sponge loaded with exosomes had significant coagulation ability; this finding was also confirmed in the liver

injury hemostasis experiment, where the gelatin sponge group loaded with exosomes reduced bleeding in rats and shortened the bleeding time. These data proved that the gelatin sponge loaded with exosomes afforded a better hemostatic effect than the conventional gelatin sponge, and had a significant effect in promoting wound healing during this stage of hemostasis.

Angiogenesis is essential for wound repair. Blood vessels provide progenitor cells, oxygen, and nutrients to maintain proliferation and remodeling of the wound site[26]. CD31 is an endothelial cell marker demonstrating the degree of tissue vascularization. In the current study, we evaluated angiogenesis by immunohistochemical staining for CD31 in the skin adjacent to the wound. The results showed that the number of CD31-positive blood vessels in the exosome-loaded gelatin sponge group was significantly higher than that in the control and gelatin sponge groups, indicating that the exosome-loaded gelatin sponge had a better angiogenic effect than the conventional gelatin sponge. This may be related to the provascular effects of exosomes. Many studies have shown that exosomes participate in angiogenesis signaling pathways and affect the occurrence, development, and maturation of blood vessels[27]. Zhang *et al*[28] have extracted exosomes from induced pluripotent stem cells and studied their effects on the proliferation, migration, and angiogenesis of hUC blood venous endothelial cells. They found that in a rat model of full-thickness skin defects, exosomes could promote not only angiogenesis at the wound site but also the maturation of blood vessels[28]. Fat-derived exosomes can also be ingested by the vascular endothelium to promote blood vessel formation *in vivo* and *in vitro*[29].

Masson's trichrome staining is a classical technique used to distinguish collagen and muscle fibers. In the current study, we performed Masson's trichrome staining on the skin near the wounds of rats. We found that the collagen fibers produced in the exosome-loaded gelatin sponge group were significantly higher than those in the gelatin sponge and control groups at the end of the observation period. This indicates that the exosome-loaded gelatin sponge could promote the formation of collagen fibers. This finding is consistent with that of Kim *et al*[30], who employed exosomes to directly treat human skin tissue and found that exosomes can facilitate the migration of fibroblasts and nearby collagen synthesis, as well as promote the synthesis of collagen and elastin in human skin tissue. Ki67 is a marker of cell proliferation, and, in general, angiogenesis begins with endothelial cell proliferation, followed by their isolation, migration, adhesion, and differentiation from adjacent tissues[31]. Cell proliferation and migration are the two key steps in angiogenesis. In this study, we detected the proliferation of integral cells of granulation tissue in the skin near the wound and found that the proportion of Ki67-positive cells in the exosome-loaded gelatin sponge group was significantly higher than that in the

control and gelatin sponge groups. This finding was consistent with the results reported by Wang *et al*[9], who found that in diabetic rats, the expression of the Ki67 in the FEP@exo group was significantly higher than that in the FEP and control groups. These observations may be related to the promotion of cell proliferation. Moreover, the application of exosomes derived from hUC-MSCs has been explored in a rat skin burn model, revealing that exosomes could dose-dependently promote fibroblast proliferation[6,32].

In summary, using an exosome-loaded gelatin sponge for wound healing could be safe and reliable and promote wound healing by promoting cell proliferation, collagen fiber formation, and blood vessel formation.

CONCLUSION

In conclusion, our study has proposed a novel method that uses hUC-MSC-derived exosomes loaded onto gelatin sponges for wound healing, which afforded good hemostatic and wound healing-promoting effects. The exosome-loaded gelatin sponge is safe and could provide new avenues for the clinical application of exosomes. Gelatin sponges are a common hemostatic material used in clinical practice. Moreover, they are inexpensive and readily available. Therefore, combining exosomes and gelatin sponges has strong clinical adaptability and is conducive to the clinical transformation and application of exosomes.

ARTICLE HIGHLIGHTS

Research background

Hemostasis and wound healing are one of the common problems in clinics which need to be paid attention to. Gelatin sponge is often used as a hemostatic material in clinics. Exosomes have been proved to play an important role in wound repair. Therefore, it is worth studying whether the combination of exosomes derived from human umbilical cord mesenchymal stem cells (hUC-MSCs) and a gelatin sponge could promote hemostasis and wound healing more efficiently.

Research motivation

Poor wound healing would contribute a negative impact on patients' quality of life and aggravate pain, stress and depression, so it is of great significance to find ways to effectively promote wound healing.

Research objectives

The present study aimed to investigate the hemostatic and wound healing efficacy of a gelatin sponge loaded with hUC-MSCs-derived exosomes.

Research methods

After the exosomes were extracted and characterized by ultracentrifugation, we loaded the exosomes on a gelatin sponge. Then, *in vitro* and *in vivo* experiments, including cell viability assay, hemolysis assay, skin irritation test, and histocompatibility assay were performed to verify the safety of the exosome-loaded gelatin sponge. Subsequently, whole blood coagulation index test, hemostatic assay using a rat liver defect hemostasis model, and full-thickness skin defect healing promoting test were performed to verify the effects of the exosome-loaded gelatin sponge in hemostasis and wound healing.

Research results

We successfully extracted exosomes from hUC-MSCs. The safety experiments showed that the gelatin sponge loaded with exosomes would not cause abnormal proliferation of L929 cells, hemolysis, or irritation to skin and tissues. In addition, the exosome-loaded gelatin sponge had a better hemostatic effect than the traditional gelatin sponge, which can promote the formation of collagen fibers and blood vessels around the wound and increase the proportion of Ki67-positive cells, thus promoting the wound healing.

Research conclusions

In a word, gelatin sponge loaded with hUC-MSCs-derived exosomes is safe. It is better than traditional gelatin sponge in stopping bleeding and promoting wound healing.

Research perspectives

The gelatin sponge loaded with exosomes derived from hUC-MSCs may be a potential material to stop bleeding and promote wound healing.

ABOUT COVER

Editorial Board Member of *World Journal of Stem Cells*, Hong-Cui Cao, MD, PhD, Professor, State Key Laboratory for the Diagnosis and Treatment of Infectious Diseases, The First Affiliated Hospital, Zhejiang University School of Medicine, Hangzhou 310003, Zhejiang Province, China. hccao@zju.edu.cn

AIMS AND SCOPE

The primary aim of *World Journal of Stem Cells* (*WJSC*, *World J Stem Cells*) is to provide scholars and readers from various fields of stem cells with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJSC* publishes articles reporting research results obtained in the field of stem cell biology and regenerative medicine, related to the wide range of stem cells including embryonic stem cells, germline stem cells, tissue-specific stem cells, adult stem cells, mesenchymal stromal cells, induced pluripotent stem cells, embryonal carcinoma stem cells, hemangioblasts, lymphoid progenitor cells, *etc*.

INDEXING/ABSTRACTING

The *WJSC* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Journal Citation Reports/Science Edition, PubMed, PubMed Central, Scopus, Biological Abstracts, BIOSIS Previews, Reference Citation Analysis, China National Knowledge Infrastructure, China Science and Technology Journal Database, and Superstar Journals Database. The 2023 Edition of Journal Citation Reports® cites the 2022 impact factor (IF) for *WJSC* as 4.1; IF without journal self cites: 3.9; 5-year IF: 4.5; Journal Citation Indicator: 0.53; Ranking: 15 among 29 journals in cell and tissue engineering; Quartile category: Q3; Ranking: 99 among 191 journals in cell biology; and Quartile category: Q3. The *WJSC*'s CiteScore for 2022 is 8.0 and Scopus CiteScore rank 2022: Histology is 9/57; Genetics is 68/325; Genetics (clinical) is 19/90; Molecular Biology is 119/380; Cell Biology is 95/274.

Abstract

Peripheral nerve injury (PNI) seriously affects people's quality of life. Stem cell therapy is considered a promising new option for the clinical treatment of PNI. Dental stem cells, particularly dental pulp stem cells (DPSCs), are adult pluripotent stem cells derived from the neuroectoderm. DPSCs have significant potential in the field of neural tissue engineering due to their numerous advantages, such as easy isolation, multidifferentiation potential, low immunogenicity, and low transplant rejection rate. DPSCs are extensively used in tissue engineering and regenerative medicine, including for the treatment of sciatic nerve injury, facial nerve injury, spinal cord injury, and other neurodegenerative diseases. This article reviews research related to DPSCs and their advantages in treating PNI, aiming to summarize the therapeutic potential of DPSCs for PNI and the underlying mechanisms and providing valuable guidance and a foundation for future research.

Key Words: Dental pulp stem cells; Peripheral nerve injury; Regenerative medicine; Neural regeneration; Schwann cells; Stem cells engineering

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: This article reviews the potential applications of dental pulp stem cells (DPSCs) and their derivatives in the field of nerve regeneration. First, this paper describes the current status of stem cell therapies for peripheral nerve injury (PNI) and discusses the advantages of DPSCs in this field. Then, the status of research on the neuroregenerative ability of DPSCs and their derivatives is reviewed. Finally, the potential of DPSCs in treating PNI and the underlying mechanism are summarized, with an aim to provide valuable guidance and a basis for future research.

INTRODUCTION

It has been reported that approximately 2.8% of trauma patients suffer from peripheral nerve injury (PNI), resulting in permanent disabilities[1]. PNI can lead to muscle function loss, sensory impairment, and painful neuropathy[2]. While autologous nerve transplantation is a standard treatment option, its drawbacks, such as the difficulty in obtaining donor nerves, the need for surgical procedures to acquire donor nerves, secondary deformities at the donor site, and potential mismatch issues, limit its widespread use[3,4]. With advancements in biomaterials and tissue regeneration, significant progress has been made in nerve regrowth techniques[5]. The restoration of function after injury is of paramount importance, and experiments on stem cells have shown that they can accelerate nerve regeneration[6]. Compared to other types of stem cells, dental pulp stem cells (DPSCs) are more advantageous because they can be obtained *via* noninvasive operation, can be preserved at low temperature long-term, are simple to use, are associated with few ethical problems, and have low immunogenicity, so they are ideal materials for tissue engineering[7]. Human DPSCs (hDPSCs) exhibit remarkable self-renewal, multilineage differentiation, and cloning capabilities[8]. Schwann cells play a critical role in nerve regeneration, and stem cells with the same embryonic origin as Schwann cells are suitable tools for PNI treatment. DPSCs originate from neural crest cells[9] and share homology with Schwann cells[10]. Therefore, due to DPSCs' unique neural differentiation and nerve regeneration abilities, DPSCs-derived Schwann cells are viable tools for achieving nerve regeneration after PNI *in vitro*[11]. To keep abreast of the latest developments in this field, articles published in PubMed between 2010 and 2023 were screened using the following search terms: "peripheral nerve", "tooth-derived stem cells", "exosomes", and "dental stem cells". The primary aim of this review is to provide information on the recent applications of DPSCs in PNI treatment, with a specific focus on both cellular therapies and noncellular therapies involving DPSCs. Additionally, the review discusses the therapeutic effects of DPSCs and their potential future applications in treating PNI.

PNI

PNI is a prevalent clinical condition often resulting in long-term functional impairments. The effectiveness of surgical treatments is frequently unsatisfactory[12], and the restoration of nerve function is often not optimal[13]. Peripheral nerve regeneration is a complex process involving Wallerian degeneration, axon sprouting, and myelin regeneration[14]. While nerves may regenerate over relatively short distances after mild nerve injury, the outcomes of nerve regeneration are often unsatisfactory. In cases of peripheral nerve amputation, a series of molecular and cellular changes occur, known as Waller's degeneration[15,16]. Subsequently, monocytes and macrophages migrate to the nerve stump to clear axon fragments and myelin sheaths at the damaged end, while the proliferation of Schwann cells results in the formation of longitudinal cell columns, known as Bungner bands[17,18]. According to the literature, various factors, such as scaffolds for axonal migration, supporting cells (including Schwann cells and macrophages), growth factors, and the extracellular matrix, play crucial roles in regeneration after PNI[2].

Schwann cells originate from neural crest cells[19] and play a crucial role in the regeneration of peripheral nerves, influenced by neurotrophic factors (NTFs) such as Krox-20, Oct-6, and Sox-10[18]. These cells play an instrumental role in nerve regeneration by selectively promoting axonal regrowth of both motor and sensory nerves[20-22]. After nerve injury, Schwann cells may undergo dedifferentiation, a process mainly regulated by the negative regulatory factor c-Jun. This dedifferentiation is vital because it can help nerve survival and facilitate axonal regeneration[23]. Researchers have explored the effect of transplanting Schwann cells isolated from peripheral nerves into rat sciatic nerve injury models and found that these cells promote the regeneration of nerve axons, proving the potential of autologous stem cell transplantation in treating PNI[24]. However, such regenerative strategies are associated with challenges, as collecting Schwann cells is difficult and their survival rate after transplantation is low[25]. In recent studies, DPSCs-derived conditioned medium (DPSCs-CM) was shown to promote the proliferation of Schwann cells and increase the production of myelin-associated proteins[26]. This may provide insight for the development of a new method for the treatment of peripheral nerve diseases.

STEM CELL THERAPY FOR PNI

Earlier studies have revealed that allogeneic stem cell transplantation has a favorable effect on nerve regeneration and thus warrants further investigation[27]. Acellular nerve allografts (ANAs) promote axon regeneration through Schwann cell proliferation[28]. However, the therapeutic efficacy of ANAs diminishes over time after nerve injury, likely due to the limitations of Schwann cell function in the host nerve. Therefore, there is an urgent need to explore alternative or more effective therapies for Schwann cell replacement.

An increasing number of studies have demonstrated the remarkable potential of stem cells in promoting neural regeneration. Adipose-derived stem cells have been shown to differentiate into Schwann-like cells and effectively promote nerve regeneration[29-31]. Additionally, Shimizu *et al*[32] reported that human bone marrow mesenchymal stem cells (MSCs) can serve as Schwann cell substitutes, making them a viable option for nerve regeneration applications. Furthermore, muscle-derived stem/progenitor cells have shown the ability to differentiate into myelinated Schwann cells *in vivo*, thereby promoting axonal regeneration[33]. Al-Zer and Kalbouneh[11] successfully induced the differentiation of DPSCs into Schwann cells by utilizing retinoic acid, mercaptoethanol, and neuromodulin β1. Among stem cell sources, dental stem cells have garnered significant attention due to their excellent nerve regeneration capabilities and ease of availability.

Recent studies have revealed that during tooth development, glial cells related to the peripheral nervous system produce a significant number of MSCs, including dental pulp cells and odontoblasts[34]. DPSCs, stem cells from human exfoliated deciduous teeth (SHEDs), periodontal ligament stem cells (PDLSCs), stem cells from the apical papilla, and dental follicle progenitor cells all fall under the category of dental stem cells[35]. These dental tissue-derived MSCs exhibit the ability of multidirectional differentiation and hold great potential in immunomodulation and tissue regeneration[36]. Moreover, MSCs derived from hair follicles, the dental pulp, and nipples show similar biological characteristics as those from the teeth of the same donor and display osteogenic, adipogenic, and chondrogenic differentiation capabilities[37].

Apical pulp-derived cells and coronal pulp cells have demonstrated the ability to differentiate into nerve cells *in vitro* and express markers associated with neural crest cells (p75, Snail, and Slug) as well as neural stem cell markers (Nestin and Musashi1)[38]. SHEDs can differentiate into many types of cells, including nerve cells[39]. Pereira *et al*[40] utilized polyglycolic acid tubes to induce SHEDs to differentiate into Schwann cells. Human PDLSCs have exhibited the ability to promote axonal regeneration after optic nerve injury, potentially through the secretion of brain-derived neurotrophic factor (BDNF)[41]. The ERK1/2 signaling pathway plays a role in the differentiation of PDLSCs into Schwann cells[42], thus making them a viable alternative source for autologous Schwann cells[43]. Ng *et al*[44] successfully induced adult PDLSCs to differentiate into retina-like cells with the biological characteristics of nerve cells. Dental embryonic stem cells have the potential to achieve nerve tissue regeneration due to their common origin with the nervous system[5,14], making them a promising source of stem cells for nerve tissue regeneration[45]. The neurological potential of DPSCs makes them a viable candidate cell type for the treatment of peripheral nerve diseases[46]. DPSCs can differentiate into neuron-like cells, and after 5 d of neuron differentiation, Tub3 is activated, accompanied by increased Nestin expression[47]. Insulin-like growth factor binding protein 5 promotes the formation of neurospheres by DPSCs. Angiogenic markers such as vascular endothelial-derived growth factor (VEGF), platelet derived growth factor subunit A, and angiopoietin-1 and neurogenic markers such as neural cell adhesion molecule, Nestin, βIII-tubulin, and tyrosine hydroxylase are upregulated in DPSCs, reflecting the vascular and neurogenic differentiation potential of DPSCs[48]. Additionally, DPSCs can secrete NTFs that support nerve cell function[49].

Compared with other stem cells, DPSCs have stronger multidifferentiation potential, self-renewal ability, and colony formation ability[8]. The Eph/ephrin interaction indicates that unlike that of other stem cells, the formation of DPSCs involves the neural crest[50,51]. Because of their spinal origin, DPSCs have the ability to differentiate into other spinal cord-related cells[52]. Unlike bone marrow MSCs (BM-MSCs), DPSCs are heterogeneous, and they also express markers of endothelial cells (vascular cell adhesion molecule 1 and MUC-18), smooth muscle (a-smooth muscle actin), bone (alkaline phosphatase, type I collagen, osteonectin, osteopontin, and osteocalcin), and fibroblasts (type III collagen and fibroblast growth factor 2)[39,53]. DPSCs express the neural precursor and glial cell markers nestin and glial fibrillary acidic protein (GFAP), which indicates that DPSCs are similar to BM-MSCs and have the potential to differentiate into neural cells[8]. Compared with BM-MSCs, DPSCs can more strongly inhibit the proliferation of PHA-stimulated T cells and exert immunosuppressive effects[54]. Compared with umbilical cord stem cells, the secretion of vascular endothelial growth factor-A and follistatin in DPSCs is more obvious, while umbilical cord stem cells tend to secrete vascular endothelial growth factor-C, which does not produce angiogenic effects. The levels of vascular endothelial growth factor-A and vascular endothelial growth factor-D secreted by DPSCs are higher than those secreted by BM-MSCs[55]. DPSCs can survive for a long time under extreme stress conditions[56]. DPSCs have the same immunomodulatory effect as BM-MSCs in the treatment of nervous system diseases. DPSCs are easier to obtain than other stem cells, have high multidifferentiation potential and a strong proliferation ability, and are not carcinogenic. They are a good substitute for stem cells in the treatment of PNI[5].

Moreover, compared with dental follicle- and papilla-derived stem cells, DPSCs have a stronger Na^+ current, indicating that they have a higher potential for neural differentiation[57]. Both DPSCs and BM-MSCs implanted in the vitreous body secrete nerve growth factor (NGF), BDNF, and neurotrophin 3 (NT-3), and the amount of NGF and BDNF secreted by DPSCs is significantly higher than that secreted by BMSCs, which support nerve survival and axonal regeneration[58]. Adipose tissue-derived stem cells also have the potential for nerve regeneration but mainly play an active role in stimulating endogenous stem cells by releasing NTFs[59]. Wang *et al*[60] successfully induced vascular endothelial cells and BM-MSCs to differentiate into neurons with tricyclodecane-9-yl xanthate. Cryopreserved DPSCs were also shown to be able to differentiate into cholinergic neurons by tricyclodecane-9-yl xanthate[61]. By comparing stem cells from

different sources, Isobe *et al*[62] found that BM-MSCs and synovial fluid-derived stem cells showed significant osteogenic effects. An increase in alkaline phosphatase and osteocalcin levels suggested that synovial fluid-derived stem cells had the highest cartilage formation ability. Reverse transcription-polymerase chain reaction showed increased expression of class III β-tubulin and microtubule-associated protein 2, suggesting that DPSCs and human deciduous tooth stem cells have the potential for neural regeneration. In addition, studies by Isobe *et al*[62] showed that DPSCs have stronger neural differentiation potential than pluripotent stem cells isolated from bone marrow and synovial fluid.

In light of these findings, DPSCs have emerged as excellent candidate stem cells for treating PNI, with stronger tissue regeneration potential than other types of stem cells (Figure 1). Consequently, the focus of this article will be on research progress related to the effectiveness of DPSCs in treating PNI.

EFFECT OF DPSCS IN THE TREATMENT OF PNI

Teeth originate from the cranial neural crest[63]. Chai *et al*[64] were the first to confirm the involvement of cranial neural crest cells in the formation of dental pulp cells. In recent years, there has been a growing interest in research on utilizing DPSCs for nerve repair[65]. Janebodin *et al*[52] demonstrated that DPSCs originate from spinal nerves and possess the potential to differentiate into tissues derived from other neural crest-derived structures. Gronthos *et al*[53] provided evidence that the dental pulp contains cells with the ability to form clones, proliferate, and regenerate tissue, classifying them as stem cells. The embryonic origin of DPSCs endows them with the potential to serve as stem cells for neural tissue engineering.

DPSCs have been shown to effectively promote axonal regeneration both *in vivo* and *in vitro*[66] (Tables 1 and 2). Typically, DPSCs exhibit several characteristics of pluripotent stem cells and display high proliferation rates, expressing CD44, CD90, and CD166[65]. Moreover, DPSCs express embryonic stem cell markers such as Oct-4, Nanog, SSEA-3, SSEA-4, TRA-1-60, and TRA-1-81, along with several other MSC markers[67]. DPSCs have the remarkable capability to differentiate into several stromal-derived cell types (Figure 2). These cell types include osteoblasts[68-72], neurons[73], adipogenic cells[69] chondrogenic cells[69,70], smooth and skeletal muscle cells[74], dental pulp cells[75], Schwann cells [76], pancreatic cell lineage cells[70,77], blood vessel cells[78], and hepatocytes[79,80]. These findings strongly support the potential of DPSCs to be applied for tissue engineering[7].

Subsequent studies have revealed that a large number of dental MSCs originate from glial cells associated with peripheral nerves[34]. Long-term cryopreserved DPSCs retain their potential to differentiate into cholinergic nerves, indicating their suitability for prolonged preservation[61], and they have demonstrated beneficial anti-inflammatory effects in nerve injury[81]. Paes *et al*[82] conducted a pioneering comparison between monolayer and spheroid cultures of hDPSCs, demonstrating that both exhibit promising nerve regeneration potential through different mechanisms. Furthermore, hDPSCs were found to be effective in treating diabetic polyneuropathy[83]. In a groundbreaking study, Omi *et al*[84] treated neuropathy in diabetic rats through DPSCs transplantation for the first time and observed nerve function recovery that was potentially attributed to basic fibroblast growth factor (bFGF), VEGF, NGF, and NT-3 secreted by DPSCs. As an effective therapeutic tool for treating PNI, DPSCs are anticipated to be widely used in clinical settings in the future. With the deepening of research (Figure 3), it has been confirmed that DPSCs can be used to treat PNI *via* many mechanisms.

CELL THERAPEUTIC ALTERNATIVE FOR DPSCS

DPSCs can differentiate into nerve-like cells, making them be of great significance in the field of nerve regeneration. Dental pulp MSCs exhibit strong expression of nerve and glial cell markers and can be induced to adopt a nerve-like morphology[5]. DPSCs can be induced to differentiate into cells that exhibit a neuronal morphology and express neuronal-specific markers, such as the immature neuron markers Nestin and PSA-NCAM, by a neural induction regimen *in vivo* and *in vitro*[85]. Moreover, DPSCs transplantation has been shown to promote macrophage polarization toward the anti-inflammatory M2 phenotype[86]. Saez *et al*[87] demonstrated that DPSCs can effectively promote peripheral nerve regeneration when used to treat unilateral nerve crush injury in rats.

The peripheral nerve transection model is widely utilized in the study of peripheral PNI, and DPSCs have demonstrated good nerve regeneration ability in this model[88]. Stocchero *et al*[89] transplanted dental pulp cells into Wistar rats with sciatic nerve defect and observed significant promotion of nerve regeneration during the first 2 wk. Combining dental pulp cells with biodegradable materials is a promising approach to avoid secondary surgery[90]. Additionally, Sasaki *et al*[91] embedded dental pulp cells in silicone tubes to repair facial nerve defects in rats, and the results indicated the formation of blood vessels and myelin sheath tissue by dental pulp cells. DPSCs have exhibited a robust capacity to promote nerve regeneration in peripheral nerve transection models, and optimizing material combination schemes to fully unleash DPSCs' potential in nerve regeneration remains a prominent research focus in this field.

As previously reported, DPSCs, being derived from the neural ridge, possess a strong ability to differentiate into neuronal lineages. Numerous studies have explored various methods to induce the neural differentiation of DPSCs, and these cells have been applied to treat PNI[92]. After neural differentiation induction, DPSCs generate neural progenitor cells, expressing the neural markers Nestin, TuJ-1, and GFAP[93]. Additionally, inner ear neurotrophins, such as BDNF and NT-3, along with glial cell-derived neurotrophic factor (GDNF), have been found to promote the differentiation of DPSCs into spiral ganglion neuron-like cells[94]. Notably, when Schwann cells differentiated from human DPSCs were

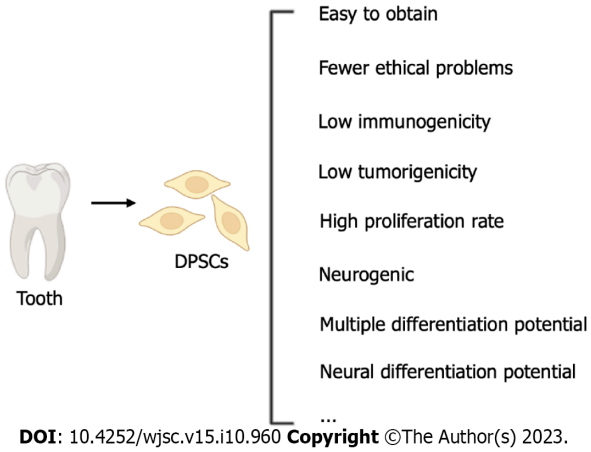
Table 1 Progress in application of dental pulp stem cells in treating models of peripheral nerve injury

Publication year	Cell source	Induction program	Pretransplantation procedure	Material(s)	Dose/concentration	Disease model	Experiment duration	Treatment effect	Ref.
2022	Human	DMEM + 10% (FBS + P/S)	3D culture	Fibrinogen, calcium chloride, and thrombin-like protein	3×10^5 cells	Avulsion of spinal motor roots in rats	12 wk	The transcription of TNF-α, IL-1β, IL-6, and IL-17 and the expression of anti-inflammatory cytokines (TGF-β, IL-4, IL-10, and IL-13) were increased; the animals in the reimplantation + 2D group showed the best functional recovery	[82]
2021	Human	α-MEM + 20% (FBS + P/S)	Collected and resuspended in GelMA-bFGF	10% GFD in a CSM tube	1×10^6 cells/mL	15 mm defect of the sciatic nerve in rats	12 wk	Cell based therapy repaired large gap defects in peripheral nerves; the differentiation of DPSCs into nerve cells and Schwann-like nerve cells and the formation of myelinated nerve fibers were observed	[98]
2021	Human	DMEM + 10% (FBS + P/S + NEAA)	NLCs differentiated from DPSCs	-	1×10^5 NLCs		12 wk	Two weeks after transplantation, approximately 75% of the transplanted cells differentiated into platelet-derived growth factor receptor alpha + OPCs expressing p75NTRd; transplantation promoted axon growth and improved nerve function	[145]
2021	Human	α-MEM + 15% FBS	Exosome collection	-	200 μg/100 μL	Mouse model of spinal cord injury	4 wk	Inhibited the ROS-MAPK-NFκB P65 signaling pathway to reduce M1 macrophage polarization, suppress the inflammatory response, and alleviate neurological damage	[121]
2020	Human	DMEM + 20% (FBS + P/S)	Preparation of scaffold-free cell sheets by coculture with FGF2	-	2×10^6 cells/cell sheet	Rat model of facial nerve crush injury	3 wk	Cell sheets promoted axonal regeneration and functional recovery through continuous delivery of neurotrophic factors such as BDNF and GDNF	[116]
2020	Human	α-MEM + 10% (FBS + P/S + NEAA)	Induction of DPSCs differentiation into N-DPSCs; induction of DPSCs differentiation into N-DPSCs	-	-	Rat model of sciatic nerve crush injury	1 mo	Both DPSCs and N-DPSCs promoted peripheral nerve repair through the expression of neurotrophic factors such as NGF, BDNF, and GDNF; the nerve repair effect of N-DPSCs was longer lasting	[146]
2019	Human (children)	DMEM + 15% (FBS+P/S)	-	-	5×10^5 cells in 4 μL DMEM	Unilateral facial nerve crush injury in rats	6 wk	Immature DPSCs promoted nerve regeneration and the formation of new myelin; the expression of nerve growth factor and anti-inflammatory cytokines (IL-6 and IL-10) increased significantly 7 d after treatment, and there was a decrease in the levels of soluble proinflammatory factors such as IL-2, IL-4, TNF-α, and IFN-γ	[87]

2019	Human	-	Induction of DPSCs differentiation into nerve cells	A PDO-based cell carrier	7.5×10^5 cells	6 mm defect of the sciatic nerve in rats	12 wk	Multiperforated PDO tubes were effective biomaterial carriers; delivery of DPSCs impacted the inflammatory environment and promoted nerve regeneration and functional recovery	[89]
2018	Human	-	Isolation of STRO-1+/c-Kit+/CD34+ cells	Collagen scaffolds	5×10^5 cells/animal	6 mm defect of the sciatic nerve in rats	4 wk	Nerve fiber regeneration and myelination and many myelinated axons were observed; DPSCs grafted into the sciatic nerve defect expressed the typical Schwann cell marker S100B and were positive for human NeuN	[12]
2018	Human	ADMEM + 10% FBS	Differentiated into neuronal cells (DF-DPSCs)	A conduit made from a Lyoplant membrane	-	7-8 mm defect of the sciatic nerve in rats	12 wk	DPSCs relieved neuropathic pain and inhibited inflammation in rats earlier than DF-DPSCs; at 12 wk after the operation, the expression of pAMPK/SIRT1 in DF-DPSCs and DPSCs increased, the expression of proinflammatory cytokines decreased, and the expression of NFκB decreased	[81]
2018	Human	ADMEM + 10% (FBS + P/S)	Differentiation into cholinergic neurons by adding D609	Biodegradable tubule and fibrin glue	1×10^6 DF-chNs	5 mm defect of the sciatic nerve in rats	8 wk	Transplanted DF-chNs promoted motor nerve regeneration and axon growth and expressed nerve growth factor receptor (p75NGFR)	[61]
2018	Human	-	-	An absorbable hemostat filled with human DPCs containing 1% atelocollagen, fibronectin, and laminin	3×10^5 cells	Crush injury of the sciatic nerve in rats	2 wk	DPCs stimulated Schwann cell differentiation and promoted peripheral nerve regeneration	[114]
2017	Human	Standard: α-MEM + 10% (FBS + NEAA + P/S). Differentiation: Standard + forskolin + bFGF + PDGF-AA + HRG1-β	Differentiation into Schwann-like cells (d-hDPSCs)	NeuraWrap™ conduits	-	15 mm defect of the sciatic nerve in rats	8 wk	Growth of axons, myelinated nerve fibers, and blood vessels; DPSCs still exerted strong angiogenic effects after differentiating into Schwann-like cells	[102]
2017	Human	α-MEM + 15% (FBS + AA + P/S + NEAA)	-	Fibrin conduits	2×10^6/20 μL	10 mm defect of the sciatic nerve in rats	2 wk	Promoted nerve and axon regeneration; the transplanted cells expressed BDNF near the cell body, and the expression level of caspase-3 decreased	[45]
2017	Human	ADMEM + 10% FBS	Induction of DPSCs differentiation into nerve cells	Fibrin glue scaffold and collagen tubulation	1×10^6 cells	5 mm defect of the sciatic nerve in rats	12 wk	Both hDPSCs and DF-hDPSCs promoted nerve regeneration and functional recovery; they could directly differentiate into nerve cells or facilitate nerve cell differentiation	[99]
2015	Human	α-MEM + 10% (FBS +	Transfection with Olig2	-	2×10^5 cells	Mouse model of local	6 wk	Recovery of sciatic nerve function; DPSCs	[108]

		P/S/AmB)	gene *via* a tetracycline (Tet) inducible system			sciatic nerve demyelination		differentiated into oligodendrocyte progenitors, and specific markers of oligodendrocyte progenitors and oligodendrocytes were expressed	
2015	Human	DMEM + 10% FBS	G-CSF-induced stem cell mobilization (mobilized DPSCs and MDPSCs)	Collagen conduits	3.0×10^5 MDPSCs	5 mm defect of the sciatic nerve in rats	5 wk	MDPSCs secreted neurogenic/angiogenic factors and promoted peripheral nerve regeneration	[112]
2015	Human	Culture dishes containing essential medium (alpha modification) + 10% (FBS + P/S + amphotericin B)	Induction of DPSCs differentiation into OPCs by transfection with a plasmid containing the human Olig2 gene		2×10^5 cells	Sciatic nerve demyelination in mice	6 wk	DPSCs differentiated into OPCs, and transplantation promoted myelin sheath formation and peripheral nerve function recovery	[107]
2015	Human	DMEM + b-ME; DMEM + 10% (FBS + RA); DMEM + 10% (FBS + FSK + b-FGF + PDGF + HRG)	Differentiation of hDPSCs into Schwann-like cells	Cells combined with a pulsed electromagnetic field (PEMF)	1×10^6 cells/10 mL/rat	Crush injury of the peripheral nerve in rats	3 wk	Schwann-like cells derived from DPSCs exhibited the characteristics of glial cells, expressing CD104, S100, GFAP, laminin, and p75NTR; application of a PEMF promoted peripheral nerve regeneration after cell transplantation	[147]
2012	Human	DMEM + 10% FBS	-	-	1×10^6 cells	Rat spinal cord transection model	8 wk	DPSCs promoted axonal growth, differentiated into oligodendrocytes to treat spinal cord injury, and protected the nerve by inhibiting apoptosis and paracrine signaling	[105]
2018	Human	α-MEM + 10% (FBS + NEAA + P/S)	Application of fresh medium containing vitamin C cells reached approximately 80% confluence	-	-	Patients diagnosed with a traumatized permanent incisor	12 mo	HDPSCs transplantation promoted the regeneration of pulp tissue including neuronal tissue, and the neuron marker NeuN was expressed	[75]
	Human	PBS + P/S	Collection of hDPSCs aggregates	The root canals of human teeth	-	Immunocompromised mice	8 wk	Dental pulp tissue containing sensory nerves and blood vessels regenerated after HDPSCs transplantation	
	Human	α-MEM + 10% (FBS + NEAA + P/S)	-	-	3×10^5 cells	Rats injected into the dorsal root ganglion	2 mo	HDPSCs exhibited the morphology of neurons and expressed TRPV1 and TRPM8	
	Pig	PBS + P/S	Collection of hDPSCs aggregates	-	-	Permanent incisors of young female minipigs	3 mo	Pig DPSCs resulted in the 3D regeneration of dental pulp with neural function	
2015	Pig	Culture medium + 10% (FBS + L-AA -2-P + P/S)	-	Fibrin membrane	-	Porcine intercostal nerve transection model	6 mo	DPSCs alleviated nerve injury and express NSE; neuroelectrophysiological evaluation showed that neurological function was restored	[88]
2020	Rat	α-MEM + 20% FBS	-	-	1×10^6 cells/rat	Diabetic rats	4 wk	Multiple factors secreted by DPSCs increased the nerve conduction velocity and blood flow to nerves	[118]

2019	Rat	α-MEM + glucose + 20% FBS	Collection of DPSCs-CM	-	1 mL/rat	Diabetic rats	4 wk	DPSCs-CM ameliorated peripheral neuropathy by exerting neuroprotective, angiogenic, and anti-inflammatory effects	[132]
2017	Rat	α-MEM + 20% FBS	-	-	1×10^6 cells	Streptozotocin-induced diabetes rat model	4 wk	Sensory disturbance was alleviated, the thickness and area of the myelin sheath increased, the transplanted DPSCs secreted multiple factors such as angiogenic factors, neurotrophic factors, and immunosuppressive factors	[84]
2015	Rat	α-MEM + glucose + 20% FBS	-	-	1×10^6 cells	Diabetic rats	4 wk	DPSCs transplantation relieved diabetic polyneuropathy by inhibiting inflammation, exerting immunomodulatory effects, and secreting neurotrophic factors	[86]
2015	Rat	α-MEM + 20% FBS	-	-	1×10^6 cells/limb	Diabetic rats	8 wk	DPSCs increased the nerve conduction velocity and blood flow to nerves and promoted an increase in the number of nerve fibers in diabetic rats	[83]
2013	Rat	DMEM + 10% (FBS + P/S)	-	-	1.5×10^5 cells	Crush injury of the optic nerve in rats	3 wk	Transplantation of DPSCs significantly increased the survival rate of retinal ganglion cells in rats and promote axonal regeneration	[58]
2007	Rat	-	Embedded in 10 mL type I collagen gel	10-mm silicone tube	1×10^5 cells	7 mm defect of the facial nerve in rats	2 wk	Regeneration of axons, blood vessels, and Schwann cells; Tuj1-positive axons and S100-positive Schwann-like supportive cells were found in regenerated nerves	[91]
2018	Rabbit	DMEM + 10% FBS	Construction of an acellular nerve graft for nerve regeneration	Xenogenic acellular nerve matrix	6×10^5 cells per graft	10 mm defect of the sciatic nerve in rabbits	3 mo	Regeneration of nerve space showed that acellular nerve grafts containing DPSCs treated with myroilysin had a strong neural induction effect	[148]



AA: Ascorbic acid; AmB: Amphotericin B; ADMEM: Advanced Dulbecco's modified Eagle medium; bFGF: Basic fibroblast growth factor; b-ME: Beta-mercaptoethanol; BG: Beta-glycerophosphate; Dex: Dexamethasone; CSM: Cellulose/soy protein isolate composite membrane; DPSCs-CM: DPSCs-conditioned medium; DMEM: Dulbecco's modified Eagle medium; DF-chNs: Differentiated cholinergic neurons; DF-DPSCs: Neuronal cells differentiated from DPSCs; FSK: Forskolin; bD609: Tricyclodecane-9-yl-xanthogenate; FBS: Fetal bovine serum; G-CSF: Granulocyte-colony stimulating factor; GFD: 10% GelMA hydrogel, recombinant human basic fibroblast growth factor and DPSCs; HRG1-β: Heregulin-β-1; L-AA-2-P: L-ascorbic acid-2-phosphate; NGF: Nerve growth factor; N-DPSCs: Neural-induced DPSCs; NSE: Neuron-specific enolase; NEAA: Nonessential amino acids; NLCs: Neural lineage cells; OPCs: Oligodendrocyte progenitor cells; P/S: Penicillin and streptomycin; PDGF-AA: Platelet-derived growth factor AA; PBS: Phosphate-buffered saline; PDGF: Platelet-derived growth factor; RA: All-trans retinoic acid; TGNCs: Trigeminal ganglion neuronal cells; IL: Interleukin; TNF: Tumor necrosis factor; TGF: Transforming growth factor.

employed to treat a rat sciatic nerve defect model, significant regeneration of blood vessels and nerve processes was observed, highlighting the crucial role of revascularization in supporting nerve regeneration and survival[95]. Moreover, Zheng *et al*[96] demonstrated that coculture of chitosan scaffold with bFGF can enhance the neural differentiation of DPSCs. The ERK signaling pathway, a classical MAPK pathway, plays a pivotal role in this process. As a downstream effector of bFGF, DPSCs are actively engaged in neural differentiation. Numerous neural induction protocols exist for DPSCs; however, an optimal scheme that is simple, efficient, and quick is currently lacking.

Table 2 Research illustrating the ability of dental pulp stem cells to promote nerve regeneration *in vitro*

Publication year	Cell source	Induction protocol	Material(s) applied	Dose/concentration	Neurocyte type	Culture duration	Results	Ref.
2022	Human	DMEM + 20% (FBS + P/S + AA + bFGF)	Dental pulp cell sheets	3200 cells/cm^2	SH-SY5Y neuroblastoma cells	3 d	Dental pulp cell sheets provided neurotrophic support by expressing NTF; the amount of neurotrophic factors produced by dental pulp cell sheets was sufficient to induce nerve regeneration *in vitro* and promote nerve repair *in vivo*; dental pulp cell sheets improved axon guidance and reduced axon branching	[113]
2020	Rat	α-MEM + 10% (FBS + P/S + NEAA)	DPSCs-CM	-	TGNCs from rats	3 wk	DPSCs-CM was found to contain significant levels of nerve growth factor, brain-derived neurotrophic factor, neurotrophic factor-3, and glial cell line-derived neurotrophic factor; DPSCs-CM increased the survival rate of primary trigeminal ganglion neurons and promoted the growth of neurites	[130]
2020	Rat	α-MEM + 10% (FBS + P/S + NEAA)	DPSCs-CM	50% DPSCs-CM	PC12 cells	8 d	DPSCs-CM was found to contain neurotrophic factors, brain-derived neurotrophic factor, and glial cell line-derived neurotrophic factor, which increased the viability and differentiation of PC12 cells and played an important role in axonal growth and survival, proving that DPSCs-CM treatment is a potential cell-free therapy for peripheral nerve repair and has a stronger effect on PC12 cells than DPSCs	[115]

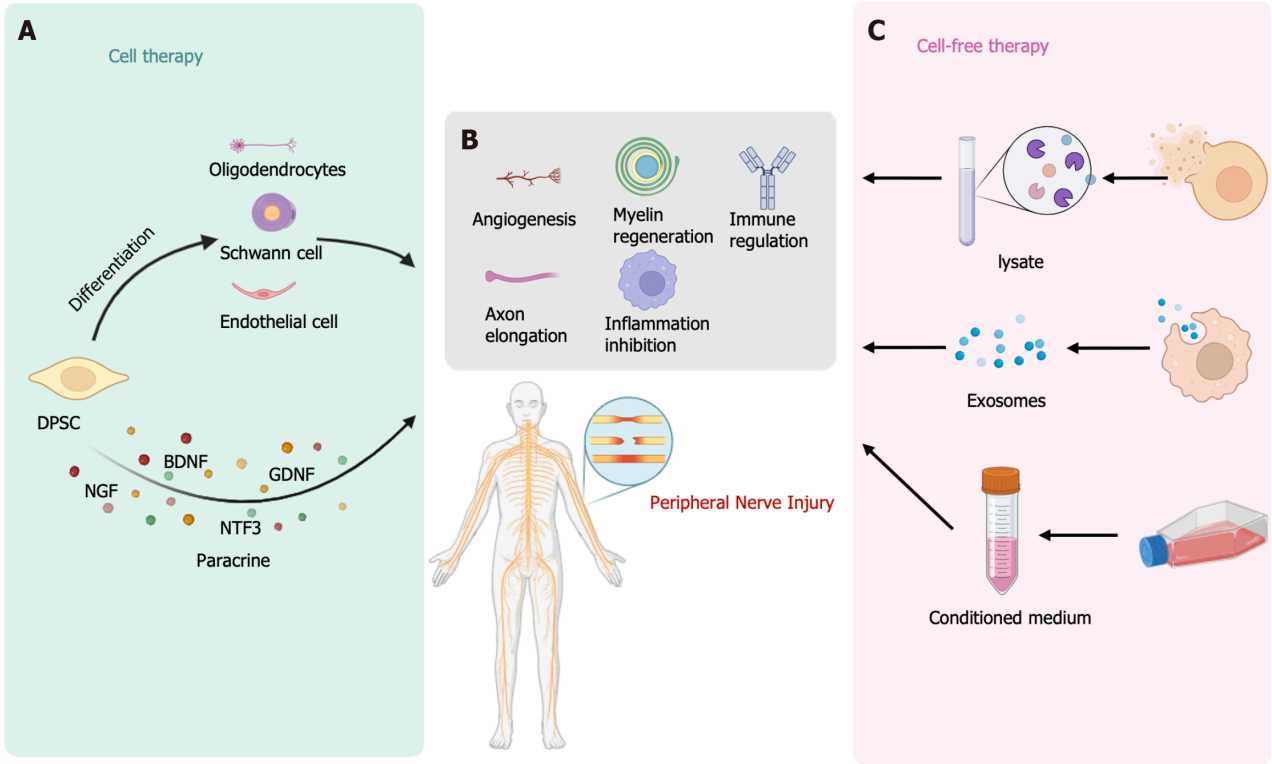

Figure 1 Advantages of dental pulp stem cells as alternative stem cells for nerve regeneration. The figure was created with BioRender.com. DPSCs: Dental pulp stem cells.

Although significant progress has been made in the tissue field, finding a nerve conduit that can match the effectiveness of autologous transplantation remains a challenge in the treatment of PNI. Das and Bellare[97] developed a uniform bead-free nanofibrous scaffold primarily composed of polycaprolactone and gelatin A, which has been shown to support DPSCs regeneration and neural differentiation. In our previous studies, we confirmed that combining DPSCs with a third-generation nerve regeneration conduit can be used to effectively repair 15 mm long defects of the sciatic nerve in rats. Remarkably, the effect of this approach is comparable to that of autotransplantation. Furthermore, we observed that nerve tissue at the repair site mainly originated from differentiating DPSCs. This promising finding offers a potential tissue engineering strategy for the treatment of PNI[98].

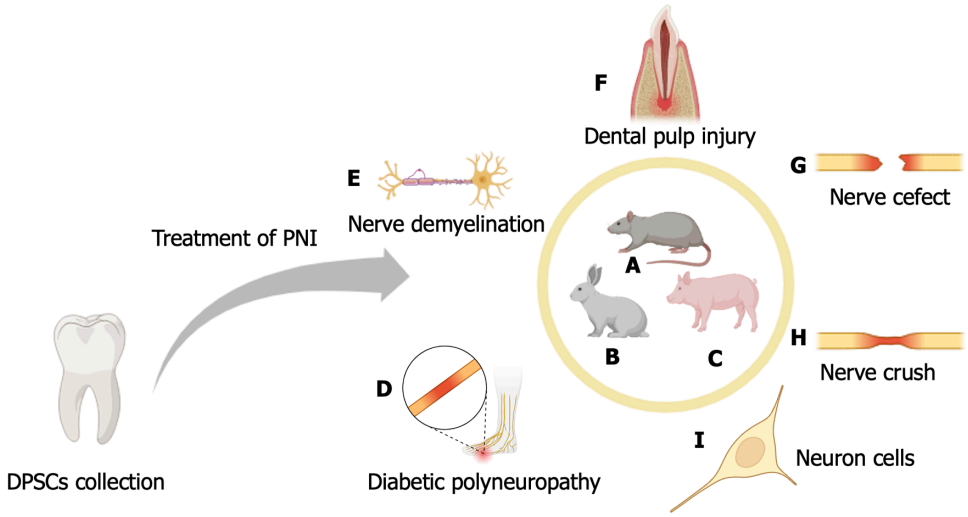
Ullah *et al*[99] made an intriguing discovery that there was no significant difference in nerve regeneration ability between hDPSCs and differentiated neuronal cells derived from hDPSCs. More research on this topic is needed to clarify the underlying mechanisms and find a more effective treatment strategy.

Differentiation into Schwann cells

Previous studies have demonstrated that autologous adult Schwann cells have a remarkable capacity to support extensive peripheral nerve regeneration and can evade rejection[100]. Currently, Schwann cells remain a focal point of animal studies on PNI. Substitutive cell therapies bring renewed hope for nerve regeneration[20]. Schwann cells play a pivotal role in Wallerian degeneration, myelin regeneration, and supporting axon growth.

Martens *et al*[76] were the first to demonstrate that Schwann cells differentiated from hDPSCs can promote nerve regeneration. These differentiated Schwann cells express neural markers such as laminin, p75, GFAP, and CD104 and exhibit an increase in the expression of NTFs such as BDNF, b-NGF, NT-3, and GDNF. Medium conditioned by these differentiated Schwann cells was found to increase the survival of dorsal root ganglion cells and stimulate axon elongation. Subsequently, Al-Zer *et al*[101] induced the differentiation of DPSCs into Schwann cells by using forskolin, bFGF, platelet-derived growth factor, and recombinant human neuregulin-β1. The results revealed that the differentiated neural stem cells strongly expressed the Schwann cell marker Sox10. Additionally, Sanen *et al*[102] demonstrated that hDPSCs, after differentiating into Schwann-like cells, have the potential to stimulate endothelial cell migration and tubule formation. Neuronally differentiated DPSCs secrete higher levels of the angiogenic factor VEGF-A, suggesting that DPSCs retain their angiogenic ability even after differentiating into Schwann cells. However, the underlying mechanism by which DPSCs-derived Schwann cells promote endothelial cell proliferation requires further investigation. These findings collectively indicate the ability of DPSCs to differentiate into Schwann cells, making them potential candidates for tissue engineering-based approaches for treating nerve injuries. Lambrichts *et al*[103] showed that hDPSCs-derived Schwann cells could form myelin sheaths and dorsal root ganglia. Similarly, Carnevale *et al*[12] discovered that STRO-1+/c-Kit+/CD34+ hDPSCs, which originate from the neural ridge, promote axonal regeneration in an animal model of PNI and express S100b, a typical marker of Schwann cells. The differentiation of DPSCs into Schwann cells thus is a potential strategy for nerve regeneration, and the refinement of differentiation protocols and materials remains an important area of investigation.

Differentiation into oligodendrocytes



The primary function of oligodendrocytes is to form myelin, creating intricate connections between neurons in the nervous system. The transcription factor OLIG-2 and proteoglycan NG2 are markers of oligodendrocyte progenitor cells (OPCs)[104]. In a previous study, Sakai *et al*[105] transplanted SHEDs into rats with spinal cord transection and found that these cells exerted promising effects in promoting axon regeneration. This effect was achieved through the inhibition of various axon growth inhibitor signals and the differentiation of the transplanted cells into oligodendrocytes to replace damaged cells. Bagheri-Hosseinabadi *et al*[106] successfully induced DPSCs to differentiate into oligodendrocytes using cerebrospinal fluid and retinoic acid and obtained cells with a fibroblastic morphology and high adherence potential. Moreover, Askari *et al*[107] successfully induced DPSCs to differentiate into OPCs by transfecting them with a virus carrying the human Orig2 gene. The differentiated oligodendrocytes displayed a typical morphology and expressed neural markers such as GFAP, oligodendrocyte lineage transcription factor 2, and MBP. Subsequently, they applied transplanted oligodendrocytes into sciatic nerve demyelination model mice and demonstrated their effectiveness in nerve repair[108]. The nerve regeneration potential of DPSCs has been substantiated through various studies, offering hope for the treatment of peripheral nerve demyelination.

Differentiation into endothelial cells

Adequate blood supply is crucial for the survival of stem cells and nerve regeneration following injury. When MSCs differentiate into Schwann cells, they increase the secretion of angiogenic factors, including angiopoietin-1 and VEGF-A [109]. DPSCs can increase the migration of endothelial cells and promote angiogenesis *in vitro* and *in vivo*[110]. Sanen *et al* [102] also confirmed this phenomenon. Moreover, research has demonstrated that stem cells can directly differentiate into endothelial cells. In a rat facial nerve defect model, it was observed that DPSCs can directly differentiate into RECA1-positive endothelial cells, promoting nerve regeneration by increasing blood supply[91]. DPSCs were found lining the blood vessel wall of newly formed braided bone, indicating that angiogenesis occurred *in vitro*. Osteoblasts and endothelial cells were found after transplantation, and ultimately, bone-containing blood vessels were produced. Flk-1 is very important for the coupling of osteogenesis and angiogenesis. d'Aquino *et al*[69] proved that DPSCs can differentiate into Flk-1+/STRO-1+/CD44+/CD54+ endothelial progenitor cells. Sasaki *et al*[91] found that regenerated nerves contained S100-positive Schwann cells and RECA1-positive endothelial cells derived from dental pulp 14 d after DPSCs transplantation into rats with facial nerve defect. Newborn blood vessels are composed of endothelial cells from both recipient and donor sources. It has been suggested that DPSCs can differentiate into nerve cells and endothelial cells at the same time to promote nerve and vascular regeneration to treat PNI[91]. Subsequently, Maraldi *et al*[71] also proved that transplanted DPSCs can differentiate into endothelial cells *in vivo*. The ability of DPSCs to differentiate into endothelial cells further increases their potential for nerve regeneration.

Paracrine action

PNI triggers the dedifferentiation of Schwann cells and induces the formation and secretion of protogranules, which play a crucial role in nerve repair and the promotion of axonal growth[111]. Yamamoto *et al*[112] discovered that mobilized DPSCs (MDPSCs) treated with a granulocyte-colony stimulating factor (G-CSF) gradient express a variety of NTFs. These

Figure 4 Main models used to study the effect of dental pulp stem cells in treating peripheral nerve injury at present. A: Rats; B: Rabbits; C: Pigs. D: Diabetic neuropathy; E: Nerve demyelination injury; F: Dental pulp injury; G: Nerve defect injury; H: Nerve crush injury; I: Nerve cells cultured *in vitro* are used. DPSC: Dental pulp stem cell. The figure was created with BioRender.com.

NTFs not only stimulate Schwann cells but also regulate their apoptosis and proliferation. Additionally, the differentiation of hDPSCs into Schwann cells increases the expression of glial markers and the secretion of NTFs, including BDNF, GDNF, NGF, NTF3, ANGPT1, and VEGFA[45,76]. Furthermore, linearly arranged dental pulp cell slices have been shown to guide and support axonal regeneration, and the abundant NTFs produced by the cells were found to make a significant contribution to this phenomenon[113]. Implantation of DPSCs into the vitreous body can effectively treat retinal ganglion cell injuries in adult rats, with the secretion of NTFs being a critical factor. The neuroprotective effect of DPSCs is weakened when K252a and Trk are blocked, indicating the importance of the NTFs NGF, BDNF, and NT-3 in this process[58]. In the repair of sciatic nerve crush injury in rat models, transplanted dental pulp cells may secrete NTFs [114]. In a rat model of sciatic nerve injury with a 10 mm defect, DPSCs were found to exert their effects on Schwann cells through paracrine signaling, leading to significant promotion of axonal regeneration[45]. The strong paracrine effect of DPSCs, coupled with their potential for nerve regeneration, makes them promising candidates for nerve tissue engineering.

CELL-FREE THERAPEUTIC ALTERNATIVES INVOLVING DPSCS

An increasing number of studies have demonstrated that odontogenic stem cells treat nerve injury through paracrine mechanisms[105]. NTFs, such as NGF, BDNF, and GDNF, can stimulate axonal growth, making DPSCs potential candidates for acellular therapy[115,116]. Kumar *et al*[117] showed that DPSCs secrete high levels of cytokines such as G-CSF, interferon gamma, and transforming growth factor (TGF)-β, which promote nerve differentiation and axonal growth. Unlike some other stem cell types, DPSCs demonstrate strong potential for nerve regeneration, supporting the use of their secreted factors for exocrine therapy for PNI. Kanada *et al*[118] found that both DPSCs and secreted factors from DPSCs (DPSCs-SFs) exerted therapeutic effects in a rat model of diabetic polyneuropathy. The effects included increases in sciatic nerve motor/sensory nerve conduction velocity and sciatic nerve blood flow. DPSCs-SFs were found to include angiogenic, neurotrophic, and immunomodulatory proteins. However, DPSCs transplantation may provide benefits over a longer duration of time[118].

With the continuous development of research on DPSCs-derived exosomes (DPSCs-Exos), DPSCs-Exos have been demonstrated to exert potential therapeutic effects in various diseases. They have shown promise for the treatment of periodontitis[119], Parkinson's disease[120], SCI[121], degenerative diseases[122], and cerebral ischemia[123] and in achieving pulp regeneration[124]. DPSCs-Exos have garnered significant attention due to their immunomodulatory properties[125], ability to promote angiogenesis[126], inhibitory effect on inflammation[127], and marked neuroregenerative and neuroprotective effects[128]. Studies have revealed that DPSCs-Exos can increase the formation of SH-SY5Y cell axons, leading to improved neuronal ultrastructure and increased expression of neural markers[129]. Research on acellular therapies involving DPSCs is still relatively limited, and the therapeutic potential of DPSCs-Exos and DPSCs lysates requires further experimentation and validation. Progress has been made in the techniques used to extract exosomes and analyze their composition, but there is still much work to be done before their clinical application can be realized.

CM derived from D-MSCs has been shown to promote axonal growth[45]. Sultan *et al*[130] conducted a study on the neuroprotective effect of DPSCs and DPSCs-CM on isolated TGNCs for the first time. The results demonstrated that DPSCs-CM can increase neuronal survival and promote axonal growth through the action of various NTFs, including GDNF, BDNF, NT-3, and CNTF[130]. CM from human dental pulp cells was found to contain bone morphogenetic

protein 7, FGF7, insulin-like growth factor (IGF)-1, FGF4, growth hormone, and VEGF-D, all of which are related to nerve regeneration and protection, vascular regeneration, and osteogenesis. Furthermore, the addition of B-27 to CM was observed to enhance the promotion of axon growth[131]. DPSCs-CM has shown the ability to alleviate polyneuropathy in diabetic rats and reduce the number of macrophages in diseased peripheral nerves[132]. DPSCs-CM holds significant promise in the treatment of peripheral nerve injuries. However, further research is needed to explore the underlying mechanisms of nerve regeneration.

