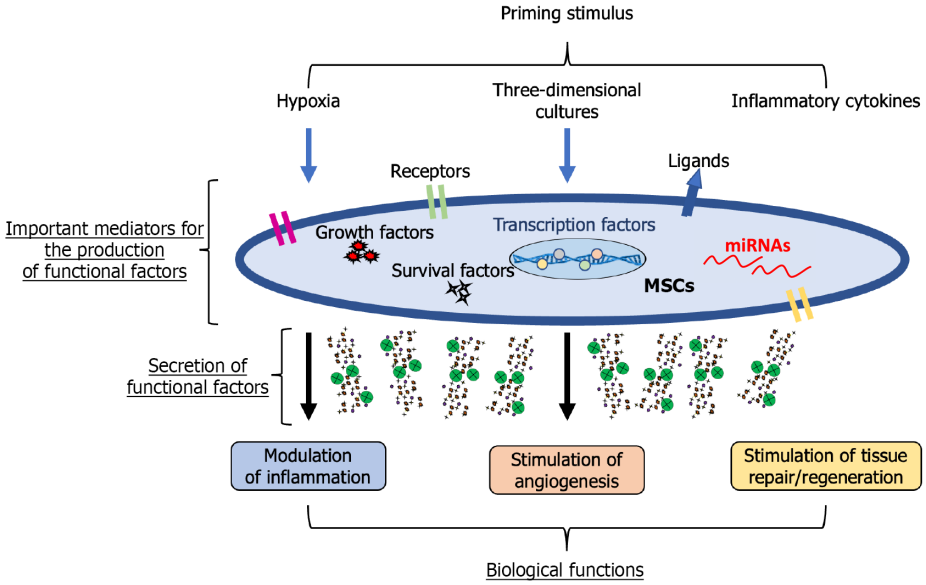
MSCs can also secrete a number of cytokines/chemokines that control both the innate and adaptive immune responses, resulting in immunoregulation and the induction of tolerance[68]. Indeed, it has been shown that MSCs can produce both anti- and pro-inflammatory factors which, depending on their ratio, regulate the pro- or anti-inflammatory activity of MSCs[69]. In this case, final immunoregulatory properties may be affected by cell culture conditions that can prime/enhance MSC properties[3,70,71]. MSCs also have the ability to roll and adhere to post-capillary venules, and migrate to injured tissues, contributing to tissue repair/regeneration[72]. In this case, once MSCs reach the site of the injury, these cells put in place an active regulation by producing paracrine factors that impact tissue survival/repair, and activate tissue resident stem cells[3,73,74]. The secretion of various soluble factors has also been found to be responsible for the pro-angiogenic and anti-apoptotic effects of MSCs[75]. Though not well understood, the beneficial effects of conditioned media (CM) derived from MSCs have been clearly demonstrated by various experimental findings, supporting the concept of paracrine effects[76]. Several preclinical studies have tested the efficacy of CM in different diseases models. MSC-derived CM has been shown capable of improving cell viability and reducing inflammation in both *in vitro* and *in vivo* models of lung ischemia/reperfusion injury (IRI)[59,77]. Moreover, it has been demonstrated that BM-MSC-derived CM was able to reduce lung inflammation and edema in a mouse model of lipopolysaccharide-induced lung injury[78], and to improve renal tissue pathology in a mouse model of cisplatin-induced kidney injury[79]. Youdim *et al*[80], in a rat model of fulminant hepatic failure, found that the CM derived from BM-MSCs reduced leukocytic infiltrates and hepatocellular death. The CM derived from the same cells, in a mouse model of antigen-induced arthritis, was also able to reduce joint swelling, cartilage loss, and tumor necrosis factor (TNF)-α secretion[81]. In a rat model of lung fibrosis

and hypertension, using CM derived from adipose MSCs (AdMSCs), demonstrated the ability of secretome to reduce collagen deposition and improve lung blood flow[82]. In a rabbit model of surgical bone lesion, Linero and Chaparro[83] found that the CM produced from AdMSC cultures induced bone regeneration.

THE SECRETION OF MSC PARACRINE FACTORS CAN BE MODULATED BY VARIOUS PRIMING STRATEGIES

Given the heterogeneity of results supporting the efficacy of MSCs in the treatment of different human disorders, there is a need to improve the therapeutic properties of MSCs, and the best way might be that of preconditioning/priming. Though this approach has been widely used in the field of immunology, has also been effectively applied to MSCs[3,84,85]. Among commonly used priming strategies, leading approaches can be attributed to three main categories: (1) MSC priming with inflammatory molecules; (2) MSC priming with hypoxia; and (3) MSC priming with 3D cultures. These priming signals activate potential MSC mediators, including surface receptors and ligands, signalling molecules that induce survival/growth, regulatory molecules such as miRNAs, and transcription factors, which can modify the MSC phenotype[86-89], with a consequent boosting of MSC therapeutic functions (Figure 1).

Priming with inflammatory molecules



Numerous studies have revealed that the immunosuppressive properties of MSCs are not intrinsically possessed, but require priming of MSCs by inflammatory factors[90-92]. Depending on the inflammatory conditions, it has been demonstrated that MSC phenotypes can be polarized into MSC type 1 (with pro-inflammatory properties) and MSC type 2 (with immunosuppressive properties)[93,94]. Several strategies have been implemented to modulate/enhance the secretion of functional molecules in MSCs. As shown in Figure 2, the treatment of MSCs with inflammatory cytokines, including interferon-gamma (IFN-γ), interleukin (IL)-1α/β, IL-25, IL-6, TNF-α, and IL-17 enhanced the immunomodulatory properties of MSCs[40,95-112]. These treatments increase the production/secretion of functional factors, including hepatocyte growth factor (HGF), transforming growth factor-β, IL-6, prostaglandin E2 (PGE2), leukemia inhibitory factor, granulocyte colony-stimulating factor, IL-10, macrophage inflammatory protein-1α, indoleamine 2,3-dioxygenase (IDO), intercellular adhesion molecule, programmed death ligand 1-2, monocyte chemoattractant protein (MCP)-1, monokine induced by IFN-γ, induced protein 10, and macrophage inflammatory protein-1β, which in turn confer more paracrine immunomodulatory properties to MSCs (Figure 2). It has been demonstrated that CM enriched with the above-described factors was able to inhibit T cell proliferation/activation, reduce the secretion of inflammatory mediators, and induce monocyte polarization towards anti-inflammatory the M2 phenotype[40,102,105-112]. It has been shown that the treatment with inflammatory cytokines was also able to improve the immunomodulatory capabilities of EXOs, and these effects appear to be mediated by specific miRNAs, such as miR-21, miR-23a, miR-26b, miR-125b, miR-130b, miR-140, miR-146a, miR-203a, miR-223, miR-224, and miR-320a[40,109,111,113].

Priming with hypoxia

Differently from inflammatory cytokines, hypoxic treatment of MSCs seems to stimulate primarily the secretion of functional factors involved in the processes of angiogenesis and tissue proliferation/regeneration (Figure 2). Hypoxic preconditioning was able to promote angiogenic potential of MSCs *via* the activation of the HIF-1α-GRP78-Akt axis, and the overproduction of vascular endothelial-derived growth factor (VEGF) and HGF[114]. Lee and Joe[115] demonstrated that hypoxia priming induces an increase in HIF-1α expression and consequent VEGF production, improving the ability of MSCs to stimulate migration and tube formation of human umbilical vein endothelial cells (HUVECs). Moreover, Bader *et al*[116] found that hypoxic preconditioning induces the anti-apoptotic and pro-angiogenic effects of MSCs compared with untreated cells. In particular, Bcl-xL, BAG1, and VEGF were overexpressed after hypoxic priming, enhancing HUVEC proliferation and migration. Hypoxic MSCs are also able to produce numerous factors related to tissue remodelling, including matrix metallopeptidase 1 (MMP1), MMP2, and MMP9[117-119], as well as crucial factors such as IL-8 and MCP-1, involved in the chemotaxis and activation of innate immune responses[120,121]. Also with regard to EVs, hypoxic priming has been shown to have important effects. Xue *et al*[122] discovered that EXOs derived from hypoxia-treated MSCs were able to increase migration and tube formation of HUVECs through the PKA signalling pathway. Moreover, Ge *et al*[123] demonstrated the efficacy of hypoxic MSC-derived EXOs in enhancing angiogenesis. In particular, they showed that hypoxic EXOs containing miR612 promoted, through HIF-1α activation, the production of VEGF in human brain microvascular endothelial cells, inducing proliferation, migration, and angiogenic activities of these cells.

Priming with 3D culture of MSCs

Various *in vitro* strategies have been applied for the production of MSCs, with improved therapeutic

Figure 1 Potential mechanisms mediating mesenchymal stromal/stem cell-primed therapeutic properties. Mesenchymal stromal/stem cells (MSCs) can be primed through different signals, including hypoxia, three-dimensional cultures, and inflammatory cytokines to obtain a therapeutic phenotype. The potential mediators of this new phenotype comprise a plethora of regulatory molecules within MSCs, including surface receptors and ligands, signalling molecules inducing survival/growth, regulatory molecules such as microRNAs, and transcription factors regulating several pathways. Thus, primed MSCs can modulate inflammation, stimulate angiogenesis, and promote tissue repair/regeneration. MSCs: Mesenchymal stromal/stem cells; miRNAs: MicroRNAs.

properties, and priming with inflammatory factors may impact the expression of HLA-DR, thus altering allogeneic therapeutic possibilities[124-126]. MSC priming through 3D culture techniques, which allows for the generation of MSC spheroids, strictly recapitulates the *in vivo* MSC niche and enhances the phenotypic profile of MSCs, increasing both trophic and immunomodulatory functionalities. MSC spheroid action is exerted by the paracrine secretion of functional factors that possess anti-inflammatory, angiogenic, anti-fibrotic, anti-apoptotic, and mitogenic properties (Figure 2)[127]. Recently, through omics approaches, such as RNA sequencing and analysis of DNA methylation, it has been demonstrated that, compared with conventional 2D culture, MSC spheroids were able to modify their transcriptome profile by overexpressing genes that can regulate proliferation/differentiation, as well as immunomodulatory and angiogenic processes[128]. Concerning immunomodulatory and regenerative effects, 3D culture of MSCs seems to have more intermediary functions than the above-mentioned priming strategies (priming with inflammatory molecules or hypoxia) (Figure 2). 3D MSC spheroids have been shown to be capable of secreting multiple functional factors. For example, it has been found that various regenerative and immunomodulatory factors, such as stromal cell-derived factor-1α, growth-related oncogene α, MCP-1/3; IL-4, IL-10; epidermal growth factor (EGF), leukemia inhibitory factor, placental growth factor-1, VEGF-A/D, HGF, insulin like growth factor 1, TNFAIP6, STC1, platelet-derived growth factor B, transforming growth factor-β, PGE2, and IDO were up-regulated in 3D MSC spheroids compared with those of the MSCs cultivated under conventional 2D conditions[43,44,59,73,128-131] (Figure 2). The paracrine effects of 3D MSC appear to be also mediated by EVs. In particular, EXOs derived from MSC 3D cultures have been shown to have higher yields and enhanced activity. Indeed, compared with 2D cultures, EXOs isolated from CM of MSC spheroids were able to inhibit T cell proliferation and stimulate angiogenesis *in vitro*[44], as well as attenuate inflammation and periodontitis *in vivo*[132], and stimulate tissue regeneration in both *in vitro* and *in vivo* models[133].

THERAPEUTIC PROPERTIES OF PRIMED MSCs IN PRECLINICAL MODELS

Principal priming strategies to treat chronic immune-related disorders

By virtue of their immunomodulatory properties, MSCs are being studied to treat numerous chronic conditions, including GVHD and inflammatory bowel disorders, in order to attenuate inflammation and induce tissue recovery (Table 1). As already mentioned, treating MSCs with inflammatory factors enhances their immunomodulatory properties, and renders these cells able to inhibit T cell proliferation/activation and induce monocytes toward an anti-inflammatory phenotype. This quality makes these cells more clinically effective when applied to chronic inflammatory-related diseases (Figure 2). Indeed, several experimental studies have demonstrated that the treatment of MSCs with inflammatory factors, such as IFN-γ, IL-1β, and IL-25, enhanced MSC therapeutic effects in *in vivo* models of chronic

Table 1 Representative priming strategies of mesenchymal stromal/stem cells and their application in preclinical studies

MSCs	Dose	Priming treatments	Study model	Observed therapeutic effects	Ref.
AMSCs	1×10^5 MSCs/5×10^5 PBMCs	IFN-γ	*In vitro* model of T cell activation and monocyte M1/M2 polarization	Regulation of T cell activation/anergy and induction of M2-like polarized phenotype in monocytes	[40]
BM-MSCs	0.5×10^6 MSCs/mouse	IFN-γ	*In vivo* model of chronic colitis	Attenuation of inflammation and colitis	[96]
BM-MSCs	NA	IFN-γ; TNF-α	*In vitro* model of MLR	Inhibition of allogeneic MLR	[97]
CB-MSC-derived EVs	NA	IFN-γ	*In vivo* model of acute kidney injury and *in vitro* model of T cell activation	Regulation of T cell activation and amelioration of kidney injury with unprimed MSCs only	[100]
BM-MSCs and CB-MSCs	1×10^6 MSCs/mouse	IFN-γ	*In vivo* model of GVHD	Reduction of the symptoms of GVHD	[101]
BM-MSCs	1×10^4 MSCs/2×10^3 macrophages	IFN-γ; LPS; TNF-α	*In vitro* model of monocyte M1/M2 polarization	Induction of monocyte polarization toward an anti-inflammatory M2 phenotype	[102]
UC-MSCs	1×10^6 MSCs/mouse	IFN-γ; TNF-α	*In vivo* model of GVHD	Reduction of the symptoms of GVHD	[103]
BM-MSCs	2.5×10^5 MSCs/5×10^5 macrophages	IFN-γ; IL-1β	*In vitro* model of monocyte M1/M2 polarization	Induction of monocyte polarization toward an anti-inflammatory M2 phenotype	[105]
BM-MSC-derived CM	NA	IFN-γ; IL-1α/β; TNF-α	*In vitro* model of LPS-injured microglial cells	Reduction in the secretion of inflammatory factors	[106]
AdMSCs; BM-MSCs; CB-MSCs.	NA	IFN-γ	*In vitro* model of T cell activation	Suppression of T cell proliferation	[110]
BM-MSCs	NA	IFN-γ; spheroids	*In vitro* model of T cell activation	Suppression of T cell activation and proliferation	[112]
BM-MSCs	2×10^6 MSCs/mouse	IFN-γ	Autoimmune encephalomyelitis	Attenuation of pathologic manifestations	[134]
BM-MSCs	1×10^6 MSCs/mL	IFN-γ	*In vitro* model of T cell activation and *in vivo* model of colonic wounds	Regulation of T cell activation and acceleration of healing of colonic mucosal wounds	[135]
UC-MSCs	2×10^6 MSCs/mouse	IL-1β	*In vivo* model of chronic colitis	Attenuation of inflammation and colitis	[98]
UC-MSCs	1×10^6 MSCs/mouse	IL-1β	*In vivo* model of sepsis	Increase in survival rate	[109]
MSC-derived EVs	40 μg/mouse	IL-1β	*In vitro* model of monocyte M1/M2 polarization and *in vivo* model of sepsis	Induction of monocyte M2 polarization and amelioration of sepsis	[111]
AdMSC-derived CM	20 μL/rat	TNF-α	*In vivo* model of wound healing	Acceleration of wound closure and angiogenesis	[99]
BM-MSCs	1.6×10^6 MSCs/mouse	TNF-α	*In vivo* model of peritonitis	Attenuation of inflammatory responses	[136]
BM-MSCs	5×10^6 MSCs/rat	IL-25	*In vivo* model of chronic colitis	Attenuation of inflammation and colitis	[95]
BM-MSCs	1×10^6 MSCs/mL	IL-6	*In vivo* model of liver fibrosis	Reduction of liver injury and fibrosis	[104]
BM-MSCs	3.91×10^4 MSCs/3.91×10^6 T cells	IL-17	*In vitro* model of T cell activation	Suppression of T cell proliferation/activation and Th1 cytokines	[108]
AdMSCs	5×10^5 MSCs/mouse	Hypoxia	*In vivo* model of hindlimb ischemia	Improvement of angiogenesis	[114]
BM-MSC-derived CM	100 μL/mouse	Hypoxia	*In vivo* model of wound healing	Acceleration of skin wound healing	[120]
BM-MSCs	2.5×10^5 MSCs/mouse	Hypoxia	*In vivo* model of pancreatic islet transplantation	Reversion of impaired glucose tolerance	[121]
BM-MSCs	5×10^5 MSCs/mouse	Hypoxia	*In vivo* model of hindlimb	Improvement of angiogenesis	[139]