Neurotrophin, BDNF, GDNF, IGF, NGF, and VEGF were detected near transplanted DPSCs 14 d after transplantation. The secretion of vascular endothelial growth factors supports angiogenesis, thus promoting nerve regeneration[112]. BM-MSCs can also secrete NTFs such as BDNF, b-FGF, and CNTF to promote peripheral nerve regeneration and thus treat peripheral nerve defects[133]. G-CSF-MDPSCs express higher levels of granulocyte-macrophage CSF, matrix metalloproteinase 3, VEGF, and NGF than BM-MSCs. The effects of G-CSF-MDPSCs in angiogenesis, neurite extension, and migration and their anti-apoptotic effects were found to be stronger than those of BM-MSCs in the same environment [134]. Compared with medium conditioned by CD31- cells derived from bone marrow and fat, medium conditioned by CD31- cells from pulp results in higher levels of angiogenesis/NTFs and exerts stronger angiogenic and neurogenic effects[135]. Kumar *et al*[117] also proved that DPSCs and their secreted factor may exert beneficial effects in treating neurological disorders and injuries. Exosomes derived from DPSCs can inhibit the differentiation of CD4+ T cells into helper T cells 17 (Th17), reduce the secretion of the proinflammatory factors interleukin (IL)-17 and tumor necrosis factor-alpha (TNF-α), promote the polarization of CD4+ T cells into regulatory T cells, and increase the release of the anti-inflammatory factors IL-10 and TGF-β. Compared with BM-derived exosomes, exosomes derived from DPSCs have a stronger immunoregulatory effect. In CD4+ T cells stimulated by exosomes derived from DPSCs, the expression levels of IL-10 and TGF-β mRNA were found to be the highest, while the transcription levels of IL-17 and TNF-α were found to be the lowest. Exosomes derived from DPSCs have stronger anti-inflammatory effects than exosomes derived from BM-MSCs[125]. Exosomes derived from DPSCs/BM-MSCs significantly decrease the activity of caspase3/7 and exert a significant antiapoptotic effect to play a neuroprotective role by upregulating endogenous expression of neuronal survival factors. Specifically, the cell survival-related PI3K-Bcl-2 pathway protects hippocampal neurons from excitotoxicity. Exosomes derived from DPSCs have stronger antiapoptotic and anti-visceral necrosis effects than exosomes derived from bone marrow stem cells[122]. Interestingly, the factors secreted by DPSCs are different in different environments[136]. There is no doubt that the neuroprotective effect of DPSCs-Exos is stronger than that of BM-MSC-derived exosomes. However, for clinical application, it is necessary to better determine the optimal composition, dosage, and culture conditions of exosomes[121].

CONCLUSION

PNI is a prevalent clinical issue that often leads to long-term pain in patients. Recent research has demonstrated the beneficial effects of Schwann cells on axonal regeneration and functional recovery after injury[137]. However, isolating and cultivating Schwann cells are challenging due to their limited availability and low proliferation rate[138]. Tissue engineering strategies involving nerve grafts consisting of physical scaffolds combined with supporting cells and/or growth factors or other biomolecules are promising approaches for treating PNI[139].

DPSCs may occupy the injury site and exert immunomodulatory effects, participate in paracrine signaling, and directly differentiate into relevant cell types, thus promoting the repair and regeneration of diseased and injured tissues. To promote the application of DPSCs and their products in nerve regeneration in the future, clinical strategies and various administration methods are being studied on a large scale[140]. A study revealed that inducing DPSCs to differentiate into oligoprogenitor cells is a potential treatment strategy for neurodegenerative diseases[141]. DPSCs have the multilineage differentiation potential and can differentiate into neurotrophoblasts. DPSCs-CM and DPSCs-Exos contain rich NTFs, and DPSCs-Exos can also cross the blood-brain barrier. In addition, DPSCs have the ability to reduce inflammation, promote axonal growth, and resist apoptosis. They have great potential in the treatment of PNI[142].

Previous *in vivo* studies have focused on the sciatic nerve and facial nerve of rats and analyzed the behavioral and pathological manifestations of rats with sciatic and facial nerve injury, but electrophysiological studies are lacking. Moreover, it is also necessary to compare therapeutic effects among different models to identify the optimal application of DPSCs. However, there are still some questions to be answered. Do DPSCs have the same effect on nerve crush injury and amputation injury? Do different treatment methods have different effects on different models. Which is better, cell therapy or acellular therapy? What are the key factors in the neuroprotective and regenerative abilities of acellular therapies? In addition, researchers should pay more attention to the function of differentiated nerve cells *in vitro*. Furthermore, organoids may become a hot research topic in the future. A DPSCs cell bank is also urgently needed[143]. It is believed that DPSCs will bring hope to patients with PNI soon.

The unique biological characteristics of DPSCs make them significant cell sources for the treatment of PNI. DPSCs exhibit neurogenic potential, are easily accessible, exhibit pluripotency, and can be preserved for extended periods, making them excellent candidates for tissue engineering applications. DPSCs (Figure 4) can be utilized directly or in combination with nerve conduits or hydrogels or used after differentiation into nerve-like cells to treat PNI. Moreover, DPSCs lysates, DPSCs-Exos, and DPSCs-CM all hold promise in the treatment of PNI. However, overcoming safety and ethical problems and avoiding tumor formation are still the keys for translating DPSCs for clinical use[144].

This review focused on the therapeutic potential of DPSCs in treating PNI, elaborating on the neuroprotective and regenerative capabilities of DPSCs through both cellular and acellular approaches. DPSCs hold significant promise for the treatment of PNI, and it is anticipated that they will play a crucial role in the clinical treatment of PNI in the future. As

research on the effect of DPSCs on PNI continues to progress, more efficient and expedient treatment protocols are expected to be developed. However, the safety of cell therapies and the efficacy of acellular therapies in treating long-gap injuries require thorough evaluation. The search for convenient and effective treatment strategies involving DPSCs and their products for PNI remains ongoing. Furthermore, the underlying mechanisms and key components of DPSCs in peripheral nerve treatment warrant further investigation. As acellular therapies are novel stem cell therapies, there is a need to refine the purification process of cell materials and establish a standardized and effective cell production plan. Comparative studies assessing the safety, efficacy, and production costs of various therapies are also essential.

Abstract

BACKGROUND

The hypoxic environment during bone healing is important in regulating the differentiation of periosteal stem cells (PSCs) into osteoblasts or chondrocytes; however, the underlying mechanisms remain unclear.

AIM

To determine the effect of hypoxia on PSCs, and the expression of microRNA-584-5p (miR-584-5p) and RUNX family transcription factor 2 (RUNX2) in PSCs was modulated to explore the impact of the miR-584-5p/RUNX2 axis on hypoxia-induced osteogenic differentiation of PSCs.

METHODS

In this study, we isolated primary mouse PSCs and stimulated them with hypoxia, and the characteristics and functional genes related to PSC osteogenic differentiation were assessed. Constructs expressing miR-584-5p and RUNX2 were established to determine PSC osteogenic differentiation.

RESULTS

Hypoxic stimulation induced PSC osteogenic differentiation and significantly increased calcified nodules, intracellular calcium ion levels, and alkaline phosphatase (ALP) activity in PSCs. Osteogenic differentiation-related factors such as RUNX2, bone morphogenetic protein 2, hypoxia-inducible factor 1-alpha, and ALP were upregulated; in contrast, miR-584-5p was downregulated in these cells. Furthermore, upregulation of miR-584-5p significantly inhibited RUNX2

expression and hypoxia-induced PSC osteogenic differentiation. RUNX2 was the target gene of miR-584-5p, antagonizing miR-584-5p inhibition in hypoxia-induced PSC osteogenic differentiation.

CONCLUSION
Our study showed that the interaction of miR-584-5p and RUNX2 could mediate PSC osteogenic differentiation induced by hypoxia.

Key Words: Periosteal stem cell; Osteogenic differentiation; RUNX family transcription factor 2; MiroRNA-584-5p

Core Tip: This study simulated the hypoxic environment of periosteal stem cells (PSCs) during fracture and examined the related cellular responses to the hypoxia-induced PSC osteogenic differentiation. Importantly, the microRNA-584-5p/RUNX family transcription factor 2 axis was determined to be one of the regulating mechanisms for the hypoxia-induced PSC osteogenic differentiations.

INTRODUCTION

The periosteum is a special connective tissue membrane that covers the surface of bone. For a long time, the types of cells that mediate osteogenic/chondrogenic differentiation at the periosteum have been unknown. The lack of generated periosteal cells following periosteal-deficient periosteal injury suggests a certain type of stem cell within the periosteum [1]. Periosteal stem cells (PSCs) were identified for the first time by Debnath *et al*[2]. PCS were extracted and identified from long bones and calvarial bones in mice, confirming the multifunctional differentiation potential of these cells in inducing the formation of tissues/organs, such as bones, cartilage, and fat. PSCs are essential for successful bone healing and provide new research ideas and directions for bone repair and maintenance since they are the main source of osteoblasts (OBs) and chondrocytes at the periosteum[3,4]. Since fracture healing is accompanied by obvious tissue hypoxia, it is worth exploring the effects of hypoxia on PSC osteogenic differentiation[5].

Noncoding RNAs are considered important biomolecules modulating cellular osteogenic differentiation[6], and microRNAs (miRNAs) are some of the most common noncoding RNAs that epigenetically modulate osteogenesis-related gene expression. Generally, aberrant miRNA expression is important in regulating stem cell differentiation into OBs/cartilage and is involved in the progression of bone diseases[7]. Based on the Gene Expression Omnibus database, a bioinformatics study[8] screened out the signature miRNAs in periodontal stem cells. MicroRNA-584-5p (miR-584-5p) was shown to be differentially expressed and inhibited during the osteogenic differentiation of periodontal stem cells. Notably, miR-584-5p might be associated with PSC osteogenic differentiation.

RUNX family transcription factor 2 (RUNX2) is a key regulatory factor for osteogenic differentiation[9]. This molecule can modulate the expression of osteogenic markers in cells by binding the functional elements of osteogenesis-related genes, regulating osteogenic differentiation[10]. RUNX2 mutation or deficiency inhibits cell differentiation into OBs, resulting in osteogenic defects[11]. Most studies have revealed the osteogenic activity of RUNX2 in bone marrow-derived mesenchymal stem cells, but its involvement in the osteogenic differentiation pathway of PSCs remains to be clarified.

This study aimed to determine the effect of hypoxia on PSCs, and the expression of miR-584-5p and RUNX2 in PSCs was modulated to explore the impact of the miR-584-5p/RUNX2 axis on hypoxia-induced osteogenic differentiation of PSCs. The findings of this study could provide new mechanistic insights into the regulation of PSC osteogenic differentiation induced by hypoxia.

MATERIALS AND METHODS

Cell isolation and experiments

PSCs were extracted from 7-d-old C57BL/6J mice (Beijing Vital River Laboratory Animal Technology). Mouse periosteal tissues were collected, chopped with a surgical blade, and digested with collagenase at 37 °C for 1 h. Then, Dulbecco's modified Eagle's medium with 2% fetal bovine serum was added to terminate digestion, and the digestive solution was centrifuged for supernatant removal. The pelleted cells were suspended in DNase solution and incubated for 5 min at 37 °C. The cells were filtered using a 70-μm cell filter, and the stem cells were induced by osteogenic differentiation medium. PSCs were incubated for 3 h under 2% O_2, 10% CO_2, and 88% N_2 to induce hypoxia; they were assigned and treated under

conditions including normoxia, hypoxia, hypoxia plus negative control (NC) mimic, miR-584-5p mimic, NC shRNA, sh-RUNX2, miR-584-5p plus mimic and pcDNA3.1, and miR-584-5p mimic plus pc-RUNX2.

Alkaline phosphatase activity assay

Alkaline phosphatase (ALP) activity in PSCs was detected according to the ALP activity detection kit (P0321S, Beyotime, Shanghai, China). The procedure was as follows: PSCs were fully lysed with cell lysis buffer composed of 20 mmol/L Tris (pH = 7.5), 150 mmol/L NaCl, and 1% Triton X-100, and the supernatant was used for ALP activity detection after centrifugation. Fifty microliters of the supernatant samples was added to each well of 96-well plates, including blank controls, and the working solution was added for 5-10 min of cultivation at 37 °C. After incubation, 100 μL of stop buffer was added to each well to terminate the reaction. A microplate reader (Thermo Fisher, United States) was used to measure the absorbance at 405 nm, and ALP activity was calculated using the standard curve set up in the assay.

Alizarin red S staining

This study determined calcified nodule formation in cells using an Alizarin red S (ARS) staining kit (C0148S, Beyotime, Shanghai, China). The cells were carefully washed with phosphate buffered saline (PBS) solution once after osteogenic differentiation induction of PSCs, incubated with a fixative for 20 min, and then washed with PBS solution three times. After addition of ARS dye for 30 min of cultivation, the cells were thoroughly rinsed with distilled water. Calcified nodule formation was observed using an optical microscope (Olympus, Japan). ARS chelated Ca^{2+} to form orange-red complexes in this experiment.

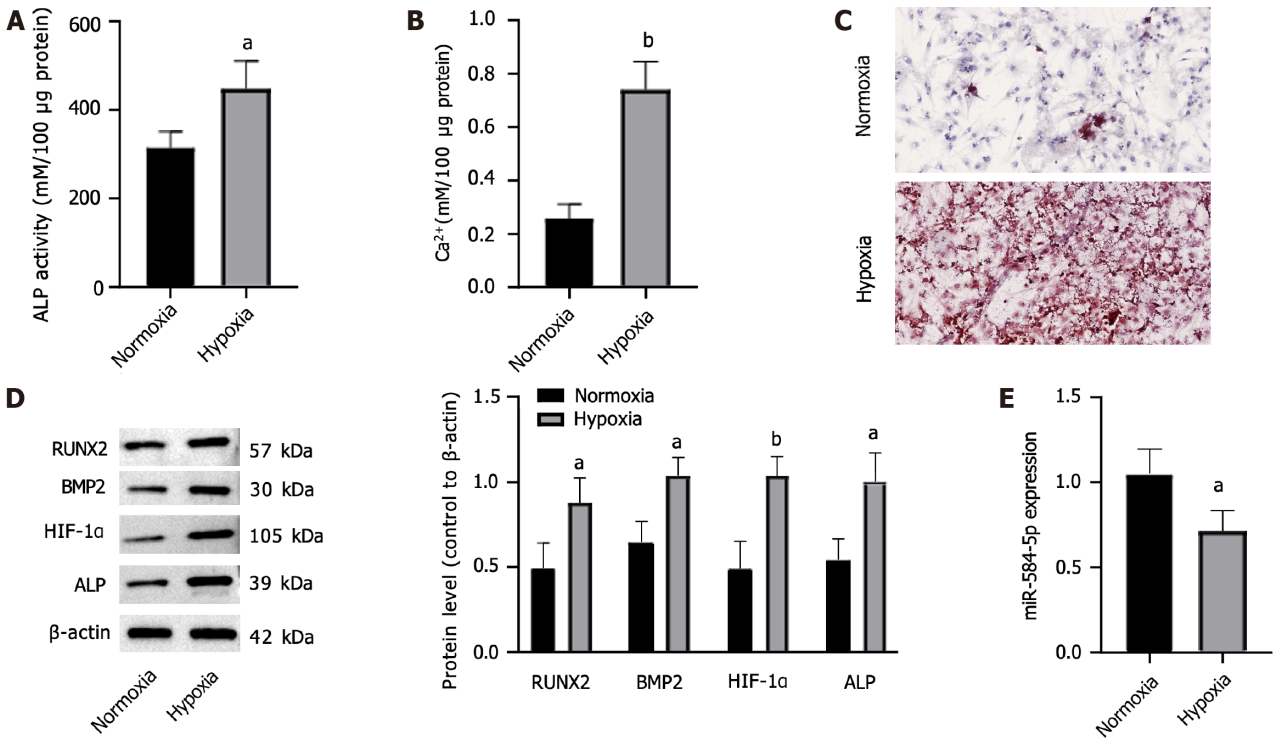
Characterization of intracellular calcium ions

The calcium ion level in PSCs was measured with a calcium-content chromogenic detection kit (S1063S, Beyotime, Shanghai, China). A lysis buffer with a volume of 100 μL was added to the cell sample for thorough lysis. Then, the lysate was centrifuged (10000 × *g*, 4 °C, 3-5 min) to obtain supernatants for calcium ion characterization. The standard curve and test working solution were prepared following the manufacturer's instructions. In a 96-well plate, the supernatant sample and 150 μL of working solution were mixed, added at 50 μL per well and incubated for 5-10 min at room temperature in the dark. The color reaction was detected at an absorbance OD of 575 nm, and the calcium ion content was calculated based on the standard curve.

Bioinformatics prediction and dual luciferase reporter gene assay

StarBase was used to predict the potential binding sites between miR-584-5p and RUNX2 mRNA, and the dual luciferase reporter (DLR) gene system was used to verify the targeting relationship between them. First, the targeted wild-type (wt) and mutant fragments of RUNX2 were cloned and inserted into pGL4 plasmids (upstream of the firefly reporter gene), yielding RUNX2-wt and RUNX2-mutant (mut), respectively, based on the predicted locus sequence information. MiR-584-5p and NC mimics were transfected into cells by the liposome method. Each constructed main reporter gene vector was then cotransfected with the Renilla reporter gene vector into cells. The firefly and Renilla luciferase activities were detected, and the relative luciferase activity (firefly/Renilla) was calculated.

Quantitative polymerase chain reaction



TRIzol solution-lysed cells were used to extract total RNA. RNA was reverse-transcribed into cDNA using a reverse transcription-fluorescence quantitative polymerase chain reaction (qPCR) kit (Tiangen, Beijing, China) and PCR apparatus (Applied Biosystems, United States) for real-time fluorescence quantification (qPCR) after determining the purity of the RNA samples. The miR-584-5p sense strand primer was 5′-CCGTTATGGTTTGCCTGGG-3′, and the miR-584-5p antisense strand primer was 5′-GTCGTATCCAGTGCAGGGTCCGAGGTATTCGCACTGGATACGACCTCAGT-3′. The RUNX2 sense strand primer was 5′-AGATGGGACTGTGGTTACCG-3′, and the RUNX2 antisense strand primer was 5′-GGACCGTCCACTGTCACTTT-3′. The $2^{-\Delta\Delta Ct}$ method was used to calculate gene expression, which was normalized to that of glyceraldehyde-3-phosphate dehydrogenase and U6.

Western blot

RIPA lysis buffer (Cell Signaling, United States) was used for cell lysis. After protein isolation, a BCA detection kit (Abcam, United States) was used to measure the protein concentration, and the loading amount of the protein samples was calculated. After sodium-dodecyl sulfate gel electrophoresis, the proteins were transferred to a nitrocellulose membrane (NCM; Cell Signaling, United States) with a wet membrane transfer instrument in an ice bath. Then, the NCM was sealed at room temperature with a sealing liquid containing 5% skim milk powder for 1 h. The NCM was incubated overnight at 4 °C with primary antibodies, including RUNX2 (ab236639, 1:1000, Abcam United States), bone morphogenetic protein 2 (BMP2) (ab284387, 1:1000), hypoxia-inducible factor 1-alpha (HIF-1α) (ab179483, 1:1000), ALP (ab229126, 1:2000), and b-actin antibodies (ab8226, 1:10000), and the corresponding secondary antibody (ab6721, 1:10000, Abcam, United States) was incubated at room temperature for 1 h. An enhanced chemiluminescence reagent was used to detect protein bands. Images of the protein bands were obtained by X-ray analysis, and the relative protein expression normalized to β-actin expression was calculated.

Statistics and analysis

The average of each variable was obtained, and the standard deviation was calculated after three repeated measurements. The independent sample *t* test and one-way analysis of variance were used to identify differences between groups. The statistical analysis was conducted with Statistical Package for the Social Sciences version 22.0 software, and the graph

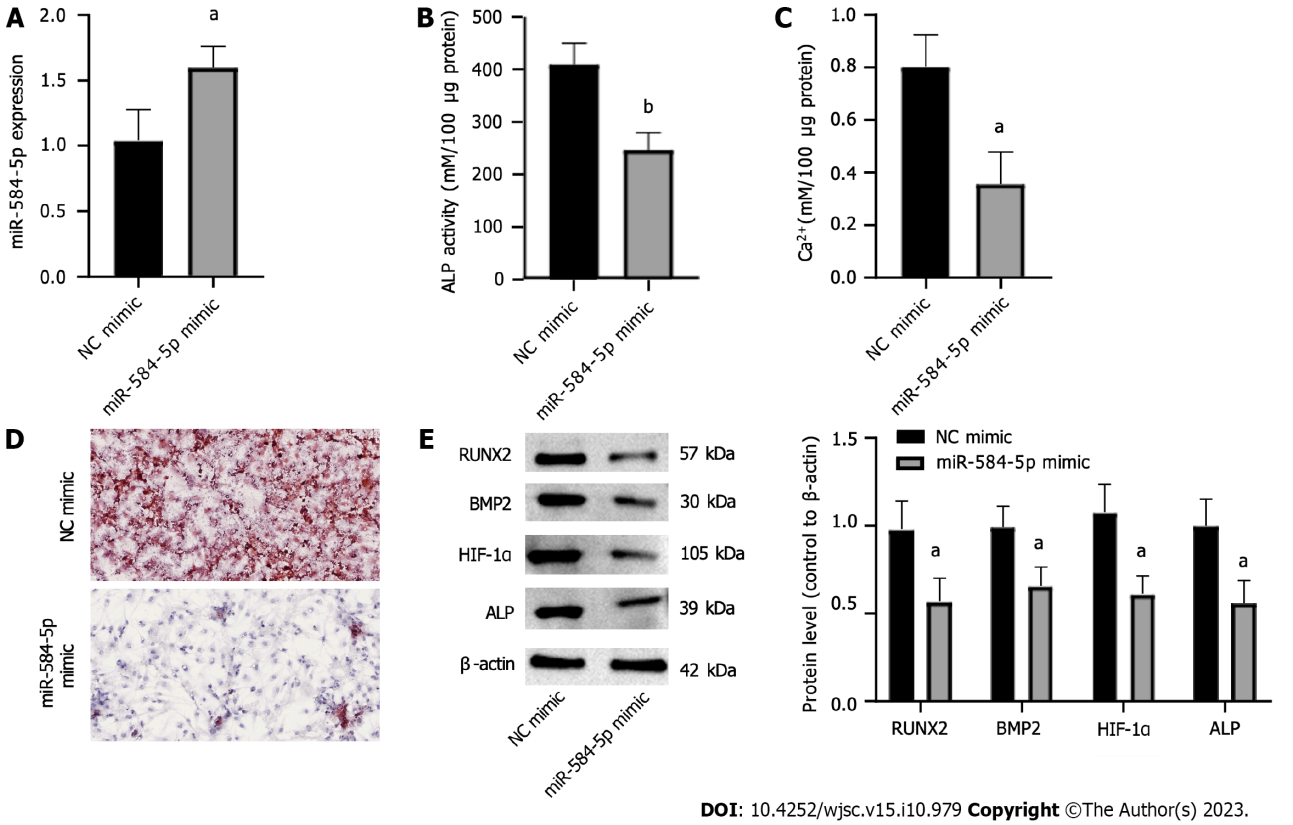
data were processed by GraphPad version 9.0. A 95% confidence interval was used, and a *P* value of < 0.05 indicated statistical significance.

RESULTS

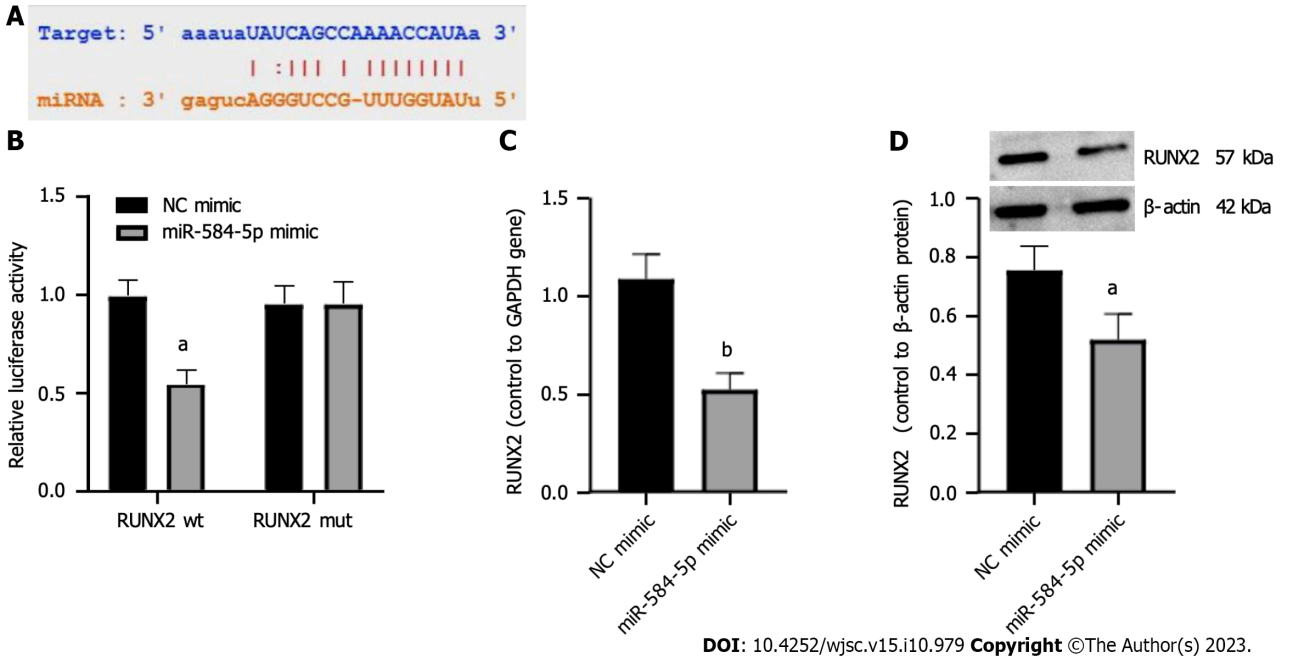
Hypoxia promotes PSC osteogenic differentiation



An osteogenic differentiation medium was used to induce PSCs, and normoxic/hypoxic atmospheres were created to observe the impact of hypoxia on PSC osteogenic differentiation. ALP activity, intracellular calcium levels, and the expression of osteogenic differentiation-related factors, including RUNX2, BMP2, HIF-1α, and ALP, were measured, and ARS staining of PSCs was performed. Hypoxia significantly enhanced ALP activity (Figure 1A), Ca^{2+} levels (Figure 1B), and calcified nodule formation (Figure 1C) compared with normoxia. Hypoxia treatment increased the RUNX2, BMP2, HIF-1α, and ALP protein levels (Figure 1D). In contrast, hypoxia significantly downregulated miR-584-5p in PSCs (Figure 1E). Therefore, hypoxia could promote PSC osteogenic differentiation while downregulating miR-584-5p expression.

MiR-584-5p upregulation affects hypoxia-induced PSC osteogenic differentiation

To investigate whether aberrant miR-584-5p expression was related to hypoxia-induced PSC osteogenic differentiation, we used a miR-584-5p mimic vector to upregulate miR-584-5p in PSCs, and the NC mimic was used as a control (Figure 2A). Furthermore, PSCs were divided into two groups, transfected with NC mimic and miR-584-5p mimic, and the cells were stimulated by hypoxia and induced to differentiate into OBs to observe the role of miR-584-5p in hypoxia-induced PSC osteogenic differentiation. The results showed that upregulation of miR-584-5p lowered ALP activity (Figure 2B) and intracellular calcium deposition (Figure 2C) while suppressing calcified nodule formation (Figure 2D). Moreover, miR-584-5p overexpression significantly decreased the expression of osteogenic differentiation genes, such as RUNX2, BMP2, HIF-1α, and ALP (Figure 2E). Therefore, upregulation of miR-584-5p can inhibit PSC osteoblastic differentiation induced by hypoxia.



Targeted regulation of the RUNX2 axis by miR-584-5p

We hypothesized that miR-584-5p binds to a sequence fragment on the 3′ untranslated region of RUNX2 based on starBase (Figure 3A). The potential binding site was validated using a DLR gene assay. Relative luciferase activity was significantly reduced in the cells cotransfected with miR-584-5p mimic and RUNX2 wt but not in the cells with miR-584-

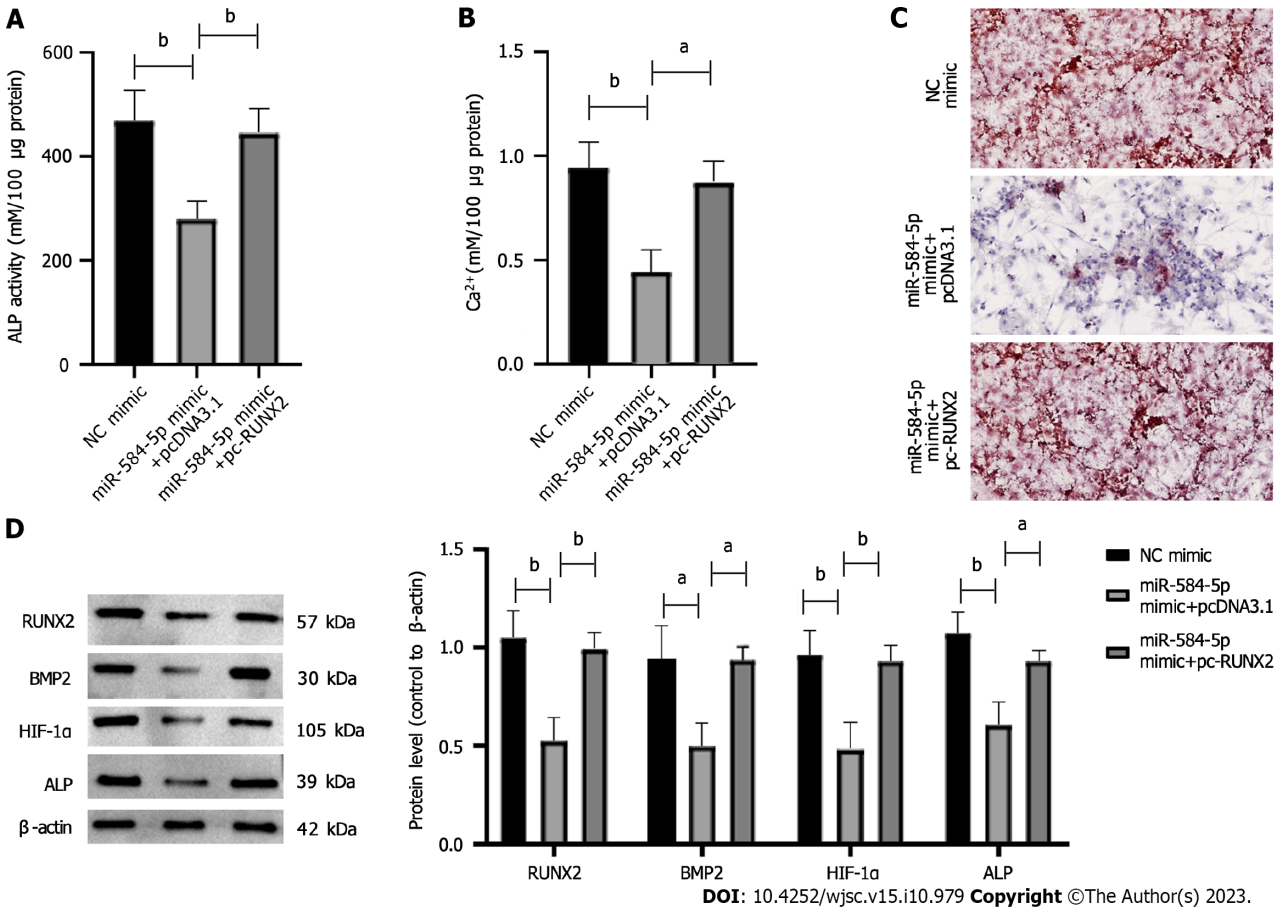
5p mimic cotransfected with RUNX2-mut (Figure 3B). Furthermore, upregulation of miR-584-5 suppressed RUNX2 expression at both the RNA level (Figure 3C) and the protein level (Figure 3D). These results indicated that miR-584-5p could regulate RUNX2 through the predicted binding site.

Impact of RUNX2 on hypoxia-induced PSC osteogenic differentiation



To investigate the role of miR-584-5p-induced RUNX2 downregulation in hypoxia-induced PSCs, we constructed a RUNX2 inhibitory expression vector (sh-RUNX2) and a negative control shRNA (NC shRNA) (Figure 4A). Downregulation of RUNX2 significantly decreased ALP activity (Figure 4B), calcium deposition (Figure 4C), and ARS staining of osteogenic differentiation (Figure 4D); in contrast, it suppressed RUNX2, BMP2, HIF-1α, and ALP expression (Figure 4E). Thus, downregulation of RUNX2 inhibited hypoxia-induced PSC osteogenic differentiation.

MiR-584-5p regulates hypoxia-induced PSC osteogenic differentiation by targeting RUNX2

To investigate whether miR-584-5p could mediate the RUNX2 response pathway in hypoxia-induced PSC osteogenic differentiation, we established gene constructs such as NC mimic, miR-584-5p in pcDNA3.1, and miR-584-5p mimic + pc-RUNX2 and transfected them into PSCs. The results showed that miR-584-5p significantly lowered ALP activity (Figure 5A) and intracellular calcium ion levels (Figure 5B) in hypoxia-induced PSCs, and it inhibited PSC osteogenic differentiation induced by hypoxia (Figure 5C). In contrast, upregulated RUNX2 partly rescued the inhibitory responses mediated by miR-584-5p (Figures 5A-C). Moreover, upregulation of RUNX2 significantly reversed the downregulation of osteogenic differentiation-related proteins induced by miR584-5p overexpression (Figure 5D). Thus, the upregulation of RUNX2 specifically reversed the inhibitory effect of miR-584-5p overexpression on hypoxia-induced PSC osteogenic differentiation.

DISCUSSION

PSCs have a strong differentiation potential. Bone defects can activate PSCs through a series of signal transduction pathways and induce cell migration, proliferation, and differentiation into OBs/chondrocytes at the injury site[12]. However, the mechanisms underlying PSC osteogenic differentiation are poorly understood. This study simulated the hypoxic environment of PSCs during fracture and examined the related cellular responses to hypoxia-induced PSC osteogenic differentiation. Importantly, the miR-584-5p/RUNX2 axis was determined to be one of the regulatory mechanisms for hypoxia-induced PSC osteogenic differentiation.

Fracture healing is a complex process in which HIFs activate the osteogenic differentiation of precursor cells in response to the hypoxic environment where the fracture occurs[13]. Hypoxia is one of the main functional mechanisms of PSC osteogenic differentiation. One study emphasized that hypoxia upregulated HIF expression in PSCs, affecting the periosteal protein-mediated osteogenic differentiation pathway[14]. Similarly, we confirmed that hypoxia could activate PSC osteogenic differentiation and upregulate osteogenic differentiation-associated genes, such as RUNX2, causing cell mineralization. We also found that RUNX2 overexpression could increase osteogenic differentiation (Figure 5C). Thus, hypoxia is important for PSC osteogenic differentiation, and adjusting the oxygen concentration could induce PSC osteogenic differentiation *in vitro*.

Furthermore, we revealed that miR-584-5p was downregulated in hypoxia-induced PSCs. MiRNAs are key regulators of osteogenic differentiation and are involved in the expression of many genes in mesenchymal stem cells[15]. MiR-584-5p seems to be an important factor in bone healing and can mediate osteogenic differentiation by regulating gene expression[16-19]. Furthermore, miR-584-5p is a vital regulatory factor for osteosarcoma cell proliferation and bone homeostasis[20]. Therefore, miR-584-5p expression might be related to bone homeostasis. The significant downregulation of miR-584-5p in PSCs suggests its potential role in osteogenic differentiation. In this study, the upregulation of miR-584-5p significantly downregulated the expression of osteogenic differentiation genes such as RUNX2. This change inhibited ALP activity while lowering the degree of cell mineralization, indicating the ability of miR-584-5p upregulation to suppress PSC osteogenic differentiation. Notably, miR-584-5p plays important functions in mediating PSC osteogenic differentiation.

The biological functions of miRNAs include regulation of gene stability by binding mRNAs of downstream target genes[21]. We initially identified a sequence fragment of RUNX2 mRNA that could bind to miR-584-5p and then confirmed a binding site between miR-584-5p and RUNX2 through the DLR gene assay. We also confirmed that miR-584-5p could directly inhibit RUNX2 functions. RUNX2 is necessary for stem cell osteogenic differentiation[22]. The RUNX2 protein mediates the expression of many downstream genes, contributing to the OB phenotype[23]. RUNX2 upregulation also neutralized the regulatory effect of miR-584-5p overexpression on PSC osteogenic differentiation in our study. Therefore, miR-584-5p can affect hypoxia-induced PSC osteoblastic differentiation by regulating the RUNX2 functional pathway.

Figure 6 The interregulation of microRNA-584-5p/RUNX family transcription factor 2 on hypoxia-induced periosteal stem cell osteogenic differentiation. The hypoxic environment induces periosteal stem cells to undergo osteogenic differentiation by activating the RUNX family transcription factor 2 (RUNX2)-related pathway; however, miR-584-5p overexpression can inhibit osteogenic differentiation by downregulating RUNX2 expression. PSC: Periosteal stem cell.

However, this study still has limitations. Skeletal reprogramming to bone regeneration requires reactivating key transcription and growth factors. The local hypoxic microenvironment can regulate cytokine synthesis. The biological performance of stem cells under hypoxia can be different from that under normoxic conditions. Thus, other key factors in the process of hypoxia-induced PSC osteogenic differentiation still need to be discovered and studied.

CONCLUSION

We revealed that miR-584-5p inhibited hypoxia-induced PSC osteogenic differentiation *via* RUNX2 (Figure 6). PSCs have good osteogenic/cartilage differentiation potential. Our findings provide a mechanism for PSC osteogenic differentiation, and modulating miR-584-5p and miR-584-5p/RUNX2 might be a new strategy for bone repair and regeneration.

ARTICLE HIGHLIGHTS

Research background

Fracture healing is accompanied by obvious tissue hypoxia, it is worth exploring the effects of hypoxia on periosteal stem cells (PSCs) osteogenic differentiation. However, the underlying mechanisms needs to be clarified.

Research motivation

RUNX family transcription factor 2 (RUNX2) is a key regulator of osteogenic differentiation, and studies have found that RUNX2 has osteogenic activity in bone marrow mesenchymal stem cells, but its role in the osteogenic differentiation pathway of PSCs is still unclear.

Research objectives

This study aimed to determine the effect of hypoxia on PSCs, and the expression of microRNA-584-5p (miR-584-5p) and RUNX family transcription factor 2 in PSCs was modulated to explore the impact of the miR-584-5p/RUNX2 axis on hypoxia-induced osteogenic differentiation of PSCs.

Research methods

PSCs were extracted from 7-d-old C57BL/6J mice. Then, PSCs were stimulated them with hypoxia, and the characteristics and functional genes related to PSC osteogenic differentiation were measured.

Research results

Hypoxia promotes PSC osteogenic differentiation. Also, miR-584-5p upregulation affects hypoxia-induced PSC osteogenic differentiation and RUNX2 axis was targeted by miR-584-59. The upregulation of RUNX2 specifically reversed

the inhibitory effect of miR-584-5p overexpression on the hypoxia-induced PSC osteogenic differentiation.

Research conclusions

MiR-584-5p inhibited the hypoxia-induced PSC osteogenic differentiation *via* RUNX2.

Research perspectives

MiR-584-5p inhibits hypoxia-induced osteogenic differentiation of PSC through RUNX2, and PSC has good osteogenic/chondrogenic differentiation potential. These results indicate that miR-584-5p/RUNX2 axis may be a key target pathway for bone repair and regeneration.

FOOTNOTES

Co-corresponding authors: Lei Zhu and Nan Lu.

Author contributions: Lu JJ, Shi XJ, Fu Q, Li YC, and Zhu L contributed equally to this work. Lu JJ, Shi XJ, Fu Q, Li YC, and Zhu L designed the research study, contributed new reagents and analytic tools, analyzed the data, and wrote the manuscript; Lu JJ, Shi XJ, Fu Q, Li YC, Zhu L, and Lu N performed the research; and all authors have read and approve the final manuscript. First, the research was performed as a collaborative effort, and the designation of co-corresponding authorship accurately reflects the distribution of responsibilities and burdens associated with the time and effort required to complete the study and the resultant paper. This also ensures effective communication and management of post-submission matters, ultimately enhancing the paper's quality and reliability. Second, the overall research team encompassed authors with a variety of expertise and skills from different fields, and the designation of co-corresponding authors best reflects this diversity. This also promotes the most comprehensive and in-depth examination of the research topic, ultimately enriching readers' understanding by offering various expert perspectives. Third, Zhu L and Lu N contributed efforts of equal substance throughout the research process. The choice of these researchers as co-corresponding authors acknowledges and respects this equal contribution, while recognizing the spirit of teamwork and collaboration of this study. In summary, we believe that designating Zhu L and Lu N as co-corresponding authors of is fitting for our manuscript as it accurately reflects our team's collaborative spirit, equal contributions, and diversity.

ABOUT COVER

Editorial Board Member of *World Journal of Stem Cells*, Jyoti Anand Kode, MSc, PhD, Associate Professor, Senior Scientist, Principal Investigator, Kode Lab, Tumor Immunology and Immunotherapy Group, Facility for Immunomodulatory Activity Testing, Anti-Cancer Drug Screening Facility, Advanced Centre for Treatment, Research and Education in Cancer, Tata Memorial Centre, Homi Bhabha National Institute, Navi Mumbai 410210, Maharashtra, India.jkode@actrec.gov.in

AIMS AND SCOPE

The primary aim of *World Journal of Stem Cells* (*WJSC*, *World J Stem Cells*) is to provide scholars and readers from various fields of stem cells with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJSC* publishes articles reporting research results obtained in the field of stem cell biology and regenerative medicine, related to the wide range of stem cells including embryonic stem cells, germline stem cells, tissue-specific stem cells, adult stem cells, mesenchymal stromal cells, induced pluripotent stem cells, embryonal carcinoma stem cells, hemangioblasts, lymphoid progenitor cells, *etc*.

INDEXING/ABSTRACTING

The *WJSC* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Journal Citation Reports/Science Edition, PubMed, PubMed Central, Scopus, Biological Abstracts, BIOSIS Previews, Reference Citation Analysis, China National Knowledge Infrastructure, China Science and Technology Journal Database, and Superstar Journals Database. The 2023 Edition of Journal Citation Reports® cites the 2022 impact factor (IF) for *WJSC* as 4.1; IF without journal self cites: 3.9; 5-year IF: 4.5; Journal Citation Indicator: 0.53; Ranking: 15 among 29 journals in cell and tissue engineering; Quartile category: Q3; Ranking: 99 among 191 journals in cell biology; and Quartile category: Q3. The *WJSC*'s CiteScore for 2022 is 8.0 and Scopus CiteScore rank 2022: Histology is 9/57; Genetics is 68/325; Genetics (clinical) is 19/90; Molecular Biology is 119/380; Cell Biology is 95/274.

Abstract

Intervertebral disc (ID) degeneration (IDD) is one of the main causes of chronic low back pain, and degenerative lesions are usually caused by an imbalance between catabolic and anabolic processes in the ID. The environment in which the ID is located is harsh, with almost no vascular distribution within the disc, and the nutrient supply relies mainly on the diffusion of oxygen and nutrients from the blood vessels located under the endplate. The stability of its internal environment also plays an important role in preventing IDD. The main feature of disc degeneration is a decrease in the number of cells. Mesenchymal stem cells have been used in the treatment of disc lesions due to their ability to differentiate into nucleus pulposus cells in a nonspecific anti-inflammatory manner. The main purpose is to promote their regeneration. The current aim of stem cell therapy is to replace the aged and metamorphosed cells in the ID and to increase the content of the extracellular matrix. The treatment of disc degeneration with stem cells has achieved good efficacy, and the current challenge is how to improve this efficacy. Here, we reviewed current treatments for disc degeneration and summarize studies on stem cell vesicles, enhancement of therapeutic effects when stem cells are mixed with related substances, and improvements in the efficacy of stem cell therapy by adjuvants under adverse conditions. We reviewed the new approaches and ideas for stem cell treatment of disc degeneration in order to contribute to the development of new therapeutic approaches to meet current challenges.

Key Words: Mesenchymal stem cells; Intervertebral disc degeneration; Extracellular vesicles; Nucleus pulposus cells; Tissue regeneration

Core Tip: Mesenchymal stem cells have a strong self-renewal capacity and multidirectional differentiation potential, and their secreted vesicles promote regeneration of myeloid cells, increase extracellular matrix production, and alleviate inflammatory status. We reviewed the current relevant targets of stem cell exosomes for the treatment of intervertebral discs and the adjuvant tools used in conjunction with stem cell therapy. This will help to improve the therapeutic efficacy of stem cells and their exosomes, which will also contribute to development of more efficient treatment strategies and approaches for the restoration of disc degeneration.

INTRODUCTION

Intervertebral discs (IDs) have a complex structure with a unique internal environment. They contain nucleus pulposus cells, fibrous rings, and extracellular matrix (ECM)[1], Mesenchymal stem cells (MSCs), a class of pluripotent stem cells with the capacity for self-renewal and the ability to differentiate into a variety of tissues in vitro, were first mentioned in 1970 in guinea pig bone marrow[2]. Isolation and culture of MSCs from human bone marrow was first described in 1992. Since then, MSCs have been isolated and cultured from different human tissues, such as fat, amniotic membrane, gingiva, thymus, and placenta. MSCs from different sources differ in phenotype and function[3], for example, in solving the problem of ID withdrawal, umbilical cord-derived MSCs have a greater capacity for cell proliferation and osteogenesis than bone marrow-derived MSCs[4]. Stem cell therapy is designed to restore this balance of secreting exosomes and vesicles, mixing other substances to promote their differentiation into nucleus pulposus cells, regulating the content of the ECM, and when treated accordingly resisting interference by the harsh environment of the IDs[5,6]. These synergistic approaches provide new possibilities for stem cell therapy of (IDD)[7,8].

MIRNA IN EXOSOMES

For signal transduction pathways, many miRNAs play a crucial role in the growth and development of IDs. MSCs deliver miRNA-31 to the nucleus pulposus and upregulate the Wnt/β-catenin pathway to inhibit apoptosis of nucleus pulposus cells and regulate production of the ECM[9]. Similarly, under the stimulation of external effects, miRNA-21 can be transfected into mesenchymal cell exosomes, enhancing the ability of MSCs to differentiate into osteoblasts and promote vascular regeneration[10]. In other related studies, exosomes derived from bone marrow MSCs inhibited apoptosis and inflammation by upregulating autophagy through the protein kinase β/mammalian target of rapamycin signaling pathway[11]. MSCs-derived exosomes can also inhibit apoptosis of nucleus pulposus cells through miRNA-532-5p transport, demonstrating that this transport is also effective in IDD therapy[12].

Exosome-delivered exogenous miRNA-26a-5p can also be delivered to IDs, as METTL14 is highly expressed in patients with IDD, and the level of NOD-like receptor family pyrin domain containing 3 regulated by it leads to an increase in proinflammatory factors and apoptosis of nucleus pulposus cells. Exogenous miRNA-26a-5p inhibits METTL4 expression and thus treats disc degeneration[13]. It has also been found that miRNA-15a in exosomes can participate in the protein balance regulated by the phosphatidylinositol 3-kinase/protein kinase β and Wnt3a/β-catenin axes of IDD and downregulate matrix metalloproteinase-3. Therefore, type II collagen and aggrecan levels can be increased, along with differentiation of MSCs to nucleus pulposus cells[14,15]. BTB-and-CNC homologue 1 is a transcription inhibitor of heme oxygenase 1, which activates autophagy in nucleus pulposus cells. miRNA-155 in exosomes inhibits BTB-and-CNC homologue 1 expression by binding to the 3′ untranslated region of this transcription inhibitor, thereby treating IDD[16] (Table 1).

SPECIAL GENETICS AND MSCsS

Microtubules are an important part of the cytoskeleton that can regulate the assembly of proteins and the transport of substances within the cell. The stability of microtubules may extend their own life and ensure their normal basic functions. A decrease in transforming growth factor (TGF)-β1 is one of the possible factors involved in ID metamorphosis.

AKT: Protein kinase B; BACH1: BTB-and-CNC homologue 1; EZH2: Enhancer of zeste homolog 2; GPX4: Glutathione peroxidase 4; GREM1: Gremlin1; KLF5: Kruppel-like factor 5; lncRNA CAHM: Long non-coding RNA colorectal adenocarcinoma hypermethylated; MAPK: Mitogen-activated protein kinase; MDM2: Murine double minute 2; mTOR: Mechanistic target of rapamycin; NRF2: Nuclear factor erythroid 2-related factor 2; PI3K: Phosphoinositide 3-kinase; TRAF6: Tumor necrosis factor receptor associated factor 6.

Stabilization of microtubules can promote the expression of collagen type 2 and SRY-box transcription factor 9 (SOX9) in nucleus pulposus cells[17], which alleviates and reduces IDD. SOX9 and TGF-β1 can be used to transfect bone marrow MSCs, and MSCs can successfully differentiate into chondrocytes, promote formation of ECM, restore ID integrity, improve the inflammatory state, and reduce pain and further IDD. Similarly, MSCs and induced cartilage progenitor cells also increase the level of SOX9 and TGF-β1 during differentiation into nucleus pulposus cells, with the purpose of regulating inflammatory states and increasing differentiation[15,18,19].

METABOLITES AND MSCsS

MSCs-derived exosomes contain martrilin-3, which regulates the content of TGF-β1 in the IDs and differentiation of nucleus pulposus cells, promotes production of ECM, and inhibits release of inflammatory mediators[20]. Urolithin A was able to hinder hydrogen peroxide in inducing the aging of nucleus pulposus cells and destroying mitochondrial function. The silent information regulator 1/peroxisome proliferator-activated receptor gamma coactivator 1-alpha signaling pathway was activated by urolithin A *in vitro*, which protected the normal physiological function of mitochondria, linked nucleus pulposus cell aging, and increased the survival time of ECM while preventing further IDD [21,22]. The compression produced by the degenerated ID can promote reactive oxygen species production by nucleus pulposus cells and cause oxidative stress, which leads to further apoptosis of nucleus pulposus cells. MSCs-derived exosomes can inhibit apoptosis of myeloid cells caused by excessive oxidative stress and ameliorate compression-induced mitochondrial damage, which relieves the pain caused by IDD[23].

GEL-LOADED MSCsS

Heat-responsive hydrogel can act as a carrier of the extracellular vesicles of MSCs. These vectors deliver vesicles in a continuous box, which contains vasorin (a type I transmembrane glycoprotein regulated by hypoxia-inducible factor 1) to the disc environment. Vasorin can regulate the expression of relevant matrix metalloenzymes in the nucleus pulposus

cells through Notch1 signaling, enhance the ability of nucleus pulposus cells to proliferate, migrate, and anabolize, and inhibit the apoptotic cells to release inflammatory mediators, preventing further exacerbation of IDD. However, whether vasorin can promote the proliferation and differentiation of MSCs has not been confirmed[21]. Therefore, the strategy of helping stem cells to treat IDD through gels is worth further study.

The combination of heat-sensitive decellularized ECM hydrogels with adipocyte-derived MSCs exosomes does not damage the therapeutic activity of MSCs. The heat-sensitive dECM@exo hydrogel system produces gelation in situ to help MSCs differentiate into nucleus pulposus cells and maintains the content of ECM. This hydrogel also creates a suitable environment for the proliferation and differentiation of nucleus pulposus cells[22]. Previous studies have demonstrated transport of MSCs with hyaluronic acid and platelet-rich hydrogels. This method enhances MSCs activity, promotes IDs to increase keratin 19 gene expression, induces differentiation of MSCs into nucleus pulposus cells, and maintains the original ID height and normal physiological activity of the ID environment[23]. This situation leads to increased expression of keratin genes, and it has been demonstrated that porcine nucleus pulposus-rich cell matrix induces differentiation into nucleus pulposus cells by stimulating porcine chordate cells[24].

CIRCULAR RNA AND EXOSOMES

Circular RNA, such as circ_0050205 and circ_0072464, is transmitted through exosomes into nucleus pulposus cells to promote cell proliferation and ECM synthesis[24,25]. Endogenous long non-coding RNA colorectal adenocarcinoma hypermethylated delivery by MSCs exosomes inhibits M1-type macrophage polarization, which reduces nucleus pulposus apoptosis, the release of inflammatory factors, and a reduction in ECM to prevent further IDD[26]. In the MSCs exosomes, miRNA-217 is transferred to the ID and binds to the forkhead box O_3 promoter by targeting enhancer of zeste homolog 2. This maintains ID homeostasis and stimulates autophagy, thereby promoting collagen II and aggrecan content and inhibiting degradation of nucleus pulposus cells[15,27,28].

In other vesicles, overexpression of miRNA-194-5p inhibits the occurrence of disc degeneration by targeting tumor necrosis factor receptor associated factor 6. Lentiviral vectors have been shown to transport the growth and differentiation factor 5 (*GDF5)* gene and integrate it into the chromosomal genome of nucleus pulposus MSCs, which then express *GDF5* along with the MSCs genes. *GDF5* can also increase the level of proteoglycan and type II collagen[12]. If vesicles are subjected to hypoxia, miRNA-17-5p regulates the proliferation and differentiation of human nucleus pulposus cells and the proliferation and synthesis of ECM through the toll-like receptor 4 pathway, alleviating progression of IDD. This is more effective than the direct injection of MSCs into the ID[29].

During disc degeneration, the release of inflammatory factors also leads to a decrease in the uptake of extracellular vesicles. Vesicles prevent excess death of nucleus pulposus cells by delivering peroxidase 2 and reversing the decline in therapeutic effectiveness of MSCs due to tumor necrosis factor-α damage[30]. miRNA-129-5p in vesicles increases MSCs proliferation and differentiation into nucleus pulposus cells by blocking the lrg1-mediated p38 mitogen-activated protein kinase pathway and polarizing macrophages to the M1 phenotype, ultimately alleviating disc degeneration[31].

The combination of electromagnetic radiation and tissue engineering can stimulate the bone morphogenetic protein/Smad and mitogen-activated protein kinase-related p38 signaling pathway of ID stem cells to regulate differentiation of MSCs and increase their osteogenic capacity for the treatment of IDD[32]. Vesicles can also transmit exogenous miRNA-105-5p to revitalized nucleus pulposus cells, and transmit miRNA-140-3p to regulate the kruppel-like factor 5/N-cadherin/Murine double minute 2/Slug axis; all of which can slow down progression of IDD and restore normal ID physiological function[33,34]. miRNA-199a also exists in MSCs exosomes, which targets gremlin1 downregulation of the TGF-β pathway to prevent apoptosis of nucleus pulposus cells and inhibit progression of IDD[35].

MSCs MIXTURE

MSCs therapy alone has been shown to be effective in IDD, but its efficacy still falls short of expectations[36]. A recent study has shown that MSCs can be mixed with cell-free bioresorbable ultra-purified alginate gel for the treatment of IDD [37]. Such mixed preparations inhibit cell necrosis in the IDs and the release of inflammatory factors and consolidate the therapeutic effect of MSCs. Similarly, the combination of MSCs with in situ bioresorbable gel (dMD-001) produced the above therapeutic effects in IDD and was used after discectomy to prevent IDD[38]. Similarly, when MSCs are combined with coenzyme Q10 for the treatment of most ID lesions, it reduces oxidative stress in the ID, inhibits degradation of nucleus pulposus cells, and steadily improves the efficacy of IDD treatment[39].

Gelatin microparticles can also be mixed with MSCs, which can regulate the release of TGF-β1 and bone morphogenetic protein-2 to promote regeneration of osteochondral tissue[38]. When bone marrow MSCs are injected into the human body, leakage and decreased viability of MSCs occur, and gelatin colloidal hydrogels using nanostructures can effectively prevent these conditions. Under the load of gelatin colloid, MSCs promote regeneration of IDs and increase the number of nucleus pulposus cells between the IDs, ECM content, and the ID height[39]. Selective cell retention technology can concentrate MSCs and then the gelatin vector described above is used, which has been shown to enhance the effect of carrier materials on MSCs in the treatment of IDD[40].

A novel amphiphilic copolymer, polyethylene glycol-PAPO, fused with lipophilic kartogenin into a complex, is an esterase-reactive micelle that can carry MSCs and maintain their activity. When this combination is injected into IDs, it protects them from oxidative stress, activates autophagy of MSCs, regulates gene expression in the ECM, promotes ECM production, and increases ID height and hydration between the IDs[41]. Previous studies have found that collagen

hydrogel can promote differentiation of MSCs[42]. A more recent study found that biocompatible earthworm gel fused with MSCs induced their differentiation into nucleus pulposus cells in a targeted manner and improved their differentiation ability and efficiency[43]. For the expression of special genes such as *SOX9*, *ACAN* and *COL2* in nucleus pulposus cells, the study found that MSCs increased the expression of appeal genes after superoxide dismutase 2 and catalase processing, thereby reducing the deterioration of inflammatory states and promoting repair of ID tissue[44]. MSCs can also fuse with connective tissue growth factor and TGF-β3, transport polydopamine nanoparticles to the corresponding positions between the nuclei of the IDs, and finally induce MSCs to differentiate into nucleus pulposus cells and fibrous ring cells, reconstructing the mechanical environment of the IDs[45] (Figure 1).

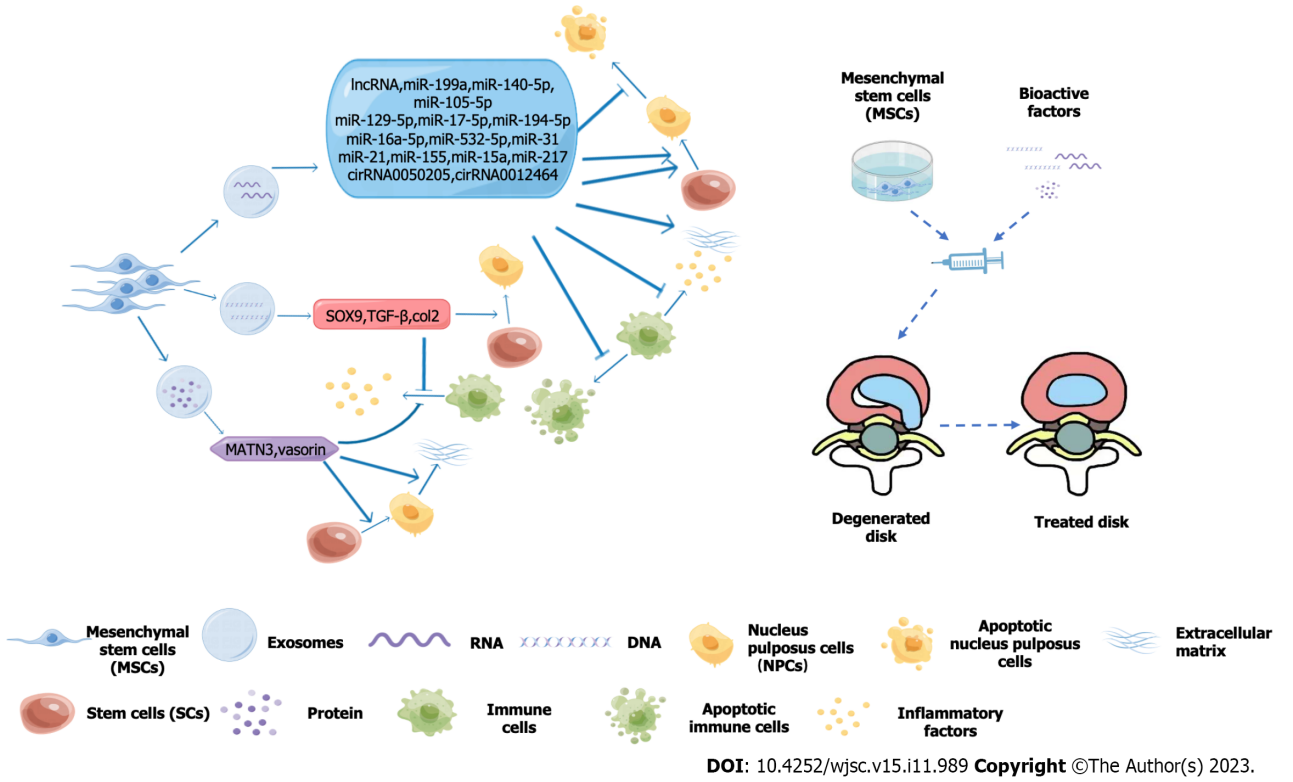
STIMULATION INDUCTION WITH MSCsS

Sustained mechanical stimulation is an innovative method of induced differentiation in MSCs, which can be continuously stimulated in a special microgel attached to them[46]. Repeated continuous stretching regulates transient receptor potential vanilloid 4 and Piezo1 channel proteins, regulates the value-added differentiation of MSCs into chondrocytes, regenerates the intercellular matrix, increases the water content in the IDs, and restores the normal structure of degenerated IDs[47]. In addition, formation of ECM has been found to correlate with tissue specificity. Therefore, the isolated nucleus pulposus cells and fiber rings are processed into corresponding hydrogels, which are specific in composition and space structure. Viscous fibrinogen-thrombin-genipin gels act specifically through the RhoA/LATS/YAP1 signaling pathway to direct differentiation of MSCs into nucleus pulposus cells or fibrous rings. This helps patients with IDD to reduce the number of nucleus pulposus cells and fibrous ring damage, which may provide a new direction for the treatment of IDD[46,48]. In the treatment of IDD and recovery of ID height by using bleomycin to induce MSCs fibrosis and by stimulating the TGFβ-SMAD2/3 signaling pathway, the gene expression of related collagen and ECM is maintained, thereby maintaining the height of the ID and increasing its ability to resist wear[49].

HARSH ENVIRONMENT OF THE ID

The treatment of IDD with MSCs has been widely applied, and the role of MSCs in delaying ID lesions has been proven [50]. However, the stability and efficacy of MSCs entering the ID are affected by the microenvironment of the ID. The IDs are located in an environment of nutritional deficiency, high tension, low pH, hypoxia, and high mechanical load[51]. In this environment with progression of IDD, most of the nucleus pulposus cells begin to die, resulting in a series of malignant chain reactions that lead to aggravation of oxidative stress, secretion of inflammatory substances, and aggravation of pain[5] (Figure 2).

Many studies have reported that the microenvironment in which cells are located has an important impact on their biological activity[52]. The low pH of IDs significantly inhibits acid-sensitive ion channels (ASICs), which are key receptors for extracellular protons in central and peripheral neurons related to IDD[53]. Due to the decreased activity of ASICs, MSCs differentiate into nucleus pulposus cells. When the number of nucleus pulposus cells decreases and production of ECM decreases, this increases the short-function peptide fragments that can recognize ASIC blockers, as ASICs can activate cell aging pathways, such as p53-p21/p27 and p16-Rb1 signaling factors, to induce apoptosis of nucleus pulposus cells[54]. ASIC blockers can significantly help stem cells overcome the acidic environment during IDD treatment, improve the ability of MSCs to proliferate and differentiate into nucleus pulposus cells, and help restore the normal state of IDs. $1,25(OH)_2D_3$-treated nucleus pulposus MSCs have better tolerance to the hypertonic and acidic microenvironment in which the IDs are located[55]. This reduces apoptosis of nucleus pulposus mesenchymal cells, restores the height between the IDs, and delays occurrence of IDD.



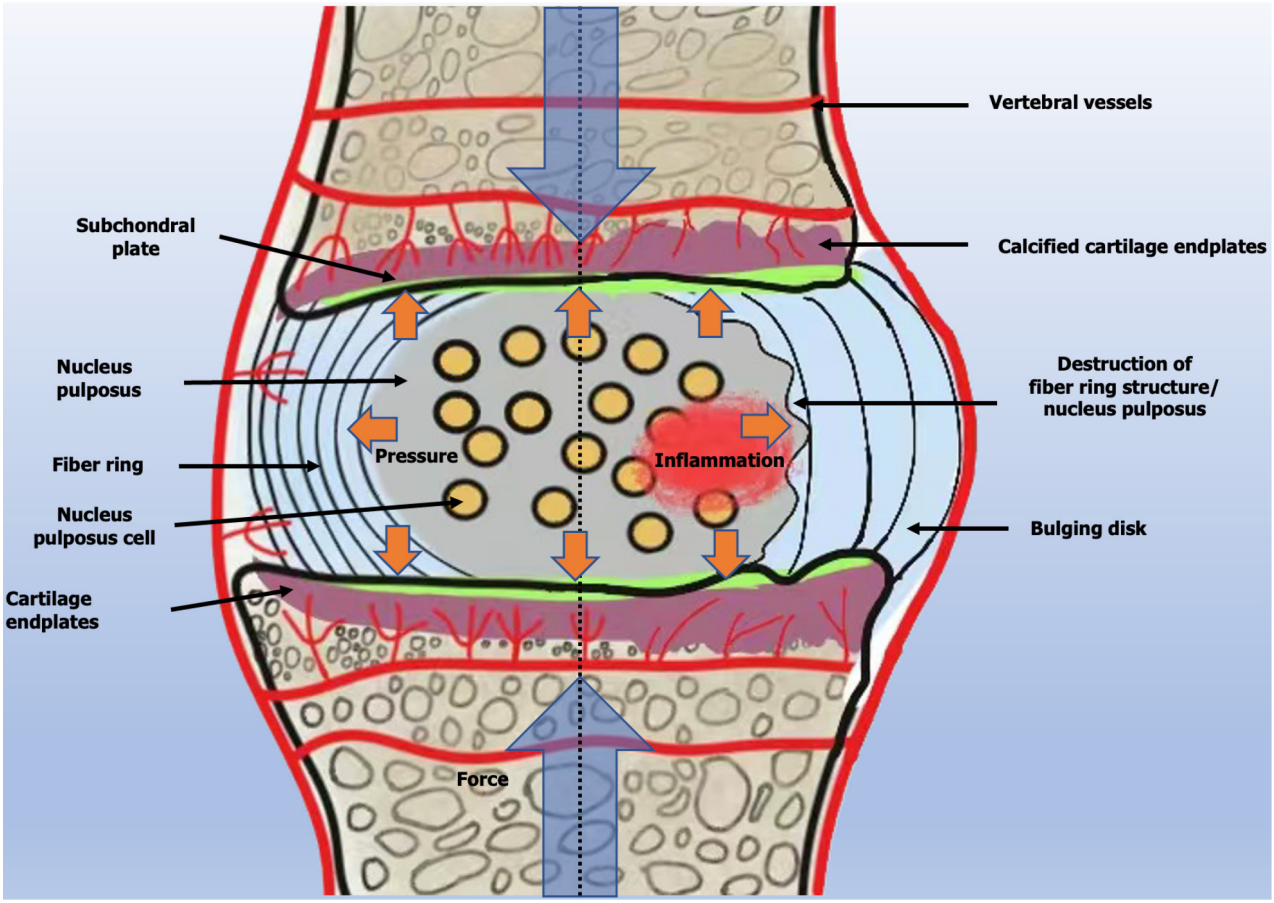
The large changes in pressure between the degenerative IDs leads to a decrease in the survival and differentiation of MSCs[56]. Medullary pulposus cell-derived hydrogels help MSCs differentiate into nucleus pulposus cells[57]. A recent study found that the current methanipine cross-linked decellularization nucleus pulposus hydrogel-like cell delivery system can transport MSCs to the IDs[58]. The changes in ID pressure ensure that MSCs differentiate into nucleus pulposus cells, repair the reduced ECM, and maintain ID height to delay IDD.

MSCs pretreated with lithium chloride can increase the adaptability of MSCs[59], as lithium chloride helps MSCs antagonize oxidative stress and protect nucleus pulposus cells by activating more extracellular signal-regulated kinase 1/2[60]. Extracellular signal-regulated kinase 1/2 plays a vital role in fighting inflammation, which is one of the main ways it works in the harsh environment of the IDs. This conduction pathway ultimately also helps to improve the ability of MSCs to reduce nucleus pulposus cell death, increase ECM production, and improve inflammatory status and IDD.

Significant progress has been made in the treatment of IDD by MSCs, but due to the harsh environment of the IDs[5], the therapeutic effect of MSCs is reduced due to the lack of oxygen in the environment[61]. However, it has been found that the differentiation of MSCs to chondrocytes under hypoxic conditions can be helped by the addition of leptin[62], which provides energy for cell differentiation through its dependent glycolysis.

FUTURE DIRECTIONS FOR STEM-CELL-BASED THERAPY

Stem cell-based therapy offers promise for disc degeneration. Related studies have applied exogenous stem cells such as



DOI: 10.4252/wjsc.v15.i11.989 **Copyright** ©The Author(s) 2023.

Figure 1 Mesenchymal stromal cell exosomes can treat disc degeneration through the appropriate target. The extracellular vesicles secreted by mesenchymal stromal cells can be enriched with a variety of RNAs, DNAs, and proteins that can be targeted to treat disc degeneration. They have been shown to have a corresponding effect in promoting stem cell differentiation into myeloid cells, increasing extracellular matrix production, and reducing the release of inflammatory factors (pain reduction). MATN3: Martrilin-3; SOX9: SRY-box transcription factor 9; TGF: Transforming growth factor.

MSCs to treat disc degeneration with promising results[63]. As the field of stem cells continues to be studied[64], the histology of the IDs becomes clearer, and studies targeting the way in which stem cells restore disc structure are becoming more advanced. How to improve the efficiency of stem cell therapy for disc degeneration and how to resist the harsh disc environment for stem cell therapy are the focus of research[65]. This also includes how to help stem cells restore the normal physiological structure of the IDs under hypoxia and lack of blood supply[5]. This is a new direction that needs to be developed in the field of stem cells.

Sometimes it is not the stem cell therapy that is ineffective, as the way MSCs are administered similarly affects their behavior once inside the body. Overall, factors such as injection point site, syringe, carrier material, and buffer can affect the therapeutic efficacy of stem cells. Different injection sites may lead to variations in reflux of the cellular injection fluid [66], and the syringe (needle size/shape) may lead to variations in the shear rate and shear stress of the cellular injection fluid, which can affect the viability of the injected cells. There are various challenges in the clinical application of stem cells, both for local administration and circulatory system administration[65]. Therefore, does the appropriate route of administration always guarantee the clinical outcome of MSCs? Obviously not. While performing stem cell therapy, we not only need to choose the appropriate delivery method but also need to consider the individualization of the patient at the same time. We need to consider all these factors together in order to make the most appropriate stem cell treatment plan, thus improving the efficiency of MSCs treatment[67].

Different sources of MSCs have their own advantages and disadvantages in terms of therapeutic efficacy, and one of the major dilemmas that needs to be explored further is the production of stable MSCs at the production site[68]. Current research allows us to understand the current potential of MSCs for cell transplantation, tissue engineering, and cell-based therapies to improve the lives of those affected by disc injuries[65]. This requires us to deepen our understanding of MSCs, refine therapeutic approaches, and address the challenges of translating research findings into clinical practice. We can do this by further optimizing the sources of MSCs[69], delivery methods and timing of interventions, as well as standardized protocols for isolation, expansion, and characterization. Conducting well-designed clinical trials will help evaluate the safety, efficacy, and long-term outcomes of MSCs-based therapies[70]. As the clinical application of MSCs continues to be studied globally, stem cell therapeutic drugs are gradually being introduced, and more research teams and medical institutions are involved, this will gradually deepen the clinical application of stem cell therapy and bring hope to the majority of lumbar disc patients.

Figure 2 The harsh environment in which the intervertebral discs are located. There is almost no vascular distribution in the intervertebral discs, and the nutrient supply relies mainly on the diffusion of oxygen and nutrients in the subendothelial vessels. The closer to the center of the nucleus pulposus, the lower the partial pressure of oxygen and the concentration of proteoglycans, which results in an extreme microenvironment, such as nutrient deficiency, high osmotic pressure, and acidic PH.

CONCLUSION

IDs have a complex structure with a unique internal environment. They contain nucleus pulposus cells, fibrous rings, and ECM, which are in a dynamic balance of self-renewal. Stem cells therapy is designed to restore this balance of secreting exosomes and vesicles, mixing other substances to promote their differentiation into nucleus pulposus cells, regulating the content of the ECM, and when treated accordingly resisting interference by the harsh environment of the IDs. These synergistic approaches provide new possibilities for stem cell therapy of IDD. They contain nucleus pulposus cells, annulus fibrosus, and ECM, and as the nucleus pulposus cells age and the ECM is lost, among other things, the disc becomes less stable. Stem cell therapy aims to restore the structure of the disc by secreting exosomes and vesicles, it mixes other substances to promote their differentiation into nucleus pulposus cells, regulates the content of the ECM and resists interference from the hostile environment of the IDs when treated accordingly. These synergistic approaches offer new possibilities for stem cell therapy for IDD. In the future, as people continue to explore the field of stem cells in disc therapy, stem cells will bring more hope to disc degeneration.

ORIGINAL ARTICLE

Basic Study

Hypoxia and inflammatory factor preconditioning enhances the immunosuppressive properties of human umbilical cord mesenchymal stem cells

Hang Li, Xiao-Qing Ji, Shu-Ming Zhang, Ri-Hui Bi

Specialty type: Cell and tissue engineering

Provenance and peer review: Unsolicited article; Externally peer reviewed.

Peer-review model: Single blind

Peer-review report's scientific quality classification

Grade A (Excellent): A
Grade B (Very good): B
Grade C (Good): C
Grade D (Fair): 0
Grade E (Poor): 0

Abstract

BACKGROUND

Mesenchymal stem cells (MSCs) have great potential for the treatment of various immune diseases due to their unique immunomodulatory properties. However, MSCs exposed to the harsh inflammatory environment of damaged tissue after intravenous transplantation cannot exert their biological effects, and therefore, their therapeutic efficacy is reduced. In this challenging context, an *in vitro* preconditioning method is necessary for the development of MSC-based therapies with increased immunomodulatory capacity and transplantation efficacy.

AIM

To determine whether hypoxia and inflammatory factor preconditioning increases the immunosuppressive properties of MSCs without affecting their biological characteristics.

METHODS

Umbilical cord MSCs (UC-MSCs) were pretreated with hypoxia (2% O_2) exposure and inflammatory factors (interleukin-1β, tumor necrosis factor-α, interferon-γ) for 24 h. Flow cytometry, polymerase chain reaction, enzyme-linked immunosorbent assay and other experimental methods were used to evaluate the biological characteristics of pretreated UC-MSCs and to determine whether pretreatment

affected the immunosuppressive ability of UC-MSCs in coculture with immune cells.

RESULTS

Pretreatment with hypoxia and inflammatory factors caused UC-MSCs to be elongated but did not affect their viability, proliferation or size. In addition, pretreatment significantly decreased the expression of coagulation-related tissue factors but did not affect the expression of other surface markers. Similarly, mitochondrial function and integrity were retained. Although pretreatment promoted UC-MSC apoptosis and senescence, it increased the expression of genes and proteins related to immune regulation. Pretreatment increased peripheral blood mononuclear cell and natural killer (NK) cell proliferation rates and inhibited NK cell-induced toxicity to varying degrees.

CONCLUSION

In summary, hypoxia and inflammatory factor preconditioning led to higher immunosuppressive effects of MSCs without damaging their biological characteristics.

Key Words: Mesenchymal stem cells; Umbilical cord; Preconditioning; Hypoxia, Inflammatory factors; Immune regulation

Core Tip: Mesenchymal stem cells (MSCs) are potential candidates for treating many immune diseases due to their unique immunomodulatory abilities, but low survival rates and weakened function after venous transplantation reduces their treatment potential. Therefore, our study reveals a combination pretreatment method based on *in vitro* hypoxia exposure and inflammatory factor treatment that simulates the harsh *in vivo* environment to protect MSCs from injury after intravenous transfusion and promote high immunosuppressive effects of MSCs.

INTRODUCTION

In recent years, mesenchymal stem cells (MSCs) have been shown to have a variety of biological properties, such as self-renewal[1], multilineage differentiation[2,3], immunomodulation functions[4,5], tissue repair effects[6], anti-aging and regeneration activity[7]. Furthermore, due to the abundance and ready availability of MSCs[8], they do not lead to rejection after allografting[9]; thus, MSCs have great economic value, importance in the cell therapy field and broad application prospects. Although many questions remain unanswered, the immunomodulatory effects of MSCs make them candidates for cell-based tissue repair and disease treatment[10-12]. For example, MSCs have great potential in treating graft-*versus*-host disease[13], cardiovascular disease[14,15], liver disease[16,17], systemic lupus erythematosus [18], autoimmune encephalomyelitis[19] and spinal cord injury[20]. Studies have shown that the immunomodulatory ability of MSCs is primarily regulated by cytokines and other soluble factors, including prostaglandin E2 (PGE2), tumor necrosis factor (TNF)-α-stimulated gene protein-6 (TSG-6), inducible indoleamine 2,3-dioxygenase (IDO), interleukin-10 (IL-10) and transforming growth factor-β1 (TGF-β1)[21]. They contribute to MSC-mediated immunosuppression by inhibiting natural killer (NK) cell proliferation, cytotoxicity and cytokine secretion[22], inhibiting T-cell proliferation, promoting regulatory T cell production[5,23,24], and inhibiting B-cell proliferation and immunoglobulin release[25,26].

It has been shown that when MSCs are injected into the body and migrate to damaged tissues or organs, the activation of innate immune cells leads to increased chemokine and cytokine release (such as TNF-α, IL-1α and IL-1β)[27] and is accompanied by the development of a harsh environment caused by hypoxic stress[28], leading to decreased MSC activity. Therefore, *in vitro* preconditioning culture developed through hypoxia exposure and inflammatory factor supplementation can effectively mimic the *in vivo* microenvironment. Preconditioning MSCs *in vitro* activates various signaling pathways, influencing the biological activities of MSCs *in vitro* and *in vivo*, thereby preparing them to survive the harsh environment to which they are subjected during *in vivo* administration and protecting them from damage[29, 30]. In addition, preconditioning can induce MSCs to secrete immunosuppressive molecules to target innate and adaptive immune cells, thereby mediating immune regulation by releasing water-soluble factors[31,32]. Therefore, pretreatment is an adaptive strategy to enhance the efficacy of MSC therapy, which can not only prolong MSC survival and function after transplantation but also endows them with higher immunomodulatory activity levels. Studies have shown that preconditioning with inflammatory factors such as TNF-α and interferon (IFN)-γ can increase MSC immunoregulatory ability[33, 34]. Hypoxia preconditioning is often used to enhance the therapeutic effect of MSCs by inducing the expression of survival genes, chemokines, growth factors, and angiogenic factors (such as vascular endothelial growth factor), enabling the MSCs to adapt to the harsh environment of damaged tissue[35,36].

Although different preconditioning methods can enhance cell properties and increase their function, many are accompanied by safety concerns. In contrast to the aforementioned positive outcomes of pretreatment, improper pretreatment can negatively impact cell morphology and function, damage mitochondrial function[37], and affect MSC surface marker expression. For example, previous studies have shown that tissue factor (TF/CD142) binds to coagulation factor VII/VIIB to initiate the exogenous coagulation system. The relative cell surface expression of TF is strongly correlated with procoagulant activity[38]. MSCs expressing surface TF show high coagulant activity and promote blood and plasma coagulation[39]. Therefore, high TF expression on MSCs increases the risk of thrombosis after intravenous injection[40-43].

We found that most studies have been focused on bone marrow- or adipose-derived MSCs (AD-MSCs), but human umbilical cord-derived MSCs (hUC-MSCs) are more suitable for clinical research and large-scale use because they are not associated with ethical problems, are abundant and highly proliferative. Therefore, we chose hUC-MSCs to study. To our knowledge, studies using a combination of hypoxia (2% O_2) exposure and inflammatory factor (IL-1β, TNF-α, IFN-γ) treatment to precondition hUC-MSCs are rare, and our study supports the current theory. Our aim was to simulate the injury-induced environment *in vitro* using a combination of hypoxia and inflammatory factor preconditioning to determine whether preconditioning increases the immunosuppressive properties of MSCs without affecting their biological characteristics.

MATERIALS AND METHODS

UC-MSC extraction and culture

Umbilical cord and cord blood were obtained with the approval of the Medical Ethics Committee of Shanxi Medical University and the consent of the donors, and experiments were performed in accordance with the Declaration of Helsinki.

Umbilical cord tissue was provided by one hospital, and the donors gave informed consent. After obtaining the umbilical cords, two veins and one artery were removed, and Wharton's jelly was cut into pieces and placed into a 10 cm^2 petri dish (Nice) with 5 mL of DMEM/F12 culture medium (Thermo Fisher Scientific, Waltham, MA, United States) containing 2.5% serum substitute (Shanxi Yinshi Cell Technology, Xian, China). Approximately 14 d later, the UC-MSCs were passaged, and P4 generation cells were used for experiments. UC-MSCs were cultured in a carbon dioxide incubator (Thermo Fisher Scientific) at standard oxygen tension with 5% carbon dioxide, 95% air, and 37 °C (*i.e.* normoxia). When UC-MSCs were 70%-80% confluent, a mixture of IFN-γ (R&D), TNF-α (R&D Systems, Minneapolis, MN, United States) and IL-1β (PeproTech, Cranbury, NJ, United States) was added to the medium. The cells were then immediately placed into a three-gas incubator (Panasonic, Osaka, Japan) with 2% O_2, 5% CO_2, and 93% N_2 at 37 °C (*i.e.* hypoxia). After 24 h, primed UC-MSCs (PUC-MSCs) were obtained. Therefore, our experiments were divided into two groups: Control (UC-MSCs) with no treatment and an experimental group (PUC-MSCs) in which cells were exposed to hypoxia and inflammatory factor supplementation.

Extraction and culture of peripheral blood mononuclear cells

Umbilical cord blood was obtained and centrifuged at 700 × *g* for 10 min and the plasma was extracted and placed into a water bath at 56 °C for 30 min for heat inactivation. The plasma was removed from the water bath, centrifuged at 850 × *g* for 10 min, and placed in a refrigerator at 4 °C for later use. The blood cells were resuspended in phosphate buffered saline (PBS) and mixed. The cell suspension was slowly added into a centrifuge tube containing Ficoll human peripheral blood lymphocyte isolation medium (Tianjin Haoyang Biological Products Technology Co., Ltd., Tianjin, China). After centrifugation at 400 × *g* for 30 min, white cells were extracted and washed twice with PBS. The cells [(1-2) × 10^6 cells/mL] were inoculated in peripheral blood mononuclear cell (PBMC) medium containing 10% of the heat-inactivated autologous plasma (Shanxi Yin Cell Technology Co., Ltd., Hebei, China) in the presence or absence of UC-MSCs or PUC-MSCs. The PBMCs were treated with 100 U/mL IL-2 (PeproTech). For coculture experiments, PBMCs were inoculated with UC-MSCs or PUC-MSCs at a PBMC/MSC ratio of 3:1 so that the cells were in direct contact, which is the appropriate proportion of cells to obtain MSC-mediated inhibition of PBMC proliferation.

NK cell extraction and culture

Umbilical cord blood was obtained and centrifuged at 700 × *g* for 10 min, and the plasma was placed into a water bath at 56 °C for 30 min for heat inactivation. The plasma was removed, centrifuged at 850 × *g* for 10 min, and placed into a refrigerator at 4 °C for later use. The blood cells were resuspended in PBS, mixed, and incubated at room temperature for 20 min with RosetteSepT NK Enrichment Cocktail. The cell suspension was slowly added into a centrifuge tube containing Ficoll human peripheral blood lymphocyte isolation medium (Tianjin Haoyang Biological Products Technology Co., Ltd.). After centrifugation at 400 × *g* for 30 min, white cells were extracted and washed twice with PBS. The cells [(1-2) × 10^6 cells/mL] were inoculated into NK medium containing 10% heat-inactivated autologous plasma (Shanxi Yin Cell Technology Co., Ltd.). NK cells were cultured with or without UC-MSCs or PUC-MSCs and treated with 100 U/mL IL-2 (PeproTech).

Cell survival rate and cell size detection

Double fluorescence acridine orange/propidium iodide (AO/PI) cell viability counting was performed. The AO/PI reagent consists of the DNA-binding dye AO, which fluoresces green, and the DNA-binding dye PI, which fluoresces red.

AO can pass through a complete cell membrane and enter the nuclei of all cells (living and dead cells), emitting green fluorescence. PI can only pass through an incomplete cell membrane and enter the nuclei of dead cells, resulting in red fluorescence. After mixing 10 μL of cell suspension with 10 μL of AOPI reagent, the viability and size of the cells in suspension were measured by a Countstar Rigel S2 (Shanghai Rui Yu Biotech, Shanghai, China).

Monoclonal antibodies and cytofluorometric analysis

Flow cytometry analysis of UC-MSCs and PUC-MSCs was performed. The cells were resuspended in staining buffer after centrifugation, and the corresponding antibodies were added to the buffer. Cells were incubated for 30 min, neutralized and washed 1-2 times. The UC-MSC or PUC-MSC antigen markers (BD Biosciences, San Jose, CA, United States) were CD105-APC, CD90-FITC, CD73-PE, CD142-PC5.5, CD29-PE, CD34-PE, CD14-PE, CD45-APC, human leukocyte antigen (HLA)-ABC-APC, CD47-APC, CD166-PE, CD44-PE, and CD31-APC.

Reactive oxygen species measurement

Mitochondrial reactive oxygen species (ROS) production was measured by flow cytometry (Beckman Coulter Life Sciences, Brea, CA, United States) using a ROS detection kit (Biyuntian, Shanghai, China). 2,7-dichlorodihydrofluorescein diacetate (DCFH-DA) was diluted in serum-free medium at 1:1000 to a final concentration of 10 μmol/L. After collection, 1 million to 20 million/mL cells were suspended in diluted DCFH-DA and incubated in an infrared carbon dioxide incubator (Thermo Fisher Scientific) at 37 °C for 20 min. The cells were turned over and mixed every 3-5 min to ensure that the probe was in full contact with the cells. The cells were washed with serum-free cell culture solution three times to fully remove excess DCFH-DA. Finally, the results were detected by flow cytometry.

Measurement of mitochondrial membrane potential

Mitochondrial membrane potential (MMP) was detected using MMP detection reagent JC-1 (Beyotime, Jiangsu, China). The culture medium was removed and the cells were washed twice with PBS. JC-1 staining solution (1 mL) was added, mixed thoroughly, and incubated with cells in an infrared carbon dioxide incubator (Thermo Fisher Scientific) at 37 °C for 20 min. During the incubation period, JC-1 staining buffer (1×) was prepared by adding approximately 4 mL distilled water to approximately 1 mL JC-1 staining buffer (5×), and the buffer was placed in an ice bath. After incubation at 37 °C, the supernatant was removed, and the cells were washed twice with JC-1 staining buffer (1×). Finally, 2 mL of the cell culture solution was added. Images were obtained with an inverted fluorescence microscope (CKX53; Olympus, Tokyo, Japan).

Real time-polymerase chain reaction

TRIzol (Invitrogen, Waltham, MA, United States) was used to lyse the cells, total RNA was extracted, and an ultratrace nucleic acid protein detector (Shanghai Jiapeng Materials, Shanghai, China) was used to determine RNA concentration. mRNA expression levels were quantitatively analyzed on a real-time polymerase chain reaction (RT-PCR) instrument (Bio-Rad, Hercules, CA, United States) using a One Step TB Green PrimeScript PLUS RT□PCR Kit (Takara Bio Inc., Shiga, Japan) to measure the levels of the following transcripts: Catalase, Istanniocalcin-1 (STC1), hemeoxygenase-1 (HOMX1), B-cell lymphoma 2-associated protein (Bax), B-cell lymphoma 2 (Bcl2), silencing information regulator 2-related enzyme 1 (SIRT1), P53, P16, P21, PGE2, kynurenine (KYN), IDO, IL-1 receptor antagonist (IL-1ra), cyclooxygenaese-2 (COX2), IL-10, TGF-β1, HLA-G5, TSG-6, ligands for programmed cell death 1 (PD-L1). All primer sequences for qRT-PCR are listed in Table 1.

Enzyme-linked immunosorbent assays

UC-MSCs and PUC-MSCs supernatants were collected and centrifuged at 210 × *g* for 5 min, and the suspended cells were removed and stored at -80 °C. The protein levels of PGE2, TSG-6, IDO, IL-10 and TGF-β1 secreted by UC-MSCs and PUC-MSCs were measured by enzyme-linked immunosorbent assay (ELISA) kits (Wuhan Eliret Biotechnology Co, Ltd., Wuhan, China). Finally, the optical density (OD) value of each well was measured on the basis of enzyme label (Thermo Fisher Scientific) absorption at 450 nm.

Annexin V-FITC apoptosis detection

UC-MSC and PUC-MSC suspensions were obtained and washed twice with PBS. Annexin V-FITC apoptosis reagent (Biyuntian) was added and incubated with the cells at room temperature for 10-20 min in the dark, and flow cytometry was performed. Annexin V-FITC emits green fluorescence, and PI emits red fluorescence.

β-galactosidase (SA-β-gal) activity detection

The cell culture medium was removed, the cells were washed once with PBS, and 1 mL/well β-galactosidase (SA-β-gal) staining fixation solution (Solarbio, Beijing, China) was added and incubated at room temperature for 15 min. Fixative was removed, and the cells were washed 3 times with PBS for 3 min each. The PBS was removed, and 1 mL of staining solution was added to each well. The plate was incubated at 37°C overnight and sealed with plastic wrap to prevent evaporation. The positive expression of blue particles was observed under an inverted microscope (CKX53; Olympus), and the number of positive cells per 100 cells was quantified. Each experiment was repeated three times.

Proliferation experiment

NK cells were cultured in the presence or absence of UC-MSCs or PUC-MSCs for 3 d at a 3:1 ratio. The cells were prelabelled with carboxyfluorescein diacetate succinimidyl ester (CFSE) dye (BioLegend, San Diego, CA, United States)

and the fluorescence intensity of CFSE was measured by flow cytometry.

Cell growth and proliferation

UC-MSCs and PUC-MSCs were collected for DNA extraction and DNA concentration was determined by an ultramicro nucleic acid protein detector (Shanghai Jiapeng Materials) to evaluate the cell proliferation rate. PBMCs were cultured in the presence or absence of UC-MSCs or PUC-MSCs at a ratio of 3:1. The number of cells (Countstar Rigel S2; Shanghai Rui Yu Biotech) was counted by a cell imaging analyzer for 5 consecutive days and the growth curve was plotted.

Cytotoxicity of K562 target cells

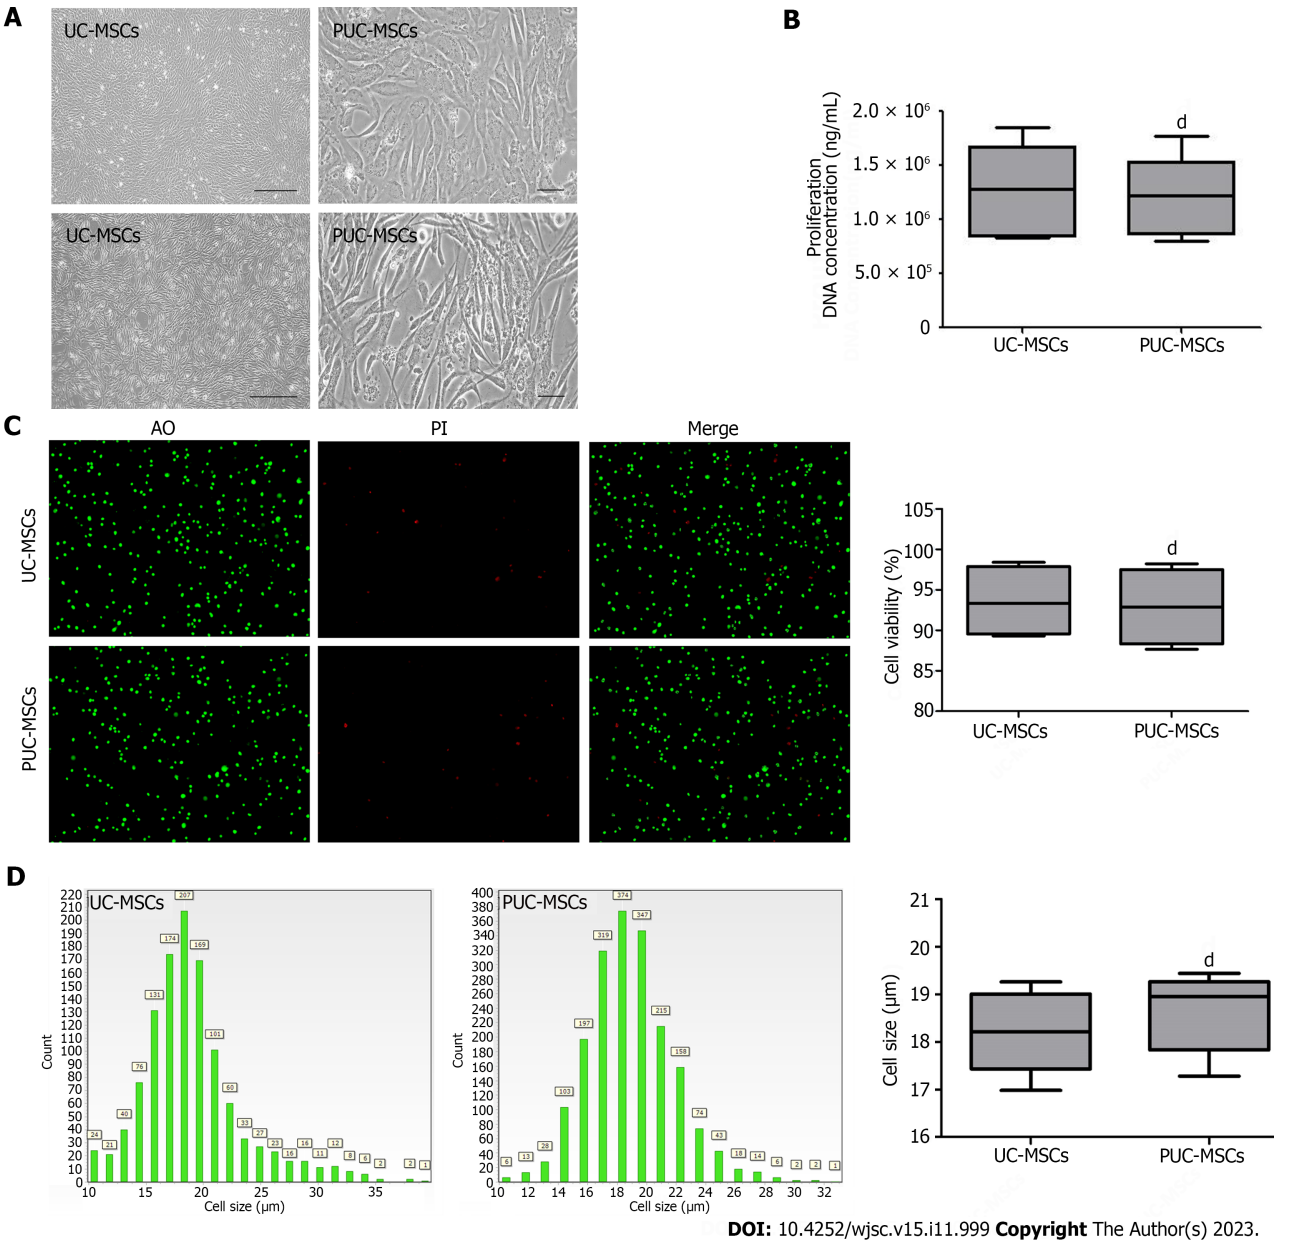
NK cells were cultured alone or in direct contact with MSCs (NK: UC-MSCs or PUC-MSCs = 3:1 ratio) for 72 h. NK cells were then collected and cocultured with CFSE-stained (Biolegend) K562 target cells for 4 h at the effective target ratio of 1:5. All cells were collected and washed twice with PBS. K562 cell apoptosis was analyzed by PI staining (Biyuntian), and the fluorescence intensity was measured by flow cytometry.

Statistical analysis

SPSS 19.0.0 and GraphPad Prism 7 (GraphPad Prism, La Jolla, CA, United States) statistical software were used for data processing. All experimental data are expressed as the mean ± SD. A *t* test was performed to compare two datasets, and $P < 0.05$ was considered statistically significant.

RESULTS

Effects of hypoxia and inflammatory factor pretreatment on UC-MSC morphology, size, proliferation and viability



We evaluated the effects of hypoxia and inflammatory factor pretreatment on UC-MSC morphology, vitality and size. The morphological differences between UC-MSCs and PUC-MSCs were compared under a microscope when cell confluency reached 80% to 90%. Untreated UC-MSCs appeared as either short rods or long spindles in an adherent state and were arranged in a spiral pattern. After 24 h of exposure to hypoxia and inflammatory factors, cell morphology changed from short and rod-like to thin and elongated (Figure 1A), but the proliferation rate did not change (Figure 1B). We further evaluated the effects of pretreatment on UC-MSC viability and size using AOPI staining and a cell imaging analyzer. UC-MSC viability (Figure 1C) in suspension was 93.59% ± 3.87% ($n = 5$) and the mean diameter (Figure 1D) was 18.216 ± 0.78 μm ($n = 5$), while PUC-MSC viability (Figure 1C) was 92.89% ± 4.13% ($n = 5$) and the mean diameter (Figure 1D) was 18.628 ± 0.76 μm ($n = 5$). These results showed that pretreated MSCs became elongated, the measured viability slightly decreased ($P = 0.84$), and the cells were slightly enlarged ($P = 0.47$), but these differences were not statistically significant.

MSC surface marker expression

We further evaluated whether preconditioning altered the cellular phenotype by analyzing MSC surface marker expression by flow cytometry. UC-MSCs (Figure 2A) and PUC-MSCs (Figure 2B) from three donors were positive for CD105, CD90, CD73, CD29, CD166, CD47 and HLA-ABC surface expression and negative for CD31, CD45, CD14 and CD34. The results showed that surface marker expression was consistent between PUC-MSCs and UC-MSCs. Interestingly, CD142 expression (59.3%) (Figure 2B) was significantly lower in PUC-MSCs compared to UC-MSCs (99.6%) (Figure 2A).

Effect of pretreatment on UC-MSC mitochondrial function

ROS play key roles in the proapoptotic signaling cascade, and excess ROS attacks the mitochondrial membrane and loss of MMP, leading to MSC apoptosis[44]. Therefore, we used flow cytometry to examine the effect of MSC pretreatment on ROS production. Intracellular ROS levels showed a three-fold increase in DCFH-DA fluorescence intensity in PUC-MSCs compared to untreated UC-MSCs (Figure 3A), but all the effects were within the range of values obtained in positive controls. STC1, catalase and HOMX1 expression levels increased (Figure 3B), indicating that the antioxidant capacity of the cells was increased and that mitochondrial ROS removal was increased, enhancing antioxidant defense effects and preventing ROS-induced DNA damage. Maintaining a stable MMP (Ψm) is essential to ensure efficient ROS clearance and prevent apoptosis or other stress-related events caused by excessive ROS[45]. Therefore, we further determined whether hypoxia and inflammatory factor preconditioning induced MMP dysfunction in UC-MSCs. We used the sensitive fluorescent probe JC-1 to evaluate the effect of pretreatment. We determined whether the membrane potential changed in UC-MSCs by measuring a change in JC-1 red fluorescence to green fluorescence. Microscopically, untreated UC-MSCs showed a normal MMP, as shown by red fluorescence staining with JC-1 (Figure 3C). Neither the red and green fluorescence nor the MMP was significantly different between PUC-MSCs and UC-MSCs. We further measured the

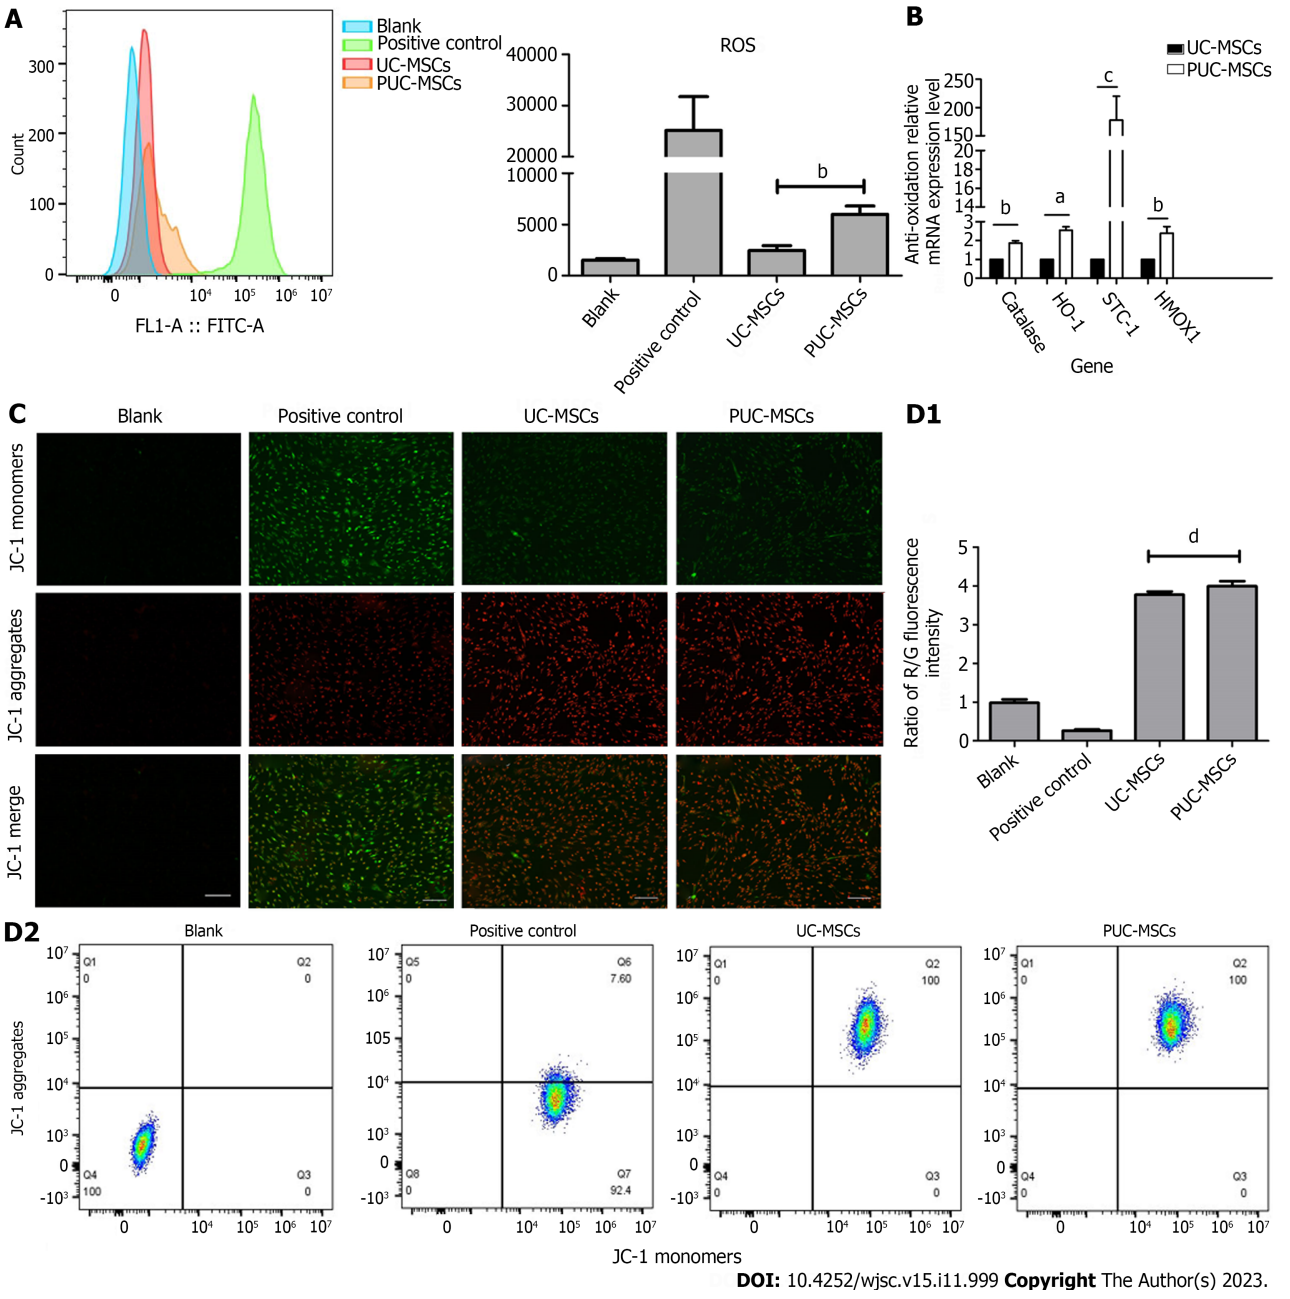
Figure 1 Morphology, viability, proliferation, and size of mesenchymal stem cells. A: Representative micrographs showing umbilical cord mesenchymal stem cells (UC-MSCs) and primed umbilical cord mesenchymal stem cells (PUC-MSCs). Microscopy observation of cell morphology revealed that UC-MSCs were elongated after hypoxia and inflammatory factor pretreatment (Bar = 200 μm); B: The DNA concentration was measured by an ultramicro nucleic acid protein detector. The DNA concentration of PUC-MSCs was not significantly different from that of UC-MSCs, and pretreatment had no effect on their proliferation; C: Cell viability was determined by an acridine orange (AO) propidium iodide (PI) staining cell image analyzer, and no significant difference between UC-MSCs and PUC-MSCs was observed; D: Cell size was determined with a cell imaging analyzer, and the sizes of the UC-MSCs and PUC-MSCs were comparable. $^{d}P > 0.05$.

JC-1 red/green fluorescence ratio by flow cytometry and confirmed our microscopy results (Figure 3D). These results showed that mitochondrial function in UC-MSCs was not damaged by hypoxia and inflammatory factor pretreatment.

Hypoxia and inflammatory factor preconditioning induces UC-MSC apoptosis and senescence



Bax expression decreased and Bcl2 and SIRT1 expression increased after pretreatment, suggesting that the anti-apoptotic capacity increased after pretreatment (Figure 4A). The expression of the senescence-related genes P53, P16 and P21 was upregulated by pretreatment (Figure 4B). We analyzed apoptosis by Annexin V-PI staining and flow cytometry. We compared the proportion of cells that were positive for both Annexin V-FITC and PI (necrotic cells), and the apoptotic index of PUC-MSCs (15.08% ± 4.11%) significantly increased (Figure 4C) compared to UC-MSCs (6.22% ± 3.03%). Next, we investigated the effect of preconditioning on cell senescence. SA-β-gal has been the most widely accepted senescence marker since Dimri first published its use in 1995[46], so we performed SA-β-gal staining to evaluate cell senescence ratios. SA-β-gal levels increased in PUC-MSCs (14.83% ± 1.57%) compared to UC-MSCs (4.83% ± 1.34%) (Figure 4D). These results suggest that hypoxia and inflammatory factor preconditioning not only induces UC-MSC apoptosis and senescence but also increases anti-apoptotic factor levels.

Figure 3 Mitochondrial function. A: Reactive oxygen species (ROS) levels in umbilical cord mesenchymal stem cells (UC-MSCs) and primed UC-MSCs (PUC-MSCs) were analyzed by flow cytometry. The fluorescence intensity of 2,7-dichlorodihydrofluorescein (DCFH-DA) in PUC-MSCs increased by 3-fold compared to UC-MSCs; B: The expression of the antioxidant-related genes catalase, stanniocalcin-1 (STC1), and hemeoxygenase-1 (HOMX1) was increased; C: Representative image showing the mitochondrial membrane potential (MMP) of mesenchymal stem cells stained with JC-1. The red fluorescence of potential-dependent JC-1 aggregation in each group and the green fluorescence of the JC-1 monomer in the cytoplasm after depolarization of the mitochondrial membrane were observed. Fluorescence microscopy showed no significant difference in red and green fluorescence between UC-MSCs and PU-MSCs; Bar = 200 μm; D: Flow cytometry was used to detect the red and green fluorescence of the JC-1 probe in UC-MSCs and PUC-MSCs. There was no difference in the ratios of red and green fluorescence. [a] $P < 0.05$; [b]$P < 0.01$; [c]$P < 0.001$; [d]$P > 0.05$.

Hypoxia and inflammatory factor preconditioning enhances UC-MSC immunosuppressive properties

MSCs are pluripotent stem cells that have been shown to hold promise in tissue regeneration due to their ability to self-renew and differentiate and their broad immunomodulatory properties[1-5]. We evaluated whether UC-MSC immunomodulatory activities increased after pretreatment. qRT-PCR analysis revealed that the expression of PGE2, IDO, KYN, COX2, IL-10, TGF-β1, TSG-6, HLA-G5, and PD-L1 increased in PUC-MSCs compared to untreated UC-MSCs. IL-1ra expression was slightly elevated, but the difference was not statistically significant (Figure 5A). Because paracrine activity

Figure 4 Effects of pretreatment on apoptosis and senescence in mesenchymal stem cells. A: Apoptosis-related gene analysis showed that the expression of B-cell lymphoma 2 (BCL-2)-associated protein (Bax) was decreased and the expression of Bcl2 and silencing information regulator 2-related enzyme 1 (SIRT1) was increased after hypoxia and inflammatory factor pretreatment; B: Expression of P53, P16 and P21 was upregulated after hypoxia and inflammatory factor pretreatment; C: Umbilical cord mesenchymal stem cells (UC-MSCs) and primed UC-MSCs (PUC-MSCs) were stained with Annexin V-FITC apoptosis assay kit reagents and apoptotic cells were detected by flow cytometry. The results showed that the apoptosis index of PUC-MSCs increased; D: Representative images of β-galactosidase (SA-β-gal) staining and quantitative analysis of positive SA-β-gal staining. Compared with that of the UC-MSCs, the number of SA-β-gal-positive PUC-MSCs was significantly increased; Bar = 100 μm. $^{a}P < 0.05$; $^{b}P < 0.01$; $^{c}P < 0.001$.

is a key mechanism underlying MSC effects, we compared the bioactive factor secretion levels in PUC-MSCs and untreated UC-MSCs. We assessed MSC paracrine function by measuring the protein levels of immunosuppression-related soluble factors released into the culture supernatant, including IDO, PGE2, TGF-β1, TSG-6, and IL-10 by ELISAs. IDO, PGE2, TGF-β1 and TSG-6 levels significantly increased in the PUC-MSC supernatant, while IL-10 levels slightly increased but did not reach statistical significance (Figure 5B). In summary, these data strongly suggest that UC-MSC preconditioning with hypoxia and inflammatory factors upregulates the expression of soluble immunomodulatory factors and enhances their immunomodulatory activity.

Hypoxia and inflammatory factor preconditioning increases UC-MSC immunosuppressive properties

Considering the high expression of immunomodulatory molecules in PUC-MSCs, we evaluated their immunosuppressive capacity. We compared UC-MSC and PUC-MSC immunosuppressive capacity using PBMC and NK cell proliferation assays by analyzing growth dynamics of PBMCs cultured alone, with UC-MSCs or with PUC-MSCs (Figure 6A). Both UC-MSCs and PUC-MSCs significantly inhibited PBMC proliferation compared to PBMCs cultured alone. However, PUC-MSCs had a stronger inhibitory effect on PBMC proliferation, further indicating that pretreatment enhanced UC-MSC immunosuppressive abilities. We further investigated MSC-mediated inhibition of NK cell proliferation in the presence of the two MSC populations. We cultured CFSE-stained NK cells in the presence of IL-2 alone or with UC-MSCs or PUC-MSCs and analyzed CFSE fluorescence intensity by flow cytometry after 3 d. The proliferation rate of NK cells was reduced in cocultures with UC-MSCs or PUC-MSCs compared to NK cells cultured alone, but the PUC-MSC group

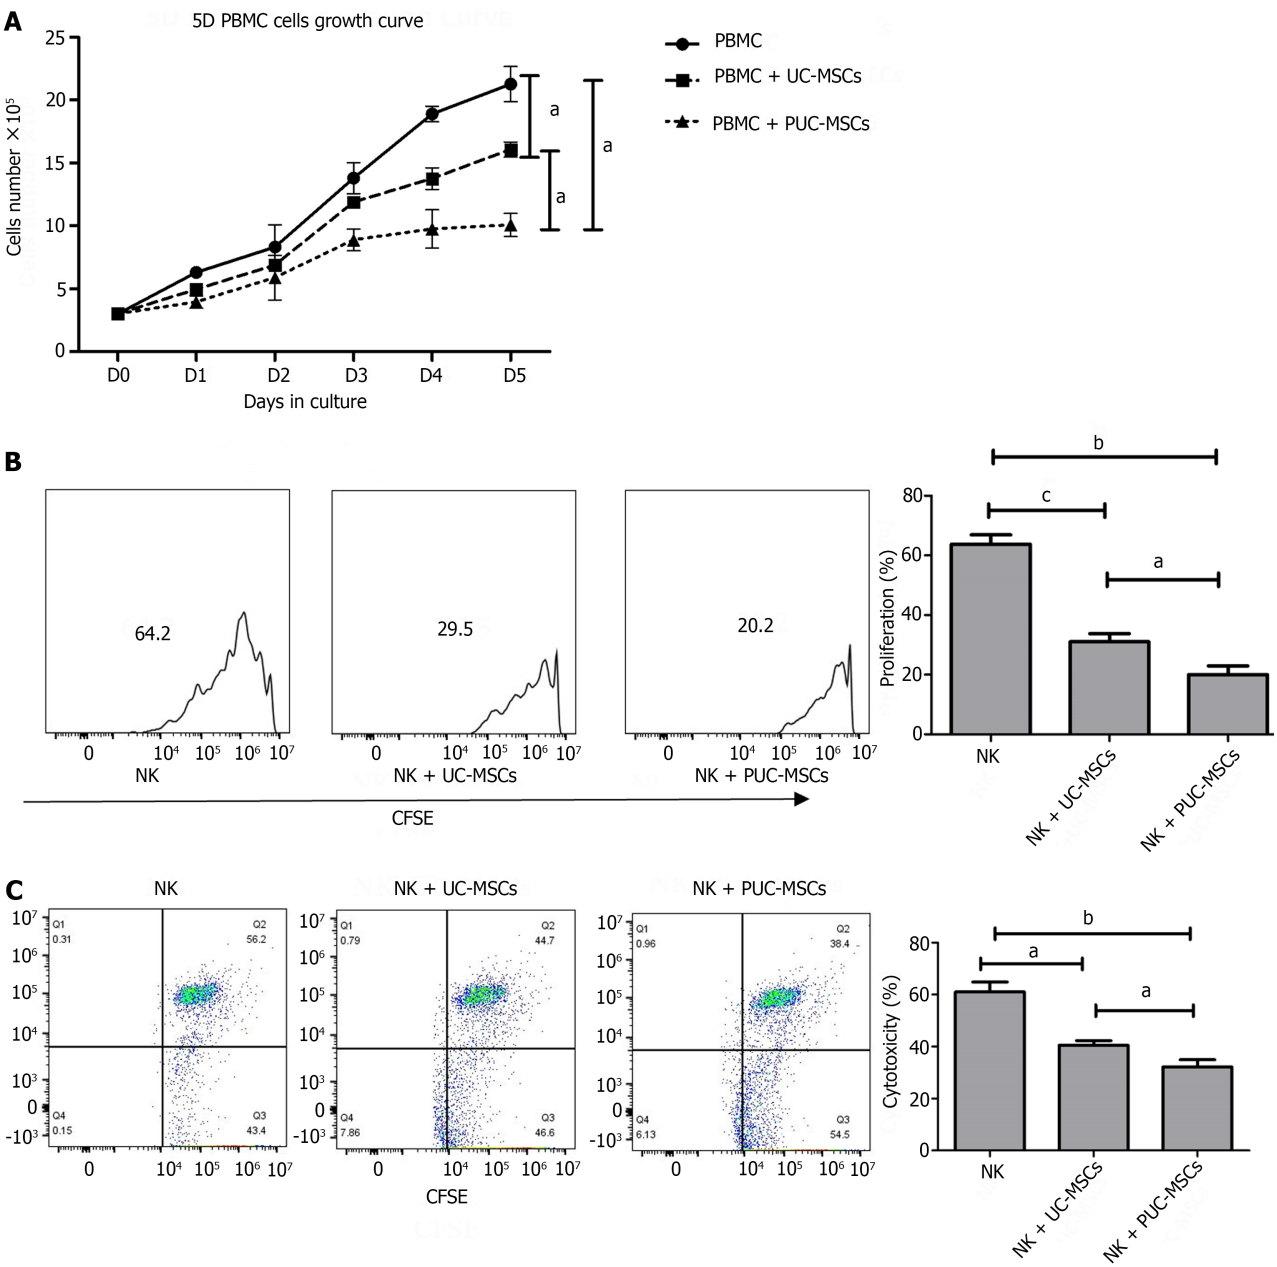

Figure 5 Relative expression of immunomodulatory genes and proteins in umbilical cord mesenchymal stem cells after pretreatment. A: Gene expression levels of umbilical cord mesenchymal stem cells (UC-MSCs) and primed UC-MSCs (PUC-MSCs) were analyzed by quantitative real-time polymerase chain reaction. Expression levels of prostaglandin E2 (PGE2), kynurenine, idoleamine-2,3-dioxygenase (IDO), cyclooxygenaese-2 (COX2), interleukin-10 (IL-10), transforming growth factor-beta 1 (TGF-β1), human leukocyte antigen-G5 (HLA-G5), tumor necrosis factor-α-induced protein-6 (TSG-6) and ligands for programmed cell death 1 (PD-L1) were all increased after hypoxia and inflammatory factor preconditioning. IL-1 receptor antagonist (IL-1ra) was not significantly different between the two groups; B: Levels of immunoregulatory proteins in UC-MSCs and PUC-MSCs were detected by enzyme-linked immunosorbent assay. After hypoxia and inflammatory factor pretreatment, the protein levels of IDO, PGE2, TGF-β1 and TSG-6 were increased, while the expression of IL-10 was not significantly different, as determined *via* three independent experiments. $^{a}P < 0.05$; $^{b}P < 0.01$; $^{c}P < 0.001$; $^{d}P > 0.05$.

exerted stronger inhibitory effects on NK cells compared to UC-MSCs (Figure 6B).