			ischemia		
AdMSCs	5 × 105 MSCs/mouse	Hypoxia	*In vivo* model of hindlimb ischemia	Improvement of functional recovery and neovascularization	[140]
AdMSC-derived CM	NA	Hypoxia	*In vivo* model of partial hepatectomy	Enhanced liver regeneration	[142]
AdMSCs	2 × 10^6 MSCs/rat	Hypoxia	*In vivo* model of acute kidney injury	Improvement of angiogenesis and inhibition of ROS generation	[145]
AdMSC-derived CM	100 μL/mouse	Hypoxia	*In vivo* model of acute kidney injury	Improvement of renal function and reduction of inflammation	[146]
BM-MSCs	1 × 10^6 MSCs/rat	Hypoxia	*In vivo* model of lung IRI	Attenuation of pathologic lung injury score by inhibiting inflammation and generation of ROS and anti-apoptotic effects	[147]
BM-MSCs	NA	Hypoxia	*In vivo* model of radiation-induced lung injury	Improvement of antioxidant ability	[148]

colitis[95,96,98]. Rafei *et al*[134], in a mouse *in vivo* model of autoimmune encephalomyelitis, found that treatment with allogeneic MSCs primed with IFN-γ reduced clinical signs in a dose-dependent manner. In this study the authors showed that, though the priming treatment induced the increase of CCL2 and MHCI/II expression in IFN-γ-primed MSCs, it inhibited manifestations of autoimmune encephalomyelitis while keeping their immunogenicity low. The use of IFN-γ- or TNF-α-primed MSCs has also been shown to attenuate symptoms of GVHD[101,103]. In these cases, in the first study it was shown that therapeutic effects of MSCs were mediated by overproduction of IDO induced through the IFN-γ-JAK-STAT1 pathway[101]. In the second study, the therapeutic function of MSCs was activated by TNF-α, which induced overexpression of Chi3 L1 and consequent suppression of T-helper 17 cells[103]. Recently, it has been revealed that the priming of MSCs with IL-1β relieved the side effects of sepsis[109,111]. In particular, Song *et al*[109] demonstrated that IL-1β makes MSCs more effective in inducing macrophage polarization toward an anti-inflammatory M2 phenotype, and this effect was mediated, at least in part, through overproduction of EXOs containing miR146a. Similar results on M2 macrophage polarization were also obtained by Yao *et al*[111], who revealed the ability of IL-1β to stimulate the production of MSC-derived EXO containing miR21. The therapeutic efficacy of MSCs primed with IFN-γ was also found in an *in vivo* model of colonic wounds. Particularly, García *et al*[135] showed that these cells were able to enhance healing of colonic mucosal wounds in both immunocompromised and immunocompetent mice. Similar results were also obtained using MSCs primed with TNF-α, which were able to accelerate wound closure and angiogenesis in an *in vivo* model of wound healing[99]. The priming with inflammatory cytokines seems to also be effective for the treatment of chronic liver diseases. Indeed, treatment with IL-6 improved the ability of MSCs to reduce liver injury[104]. The study reported that in a mouse *in vivo* model of liver fibrosis, treatment with IL-6-primed MSCs reduced both fibrosis and apoptosis, and improved liver functions[104]. Moreover, TNF-α-primed MSCs were also able to attenuate inflammation in an *in vivo* model of peritonitis[136]. In this study, the authors demonstrated that TNF-α induced the overproduction of the anti-inflammatory factor TSG-6, generating a mechanism that reduces inflammation in an *in vivo* model of zymosan-induced peritonitis[136]. Interestingly, in a similar experimental model, Bazhanov *et al*[137] found that after intraperitoneal injection MSCs formed 3D aggregates, and stimulated the production of anti-inflammatory cytokines, such as IL-10 and PGE2. In this regard, Bartosh *et al*[138] showed that the priming of MSCs with 3D culture decreased inflammation in an *in vivo* model of peritonitis[138]. In particular, the authors suggest that MSC spheroids overexpressed TSG-6, and these cells were more effective than conventional MSCs as therapy for diseases characterized by unresolved inflammation.

Overall, the above-mentioned studies suggest that treatment with pro-inflammatory cytokines or the 3D culture of MSCs represents promising priming strategies for enhancing the MSC immunoregulatory phenotype, making these cells more suitable for clinical disorders related to exacerbated immune responses (Figure 2).

Figure 2 Schematic representation of the molecular effects after priming of mesenchymal stromal/stem cells. Mesenchymal stromal/stem cells (MSCs) can be primed through various stimuli, including hypoxia, three-dimensional cultures, and pro-inflammatory cytokines to enhance their therapeutic potential. Each priming method induces the production of specific factors (*e.g.*, trophic factors, angiogenetic factors, chemokines, cytokines, and exosomes containing both proteins and microRNAs), which induce the activation of biological processes such as angiogenesis, tissue repair/regeneration, chemoattraction, and modulation of inflammation. Each priming strategy seems to stimulate the production of functional factors in a different way, thus eliciting different responses. miRNA: MicroRNA; VEGF: Vascular endothelial-derived growth factor; CXCR: Chemokine receptor; HGF: Hepatocyte growth factor; MMP: Matrix metallopeptidase; BDNF: Brain-derived neurotrophic factor; SDF: Stromal cell-derived factor; HIF: Hypoxia-inducible factor; ICAM: Intercellular adhesion molecules; MCP: Monocyte chemoattractant protein; IL: Interleukin; LIF: Leukemia inhibitory factor; PIGF: Placental growth factor; EGF: Epidermal growth factor; FGF: Basic fibroblast growth factor; PDGF: Platelet-derived growth factor; GRO: Growth-related oncogene; TGF: Transforming growth factor; PGE2: Prostaglandin E2; IDO: Indoleamine 2,3-dioxygenase; PDL1-2: Programmed death ligand 1-2; MIG: Monokine induced by interferon-gamma; G-CSF: Granulocyte colony-stimulating factor; IP-10: Induced protein 10; MIP: Macrophage inflammatory protein; IRI: Ischemia/reperfusion injury; MSCs: Mesenchymal stromal/stem cells; 3D: Three-dimensional.

Main priming strategies for treating acute injury

Priming strategies for MSCs have been considered a crucial tool for enhancing their therapeutic effects, making these cells more suitable for application in the field of regenerative medicine[3,85]. However,

while the priming of MSCs with pro-inflammatory cytokines potentially represents the principal strategy modulating inflammation in chronic immune-related disorders (or, in any case, conditions in which the inflammation is exacerbated), the priming of MSCs with hypoxia is thought to represent the more appropriate priming strategy for boosting MSC effects for the stimulation of tissue function recovery after acute injury (Figure 2). This has been demonstrated in numerous study models, and on different organs (Table 1). For example, hypoxia pre-conditioning significantly improved blood flow recovery in mouse models of hindlimb ischemia. Rosová *et al*[139] demonstrated that hypoxic MSCs better migrate to the injured site compared with non-hypoxic MSCs, thus speeding up the restoration of blood flow. The authors demonstrated that the observed effects were likely mediated by the HGF-cMET axis. It has been shown that hypoxia helps MSCs to better integrate in the damaged tissue. Han *et al*[140] revealed that hypoxic priming enhanced survival and proliferation of transplanted MSCs, thus improving the regeneration of hindlimb ischemic tissues. After MSC treatment, the authors observed inhibition of apoptosis and promotion of neovascularization and, as they showed the increased expression of the normal cellular prion protein upon hypoxia pre-conditioning, they identified this prion as a potential target for MSC therapy. In a similar manner, Lee *et al*[115] recently identified GRP78 as new potential target for the development of functional MSCs. GRP78 has been shown to be induced by hypoxia, thus increasing transplanted-MSC survival and proliferation in a mouse model of hindlimb ischemia. Moreover, the authors found that the HIF-1α-GRP78-Akt axis regulates the suppression of cell death signals, and increases angiogenic cytokine secretion, thus strongly improving tissue recovery from the damage[114]. Recently, it has been found that mild hypoxia can be induced in MSCs when they are cultured as spheroids. Various studies have clearly demonstrated that 3D culture conditions induce hypoxia in the core of the spheroid, thus stimulating the production of both growth and pro-angiogenic factors, which in turn stimulate the fast recovery of damaged tissues in mouse models of hindlimb ischemia[141,142]. Interestingly, it has also been shown that the CM derived from MSCs primed by 3D culture attenuated injury and inflammation in two IRI *in vitro* models of both lung and liver[59,131]. 3D pre-conditioning has been shown to also be effective for other type of diseases, such as acute kidney injury (AKI). Xu *et al*[143] found that 3D pre-conditioned MSCs, when transplanted in mice with AKI, are more viable than the 2D cultured cells, and exhibit higher paracrine secretions, as evidenced by the increased levels of VEGF and TSG-6. Furthermore, the authors show that the paracrine secretion, which also includes basic fibroblast growth factor, insulin like growth factor, and EGF, significantly improved renal function and reduced tissue apoptosis, thus speeding up the regeneration of renal tissues upon injury[143]. Recently, the secretome of 3D MSCs transplanted for the treatment of AKI was furtherly investigated. For example, Cao *et al*[144] found that the paracrine effect on AKI was mediated not only by soluble factors, such as anti-inflammatory cytokines, but also by EXOs, whose production is increased after 3D pre-conditioning. Furthermore, by using a cisplatin-inducing AKI model in mice, the authors showed that the increased number of EXOs upon 3D culture enhanced the renoprotective and anti-inflammatory efficacy of MSCs[144]. Treatment of AKI with MSC therapy has been implemented in recent years by defining new protocols of MSC pre-conditioning. Along with 3D culturing, hypoxia priming has been used for the treatment of IRI-inducing AKI in animal models, and Zhang *et al*[145] demonstrated that hypoxia priming enhanced angiogenic and antioxidative MSCs properties in a rat model of renal IRI. In addition, in the same model, the authors found that transplanted MSCs attenuated renal apoptosis by reducing cleaved caspase3 activation. Notably, hypoxia also enhanced MSC therapeutic potential in a cisplatin-induced mouse model of AKI. Overath *et al*[146] found that hypoxic conditions increased the efficacy of transplanted MSCs in attenuating renal damage upon injury both by reducing creatinine and N-GAL serum levels, and decreasing pro-inflammatory cytokine release. MSC hypoxia pre-conditioning has also been found to be strongly effective for the treatment of IRI in the lung. For example, MSC infusion in lung perfusates demonstrated that hypoxic MSCs quickly migrate from the pulmonary artery to the lung tissue, where they attenuate parenchymal damage by reducing oxidative stress, inflammation, and apoptosis, and by stimulating cell proliferation and survival[147]. In a similar manner, MSC hypoxia has been found to have important effects also for radiation-induced lung injury (RILI). A mouse model of RILI was recently established by exposing the lungs of mice to irradiation, thus generating tissue damage. Upon irradiation, the authors demonstrated that hypoxic MSCs reside for longer in the injured tissue compared with normoxic MSCs. In addition, Li *et al*[148] showed that hypoxia-primed MSCs enhanced cell viability and proliferation, as well as anti-oxidative and anti-apoptotic capabilities in lung parenchymal cells. Finally, the authors highlighted the role of HIF-1 in modulating resistance to lung hypoxic stress induced by RILI, thus promoting tissue repair and regeneration upon injury.

The use of MSCs as cellular therapy has also been shown to be effective for the treatment of acute myocardial injury in several preclinical models (Table 1). Also in this case, to ameliorate the therapeutic effects of MSCs various priming strategies have been evaluated. In particular in myocardial infarction (MI), it has been widely believed that tissue injury is related to ischemia and the hypoxic environment. Therefore, the *in vitro* hypoxic condition was tested to improve MSC therapeutic effects in MI animal models[149]. In a mouse model of MI, it was found that intramyocardial injection of hypoxia-preconditioned MSCs reduces infarct size, influences heart remodelling by modulating vasculogenesis, and improves heart functions, promoting cell survival[150,151]. Of note, expression analysis in hypoxic MSCs has revealed an increase in expression of pro-survival and pro-angiogenic factors, including HIF-