Finally, we evaluated the effect of UC-MSC pretreatment with hypoxia exposure and inflammatory factor treatment on NK cell cytotoxic activity. NK cells were cultured alone or with UC-MSCs/PUC-MSCs at a 3:1 ratio for 72 h, then collected and incubated with CFSE-stained K562 target cells at an effective target ratio (E:T = 1:5) for 4 h. The cells were collected, and K562 cell apoptosis was analyzed by PI staining. The results showed that NK cells cocultured with UC-MSCs or PUC-MSCs had lower cytolytic activity, and the inhibition of NK cell-mediated cytotoxic activity was higher with PUC-MSCs than UC-MSCs (Figure 6C).

DISCUSSION

Intravenous injection of MSCs has been increasingly used in clinical research and has shown great potential in the treatment of various diseases. Because of their immunomodulatory functions, MSCs have become a promising alternative treatment for inflammatory diseases. MSCs come from a wide range of sources. Currently, the most studied MSCs are derived from bone marrow and adipose tissue, followed by those from umbilical cord tissue[47]. Compared with those from other sources, umbilical cord-derived MSCs are abundant, easy to collect, genetically stable, and do not readily

Figure 6 Detection of the immunomodulatory function of umbilical cord mesenchymal stem cells after preconditioning. A: Peripheral blood mononuclear cells (PBMCs) alone or directly exposed to umbilical cord mesenchymal stem cells (UC-MSCs/primed UC-MSCs) for 5 d in a 3:1 ratio. The number of PBMCs in three groups was measured daily and the growth curve was plotted; B: Carboxyfluorescein diacetate succinimidyl ester (CFSE)-stained natural killer (NK) cells were cultured alone or cocultured with UC-MSCs/PUC-MSCs at a 3:1 ratio for 72 h. NK cells were harvested, and the fluorescence intensity of CFSE was measured by flow cytometry to measure the proliferation rate of NK cells; C: NK cells were collected and incubated with CFSE-stained K562 target cells for 4 h at an effector ratio (E:T = 1:5). Effector cell (NK cell)-mediated cytotoxicity of K562 cells was analyzed by flow cytometry. $^{a}P < 0.05$; $^{b}P < 0.01$; $^{c}P < 0.001$; $^{d}P > 0.05$.

mutate. Therefore, umbilical cord MSCs have broad application prospects in the cell therapy field[48-50]. Therefore, we focused on UC-MSCs in this study.

In addition to the effects of their origin, MSCs exhibit decreased biological performance when subjected to vein transplantation and exposure to the harsh inflammatory environment of damaged tissue[29]. Studies have shown that preconditioning cells by exposing them to the external environment can enhance their therapeutic effects by preparing them for the harsh conditions they encounter when injected into the body. Antebi *et al*[51] showed that hypoxic preconditioning of bone marrow MSCs enhanced the therapeutic function of these cells. Gorgun *et al*[34] analyzed the effects of hypoxia and inflammatory factor (TNF-α, IL-1α) pretreatment on AD-MSC angiogenic potential. In addition, Rodriguez *et al*[52] pretreated AD-MSCs with a mixture of inflammatory factors under anoxic culture conditions, which significantly enhanced their functional characteristics and immunosuppressive and immunoregulatory functions.

In this study, we developed a combination strategy of hypoxia plus a mixture of TNF-α, IL-1β, and IFN-γ preconditioning to enhance hUC-MSC immunomodulatory capacity. To our knowledge, this is a previously unanalyzed combination pretreatment. We found that this preconditioning approach successfully mimicked the harsh inflammatory

environment and effectively enhanced the immunosuppressive function of MSCs. To simulate hypoxia, we cultured UC-MSCs in a special three-gas incubator containing 2% O_2, 5% CO_2 and 93% N_2 at 37°C for 24 h. We had previously evaluated these gas conditions and found them to be most suitable for preserving the functional characteristics of MSCs. To simulate the harsh inflammatory environment, we independently developed and utilized a mixture of IL-1β, IFN-γ and TNF-α. After pretreatment, we found that the cells became elongated, but their proliferation, viability and size did not significantly change. Notably, Klinker *et al*[53] recently demonstrated that the morphological characteristics of MSCs were significantly correlated with their immunosuppressive ability and can be used to predict their overall immunosuppressive effects[53]. The results of the study by Klinker *et al*[53] showed that pretreated UC-MSCs became elongated and had stronger immunosuppressive ability, consistent with the results of our study.

Although different forms of preconditioning have been shown to successfully enhance cell properties and increase cell function, there are still noteworthy safety concerns. Because pretreatment may have negative effects on cell function, we used flow cytometry to characterize MSC phenotypes. The expression of specific MSC surface markers can be used as indicators of cell differentiation potential, lineage commitment, aging, and therapeutic function[54]. The International Society for Cell and Gene Therapy defines minimum standards for MSC characterization, and most experiments are conducted on this basis[55]. However, we examined additional MSC surface markers. We found that UC-MSCs and PUC-MSCs from three donors retained high expression levels of CD105, CD90, CD73, CD29, CD166, CD47 and HLA-ABC and were negative for CD31, CD45, CD14, and CD34 expression. These findings indicated that UC-MSCs retained MSC properties after pretreatment. Interestingly, we found that CD142 expression significantly decreased after pretreatment. Oeller *et al*[39] found that UC-MSCs showed higher procoagulant activity than adipose-derived MSCs, and UC-MSCs showed extensive TF (CD142) expression and long-lasting clotting; a higher cell number significantly increased clot formation, which was partially dependent on coagulation factors[43]. Our study showed that CD142 expression in UC-MSCs without treatment exceeded 99% and CD142 expression significantly decreased after pretreatment (59.3%). Our experiment showed significant decreases in TF expression, which has been shown to be closely related to procoagulant activity[38]. However, Rodriguez *et al*[52] demonstrated that bone marrow-derived MSCs (BM-MSCs) and AD-MSCs that were pretreated with a combination of hypoxia and inflammatory factors showed increased CD142 expression, which was inconsistent with previous studies[53]. We determined that these discrepancies may be due to different origins of MSCs, MSC heterogeneity and/or differences between culture systems. However, we found pretreatment significantly reduced CD142 expression. In addition, studies have suggested the use of anticoagulants or genetic methods to inhibit TF activity for the clinical application of MSCs to maximize clinical benefits for patients, which also underscores the importance of insights into the mechanisms underlying safety issues related to nonhematopoietic cell transplantation[43].

The efficacy of MSCs depends on the full function of their mitochondria, which can be damaged after cell exposure to harmful environments[56]. Therefore, we examined the effects of hypoxia and inflammatory factor pretreatment on mitochondrial function. ROS levels were increased after pretreatment but were within the range of those in the positive controls. In addition, the increased expression of antioxidants such as STC1, catalase and HOMX1 can eliminate ROS to maintain cell redox homeostasis[57]. Previous studies have shown that both HMOX1 and catalase play key roles in protecting cells from ROS-induced damage[58,59]. Therefore, although ROS levels increased after pretreatment, the antioxidant capacity of the cells also correspondingly increased and the ROS removal rate increased. In addition, the MMP (Δψm) plays a key role in important mitochondrial functions, and its dissipation is an indicator of mitochondrial dysfunction[60]. Maintaining a stable MMP (Ψm) is essential for ensuring efficient ROS clearance and preventing apoptosis or other stress-related events caused by excessive ROS. Therefore, we examined the MMP and found that pretreatment had no effect on MMP. In summary, although ROS levels increased after pretreatment, the antioxidant capacity also increased, and the MMP did not change, indicating that there was no damage to mitochondrial function after pretreatment.

We next examined the effect of pretreatment on MSC apoptosis and senescence and found that the apoptosis index of UC-MSCs increased to a certain extent after pretreatment. Galleu *et al*[61] showed that all patients can receive apoptotic MSCs for *in vivo* injection and that these cells can induce receptor-mediated immune regulation. MSC apoptosis of is critical to their therapeutic functions[62]. BCL-2, BAX and SIRT1 genes play important roles in the apoptosis pathway. In this study, we found increased expression of the SIRT1 gene, which protected cells from apoptosis by activating autophagy[63]. The ratio of BAX/BCL-2 is closely related to the apoptosis potential of cells[64]. In this study, an inverse proportional relationship between BAX and BCL-2 indicated that MSCs exerted stronger anti-apoptosis effects after pretreatment. This may indicate that the cells were protecting themselves from the harmful inflammatory environment. In addition, MSCs showed increased SA-β-gal activity and p53, P16 and p21 expression after hypoxia and inflammatory factor pretreatment, suggesting that MSCs underwent senescence after pretreatment. Salminen *et al*[65] found that aging MSCs exert stronger immunosuppressive effects. The experimental results showed that even when some of the pretreated UC-MSCs underwent senescence and apoptosis, these effects did not reduce their immunoregulatory abilities, and even apoptotic and senescent MSCs showed increased immunosuppressive abilities.

The pleiotropic effect of MSCs is mostly mediated by soluble paracrine factors, and active paracrine factors produced by these cells regulate cellular immunity when they come into contact with the host[66]. Therefore, we investigated the response of paracrine factors involved in the immune regulation of MSCs to preconditioning. Many bioactive molecules produced by MSCs, such as IDO, PGE2, IL-10, TSG-6, and TGF-β1, effectively regulate innate and adaptive immunity and play a key role in the immunosuppressive effect of MSCs[67]. The detection of immunomodulation-related genes showed that the expression levels of PGE2, KYN, IDO, COX2, IL-10, TGF-β1, TSG-6, HLA-G5 and PD-L1 were significantly increased in addition to that of IL-1ra. In addition, PGE2, TSG-6, TGF-β1 and IDO protein levels in the supernatant were significantly increased. IL-10 levels were slightly increased, but the difference between the pretreatment and control groups was not significant. These results showed that preconditioning can promote the production of immunomodulatory paracrine factors in UC-MSCs and increase their immunomodulatory effect.

Finally, we studied the immunosuppressive effects of MSCs on PBMCs and NK cells. We found that UC-MSCs and PUC-MSCs inhibited PBMCs and NK cell proliferation, but PUC-MSCs exerted a stronger inhibitory effect. Some work has been done to characterize the interaction between BM-MSCs and NK cells[22,68,69]. However, the interaction of UC-MSCs with NK cells has been largely unexplored. Our results add to our understanding of the immunosuppressive effects of UC-MSCs[70,71]. In addition, we found that PUC-MSCs exerted a stronger inhibitory effect on NK cell-mediated cytotoxic activity. Reportedly, IDO and PGE2 or TGF-β1 produced by MSCs are critical for inhibiting NK cell cytotoxicity[22,72]. PUC-MSCs may exert stronger inhibitory effects on NK cell-mediated toxicity due to increased IDO, TGF-β1 and PGE2 expression.

We acknowledge that this study has limitations. Whether the combination of hypoxia (2% O_2) and inflammatory factors (IL-1β, TNF-α, IFN-γ) is superior to other preconditioning methods is unclear. However, our study shows a preconditioning strategy that adds to the existing experimental options to use in further research. In addition, whether these cells exhibit superior immunomodulatory functions under harsh *in vivo* inflammatory conditions remains to be demonstrated and is the focus of our future work. Moreover, although TF expression is reduced by preconditioning, the mechanism is unclear. Thromboembolism may still have significant clinical consequences for patients who receive MSCs after preconditioning. Therefore, for whole-body cell administration, it is still necessary to use anticoagulants during the clinical application of MSCs to inhibit TF activity and increase the clinical benefits to patients.

CONCLUSION

In conclusion, we successfully developed an *in vitro* preconditioning method that mimics the impaired environment through a combination of hypoxia (2% O_2) and inflammatory factors (IL-1β, TNF-α, IFN-γ) to enhance UC-MSC immunosuppressive ability without compromising their biological characteristics. Most notably, this approach greatly reduced the expression of the clotting-related TF in MSCs, which was a surprising result.

ARTICLE HIGHLIGHTS

Research background

Mesenchymal stem cells (MSCs) have great potential in the treatment of a variety of immune-related diseases due to their unique immunomodulatory and anti-inflammatory abilities. However, after intravenous transplantation, MSCs cannot effectively exert their biological effects when they encounter a harsh environment *in vivo*, which reduces the efficacy of cell therapy. To increase transplantation efficacy, appropriate pretreatment methods are particularly important.

Research motivation

Although a variety of pretreatment methods are used to increase MSC transplantation efficacy, suitable and effective *in vitro* pretreatment methods are still worth studying.

Research objectives

To evaluate whether umbilical cord MSCs (UC-MSCs) pretreated with hypoxia exposure and inflammatory factors show enhanced immunosuppressive effects without affecting cell biological characteristics.

Research methods

In this study, we used a combination of hypoxia (2% O_2) and inflammatory factors (interleukin-1β, tumor necrosis factor-α , interferon-γ) to pretreat UC-MSCs for 24 h to simulate the *in vivo* injury environment. We then comprehensively evaluated the biological properties of pretreated UC-MSCs and investigated their immunosuppressive properties.

Research results

Our results showed that compared to UC-MSCs, pretreated UC-MSCs were morphologically elongated, but their viability, proliferation and size were not affected, the expression of coagulation-related tissue factors was significantly reduced, and mitochondria maintained their function and integrity. Although some cells underwent apoptosis or senescence, polymerase chain reactions and enzyme-linked immunosorbent assays revealed a significant increase in the levels of immunomodulation-related factors. Coculture with peripheral blood mononuclear cell and natural killer cells exerted a stronger immunosuppressive effect.

Research conclusions

The combined pretreatment of hypoxia exposure and inflammatory factors enhanced the immunosuppressive ability of MSCs but did not affect the biological characteristics of these cells.

Research perspectives

Our study provides new strategies for the preconditioning of UC-MSCs.

Abstract

BACKGROUND

Ferroptosis can induce low retention and engraftment after mesenchymal stem cell (MSC) delivery, which is considered a major challenge to the effectiveness of MSC-based pulmonary arterial hypertension (PAH) therapy. Interestingly, the cystathionine γ-lyase (CSE)/hydrogen sulfide (H_2S) pathway may contribute to mediating ferroptosis. However, the influence of the CSE/H_2S pathway on ferroptosis in human umbilical cord MSCs (HUCMSCs) remains unclear.

AIM

To clarify whether the effect of HUCMSCs on vascular remodelling in PAH mice is affected by CSE/H_2S pathway-mediated ferroptosis, and to investigate the functions of the CSE/H_2S pathway in ferroptosis in HUCMSCs and the underlying mechanisms.

METHODS

Erastin and ferrostatin-1 (Fer-1) were used to induce and inhibit ferroptosis, respectively. HUCMSCs were transfected with a vector to overexpress or inhibit expression of CSE. A PAH mouse model was established using 4-wk-old male BALB/c nude mice under hypoxic conditions, and pulmonary pressure and vascular remodelling were measured. The survival of HUCMSCs after delivery was observed by *in vivo* bioluminescence imaging. Cell viability, iron accumulation, reactive oxygen species production, cystine uptake, and lipid peroxidation in HUCMSCs were tested. Ferroptosis-related proteins and S-sulfhydrated Kelch-like ECH-associating protein 1 (Keap1) were detected by western blot analysis.

RESULTS

In vivo, CSE overexpression improved cell survival after erastin-treated HUCMSC delivery in mice with hypoxia-induced PAH. *In vitro*, CSE overexpression improved H_2S production and ferroptosis-related indexes, such as cell viability, iron level, reactive oxygen species production, cystine uptake, lipid peroxidation, mitochondrial membrane density, and ferroptosis-related protein expression, in erastin-treated HUCMSCs. In contrast, *in vivo*, CSE inhibition decreased cell survival after Fer-1-treated HUCMSC delivery and aggravated vascular remodelling in PAH mice. *In vitro*, CSE inhibition decreased H_2S levels and restored ferroptosis in Fer-1-treated HUCMSCs. Interestingly, upregulation of the CSE/H_2S pathway induced Keap1 S-sulfhydration, which contributed to the inhibition of ferroptosis.

CONCLUSION

Regulation of the CSE/H_2S pathway in HUCMSCs contributes to the inhibition of ferroptosis and improves the suppressive effect on vascular remodelling in mice with hypoxia-induced PAH. Moreover, the protective effect of the CSE/H_2S pathway against ferroptosis in HUCMSCs is mediated *via* S-sulfhydrated Keap1/nuclear factor erythroid 2-related factor 2 signalling. The present study may provide a novel therapeutic avenue for improving the protective capacity of transplanted MSCs in PAH.

Key Words: Human umbilical cord mesenchymal stem cells; Cystathionine γ-lyase/hydrogen sulfide pathway; Ferroptosis; Pulmonary arterial hypertension; S-sulfhydration

INTRODUCTION

Mesenchymal stem cells (MSCs), derived from placenta, bone marrow, adipose, or other tissues, have emerged as a new regenerative therapy for pulmonary arterial hypertension (PAH) over the last decade[1]. MSC delivery significantly inhibits pulmonary artery remodelling, resulting in the reduced progression of PAH. However, low cell retention and engraftment after cell delivery are considered major challenges to the effectiveness of MSC-based therapy[2]. Interestingly, increasing evidence indicates that programmed cell death (PCD) is closely linked to the low engraftment and survival rates of transplanted MSCs[3].

Ferroptosis is a novel type of PCD with distinct properties. Ferroptosis essentially consists of polyunsaturated fatty acid-containing phospholipid synthesis and peroxidation, iron metabolism, and mitochondrial metabolism, which result in oxidative stress and lipid peroxidation, triggering cell death[4]. Studies have shown a relationship between ferroptosis and MSCs; ferroptosis can be induced by erastin in MSCs[5,6]. Inhibiting ferroptosis maintained the viability and differentiation of MSCs[7,8]. Moreover, suppressing ferroptosis worsened MSC fate and enhanced the exposure and efficacy of transplanted MSCs in live disease[9]. However, few studies have directly evaluated the effect of ferroptosis on MSC delivery in PAH.

Decreased antioxidative stress can cause ferroptosis[10]. In addition, the mediation of antioxidative stress-related proteins, such as nuclear factor erythroid 2-related factor 2 (Nrf2), can inhibit ferroptosis[11]. Thus, understanding the signalling pathways that maintain redox balance will provide new approaches for inhibiting ferroptosis. The novel gaseous mediator hydrogen sulfide (H_2S) has been shown to exert protective effects, including its antioxidant properties [12]. Therefore, the impact of H_2S on the contribution of antioxidative stress to decreased ferroptosis is worth exploring. In mammalian cells, cystathionine γ-lyase (CSE) is predominantly responsible for endogenous H_2S production in the cardiovascular system[13]. However, the effect of CSE on the ferroptosis of MSCs remains unclear.

Hence, the present study aimed to clarify whether ferroptosis is involved in the therapeutic effect of human umbilical cord MSCs (HUCMSCs) in PAH mice. Furthermore, we investigated the role of the CSE/H_2S pathway in ferroptosis in HUCMSCs.

MATERIALS AND METHODS

Cell culture

Primary HUCMSCs were purchased from ScienCell Research Laboratories, Inc. HUCMSCs were cultured in MSC medium (7501, ScienCell Research Laboratories, United States) containing 5% foetal bovine serum, 1% penicillin/streptomycin, and 1% MSC growth supplement at 37 °C in a 5% CO_2 atmosphere. HUCMSCs at passages three to five were used in this study.

Cell transfection

HUCMSCs were transduced with a lentiviral vector expressing firefly luciferase (HBLV-LUC-BSD, Hanbio, China) in serum-free medium containing 3 μg/mL blasticidin (SBR00022, Sigma-Aldrich, United States) at a multiplicity of infection of 100. Transduction was analysed by luciferase imaging 72 h after transfection. The expression of LUC was confirmed by measuring luciferase activity [*in vivo* imaging system (IVIS) Lumina imaging station, Caliper Life Sciences]. Surface markers and the differentiation of HUCMSCs-LUC into osteoblasts and adipocytes were evaluated as previously described[14]. The antibodies that were used are shown in Supplementary Table 1.

Short hairpin RNAs targeting CSE were designed, cloned, and inserted into a modified pLKO.1-TRC vector by GenePharma Co. Ltd. (Shanghai, CHN). To genetically engineer cells to overexpress CSE, the open reading frame of human CSE was cloned and inserted into the vector pLVX-IRES-Puro by GenePharma Co. Ltd. (Shanghai, CHN). HUCMSCs-LUC were transfected with the PLKO.1-sh-CSE vector (HUCMSC/sh-CSE), negative control vector (HUCMSCs/sh-NC), PLVX-CSE-Puro vector (HUCMSCs/CSE), or PLVX-empty-Puro vector (HUCMSCs/NC) using Lipofectamine 2000 (11668019, Invitrogen, United States). After 48 h, the transfection efficacy was determined using western blot and real-time polymerase chain reaction (RT-PCR) (Supplementary Figure 1).

Drug treatments

Erastin (S7242), ferrostatin-1 (Fer-1, S7243), and the Nrf2 inhibitor brusatol (S7956, 10 nM, 6 h) were purchased from Selleck Chemicals (Houston, United States) and initially dissolved in DMSO before being diluted in the culture medium to their final concentration.

Quantification of cell viability

Cell Counting Kit-8 (CCK8, 96992, Sigma-Aldrich, United States) was used to examine cell viability according to the manufacturer's instructions. Briefly, cells were seeded at a density of 5000 cells/well in 96-well plates in three replicates and incubated overnight. At the end of the different treatments, CCK8 reagent was added to each well and incubated for 2 h. The optical density (OD) values at 450 nm were measured using a plate reader (Bio-Rad).

Lactase dehydrogenase release assay

Lactate dehydrogenase (LDH) release was measured using an LDH cytotoxicity detection kit (CK12, Dojindo Laboratory, JPN) in accordance with the manufacturer's instructions to evaluate cell membrane integrity. In brief, cells were seeded at a density of 5000 cells/well in 96-well plates. At the end of the different treatments, 100 μL of fresh reaction mixture was added to each well and incubated for 30 min, and the OD values at 490 nm were measured using a microplate reader.

Animal experiments

Animal procedures were performed in compliance with the Institutional Animal Care and Use Committee of Wuhan Servicebio Technology Co., Ltd., China (No. 2022231). Four-week-old male mice (BALB/c nude mice) were used to establish a hypoxia-induced PAH mouse model. The mice were obtained from Wuhan Servicebio Technology Co., Ltd. (Wuhan, China) and cared for in strict accordance with the Guidelines for the Care and Use of Laboratory Animals of the National Institutes of Health. All animals were housed in the same specific pathogen-free room under a constant temperature and humidity on a 12-h light and 12-h dark cycle, and the animals were fed sterile food and water *ad libitum*. Each animal was considered one experimental unit. Researchers who analysed the data were blinded to the group allocation until all the statistical results were finally obtained.

The mice (totally 42) were numbered and divided into the following seven groups based on a table of random numbers: Control group: The mice received phosphate buffered saline (PBS) (n = 6); hypoxia group: The mice were exposed to hypoxia under 10% O_2 for 4 wk (n = 6); HUCMSCs group: After 2 wk of exposure to hypoxia, the mice were injected with 1.5 × 10^5 HUCMSCs-LUC per mouse *via* the tail vein and then housed under hypoxia for 2 wk (n = 6); HUCMSCs + erastin group: After 2 wk of exposure to hypoxia, the mice were infected with 1.5 × 10^5 HUCMSCs-LUC that were treated with erastin (4 μM, 6 h) per mouse *via* the tail vein and then housed under hypoxia for 2 wk (n = 6); HUCMSCs/CSE + erastin group: After 2 wk of exposure to hypoxia, the mice were injected with 1.5 × 10^5 HUCMSCs-LUC/CSE that were treated with erastin (4 μM, 6 h) per mouse *via* the tail vein and then housed under hypoxia for 2 wk (n = 6); HUCMSCs + Fer-1 group: After 2 wk of exposure to hypoxia, the mice were injected with 1.5 × 10^5 HUCMSCs-LUC that were treated with Fer-1 (4 μM, 6 h) per mouse *via* the tail vein and then housed under hypoxia for 2 wk (n = 6); and HUCMSCs/sh-CSE + Fer-1 group: After 2 wk of exposure to hypoxia, the mice were injected with 1.5 × 10^5 HUCMSCs-LUC/sh-CSE that were treated with Fer-1 (4 μM, 6 h) per mouse *via* the tail vein and then housed under hypoxia for 2 wk (n = 6).

One day and seven days after intravenous injection *via* the tail, mice were anaesthetized using isoflurane and placed in an IVIS Lumina imaging station. Images of regions of interest were collected 10 min after the intraperitoneal injection of D-luciferin (L6152, Sigma-Aldrich, United States), the luciferase substrate, at 3.75 mg per 25 g mouse weight.

Measurement of pulmonary artery pressure and right ventricular hypertrophy

After 4 wk, the mice were anaesthetized using isoflurane for haemodynamic assessment. Briefly, a Miler catheter was used to obtain the right ventricular systolic pressure (RVSP) *via* insertion into the right external jugular vein. After exsanguination and collection of the blood, the cardiopulmonary tissues were removed. The right ventricle (RV) free wall and the left ventricle plus septum (LV + S) were weighed separately. The degree of right ventricular hypertrophy was determined by the ratio RV/(LV + S).

Assessment of pulmonary vascular morphometry

After the lung tissue was embedded in paraffin and cut into slices with a thickness of 5 μm, the slices were dewaxed, rehydrated, and stained with haematoxylin and eosin staining. Then, the ratio of the vascular medial cross-sectional area to the total arterial cross-sectional area was calculated as a measurement of distant small pulmonary artery (50-100 μm) remodelling.

For immunofluorescence staining of the lung tissue, after deparaffinization and washing with PBST, lung tissue slides were heated for 20 min at 95 °C in a Tris-EdTA solution for antigen retrieval and then blocked with 3% H_2O_2 for 15 min to block endogenous peroxidase activity and 5% goat serum for 1 h to eliminate nonspecific staining. These slides were incubated with VEcadherin rabbit polyclonal antibody (1:100, ab205336, Abcam) and alpha-smooth muscle actin rabbit monoclonal antibody (1:100, 19245S, CST) at 4 °C overnight and then incubated with the secondary antibody: Antirabbit immunoglobulin G (IgG) (1:500, 4413s, CST) or antirabbit IgG (1:500, 4412S, CST). Nuclei were counterstained with DAPI (D9542, Sigma-Aldrich, United States) at room temperature for another 2 min. Immunofluorescence was visualized under a microscope.

Analysis of cell apoptosis

After treatment, the cells were washed, trypsinized, resuspended, and stained with 5 μL of Annexin V/FITC (331200, Invitrogen, United States) and 5 μL of propidium iodide (PI, P1304MP, Invitrogen, United States) at room temperature for 15 min. Then, cell apoptosis was evaluated by flow cytometry.

Iron assays

Two different methods were used to measure the levels of intracellular ferrous iron. For a colorimetric method using the Iron Assay Kit (ab83366, Abcam, United Kingdom), cells were collected, homogenized (in cold iron assay buffer), and centrifuged. After adding 5 μL of iron reducer to each sample, the supernatant was incubated for 30 min at 37 °C. Next, 100 μL of iron probe was added to each sample and incubated for 60 min at 37 °C in the dark. The absorbance at 593 nm was measured using a microplate reader. For FeRhoNox-1 staining, cells were incubated away from light in a 37 °C, 5% CO_2 incubator for 40 min after the addition of 5 μM FeRhoNox-1 (MX4558, MKbio, CHN). Then, the cells were washed with PBS three times and imaged by fluorescence microscopy.

Reactive oxygen species assay

Intracellular reactive oxygen species (ROS) levels were measured by applying DCFH-DA (S0033, Beyotime, CHN). Briefly, after treatment, the cells were washed with PBS three times and treated with 10 μM DCFH-DA for 30 min away from light. Then, the cells were washed with PBS and observed under a fluorescence microscope.

Lipid peroxide measurement

Cells were labelled with BODIPY™ 581/591 C11 (D3861, Thermo Fisher Scientific, United States) at a final concentration of 2 μM for 20 min at 37 °C. After trypsinization and resuspension in PBS, lipid peroxidation was analysed using a flow cytometer. A lipid peroxidation [malonaldehyde (MDA)] assay (ab118970, Abcam, United Kingdom) was used according to the manufacturer's protocol to quantify the MDA concentration. The results were quantified colorimetrically (OD = 532 nm). The reduced glutathione/oxidized glutathione disulfide (GSH/GSSG) ratio in cells was determined using the GSH/GSSG Ratio Detection Assay Kit (ab205811, Abcam, United Kingdom) following the manufacturer's instructions.

Cystine uptake

Cystine uptake was measured with BioTracker Cystine-FITC Live Cell Dye (SCT047, Sigma-Aldrich, United States). The pretreated cells were incubated with complete medium containing 5 μM cystine-FITC in the dark for 30 min. Then, the cells were washed with PBS and harvested by trypsinization. The cells were resuspended in PBS and assessed by flow cytometry.

Transmission electron microscopy

Cells were fixed, postfixed, dehydrated, cut, and stained as previously described[15]. The cells were viewed under a transmission electron microscope (JEM1200, Tokyo, Japan), and images were taken.

Measurement of the H_2S concentration

The dye 7-azido-4-methylcoumarin (AzMC) was used to measure the H_2S concentration *in vitro*. Cells were plated at a density of 10000 cells per well in 96-well plates. After treatment, cells were loaded with the fluorogenic dye AzMC (802409, Sigma-Aldrich, United States) at 10 μM for 30 min. Then, the cells were washed three times with PBS and measured on a SpectraMax M5 plate reader.

Nrf2 activity assay

Nuclear lysates were isolated following extraction using NE-PER Nuclear and Cytoplasmic Extraction Reagents (78835, Thermo Fisher Scientific, United States) according to the manufacturer's instructions. Nrf2 transcriptional activity was then measured by ELISA using an Nrf2 Transcription Factor Assay Kit (ab207223, Abcam, United Kingdom) in accordance with the manufacturer's guidelines.

S-sulfhydration assay

Kelch-like ECH-associating protein 1 (Keap1) S-sulfhydration was detected with standard procedures using the "tag-switch" method[16]. The Keap1 protein was pulled down by immunoprecipitation. The proteins were dissolved in solution buffer, purified with streptavidin-agarose beads, and subjected to western blotting with anti-Keap1 (sc-365626, Santa Cruz Biotechnology, United States). Cells were treated with 1 mmol/L 1,4-dithio-DL-threitol (DTT, 43815, Sigma-Aldrich, United States) for 3 h as a negative control group.

Quantitative real-time polymerase chain reaction

qPCR was performed as previously described[15,17]. Human GAPDH expression was used for normalization. Fold changes were calculated using the comparative Ct method (ΔΔCt). The sequences of the primers used are as follows: CSE: Forward: GGCCTGGTGTCTGTTAATTGT and reverse: GCCATTCCGTTTTTGAAATGCT; GAPDH: forward: GACATCAAGAAGGTGGTGAAGCAGG and reverse: GTGTCGCTGTTGAAGTCAGAGGAGA.

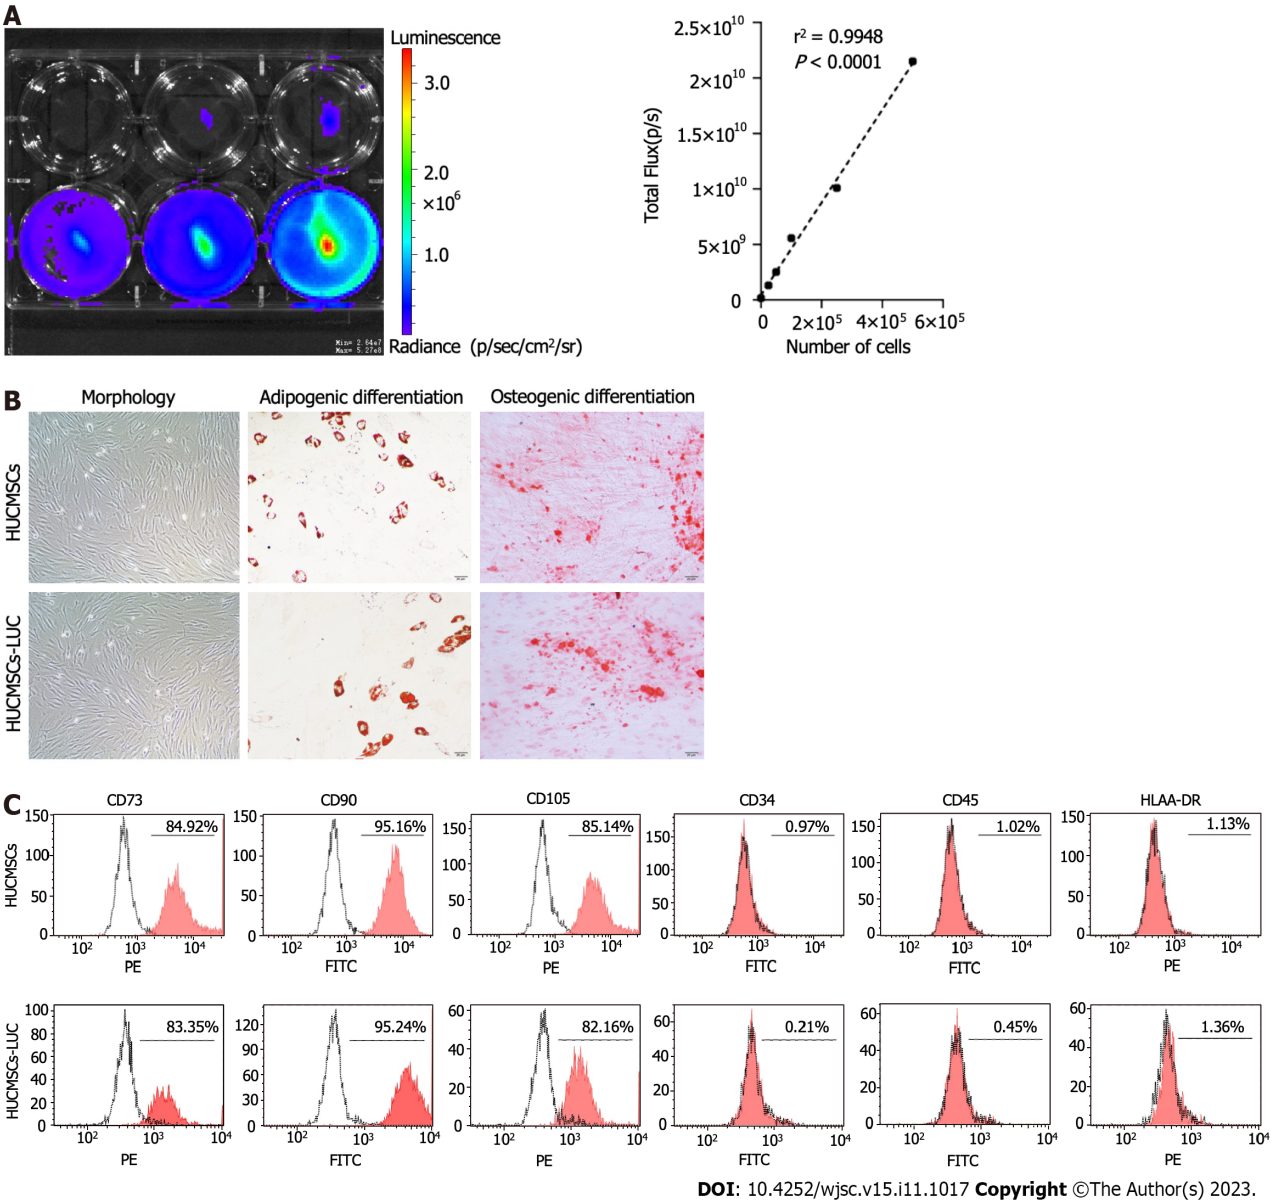
Western blot analysis

Whole-cell, cytosolic, and nuclear proteins were extracted using RIPA Lysis and Extraction Buffer (89900, Thermo Fisher Scientific, United States) or NE-PER Nuclear and Cytoplasmic Extraction Reagents (78835, Thermo Fisher Scientific, United States). The extractions were performed as previously described[17]. Primary antibodies against the following were used: Glutathione peroxidase 4 (GPX4, 1:1000, 59735S, CST), intracellular ferritin heavy chain 1 (FTH1, 1:1000, 4393S, CST), nuclear receptor coactivator 4 (NOCA4, 1:1000, 66849S, CST), Fe^{3+}-bound transferrin receptor 1 (TFRC1, 1:1000, ab214039, Abcam), 4-hydroxynonenal (4-HNE, 1:1000, ab46545, Abcam), SLC7A11 (1:1000, ab175186, Abcam), Nrf2 (1:1000, ab62352, Abcam), Keap1 (sc-365626, Santa Cruz Biotechnology), CSE (1:1000, 19689S, CST), GAPDH (1:1000, 5174S, CST), and Histone H3 (1:1000, ab1791, Abcam). The intensity of the resulting bands was analysed with ImageJ software.

Statistical analysis

All experimental data are presented as the mean ± SEM. Statistical significance was analysed with GraphPad Prism version 5.01 (San Diego, CA, United States) using one-way analysis of variance (ANOVA). Differences at $P < 0.05$ were considered statistically significant. All experiments were performed with at least three independent replicates.

RESULTS



In vitro assessment of HUCMSCs

HUCMSCs-LUC were analysed *in vitro* by bioluminescence imaging (BLI), cell morphology assessment, flow cytometry, and differentiation potential determination to confirm the properties typical of HUCMSCs. A linear relationship between the number of cells and the bioluminescent signal was observed (Figure 1A). Cells displayed a spindle-like shape and were arranged in radial concentric circles (Figure 1B). Adipogenic and osteogenic differentiation confirmed the multipotentiality and differentiation capacity of the HUCMSCs-LUC (Figure 1B). Flow cytometry confirmed the presence of the following stem cell-specific molecules on the cell surface: CD90 in 94.25% of the cells, CD73 in 83.35%, CD105 in 90.18%, CD44 in 82.16%, CD34 in 0.21%, CD45 in 0.45%, and HLA-DR in 1.36% (Figure 1C).

Ferroptosis could be induced in HUCMSCs

To verify whether ferroptosis could be induced in HUCMSCs and to ascertain the optimal concentration and time, HUCMSCs were exposed to increasing doses (1 μM, 2 μM, 3 μM, 4 μM, and 5 μM) of erastin, a ferroptosis inducer, for three different durations (12 h, 24 h, and 48 h). As shown in Figures 2A-C, the CCK-8 assay illustrated that compared to that in untreated cells, cellular viability was notably reduced to 50% by erastin treatment at concentrations greater than 3 μM for less than 24 h of exposure. In addition, because cell membrane structures can be destroyed by ferroptosis, which leads to the release of LDH from the cytoplasm into the culture medium[18], the levels of LDH in the supernatant were monitored after treatment with increasing erastin concentrations for 12 h, 24 h, and 48 h (Figures 2E-G). The results showed that LDH release increased in a time- and dose-dependent manner. Similarly, treatment with erastin at a concentration greater than 3 μM for 24 h significantly increased LDH release to about 50% compared with that of the untreated HUCMSCs. Thus, HUCMSCs were treated with erastin at a concentration of 3 μM for 24 h in subsequent experiments.

Fer-1 was used to determine whether ferroptosis inhibition could protect HUCMSCs from erastin-induced cell death. Erastin-treated HUCMSCs were cotreated with Fer-1 at concentrations of 0, 2, 4, 6, and 8 μM for 24 h. As shown in Figures 2D and H, Fer-1 above 4 μM had a significant protective effect over treatment without Fer-1.

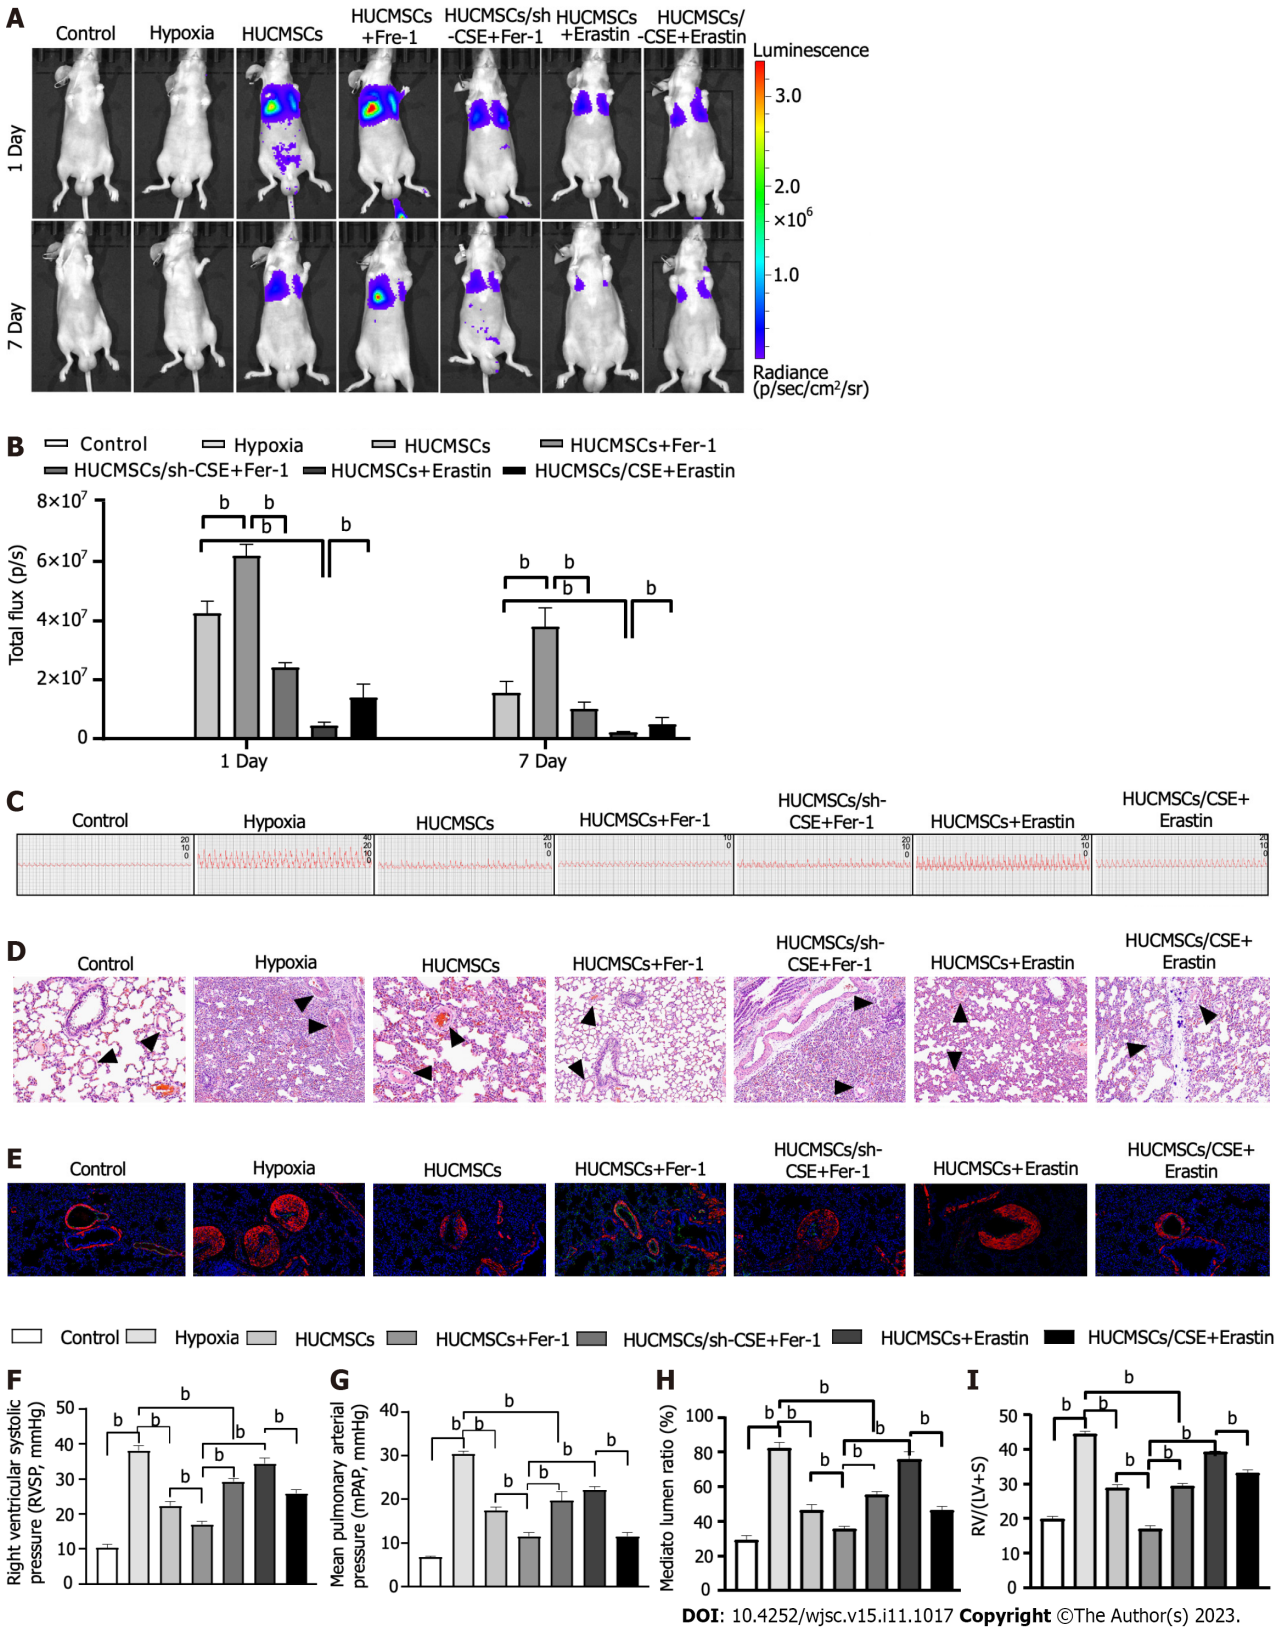
Longitudinal in vivo BLI of HUCMSC grafts

After 1.5 × 10^5 HUCMSCs-LUC were grafted in each mouse, longitudinal *in vivo* BLI was performed on day 1 post-implantation. For quantitative analysis of the observed BLI signals, cell graft-specific BLI signals from fixed regions on the mouse chest and the mean background BLI signals from fixed control regions on the mouse head were plotted *vs* time post-implantation (Figure 3A). The BLI signal was decreased in the HUCMSCs + erastin group and increased in the HUCMSCs + Fer-1 group compared to the HUCMSCs group (Figure 3B). In addition, the signal was further increased in the HUCMSCs/CSE + erastin group but decreased in the HUCMSCs/sh-CSE + Fer-1 group (Figure 3B).



Pulmonary artery remodelling in each group

In PAH, pulmonary artery remodelling results in progressively elevated pulmonary arterial pressure, which ultimately leads to right heart failure[19]. As shown in Figures 3C, F, G, and I, the administration of HUCMSCs or HUCMSCs + Fer-1 decreased the RVSP and RV/(LV + S) ratio in mice with hypoxia-induced PAH ($P < 0.01$). Interestingly, compared to those in the HUCMSCs group, the RVSP and RV/(LV + S) decreased to a greater extent in the HUCMSCs + Fer-1 group (17.000 ± 2.215 *vs* 22.280 ± 3.115, 23.376 ± 0.537 *vs* 28.781 ± 2.311, both $P < 0.01$) and increased in the HUCMSCs + erastin group (34.363 ± 4.065 *vs* 22.280 ± 3.115, 39.158 ± 0.809 *vs* 28.781 ± 2.311, both $P < 0.01$). Moreover, compared to those in the HUCMSCs + erastin group, the RVSP and RV/(LV + S) were decreased in the HUCMSCs/CSE + erastin group (25.817 ± 2.843 *vs* 34.363 ± 4.065, 33.082 ± 2.405 *vs* 39.158 ± 0.809, both $P < 0.01$). Furthermore, the RVSP and RV/(LV + S) were

increased in the HUCMSCs/sh-CSE + Fer-1 group compared with those in the HUCMSCs + Fer-1 group (29.232 ± 2.333 *vs* 17.000 ± 2.215, 29.820 ± 1.526 *vs* 23.376 ± 0.537, both $P < 0.01$).

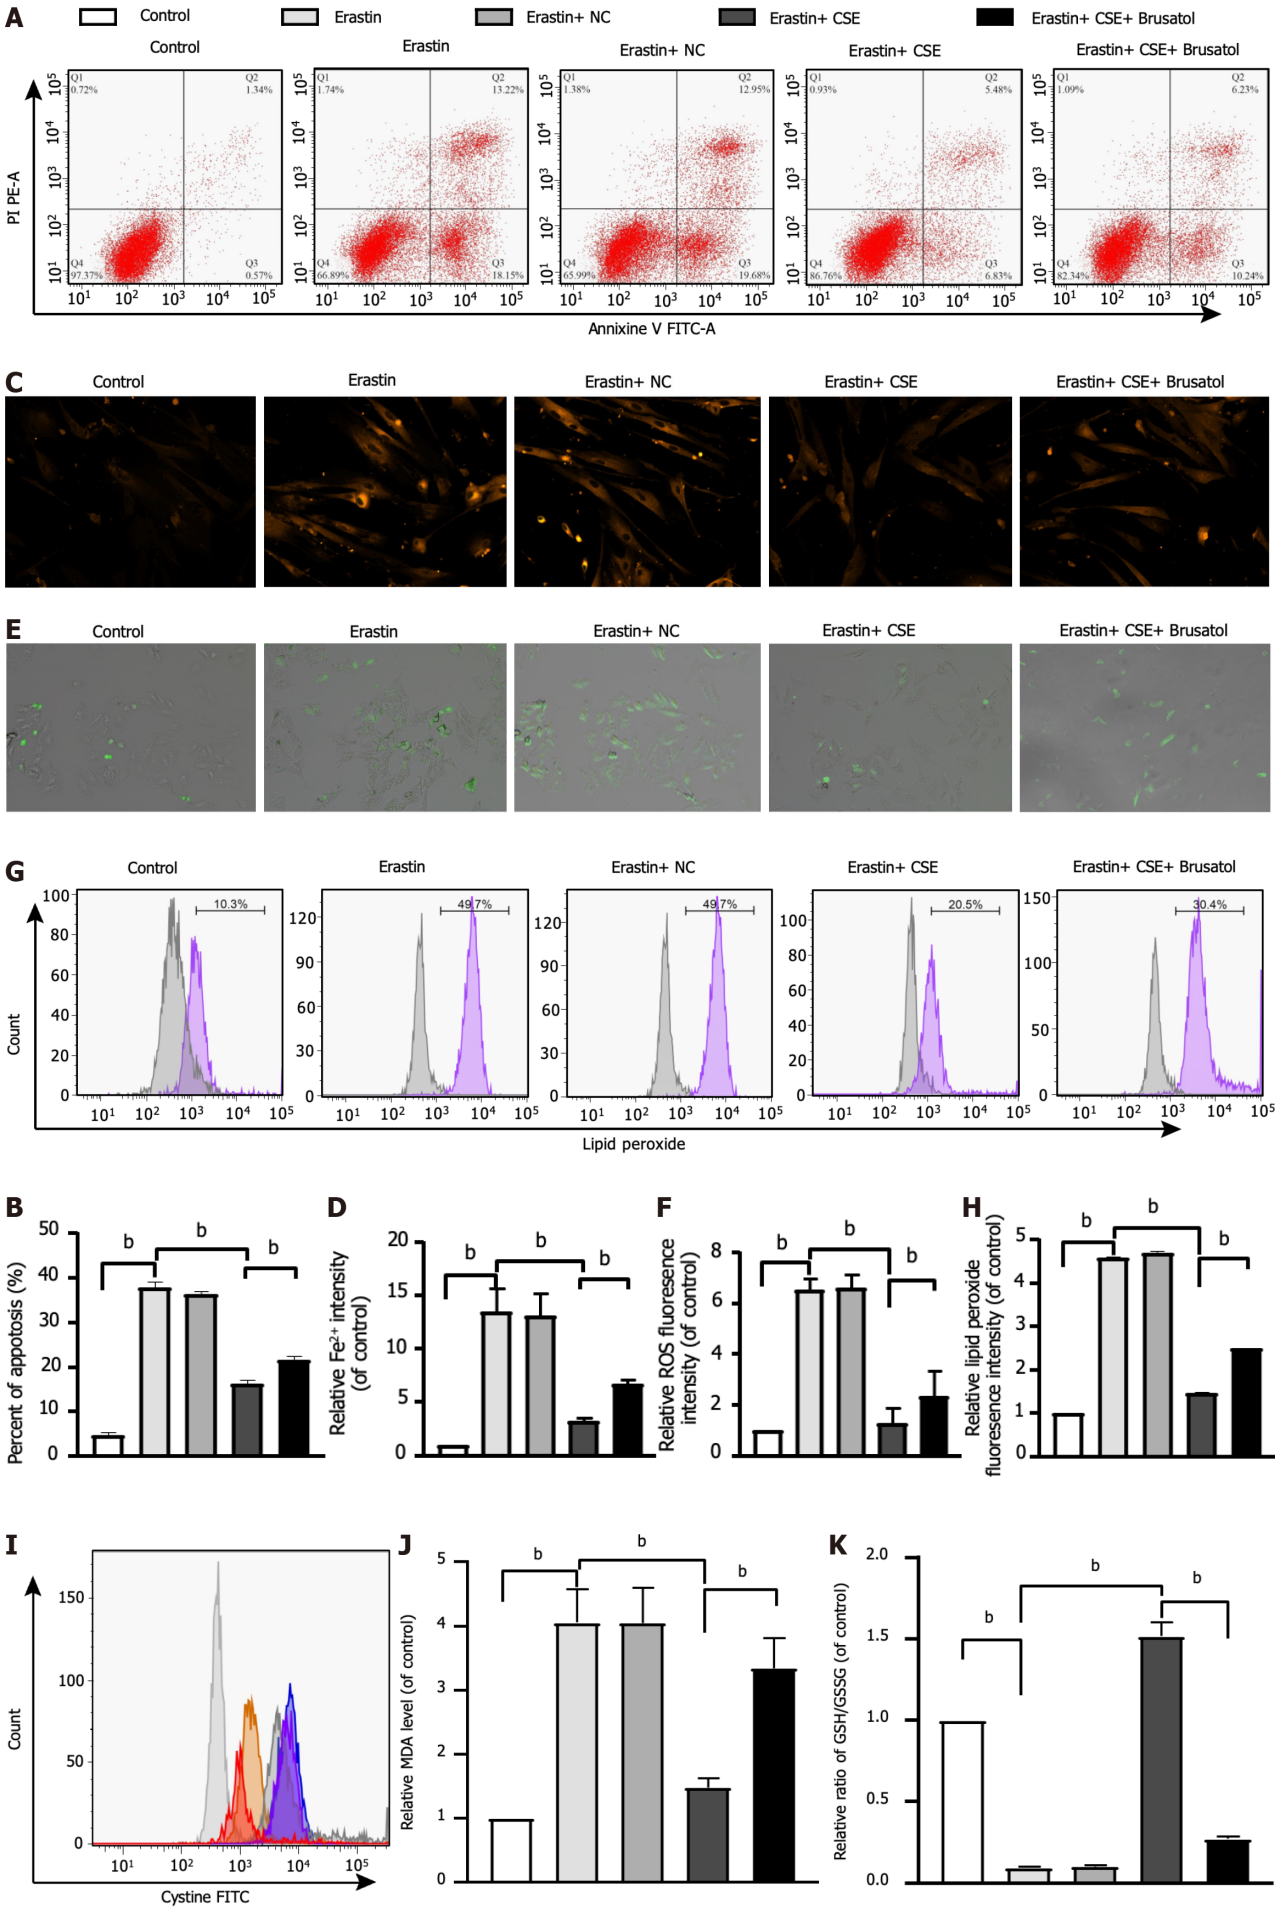
Endothelial to mesenchymal transition (EnMT) has been causally linked to pulmonary arterial remodelling in PAH[20, 21]. EnMT is a form of cellular plasticity described as a phenotypic conversion whereby endothelial cells lose endothelial characteristics (CD31 expression) and acquire mesenchymal characteristics (VE-cadherin expression)[22]. Here, as shown in Figures 3D, E and H, histological and immunofluorescence staining showed slight pulmonary artery stenosis and EnMT in the groups exposed to hypoxia, and these effects were largely attenuated by treatment with HUCMSCs and HUCMSCs + Fer-1 ($P < 0.01$). Interestingly, the inhibitory effect of HUCMSCs + Fer-1 on small pulmonary artery stenosis and EnMT was stronger than that of HUCMSCs. In addition, compared to those in the HUCMSCs + erastin group, small pulmonary artery stenosis and EnMT were alleviated in the HUCMSCs/CSE + erastin group ($P < 0.01$). Meanwhile, small pulmonary artery stenosis and EnMT were aggravated in the HUCMSCs/sh-CSE group compared with the HUCMSCs/Fer-1 group ($P < 0.05$).

CSE inhibition exacerbates Fer-1-mediated suppression of ferroptosis in HUCMSCs

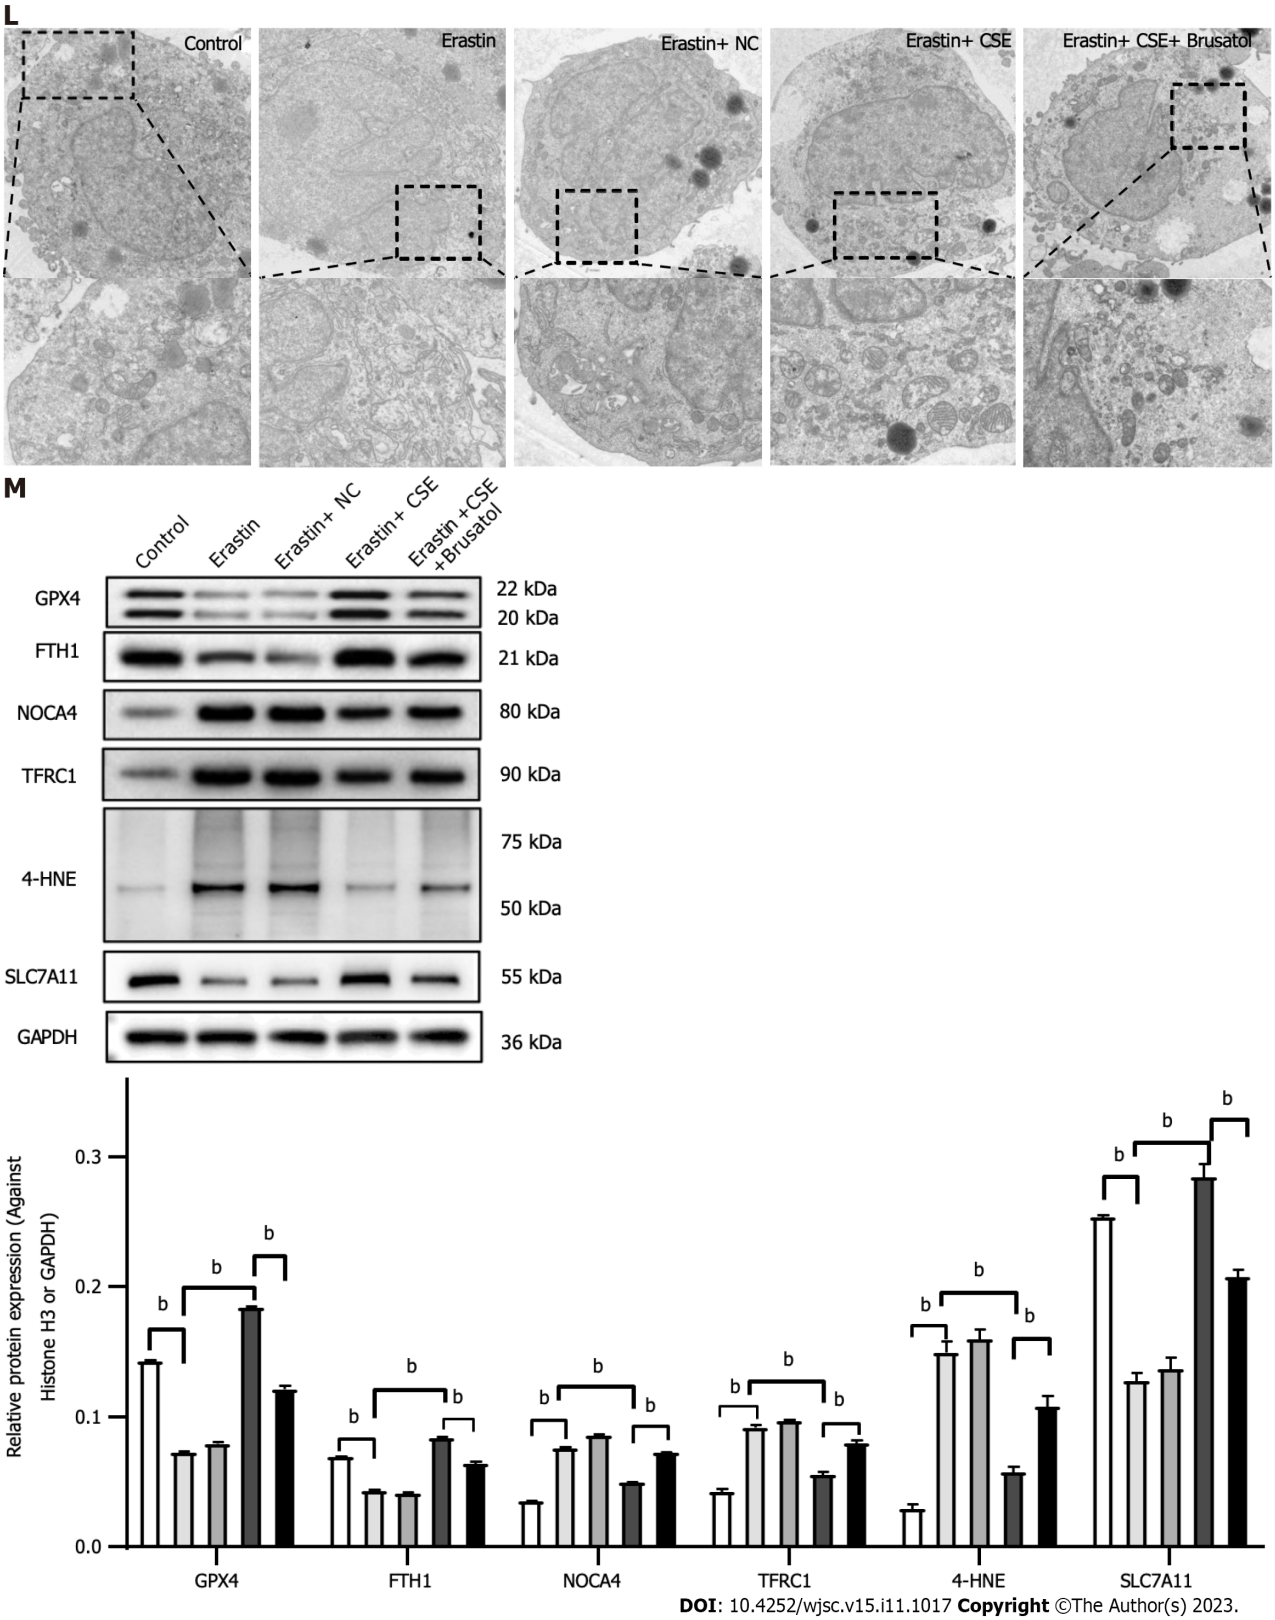
We observed ferroptosis-related changes in erastin-treated HUCMSCs. As shown in Figure 4, cell apoptosis; the levels of Fe^{2+}, ROS, lipid peroxidation, and MDA; and the expression of 4-HNE, TFRC1, and NOCA4 were significantly increased, while the GSH/GSSG ratio; cystine uptake; and GPX4, FTH1, and SLC7A11 expression were decreased in the erastin group compared with the control group (all $P < 0.05$). Consistent with these results, transmission electron microscopy (TEM) also showed an increased mitochondrial membrane density and shorter mitochondrial cristae in the erastin group (Figure 4L). Moreover, the above changes in erastin-treated HUCMSCs were reversed by Fer-1 administration (all $P < 0.05$). Interestingly, the inhibitory effect of Fer-1 on ferroptosis was aggravated by CSE inhibition (all $P < 0.05$).

CSE overexpression negatively regulates erastin-induced ferroptosis in HUCMSCs

As shown in Figure 5, there was a significant decrease in cell apoptosis; the levels of Fe^{2+}, ROS, lipid peroxidation, and MDA; and the expression of 4-HNE, TFRC1, and NOCA4, whereas there was an increase in the GSH/GSSG ratio; cystine uptake; and the expression of GPX4, FTH1, and SLC7A11 in the erastin + CSE group compared to the erastin group (all $P < 0.05$). Consistent with these results, TEM also showed that the mitochondrial membrane was intact and that the mitochondria were narrower with an increased number of cristae in the erastin + CSE group (Figure 5L). In addition, the inhibitory effect of CSE overexpression on ferroptosis was abolished by brusatol, an Nrf2 inhibitor (all $P < 0.05$).



The CSE/H_2S pathway induces Keap1 S-sulfhydration and nuclear translocation of Nrf2



We examined whether Nrf2 is involved in the protective effect of the CSE/H_2S pathway against the ferroptosis of HUCMSCs. First, we found that CSE inhibition decreased H_2S production (Figure 6A), while CSE overexpression increased H_2S levels in HUCMSCs (Figure 6B). In addition, CSE inhibition further downregulated Fer-1-induced Nrf2 activation (Figure 6C), while CSE overexpression further upregulated erastin-induced Nrf2 inactivation (Figure 6D).

Then, the expression of Nrf2 was examined. Western blot analysis revealed that erastin treatment significantly inhibited Nrf2 nuclear translocation, and this effect was markedly enhanced when erastin treatment was combined with Fer-1 treatment (Figure 6E). Moreover, CSE inhibition upregulated Nrf2 expression in the cytoplasm and downregulated Nrf2 expression in the nucleus (Figure 6E). In contrast, CSE overexpression increased nuclear Nrf2 expression and decreased cytoplasmic Nrf2 expression (Figure 6F).

Next, we found that CSE overexpression-induced ferroptosis inhibition was successfully abolished by treatment with 10 nM brusatol, an Nrf2 inhibitor, for 6 h in HUCSMCs (Figure 6F). We also found no difference in the expression of Keap1 among the groups (Figures 6E and F).

Finally, with the "tag-switch" assay, the S-sulfhydration of Keap1 was tested. S-sulfhydration is a novel posttranslational modification involving H_2S. However, S-sulfhydration, a covalent modification, can be reversed by DDT. Increased S-sulfhydration of Keap1 was found in the HUCMSCs/CSE + erastin group than in the HUCMSCs + erastin group, and decreased S-sulfhydration of Keap1 was detected in the HUCMSCs/sh-CSE + Fer-1 group than in the HUCMSCs + Fer-1 group (Figure 6G). Moreover, the S-sulfhydration of Keap1 was further decreased after treatment with DTT, which indicated that Keap1 is S-sulfhydrated (Figure 6G). As shown in Figure 6H, S- of Keap1 led to decreased nuclear Nrf2 expression, which indicated that the activation of Nrf2 by the CSE/H_2S pathway is dependent on Keap1 S-sulfhydration in HUCMSCs.

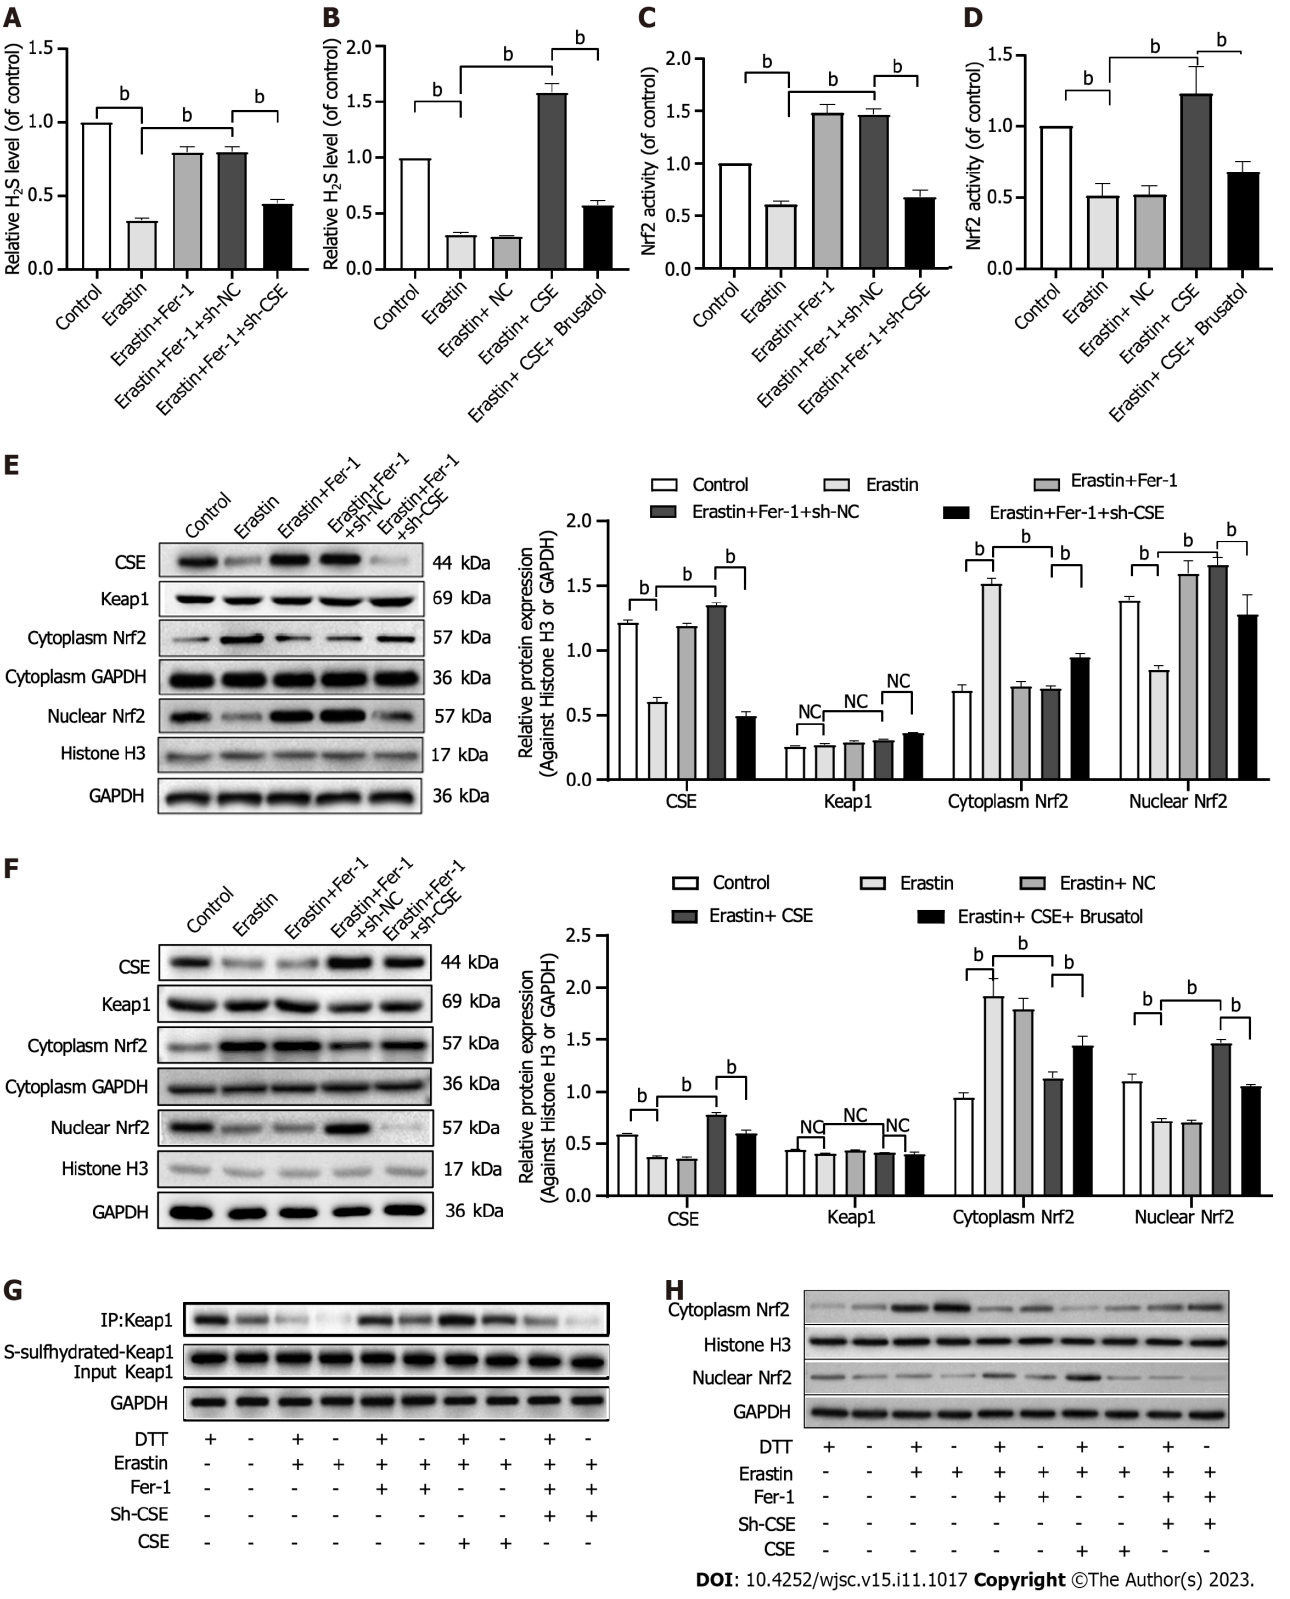
DISCUSSION

Ferroptosis has been reported as a form of cell death; however, to date, understanding the potential effects of ferroptosis on MSC delivery requires further investigation. In the present study, we showed that ferroptosis occurred during HUCMSC delivery in mice with hypoxia-induced PAH. Moreover, mediation of the CSE/H_2S pathway suppressed ferroptosis in HUCMSCs.



A desirable advantage of MSCs is their ability to home to damaged tissue sites. Evidence has demonstrated that transplanted MSCs can accumulate in lung tissue, inhibit vascular remodelling, and effectively attenuate pulmonary hypertension. In the present study, HUCMSCs were chosen because of their many characteristics, which include their ability to be extracted *via* a noninvasive procedure and high differentiation potential, the ease of their *in vitro* expansion, and their prominent repair properties. To detect transplanted HUCMSCs *in vivo*, HUCMSCs were labelled with firefly luciferase by transduction with a lentiviral vector. Furthermore, we determined that the surface markers and differentiation potential of the HUCMSCs were not disrupted after transduction. In this study, we monitored the survival of HUCMSCs in lung tissue 1 d and 7 d after intravenous injection and found that the HUCMSCs homed to injured lung tissue. Moreover, our data indicated the protective roles of HUCMSCs against pulmonary artery remodelling in mice under hypoxia.

Although MSCs can reach impaired sites due to their homing capacity, cell survival in these places is rare. At present, many potential methods to reduce MSC fate *in vivo* have been identified, including drug pretreatment, genetic modification, and preconditioning. However, our study indicated that pretreatment with Fer-1, an inhibitor of ferroptosis, increased HUCMSC survival in the lung, and combined treatment of HUCMSCs with Fer-1 further decreased vascular remodelling in mice with PAH. Conversely, worse cell survival and decreased therapeutic effects were detected in PAH mice after the delivery of HUCMSCs pretreated with erastin, which induces ferroptosis. Thus, the results showed that ferroptosis may have been linked to HUCMSCs survival in mice with hypoxia-induced PAH.

Researchers have indicated that ferroptosis can be activated by iron overload or the inactivation of GPX4[23-25]. During ferroptosis, following its import through TFRC1, Fe^{3+} is catalysed and converted to Fe^{2+} in the cytoplasm, which then participates in the Fenton reaction, causing ferroptosis. Moreover, Fe^{2+} also binds intracellular FTH1, which can be transported to lysosomes by NCOA4, leading to intracellular iron overload. However, GPX4 is the major endogenous factor that reduces lipid peroxidation[26]. Cystine is converted to cysteine by the cystine/glutamate antiporter system (Xc-), which generates GSH, a cofactor for GPX4[27,28]. In addition, the inhibition of SLC7A11, a key component of system Xc^-, initiates ferroptosis[29], and MDA and 4-HNE, which are byproducts of lipid peroxidation, represent stable markers of oxidative stress that are also associated with ferroptosis[30]. In the present *in vitro* experiments, after Fer-1 administration, we detected decreased cell death, the rebalancing of intracellular iron homeostasis, and reduced levels of lipid peroxidation products, indicating that ferroptosis was suppressed by Fer-1 in erastin-treated HUCMSCs. This is consistent with the ability of Fer-1 and erastin to induce and inhibit ferroptosis, respectively[31].

On the basis of our *in vitro* and *in vivo* experimental results, we suggest that the CSE/H_2S pathway mediates ferroptosis in HUCMSCs. Synthesized by CSE in mammalian cells, H_2S has been shown to directly scavenge ROS[32], facilitate GSH production[33], inhibit GPX4 inactivation[34], and enhance the activity of system Xc[35], mitigating ferroptosis. Indeed, in our study, CSE inhibition decreased endogenous H_2S levels and exacerbated ferroptosis in HUCMSCs, while CSE overexpression increased intracellular H_2S production and inhibited ferroptosis in HUCMSCs. Although emerging evidence has shown that Nrf2 is among the major cellular defences against ferroptosis as it promotes the translation of antioxidant genes, such as FTH1[36], GPX4[37], and Xc[38], the effects of the CSE/H_2S pathway on Nrf2 activation in HUCMSCs have not been described. In our investigation, it was apparent that upregulation of the CSE/H_2S pathway promoted the translocation of Nrf2 into the nucleus, which indicated that Nrf2 was activated. In addition, using an Nrf2 inhibitor, we demonstrated that the inhibitory effects of the CSE/H_2S pathway against ferroptosis were mediated through the activation of Nrf2. Interestingly, we also found that the inactivation of Nrf2, in turn, led to the downregulation of CSE, which may have been caused by excessive oxidative stress-induced oxidation of CSE.

Keap1 is known to bind Nrf2 in the cytoplasm and inhibit it, preventing Nrf2 translocation to the nucleus. Under oxidative stress, the dissociation of Keap1 and Nrf2 results in the entrance of Nrf2 into the nucleus, where it initiates gene transcription[39]. In this study, we found that the CSE/H_2S pathway had little effect on total Keap1 protein expression in HUCMSCs. Thus, to further explore the mechanism underlying the effects of the CSE/H_2S pathway on Nrf2 activation, Keap1 S-sulfhydration was investigated in HUCMSCs. S-sulfhydration is a posttranslational modification induced by H_2S that leads to the attachment of sulfhydryl groups to selective proteins, yielding a hydropersulfide moiety (-SSH)[40]. However, the covalent modification that occurs in sulfhydration is reversable by DTT[40]. Recent publications have revealed that H_2S induces the S-sulfhydration of transcription factors, such as Keap1[41]. In this study, we found that Keap1 S-sulfhydration was inhibited upon ferroptosis. By comparing the difference in Keap1 S-sulfhydration between the HUCMSCs/CSE and HUCMSCs/sh-CSE groups, we demonstrated the significant role of Keap1 S-sulfhydration in the protective effects of the CSE/H_2S pathway against ferroptosis in HUCMSCs.

CONCLUSION

In conclusion, the present data provide evidence for the first time that inhibiting ferroptosis improves the survival of HUCMSC transplanted in mice with hypoxia-induced PAH. Moreover, ferroptosis can be suppressed by regulating the CSE/H_2S pathway *via* S-sulfhydrated Keap1/Nrf2 signalling in HUCMSCs. Collectively, the ability of CSE to inhibit ferroptosis suggests that genetic approaches to manipulate CSE expression and H_2S production may provide a novel therapeutic avenue for improving the protective capacity of transplanted MSCs in PAH.

ARTICLE HIGHLIGHTS

Research background

Ferroptosis can decrease retention and engraftment after mesenchymal stem cell (MSC) delivery, which is considered a major challenge to the effectiveness of MSC-based therapy for pulmonary arterial hypertension (PAH). Interestingly, the cystathionine γ-lyase (CSE)/hydrogen sulfide (H_2S) pathway may contribute to mediating ferroptosis.

Research motivation

We aimed to investigate the influence of the CSE/H_2S pathway on ferroptosis in human umbilical cord MSCs (HUCMSCs).

Research objectives

We aimed to clarify whether the effect of HUCMSCs on vascular remodelling in mice with PAH is by CSE/H_2S pathway-mediated ferroptosis. Furthermore, the effect of the CSE/H_2S pathway on ferroptosis in HUCMSCs and the underlying mechanisms were investigated.

Research methods

Erastin and ferrostatin-1 (Fer-1) were used to induce and inhibit ferroptosis, respectively. HUCMSCs were transfected with a vector that overexpressed or inhibited CSE. A PAH mouse model was established using 4-wk-old male BALB/c nude mice under hypoxic conditions, and pulmonary pressure and vascular remodelling were measured. The survival of HUCMSCs after delivery was observed by *in vivo* bioluminescence imaging. Cell viability, iron accumulation, reactive oxygen species (ROS) production, cystine uptake, and lipid peroxidation in HUCMSCs were tested. Ferroptosis-related proteins and S-sulfhydrated Kelch-like ECH-associating protein 1 (Keap1) were detected by western blot analysis.

Research results

In vivo, CSE overexpression improved cell survival after erastin-treated HUCMSCs were delivered to mice with hypoxia-induced PAH. *In vitro*, CSE overexpression improved H_2S production and ferroptosis-related indexes in erastin-treated HUCMSCs, such as cell viability, the iron level, ROS production, cystine uptake, lipid peroxidation, mitochondrial membrane density, and ferroptosis-related protein expression. In contrast, *in vivo*, CSE inhibition decreased cell survival after Fer-1-treated HUCMSC delivery and aggravated vascular remodelling in the PAH mice. *In vitro*, CSE inhibition decreased H_2S levels and restored ferroptosis in Fer-1-treated HUCMSCs. Interestingly, we found that upregulation of the CSE/H_2S pathway induced the S-sulfhydration of Keap1, which contributed to the inhibition of ferroptosis.

Research conclusions

Regulation of the CSE/H_2S pathway in HUCMSCs contributes to the inhibition of ferroptosis and improves the effect of vascular remodelling suppression in hypoxia-induced PAH mice. Moreover, the protective effect of the CSE/H_2S pathway on ferroptosis in HUCMSCs is mediated *via* S-sulfhydrated Keap1/nuclear factor erythroid 2-related factor 2 (Nrf2) signalling. The present study may provide a novel therapeutic avenue for improving the protective capacity of transplanted MSCs in PAH.

Research perspectives

Regulation of the CSE/H_2S pathway in HUCMSCs contributes to the inhibition of ferroptosis and improves the ability of HUCMSCs to suppress vascular remodelling in mice with hypoxia-induced PAH. Moreover, the protective effect of the CSE/H_2S pathway on ferroptosis in HUCMSCs is mediated *via* S-sulfhydrated Keap1/Nrf2 signalling. The present study may provide a novel therapeutic avenue for improving the protective capacity of transplanted MSCs in PAH.

sujeong.jjang@gmail.com

AIMS AND SCOPE

The primary aim of *World Journal of Stem Cells* (*WJSC*, *World J Stem Cells*) is to provide scholars and readers from various fields of stem cells with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJSC* publishes articles reporting research results obtained in the field of stem cell biology and regenerative medicine, related to the wide range of stem cells including embryonic stem cells, germline stem cells, tissue-specific stem cells, adult stem cells, mesenchymal stromal cells, induced pluripotent stem cells, embryonal carcinoma stem cells, hemangioblasts, lymphoid progenitor cells, *etc*.

INDEXING/ABSTRACTING

The *WJSC* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Journal Citation Reports/Science Edition, PubMed, PubMed Central, Scopus, Biological Abstracts, BIOSIS Previews, Reference Citation Analysis, China Science and Technology Journal Database, and Superstar Journals Database. The 2023 Edition of Journal Citation Reports® cites the 2022 impact factor (IF) for *WJSC* as 4.1; IF without journal self cites: 3.9; 5-year IF: 4.5; Journal Citation Indicator: 0.53; Ranking: 15 among 29 journals in cell and tissue engineering; Quartile category: Q3; Ranking: 99 among 191 journals in cell biology; and Quartile category: Q3. The *WJSC*'s CiteScore for 2022 is 8.0 and Scopus CiteScore rank 2022: Histology is 9/57; Genetics is 68/325; Genetics (clinical) is 19/90; Molecular Biology is 119/380; Cell Biology is 95/274.

Abstract

Pain can be defined as an unpleasant sensory and emotional experience caused by either actual or potential tissue damage or even resemble that unpleasant experience. For years, science has sought to find treatment alternatives, with minimal side effects, to relieve pain. However, the currently available pharmacological options on the market show significant adverse events. Therefore, the search for a safer and highly efficient analgesic treatment has become a priority. Stem cells (SCs) are non-specialized cells with a high capacity for replication, self-renewal, and a wide range of differentiation possibilities. In this review, we provide evidence that the immune and neuromodulatory properties of SCs can be a valuable tool in the search for ideal treatment strategies for different types of pain. With the advantage of multiple administration routes and dosages, therapies based on SCs for pain relief have demonstrated meaningful results with few downsides. Nonetheless, there are still more questions than answers when it comes to the mechanisms and pathways of pain targeted by SCs. Thus, this is an evolving field that merits further investigation towards the development of SC-based analgesic therapies, and this review will approach all of these aspects.

Key Words: Inflammation; Neuropathy; Nociceptive; Pain; Pain treatment; Stem cells

Core Tip: Since the discovery of stem cells (SCs), they have emerged from a distant dream into a routine therapeutic approach depending on the field. Nowadays, the use of SCs in pain management is mainly based on their anti-inflammatory capacities, releasing neurotrophic factors and providing cellular support to replace damaged neural cells. Evidence supports that SCs can influence nociceptor neuron sensitization building a foundation for the application of these versatile cells in the treatment of neuropathic and inflammatory pain.

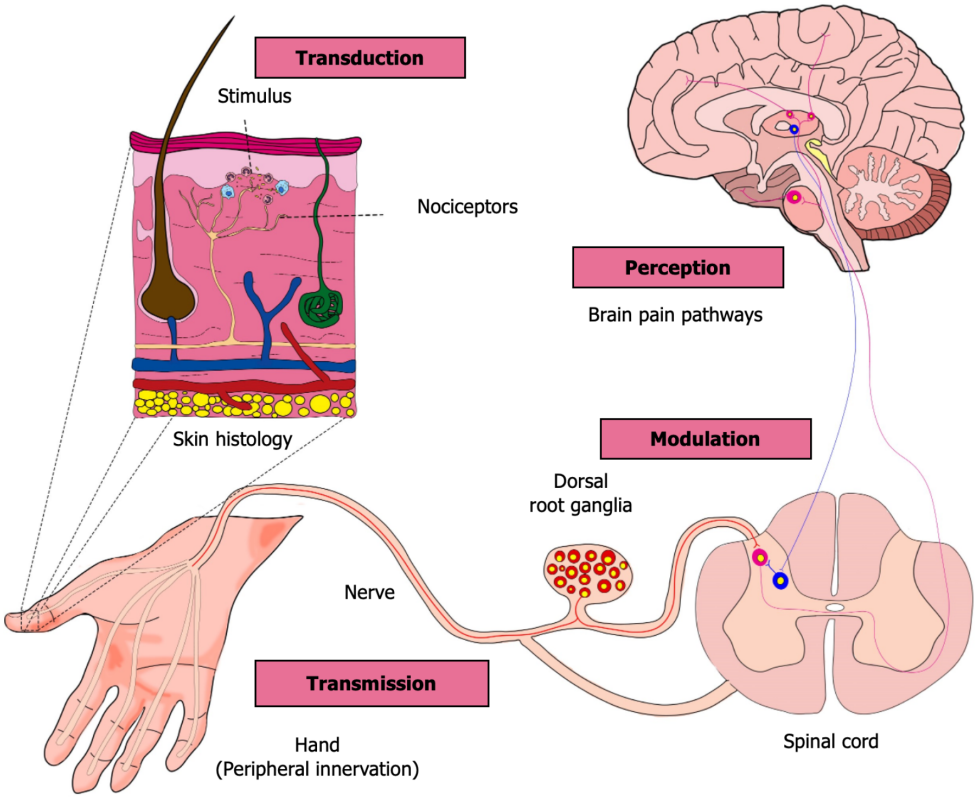
INTRODUCTION

Pain is a major cause of suffering and disability, and can be characterized as a distressing experience that usually signals the presence of injury or disease, generating complex physiologic and emotional responses[1]. According to the Global Pain Index Study by GlaxoSmithKline released in 2020, interviews with 19000 individuals around the world indicate that 34% of the globe's population is in pain every day[2]. Consistently, United States's National Center of Health and Statistics revealed that 20.4% of adults suffered from chronic pain in 2019, and indicated the three major consequences of the condition were: Decreased quality of life, opioid dependence, and poor mental health[3]. This alarming scenario highlights the urgency to pinpoint the physiopathological mechanisms underlying pain and how they interconnect with other systems, which are essential to developing and improving the availability of therapeutic approaches. In this review, we highlight the stem cell (SC)-based therapies aiming to reduce pain. Despite the existence of review articles on SCs and specific types of pain, we observed that there is a gap in the literature regarding comprehensive review articles in this topic approaching various types of pain, the mechanisms of action of SC-based analgesic therapies, and pre-clinical and clinical articles. Therefore, the present review article aims to fill this gap. Data supports that SC-based approaches will revolutionize the field of pain treatment of varied etiologies as we will discuss.



GENERAL VIEW OF PAIN MECHANISMS AND DEFINITIONS

According to the International Association for the Study of Pain (IASP), pain can be defined as "an unpleasant sensory and emotional experience associated with, or resembling that associated with, actual or potential tissue damage"[4]. The mechanisms underlying the physiology of pain are extremely complex, involving at least two types of neurons; one whose cellular bodies are in the dorsal root ganglia (DRG) and axons projecting to peripheral tissues and the spinal cord, which are specialized in the perception of potentially harmful stimuli, and then neurons which are present in the spinal cord and in the cortex of the brain, responsible for interpreting the harmful stimuli[5] (Figure 1).

To fully comprehend the pain-related states that can affect the human body, it is imperative to define their source or the causal initiators. The present review will divide pain scenarios as: (1) Inflammatory pain, which involves the presence of inflammation as the primary cause of pain and is responsible for nociceptor neuron activation and plasticity to induce chronic pain[4]; (2) Pathogen-induced pain, a painful state caused by microbial pathogens that directly activate pain-related receptors, which also involves inflammation, but with the presence of a microorganism initiating the process[6]; and (3) Neuropathic pain (NP), a consequence of damage to the nervous system and extensive tissue repair, leading to residual nerve-healing pain[7].

Usually, pain begins with the recognition of possible damage or potentially harmful molecules. When facing a noxious stimulus, our body is able to respond, at cellular and molecular levels, through the immune and nervous system in an attempt to neutralize and repair the damage caused by such stimulus[8]. The immune system and nervous system are responsible for mediating the inflammatory process, generating edema, heat, redness, pain, and loss of function depending on the intensity of those cardinal signs of inflammation[9,10].

For an inflammatory response to occur, the harmful agent must cause tissue damage in the host, or possess molecules that are recognized by immune cells or neurons to trigger either a pro-inflammatory cascade or neurogenic inflammation, respectively[9]. After recognition, a complex cell signaling process begins, inducing vascular alterations to recruit leukocytes that will reach the primary inflammatory foci by diapedesis[10]. Several molecules secreted by immune cells (*e.g.*, cytokines, chemokines, prostanoids) as well as receptors present in their cell membranes and molecules expressed by the pathogen itself are capable of activating nociceptors[9,11]. Nociceptors consist of a subset of sensory neurons, which innervate peripheral tissues (*e.g.*, joints, skin, respiratory and gastrointestinal tract) and have a role in sensing nociceptive stimuli that will be interpreted in the cortex as pain with all its affective and cultural aspects[12].

Figure 1 Pain mechanism. Representative diagram of anatomical levels involved in the steps of pain from detection of stimulus up to its interpretation and modulation. Starting from the left to the right sides of the figure. The initiation of pain processing starts with the sensing of a noxius stimulus on the skin. This stimulus is detected by nociceptors (whose cellular bodies are in dorsal root ganglia and axons that project to the peripheral tissues and spinal cord) and then relayed to the spinal cord before ultimately reaching the brain (depicted by the ascending pathways in pink). In the brain, the stimulus is interpreted and converted into the sensation of pain. Subsequently, descending pathways (represented in blue) become active, limiting nociceptive input at the spinal cord level. It is crucial to emphasize that glial cells play a significant role in the transmission and modulation of pain. They are activated by neuropeptides released by neurons as well as inflammatory molecules released by immune cells. The recognition of these molecules, whether they are pro-nociceptive or anti-nociceptive, can stimulate glial cells to alter their behavior and contribute to the persistence of the stimulus by releasing nociceptive molecules. Nociceptive neurons can also interact with immune cells that release molecules capable of activating and sensitizing these neurons as well as cause neurogenic inflammation. Varied pathogens (*e.g.*, bacteria, parasites, virus) present virulence factors that can activate nociceptor neurons. For a further in-depth understanding of pain mechanisms in varied conditions we recommend the following review articles[125,174-177].

These stimuli (*e.g.*, inflammatory molecules, pathogen virulence factors) can activate receptors present in nociceptors triggering the phosphorylation of ion channels controlled by ligands [transient receptor potential (TRP) channels] or modify sodium channels controlled by voltage [Voltage-gated sodium (Nav) channels]. Those stimuli, therefore, cause changes in the ion channels facilitating and/or inducing nociceptive neuron depolarization resulting in their sensitization to mechanical and thermal stimulation as well as neuronal firing to transduce the nociceptive information, respectively[9,13]. It is important to stress that the expression of these channels can also be increased due to chronic stimulus, so that neurons that initially express low levels of an ion channel or cytokine receptor start to express them at higher levels[14].

Another important fact, as touched on above, is that the receptor/ion channel activation and pattern of expression can lead to pain sensitization. According to IASP, pain sensitization is defined as increased responsiveness of nociceptors to their normal or subthreshold afferent, and can be divided as hyperalgesia, characterized by increased pain due to a noxious stimulus, or allodynia, a painful response to normally innocuous mechanical or thermal stimuli[15]. Thus, the modifications of what is expressed by nociceptive neurons, and modulating their activation state and responsiveness to stimuli are plastic changes potentially leading to chronic pain.

The functions of the TRP ion channels are related to thermal and mechanical perception[16]. For example the TRP cation channel subfamily V member 1 (TRPV1), involved in heat hypersensitivity and activated by capsaicin; TRP melastatin 8 (TRPM8), involved in cold hypersensitivity; and TRP ankyrin 1 (TRPA1), involved in hypersensitivity to chemical and mechanical stimulation[17]. Furthermore, Nav channels (Nav1.7, Nav1.8 and Nav1.9) are directly responsible for neuronal depolarization, and their expression and activation state can also be modulated during inflammation, infection, and nerve lesions leading to acute and chronic pain[18].

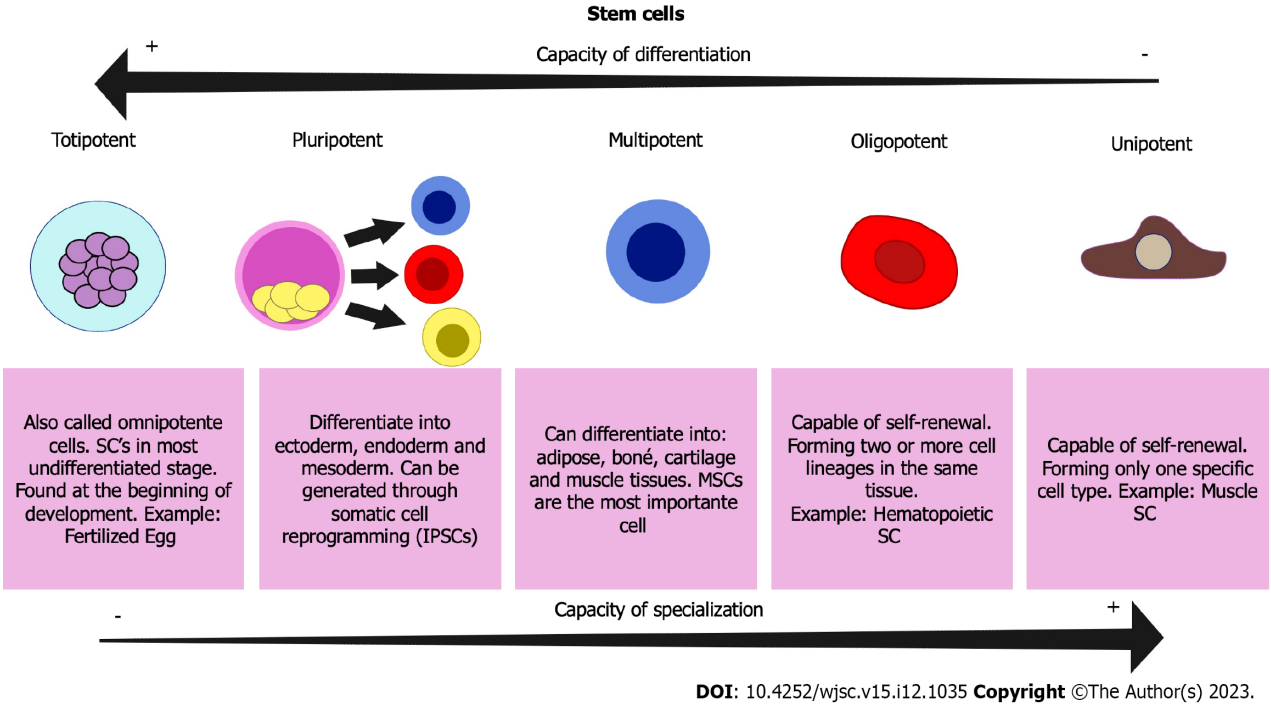
HOW CAN PAIN BE QUANTIFIED IN ANIMAL MODELS?

As this review will approach in great part pre-clinical data using animals, it is important to briefly discuss how "pain" is quantified in animal models. The usage of the term pain to define the quantification of nociceptive behavior in animal models is not widely accepted, because pain assessment involves an emotional component that is often lost in the evaluation of animal responses in most tests. On the other hand, simplifying the terminology by using the word pain, facilitates the understanding by the non-specialized reader about what is under discussion. As an essential physiological mechanism that helps to guarantee the integrity of the organism, pain triggers behavioral responses, for example, moving the hand or paw from a noxious stimulus that can cause tissue damage[19]. In fact, there are subjective components associated with the painful sensation that can only be assessed in humans, since there are variations in the quality and intensity of pain experienced by different individuals for similar injuries, influenced by culture, sex, age, personal experiences, comorbidities and genetic factors[20].

There are different methods to analyze the presence of pain, as well as methods to quantitate it. Most laboratory studies use experimental rodent models, thus, the methodologies are focused on the evaluation of behaviors that can be quantified, such as paw withdraw, paw flinching, paw licking, and abdominal contortions[21], with or without the combination of other methodologies (*i.e.,* place preferences to temperatures or even self-administration of treatment).

Nociceptive assessment methods can be divided into stimulus-evoked and non-stimulus-evoked (spontaneous) behaviors. Spontaneous pain occurs regardless of the presence of an additional evoking stimulus and can be assessed using grimace scales, burrowing assays, gait analysis and weight-bearing methods[21]. Pain evoked by a stimulus can be described as hyperalgesia or allodynia[22]. This parameter is evaluated according to the type of stimulus, being subdivided into mechanical, heat and cold stimuli. Methods that assess pain evoked by mechanical stimuli seek to assess nociceptive sensitivity to a mechanical stimulus (*i.e.,* mechanical pressure on the paw), normally using the von Frey filament method (allodynia indicator), electronic pressure meter test (hyperalgesia indicator), and Randall & Sellito tests (which use increasing pressure or constant pressure over time, assessing hyperalgesia). The analysis of pain evoked by temperature stimuli seeks to assess thermal nociception, either by a heat source (*i.e.,* hot plate, Hargreaves test, tail flick), cold (*i.e.,* cold plate, cold plantar assay and acetone application/evaporation test) or both (*i.e.,* temperature place preference)[21].

Furthermore, behavioral tests are usually analyzed in conjunction with data obtained from cellular and molecular experimental approaches. For instance, neuronal function, activity, and phenotype can be assessed *in vivo* and *in vitro* using electrophysiology studies, intracellular calcium levels, immune staining of neuronal populations and their markers of activation and/or function, release of neuropeptides, cytokines and neurotransmitters, patterns of mRNA, protein and lipid profiles, and optogenetics. Additionally, it is also possible to study the contribution of non-neuronal cells in the nociceptive processes by staining glial immune and parenchymal cells, phenotype markers, and quantitating their production of mediators and functions. Thus, behavioral assays can be accompanied by a great variety of non-behavioral methods to demonstrate a specific hypothesis[23,24].



SCS: TYPES AND SOURCES

SCs are non-specialized cells with a high capacity for replication and self-renewal that have a wide range of differentiation possibilities[25]. These cells are present in all stages of life (embryonic, fetal, and adult), they give rise to differentiated cells in organs[26] and are involved in the development, maintenance, repair and renewal of tissues[27].

SC can be categorically divided into five distinct groups (totipotent, pluripotent, multipotent, oligopotent, and unipotent) according to their ability to differentiate, which varies according to the origin and derivation of the cell[26]. Totipotent SC, also called omnipotent, are the cells in the most undifferentiated stage and are found at the beginning of development (*i.e.,* fertilized oocyte)[28]. Pluripotent SC are cells that differentiate from the three germ layers (ectoderm, endoderm and mesoderm)[29]. These cells can be generated through somatic cell reprogramming and are called induced pluripotent SC (iPSC)[26]. Multipotent SC are found in most tissues and have the ability to differentiate into varied tissues, such as adipose, bone, cartilage, and muscle[30]. Within this group, mesenchymal SC (MSC) are the most important cells as will be discussed[26]. Oligopotent SC (*i.e.,* hematopoietic SC) are cells capable of self-renewal, forming two or more cell lineages in the same tissue[31]. Finally, unipotent SC are cells capable of self-renewal and differentiation into only one specific cell type[26] (Figure 2).

Although it might seem that specialization could mean restriction in some tissue types, totipotent SC have virtually no boundaries for differentiation, whereas pluripotent SC demonstrate some degree of specialization. As for the multipotent subgroup, MSC have the advantage of originating in different tissues. MSC have a differentiation rate compatible with the potential application as a pain treatment, particularly for inflammatory and autoimmune diseases[25,32,33].

In addition to classification according to their ability to differentiate, SC can also be classified according to their origin, forming four distinct groups (embryonic, fetal, adult and induced). Embryonic SC (ESC) are pluripotent SC derived from the blastocyst after fertilization (5 to 6 d)[34]. Similar to pluripotent SC, ESC differentiate into the three germ layers or remain in an undifferentiated stage[29,35]. Fetal SC are cells that remain in tissues in a quiescent state until local stimulus induces their proliferation and differentiation into specific cells of the tissues in which they are located[26]. Adult SC are cells derived from the three germ layers and the placenta[26] and depend on specific signals to enter cell division[36]. These cells are important resources in the cell repair and healing processes, as they help to maintain tissue homeostasis by replacing senescent or damaged cells[36]. Finally, iPSC are pluripotent SC produced from the genetic reprogramming of adult somatic cells[26], developing a state similar to ESC, both in morphology, proliferation and gene expression[37].

Figure 2 Types of stem cells: Different types and characteristics. Representative scheme of the different subtypes of stem cells and their main characteristics. SC: Stem cells; MSC: Mesenchymal stem cell; iPSC: Induced pluripotent stem cell.

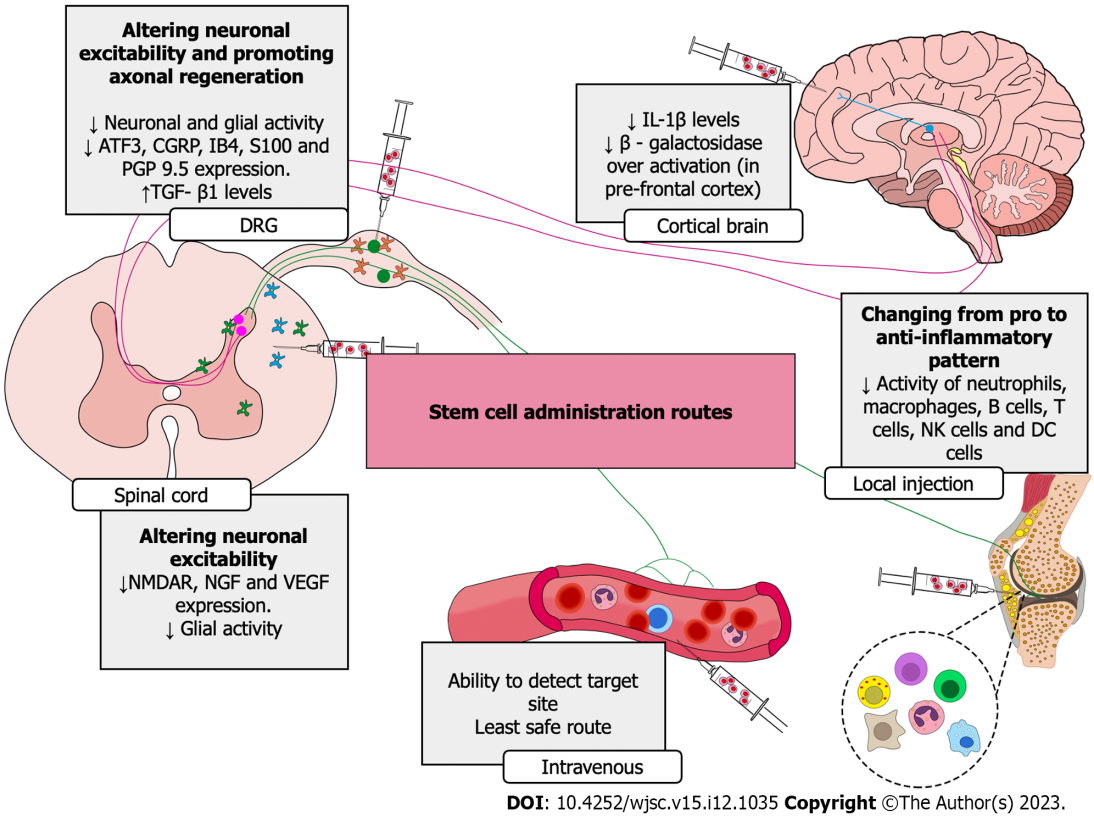
Currently, MSC are the main subset of SC used in therapeutic approaches, as they can be isolated from any source of human tissue and reprogrammed. MSC have the advantage of being derived from the patient and, therefore, are adequate for the donor/patient, minimizing the possible ethical issues that could arise from the use of cells from a third-party donor[38,39].

In this review, we discuss recent studies that illustrate the advantages and disadvantages of SC technology to treat painful conditions. Although SC studies have become a popular field of research, there are still a lot of unanswered questions regarding the possible application of SC in pain treatment as well as data supporting their therapeutic benefit.

HOW CAN SC TREATMENT BE USED IN PAIN MANAGEMENT?

Currently, analgesic treatment strategies include acetaminophen, nonsteroidal anti-inflammatory drugs, antidepressants, antiepileptics, local anesthetics, and opioids; and their use is closely linked to significant side effects such as: High renal and hepatic toxicity, headaches, mood swings, constipation, nausea, weight gain and even dependence[40]. Furthermore, these drugs have limited efficacy (Table 1). The statistical measurement for this effectiveness is the number needed to treat (NNT), which is the number of people who must be treated with a given drug for the desired effect to be observed in one person. Thus, the closer the NNT is to 1 the higher the treatment efficacy is[41]. Along with concerning adverse effects, the present scenario highlights the need of additional options to control and treat painful conditions[40].

In this context, the use of SC as a therapeutic approach for pain treatment has great potential due to their unique properties. In general, the use of SC for pain treatment is based on their ability to: (1) Modulate the inflammatory process, switching the pro-inflammatory profile into a pro-resolving state; (2) Interacting directly on the peripheral nervous system, promoting changes on neuronal excitability of primary afferent nociceptor neurons; and (3) Acting on the central nervous system (CNS), *via* alteration of neuronal excitability in the spinal cord and brain (Figure 3). These mechanisms will be discussed in detail throughout the following paragraphs.



The first mechanism of action of SC to control pain is to modulate the inflammatory process. SC can shape the activity of neutrophils, macrophages, B cells, T cells, natural killer (NK) cells and dendritic cells[42] (Figure 3). In innate immunity, SC regulatory action is based on their ability to produce soluble human leukocyte antigen G5 [capable of inhibiting NK cell-mediated cytolysis and interferon-gamma (IFN-γ) secretion][43]. Another important point is that SC are able to increase the production of interleukin-10 (IL-10), an important cytokine involved in the polarization of M2 macrophages, inducing tissue repair effects[44]. In adaptive immunity, the effects of SC actions involve increased nitric oxide (NO) production (suppressing T cell activity)[45], reduced prostaglandin E_2 (PGE_2) levels[46] and increased indoleamine 2,3-dioxygenase (IDO) activity[47]. Furthermore, it has also been described that treatment with SC increase the expression of IL-4 (by type 2 helper cells)[46] and IL-10[44].

On the other hand, SC can also produce soluble mediators to shape the inflammatory response. SC can be stimulated by inflammatory cytokines such as IFN-γ, IL-1α, IL-1β and tumor necrosis factor alpha (TNF-α)[45,48]. However, in response to those inflammatory cytokines, SC produce transforming growth factor-beta (TGF-β) and IL-10, which are

Figure 3 Analgesic mechanisms of stem cells depending on the route of administration and targets/tissues. This scheme summarizes the mechanistic changes caused by stem cell (SC) treatment that resulted in analgesia. The explanation of analgesic mechanisms of SC treatments in the cerebral cortex, spinal cord, dorsal root ganglia, intravenous and local treatment (intra articulary) (indicated by the syringes) can be observed by up and down arrows plus the changed parameter. ATF3: Activating transcription factor 3; CGRP: Calcitonin gene-related peptide; IB4: Isolectin B4; NMDAR: N-methyl-D-aspartate receptor; NGF: Nerve growth factor; PGP9.5: Protein gene product 9.5; VEGF: Vascular endothelial growth factor; TGF: Transforming growth factor; IL: Interleukin.

anti-inflammatory and analgesic cytokines[49,50].

Added to their anti-inflammatory capabilities, SC become promising potential candidates to reduce peripheral sensitization of afferent sensory neurons[51] (Figure 3). SC can decrease the production of cytokines (IFN-γ[46], IL-2[46], IL-17[52] and TNF-α[46]) capable of sensitizing nociceptors and leading to hyperalgesia. SC can also increase the level of cytokines capable of decreasing nociception such as IL-4[46] and IL-10[53,54]. On the other hand, treatment with SC can increase the level of molecules indirectly linked to the promotion of hyperalgesia, such as NO (has a dual role in pain)[45,55], PGE_2[46,56] and IDO[47,57].

These data provide evidence that the applicability of treatment in inflammatory conditions directly depends on the inflammatory microenvironment, which can be positively influenced by SC both by decreasing molecules linked to nociceptive sensitization and by increasing molecules indirectly linked to reducing pain (Figure 3). However, specific cellular targets and the source of soluble mediators were not fully investigated in the experimental settings. We envisage that the field would present a huge evolution if the studies focused not only in quantitating the modulation of soluble mediators, but also investigating the cellular targets and interactions explaining the activity of SC.

In addition to their action on the neuroimmune axis (DRGs and the immune system), an interesting fact that has not been explored much is that SC have a key structural similarity with primary afferent nociceptive sensory neurons. Primary afferent nociceptive sensory neurons and bone marrow-derived mesenchymal stromal cells express the TRPM8 receptor. Recent studies demonstrate that the influence of this receptor on neurons involves the detection of cold temperatures (18-23 °C), and that TRPM8 inhibition reduces pain[58]. In addition, this channel is also capable of modulating cell differentiation in SC, as its activation increases osteogenic differentiation in human bone marrow MSC[59].

The use of SC in pain treatment is also based on the ability of these cells to act on the CNS since they have the ability to desensitize the CNS by inhibiting glutamate-related pathways (reduction of NMDAR expression and TGF-β1 secretion) [60]. Furthermore, SC can decrease central sensitization, *via* reduced glial cell activity, once again contributing to the attenuation of hyperalgesia[61] (Figure 3), these points will be discussed in further details in the following topics.

SC IN THE TREATMENT OF INFLAMMATORY DISEASES AND INFLAMMATORY PAIN

The number of articles investigating the relationship between pain and SC is still small, so this section was divided into two parts: (1) The use of SC to treat inflammatory diseases. This part is of interest in terms of the perspective of application to inflammatory pain since inflammatory mediators can induce nociceptor sensitization mechanisms; and (2) Articles that analyze the analgesic activity of SC treatment.

SC in the treatment of inflammatory diseases without the assessment of pain

In this topic we will present the mechanisms behind the ability of SC to modulate the inflammatory response, and the most recent discoveries involving SC and inflammation. Reducing pain is a potential outcome since inflammation was reduced in these studies, however, this specific disease symptom was not tested.

As previously discussed, the inflammatory process is composed of a series of signals. Through the release of inflammatory molecules (cytokines, leukotrienes, and prostanoids), which are used for cellular communication, tissue resident immune cells start the inflammatory response process. Examples of these inflammatory molecules include, for instance, IL-1β, IL-5, IL-6, IL-17A, TNF-α, nerve growth factor (NGF), LTB_4, 5-HT and PGE_2. They have a role in the recruitment and activation of leukocytes and some can also activate receptors expressed by the primary afferent nociceptor sensory neurons inducing the activation (causing depolarization) or sensitization (causing an enhancement of response upon other chemical, mechanical or thermal stimulation) of these neurons. This neuro-immune interaction is relevant to pain and inflammation[62] and we will discuss how SC can interfere with it.

Neutrophils are the most abundant cell type in the blood and large numbers are recruited in acute inflammation[63]. SC activity on neutrophils may present two distinct patterns[64]. MSC can suppress hydrogen peroxide production in activated neutrophils in vitro. On the other hand, tissue resident glandular MSC seem to play an early role in lipopolysaccharide (LPS)-triggered inflammation by producing cytokines and chemokines to recruit neutrophils. These polymorphonuclear leukocytes presented an increase in their lifespan, chemokine production and response to LPS stimulation[65]. This MSC-dependent response is protective in the sense that LPS stimulation represents part of an infection. On the other hand, neutrophils can participate in the induction of pain by producing LTB_4 and PGE_2, which activate and sensitize nociceptor neurons[66,67]. Reactive oxygen species can also activate nociceptor neurons[9].

One of the most important anti-inflammatory mechanisms of SC is to induce a class switch in the pattern of macrophages from M1 phenotype to M2 phenotype. This ability was observed in models of osteoarthritis using the treatment with exosomes from iPSC and MSC. The M2 macrophage phenotype is involved in tissue repair as well as in the resolution phase of inflammation[68]. Upon inducing this macrophage phenotype switch, there is a decrease in the production of pro-inflammatory cytokines IL-1β and TNF-α produced by M1 macrophages[68,69]. Interestingly, this activity seems to be related to SC-derived PGE_2. Contrasting with the hyperalgesic role of PGE_2 in inflammation by sensitizing primary nociceptive sensory neurons[70], this prostanoid also has other regulatory functions. For instance, when dendritic cells are stimulated to produce PGE_2 and IL-10, these antigen presenting cells reduce the expression of major histocompatibility complex (MHC)-II and CD86, thus, reducing their function of presenting antigens. As a result, there is a reduction of lymphocyte proliferation and adaptive immune response[71]. This evidence points to specific roles of PGE_2 and how somewhat opposing effects can be triggered by this prostanoid depending on the site of production and cellular target as well as explain anti-inflammatory activities of SC. Furthermore, PGE_2 can induce the production of TSG-6[72], which is capable of converting the macrophage phenotype from pro-inflammatory to anti-inflammatory[73]. Finally, MSC can recruit monocytes and macrophages through the production of chemokines such as C-C motif chemokine ligand (CCL)2, CCL3 and CCL12 in inflamed tissue, which contributes to the tissue repair[72,74].