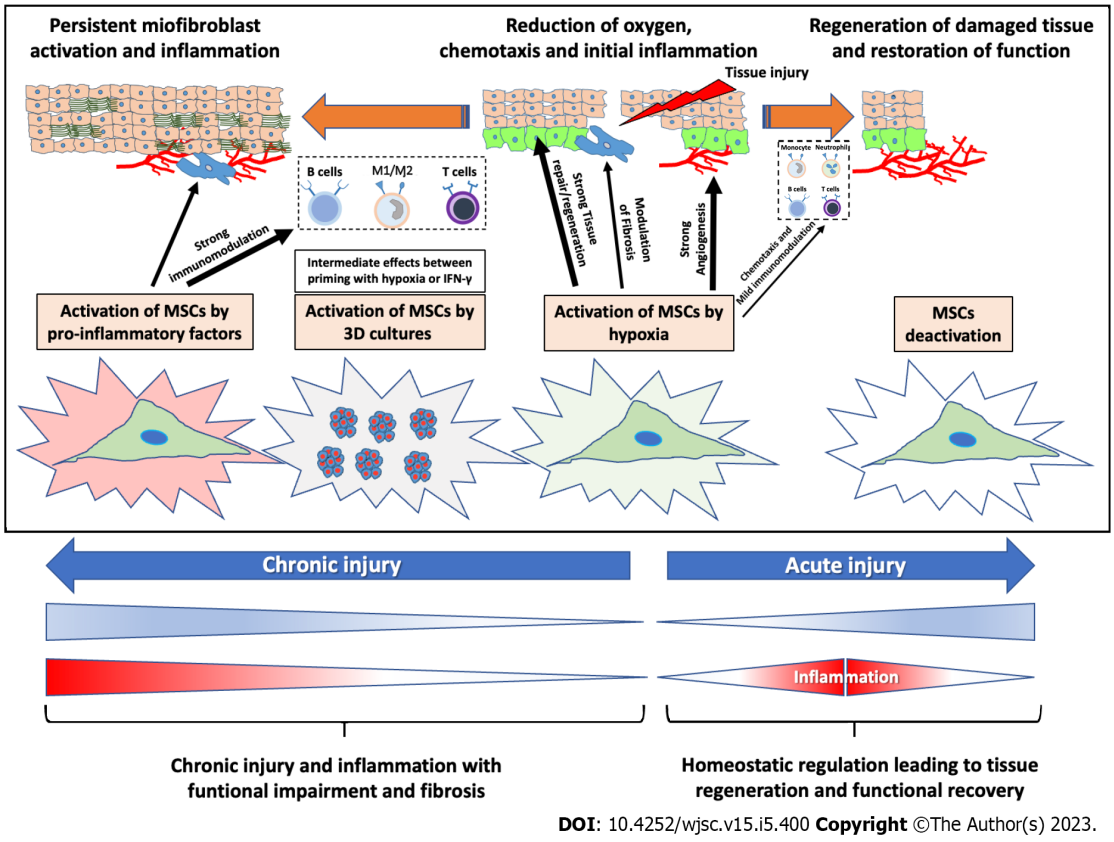
1α, ANGPT1, VEGF, Flk-1, Bcl-2, Bcl-xL, and these proteins can act in a paracrine manner on MI, inducing functional recovery[150]. It has also been observed that hypoxic MSCs influence the expression of specific miRNAs that can be secreted through EVs. In particular, Feng *et al*[152] demonstrated that after hypoxic treatment of MSCs an increase of miR22 was observed in EXOs, and this miRNA was considered responsible for targeting Mecp2, with beneficial effects on survival of cardiomyocytes exposed to ischemia. Similarly, EVs derived from hypoxic MSCs overexpressing miR26 were able to reduce the damage from ischemia/reperfusion in a rat model[153]. In the same way, in an MI mouse model the intracardial injection of hypoxic-preconditioned MSC-derived EXOs was able to positively regulate cardiomyocyte proliferation and survival, and this effect was ascribable to the overexpression of miR125b[154]. In addition to the use of hypoxia priming, the use of 3D culture has also been shown to be effective in the improvement of MSC therapeutic effects on the treatment of acute myocardial injury. You *et al*[155], in an acute MI rat model, found that treatment with 3D-primed MSCs resulted in a retention of MSCs at the epicardium, where MSCs exerted cardiac protection/repair, and functional recovery. Moreover, in the same animal model, Wang *et al*[156] revealed that 3D MSCs were able to stimulate vascular density and improve cardiac function after MI.

Over the last decade, MSCs have also been intensively studied for their potential use in the treatment of neurological acute injury, including cerebral ischemia, traumatic brain injury, and spinal cord damage. For example, in an *in vivo* model of cerebral ischemia, it has been shown that hypoxic-preconditioned MSCs enhanced angiogenesis and neurogenesis after ischemia[157]. In an *in vivo* model of traumatic brain injury, Chang *et al*[158] demonstrated that the priming of MSCs with hypoxia improved their therapeutic function, and resulted in an amelioration of neurogenesis, and motor and cognitive functions. Moreover, in a rat model of spinal cord injury, hypoxic MSCs were also able to increase axonal preservation and decrease apoptosis[159].

Principal priming strategies for stimulating tissue regeneration

MSCs are involved in tissue homeostasis, which is necessary for physiologically coordinating regeneration/repair of tissue, also after injury[3,6,36]. Thus, the use of MSCs in regenerative therapies is garnering great interest due to their potentially numerous clinical applications.

In the complex process of cutaneous wound healing, a central role is played by fibroblasts, which contribute, through the interaction with surrounding cells, to the production of ECM, glycoproteins, adhesive molecules, and various growth factors[160]. Recent evidence suggests that CM produced by primed MSCs from different sources, such as bone marrow[120], adipose tissue[160], amnion fluid[161], and placenta[162] enhanced the migration and proliferation of fibroblasts *in vitro*, and accelerated wound healing in *in vivo* models (Table 1). In all these cases, hypoxia treatment represented the chosen priming strategy for driving MSCs in increasing secretion of various angiogenic factors, cytokines, and chemokines. Therefore, the priming of MSCs with hypoxia might well represent the main approach to improving the therapeutic effects of MSCs to be applied in the stimulation of tissue regeneration (Figure 2). This idea has also been supported by other studies (Table 1). Indeed, in both hepatectomized mouse and rat models, it has been demonstrated that hypoxic MSCs produce crucial functional molecules, including HGF and VEGF, which were considered responsible for the induction of liver regeneration[163,164]. Kuo *et al*[165] showed that systemic infusion of MSCs restored liver function and promoted liver regeneration in rodents. In this regard, in a rat massive hepatectomy model, Yu *et al*[164] found that hypoxia-conditioned MSCs secreted significantly more VEGF than normoxia-conditioned cells, and the infusion of primed MSCs promoted proliferation of hepatocytes and liver regeneration. Several studies have focused on the signalling pathways up-regulated by MSC during liver regeneration. Lee *et al*[163] using a partially hepatectomized mouse model, found that treatment with hypoxic MSC-derived CM increased the viability of hepatotoxic hepatocytes, and enhanced liver regeneration through JAK/STAT3 signalling. These data were also confirmed by Lee *et al*[166], who confirmed the activation of JAK/STAT3 signalling induced by MSC CM during mouse liver generation. Hypoxic MSCs that secrete high level of VEGF were also able to regenerate pulp-like tissues and vasculature similar to the native pulp in a rat model of pulp repair[167]. HGF and VEGF produced by hypoxic MSCs were considered by Chang *et al*[158] to be responsible for improvement of neuronal proliferation. Moreover, Zhilai *et al*[159] demonstrated that both HGF and VEGF produced by hypoxia-primed MSCs facilitated axonal survival in a rat model of spinal cord injury. Han *et al*[140], in a murine hindlimb ischemia model, found that the expression levels of EGF, VEGF, fibroblast growth factor, and HGF were significantly higher in ischemic tissue treated with hypoxic MSCs, where an improvement of neovascularization was observed. The efficacy of hypoxic MSCs was also tested in reducing scar formation and inducing wound healing in various *in vivo* models[120,162,168].



Despite the fact that the principal MSC priming strategy used for both *in vitro* and *in vivo* regeneration experiments was hypoxia treatment, 3D culture of MSCs as priming strategy has also been investigated in tissue regeneration (Figure 2). In fact, MSC spheroids have also shown therapeutic abilities with regard to both bone and cartilage regeneration. In particular, it has been found that treatment with MSC spheroids was effective in inducing disc repair in an *in vivo* model of disc degeneration, bone regeneration in an *in vivo* model of bilateral calvarial defects, and cartilage regeneration in an *in vivo* model of osteochondral defects[169-171].

CONCLUSION

The therapeutic effects of MSCs have been demonstrated in both *in vitro* and *in vivo* studies. Nevertheless, due to their heterogeneity related mainly to tissue source, which can impact MSC functional properties[85,172], the application of MSCs in clinical trials has shown moderate or poor efficacy. MSCs are considered key regulators of tissue repair and, in this case, different stimuli are crucial in modulating the functional properties of these cells. In fact, it is believed that inflammation and low oxygen levels are essential signals for triggering MSC activity in a suitable manner. Moreover, it has recently been shown that different priming approaches can eliminate the functional heterogeneity of MSCs[173]. Therefore, specific priming strategies have been implemented to improve the regenerative and immunomodulatory properties of MSCs. In this review, we have explored data regarding the principal priming approaches used to enhance the therapeutic potential of MSCs. The above-mentioned data underscore that several factors play a role in the ability to modify MSC properties. Moreover, some therapeutic effects, on different disease models, can be obtained in relation to dose and/or combination of the priming factors used.