Another characteristic of SC is their ability to interfere with the lymphocytic pattern. In Crohn's disease patients, it was observed that treatment using MSC was able to decrease lymphocyte proliferation, the proportion of CD4+ T cells, and decreases the levels of TNF-α and IL-6. The authors also demonstrated an increase in regulatory T cells (Tregs) and IL-10 production, thus, suggesting that an MSC would shift the T cell population towards an increase of Tregs that produce IL-10 to limit inflammation and reducing CD4+ T cells[75]. It has also been reported that SC are able to inhibit the prolif-

eration of B lymphocytes[76]. The mechanism by which SC can affect these changes in both T and B lymphocytes is not fully elucidated. However, Lin *et al*[77] demonstrated that SC express adhesion molecules vascular cellular adhesion molecule-1 and intracellular adhesion molecule 1, which lead to adhesion to lymphocytes indicating a possible SC contact dependent regulation of lymphocyte function[78]. In addition, SC release NO, PGE_2 and hepatocyte growth factor[79], as well as activate the programmed cell death 1 death receptor[80], suggesting that SC could reduce lymphocyte proliferation and survival[81-83].

In addition to its influence on the immune system, it is also interesting to note the opposite. One of the reasons why most studies use MSC is due to their ability to evade the immune system explained by their lack of HLA class I and II surface markers. Both molecules are necessary for recognition by immune cells, thus, lacking such molecules is an essential characteristic to avoid the rejection of the transplanted SC and also leaves open the possibility of transplanting cells from one donor to a patient, and not solely autologous transplantation[77]. Despite this characteristic, most human studies involving SC and inflammation use MSC in a non-randomized manner. It is also noteworthy that MSC are believed to be the only SC with immunoregulatory and regenerative capabilities, in addition to presenting almost all of the effects mentioned above in this topic[77].

Application of SC in the treatment of inflammatory pain

Inflammatory pain occurs when afferent sensory neurons detect specific molecules that are able to sensitize or activate these neurons, such as cytokines, peptides, and other molecules[84]. Most of these molecules are secreted by immune and glial cells, which normally communicate in a controlled and homeostatic manner. In inflammatory diseases, there is an imbalance between pro and anti-inflammatory molecules, leading to the activation of membrane receptors in nociceptive neurons and the consequent activity of sodium channels and TRP channels resulting in neuronal sensitization and activation[9]. Inflammation also leads to neuronal plasticity in which they express higher levels of ion channels, additional receptors, and present enhanced activity and response when compared to a non-sensitized neuron. These plastic alterations cause the transition from an acute to a chronic pain state[85].

Table 2 summarizes the current literature in which SC treatment was applied to reduce pain; taking as a principle that these cells can reduce the production of pro-hyperalgesic molecules. It is noteworthy that studies on the analgesic activity of SC in inflammatory pain have been increasing in the last 10 years. Before that, the articles were mainly focused on the mechanisms of inflammation control using SC, but not necessarily on pain. Evidence supports that the mechanism by which SC reduce thermal and mechanical hypersensitivity is based on three perspectives: (1) Targeting the inflammatory response: By having the ability to reduce the secretion of pro-inflammatory cytokines (capable of sensitizing nociceptors) such as IL-6, TNF-α and IL-17[69,86,87] as well as increasing IL-4 levels, a cytokine capable of mediating analgesia[88]; (2) Modifying cell phenotype: the effects of these cytokines (mentioned in the perspective 1) are also based on the ability of SC to induce a change in the macrophages phenotype from M1 to M2 (non-phlogistic macrophage)[88], in addition to decreasing CCL2, CCL5 and CXC10 (macrophage recruiting factors)[87]. Additionally, SC participate in the reduction of mast cell degranulation, which would result in the secretion of varied molecules with nociceptive activities such as 5-HT, histamine, LTB_4 and cytokines[89]; and (3) Neuronal and glial effects: The treatment with SC can decrease the expression in the spinal cord of calcitonin gene-related peptide (CGRP)[90] and ionized calcium-binding adaptor molecule 1 (IBA-1) (marker of glial activation, related to central sensitization)[91] and decrease the activity of immune cells. The current understanding is that SC activity occurs through the secretion of TSG-6[92], a soluble chemokine-binding protein. In turn, TSG-6 acts through inhibiting the expression of protein kinase C-γ[87] and suppressing the Toll-like receptor 2 (TLR2)/myeloid differentiation factor-88 adaptor protein (MyD88)/nuclear factor kappa B (NF-κB)[91] signaling pathway. This TLR2/MyD88/NF-κB cascade occurs in glial cells in the spinal cord and its activation leads to the production of pro-inflammatory/hyperalgesic cytokines.

The studies that address treatment in humans do not address possible signaling mechanisms of SC. However, SC treatment decreases pain for 6 mo [autologous bone marrow concentrate, one treatment, (0.5-1) × 10^6 cells][93] to 1 year (autologous adipose-derived stromal vascular cells, one treatment, 14 × 10^6 cells)[90] in knee osteoarthritis patients and for 2 years for discogenic back pain patients[93]. Thus, although the analgesic mechanisms of SC in humans remains elusive, the data supports the analgesic effect of clinical SC treatment.

SC TREATMENT OF PATHOGEN-INDUCED PAIN

In general, treatment using SC has great analgesic and anti-inflammatory potential. Similarly to sterile inflammatory diseases, infections also cause inflammation, however, there is a dual role in which inflammation involves the immune response against the pathogen as well as being responsible for tissue damage. Finding the balance between these two effects is difficult[94]. Studies involving SC and infections caused by bacteria and viruses are restricted only to the inflammatory context of infections. On this topic we will present data that demonstrate a potential analgesic effect in diseases caused by SC in bacterial and viral infections.

Bacteria-induced pain

Bacterial infections can commonly cause discomfort and pain[95]. It is believed that pain caused by bacteria and their bacterial components can occur in two different manners: The first and most classic one occurs through the activation of immune cells, production of pro-inflammatory cytokines, and the consequent nociceptor sensitization by neuronal effects of inflammatory molecules[96,97]. The second occurs through the direct activation of nociceptor neurons by bacterial virulence components, such as α-hemolysin, capable of forming pores (as its primary activity), thus activating both

Table 2 Articles that used stem cells to treat inflammatory pain (stem cell-based treatment of inflammatory pain or in models where pain is certainly involved, but was not investigated)

Ref.	Stem cell therapy design	Key findings	Pain-related highlights	Route of administration	Number of cells or amount of extracellular vesicles and exosomes
Hsueh *et al* [69], 2023	iPSC-derived EVs for the treatment of rabbit articular cartilage OA in an *in vivo* model and an *in vitro* interleukin (IL)-1 β-induced model	Improvement in both *in vivo* and *in vitro* models of OA by stimulation of chondrocytes proliferation and decreasing senescence were accompanied by: Decreasing of TNF-α); IL-6; protein 21 (p21); MMP 13; ADAMTS5; and increasing of collagen II	Indirect: Specific pain receptors/pathways weren't investigated	i.a.	100 μg iPSC-EV
Gao *et al* [184], 2022	Small EVs from iPSC-derived mesenchymal stem-cells ameliorate tendinopathy pain by inhibiting mast cell activation	The treatment was able to decrease acute pain in tendinopathy, as well as inhibit infiltration of activated mast cells and interactions with nerve fibers *in vivo*. In the *in vitro* experiments, the treatment decreased mast cell degranulation and the expression of pro-inflammatory cytokines and genes involved in the hypoxia inducible factor-1 signaling pathway	Pain behavior was measured by the von Frey method. And the weight distribution on the knees by SWB; immunofluorescence staining of tendon sections for tryptase (mast cell marker) and PGP9.5 (nerve fiber marker) was performed to assess the number of activated mast cells and the anatomical interaction between mast cells and nerve fibers. In addition, the SWB and CatWalk test was also. carried out	Local injection (quadriceps tendon)	1×10^9 particles
Yu *et al* [185], 2022	Intravital imaging and single cell transcriptomic analysis for engraftment of mesenchymal stem-cells in an animal model of interstitial cystitis/bladder pain syndrome	The transplanted cells formed a perivascular-like structure. They were also shown to express cyclin-dependent FOSe kinase-1 which played a key role in modulating the migration, engraftment and anti-inflammatory functions of multipotent MSCs, which determined their therapeutic potency *in vivo*	*In vivo* two-photon intravital microscopy and single-cell transcriptome analysis were used to assess the effects of stem cell treatment on interstitial cystitis/bladder pain syndrome	Injected into the outer layer of the anterior wall and dome of the bladder	10^6
Zhang *et al* [186], 2022	EVs derived from MSCs alleviate neuroinflammation and mechanical allodynia in interstitial cystitis rats by inhibiting NLRP3 inflammasome activation	SC treatment decreased suprapubic mechanical allodynia and frequent urination in rats with interstitial cystitis. It also decreased glial cell activity as well as neuroinflammation in the spinal cord. Furthermore, the treatment was able to decrease the activation of NLRP3 inflammasomes and the TLR4/NF-κB signaling pathway	Behavioral test (von Frey) was performed to measure allodynia and western blot and immunofluorescence for protein related to inflammation and central sensitization analysis: CD9, CD63, CD81, ALIX, TNF-α, IL-1β, IL-6, IBA-1, GFAP, NLRP3, Caspase-1, IL-18, TLR4, p65 NK-κB, phospho-p65 NK-κB (western blot). NLRP3, neuron-specific nuclear protein, GFAP and OX-42 labeling (immunofluorescence)	i.t.	20 μg
González-Cubero *et al* [86], 2022	EV and soluble fractions of adipose tissue-derived MSCs secretome induce inflammatory cytokines modulation in an *in vitro* model of discogenic pain	There was a decrease in the expression of IL-6, IL-8 and IL-17	Indirect method: The authors measured the regulatory capacity of EVs on the inflammatory molecules IL-1α, IL-1β, IL-6, IL-8, IL-17, nerve growth factor, brain-derived neurotrophic factor, IFN-γ, NF-κB and TNF and MMP-1, MMP-2, MMP-3, MMP-13 and ADAMTS-5	*In vitro* model	1×10^6
Yang *et al* [91], 2020	Anti-inflammatory protein TSG-6 secreted by bone marrow MSCs attenuates neuropathic pain by inhibiting the TLR2/MyD88/NF-κB signaling pathway in spinal microglia	Stem cells are capable of secreting TSG-6. This article demonstrated that i.t. administration of this protein leads to a decrease in mechanical allodynia and heat hyperalgesia. In addition to inhibiting neuroinflammation in the spinal cord (IBA-1), the protein administration inhibited the activation of the TLR2/MyD88/NF-κB pathway in the dorsal horn of the ipsilateral spinal cord by the secretion of TSG-	The activation of the TLR2/MyD88/NF-κB signaling pathway was evaluated by western blot and by immunofluorescence. Mechanical allodynia and heat hyperalgesia were observed by behavioral tests	i.t.	5×10^6

		6 and reduced the production levels of pro-inflammatory cytokines, such as IL-1β, IL-6 and TNF-α			
Zhang *et al* [187], 2019	MSCs exosomes alleviate temporomandibular joint OA by attenuating inflammation and restoring matrix homeostasis	It was observed that the treatment led to repair of the temporo-mandibular joint, along with a reduction in inflammation and pain. Treatment increased IL-1β-impaired sulfated glycosa-minoglycan synthesis and suppressed IL-1β-induced nitric oxide and MMP13 production. These effects were partially abrogated by inhibitors of adenosine receptor, protein kinase B, ERK and adenosine monophosphate activated protein kinase phosphorylation	Mechanical hyper-nociception was assessed using the von Frey microfilament. The expression of inflammatory mediators and other components was measured using quantitative polymerase chain reaction	i.a.	100 μg
Ebbinghaus *et al*[88], 2018	A promising new approach for the treatment of inflam-matory pain: Transfer of stem cell-derived tyrosine hydroxylase-positive cells (mouse model)	It has been demonstrated that the administration of endogenous tyrosine hydroxylase positive cells (iTH+) cells, prior to the induction of antigen-induced arthritis, was not sufficient to suppress the disease. However, the treatment was able to decrease pain behavior evoked by inflammation, largely due to the production of IL-4 induced by iTH+ cells. Furthermore, the treatment was able to reduce the levels of pro-inflammatory molecules, in addition to increasing the number of M2 macrophages in dorsal root ganglia	Inflammatory molecules were quantified, such as: IFN-γ, IL-2, IL-4, IL-6, IL-10, CCL3, CCL5, CXCL1, CXCL2, CXCL10, and CXCL12. Additionally, pain-related behavior tests and IBA-1 and arginase 1 labeling in the dorsal root ganglion *via* immunofluorescence was performed	i.v.	10^6
Ichiseki *et al* [92], 2018	I.a.-injected MSC stimulate anti-inflam-matory molecules and inhibits pain related protein and chondrolytic enzymes in a monoiodo-acetate-induced rat arthritis model	The treatment was able to inhibit central pain sensitization (decreased expression of CGRP in the spinal cord) and increase the secretion of TSG-6 by stem cells, an anti-inflammatory factor and cartilage protector	For the evaluation of central sensit-ization, CGRP staining was performed by immunofluorescence. And the histochemical technique was also used for the evidence in the joint of ADAMTS5 and TSG-6	i.a.	5.0×10^6
Fodor and Paulseth [90], 2016	Adipose derived stromal cell injections for pain management of OA in the human knee joint	After 3 mo of treatment, patients showed improvement in WOMAC and VAS scores, which were maintained for 1 yr. ROM and TUG improved until the third month. All patients achieved full activity with decreased knee pain and no infections or adverse effects reported	Patients were evaluated by following scores on the WOMAC, VAS pain scale, ROM, TUG, and magnetic resonance imaging	i.a.	14.1×10^6 nucleated stromal vascular fraction cells per knee
Pettine *et al* [93], 2016	Treatment of discogenic back pain with autologous bone marrow concentrate injection with minimum two-year follow-up (humans)	Stem cell treatment reduced visual analog scale and Initial Oswestry Disability Index scores. In addition to reducing pain in patients. The treatment proved to be effective for up to 2 yr after the injection	Pain was assessed using scores provided by patients	Intradiscal injection	$(0.5\text{-}1) \times 10^6$
Durand *et al* [89], 2015	Persistent visceral allodynia in rats exposed to colorectal irradiation is reversed by MSC treatment	Induced a time-dependent reversion of the visceral allodynia and a reduction of the number of anatomical interactions between mast cells and PGP9.51 nerve fibers	Spinal sensitization (was available for labeling of phospho-ERK neurons), colonic neuroplasticity (as increased density of substance P1 nerve fibers); s, visceral sensitivity was evaluated by studying the contraction of the abdominal muscles in response to colorectal distension	i.v.	1.5×10^6
Watanabe *et al*[87], 2015	Early transplantation of MSC after SCI relieves pain hypersensitivity through suppression of pain-related signaling cascades and reduced inflammatory cell	The treatment was able to decrease thermal and mechanical hypersens-itivity. Improvements in pain were mediated by suppression of PKC-γ and p-CREB expression in dorsal horn neurons. The authors also reported a decrease in the levels of	Mechanical allodynia and thermal sensitivity were recorded. In addition, immunofluorescence was performed on spinal cord sections, labeling for: PKC-γ or p-CREB, GFAP, cD11B and phospho-protein 38. For immunoblot analysis,	Injection into the middle of the contusion site, identified as the middle point of the laminectomy area	2.0×10^5

	recruitment	pro-inflammatory cytokines (TNF-α, IL-6), mediators of early secondary vascular pathogenesis (MMP9) and macrophage recruitment factors (CCL2, CCL5 and CXCL10). All in addition to increased levels of a microglial stimulating factor GM-CSF)	components of the mitogen-activated protein kinase family, inflammatory mediators (TNF-α, IL-6, MMP-9), macrophage recruiting factors (CCL2, CCL5, and CXCL10) and GM-CSF (a microglial stimulating factor) were analyzed		
Emadedin *et al*[188], 2012	Intra-articular injection of autologous MSC in six patients with knee OA	The treatment was able to improve scores related to pain, the functional status of the knee and the distance covered up to six months after the injection	VAS which is a subjective assessment that represents the patient's perception of the current pain state with a higher score reflecting more severe pain. Functional status of the knee was assessed by WOMAC OA index. This index evaluates pain, joint stiffness, physical and social function of patients with OA of the knee	i.a.	(20-24) × 10^6

Nav1.8+ and TRPV1+ neurons[98,99]; or by LPS, which is capable of activating TLR4 expressed by neurons or be sensed by TRPA1 (at lower doses) and even TRPV1 (at higher doses)[100,101]. Thus, bacteria can induce nociceptor sensory neuron sensitization indirectly by activating immune cells that will produce nociceptor sensitization molecules or directly by activating neuronal receptors and triggering nociceptor depolarization by forming membrane pores[96].

As discussed in the topic "SC in the treatment of inflammatory diseases and inflammatory pain", the effects of SC activity on bacterial infections have two main characteristics. The first is that treatment with SC can increase phagocytic activity and neutrophil survival in bacterial infections[102,103]. Second, SC treatment can attenuate exacerbated immune responses, as seen in a murine model of endotoxemia induced by LPS, the administration of MSC by the intraperitoneal route is capable of reducing the severity of the disease, mainly by reducing the levels of IL-1β, IL-6, IL-8 and TNF-α and increasing IL-10 in the plasma, as well as reducing the recruitment of neutrophils in the liver[104].

Despite demonstrating great analgesic potential by reducing the levels of cytokines causing hypersensitivity and increasing bacterial clearance, no articles were found that investigated a possible decrease in pain in models that use bacteria and SC treatment. This fact highlights a gap in the literature and potential field to be explored.

Viral infection-induced pain

In general, viral infections can cause pain. Depending on the type of virus and site of infection, an inflammatory process begins, characterized by the high release of inflammatory mediators. The detection of these mediators can occur through the central or peripheral nervous system[11]. A recent study demonstrated that most of the symptoms of intranasal H1N1 infection (reduction in food intake, water intake, and mobility during early-stage infection and improved survival) come from the detection of PGE_2. This prostanoid activates EP3 receptors, which are expressed in both the hypothalamus and circumventricular organs, as well as in nerve endings in the nasopharynx[105]. It has also been demonstrated that the herpes simplex virus 1 can also infect the neurons present in the DRG, and the persistence of the virus leads to the recruitment of leukocytes to the region, TNF-α secretion and neuronal hypersensitivity[106]. While the pain caused by Chikungunya virus depends on its envelope protein E2 activation of TRPV1+ nociceptor sensory neurons[107].

As discussed earlier, SC have a high anti-inflammatory capacity. This characteristic is also observed against viruses since treatment with SC can decrease the levels of cytokines[108] that sensitize nociceptors. An interesting fact about SC is that these cells have IFN-responsive genetic machinery. Therefore, upon detecting the presence of the signal produced in viral infections (flavivirus, dengue and Chikungunya virus), they express genes related to IFN-induced transmembrane proteins, which prevents the contamination of these cells[109]. In murine models, treatment with MSC reduces the levels of IL-1α, IL-6, TNF-α and IFN-γ in response to H9N2 infection[110]. It has also been described that the administration of extracellular vesicles derived from MSC was able to reduce the viral load in lung epithelial cells of pigs infected with H1N1/H7N2/H9N5[111]. Recent evidence demonstrates that extracellular cells derived from MSC have the *in vitro* capacity to inhibit the replication of the Influenza virus and severe acute respiratory syndrome coronavirus 2[112]. It is also important to report that recently a number of clinical studies have been carried out in humans using MSC treatment in coronavirus disease (results not yet reported)[113-117]. Despite the potential of SC treatment to reduce pain and the fact that viral infections can cause pain, there is a gap in the literature of studies investigating the analgesic effectiveness of SC in the treatment of viral infection-triggered pain.

SC-BASED TREATMENTS FOR NP

Studies involving inflammation and pain are still somewhat restricted when compared to the volume of articles that study NP and treatment using SC. On this topic, we will present an overview of the mechanisms involved in the development of NP and then explain the mechanisms underpinning SC therapy.

What mechanisms are involved in the development of NP?

To fully comprehend the mechanisms that modulate NP, it is essential to understand how our body processes the external and internal stimuli that can lead to nociceptive alterations. Pain sensation is the product of higher brain center perception and can be influenced by a number of factors like attention, affective dimensions, autonomic variables, immune variables, and hormones[118].

In normal tissue, pain is triggered by intense or noxious stimuli that leads to the activation of high threshold transmembrane ion channels, a process defined as nociceptive pain. These ion channels present on nociceptor neurons convert mechanical, thermal or chemical stimuli - that can vary from pinpricks and light touch to vibrations, indentations, gravity and sound waves - into biochemical regulated electrical signals that are directed to the brain through the generation and conduction of action potentials, characterizing mechanotransduction[119].

NP, on the other hand, occurs when a pathological process leads to nerve damage, and the healing process of the nervous system results in maladaptation observed by the lower unbalanced threshold of neuronal activation that can involve numerous pain-related processes, from the detection by the nociceptor neuron to the acknowledgement of nociceptive signaling by the brain[120]. NP comprises peripheral neuropathy, postherpetic neuralgia, trigeminal neuralgia, nerve root pain, and phantom limb pain; and can be caused by lesions or diseases involving the primary afferent sensory neurons of the somatosensory nervous system, including peripheral fibers (Aβ, Aδ and C fibers) and CNS neurons[121-123].

The extensive modulatory possibilities that can unravel during the healing process of nervous tissue make evident the importance of neuroplasticity, a phenomenon that can be defined as the ability of the nervous system to adapt its responses according to intrinsic or extrinsic stimuli by reorganizing its structure, functions, or connections after injuries. Thus, neuroplasticity is a key factor in the development of NP[124].

NP typically arises from an incorrect healing process due to an imbalance between neuroimmune interactions, glial cells, and neurotrophic factors. Briefly, a nervous system lesion triggers inflammatory and repair responses that are not always successful. Unsuccessful nerve repair will lead to plastic changes causing the sensitization of nociceptive neurons, sympathetic sprouting forming basket structures that explain sympathetic maintained chronic pain, incorrect formation of novel synapses causing the stimulation of second order neurons upon touch (causing allodynia). Maladaptive tissue repair can also involve the activation of glial cells that further stimulate nociceptive neurons causing retrograde sensitization and boosting second order nociceptive signaling to the brain when a nervous fiber is sectioned. Cellular events occur at the site of injury and in the neuronal soma corresponding to the area in the DRG. These cellular events include, for instance, local immune cell signaling *via* purinergic P2 receptors-ATP signaling[125]. Nerve damage is, therefore, an initiating event, but it is not the sole orchestrating factor. Neuronal plastic changes include the alteration of ion channel properties, affecting spinal and brain sensory signaling, shifting pain perception so that normal innocuous stimuli can result in pain by facilitating neuronal depolarization upon thermal and mechanical stimulation as a result of nociceptor neuron sensitization owing to increased membrane excitability. Spontaneous neuronal firing can also be observed[119,125,126].

The regeneration process can be divided into five steps: (1) Fluid phase; (2) Matrix phase; (3) Cellular migration phase; (4) Axonal phase; and (5) Myelination phase[127]. After injury, neuronal genetic expression is altered to induce the release of neurotrophic and angiogenic factors like NGF, brain-derived neurotrophic factor, glial cell-derived neurotrophic factor (GDNF), vascular endothelial growth factor-A and angiopoietin-1[128], and to upregulate the expression of their corresponding receptors. These growth factors support the axonal lengthening of the injured nerve from its proximal fragment, as the damaged axons in the distal nerve fragments undergo degeneration, a process known as Wallerian degeneration[127]. Infiltrating macrophages and Schwann cells also take part by clearing myelin debris and retro feeding the secretion of neurotrophic and pro-angiogenic factors, enabling the formation of connective tissue bridging the nerve clefts, as Schwann cells create an endoneurial tube that guides the axonal regeneration process starting from a growth cone located at the Ranvier's node[129].

The accurate balance between compensatory and decompensatory reactions of the nervous system when facing neural damage is of the utmost importance, because many of the changes that occur in response to neural injury are potentially adaptive, such as the removal of cell and myelin debris, regulation of receptors that counterbalance the loss of input, and appropriate signaling in order to dampen ion fluxes and metabolic stress after the acute injury[130]. Among the adaptive modifications, we can also cite anti-apoptotic signaling to prevent neuronal cell death, induction of axonal growth and sprouting, synaptic remodeling, and remyelination[131].

A defining characteristic that is often present in NP is the absence of an identifiable stimulus upon spontaneous pain. Such abnormal sensitization can be generated at any anatomical level related to the nociceptive sensory experience: (1) The site of the injury that induced the NP in the first place and underwent maladaptive healing - or neuroma - where the regenerated axon can get misdirected and become unable to reach the desired target[132]; (2) Cell death of the corresponding DRG neurons; (3) Alterations in gene regulation and expression of the surrounding intact afferent fibers; (4) Central sensitization and altered connectivity in the spinal cord of low-threshold large myelinated afferents *via* synaptic facilitation and loss of inhibition at multiple levels of the neuraxis; and (5) Voltage-gated channel-related generation of spontaneous ectopic activity in nociceptors, a mechanism whose importance is supported by the effectiveness of nonselective sodium channel blockers as local anesthetics[133]. Increased synaptic strength enables previously sub-

threshold inputs to activate nociceptive neurons, reducing their threshold and enhancing their responsiveness, which results in the expansion of their receptive fields. In addition, phenomena like conduction slowing or blocking, reduced inhibition, inappropriate connectivity, altered processing of both nociceptive and innocuous afferent input, abortive growth, neuronal loss, and glial scarring can be decisive factors underlying the pathogenesis of NP and the onset of spontaneous pain[126,134].

It is important to note that once NP is generated, the sensory hypersensitivity tends to persist for prolonged periods, even though the original initiator factor may have long since disappeared[126]. The complexity and abundance of factors involved in the central and peripheral nervous system modifications, make the treatment of NP challenging and expensive[51].

The use of SC as a therapy for NP

Given the fact that current treatments for NP are not fully effective, there is a need for improving NP treatment. Among the characteristics that stand out in the use of SC for NP is the ability of these cells to migrate to the injured site and repair damaged cells, even when administered systemically[135]. Most literature reports address SC treatment in the context of NP models, in which strategies are based on replacing damaged nerve cells and induce the production of neurotrophic factors. In addition, SC inhibit apoptosis and degeneration processes, and increase the survival of both injured and uninjured nerves[136] (Table 3). Furthermore, the mechanisms of action of SC modulating NP vary according to the stimulus in question (disease model/condition), since each disorder presents its own alterations that can be classified as peripheral and/or central, we will follow this rationale in the next sections.

Peripheral nervous system-related analgesic mechanisms of SC

The peripheral actions of SC focus on their anti-neuro-inflammatory capacity and their neuroprotective potential and ability to promote growth. SC anti-neuro-inflammatory capacity (described in the previous topics) includes the ability to reduce the levels of pro-inflammatory cytokines IL-1β, IL-6[137] and TNF-α[87]. These cytokines are extremely important in peripheral sensitization, because they are capable of sensitizing nociceptors and increase the expression of TRP and Na channels, consequently leading to mechanical and thermal sensitization[9]. In addition to reducing the production of hyperalgesic cytokines, SC can increase IL-10 levels in NP models[137], which also explains the decrease in the pro-inflammatory cytokine production[138] and induction of the class switch of macrophages from an M1 to an M2 profile. M1 macrophages are responsible for proinflammatory responses, overexpress CD80, CD86, and CD16/32 which are essential for activating lymphocytes and thus adaptive immunity. Moreover, M1 phenotype macrophages are capable of secreting pro-inflammatory cytokines[139]. In contrast, M2 macrophages express chemokines CCL17 and CCL22 that mediate the control of Treg cell biology[140], mannose receptor (CD206) that induces endocytosis[141], as well as anti-inflammatory responses and contribute to the repair of damaged tissues by the phagocytosis of debris[138]. Moreover, M2 macrophages can be manipulated *in vitro* to produce an opioid-mediated analgesic effect, demonstrated by its complete blockade by the opioid receptor antagonist naloxone methiodide in an *in vivo* model of chronic constriction injury (CCI) of the sciatic nerve induced NP[142]. Although there is no data on SC and microglia polarization, considering the activity of SC to polarize macrophages towards a M2 profile, if this activity is also true for microglia polarization to an M2 profile, this would be an important analgesic mechanism in NP. M1 microglia are actively involved in NP by producing mediators that sensitize nociceptors[143].

SC are also able to directly interact with the DRG neurons through GDNF production[144]. GDNF is of great importance for studies where there is neuronal damage, such as in sciatic nerve injury[136]. Since the administration of GDNF is capable of decreasing pain-related behaviors, due to its inhibitory action on the molecules such as activating transcription factor 3 - marker of neuronal injury and IB4 (a noceptive neuron marker of a neuronal population that do not express CGRP, and that downregulate NGF and receptor tyrosine kinase)[145,146].

The actions of SC on DRG neurons also affect the production of neuropeptides related to pain signaling. In models of CCI-induced NP, SC treatment was able to decrease nociceptive behavior by releasing TGF-β1, which activates neuronal TGF-β1R[147], as well as reducing the production of hyperalgesic cytokines IL-1β and TNF-α[148].

CNS-RELATED ANALGESIC MECHANISMS OF SC

The actions of SC treatment targeting mechanisms in the CNS environment are based on three hypotheses: (1) Desensitization of the CNS; (2) Inhibition of glial cells; and (3) Reduction in apoptosis and autophagy[149].

The SC mechanisms that are dependent on: (1) Desensitizing the CNS in NP mainly involve the downregulation of glutamate neurotransmission. After the damage of peripheral neurons, glutamate is released in the spinal cord as well as N-methyl-d-aspartate (NMDA) and an increase of its receptor (NMDAR) expression is seen. This mechanism aims to maintain the transmission of the captured noxious signal to the cerebral cortex, where it will be interpreted as pain[150]. Treatment with SC decreases the CNS expression of NMDAR, interrupting the maintenance of nociceptive signaling [150]. In addition, SC can secrete TGF-β1, which inhibits the signaling carried out by glutamate that would otherwise stimulate nociceptive signaling by the activation and proliferation of microglia and astrocytes in NP. TGF-β1 also reduces the expression of proinflammatory cytokines in the CNS in NP, thus, reducing neuroinflammation and nociceptor neuron sensitization[147].

Second, glial cells play a key role in central sensitization. As previously explained, after the detection of noxious stimuli by nociceptors, primary sensory afferent neurons secrete neuropeptides in the spinal cord dorsal horn, where central signaling takes place. If the noxious stimulus persists, glial cells can be activated by these neuropeptides (CGRP and

Table 3 Articles that used stem cells for neuropathic pain treatment (stem cell-based treatment of neuropathic pain)

Ref.	Stem cell therapy design	Key findings	Pain-related highlights	Delivery route	Number of cells or amount of extracellular vesicles and exosomes
Gao *et al* [189], 2023	Huc-MSCs-derived exosomes attenuate neuropathic pain by inhibiting activation of the TLR2/MyD88/NF-κB signaling pathway in the spinal microglia by targeting radical S-adenosyl methionine domain containing 2	Huc-MSCs-derived decreased protein levels of TLR2, MyD88, and p-p65 that were significantly upregulated in the CCI group in model rats	The protein levels of TLR2, MyD88, p65, and p-p65 were examined by western blotting	i.t.	5 μg
Miyano *et al* [190], 2022	I.v. administration of human MSCs derived from adipose tissue and umbilical cord improves neuropathic pain *via* suppression of neuronal damage and anti-inflammatory actions in rats	Both the mechanical threshold and the differences in weight bearing of the right and left hind paws improved significantly. In addition, the authors also reported a decrease in the ATF-3 and IBA-1 in DRG. The authors also reported that the treatment significantly improved the partial sciatic nerve ligation-induced decrease in the level of myelin basic protein in the sciatic nerve	Was performed by von Frey and dynamic weight bearing. Also, the authors did I against ATF-3, IBA-1, myelin basic protein, NeuN, neurofilament (NF) 200	i.v.	5×10^6
González-Cubero *et al* [191], 2022	Application of adipose-derived MSCs in an *in vivo* model of peripheral nerve damage	Rat sciatic nerve damage models both *ex vivo*, on TNF-induced Schwann cells, and *in vivo* using biomaterial implants containing TNF. Upregulation of c-Jun and downregulation of early growth response protein 2 myelin-associated transcription factors were induced by TNF-related damage, but the addition of ASCs or ASC-conditioned medium (secretome) were able to revert the profile	qPCR, western blot, and confocal microscopy were chosen to quantify nerve healing-related protein expression and production *in vivo* and *ex vivo*. The sciatic functional index was calculated to assess nerve regeneration, but no pain-specific mechanisms were investigated	Sciatic nerve	*ex vivo* 0.5×10^6 cells; *in vivo* 4×10^6 ASCs
An *et al* [192], 2022	Immortalized bone MSCs with inducible galanin expression produce controllable pain relief in neuropathic rats	hTERT-BMSCs/Tet-on/GAL cells were able to induce controllable pain relief by spared nerve injury of sciatic nerve under the transcriptional control of doxycycline	To determine the analgesic efficacy acted through GalR1, GalR2, and phospho-protein kinase Mζ expression levels in spinal dorsal horn were analyzed by western blot assay	Subarachnoid space	10^6
Lee *et al* [193], 2022	MSCs spheroids alleviate neuropathic pain by modulating chronic inflammatory response genes	The authors report a decrease in mechanical allodynia, related to a decrease in TNF-α and IFN-γ levels. In addition to a smaller number of cells marked with cluster of differentiation (CD) 68 in the region	The von Frey test was performed to assess mechanical allodynia, while immunofluorescence was used to observe changes in CD68 and IBA-1 levels. TNF-α and IFN-γ levels were assessed by the ELISA assay	Intramuscular	10^6
Chen *et al* [194], 2022	Synergic Effect of early administration of probiotics and adipose-derived MSCs on alleviating inflammation-induced chronic neuropathic pain in rodents	The authors demonstrate that treatment with stem cells alone can reduce thermal hyperalgesia and mechanical allodynia, with the potentiated effects after combined treatment with probiotics. Interestingly, they found a reverse correlation between protein expressions of inflammatory (phospho-NF-κB, IL-1β, TNF-α and MMP-9), apoptotic (cleaved-caspase-3, cleaved-PARP), oxidative-stress (NOX-1, NOX-2), deoxyribonucleic acid (DNA)-damaged (γ-H2AX) and MAPK-family (p-P38, p-JNK, p-ERK 1/2) biomarkers as	To observe pain-related behavior alterations, Hargreaves and von Frey tests were applied. Immunofluorescence was performed for p-p38; NF200; peripherin, 53BP1, β3 Tubulin analysis. Western blot was chosen to identify alteration of p-NF-kB, IL-1ß, TNF-α, MMP-9, NOX-1, NOX-2, caspase 3, cleaved-PARP, γ-H2AX, p-ERK1/2, p-JNK, p-p38, Nav.1.3, Nav.1.8, Nav.1.9 and immunoglobulin G	i.v.	3.0×10^5

		well as the protein levels of voltage-gated sodium channels (Nav.) 1.3, Nav.1.8, and Nav.1.9 in L4-L5 in DRG to the pain-behavior results obtained by thermal hyperalgesia and mechanical allodynia testing, characterizing a set of "pain-connived cells" presenting the following profiles: Nav1.8+/peripherin+, p-ERK+/peripherin+, p-p38+/peripherin+ and p-p38+/NF200+. Mainly by suppressing inflammation and oxidative stress, the combination of probiotic and ASCs therapy was found superior for alleviating CCI-induced neuropathic pain			
Zhang *et al* [195], 2021	Lncenc1 is identified as a novel regulator in neuropathic pain by interacting with EZH2 and downregulating the expression of Bai1 in mouse microglia	Virgin embryonic stem cells express Lncenc1, which can activate microglia in DRG and induce the production of TNF-α, IL-1β, and MCP-1. Lncenc1 silencing reduced mechanical and thermal hyperalgesia, as well as lower levels of pro-inflammatory cytokines	The mechanical withdrawal threshold was measured by von Frey filaments and thermal hyperalgesia *via* hot plate assay. Immunofluorescence was performed to analyze OX-42, western blot to assess EZH2, suppressor of zeste 12, embryonic ectoderm development, BAI1, tri-methylation of histone 3 lysine 27 (H3K27me3), H3K27ac, total histone H3, glyceraldehyde-3-phosphate dehydro-genase and OX-42. RT-qPCR was performed to identify expression alterations on Lncenc1, EZH2, BAI1, OX-42, inflammatory factors TNF-α, IL-1β and chemokine MCP-1. TNF-α, IL-1β and MCP-1 protein changes were assessed by ELISA	Not informed	Not informed
Masoodifar *et al*[161], 2021	Effect of the conditioned medium of MSCs on the expression levels of P2X4 and P2X7 purinergic receptors in the spinal cord of rats with neuropathic pain	Animals treated with the conditioned medium (stem cells secretome) showed a reduction in mechanical and thermal hyperalgesia. A decrease in the expression of P2X4 and P2X7 receptors was related to the interaction of neurons and glial cells in neuropathic pain	The von Frey and hot plate tests were applied to measure mechanical and thermal hyperalgesia, respectively. In addition, qPCR was performed to measure the expression of P2X4 and P2X7 receptors	i.p.	1×10^5
Kotb *et al* [196], 2021	Preemptive stem cells ameliorate neuropathic pain in rats: A central component of preemptive analgesia	MSCs-treatment increased allodynia, mechanical hyperalgesia, and thermal hyperalgesia thresholds. Stem cells were able to reach the cerebral cortex, as the CCI group had few stem cells expressing PCNA, CD117 and nestin in the cerebral cortex. The treated group had numerous CD117-, nestin-, PCNA-positive stem cells recently proliferated in the cerebral cortex. Together, the results indicate a potential central analgesic effect of i.v. MSC-treatment	To evaluate pain behavior, von Frey, Randall and Selitto, and hot plate tests were performed. Immunohistochemical analyses of GFAP, PCNA and nestin were also performed	i.v.	1×10^6
Zhang *et al* [197], 2021	Therapeutic effects of peripherally administered neural crest stem cells on pain and spinal cord changes after sciatic nerve transection	The treatment was able to induce thermal and mechanical analgesia, possibly by decreasing the expression of TRPV1, cFOS, p-ERK, ERK, iNOS and NF-κB, p65 and increasing BDNF and GAP-43 in the spinal cord	To assess mechanical allodynia, the authors used the BEM-404 device (similar to the von Frey). For thermal withdrawal latency, they use Hargreaves. In the western blot, they had the following targets: BDNF, cFOS, GAP-43, p-ERK, ERK 1/2, TRPV1 and iNOS. Immunofluor-escence: IBA-1, GFAP and CGRP were assessed	Local injection	2×10^6
Yang *et al* [91], 2020	Anti-inflammatory protein TSG-6 secreted by BMSCs attenuates neuropathic pain by inhibiting the TLR2/MyD88/NF-κB	I.t. administration of TSG-6 secreted from stem cells decreases mechanical allodynia and thermal hyperalgesia, inhibiting IBA-1 and the activation of the	The activation of the TLR2/MyD88/NF-κB signaling pathway was evaluated by western blot and immunofluorescence, while allodynia and hyperalgesia were assessed by the behavioral tests Dynamic Plantar Aesthesiometer, Hargreaves and	i.t.	5×10^6

	signaling pathway in spinal microglia	TLR2/MyD88/NF-κB pathway in the dorsal horn of the ipsilateral spinal cord. Levels of pro-inflammatory cytokines, such as IL-1β, IL-6 and TNF-α, were also reduced	rotarod system		
Jwa *et al* [198], 2020	ASCs alleviate cold allodynia in a rat spinal nerve ligation model of neuropathic pain	ASCs or ASC-derived culture medium decreased neuropathic pain behaviors in a rat model with L5 spinal nerve ligation	Mechanical and cold allodynia were assessed by von Frey filaments and acetone assay, respectively. Mechanisms were not assessed	Intrathecal or injection into the right retro-orbital sinus	10^6
Gama *et al* [164], 2018	Conditioned medium of BMSCs as a therapeutic approach to neuropathic pain: A preclinical evaluation	The animals showed improvement in thermal hyperalgesia and mechanical allodynia. They also showed reduced levels of IL-1β, TNF-α and IL-6 and increased IL-10 in the spinal cord and sciatic nerve	To evaluate thermal hyperalgesia, the Hargreaves test was performed, and von Frey mechanical allodynia. To evaluate the motor function test, the rotarod test was performed. Using the ELISA method, TNF-α, IL-1β, IL-6 and IL-10 were quantified	i.v.	10^6
Lin *et al* [165], 2017	Autologous ASCs reduce burn-induced neuropathic pain in a rat model	There was no difference between the groups regarding thermal hyperalgesia, whereas in mechanical allodynia, the treated group presented analgesia from the 3rd wk of the first treatment. Western blot analyses revealed a decrease in p-Akt/Akt and Bax/Bcl-2 and levels of LC3B-II and Beclin 1 in the spinal cord, suggesting that the treatment also decreased apoptosis and autophagy. This effect was accompanied by a reduction in COX-2, iNOS and nNOS. The treated group also showed lower expression of p-JNK (an inflammatory marker), TUNEL (apoptosis marker), phospho-NFκB (inflammatory marker) and increased p-IκB (an inhibitor of NFκB activation)	Immunofluorescence were performed to analyze p-IκB; NeuN, GFAP, phospho-NFκB and p-JNK; and western blot for COX-2, iNOS, nNOS, Akt/protein kinase B, p-Akt, B-cell lymphoma 2, Bcl-2-associated X protein, β-actin, LC3B and Beclin 1	Subcutaneous into the scar tissue of the right hind paw	10^6
Vaquero *et al*[199], 2018	I.t. administration of autologous bone marrow stromal cells improves neuropathic pain in patients with SCI	Treatment with mesenchymal stromal cells for human chronic SCI: Pain scores demonstrated a continuous decrease in neuropathic pain from the first month until the 10th	Intensity of neuropathic pain was evaluated by standard numerical rating scale (visual analogue scale) from 0 to 10. Mechanisms were not assessed	i.t.	10^6
Sun *et al* [200], 2017	I.t. administration of hBMSCs genetically modified with human proenkephalin gene decrease nociceptive pain in neuropathic rats	hBMSCs engineered with human proenkephalin gene were used on sciatic nerve (CCI)-induced model to reduce neuropathic pain in rats	Mechanical withdrawal threshold (von Frey filaments) and paw thermal withdrawal assays were used to assess the changes in pain-related behavior. Levels of Leu-enkephalin, a neurotransmitter that activates opioid receptors and is released by hBMSCs were found augmented *via* ELISA assay in genetically modified BMSCs compared to secretions released by naıve BMSCs	i.t.	6×10^6
Fischer *et al* [201], 2017	Inhibition of neuropathic hyperalgesia by i.t. BMSCs is associated with alteration of multiple soluble factors in cerebrospinal fluid	BMSCs decrease the levels of intracellular adhesion molecule 1, IL-1β, hepatocyte growth factor), IL-10, and Nope protein relacionated by Tibial nerve injury	Antibody array analysis was performed and the levels of cytokines and other soluble factors in cerebrospinal fluid samples was measured	i.t.	2.5×10^5
Xie *et al* [202], 2017	Active nerve regeneration with failed target reinnervation drives persistent neuropathic pain	Semaphorin 3A, an inhibitory axonal guidance molecule, reduces functional regeneration, spontaneous activity, and pain behaviors when applied to the injury site in vivo. Silencing of the upregulated GAP43 with interfering RNA injected into the axotomized sensory ganglion reduced pain behaviors	Behavior assays: von Frey filaments acetone cold sensitivity, dynamic tactile allodynia with a wisp of cotton across the plantar surface of the hindpaws, and spontaneous guarding behavior score. Immunohistochemistry for GAP43 tracer methods to assess anatomical nerve regeneration	Injury site	

Brini *et al* [203], 2017	Therapeutic effect of human ASCs and their secretome in experimental diabetic pain	Treatments with both human ASC and their secretome were able to reverse mechanical, thermal allodynia and thermal hyperalgesia inducing high IL-1β, IL-6 and TNF-α and low IL-10 levels, restoring cytokine balance, Th1/Th2 balance and preventing skin innervation loss in neuropathic STZ-diabetic mice model	Mechanical allodynia was tested using the Dynamic Plantar aesthesiometer, a drop (50 μL) of acetone was placed in the middle of the plantar surface of the hind paw to evaluate cold allodynia and the hot-plate test was used to assess thermal hyperalgesia. Immunohistochemistry and ELISA were performed for cytokines assessment	i.v.	1×10^6
Watanabe *et al*[87], 2015	Early transplantation of MSCs after SCI relieves pain hypersensitivity through suppression of pain-related signaling cascades and reduced inflammatory cell recruitment	BMSC improved SCI model *via*: Down of protein kinase C-γ and phosphocyclic AMP response element binding protein on DRG neurons, both of which are upregulated in association with at-level allodynia after contusion spinal cord. Decreased activation of MAPK signaling in injured spinal cord by p-p38 and p-ERK1/2 decrease. Decreasing macrophage recruitment through. Down TNF-α, IL-6, MMP-9, CCL2, CCL5, and C-X-C motif chemokine ligand 10. Decreased microglia stimulation factor, granulocyte-macrophage colony stimulating factor, platelet-derived growth factor receptor α	For behavioral and sensory testing, the Basso Mouse Locomotor Scale, the Dynamic Plantar Aesthesiometer (allodynia), and the Plantar Test Apparatus (thermal sensitivity) were assessed. immunohistochemistry, flow cytometry and immunoblot assays were performed to determine protein levels	BMSCs were injected into the middle of the contusion site, identified as the middle point of the laminectomy area	2×10^5
Zhang *et al* [204], 2014	I.t. administration of MSCs reduces the ROS and pain behavior in neuropathic rats	I.t. rat MSCs injection reduced pain response and ROS production in the dorsal horn of neuropathic rats induced by spinal nerve L5 ligation model	Mechanical sensitivity was assessed using von Frey filaments and production of ROS *via* dihydroethidium fluorescent staining	i.t.	10^5
Liu *et al* [205], 2014	MSCs inhibit lipopolysaccharide-induced inflammatory responses of BV2 microglial cells through TSG-6	Anti-inflammatory effects of MSCs and TSG-6 in an *in vitro* LPS-induced BV2 microglial activation model inhibiting NF-κB and MAPK pathways. MSCs can modulate microglia activation through TSG-6 and TSG-6 attenuates the inflammatory cascade in activated microglia	RT-qPCR, western blot, electrophoretic mobility shift assay, immunofluorescence and laser-scanning confocal microscopy techniques were used	*In vitro*	1.0×10^5 LPS-activated MSCs
Vicker *et al* [206], 2014	A preliminary report on stem cell therapy for neuropathic pain in humans	Treatment led to a reduction in stem cell treatment pain intensity scores in 7/9 patients (two with marginal improvement and five subjects with good to excellent pain reduction). Five of these positive responders also reduced their need for gabapentin medication	Patients were assessed for: Change in pain intensity and the secondary outcome was any reduction in daily consumption of anti-neuropathic medication	Perineural, directly in the center or source of pain, and in the adjacent pain field of the affected branches of the trigeminal nerve	Number of cells not reported, but extracted from 100-200 g of patient tissue
Tao *et al* [154], 2013	Role of NRG1/ErbB signaling in stem cell therapy for SCI-induced chronic neuropathic pain	The treatment induces remyelination in the injured spinal cord and reduces SCI-injury-induced chronic neuropathic pain. In addition to increasing levels of NRG1 and ErbB4 slightly reduced by SCI. Also, the author related that Stem cells differentiated into oligodendrocytes	To evaluate mechanical allodynia, the von Frey filament test was applied. Immunofluorescence for NG2, APC-CC1, GFAP, NeuN, and western blot for NRG1 and ErbB4 levels assessment	i.t.	10^6
Xu *et al* [207], 2013	I.t. transplantation of NSCs appears to alleviate neuropathic pain in rats through release of GDNF	The treatment was able to cause thermal and mechanical analgesia. Accompanied by an increase in GDNF in the DRG and spinal cord. The authors also suspected that these changes occurred due to the transformation of stem cells into astrocytes in the spinal cord	To evaluate the mechanical withdrawal threshold, the Electric von Frey test was used. For thermal withdrawal latency, a method with a high-intensity projection lamp bulb was used. For immunofluorescence: Nestin; βIII-tubulin; GFAP. For ELISA: BDNF and GDNF	i.t.	10^6

Choi *et al* [208], 2013	Core-shell nanoparticle controlled human adipose tissue-derived stem cells neurogenesis for neuropathic pain therapy	Treatment activated biochemical functions of Dicer, Oct4, Sox2, Nanog, and glutathione peroxidase 3 improving stem cells self-renewal and differentiation abilities	von Frey and Hargreaves behavior tests were performed to assess mechanical and thermal hyperalgesia changes, respectively. Immunofluorescence, western blot and RT-qPCR techniques were used to study alterations in protein production/expression/localization	i.t.	Unspecified
Franchi *et al* [137], 2012	I.v. NSCs abolish nociceptive hypersensitivity and trigger nerve regeneration in experimental neuropathy	NSCs administration in CCI mouse model significantly decreased proinflammatory (IL-1 β, IL-6), activated anti inflammatory (IL-10) cytokines in the sciatic nerve, and reduced spinal cord Fos expression in laminae I-VI	Thermal hyperalgesia was tested according to the Hargreaves using a Plantar Test Apparatus, while mechanical allodynia was assessed using the Dynamic Plantar Aesthesiometer. Immunohistochemistry, immunofluorescence, and qPCR plus ELISA assays were performed for Fos and GFPI; substance P and CGRP; and IL-1β, IL-6 and IL-10, respectively	i.v.	10^6
Sacerdote *et al*[209], 2013	Systemic aAdministration of human ASCs reverts nociceptive hypersensitivity in an experimental model of neuropathy	Human ASCs were able to completely revert neuropathic pain symptoms in a murine CCI model by: IL-1β decreased and IL-10 increased in the lesioned nerve. Restored normal iNOS expression	Thermal hyperalgesia was tested according to the Hargreaves, while mechanical allodynia was assessed using the Dynamic Plantar Aesthesiometer (von Frey filament)	i.v.	1×10^6, 3×10^6 and 6×10^6
Choi *et al* [73], 2011	Anti-inflammatory protein TSG-6 secreted by activated MSCs attenuates zymosan-induced mouse peritonitis by decreasing TLR2/NF-κB signaling in resident macrophages	TSG-6 interacts through the CD44 receptor on resident macrophages to decrease zymosan/TLR2-mediated nuclear translocation of the NF-κB	RT-qPCR, ELISA, NF-κB translocation assays and isolation of resident macrophage RNA was performed	i.p.	1.6×10^6
Siniscalco *et al*[210], 2011	Long-lasting effects of human MSCs systemic administration on pain-like behaviors, cellular, and biomolecular modifications in neuropathic mice	The treatment was able to reduce pain-like behaviors such as mechanical allodynia and thermal hyperalgesia. In addition to reducing IL-1β and IL-17 levels and increasing IL-10 in the spinal cord and reducing labeling for alternatively activated macrophages (CD106)	For behavior analysis, the following tests were applied: von Frey filaments, Rotarod and Hargreaves. Immunofluorescence: CD73; IL-1β; IL-17; CD4; GFAP; IBA-1; western blot: IL-1β, IL-17, IL-10 e CD106	i.v.	2×10^6

Huc-MSCs: Human umbilical cord mesenchymal stem cells; TLR2: Toll-like receptor 2; MyD88: Myeloid differentiation primary response 88; NF-κB: Nuclear factor kappa B; Rsad2: Radical S-adenosyl methionine domain containing 2; p-p65: Phospho-protein 65; CCI: Chronic constriction injury; i.t.: Intrathecal; i.v.: Intravenous; MSCs: Mesenchymal stem cells; ATF-3: Activating transcription factor 3; IBA-1: Ionized calcium-binding adapter molecule 1; DRG: Dorsal root ganglion; MBP: Myelin basic protein; NeuN: Neuron-specific nuclear protein; NF: Neurofilament; TNF: Tumor necrosis factor; ASCs: Adipose tissue derived-mesenchymal stem cells; RT-qPCR: Real time quantitative polymerase chain reaction; hTERT-BMSCs/Tet-on/GAL: Rafted human telomerase reverse transcriptase-immortalized bone marrow mesenchymal stromal cells with inducible galanin expression; GalR: Galanin receptor; SDH: Spinal dorsal horn; IFN-γ: Interferon gamma; CD: Cluster of differentiation; ELISA: Enzyme-linked immunosorbent assay; i.m.: Intramuscular; IL: Interleukin; MMP: Matrix metalloproteinase; PARP: Poly ADP-ribose polymerase; NOX: NADPH oxidase; MAPK: Mitogen-activated protein kinase; p-JNK: Phosphorylated Jun N-terminal kinase, p-ERK: Phospho-extracellular signal-regulated kinase; Nav: Voltage-gated sodium channels; LncRNA: Long-chain noncoding ribonucleic acid; Lncenc1: Long-chain noncoding RNA embryonic stem cells expressed 1; EZH2: Enhancer of zeste homologue 2; MCP-1: Monocyte chemoattractant protein-1; SUZ12: Suppressor of zeste 12; EED: Embryonic ectoderm development; BAI1: Brain-specific angiogenesis inhibitor 1; H3K27me3: Tri-methylation of histone 3 lysine 27; P2X4: P2X purinoceptor 4; i.p.: Intraperitoneal; PCNA: Proliferating cell nuclear antigen; GFAP: Glial fibrillary acidic protein; TRPV1: Transient receptor potential cation channel subfamily vanilloid 1; iNOS: Inducible nitric oxide synthase; p65: Protein 65; BDNF: Brain-derived neurotrophic factor; GAP-43: Growth-associated protein 43; CGRP: Calcitonin gene-related peptide; TSG-6: Tumor necrosis factor-α-stimulated gene 6 protein; BMSC: Bone marrow mesenchymal stem cells; p-Akt: Phospho protein kinase B; LC3B: Light chain-3B; COX-2: Cyclooxygenase 2; nNOS: Neural nitric oxide synthase; hBMSCs: Human bone marrow stem cells; CSF: Cerebrospinal fluid; Th1: Type 1 helper; SCI: Spinal cord injury; p-CREB: Phosphocyclic AMP response element binding protein; CCL: C-C motif chemokine ligand; CXCL: C-X-C motif chemokine ligand; GM-CSF: Granulocyte-macropgahe colony stimulating factor; PDGFR-α: Platelet-derived growth factor receptor α; ROS: Reactive oxygen species; LPS: Lipopolysaccharides; NRG1: Neuregulin-1; GDNF: Glial cell derived neurotrophic factor; NSC: Neural stem cells.

substance P)[151]. When activated, glial cells' function will be related to the maintenance and enhancement of the interaction between the peripheral and CNSs, secreting, for instance, cytokines that will activate spinal cord neurons [152]. Interestingly, this glial activation can be detected by the expression of some targets, such as IBA-1 for microglia and glial fibrillary acidic protein (GFAP) for astrocytes[61]. These glial cells are responsible for the subsequent release of cytokines inducing a series of cellular responses, such as upregulation of glucocorticoids and glutamate receptors, leading to spinal cord excitation and neuroplasticity[136].

It has been reported that in experimental conditions involving spinal cord injury and spinal cord treatment with SC, embryonic stem (ES) cells differentiate into oligodendrocytes using positive selection and mechanical enrichment[153],

promoting functional recovery after a spinal cord injury producing myelination[154]. Spinal cord SC treatment also decreases GFAP[155] and IBA1[156] indicating the down-regulation of astrocyte and microglia activation, respectively. SC express high levels of CXCL12[157]. CXCL12 can reduce the activation of astrocytes and microglia in spinal nerve ligation models, thus, potentially contributing to the activity of SC in NP[158]. There are other potential repercussions of glial inhibition. For instance, the decrease of IBA1 also occurs by inhibiting gasdermin D-induced microglia pyroptosis, thus, promoting autophagy[159]. In fact, impaired autophagic flux aggravates NP by increasing neuroinflammation[160]. Moreover, the mitogen-activated protein kinase signal pathway is activated after microglial activation, which promotes long-term potentiation and central sensitization in pain[136].

Another mechanism of action of SC that explains their analgesic activity by down-modulating glial cell activation is the capability they have at reducing the expression of purinergic P2X purinoceptor 4 (P2X4) and P2X7 receptors in a rat model of NP induced by CCI of the sciatic nerve[161]. P2X4 and P2X7 receptor activation mainly by ATP (coming from nerve damage) leads to the activation of glial cells and the release of IL-1β, TNF-α and IL-6, capable of sensitizing nociceptors and perpetuating NP[162,163].

In a different perspective, it has also been shown that SC are capable of increasing IL-10 levels in the spinal cord[164], in addition to secreting TSG-6 in the spinal cord[91], and decreasing IBA-1 activity by inhibiting the TLR2/MyD88/NF-κB signaling pathway in spinal microglia. These activities reduce nociceptor neuron activation and neuronal plasticity.

The third analgesic mechanism of SC in the CNS involves the inhibition of neuronal death in the CNS. SC treatment can reduce the levels of p-Akt/Akt and Bax/Bcl-2, LC3B-II, Beclin 1 and TUNEL (markers of cellular death) in the dorsal horn of lumbar spinal cords in burn-induced NP. Thus, suggesting that SC can reduce the levels of apoptosis, necrosis and autophagy related to inflammation in spinal cord neurons of dorsal horn cells[165].

SC TECHNOLOGY AS A TOOL FOR INVESTIGATING PAIN-RELATED MECHANISMS

Although most of the efforts in scientific research regarding SC and pain are guided towards finding suitable painkillers, it is worth mentioning that SC technology can also be proven valuable to create different experimental models, which can contribute to understanding pathophysiological mechanism of pain and thus, evolving towards therapy. As an example, Kaneski *et al*[166] developed a human ESC (hESC)-based model to study the poorly understood pathophysiology of pain in Fabry disease. This X-linked glycolipid storage disorder that results in a deficiency in the lysosomal enzyme alpha galactosidase A (AGA) can cause recurrent attacks of excruciating pain ("Fabry pain crisis") that occur spontaneously or in response to extreme temperatures, fever, fatigue, stress, overheating, or exercise. The group generated two AGA-deficient hESC clones using CRISPR-Cas9 gene editing techniques and demonstrated that AGA-deficient human SC could be differentiated into peripheral neurons with nociceptor properties, offering a tool for the investigation of cellular mechanisms for this and other peripheral neuropathies[166].

Some studies utilized dental pulp SC to investigate the possible effects of sirtuin 6 (SIRT6) - an NAD-dependent protein deacetylase known for its role as a differentiation regulator - as a modulation factor using a model of LPS-induced pulpitis (inflammation in the dental pulp). LPS is the major virulence component of gram-negative bacteria cell walls and is widely recognized as a potent activator of inflammation[167]. Their results demonstrated that injection of lentiviral vector-expression SIRT6 leads to SIRT6 overexpression in rats, reduced LPS-induced neutrophils infiltration, a marked decrease in proinflammatory cytokines (IL-6, IL-1β, and TNF-α) and deactivation of the NF-κB pathway. LPS-induced pulpitis in turn, upregulated TRPV1 expression and activity, by downregulating SIRT6. Interestingly, CGRP release was induced by pulpitis while the overexpression of SIRT6 inhibited TRPV1 expression and CGRP release. The expression of inflammatory cytokines, dentin matrix acidic phosphoprotein 1, and NF-κB activation were upregulated after the addition of capsaicin, a TRPV1 channel agonist. Taken together, their results suggest that SIRT6 may be both a negative regulator of pulpitis and an inflammatory pain modulator[168].

DOWNSIDES AND POSSIBLE TREATMENT SIDE-EFFECTS

The biggest concern surrounding SC treatment is the onset of tumors as a result of the therapy, particularly *via* systemic administration routes. This concern is due to the proliferation potential that these cells have, thus, raising the possibility of tumor development if they continue to proliferate after transplantation[169]. The literature lacks *in vivo* studies evaluating the tumorigenic effect of SC treatment. However, it is currently acknowledged that tumorigenicity can develop through three different manners. Firstly, the presence of undifferentiated SC anchored in other already differentiated lineages can lead to tumor formation, due to their high replication rate[169]. Second, reprogramming factors may remain active in transplanted SC, promoting the transformation of these cells and, consequently, tumorigenic transplantation[169]. Finally, tumorigenicity can also develop during *in vitro* culture through genetic mutations[169]. Studies demonstrate that a significant rate of SC derived from bone marrow undergo spontaneous transformations towards a malignant profile in long-term cultures (5 to 106 wk), showing an increase in the rate of proliferation and morphological and phenotypic changes[170].

Another disadvantage is the possible development of cellular rejections. This can occur when the individual's immune system recognizes the SC as foreign antigens and develops an immune response against them[25,169]. Polymorphic molecules of the MHC are an example of immunologically recognized molecules that induce rejection[171]. In fact, studies have already demonstrated that the administration of ESC in the myocardium of allogeneic mice results in the development of an immune response with significant infiltration of T lymphocytes and dendritic cells[172]. Likewise,

abnormal gene expression in cells differentiated from iPSC can induce a T cell-dependent immune response[173]. Finally, even though there are studies that demonstrate the effects of systemic administration of SC, there is a lack of data in the literature that assess their distribution and actions in the body after treatment.

CONCLUSION

In this review, we provide evidence on the therapeutic potential of the use of SC in pain treatment. Analgesia was observed with SC administration as well as SC extracellular vesicle administration. This analgesic effect was found to be achieved with a variety of routes, such as intra-articular, intravenous, intrathecal, intramuscular, intraganglionar, perineural, subcutaneous, and local injection. Additionally, the SC load for these administrations varied between 1.0×10^5 to 24×10^6 for SC, and 1×10^6 to 1×10^9 for SC extracellular vesicle. The specific conditions of each experiment can be appreciated in the Tables 2 and 3.

This review discussed that the analgesic mechanism of action of SC treatment can be indirect by acting on inflammation, changing the pattern from pro-inflammatory to anti-inflammatory mediators. SC can decrease the levels of cytokines that have a role in mechanical and thermal hyperalgesia in addition to promoting the secretion of cytokines with analgesic roles. These anti-inflammatory analgesic mechanisms have been demonstrated in peripheral tissue. In the CNS, SC can cause analgesia by inhibiting the effects of glutamate on spinal cord neurons and by its ability to decrease glial activity and therefore central sensitization.

There are still gaps in the elucidation of the mechanism of action of SC, since most of the articles in the literature aim mainly at the treatment of NP. Among the literature hiatus we can cite the lack of studies on the analgesic mechanisms of SC in models using microorganisms as stimuli. Confirmatory studies on SC therapy long-term safety are also missing. SC rejection is also a potential drawback and there are no studies comparing the success of therapy using autologous cells to the patient, and cells of exogenous origin. On the other hand, much of the success of therapy using SC comes from the use of MSC, which have a lower possibility of rejection, as well as greater effectiveness in the treatment.

Even with all the limitations and shortcomings, there are already clinical studies using SC both in the treatment of inflammatory diseases and in NP. In all reports, treatments were able to decrease pain scores and restore mobility-related functions. Therefore, SC treatment is a potential approach for pain relief and to achieve such biotechnological advancements, there is a need to fill the current knowledge gaps in order to develop efficient and safe therapies based on SC.

Abstract

BACKGROUND

Osteoarthritis (OA) is the most prevalent form of degenerative whole-joint disease. Before the final option of knee replacement, arthroscopic surgery was the most widely used joint-preserving surgical treatment. Emerging regenerative therapies, such as those involving platelet-rich plasma, mesenchymal stem cells, and microfragmented adipose tissue (MFAT), have been pushed to the forefront of treatment to prevent the progression of OA. Currently, MFAT has been

successfully applied to treat different types of orthopedic diseases.

AIM
To assess the efficacy and safety of MFAT with arthroscopic surgery in patients with knee OA (KOA).

METHODS
A randomized, multicenter study was conducted between June 2017 and November 2022 in 10 hospitals in Zhejiang, China. Overall, 302 patients diagnosed with KOA (Kellgren-Lawrence grades 2-3) were randomized to the MFAT group (n = 151, were administered MFAT following arthroscopic surgery), or the control group (n = 151, were administered hyaluronic acid following arthroscopic surgery). The study outcomes were changes in the Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC) score, the visual analog scale (VAS) score, the Lequesne index score, the Whole-Organ Magnetic Resonance Imaging Score (WORMS), and safety over a 24-mo period from baseline.

RESULTS
The changes in the WOMAC score (including the three subscale scores), VAS pain score, and Lequesne index score at the 24-mo mark were significantly different in the MFAT and control groups, as well as when comparing values at the posttreatment visit and those at baseline (P < 0.001). The MFAT group consistently demonstrated significant decreases in the WOMAC pain scores and VAS scores at all follow-ups compared to the control group (P < 0.05). Furthermore, the WOMAC stiffness score, WOMAC function score, and Lequesne index score differed significantly between the groups at 12 and 24 mo (P < 0.05). However, no significant between-group differences were observed in the WORMS at 24 mo (P = 0.367). No serious adverse events occurred in both groups.

CONCLUSION
The MFAT injection combined with arthroscopic surgery treatment group showed better mid-term clinical outcomes compared to the control group, suggesting its efficacy as a therapeutic approach for patients with KOA.

Core Tip: Microfragmented adipose tissue (MFAT) has been successfully applied to treat different types of orthopedic diseases. To assess the efficacy and safety of MFAT with arthroscopic surgery in patients with knee osteoarthritis (OA). In this study, patients' own MFAT combined with arthroscopic surgery was used to promote recovery from OA. Our findings provide evidence supporting the safety and feasibility of this approach in treating knee OA.

INTRODUCTION

Osteoarthritis (OA) is the most prevalent form of degenerative whole-joint disease, resulting in joint pain, stiffness, and decreased function. It is also a leading cause of disability in adults, with an enormous and ever-increasing burden on society[1,2]. Although several nonsurgical treatments are available for OA, such as physical therapy and medication, current mainstream medicine mainly focuses on relieving symptoms and cannot prevent the disease from progressing to the late stages of arthritis that require knee replacement[3]. Before this final option of knee replacement, arthroscopic surgery was the most widely used joint-preserving surgical treatment. Available evidence suggests that arthroscopic knee surgery temporarily improves pain or function in patients with mild arthritis; however, its long-term efficacy in treating moderate-to-severe knee OA (KOA) has not been generally accepted[4-7].

In contrast to limited symptom relief therapy, emerging regenerative therapies, such as those involving platelet-rich plasma (PRP), mesenchymal stem cells (MSCs), and microfragmented adipose tissue (MFAT), have been pushed to the forefront of treatment to prevent the progression of OA[8-10]. MFAT is obtained with a Lipogems (Lipogems Int Spa, Milan, Italy) device, which concentrates extracted autologous adipose tissue into small fragments using mild mechanical forces[11]. This one-step procedure is simple, time-saving, cost-effective, and minimally invasive; hence, it eliminates the need for complicated and time-consuming cell culture procedures. MFAT retains an intact stromal vascular niche harboring abundant functional cells, including adipose-derived stem cells (ADSCs: CD90+CD45-, CD90+CD45-, CD73+CD45-, CD73+CD45-, CD105+CD45-, and CD105+CD45-) and pericytes (CD146+CD34-), and secretes various

functional molecules, such as growth factors, cytokines, and exosomes[12,13]. MFAT can match and sometimes even outperform ADSCs due to its functional advantages over ADSCs; notably, the use of MFAT preserves the microenvironment and the most primitive state of cells, MFAT can be conveniently and easily acquired, there are a wide range of sources of MFAT, and autologous tissues are safe to use[14].

MFAT was initially used in the field of plastic surgery and then expanded to orthopedic procedures due to its antibacterial, anti-inflammatory, antiapoptotic, angiogenesis-promoting, and tissue repair functions[15-17]. Currently, MFAT has been successfully applied to treat different types of orthopedic diseases, such as diabetic foot minor amputations, spinal cord injury, cartilage defects, and articular disease[18-22]. Previous animal studies have successfully shown the benefit of intra-articular MFAT therapy for OA in pain relief and functional improvement[23,24]. Moreover, several clinical trials have reported an overall positive result for pain relief and functional improvement in patients with symptomatic KOA following MFAT therapy[25-27].

However, these successful single-center clinical trials are insufficient to demonstrate widespread therapeutic utility. Hence, well-controlled, high-quality scientific evidence to support the efficacy of MFAT is needed. This multicenter, prospective, randomized controlled trial aimed to evaluate the efficacy and safety of a single intra-articular injection of MFAT during arthroscopic surgery in a larger and more heterogeneous population of patients with KOA.

MATERIALS AND METHODS

Study design and participants

This was a prospective, randomized, controlled, single-blind (blind observer), multicenter trial performed in 10 hospitals in Zhejiang, China, including the First Affiliated Hospital of Zhejiang Chinese Medical University, the First Affiliated Hospital of Wenzhou Medical University, Ningbo First Hospital, Ruian Hospital of Traditional Chinese Medicine, Taizhou Hospital of Zhejiang Province, Hangzhou Red Cross Hospital, Huzhou First Hospital, the First People's Hospital of Hangzhou Linan District, Xiaoshan Hospital of Zhejiang, and Zhuji First Hospital (Table 1). A 24-mo follow-up was performed between June 2017 and November 2022. The inclusion criteria were participants aged 30-80 years with KOA symptoms for over 6 mo, including mechanical (locking and grinding) or meniscal (pain with pivoting) symptoms; Kellgren-Lawrence grades 2-3; and being unresponsive to conservative treatment. The exclusion criteria included local infection of the knee joint; systemic diseases such as blood disorders or diabetes, rheumatoid arthritis, gout, autoimmune disease, or malignancy in the past 5 years; prior injection or use of oral steroids within 3 wk before screening; and knee surgery within 6 mo before screening. The trial was registered at chictr.org.cn (registration number ChiCTR2200055124). All participants provided informed consent, and this study was approved by the Institutional Review Board of the First Affiliated Hospital of Zhejiang Chinese Medical University.

Interventions

Enrolled patients were randomly assigned to the MFAT or control group at a 1:1 ratio using a computer-generated method, stratified by hospital and patient age (30-55 and 56-80 years). The control group received arthroscopic and hyaluronic acid (HA) treatment, while the MFAT group received arthroscopic surgery and MFAT therapy.

All participants underwent one or more of the following knee arthroscopic treatments: Debridement; abrasion or microfracture of chondral defects; trimming of degenerative meniscal tears, fragments of articular cartilage, or chondral flaps; and trimming of osteophytes that blocked full extension. Patients randomized to the MFAT group received an MFAT injection during the same arthroscopic procedure. After subcutaneous infiltration with a solution (a total of 250 mL of a saline solution mixed with 0.5 mL adrenalin 1:1000 and 25 mL lidocaine 0.02%) and resting for at least 15 min, liposuction was performed to obtain abdominal fat. We then introduced the harvested fat into Lipogems® (Lipogems International SpA, Milan, Italy) to produce MFAT according to the manufacturer's instructions[12]. Finally, the processed final product was transferred to 10 mL syringes and injected into the knee after the arthroscopic procedure. Patients in the control group received three injections of HA at a dosage of 5 mL once every month, as previously mentioned.

Outcomes

All patients were clinically evaluated before surgery and during follow-up visits at 6, 12, and 24 mo. The primary outcomes were the change in the total Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC) score from baseline to 24 mo. Secondary outcome measures included the WOMAC pain, stiffness, and function score from baseline to 24 mo, the visual analog scale (VAS) score for pain, the Lequesne index score, and the Whole-Organ Magnetic Resonance Imaging Score (WORMS).

Safety assessment

The safety assessment was based on adverse events reported by the patients and physical findings by the evaluators at each follow-up. Mild adverse events were defined as the presence of infection, significant pain, or swelling. A serious adverse event was defined as one that posed a life-threatening risk, was permanently disabling, or required hospitalization.

Statistical analysis

The sample size was based on the endpoint of the total WOMAC score at 24 mo. According to a previous pilot study, the standard deviation of the total WOMAC score at 24 mo was 12.8 points. Considering a 2-sided error alpha of 0.05, a

Table 1 Baseline characteristics of the patients

Characteristics	MFAT group	Control group	*P* value
No. of knees	146	146	
Age, yr	56.4 ± 10.6	54.8 ± 10.1	0.183

WORMS: Whole-Organ Magnetic Resonance Imaging Score; VAS: Visual analog scale; BMI: Body mass index; MFAT: Microfragmented adipose tissue.

minimum power of at least 0.9, a margin of 5.3 points on the total WOMAC, and a 15% drop-out rate, the final sample size was 290 knees (145 for each group).

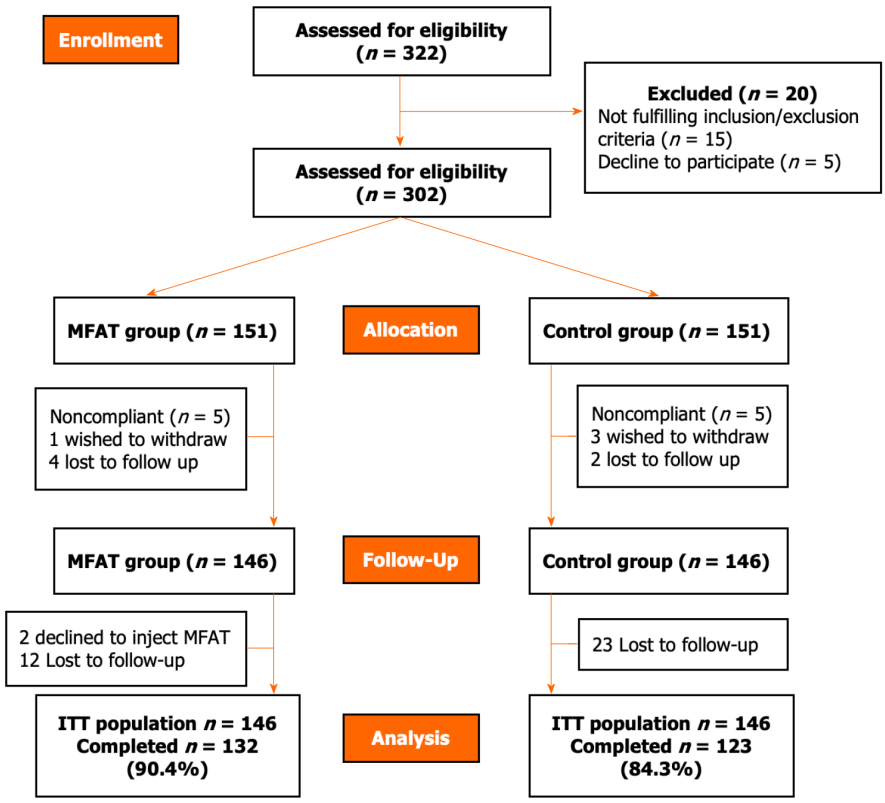
SPSS Statistics version 25.0 (IBM Corp., Armonk, NY, United States) was used for statistical analyses. The χ^2 test or Fisher's exact probability test, was used to compare count data. The normal distribution of the data was evaluated using a QQ plot and histogram. Different variables are described as the mean ± SD. When comparing the means between groups, a one-way ANOVA or Student's *t* test was used. Changes in primary and secondary outcome measures among the baseline, 6-, 12-, and 24-mo follow-up evaluations were assessed using repeated-measures one-way ANOVA and the Bonferroni post hoc test. A *P*-value < 0.05 indicated statistical significance.

Outcomes were assessed in an intention-to-treat analysis. The intention-to-treat population comprised all patients who had received the injection and had undergone at least one postbaseline assessment; the last-observation-carried-forward method was used to account for missing data.

RESULTS

A total of 322 patients were assessed for eligibility. Fifteen patients were not eligible, and five declined to participate; hence, a total of 302 participants were randomized to either the MFAT group (*n* = 151) or the control group (*n* = 151). Four patients (two in the MFAT group and two in the control group) withdrew consent, and six patients (four in the MFAT group and two in the control group) were lost to follow-up after randomization. It was decided that two patients assigned to the MFAT treatment group should not receive the procedure; according to the intention-to-treat principle, the results from these patients were evaluated with the results of the MFAT group. Thirty-seven patients did not return for follow-up visits; hence, 255 participants (87.3%) completed follow-up after 24 mo (Figure 1). The baseline characteristics of the two groups were similar (Table 1).

Primary and secondary outcomes



A comparison of the WOMAC scores, VAS scores, and Lequesne index scores between the MFAT group and the control group before and after treatment is shown in Table 2, Figures 2 and 3. In both groups, the WOMAC total score was

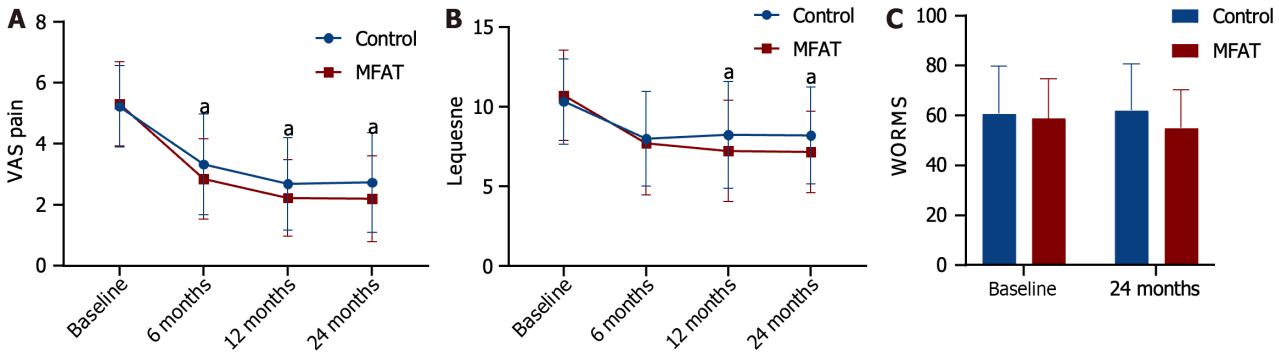
Figure 1 Participant enrollment flow diagram. ITT: Intention-to-treat; MFAT: Microfragmented adipose tissue.

significantly different between time before and after treatment, with separate effect analyses in the MFAT group (F = 379.38) and control group (F = 141.916) (all P < 0.001). The WOMAC total score in the MFAT group was lowest after 12 mo and then increased slightly but remained lower than the values at baseline. The WOMAC total score in the control group decreased, with a maximum decline observed at 6 mo after treatment, and slightly increased at 24 mo. The overall WOMAC total score in the MFAT group was significantly lower than that in the control group after treatment (F = 838.277, P < 0.001). There was also a crossover effect between time and treatment (F = 23.468, P < 0.001). We performed an analysis of the separate effects for each time point. The WOMAC total score in the MFAT group was significantly lower than that in the control group at the same time points during all follow-ups (P < 0.001) (Figure 2A, Table 2). These results indicated the therapeutic benefit of MFAT injection combined with arthroscopy in patients with KOA.



Both groups had a significant reduction in WOMAC pain scores and VAS scores from baseline to posttreatment at 6 to 24 mo ($F_{WOMAC\ pain}$ = 676.741, F_{VAS} = 581.206 for the MFAT group; $F_{WOMAC\ pain}$ = 240.46, F_{VAS} = 527.797 for the control group; all P < 0.001). The most significant decreases in the WOMAC pain score and VAS score from baseline to posttreatment were observed at months 12 and 24 in the MFAT group and at month 12 in the control group. A significant difference in the mean WOMAC pain score and VAS score was observed at all follow-ups in the MFAT group in comparison with the control group (WOMAC pain: All P < 0.001, VAS: All P < 0.01) (Figures 2B and 3A, Table 2). These results indicated that MFAT injection combined with arthroscopy significantly improved pain in patients with KOA.

The WOMAC stiffness score, WOMAC function score, and Lequesne index score at all follow-ups progressively decreased compared with their respective baseline values in both the MFAT group ($F_{WOMAC\ stiffness}$ = 155,117, $F_{WOMAC\ function}$ = 379.38, $F_{Lequesne}$ = 216.554, all P < 0.001) and the control group ($F_{WOMAC\ stiffness}$ = 29.140, $F_{WOMAC\ function}$ = 141.915, $F_{Lequesne}$ = 45.136, all P < 0.001). The WOMAC stiffness score and Lequesne index score in the MFAT group maintained a downward trend up to 24 mo after treatment. Additionally, the WOMAC function score decreased most significantly at 12 mo and slightly increased at 24 mo. The WOMAC function score and Lequesne index score in the control group were lowest after 6 mo and then increased monthly, while the WOMAC stiffness score was lowest at 24 mo. The WOMAC stiffness score, WOMAC function score, and Lequesne index score in both groups were lower than the values at baseline. However, the WOMAC function score of patients in the MFAT group was still lower than that of the control group at all follow-ups (all P < 0.001) (Figure 2D, Table 2). Similar patterns were observed in the WOMAC stiffness score and Lequesne index score

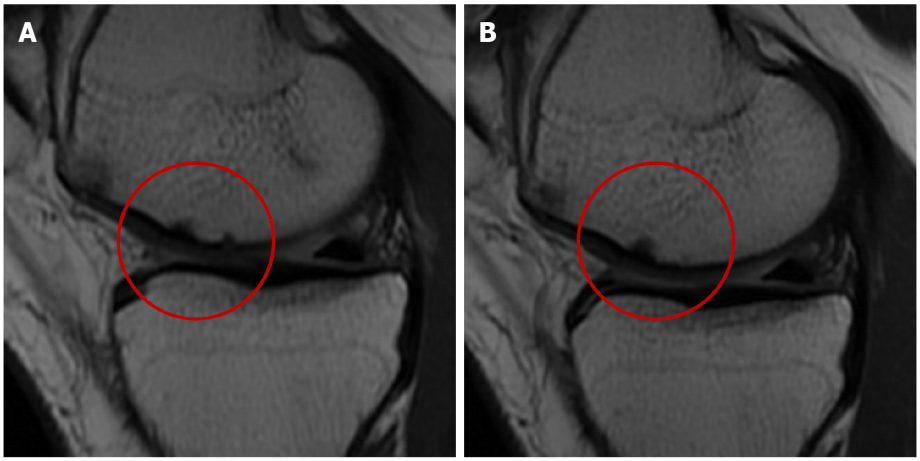
Figure 3 Trends of the visual analog scale pain score, Lequesne index score, and Whole-Organ Magnetic Resonance Imaging Score during the 24-mo follow-up for both groups. A: Visual analog scale pain score trends; B: Lequesne index score trends; C: Whole-Organ Magnetic Resonance Imaging Score change (n = 10 for each group). Statistically significant differences have been reported as $^{a}P < 0.05$ (microfragmented adipose tissue *vs* control). Results are presented as the means ± SD. WORMS: Whole-Organ Magnetic Resonance Imaging Score; VAS: Visual analog scale; MFAT: Microfragmented adipose tissue.



of the two groups at 12 and 24 mo (all $P < 0.001$), while there was no significant difference between the two groups at 6 mo ($P_{WOMAC\ stiffness\ score} = 0.054$, $P_{Lequesne\ index\ score} = 0.458$) (Figures 2C and 3B, Table 2). The WOMAC stiffness score, WOMAC function score, and Lequesne index score showed that MFAT injection combined with arthroscopy effectively improved function and quality of life in patients with KOA.

The WORMS as an indicator of radiological changes at 24 mo is documented in Table 3. The mean WORMS at 24 mo had significantly greater improvements than at baseline in the MFAT group ($P = 0.020$), while no statistically significant difference was observed compared to the baseline score in the control group ($P = 0.850$). There were no significant between-group differences in the WORMS at 24 mo (55.0 ± 15.5 *vs* 62.1 ± 18.7, $P = 0.367$) (Figure 3C, Table 2). However, a higher proportion of patients in the MAFT group had reduced femoral and tibia bone marrow lesions (BML), repaired meniscus, and improved osteochondral defect compared with the control group (Figures 4 and 5).

Table 3 Comparison of the Whole-Organ Magnetic Resonance Imaging Score before and after treatment in the microfragmented adipose tissue and the control group

	MFAT group	Control group	*t* value	*P* value
Baseline	58.9 ± 15.9	60.8 ± 19.0	0.243	0.811
24 mo	55.0 ± 15.5	62.1 ± 18.7	0.924	0.367
t value	2.814	-0.195		
P value	0.0203	0.85		

WORMS: Whole-Organ Magnetic Resonance Imaging Score; MFAT: Microfragmented adipose tissue.

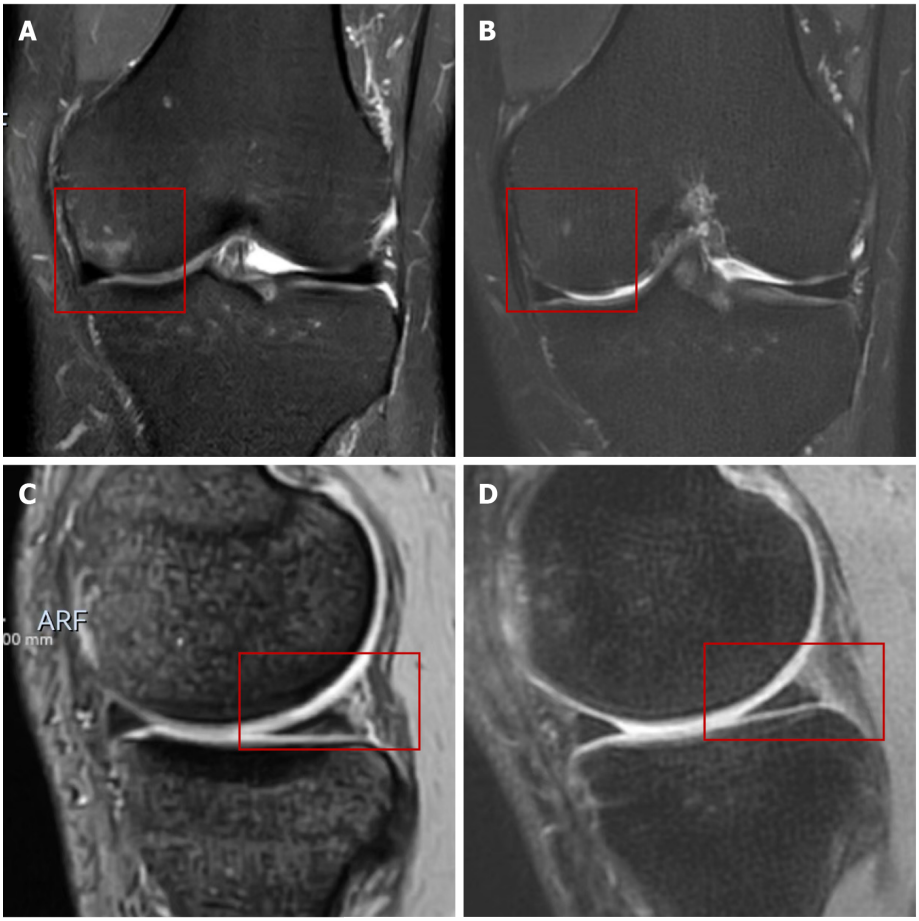
Figure 4 Magnetic resonance imaging evaluation of osteochondral defect changes at 24 mo. A: Sagittal images of the medial femur and tibia before injection of microfragmented adipose tissue (MFAT); B: Sagittal images of the medial femur and tibia 24 mo after MFAT injections. The osteochondral defect in the circled area was reduced, indicating articular cartilage regeneration at the site of the osteochondral defect.



Safety outcomes

No serious adverse events occurred in the two groups. A total of 17 non-serious adverse events were observed: In eight knees (5.4%) in the MFAT group and nine knees (6.2%) in the control group, joint effusion, pain, or swelling were reported for over 5 d. None of these adverse events led to trial suspension in either group.

DISCUSSION

This multicenter study prospectively analyzed the safety and potential benefits of using MFAT as an adjuvant in the arthroscopic treatment of KOA. The results showed that over a 24-mo follow-up period, the injection of MFAT plus arthroscopic surgery was superior to HA plus arthroscopic surgery across multiple outcome measures, including reductions in the total WOMAC score and the scores for each subscale, VAS pain score, Lequesne index score, and WORMS.

Comprehensive studies and characterization of the injected MFAT have been performed *in vitro*[11-13]. MFAT has been shown to contains large amounts of cells; moreover, various bioactive molecules are released by these cells through a paracrine mechanism to prime and preserve angiogenic, antifibrotic, antiapoptotic, antimicrobial, and immunomodulatory responses in the target tissue. Therefore, MFAT might be a novel source of cell therapy for KOA. Striano *et al*[28] first showed that MFAT transplantation significantly improved the VAS score and expanded the joint space in a 59-year-old male patient with severe knee pain. PRP is an established regeneration therapy for KOA treatment. Recently, a study demonstrated that a single intra-articular injection of MFAT did not differ from an injection of PRP in terms of clinical outcomes at up to 24 mo[29]. This study indirectly reflected the efficacy of MFAT in KOA. Several studies have also confirmed the efficacy and safety of MFAT in the treatment of KOA, including four studies that used MFAT associated with arthroscopic surgery for the treatment of KOA in humans[25,30-39]. The first clinical trial showed that a combination of arthroscopy and a single intra-articular injection of MFAT improved the International Knee Documentation Committee (IKDC) subjective score and total knee injury and OA outcome score (KOOS) in 30 patients affected by diffuse degenerative chondral lesions at 12 mo posttreatment (70% and 67% of the patients improved by at least 10 points for the IKDC subjective score and total KOOS, respectively)[32]. In another study, Cattaneo *et al*[37] reported on 38 patients

Figure 5 Magnetic resonance imaging evaluation of bone marrow lesions and meniscus tear changes at 24 mo. A and C: Coronal and sagittal images of the medial femur and tibia before injection of microfragmented adipose tissue (MFAT). The bone marrow lesions (BML) and meniscus tears can be observed in the rectangle; B and D: Coronal and sagittal images of the medial femur and tibia 24 mo after MFAT injections. The BML in the rectangular area was reduced, and the meniscus injury was repaired. ARF: Anterior right inferior.

treated with an arthroscopic procedure combined with an injection of MFAT. The results showed that all the patients were satisfied with the treatment and that 92% of them had improved KOOSs on direct physical examination at the final follow-up. A steady and statistically significant improvement in all KOOSs from the preoperative evaluation to the 1-, 3-, and 6-mo follow-ups was observed. However, the KOOS slightly, but not statistically significantly, decreased at 12 mo. The latest published trial in 2023 included two groups of 78 patients with severe KOA (Kellgren-Lawrence grade 3-4). The study results indicated that compared to arthroscopic debridement (AD) alone, injection of MFAT along with AD was more effective in improving the KOOS score, VAS score, WOMAC score, and KSS score at the 24-mo follow-up. Additionally, magnetic resonance imaging (MRI) T2-mapping scores significantly improved in the medial and lateral condyle compartments[39]. These studies preliminarily confirmed the efficacy of MFAT for treating KOA. However, the results of efficacy trends at different time points following treatment were not consistent. In this multicenter, randomized, placebo-controlled study, patients in the MFAT combined with arthroscopy group achieved better primary and secondary endpoints at 24 mo following treatment than those in the control group. Furthermore, clinical symptoms improved following MFAT treatment in a time-dependent manner, which suggested the efficacy of MFAT treatment for patients with KOA. However, the improvement in clinical outcomes in patients in our MFAT group was smaller than those reported in other studies, which might be explained by the heterogeneity of the enrolled participants.

In our study, arthroscopic surgery in the control group had a favorable mid-term outcome at 6 mo, but this efficacy was not long-lasting, which was consistent with the findings of earlier trials[40]. Interestingly, injecting MFAT could prolong the improving trend in most of the indicators to 24 mo. Regarding the mechanism of MFAT for KOA treatment, we speculate that MFAT may first act through differentiation or paracrine action of the different cells it contains. There is evidence that MFAT itself, not only its derived human MSCs, can directly differentiate into chondrocytes in vitro[20]. Other differentiated cells, such as pericytes in MFAT, may also play important roles since MFAT releases many more growth factors and cytokines involved in tissue repair and regeneration than the enzymatically derived stromal vascular fraction[41]. Second, matrix metalloproteinases and proinflammatory mediators, such as interleukin-1β and tumor necrosis factor-α cause cartilage degradation and synovial swelling, stimulating synovial proliferative and inflammatory responses of both resident synoviocytes and macrophages[42]. After co-cultivation of MFAT and inflamed synoviocytes, the levels of macrophage-specific chemokines [C-C motif ligand 2 (CCL2)/monocyte chemoattractant protein-1 and CCL3/macrophage inflammatory protein-1α) and the degradative marker matrix metalloproteinase-9 were downreg-

ulated, and the mRNA levels of inflammatory factors were reduced, which was partially dependent on Toll-like receptor 4 and nuclear factor-kappaB signaling[43,44]. Additionally, other secreted molecules in MFAT may play anti-inflammatory roles. Ragni *et al*[42] identified extracellular vesicle-shuttled microRNAs (miRNAs) (miR-24-3p, miR-222-3p, and miR-193b-3p) and soluble factors [tissue inhibitor of metalloproteinases-1 (TIMP1), TIMP2, PLG, and CTSS) as both cartilage-protective factors and factors that trigger the switch from M1 to M2 macrophages in the secretome of adipose-derived stem cells cultivated *in vitro* under inflammatory conditions. Third, preserving cartilage function and integrity is a feasible mechanism. Chen *et al*[23] demonstrated that MFAT attenuated pain symptoms and protected chondrocytes and cartilage extracellular matrix from damage in a monoiodoacetate-induced OA rat model. Another clinical trial also indicated that the contents of cartilage glycosaminoglycans significantly increased in specific areas of the treated knee joint by delayed gadolinium-enhanced MRI of cartilage[45]. Finally, MFAT may act as a natural scaffold and display interesting mechanical properties, such as the infrapatellar fat pad[20,46].

MRI can provide a more accurate and reliable basis for assessing factors, such as the lesion location and morphological organization, in patients. A 12-mo follow-up of 64 patients undergoing MFAT therapy revealed that BML was negatively correlated with the therapeutic response rate at 12 mo[47]. Similarly, another study showed that BML was significantly deceased 12 mo after surgery in the treatment group. However, the cartilage scores were nonsignificant between the treatment and placebo groups, although the cartilage layer was thicker in the treatment group at 12 mo[48]. We compared the MRI results of the MFAT group to those of the control group using WORMS, which revealed no significant differences between these two groups at 24 mo. However, similar to the findings of a study by Nguyen *et al*[48], we found that the WORMS at the 24-mo follow-up in the MFAT group had significantly reduced, while it was relatively increased in the control group. Furthermore, MRI of a higher percentage of patients in the MFAT group showed signs of repaired cartilage damage, meniscus repair, and reduced BML, supporting the therapeutic potential of MFAT from the perspective of MRI findings. Additionally, the insignificant results at 24 mo might be partially explained by the limited number of postoperative MRI results in this study due to economic reasons (n = 10 for each group). Although it is well known that BML is closely related to pain in the arthritic knee joint, the current conclusions about the imaging changes in MFAT in the treatment of KOA and the association of imaging with clinical results are inconsistent[49]. Therefore, well-controlled studies with larger sample sizes are needed.

In the current study, we only found a handful of mild adverse events with pain or swelling in the liposuction or injection area, without severe adverse events or complications. This result is consistent with those of a previous study in which only 5.8% of patients who were administered MFAT injections had a transitory hematoma of the abdominal region that had no impact on the knee[50]. Likewise, Bisicchia *et al*[38] reported no adverse events related to MFAT injection at the 12-mo follow-up, and there was only one case of knee effusion 3 d postoperatively in the microfracture control group, demonstrating the safety of MFAT for clinical use.

A major strength of this study is that, as the first multicenter prospective randomized trial in a Chinese population, the study's sample size was relatively large. Moreover, the primary and secondary outcomes included both patient-reported indexes and imaging technologies, and most patients completed the final 24-mo follow-up. However, our study has some limitations. First, we only recruited patients with Kellgren-Lawrence grades of 2-3. We excluded a Kellgren-Lawrence grade of 4 because it indicated marked joint-space narrowing and definite deformity, which may not be suitable for arthroscopic treatment; however, other studies have demonstrated the efficacy of MFAT in patients with severe OA[33,39]. Second, the patients and the surgeons who performed the surgeries could not be blinded to the patients' groups owing to the extra liposuction in the MFAT group. Nevertheless, the operator who processed the data was unaware of the patients' groups. Third, the follow-up time was short, and differences in the volume of MFAT were not examined. Moreover, the differences in the intervention in the control and study groups may have influenced the results. In addition, we should also consider cost-effectiveness since the cost of MFAT might be prohibitive for some patients. Finally, this study was conducted in only Zhejiang, China, as a representative sample of the Chinese population. Long-term studies on the potential dose-dependent effect, including more districts, should be conducted in the future.

CONCLUSION

In conclusion, our study demonstrates that MFAT injection combined with arthroscopic surgery is a safe and effective approach for improving function and alleviating pain in patients with KOA. MFAT therapy produced longer-lasting, statistically significant durations of efficacy at 12 and 24 mo in comparison to those of the control (HA) group. Based on these results, MFAT injection combined with arthroscopic surgery may be considered a potential therapeutic option for KOA.

ARTICLE HIGHLIGHTS

Research background

The most common kind of degenerative whole-joint disease is osteoarthritis (OA). Before the ultimate choice of knee replacement, the most common joint-preserving surgical procedure was arthroscopic surgery. Mesenchymal stem cells, platelet-rich plasma, and microfragmented adipose tissue (MFAT) are examples of emerging regenerative medicines that have been thrust into the forefront of treatment to stop the progression of OA. MFAT is now being used to treat various orthopedic diseases with effectiveness.

Research motivation
Current mainstream medicine mainly focuses on relieving symptoms and cannot prevent the disease from progressing to the late stages of arthritis that require knee replacement. MFAT as a novel way of treatment may be of great significance in alleviating knee OA (KOA).

Research objectives
The present study aimed to assess the efficacy and safety of MFAT with arthroscopic surgery in patients with KOA.

Research methods
Patients diagnosed with KOA (Kellgren-Lawrence grades 2-3) were included in a multicenter, prospective, single-blind randomized trial. In this trial, 302 patients were randomized into the MFAT group (n = 151, were administered MFAT following arthroscopic surgery), or the control group (n = 151, were administered hyaluronic acid following arthroscopic surgery). The study outcomes included changes in the Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC) score, the visual analog scale (VAS) score, the Lequesne index score, the Whole-Organ Magnetic Resonance Imaging Score (WORMS), and safety, from baseline to 24 mo.

Research results
The changes in the WOMAC score (including the 3 subscale scores), VAS pain score, and Lequesne index score at 24 mo showed significant differences in both groups between the posttreatment visit and baseline ($P < 0.001$). The MFAT group exhibited significant decreases in the WOMAC pain scores and VAS scores at all follow-ups, suggesting the pain-relieving potential of MFAT combined with arthroscopy compared to arthroscopy alone HA treatment ($P < 0.05$). The significant differences in the WOMAC stiffness score, WOMAC function score, and Lequesne index score at 12 and 24 mo after MFAT administration and surgery suggested the potential of MFAT combined with arthroscopy compared to arthroscopy alone control group to improve function and quality of life ($P < 0.05$). There were no significant between-group differences in the WORMS at 24 mo ($P = 0.367$). No serious adverse events occurred in the two groups.

Research conclusions
In summary, our study demonstrates that MFAT injection combined with arthroscopic surgery is a safe and effective approach for improving function and alleviating pain in patients with KOA. Based on these results, MFAT injection combined with arthroscopic surgery may be considered a potential therapeutic option for KOA.

Research perspectives
We demonstrated that MFAT injection combined with arthroscopic surgery had better clinical efficacy than control group for treating KOA at a mid-term follow-up and could be a potential therapeutic approach for patients with KOA.

Abstract

BACKGROUND

Mesenchymal stem cells (MSCs) have protective effects on the cornea, lacrimal gland, retina, and photoreceptor cell damage, which may be mediated by exosomes (exos) released by MSCs.

AIM

To investigate the ameliorating effect of exos derived from different MSCs on retinal ganglion cell (RGC) injury induced by hydrostatic pressure.

METHODS

The RGC injury model was constructed by RGC damage under different hydrostatic pressures (40, 80, 120 mmHg). Then RGCs were cultured with adipose-derived stem cell (ADSC)-Exos and bone marrow-derived stem cell (BMSC)-Exos. Cell Counting Kit-8, transmission electron microscopy, flow cytometry, immunofluorescence, real-time quantitative polymerase chain reaction, and western blotting were performed to detect the ameliorating effect of exos on pressure-induced RGC injury.

RESULTS

ADSC-Exos and BMSC-Exos were successfully isolated and obtained. The gibbosity of RGCs was lower, the cells were irregularly ellipsoidal under pressure, and the addition of ADSC-Exos and BMSC-Exos significantly restored RGC morphology. Furthermore, the proliferative activity of RGCs was increased and the apoptosis of RGCs was inhibited. Moreover, the levels of lactate dehydrogenase and apoptosis-related proteins were increased, and the concentrations of antiapoptotic proteins and neurotrophic factors were decreased in damaged RGCs. However, the above indicators were significantly improved after ADSC-

Exos and BMSC-Exos treatment.

CONCLUSION
These findings indicated that ADSC-Exos and BMSC-Exos could ameliorate RGC injury caused by hydrostatic pressure by inhibiting apoptosis and increasing the secretion of neurotrophic factors.

Key Words: Adipose-derived stem cells; Bone marrow-derived stem cells; Exosomes; Glaucoma

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: We discovered for the first time that adipose-derived stem cell-exosomes (ADSC-Exos) significantly ameliorate retinal ganglion cell (RGC) injury caused by hydrostatic pressure by inhibiting apoptosis and increasing the secretion of neurotrophic factors. ADSC-Exos manifested better ameliorating effects than bone marrow-derived stem cell (BMSC)-Exos in ameliorating the RGC injury induced by hydrostatic pressure. BMSC-Exos ameliorate optic nerve injury caused by hydrostatic pressure by inhibiting apoptosis and increasing the secretion of neurotrophic factors.

INTRODUCTION

Glaucoma is the main cause of irreversible blindness around the world and is a chronic degenerative optic nerve disease [1]. The early pathological changes of glaucoma include reduced axonal transport, axon loss, and dendrite reconstruction, leading to retinal ganglion cell (RGC) apoptosis and thinning of the retinal nerve fiber layer, eventually resulting in visual field defects and loss of vision[2,3]. Apoptosis of RGCs in glaucoma has been demonstrated *in vivo* in several animal models and in humans[4,5]. The mechanism of RGC apoptosis in glaucoma, including oxidative injury[6], inflammatory response[4], and glutamate toxicity[7], particularly how elevated intraocular pressure (IOP) leads to RGC apoptosis, is yet to be fully elucidated. There are three treatment methods for glaucoma caused by high IOP, including using drugs to reduce the production of aqueous humor, surgically aqueous humor drainage, and laser stimulation for cell proliferation and differentiation to repair damaged eye tissue[8]. However, existing IOP-lowering treatments cannot prevent the reduction of RGCs[9], and there is the limitation of repeated treatment, even worse.

The only hope for glaucoma patients with RGC loss to regain vision is preventing RGC apoptosis[10]. Current research is focused on developing neuroprotective measures, particularly the use of stem cell therapy to protect RGCs[11]. Stem cells produce many molecules responsible for cell signaling, such as cytokines, growth factors, morphogens, chemokines, and extracellular vesicles (EVs), improving various cellular mechanisms[12-15]. However, the direct transplantation of stem cells has some risks such as safety, tumorigenesis, and immune rejection[16]. Recent studies have shown that stem cells play a therapeutic role in a paracrine manner, with stem cell-derived exosomes (exos) being the major contributors to stem cell function, carrying and transporting cytokines, proteins, and nucleic acids from stem cells[17]. It also has stronger target specificity and lower carcinogenic and immune risks[18], which can avoid the problems existing in the direct use of stem cell therapy, and increasing the use of stem cell-derived exos is the focus of research to enhance the efficacy of stem cell therapy.

Mesenchymal stem cells (MSCs) are fibroblast-like, self-renewing cells that are present in almost all postpartum tissues and organs, including bone marrow, adipose tissue, blood, umbilical cord, amniotic fluid, and dental pulp and are responsible for regulating the normal development and maintenance of mesenchymal tissue[19]. Bone marrow, adipose tissue, and human MSCs of the umbilical cord have protective effects on cornea, lacrimal gland, retina, and photoreceptor cell damage[20]. This ameliorating effect may be mediated at least in part by exos. MSC-Exos can maintain activity for at least 4 wk after vitreous injection and can integrate into tissues more quickly to provide nutritional factors for RGCs due to their smaller diameter[15]. Bone marrow stem cell (BMSC)-derived exos are also more effective than directly transplanted BMSCs in the treatment of glaucoma because BMSCs have a poor ability to integrate into the retina, remain in the vitreous after injection, and cannot deliver neurotrophic factors to RGCs[21]. Mead *et al*[22] found that the neural function of RGCs was significantly improved after intravitreal injection of BMSC-Exos in a glaucoma rat model. A similar result was reported in the hereditary DBA/2J mouse model of glaucoma[23]. Moreover, studies have shown that BMSC-Exos injected in an optic nerve compression rat model by intravitreal injection can integrate into the cell bodies and axons of retinal neurons and promote axon regeneration by activating the Akt pathway dependent on microRNA (miRNA)[24]. These findings indicate that BMSC-Exos have an ameliorative effect on glaucoma. Moreover, Sheykhhasan *et al*[25] demonstrated that adipose-derived stem cell (ADSC)-Exo and CoQ10 administration could ameliorate memory deficits by modulating SOX2 and brain-derived neurotrophic factor (BDNF) expression in a rat model of Alzheimer's disease. Numerous preclinical studies have confirmed the therapeutic potential of ADSC-Exos in neurodegenerative diseases[26,

27]. Glaucoma is a neurodegenerative disease in which the role of ADSC-Exos has not been studied yet. Therefore, this study aimed to investigate the protective effect of BMSC-Exos and ADSC-Exos on RGC injury, which is the main feature of glaucoma, induced by hydrostatic pressures.

MATERIALS AND METHODS

Extraction of ADSC-Exos and BMSC-Exos

ADSCs and BMSCs were a kind gift from Kunming Cell Bank of Chinese Academy of Sciences (Kunming, China). Cells in the third generation with good logarithmic phase growth were selected. The cell culture medium was discarded, and the cells were washed 3 times with phosphate-buffered solution (PBS) and replaced with serum-free medium. After 48 h in culture, the cells were adjusted to a concentration of 1×10^5 cells/mL. The cells were then centrifuged at 3000 r/min for 10 min at room temperature to collect the supernatant. The supernatant was centrifuged at 20000 r/min for 20 min at 4 °C to remove dead cells and debris, and the supernatant was then filtered through a sterile, 0.22 μm pore size syringe filter to obtain the crude extract of exos. Then the crude extract was centrifuged at 50000 r/min at 4 °C for 1 h. The white precipitate could be seen at the bottom of the tube after centrifugation, and the supernatant was removed. The white precipitate was cleaned with 0.9% sodium chloride injection several times, and the resulting suspension was collected and centrifuged at 4 °C for 10 min at 3000 r/min. Exo protein quantification was performed using a BCA protein assay kit (Beyotime, Shanghai, China). Dynamic light scattering was used to detect the size distribution of the exos. The structure of exos was observed by transmission electron microscopy (TEM) (HITACHI, Japan).

Primary RGCs extraction, culture[28,29], and grouping

Mice 1-3 d old were sacrificed by intraperitoneal injection of 4.3% chloral hydrate, and the eyeballs were removed under aseptic conditions and rinsed three times. Under the microscope, the retinal neuroepithelial layer tissue was isolated. The tissue was rinsed 3 times and digested in 0.5 g/L trypsin for 30 min at 37 °C. The digestion was terminated by the addition of DMEM containing 10% foetal bovine serum (FBS) and filtered through a 40-μm filter. Centrifuge at room temperature for 5 min, discard the supernatant, and add complete DMEM. After adjusting the cell density, the cells were inoculated into cell culture flasks. The cells were placed in a 5% CO_2 incubator at 37 °C for 7-10 d. The obtained cells were taken and identified by immunofluorescence staining using a Thy1.1 antibody. The project was approved by the Yunnan University Ethics Committee (approval number YUN20230463).

Then, the cells were grouped into different experiments as follows: (1) Normal control (NC) group, 40 mmHg group, 40 mmHg + ADSC-exo group, and 40 mmHg + BMSC-exo group; (2) NC group, 80 mmHg group, 80 mmHg + ADSC-exo group, and 80 mmHg + BMSC-exo group; and (3) NC group, 120 mmHg group, 120 mmHg + ADSC-exo group, and 120 mmHg + BMSC-exo group.

Hydrostatic pressure damage model preparation

RGC culture dishes were placed within the pressure chamber[30,31], and the incubating gas mix was pressurized. The cells were exposed to conditions of elevated ambient hydrostatic pressure (40 mmHg, 80 mmHg, 120 mmHg) over and above atmospheric pressure for a period of 2 h. The pressure conditions were then restored to atmospheric, and the culture dishes were removed from the chamber. Under normal cell culture conditions (37 °C, 5% CO_2), the culture was continued for 24 h.

Coculture of ADSC-Exos or BMSC-Exos and RGCs

The concentrations of ADSC-Exos and BMSC-Exos were measured by a BCA kit (P0010, Beyotime). P3-generation SCs with good digestive state were taken from each group to make a uniform cell suspension and put 100 μL per well in 96-well cell culture plates. ADSC-Exos (20 μg/mL)[32] were added after the stem cells were completely attached to the wall. BMSC-Exos (20 μg/mL)[33] were cultured for 24 h, and the cells of each group were collected for subsequent experiments. Then, cell morphology was observed under an inverted phase contrast microscope (Olympus).

Ultrastructure observation of RGCs by transmission electron microscopy

After the cells were treated for 24 h according to the above groups, the cells were digested and collected with Trypsin-EDTA Solution (Beyotime, Shanghai, China), centrifuged in a 1.5 mL EP tube, and the supernatant was discarded. Then, 2.5% glutaraldehyde fixing solution was quickly added to completely cover the cell specimens, which were refrigerated at 4 °C overnight. The fixing solution was poured away, and the samples were rinsed with PBS first and then fixed with 1% osmic acid solution. The samples were subjected to gradient dehydration with an ethanol solution and finally treated with pure acetone for 20 min. The samples were treated with a mixture of equal volume embedding medium and acetone for 1 h. Then, the samples were treated with a mixture of embedding medium and acetone (V/V = 3/1) for 3 h. Next, the embedding medium was used to treat the sample overnight. The samples with osmotic treatment were embedded and heated at 70 °C overnight to prepare the needed samples. The samples were sliced in a Leica EM UC7 ultramicrotome, and slices of 70-90 nm were obtained, double-dyed with lead citrate solution and 50% ethanol saturated solution of uranyl acetate, dried and observed under a transmission electron microscope (Tecnai G2 spirit).

RGCs were labeled by immunofluorescence with β-III tubulin

RGCs were collected in each group, washed twice with PBS, fixed at room temperature for 30 min with 4% paraformal-

dehyde, permeated with 0.1% Triton X-100 for 10 min, washed with PBS 3 times, and sealed with 10% goat serum at room temperature for 1 h. The blocking buffer was removed, and β-III tubulin primary antibody (ab78078, Abcam) was added and incubated overnight at 4 °C. After washing with PBS 3 times, sheep anti-rabbit IgG fluorescent secondary antibody (P0186, Beyotime) was added to the dark, and incubated at room temperature for 2 h. After 3 washes with PBS, 5-10 nonrepetitive visual fields were randomly taken under a fluorescence microscope (Nikon fluorescence microscope), and the number of retinal ganglion cells was quantified by ImageJ software (ImageJ, RRID:SCR_003070).

Detection of cell activity by Cell Counting Kit-8 assay

The cells of each group were digested with Trypsin-EDTA Solution, and the cells were suspended in 10% FBS medium. Each well was inoculated with 1×10^5 cells in 96-well plates. The 96-well plates were cultured in a constant temperature incubator containing 5% CO_2 at 37 °C for 0, 24, 48, 72, and 96 h. At the corresponding time, 10 μL Cell Counting Kit-8 (CCK-8) reagent (Beyotime) was added, and the absorption value at 450 nm was detected by a microplate reader after continuous culture for 2 h.

Detection of the cell apoptosis rate by Annexin V-FITC kit flow cytometry

Cells in each group were digested with trypsin-EDTA solution, collected, washed with PBS, resuspended in 300 μL of binding buffer, and incubated with 10 μL of Annexin V-FITC at room temperature for 15 min in the dark. Before the operation, 5 μL PI was added and then 200 μL binding buffer was added. The apoptosis rate of cells was detected by a flow cytometer.

The localization of CREB and p-CREB detected by immunofluorescence chemical staining

The cells were inoculated into 24-well plates with 5×10^4 cells per well, and each well was cultured with 500 μL medium for 12 h. Then, the cells were fixed with 4% paraformaldehyde at room temperature. PBS containing 0.1% Triton X-100 was added, and permeabilization was performed at room temperature for 10 min. The cells were sealed with 5% BSA at room temperature for 30 min. The liquid was removed and rabbit CREB antibody (Beyotime) and rabbit p-CREB antibody (Beyotime) diluted with 1% BSA were added. Next, the cells were incubated at 4 °C overnight and washed with PBS. The goat anti-rabbit secondary antibody was incubated at room temperature for 1 h and washed with PBS. Finally, the samples were dyed with DAPI solution at room temperature for 5 min and washed with PBS. A fluorescence microscope was used to observe and photograph the cells.

The degree of RGC neuron damage evaluated by the lactate dehydrogenase release test

One hundred microliters of the cell supernatant in each group was collected for the lactate dehydrogenase (LDH) concentration test according to the LDH kit (Keygen, Nanjing, China) instructions. Then, the reaction mixture was added and incubated in the dark for 30 min at room temperature. The LDH concentration was quantified by measuring the absorbance at 490 nm.

Detection of the expression of Bcl-2, Bax, Caspase-3/9, TRkA, TrkB, CREB, and p-CREB by western blotting

The cells of each group were collected and lysed with RIPA lysis buffer containing a protease inhibitor, and the protein concentration was determined with a BCA protein concentration detection kit. The sample was loaded at 30-50 μg/well, separated by 10% sodium-dodecyl sulfate gel electrophoresis for 1 h, transferred to a polyvinylidene fluoride membrane, sealed with PBS buffer containing 5% skim milk powder for 2 h, added to the corresponding primary antibody, and incubated overnight at 4 °C. Then, the cells were rinsed with PBST buffer 3 times for 5 min each, the corresponding secondary antibody was added, and the cells were incubated at 37 °C for 4 h. Next, PBST buffer was used to rinse the cells 3 times. Color development was achieved by using the ECL Western Blot Detection Kit (Thermo Scientific). β-Actin was used as the internal reference. All antibodies were purchased from Abcam Company in Shanghai, China. Image J was used to analyze the gray value of the target protein.

Detection of the relative expression of CNTF, BDNF, NGF, TrkB, TrkA, and CREB mRNA by real-time quantitative polymerase chain reaction

TRIzol reagent (TRIzol Invitrogen) was employed to extract total RNA from cells, which were then treated with DNA enzymes for reverse transcription using a reverse transcription kit (Takara Biotechnology). Two microliters of cDNA product was placed into an EP tube and amplified by a SYBR Green Master Mix reaction system. The Ct value of the template was determined using GAPDH as the internal parameter, and the relative expression level of the target mRNA was quantified by the cycle counting method ($2^{-\Delta\Delta Ct}$). The primer sequences are shown in Table 1.

Statistical analyses

All data in this study were analyzed using SPSS 22.0 statistical software. Data are shown as the means ± SE (the number of samples was 3 per group, and each sample was repeated three times). Comparisons between the two groups were made using independent *t* tests, and comparisons between multiple groups were made using one-way ANOVA. $P < 0.05$ was considered to be a statistically significant difference.