Several diseases have in common tissue injury and repair processes, in which inflammation plays a central role in coordinating different pathways that regulate tissue regeneration and functional recovery. Indeed, after acute injury, a low level inflammation (acute inflammation) occurring after specific triggers, is crucial in stimulating wound healing and tissue repair, facilitating the resolution of inflammation and restoring tissue structure/function (inflammation drives regeneration). On the other hand, in the case of abnormal damage repair, chronic unregulated inflammation can lead to pathological processes, including hormonal metabolic changes, which culminate in the onset of specific diseases, including cancer and fibrosis[174,175]. Therefore, the regulation of both acute and chronic inflammation is essential for a proper restorative response and, in this scenario, MSCs can have a crucial physiopathological role. In fact, it has been shown that when MSCs coordinate damaged tissue for repair, they undergo local stimuli such as inflammatory cytokines, and hypoxia, which in turn boost and direct the reaction of MSCs to orchestrate tissue regeneration[85,176]. In Figure 3, we depict a hypothetical model that occurs during physiopathologic tissue injury and repair. In this model, MSCs are activated differently by various microenvironment stimuli to manage tissue functional recovery. One of the first factors that arises after tissue injury is the establishment of a hypoxic and weakly inflammatory microenvironment, which in turn activates local cells to protect/regenerate tissues[3,177]. Hypoxia rapidly up-regulates the level of intercellular adhesion molecule-1 in local-inflamed endothelium, promoting MSC migration to injured tissues[178,179]. Moreover, a mild inflammation may stimulate MSCs to release chemokines for attracting immune cells and amplifying immune responses[180]. Once MSCs reach the site of injury, the paracrine properties of MSCs to release chemotactic and angiogenic factors is significantly amplified under hypoxic conditions[181]. In this case, naïve MSC are activated to recruit neutrophils and stimulate the formation of new blood vessels. Neutrophil action is followed by monocyte/macrophage activity that ensures sustained release of pro-inflammatory cytokines and potentiation of the fibroproliferative response[182,183]. If these processes are not adequately regulated, a state of chronic inflammation occurs. Thus, cytokines such as IFN-γ, TNF-α, and IL-1 accumulate in the injured tissues, and the inflammatory environment becomes central in affecting the regulatory role of MSCs that exhibit immunosuppressive capacities[184]. The MSC phenotype is switched into a lower regenerative potential and a higher anti-inflammatory phenotype (Figure 3). Thus, high amounts of pro-inflammatory cytokine confer a dramatic immunomodulatory ability to MSCs[40,91,124,125,185,186] which, in turn, act as a homeostatic regulator to control the inflammatory response. Overall, this scenario describes what occurs when MSCs are exposed to low levels of both oxygen and inflammation, and their phenotype is potentially inclined to low immunomodulation and high stimulation of tissue regeneration. Otherwise, high levels of inflammation can imprint a MSC phenotype inclined toward high immunomodulation and weak stimulation of tissue regeneration (Figure 3). In this regard, Vigo *et al*[87] found that IFN-γ can orchestrate MSCs functions in a dose-manner, and this is reflected in the opportunity to modulate MSC properties before their use in clinical practice. In addition, considering the heterogeneous immune regulatory functions of MSCs due to intrinsic characteristics of individual clones, the priming of MSCs with pro-inflammatory factors can equally amplify immune therapeutic properties of MSCs, and eliminate the variances among different MSC clones[173].

Priming with inflammatory signals polarizes MSCs toward an anti-inflammatory and pro-trophic phenotype allowing, on the one hand, the regulation of inflammatory responses, and on the other the final remodelling and recovery of damaged tissue. Likewise, different priming strategies can be used to direct the therapeutic effects of naïve MSCs toward specific pathological processes. As also highlighted by the studies we have noted in this review, while hypoxic priming of MSCs could be used mainly to treat acute disease, to principally stimulate angiogenesis and tissue regeneration, inflammatory cytokines could be used mainly to prime MSCs for treating chronic immune-related disorders. The change of perspective from regeneration to inflammation implies in the MSCs the shift in the production of functional factors that stimulate regenerative or anti-inflammatory pathways (Figure 2). Interestingly, the 3D culture of MSCs as priming strategy appears to be an intermediate functional priming between the two mentioned above. The production of priming type-specific functional factors in MSCs could well pave the way for optimizing their therapeutic potential, aimed at a greater effectiveness as an

Figure 3 Schematic illustration of the physiological role and biological action of mesenchymal stromal/stem cells primed *in vivo* in a model of tissue injury and repair. During tissue injury and repair, mesenchymal stromal/stem cells (MSCs) are differently activated by various microenvironment stimuli to orchestrate tissue repair and functional recovery. First, naïve MSC activation (hypoxic activation) leads to the release of both angiogenic factors and chemokines, which stimulate the formation of new blood vessels, the recruitment of neutrophils, and the expression of adhesion molecules. Neutrophil action is followed by macrophage activity, which ensures sustained release of pro-inflammatory cytokines, and potentiation of the fibroproliferative response. If this process is not adequately regulated, a state of chronic inflammation occurs; the MSC phenotype is switched into an anti-inflammatory phenotype. MSCs: Mesenchymal stromal/stem cells; 3D: Three-dimensional.

Abstract

Multiple myeloma (MM) is a hematological malignancy characterized by the accumulation of immunoglobulin-secreting clonal plasma cells at the bone marrow (BM). The interaction between MM cells and the BM microenvironment, and specifically BM mesenchymal stem cells (BM-MSCs), has a key role in the pathophysiology of this disease. Multiple data support the idea that BM-MSCs not only enhance the proliferation and survival of MM cells but are also involved in the resistance of MM cells to certain drugs, aiding the progression of this hematological tumor. The relation of MM cells with the resident BM-MSCs is a two-way interaction. MM modulate the behavior of BM-MSCs altering their expression profile, proliferation rate, osteogenic potential, and expression of senescence markers. In turn, modified BM-MSCs can produce a set of cytokines that would modulate the BM microenvironment to favor disease progression. The interaction between MM cells and BM-MSCs can be mediated by the secretion of a variety of soluble factors and extracellular vesicles carrying microRNAs, long non-coding RNAs or other molecules. However, the communication between these two types of cells could also involve a direct physical interaction through adhesion molecules or tunneling nanotubes. Thus, understanding the way this communication works and developing strategies to interfere in the process, would preclude the expansion of the MM cells and might offer alternative treatments for this incurable disease.

Key Words: Multiple myeloma; Mesenchymal stem cells; Bone marrow microenvironment; Soluble factors; Extra-cellular vesicles; Cells adhesion molecules; Tunnelling-

nanotubes

Core Tip: Mesenchymal stem cells (MSCs), the main cell population of the bone marrow (BM) stroma, can influence BM microenvironment through their paracrine activity, involving both soluble factors and extracellular vesicles, but also through direct communication. Being the BM the predominant localization of multiple myeloma cells (MM), finding the appropriate conditions at this niche, is key for the survival and expansion of tumour cells and thus, for the progression of the disease. Since the activity of BM-MSCs could determine the fate of MM cells at BM, these cells could be interesting targets for the design of new antitumor drugs.

INTRODUCTION

Multiple myeloma (MM) is one of the most common hematological diseases, only second to non-Hodgkin lymphoma[1]. MM affects mainly older adults, with the median age of diagnosis being around 69 years. Only in 2020, 32270 new cases and 12830 deaths in the United States were estimated by the American Cancer Society Statistics Centre. In global terms, the cases would reach 160000, accounting for 0.9% of all cancer diagnosis. Importantly, incidence of MM has risen 126% globally, and hence, there is an increasing need to find new effective treatments for this incurable disease[2,3].

Besides the initial treatments for MM, consisting in alkylating agents often combined with corticosteroids, the last couple of decades have seen an important advance in the available treatments for this disease. We first saw the introduction of proteasome inhibitors (Bortezomib), histone deacetylase inhibitors (Panobinostat) and drugs such as Selinexor, with a nuclear export inhibition activity. In recent years monoclonal antibodies such as Daratumumab (anti-CD38) or Elotuzumab (anti-SLAMF7), and more recently the use of chimeric antibody receptor (CAR) T-cell products, has introduced immunotherapy as a viable approach to MM treatment[4]. According to data from the National Cancer Institute (Bethesa, MD, United States), all these treatments have had a deep impact on patients' survival, substantially raising the survival rate to 55% in the period between 2011 and 2017. More recently, the use of small molecules, with a molecular weight smaller than 1kDa, has also improved treatments, since it offers important advantages compared to the former therapies, as the easy cell entry, the simplicity of the molecules, and a much lower production cost than other drugs[5]. However, despite these advancements, there are still limitations to existing treatment options. Some patients may not respond to or may develop resistance to certain medications, many patients can become refractory to treatment and thus, there is a high risk of relapse. This promotes the search for new treatments to handle relapsed or refractory MM.

MM is caused by aberrant plasma cells (PC) proliferation in the bone marrow (BM). The premalignant states, known as monoclonal gammopathy of undetermined significance (MGUS) and smoldering MM, transition under specific conditions to the malignant state of PC leukemia or extramedullary myeloma [6]. A key characteristic of MM is the infiltration into and the colonization of the BM, one of the two primary lymphoid organs[7]. This colonization produces typical lytic bone lesions that would be present in approximately 80% of patients with newly diagnosed MM and are the major source of morbidity[8]. The bone lesions, resulting from the stimulation of bone resorption by B-cell plasmacytomas, are associated with hypercalcemia and often, severe bone pain and bone fractures[8,9].

While the initiation of a tumor mainly depends on the accumulation of genetic defects, the transition from a premalignant to a malignant state highly relies on the interaction of the tumor cell with a permissive microenvironment that would support the malignant transformation and the proliferation of the tumor cells, aiding them to evade apoptosis. The relevance of tumor microenvironment in disease progression was first discussed in the "seed and soil hypothesis" formulated by Stephen Paget in 1889, where the establishment of tumor metastatic sites is influenced by the cross-interaction between the seeds (cancer cells) and the soil (a particular microenvironment)[10]. This is not different in MM[11,12]. The progression to MM, which would occur in approximately 50% of patients diagnosed with MGUS [6], requires multiple genomic events, but also a permissive BM microenvironment[13]. MM cells proliferate almost exclusively within the BM niche, highlighting the role of this microenvironment in

supporting cancer growth. In fact, there is also mounting evidence indicating this BM microenvironment is not only key for PCs survival, but also has a crucial role in resistance to treatment and disease recurrence[14,15].

The MM cells infiltrating the BM will encounter a complex microenvironment formed by cellular and non-cellular components. Amongst the non-cellular components influencing the BM microenvironment, it is important to consider the extracellular matrix (ECM) proteins as well as a milieu of cytokines, chemokines, and growth factors. Many of these factors can have a positive effect on MM cells, boosting their proliferation and survival and the resistance to different types of drugs. A good example of these cytokines supporting MM progression are interleukin (IL)-6 and ligands of the B-cell maturation antigen, such as a proliferation-inducing ligand and B-cell activating factor (BAFF)[16,17]. Regarding the cellular components of the BM niche, many different types of bone cells (osteoblasts, or bone forming cells, and osteoclasts, or bone resorbing cells, and osteocytes) and cells from the immune system (macrophages, natural killer cells and regulatory T-cells) share this niche. Other cells present here are fat cells (adipocytes), fibroblasts, endothelial cells and two multipotent stem cells, BM mesenchymal stem cells (BM-MSCs), which differentiate into different mesodermal cell lineages, and hematopoietic stem cells (HSCs), that would differentiate into hematological lineages, including the myeloid lineage that would give rise to osteoclasts. MM cells are likely to interact with all the cells in the BM niche and elicit mutual influence[18]. In fact, it is known that communication between MM cells and BM-MSCs is essential in the progression of MM[19]. Once MM cells infiltrate the BM, their presence in the BM niche alters the activity of many of the cells found there, including those involved in bone homeostasis such as osteoclasts[20,21] and osteoblasts[22-24]. While in normal bone homeostasis, the activities of osteoblast and osteoclasts are carefully balanced to ensure a correct bone regeneration, the influence of MM cells disrupts this balance increasing both the resorptive activity of osteoclast and their numbers, and decreasing osteoblasts numbers as well as their osteogenic capacity[25], overall leading to an increase in bone destruction and the appearance of the aforementioned osteolytic lesions typical of this disease. Other cells at the BM niche which activity is highly influenced by MM cells are BM-MSCs. The presence of MM cells at the BM niche alters the MSCs behavior in different ways. In fact, changes in the expression of certain microRNAs (miRNAs) in BM-MSCs leading to important alterations of their secretory profile and osteogenic differentiation potential have been observed after co-cultivation of BM-MSCs and MM cells[26,27]. These changes at the BM niche upon MM invasion produce a microenvironment that would support disease progression. Indeed, there is strong evidence indicating that is precisely this interaction what leads to the formation of the lytic bone lesions[28]. One of the characteristics of this permissive microenvironment is the high presence of pro-inflammatory cytokines that would favor the progression of neoplasia[29]. The crosstalk between MM cells and the BM-MSCs at the BM niche is key to sustain this pro-inflammatory microenvironment and thus, to allow MM cell persistence and growth[30]. It is important to clarify, that this pro-inflammatory microenvironment would be the result of the action not only of the infiltrated MM cells but also of other cells residing at the BM niche, including BM-MSCs.

MSCs, have a key role in regulating the BM microenvironment through their paracrine activity, but also through direct cell-to-cell interaction. Regarding their paracrine activity, these cells produce a plethora of soluble biomolecules and vesicular components, known altogether as "secretome", that exert multiple actions on other cells at the BM microenvironment[31]. BM-MSCs role in MM disease development and progression has been reported as having both inhibitory[32] and supportive roles[33,34]. Sadly, the latter is the most frequent. Once at the BM niche, MM will exert their influence on resident MSCs, altering their signaling and gene expression pattern and thus, also their secretion pattern. After interaction with MM cells, MSCs will produce a secretome rich in pro-inflammatory cytokines. In fact, it has been previously described how MSCs react to IL-1 produced by the myeloma PCs by producing large quantities of IL-6, a cytokine that would in turn stimulate the survival of the MM cells[35,36]. Therefore, the soluble part of this secretome has a key role in the progression of tumor. Moreover, in the last few years, several molecules (miRNAs) that are present in the cargo in the extracellular vesicles (EVs) produced by BM-MSCs upon MM cells stimulation also seem to have a key role in the disease promotion. Although the soluble proteins and EVs produced by the BM-MSCs are the main actors in the communication between BM-MSCs and MM cells, other ways of communication have also been implicated. This will be discussed in the following sections.

Current available treatments for MM patients mainly target MM cells but have none or limited effect on other cells in the BM or de BM microenvironment. Knowledge of the different interactions between BM-MSCs and MM cells is key to understand how MM cells behave and grow within the BM and how osteolytic lesions are formed. In this work, we will address key aspects of the different ways of communication between MSCs and MM cells as well as the outcome of this crosstalk.