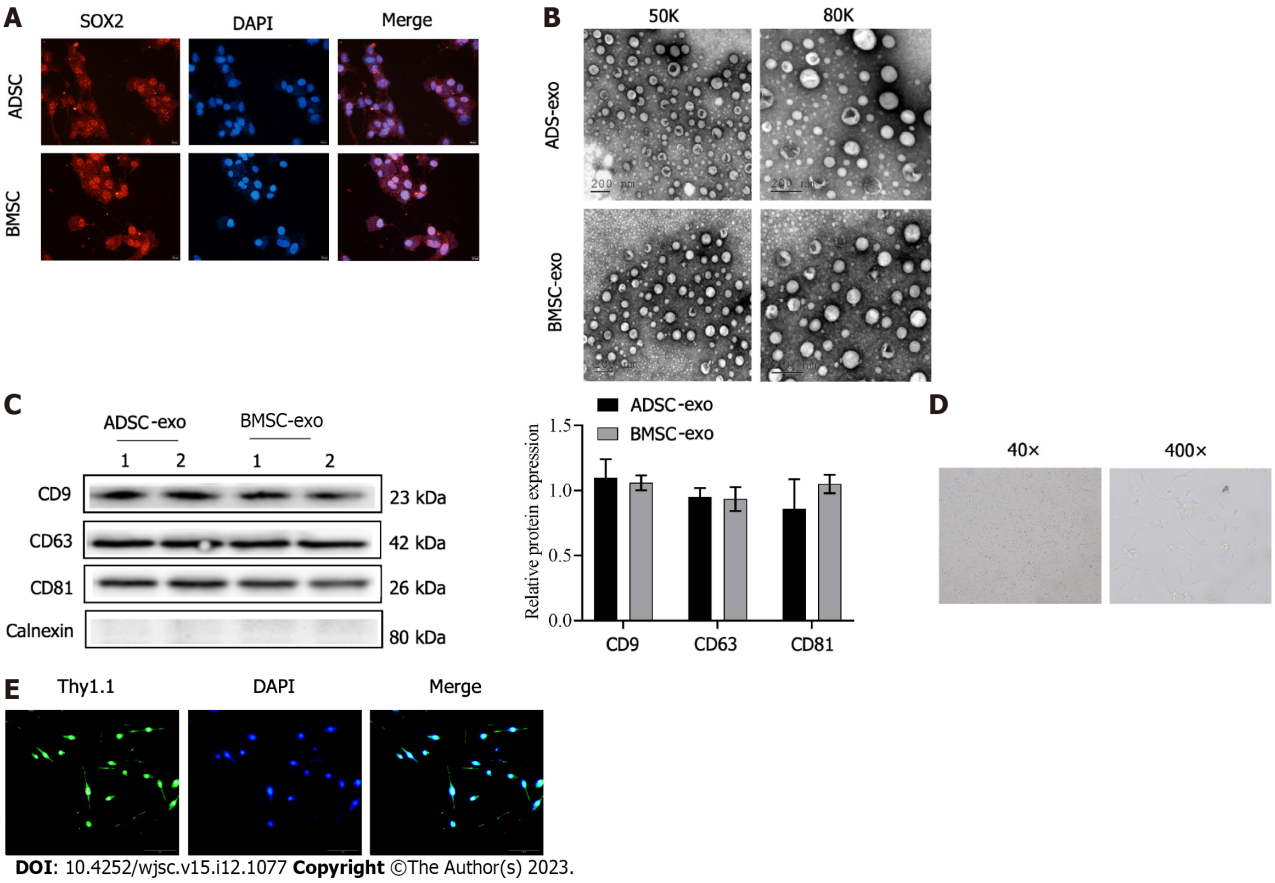
RESULTS



Characterization of ADSC- and BMSC-Exos and RGCs

The immunofluorescence labeled SOX2, which is the marker protein of stem cells was highly positive in the two kinds of stem cells (Figure 1A). Then, exos were further isolated from the stem cell solution, and suborbicular vesicles in the form of complex exo were observed by electron microscopy (Figure 1B). The exo marker molecules CD9, CD63, and CD81 detected by western blot were positive (Figure 1C), which proved that ADSC- and BMSC-Exos were successfully isolated and obtained. Finally, primary RGCs were extracted. Figure 1D shows light microscope images of RGCs. The isolated RGCs were examined by Thy1.1 immunofluorescence (Figure 1E).

ADSC-Exos and BMSC-Exos ameliorate RGCs

RGC growth observation: The RGC damage models under 40, 80, and 120 mmHg pressure were constructed, and cultured with ADSC-Exos (20 μg/mL) and BMSC-Exos (20 μg/mL) for 24 h, and then the morphology of RGCs was observed. The results of phase contrast microscopy showed that the gibbosity of RGCs was lower and that the cells were irregularly ellipsoidal under pressure. The addition of ADSC-Exos significantly restored the morphology of RGCs, but BMSC-Exos failed to restore the morphology of RGCs in the 120 mmHg pressure group (Figure 2A). After pressure was applied, transmission electron microscopy observations showed that RGCs had nuclear swelling, structural disorder, atrophy, malformation, and nucleolar shrinkage or disappearance. The addition of ADSC-Exos and BMSC-Exos significantly restored RGC morphology (Figure 2B).

The number of RGCs: To further explore the effect of ADSC-Exos and BMSC-Exos on RGCs, we performed neuron-specific β III-tubulin expression by immunofluorescence. The results showed that the number of RGCs was significantly reduced after pressure was applied, while the number of RGCs was markedly increased after ADSC-Exos and BMSC-Exos were administered (Figures 3A-C).

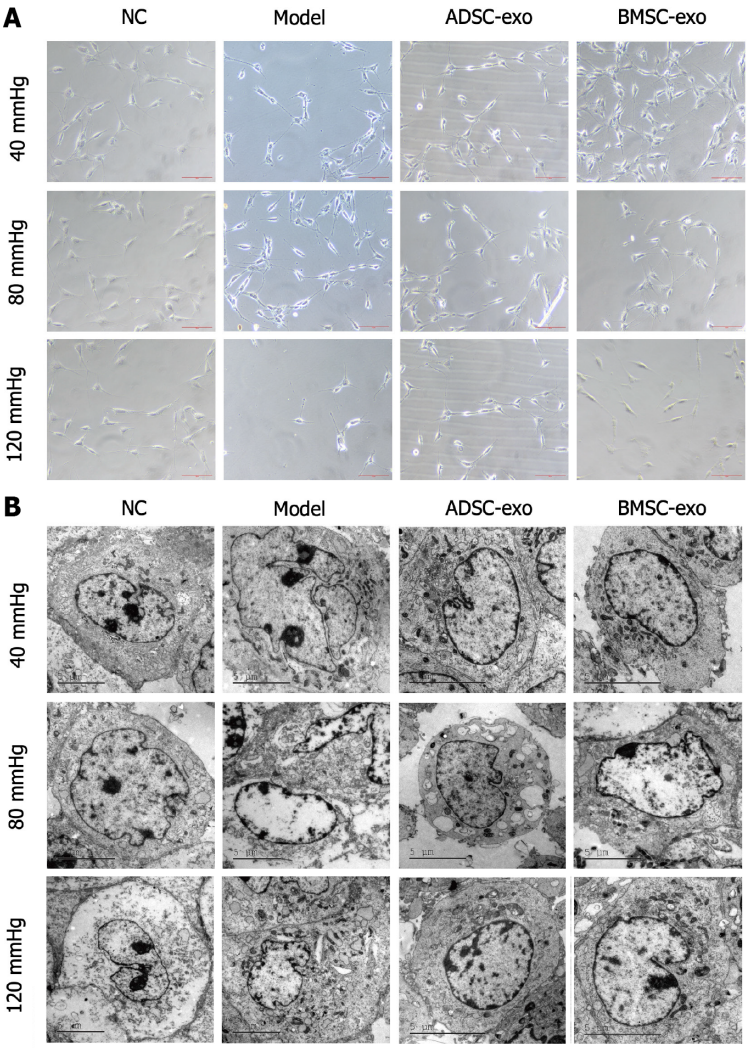
Figure 1 Adipose-derived stem cell and bone marrow-derived stem cell-exosomes, and retinal ganglion cells were isolated and identified. A: The immunofluorescence staining of stem cell markers SOX2 (Scale bar: 20 μm); B: The morphology of adipose-derived stem cell-exosomes (ADSC-Exos) and bone marrow-derived stem cell (BMSC)-Exos was observed by electron microscopy (scale bar: 200 nm); C: The ADSC-Exos and BMSC-Exos marker molecules (CD9, CD63, and CD81) were detected by western blotting; D: The light microscope images of retinal ganglion cells (RGCs) (magnification: 40 × and 400 ×); E: The isolated RGCs was examined by Thy1.1 immunofluorescence (scale bar: 50 μm). ADSC: Adipose-derived stem cell; BMSC: Bone marrow-derived stem cell; Exo: Exosome.



RGC proliferation and apoptosis: The CCK-8 results showed that RGC proliferation activity in the pressure injury group was significantly lower than that in the NC group, while proliferation activity was elevated after ADSC- and BMSC-Exos treatment (Figure 4A). The flow cytometry results indicated that compared with that in the NC group, the apoptosis rate in the pressure injury group was significantly increased, while the apoptosis rate was significantly decreased after ADSC- and BMSC-Exos treatment (Figure 4B).

The expression of CREB and p-CREB in RGCs

CREB inhibits apoptosis by upregulating the expression of the antiapoptotic genes Bcl-2 and Bcl-xL through a transcription-dependent mechanism. Therefore, this study further explored the effects of exos from different sources on the apoptosis-related protein CREB in RGCs. As shown in Figures 5A-C, the ratio of p-CREB/CREB in the pressure injury group was significantly reduced compared with that in the NC group, while the ratio of p-CREB/CREB was significantly increased after ADSC- and BMSC-Exos treatment.

The expression of LDH, neurotrophic factor and apoptosis-related mRNA and protein

LDH is present in all cells. When RGCs are damaged, they are released rapidly. When LDH is elevated, RGCs are damaged or dysfunctional, which leads to apoptosis. Therefore, this study further explored the effects of exos from different sources on LDH in RGCs. The LDH test kit results showed that compared with that in the NC group, the LDH level was significantly increased in the pressure injury group, while the LDH level was significantly decreased after ADSC-Exos and BMSC-Exos treatment (Figure 6A). western blot and real-time quantitative polymerase chain reaction results indicated that compared with the NC group, the anti-apoptotic protein (Bcl-2) and neurotrophic factor (BDNF, NGF, CNTF, TRKA, TRKB) were significantly decreased and the pro-apoptotic protein (Bax, caspase3, caspase9, CREB) was significantly increased in the pressure injury group, while the above indices could be reversed after ADSC-Exos and BMSC-Exos treatment (Figures 6B and C).

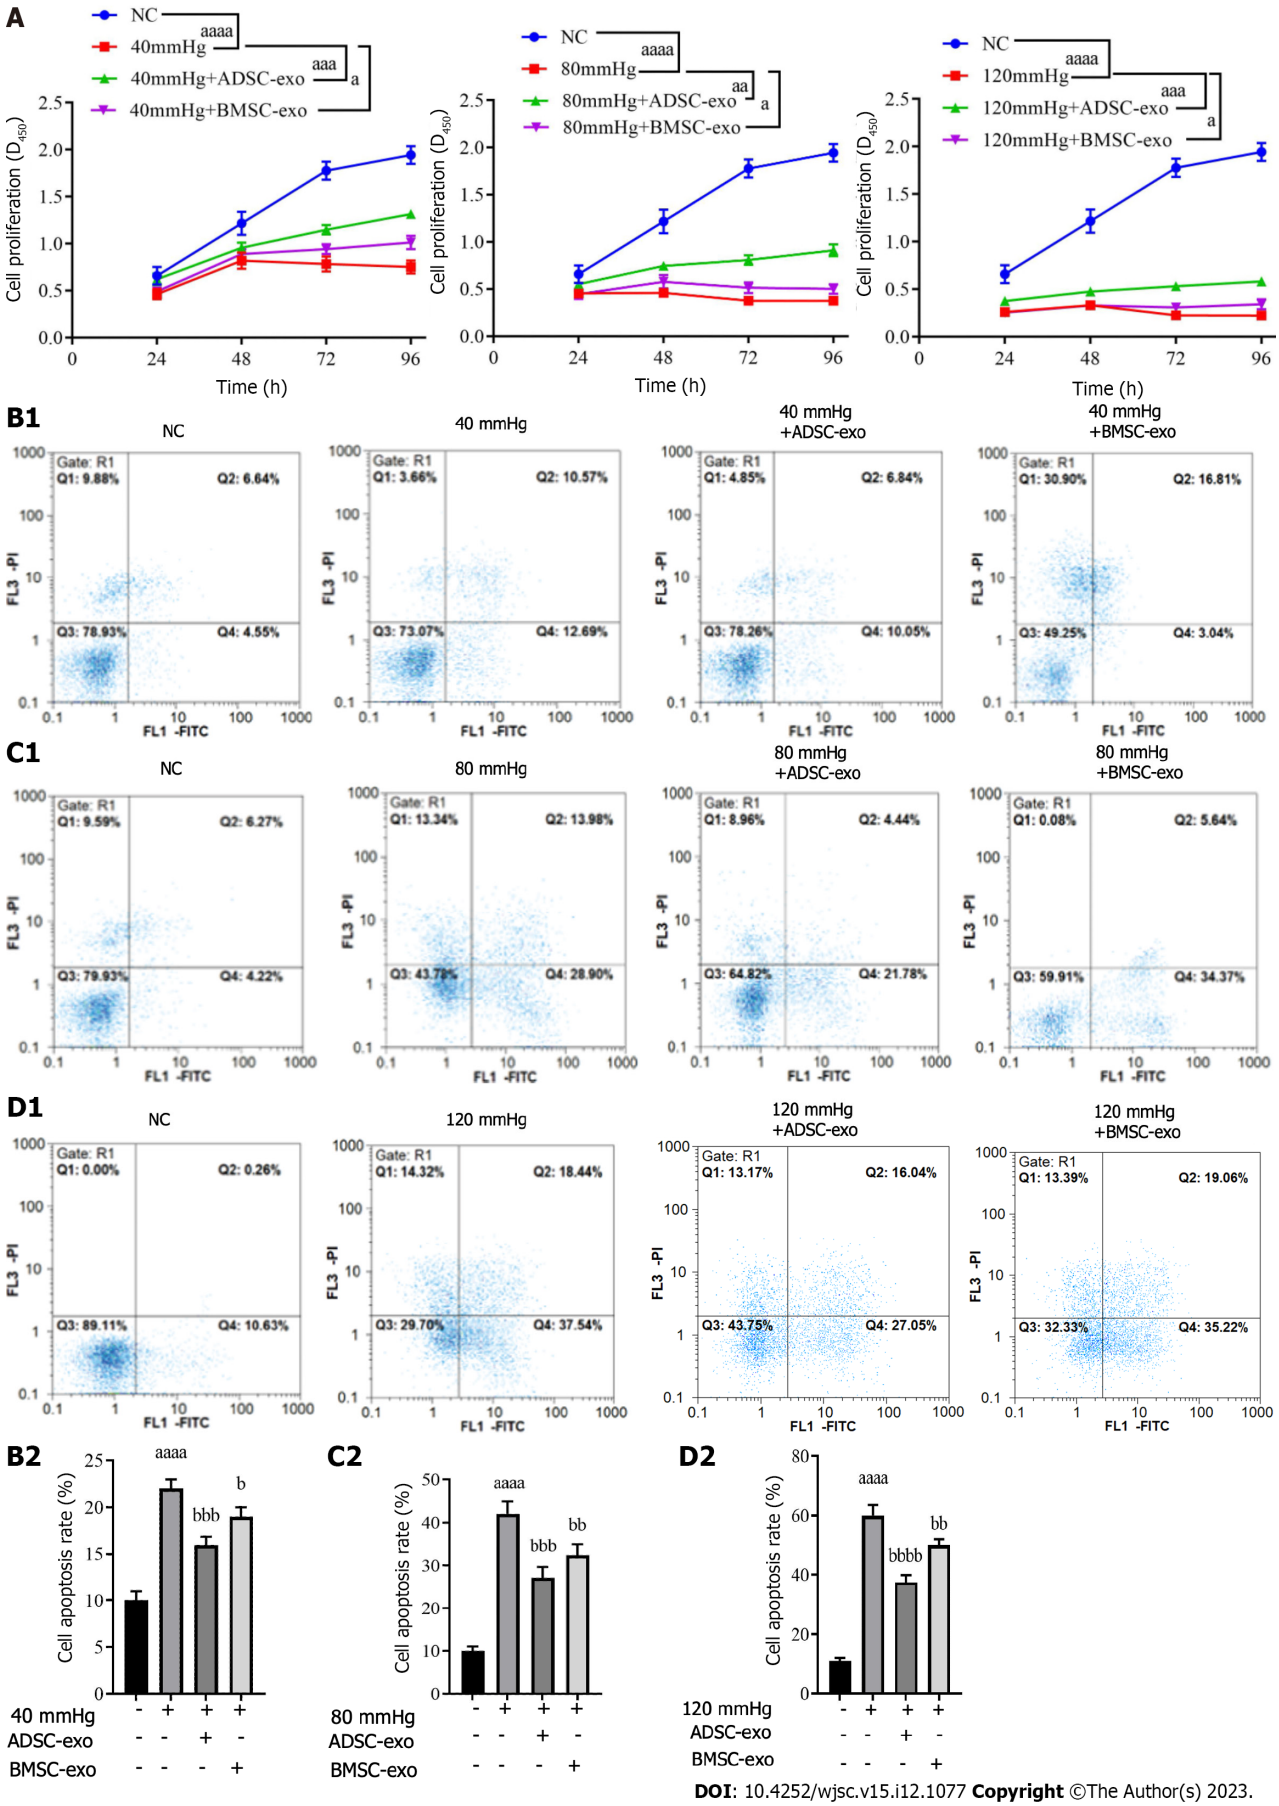
DISCUSSION



Hydrostatic pressure is known to impact various aspects of cellular anatomy and physiology. Morphological changes in cell shape, alignment and processes and cytoskeletal actin redistribution have been demonstrated in rat RGCs[34,35]. Agar *et al*[36] showed that neurons may undergo apoptosis in direct response to increased pressures at clinically relevant levels. Cell cultures were subjected to elevated hydrostatic pressures in an *in vitro* system based on established pressure chamber models[37,38]. Experimental pressure conditions were selected to be relevant to the IOPs seen in clinical settings, with levels of 100 mmHg analogous to acute glaucoma, 30 mmHg for chronic glaucoma and 15 mmHg for the so-called 'normal' IOP. Therefore, hydrostatic pressures of 40, 80, and 120 mmHg were chosen for this study and the intervention of ADSC- and BMSC-Exos could improve RGC damage by inhibiting RGC apoptosis and promoting neural restoration of RGCs.

Stem cells are a kind of cell population with the potential for self-renewal, high proliferation and differentiation, and multidirectional differentiation. MSCs are derived from connective tissue and can be differentiated into osteoblasts, chondrocytes, fat cells, and so on. In neurodegenerative diseases, MSC secretes a variety of neurotrophic factors that directly promote the survival and growth of nerve cells and act on the microenvironment of nerve tissue[39,40]. MSCs isolated from rat femoral bone marrow injected into a vitreous body can integrate into the retina, survive for at least 5 wk, significantly reduce IOP and have a protective effect on RGCs[41]. Liu *et al*[42] found that BMSC transplantation can significantly reduce photoreceptor cell death and preserve retinal structure in retinal detachment models. Hu *et al*[43] reported that BMSCs promoted the survival of RGCs in the transplanted eye compared with the control eye. MSCs play a role in neuroprotection mainly by regulating the intraocular microenvironment. This suggests that BMSCs have an ameliorating effect. However, the structural integration of MSCs into retinal tissue is complex and difficult due to the barrier action of the inner boundary membrane of the retina and the intercellular junctions[44]. In addition, transplanting MSCs in tissue reconstruction carries risks of tumorigenesis and immunological rejection. Transplanting MSC-Exos may overcome these obstacles in future applications. For example, MSC-Exos have an ameliorating effect on RGCs in some

optic neuropathy rat models[45,46]. Therefore, exos derived from stem cells are emerging as a promising method for glaucoma treatment.

This study elucidated that BMSC-Exos significantly reversed RGC damage induced by hydrostatic pressure in a RGC injury model *in vitro*. The protective effect was mainly reflected in the fact that ADSC-Exos and BMSC-Exos promoted the proliferation of RGCs, the regeneration of RGC axons, and the secretion of RGC neurotrophic factors while inhibiting RGC apoptosis. We emphasized its potential in the prevention or treatment of glaucomatous optic neuropathy. Our study confirmed previous findings that MSC-Exos have an ameliorating effect against RGC damage in some optic neuropathies. BMSC-Exos have been found to increase RGC survival and promote axon regeneration. This ameliorating effect of BMSC-Exos was also observed in a genetic modification DBA/2J glaucoma mouse model[23]. Furthermore, in rats with optic nerve compression, Pan *et al*[47] found that umbilical cord-MSC-Exos enhanced RGC survival. Yu *et al*[48] confirmed that MSC-derived EVs can help alleviate optic nerve injury caused by chronic ocular hypertension, and this effect is achieved by inhibiting cell apoptosis. In addition, we discovered for the first time that ADSC-Exos significantly reversed high-pressure-induced RGC damage. It was reported that after ADSCs and ADSC-the trabecular meshwork (ADSC-TM) were transplanted into the eyes of infantile mice, the cells integrated into TM tissue expressed TM cell markers, and maintained

normal IOP, outflow facility, and extracellular matrix[49]. The results demonstrated the possibility of applying autologous or allogeneic ADSC and ADSC-TM cells as a potential therapeutic approach to restore the structure and function of the TM in glaucoma. Therefore, combined with literature reports and our study, ADSC-Exos are expected to be an adjunct therapeutic agent for glaucoma in the future.

Surprisingly, ADSC-Exos manifested better protective effects than BMSC-Exos in the present study. There is evidence that ADSCs are most conducive to clinical utilization. In addition, adipose tissue is relatively abundant in the human body compared with other tissues. ADSCs can be isolated from adipose tissue. In addition, Kern *et al*[50], through comparative analysis of MSCs from bone marrow, umbilical cord blood, or adipose tissue, concluded that 500 times more stem cells were obtained from adipose tissue than from the same amount of bone marrow. Moreover, ADSCs are easier to obtain from adipose tissue due to their subcutaneous location than BMSCs. Patients tend to choose less traumatic sites for collecting tissue. Significant discrepancies are observed in cellular exos from different sources, including the type and content of mRNAs, miRNAs, and proteins[51]. Importantly, ADSCs have a higher proliferation capacity than BMSCs[52]. Moreover, ADSC-Exos possess the advantages of ADSCs. Hence, ADSC-Exos seem to be more favorable than BMSC-Exos because they are easily obtained and have a high proliferation capacity. ADSC-Exos could also be considered for the treatment of glaucoma. The graphic abstract is shown in Figure 7.

Some limitations should be stated. First, we lacked the comparison of neurotrophic factors and miRNAs between ADSC-Exos and BMSC-Exos by bioinformatics and other basic biological methods. Second, the effects of ADSC-Exos and BMSC-Exos on RGCs should be further validated by an *in vivo* experiment. Last but not least, more *in vivo* and *in vitro* experiments are needed to provide theoretical evidence for that MSC-Exos protect RGCs.

CONCLUSION

These findings indicated that ADSC-Exos and BMSC-Exos could ameliorate RGC injury caused by hydrostatic pressure by inhibiting apoptosis and increasing the secretion of neurotrophic factors.

ARTICLE HIGHLIGHTS

Research background

Mesenchymal stem cells (MSCs) have a protective effect against damage to the cornea, lacrimal gland, retina and photoreceptor cells, and this protective effect can be mediated through exosomes (exos) released by MSCs.

Research motivation

Experimental pressure conditions were selected to be relevant to intraocular pressures seen in clinical settings, with levels of 100 mmHg analogous to acute glaucoma, 30 mmHg for chronic glaucoma and 15 mmHg for the so-called 'normal' intraocular pressure. Bone marrow-derived stem cell (BMSC)-Exos have an ameliorative effect on glaucoma. However, the effect of adipose-derived stem cell (ADSC)-Exos which is the ideal source of exos on optic neural degeneration has not been studied yet.

Research objectives

This study investigated the ameliorating effect of exos derived from different MSCs on retinal ganglion cell (RGC) injury induced by hydrostatic pressure.

Research methods

The RGC injury model was constructed by RGC damage under different hydrostatic pressures (40, 80, 120 mmHg). Then RGCs were cultured with ADSC-Exos and BMSC-Exos. Cell Counting Kit-8, transmission electron microscopy, flow cytometry, immunofluorescence, real-time quantitative polymerase chain reaction, and western blotting were performed to detect the ameliorating effect of exos on pressure-induced RGC injury.

Research results

ADSC-Exos and BMSC-Exos were successfully separated. RGCs were in the shape of irregular ellipsoids, and the addition of ADSC-Exos and BMSC-Exos significantly restored the morphology of RGCs. In addition, the proliferative activity of

RGCs was increased and cell apoptosis was inhibited. Increased levels of lactate dehydrogenase and apoptosis-related proteins, and increased concentrations of anti-apoptotic proteins and neurotrophic substances.

Research conclusions

The results indicate that ADSC-Exos and BMSC-Exos can improve hydrostatic pressure-induced RGC damage by inhibiting apoptosis and increasing neurotrophic factor secretion.

Research perspectives

The results of this study will be verified by the experiment *in vivo* in the future.

Abstract

BACKGROUND

Mesenchymal stem cells (MSCs) are a type of stem cells that possess relevant regenerative abilities and can be used to treat many chronic diseases. Diabetes mellitus (DM) is a frequently diagnosed chronic disease characterized by hyperglycemia which initiates many multisystem complications in the long-run. DM patients can benefit from MSCs transplantation to curb down the pathological consequences associated with hyperglycemia persistence and restore the function of damaged tissues. MSCs therapeutic outcomes are found to last for short period of time and ultimately these regenerative cells are eradicated and died in DM disease model.

AIM

To investigate the impact of high glucose or hyperglycemia on the cellular and molecular characteristics of MSCs.

METHODS

Human adipose tissue-derived MSCs (hAD-MSCs) were seeded in low (5.6 mmol/L of glucose) and high glucose (25 mmol/L of glucose) for 7 d. Cytotoxicity, viability, mitochondrial dynamics, and apoptosis were deplored using specific kits. Western blotting was performed to measure the protein

expression of phosphatidylinositol 3-kinase (PI3K), TSC1, and mammalian target of rapamycin (mTOR) in these cells.

RESULTS

hAD-MSCs cultured in high glucose for 7 d demonstrated marked decrease in their viability, as shown by a significant increase in lactate dehydrogenase ($P < 0.01$) and a significant decrease in Trypan blue ($P < 0.05$) in these cells compared to low glucose control. Mitochondrial membrane potential, indicated by tetramethylrhodamine ethyl ester (TMRE) fluorescence intensity, and nicotinamide adenine dinucleotide (NAD+)/NADH ratio were significantly dropped ($P < 0.05$ for TMRE and $P < 0.01$ for NAD+/NADH) in high glucose exposed hAD-MSCs, indicating disturbed mitochondrial function. PI3K protein expression significantly decreased in high glucose culture MSCs ($P < 0.05$ compared to low glucose) and it was coupled with significant upregulation in TSC1 ($P < 0.05$) and downregulation in mTOR protein expression ($P < 0.05$). Mitochondrial complexes I, IV, and V were downregulated profoundly in high glucose ($P < 0.05$ compared to low glucose). Apoptosis was induced as a result of mitochondrial impairment and explained the poor survival of MSCs in high glucose.

CONCLUSION

High glucose impaired the mitochondrial dynamics and regulatory proteins in hAD-MSCs ensuing their poor survival and high apoptosis rate in hyperglycemic microenvironment.

Key Words: Mesenchymal stem cells; High glucose; Mitochondrial dynamics; Apoptosis; Poor survival; Phosphatidylinositol 3-kinase/mammalian target of rapamycin pathway

Core Tip: Mesenchymal stem cells (MSCs) have significant regenerative properties that make them a potential treatment for many chronic diseases. Among these, diabetes mellitus (DM) was found to benefit from MSCs transplantation in which they restored the damaged tissues and prevented hyperglycemia-related complications. However, these therapeutic are short-lived hindering the clinical use of MSCs in the treatment of DM. This study aims to elucidate the mechanisms of hyperglycemia-induced effects on MSCs which will help in improving the therapeutic functions of these cells in this stress environment.

INTRODUCTION

Mesenchymal stem cells (MSCs) are the most commonly studied forms of stem cells as they possess powerful regenerative and immunomodulatory abilities[1]. MSCs have unique molecular machinery that empowers them to modulate many cellular signaling pathways and restore the functionality of damaged tissues rendering them suitable to treat many acute and chronic diseases[1]. Despite their unprecedented abilities to adapt to many stress conditions, they can still behave unexpectedly under certain stress microenvironments. Many preclinical and clinical studies not only demonstrated the positive outcomes after transplanting MSCs to injured sites[2,3], but also reported the short-lived therapeutic results in hostile microenvironments which need to be figured out[4]. When MSCs are undifferentiated, they rely mainly on glycolysis to support their proliferation, expansion, and immunomodulation[5]. When MSCs are programmed to differentiate, they switch to oxidative phosphorylation (OxPhos)[6], thereby, intact mitochondria are also important to maintain their multi-lineage differentiation capacities[6].

In the last decades, diabetes mellitus (DM) incidence has increased rapidly, and it is deemed among top five chronic diseases[7]. DM is associated with serious multisystem complications that impair the life quality of many patients[8]. DM is characterized mainly by chronic hyperglycemic state that causes many devastating, long-term complications[8]. DM patients can benefit remarkably from MSCs therapy to repair and regenerate damaged tissues, restore their functionality, and reduce the severity of DM-related pathological complications[7]. Several studies reported a significant improvement in glycemic parameters and cardiovascular complications after transplanting MSCs in DM patients[7,9,10]; however, other studies reported that DM can accelerate the decline in MSCs quantity and therapeutic quality, and impair their regenerative capabilities[11]. When MSCs turn into a dysfunctioning cells, they may increase the severity of DM-related complications[11]. Although previous studies had addressed the effects of hyperglycemia on the molecular and cellular characteristics of transplanted MSCs, many aspects still need to be elucidated. Thus, it is important to investigate the effect of high glucose on MSCs biological dynamics, which are essential to understand their fate and performance in

diabetic microenvironment, and provide new avenues on possible molecular targets to modulate their survival and therapeutic outcomes in DM patients.

MATERIALS AND METHODS

Human MSCs

Human adipose tissue-derived MSCs (hAD-MSCs) were commercially purchased from Lonza (Cat# PT5006, Lot# 21TL138912) and expanded using Dulbecco's Modified Eagle's Medium Low Glucose (DMEM-Low Glucose, Euroclone) which contained 5.6 mmol/L glucose and were supplemented with 10% fetal bovine serum (FBS, Gibco)[12], 0.1 mg/mL streptomycin and 100 units/mL penicillin G in standard cell culture incubators (5% CO_2/95% air; 37 °C). Medium was changed every 72 h, and cells were sub-cultured when confluence exceeded 60%[13]. For high glucose conditions, cells were cultured in Dulbecco's Modified Eagle's Medium High Glucose (DMEM-High Glucose, Euroclone) which contained 25 mmol/L glucose[14] and were supplemented with 10% FBS, 0.1 mg/mL streptomycin and 100 units/mL penicillin G for 3, 7, and 14 d in standard cell culture incubators (5% CO_2/95% air; 37 °C). High glucose complete medium was changed every 72 h. MSCs that were cultured in low glucose were considered as our study control. MSCs of passage 5 and 6 were used to perform the experiments. AD-MSCs characterization markers can be found in (Table 1).

Cytotoxicity assays

To measure the level of cytotoxicity in human MSCs after being cultured in low and high glucose, we seeded 5 × 10^4 cells/well in 96 well plate and we measured the lactate dehydrogenase (LDH) which was released from the damaged MSCs (LDH Assay Kit, Abcam, Cat# ab102526) and the absorbance values were obtained using Cytation 5 (BioTek, United States). The viability of MSCs in low and high glucose were also assessed using 0.4% Trypan blue and the percentage of viable cells as well as representative fluorescent images were obtained using Corning® CytoSmart Cell Counter.

Tetramethylrhodamine ethyl ester (MtMP measurement)

Mitochondrial membrane potential was assessed using tetramethylrhodamine ethyl ester (TMRE)-Mitochondrial Membrane Potential Assay Kit (Abcam, Cat # ab113852). Briefly, human AD-MSCs were placed in 24-well plate at 1 × 10^4 cells per well and allowed to adhere overnight. After that, cells were cultured either in low glucose or high glucose for 7 d. Then, media were aspirated, and cells were stained using 400 nM TMRE in culture media for 30 min in the incubator, and then media were replaced with 200 µL phosphate buffered saline (PBS) per well. Fluorescence intensity was detected using Cytation 5 (BioTek, United States). (λex = 549 nm, λem = 575 nm), and TMRE fluorescent images were captured at Texas red filter using Cytation 5 (BioTek, United States).

Nicotinamide adenine dinucleotide /NADH assay

Nicotinamide adenine dinucleotide (NAD+)/NADH ratio in AD-MSCs that were cultured in low and high glucose media was assessed using NAD/NADH-Glo™ assay kit (Promega, Cat# G9071). Briefly, cells were cultured in low and high glucose media for 7 d. After that, cells were detached and placed in 96 well plate at 5 × 10^5 in 50 µL of either low or high glucose media and were allowed to adhere overnight. 50 µL of NAD/NADH-Glo™ Detection Reagent was added to each well and the plate was gently shaken to mix and lyse the cells and was incubated with the added reagent for 60 min at room temperature. The luminescence values were recorded using Cytation 5 (BioTek, United States) which were corresponding to the total amount of NAD+ produced from NADH.

Western blotting

The protein levels for phosphatidylinositol 3-kinase (PI3K) (Santa Cruz Biotechnology Cat # sc-1637), TSC1 (Santa Cruz Biotechnology Cat # sc-377386), and mammalian target of rapamycin (mTOR) (Santa Cruz Biotechnology Cat # sc-293133), NDUFB8 (Abcam, Cat # ab192878), SDHB (Santa Cruz Biotechnology Cat # sc-271548), UQCRC2 (Santa Cruz Biotechnology Cat # sc-390378), COX5a (Santa Cruz Biotechnology Cat # sc-376907), ATP5A (Santa Cruz Biotechnology Cat # sc-136178), and β-actin (Santa Cruz Biotechnology Cat # sc-47778 HRP) were measured by western blot. Briefly, total protein levels were measured using NanoDrop™ Lite Spectrophotometer, and 40 µg of protein was loaded onto sodium-dodecyl sulfate gel electrophoresis. Following electrophoresis, proteins were transferred to polyvinylidene fluoride membrane and were incubated with appropriate primary and secondary antibodies. The membranes were visualized using VILBER FUSION Gel Documentation System, and bands were quantified using ImageJ for densitometry.

Apoptosis assay

To detect apoptosis in hAD-MSCs after being cultured in low and high glucose, we used RealTime-Glo™ Annexin V Apoptosis live assay (Promega, Cat# JA1011, Lot# 0000400486 following the manufacturer's guidelines. Briefly, cells were seeded 1 × 10^4 cells/well in 24 well plate and then cultured in low and high glucose for 7 d. The media were aspirated and each well was washed with PBS followed by the addition of 100 µL of fresh medium having Annexin V-LgBiT, Annexin V-SmBiT, CaCl2, and Annexin V NanoBiT Substrate to each well. After 1 h incubation, the fluorescent images of green color which represented cells undergoing apoptosis were detected at GFP filter using Cytation 5 (BioTek, United States).

Table 1 Cell surface characterization of human adipose tissue-derived mesenchymal stem cells based on the company analysis report

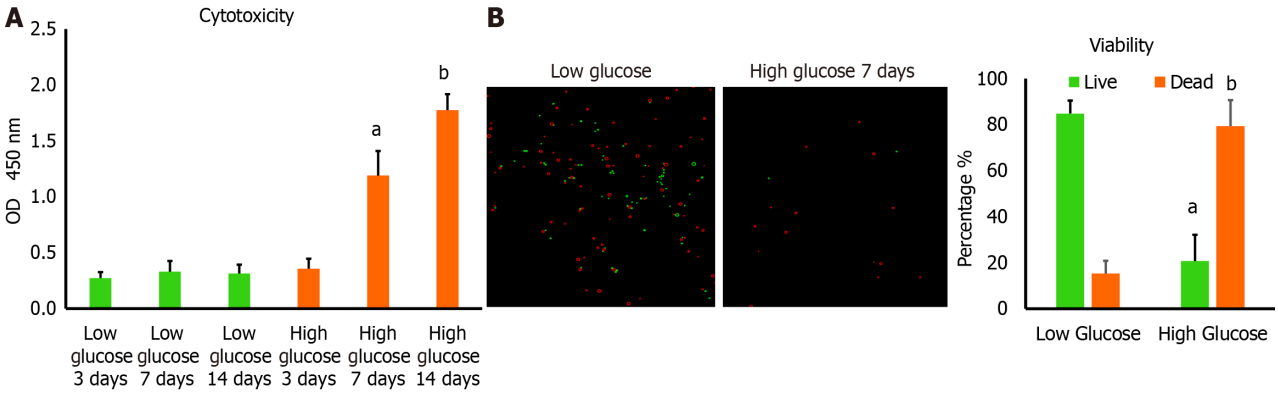
Statistical analysis

Data were reported as mean ± SD. Comparison of data between multiple groups was performed using one-way analysis of variance (ANOVA) followed by Tukey's post-hoc multiple comparison test, and analysis between two groups was made using Student's *t*-test (two-tailed). Statistical significance is determined as $P < 0.05$. Each figure represents one of at least three independent quantifiable experiments.

RESULTS

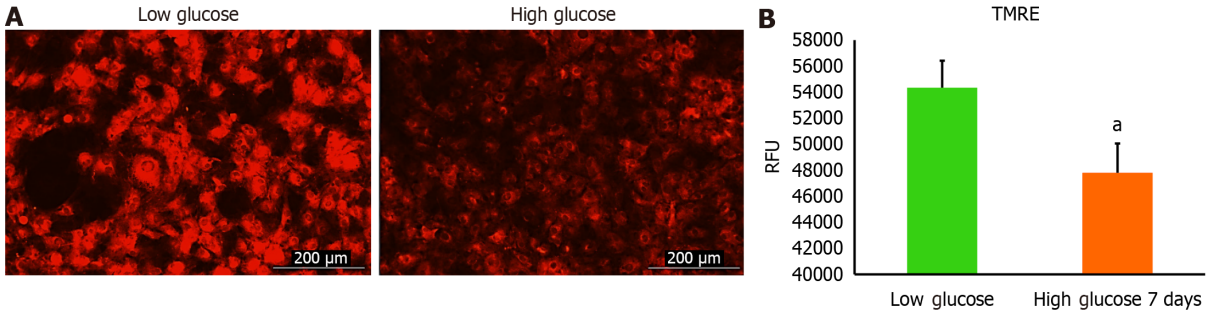
Culturing MSCs in high glucose triggers massive cytotoxicity and poor survival



MSCs are known to survive well in low glucose medium which is a physiological requirement to preserve their stemness features. We want to determine the viability of these cells in high glucose microenvironment. hAD-MSCs were cultured in high glucose medium containing 25 mmol/L of glucose for 3, 7, and 14 d. The cytotoxicity was measured by determining the amount of LDH released and was found to be significantly greater ($P < 0.01$) in hAD-MSCs cultured in high glucose for 7 and 14 d compared with hAD-MSCs cultured in normal low glucose medium containing 5.6 mmol/L of glucose (Figure 1A). To confirm these findings, the viability of hAD-MSCs was measured using 0.4% Trypan blue and found to be remarkably low ($P < 0.05$) in hAD-MSCs that were cultured in high glucose for 7 d compared to hAD-MSCs cultured in a low glucose medium (Figure 1B).

The mitochondrial dynamics of MSCs impaired by high glucose

Mitochondria are integral intracellular organelles promoting cells survival and viability. The variance of mitochondrial dynamics depends on the type of microenvironment where cells exist. Previous reports demonstrated that high glucose can induce the fission and fragmentation of mitochondria in glomeruli podocytes[15], but the knowledge surrounding the impact of high glucose on the mitochondrial dynamics of MSCs is still limited. The mitochondrial membrane potential (ΔΨm) generated by proton pumps (complexes I, III and IV) is imperative to ensure proper ATP production by mitochondrial OxPhos. Abnormalities in the mitochondrial membrane potential (ΔΨm) can significantly elicit a decline in cells viability and trigger unwanted signaling pathways. We measured the mitochondrial membrane potential (ΔΨm) in hAD-MSCs after being grown in a high glucose medium for 7 d using TMRE which is sequestered by active mitochondria. Our results illustrated that the fluorescent intensity of TMRE was significantly low ($P < 0.05$) in hAD-MSCs cultured in a high glucose medium compared to hAD-MSCs cultured in a normal low glucose medium indicating an impairment in the mitochondrial membrane potential in these cells (Figures 2A and B). NAD+ and its reduced form (NADH) regulate many metabolic pathways, including mitochondrial OxPhos. Maintaining NAD+/NADH pool is required to ensure that the influx of electrons is coupled with the translocation of protons to the intermembrane space to generate the required membrane potential (ΔΨm) across the inner mitochondrial membrane to be harnessed by complex V to produce ATP[16]. To investigate if the decrease in the mitochondrial membrane potential (ΔΨm) is correlated with abnormalities in NAD+/NADH pool, we measure the NAD+/NADH ratio in hAD-MSCs cultured in low and high glucose media (Figure 3). The findings revealed a considerable drop ($P < 0.01$) in NAD+/NADH ratio when hAD-MSCs were cultured in high glucose. This may explain the disturbance in the inner mitochondrial potential detected by TMRE assay (Figures 2A and B).



Disturbance of MSCs mitochondria dynamics parameters in high glucose engenders their apoptosis

Apoptosis is a programmed cell death that can be physiological or pathological depending on the triggering factors that enkindle it. Mitochondrial dysfunction is a notable inciting factor which is able to fire up debilitating cellular apoptosis and impact the survival of numerous cells. The noticeable deterioration in the mitochondrial parameters detected in hAD-MSCs after being cultured in high glucose prompted us to examine the level of apoptosis in these cells. To achieve that, we used RealTime-Glo™ Annexin V Apoptosis kit to unveil the presence of apoptosis or not. The luminescence signal which is proportionally linked to apoptosis intensity was considerably higher in hAD-MSCs that were cultured in high glucose (Figure 4). Fluorescent microscopic images showed that apoptosis (marked by green stained cells) was more in

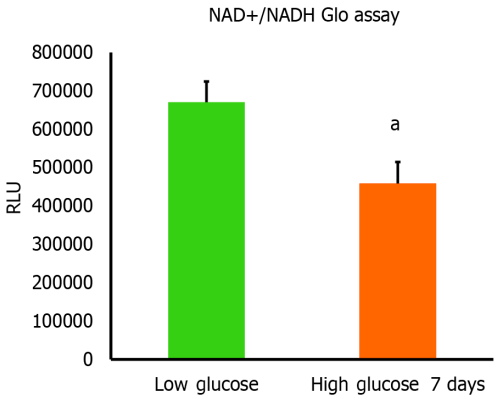
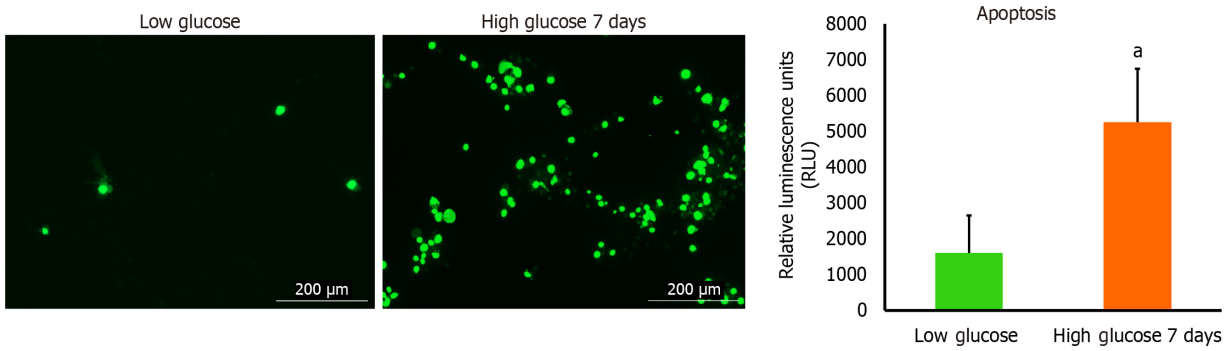
Figure 2 High glucose decreased the mitochondrial membrane potential level of human adipose tissue-derived mesenchymal stem cells. The tetramethylrhodamine ethyl ester (TMRE) fluorescence intensity values of human adipose tissue-derived mesenchymal stem cells (hAD-MSCs) cultured in high glucose for 7 d were substantially declined compared to fluorescent intensity values of cells cultured in low glucose. Live fluorescent images showed a weak signal of TMRE stain in hAD-MSCs after being placed in high glucose for 7 d compared to strong TMRE signal in low glucose cultured cells. n = 4, ^{a}P < 0.05 compared to low glucose control. Fluroscnet images were captured at Texas Red filter using Cytation 5 (BioTek, United States). TMRE: Tetramethylrhodamine ethyl ester; RFU: Relative fluorescence units.



high glucose cultured hAD-MSCs (Figure 4).

High glucose affects the level of PI3K and mTOR in MSCs

PI3K orchestrates many vital signaling pathways and targets downstream factors that are required to maintain the vivacity of cells. PI3K controls integral proteins that are necessary to preserve mitochondrial dynamics[17,18]. PI3K is a known activator of mTOR which is a central regulator of cell survival and metabolism. It has been reported that mTOR is important to preserve mitochondrial dynamics and generate the required mitochondrial potential to produce ATP. PI3K is required to remove the inhibitory effect of tuberous sclerosis tumor suppressor (TSC1) which binds mTOR and inactivates it[19]. We performed western blotting analysis to measure the expression levels of PI3K, TSC1, and mTOR in high glucose treated hAD-MSCs. Western blotting results demonstrated the loss of PI3K and mTOR in high glucose treated hAD-MSCs (P < 0.05 compared to low glucose), while TSC1 is significantly increased in these cells (P < 0.05 compared to low glucose) (Figure 5). Those findings indicated impaired PI3K/mTOR axis which may explain the disruption in mitochondrial parameters in high glucose cultured MSCs. Taking together, our findings highlight a new mechanism that can be released by high glucose causing the poor survival of MSCs in diabetic microenvironment.



High glucose disturbs major mitochondrial complexes in MSCs

The reduction in mTOR which is essential for inducing the biogenesis of mitochondrial complexes, most importantly complex I and V[20] prompted us to investigate the expression of mitochondrial complexes in low and high glucose-cultured hAD-MSCs. The results demonstrated that hAD-MSCs that were cultured in high glucose exhibited significant downregulation (P < 0.05) in the level of complex I, IV, and V comparing to hAD-MSCs that were cultured in low glucose (Figure 6), while the expression of complex II and III showed no significant changes (P = 0.85) in both culturing

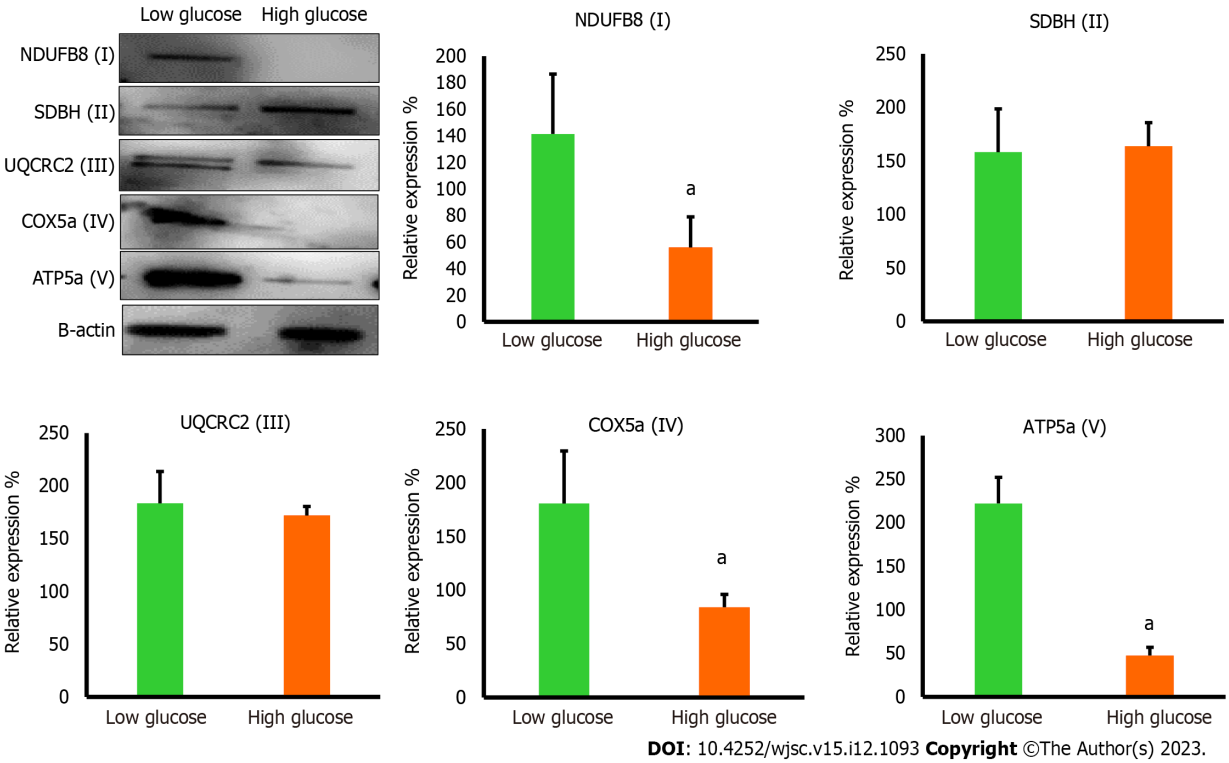
Figure 4 The level of apoptosis was higher in human adipose tissue-derived mesenchymal stem cells cultured in high glucose. RealTime-Glo™ Annexin V Apoptosis live assay was used. The level of apoptosis was remarkably increased in human adipose tissue-derived mesenchymal stem cells cultured in high glucose for 7 d. Green fluorescence intensity is corresponding to the number of cells undergoing apoptosis. Fluorescent images were captured at GFP filter using Cytation 5 (BioTek, United States). n = 3, ^{a}P < 0.05 compared to low glucose control.

conditions (Figure 6). The disturbance in the level of these major complexes can impact the mitochondrial OxPhos and trigger the mitophagy of mitochondria[21].



DISCUSSION

MSCs are the most promising type of stem cells for regenerating damaged tissues and restoring their normal functions which can improve the quality of life of many patients who suffer from debilitating disorders[1]. However, the remarkable improvements in pathological markers reported after transplanting MSCs[22,23] were hindered by the short-lived outcomes and poor survival rate, which need extensive investigation[24,25]. Many pathologies are characterized by stress microenvironments, including hypoxia, inflammation, and nutritional imbalances, which can impact the expected outcomes of transplanting MSCs[26-29], by either inhibiting or activating cellular signaling pathways. DM is a frequent chronic disease that leads to significant multi-system complications[8]. The major hallmark of DM is glucotoxicity, which is featured by the presence of high glucose levels and impaired insulin secretion and function[8]. This glucotoxicity produces massive molecular changes in the residing cells and cause the appearance of DM-related complications, such as cardiovascular and neurological complications[8]. Both animal and clinical studies have demonstrated the great therapeutic efficacy of MSCs transplantation in alleviating chronic hyperglycemia by reversing insulin resistance, improving insulin sensitivity, controlling inflammation, relieving metabolic syndrome symptoms, and ameliorating β-cell destructive abilities[10,30]. Nevertheless, studies also revealed that MSCs exhibited short-lived outcomes due to their poor survival after being transplanted in DM disease model[4]. Several studies have asserted the importance of investigating the mechanisms leading to the poor survival of MSCs in hyperglycemia which is the major insult to DM patients [24,31]. Up to date little is known about the molecular and biological changes in MSCs under hyperglycemia. MSCs are

Figure 7 Graphical summary of the study findings. High glucose impaired the mitochondrial function in mesenchymal stem cells (MSCs) by perturbing many mitochondrial regulatory dynamics and factors, particularly mitochondrial membrane potential, nicotinamide adenine dinucleotide (NAD+)/NADH pool, and mammalian target of rapamycin protein. This mitochondrial dysfunction is associated with triggering apoptosis in MSCs, which mechanistically explained the poor survival of MSCs in hyperglycemia. MSCs: Mesenchymal stem cells; PI3K: Phosphatidylinositol 3-kinase; mTOR: Mammalian target of rapamycin; NAD+: Nicotinamide adenine dinucleotide.

capable of switching their metabolism on to support their regenerative and immunomodulation abilities[32]. MSCs rely primarily on glycolysis when they are undifferentiated as it is important to preserve their stemness and proliferation[33]. Several reports illustrated that glycolysis is required to preserve the immunosuppressive characteristics of MSCs[34]. Upregulation in glycolysis has been found to increase the immunomodulatory abilities of MSCs and promote their capabilities to reprogram immune cells[35]. MSCs use mitochondrial OxPhos when they are induced to differentiate, thus the multi-lineage differentiation capacities of MSCs require intact mitochondria[6]. Maintaining intact mitochondrial dynamics is not only required to support the differentiation capacities of MSCs, but it is also crucial for redox regulation and prevention of excessive production of reactive oxygen species[36]. Recently, it has been proposed by many studies that MSCs are capable of transferring mitochondrial DNA to recipient cells and restoring the normal mitochondrial functions in these cells[37,38]. MSCs-mediated mitochondrial transfer further supports the necessity to conserve normal mitochondrial parameters[38]. Previous reports revealed that the MSCs proliferation decreased in high glucose medium [13,14]. Furthermore, other studies showed that MSCs differentiation capacities might vary when they are cultured in high glucose conditions[39,40]. Our study illustrated that high glucose can reduce the survival rate of MSCs. The reduction in MSCs viability reported in our study is correlated with an impairment in the inner mitochondrial membrane potential (ΔΨm) which is an important parameter and the energy generated from this potential gradient will be utilized by complex V to produce ATP molecules. The maintenance of mitochondrial membrane potential depends on the presence of a plentiful amount of NAD+ molecules[41]. NAD+ serves as an oxidoreductase cofactor that controls many vital energy production pathways. Maintaining normal NAD+/NADH ratio is integral to providing the required electron flux that will be used to generate proper mitochondrial membrane potential (ΔΨm)[41]. High glucose insult causing a substantial drop in NAD+/NADH ratio in hAD-MSCs indicates a needed disturbance in the oxidization power to produce NAD+ and donating electrons that will keep the functionality of mitochondrial complexes. Another important complex that is required to preserve the mitochondrial dynamics is mTOR complex[42]. mTOR is a known regulator of many cellular processes, including the biogenesis of mitochondrial complexes, most importantly complex I and V and physiological mitophagy[42]. The downregulation in the level of mTOR in MSCs cultured in high glucose was associated with significant disturbances in mitochondrial complexes I, IV, and V which can induce mitochondrial dysfunction, mitophagy and massive oxidative stress. The effect of high glucose on modulating mitochondrial functions by targeting mTOR is barely investigated and with controversial results[43]. While other studies found that hyperglycemia activate mTOR pathway in cardiomyocytes[44,45], other evidence showed that insulin can activate mTOR pathway in DM patients and protect cells from developing mitochondrial dysfunction[46], indicating that high glucose can deactivate mTOR and cause pathological consequences[46]. These discrepancies regarding the effect of high glucose on mTOR level and activity seem to differ depending on the type of cells and the upstream molecular regulators. Based on that, the role of high glucose in modulating the level of mTOR needs further investigation in different cell types. In our study, the upstream regulatory protein PI3K decreased remarkably in hAD-MSCs exposed to high glucose. A plentiful number of reports corroborated that PI3K-AKT pathway is required to activate mTOR by removing the inhibitory effect produced by TSC1 or Hamartin protein. We reported in this study that the reduction in PI3K protein level was coupled with marked elevation in TSC1 and downregulation in mTOR in hAD-MSCs cultured in high glucose. Our findings provide a mechanistic explanation of poor survival of MSCs in hyperglycemic microenvironment and suggests new targets that can be modified to enhance the survival rate of MSCs in DM patients. Moreover, our results highlighted the importance of maintaining the desirable pre-transplantation culturing conditions that preserves the salutary properties of MSCs by controlling the level of glucose in the culture media. Schematic summary of the study findings was illustrated in (Figure 7) which highlighted that high glucose microenvironment reduced the level of PI3K and removed its inhibitory effect on TSC1 and caused its upregulation. The increase in the level of TSC1 caused a reduction in mTOR which

disturbed many mitochondrial dynamics, mainly MtMB, NAD+/NADH ratio, and mitochondrial complexes that triggered the apoptosis of hAD-MSCs.

CONCLUSION

MSCs have the potential to regenerate damaged tissues and restore their functions. DM patients can hugely benefit from MSCs transplantation to abrogate the pathological consequences and improve their quality of life. The poor survival and short-lived positive outcomes following MSCs transplantation in DM patients are considered stumbling blocks. High glucose impaired mitochondrial function in MSCs by perturbing mitochondrial regulatory factors, particularly mitochondrial membrane potential, NAD+/NADH pool, and mTOR protein. This mitochondrial dysfunction is associated with triggering apoptosis in MSCs. Preserving these factors may help in improving the survival rate of MSCs in diabetic microenvironment and initiate long-lasting therapeutic outcomes. Future studies should focus on providing new strategies to overcome the poor survival of MSCs in high glucose using genetic modification or biomaterials and nanoparticles. Moreover, the impact of other stressors existed in DM patients other than hyperglycemia should be studied.

ARTICLE HIGHLIGHTS

Research background

Mesenchymal stem cells (MSCs) have the ability to cure many chronic diseases, including diabetes mellitus (DM) and its related multisystem complications.

Research motivation

The therapeutic outcomes of MSCs transplantation in DM are short-lived which require thorough investigation.

Research objectives

This study aimed to determine the effects of hyperglycemia microenvironment on various mitochondrial-related parameters in MSCs to better understand their fate in DM patients.

Research methods

Adipose tissue-derived MSCs were exposed to low and high glucose media and mitochondrial dynamics and regulators were measured and analyzed.

Research results

High glucose induces the apoptosis of adipose tissue-derived MSCs by disturbing many mitochondrial parameters, including mitochondrial membrane potential, nicotinamide adenine dinucleotide (NAD+)/NADH pool, mammalian target of rapamycin, and mitochondrial complexes I, IV, and V.

Research conclusions

Hyperglycemia decreases the survival of MSCs by triggering mitochondrial dysfunction in these cells causing their short-lived therapeutic outcomes.

Research perspectives

New strategies to improve the survival rate of MSCs in hyperglycemia should be the focus of future studies which can help in increasing the chances of using these cells clinically for the treatment of DM.

ACKNOWLEDGEMENTS