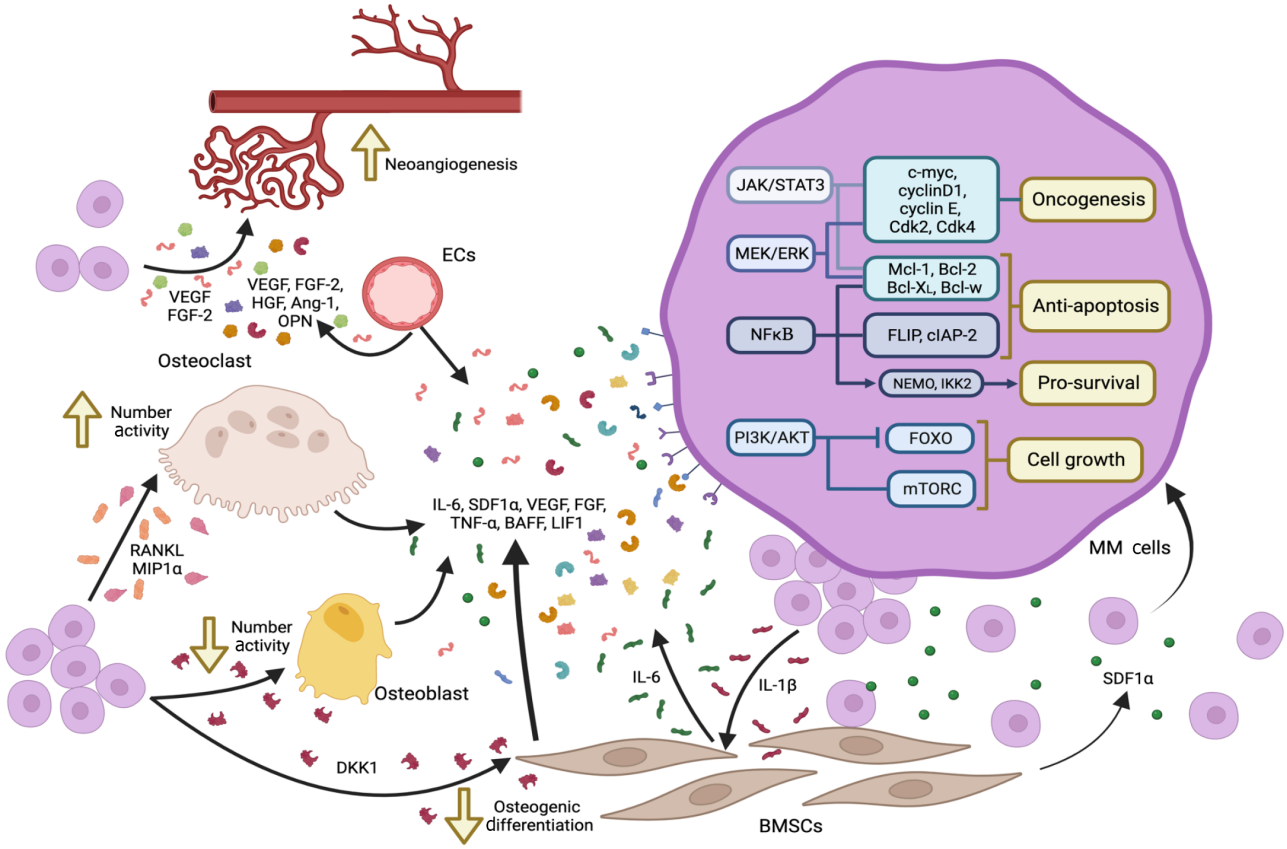
SOLUBLE FACTORS IN THE COMMUNICATION BETWEEN BM-MSCs AND MM CELLS

The multiple cellular interactions taking place in the BM, make this microenvironment a dynamic compartment with a myriad of soluble factors that would affect the behavior of the various cell types

concurring at that microenvironment. Although many of those cells have paracrine activity, BM-MSCs are the ones that have a stronger impact in the BM microenvironment due to the wide variety of soluble and non-soluble factors secreted by these cells. Various constituents of the, so called, BM-MSC secretome orchestrate the fate of the MM cells, from the first step encompassing the homing of those cells to the BM, onwards.

Role of soluble factors in the homing of MM cells to the BM

A key factor in the communication between BM cells and MM cells during the first stages of BM colonization, is the cytokine stromal cell derived factor 1α (SDF1α), also known as CXCL12. This factor, produced by BM-MSCs, works as a chemoattractant, being responsible of the homing of HSCs to the BM once they abandon the fetal liver during development[37]. SDF1α activity is mediated by the binding to a specific G-protein 7-span transmembrane receptor (CXCR4) at the target cells. CXCR4 is expressed at the surface of different cells in the BM microenvironment[38], and also at the surface of MM cells and other tumor cells[39]. Thus, SDF1α/CXCR4 interaction might have a relevant role in directing de metastasis of hematopoietic malignancies. Similar to its effect on HSCs, the interaction of SDF1α with its receptor at the MM cells, increases their migration, homing and adhesion towards the BM, in fact, knock down of CDCR4 in BM-MSCs or the use of the CXCR4 inhibitor AMD3100 (AnorMED), that blocks the binding of SDF1α to its receptor[40], seems to inhibit the migration of MM towards the BM[41]. The binding of SDF1α to its receptor at the MM cells, also triggers the activation of the phosphatidylinositol 3-kinase (PI3K) and the MAPK kinase (MEK)-extracellular signal regulated kinase (ERK, MEK/ERK) pathways, inducing a rearrangement in the cytoskeleton of MM cells that facilitates BM colonization [41]. SDF1α has also been described to act in a more indirect way, not mediated by the binding to CXCR4. SDF1α interacts with other molecules including matrix metalloproteinases (MMPs), integrins or growth factors such as hepatocyte growth factor (HGF), insulin like growth factor-1 (IGF-1) or molecules of the GTPases family. All of these effects elicited by SDF1α, in one way or another, lead to a promotion in MM cells migration, homing or adhesion into the BM[38].



Role of soluble factors in the promotion of proliferation and MM cell survival

Many of the factors secreted by BM-MSCs and by other cells of the BM microenvironment, activate key signaling pathways in the MM cells that would increase their chances to survive and proliferate in the BM microenvironment. A summary of these factors as well as the signaling pathways involved in this communication are shown in Figure 1. In fact, some mutations activating those pathways have also been found in patients with MM. We will address some of those key pathways in this section.

Once in the BM, for the tumor to progress further, MM cells would need a permissive microenvironment. This microenvironment would be created by multiple soluble factors secreted by the different cell types present at the BM. The soluble factors produced by the BM-MSCs seem to be the main, but not the only, effectors of the changes elicited in the MM cells. Besides SDF1α, BM-MSCs seem to secrete other important soluble factors such as IL-6, IL-17, vascular endothelial growth factor (VEGF), fibroblast growth factors (FGF), tumor necrosis factor-α (TNF-α), BAFF or leukemia inhibitory factor-1; osteoclasts mainly secrete IL-6 and VEGF; and vascular endothelial cells secrete cyclophilin-A[42,43]. These factors will activate specific signaling pathways in the MM cells such as PI3K/Akt, MEK/ERK, Janus kinase 2 (JAK2)-signal transducer and activator of transcription 3 (STAT3, JAK2/STAT3) pathways, related to cell survival, proliferation and drug resistance[43]. It is important to highlight that this communication is bi-directional, since MM cells would also produce cytokines such as IL-1β, VEGF, and transforming growth factor-beta (TGF-β) that would exert their effect on BM-MSCs, activating the nuclear factor kappa-B (NFκB) pathway and thus, inducing further secretion of cytokines by the BM-MSCs into the BM microenvironment, particularly IL-6[44,45].

IL-6 is the main activator of the JAK2/STAT3 pathway, known to be implicated in the pathogenicity of cancer. JAK2/STAT3 pathway activation promoted by IL-6 leads in MM cells to the expression not only of potent proto-oncogenes such as c-myc and cyclin D1, but also of anti-apoptotic genes like Mcl-1, Bcl-XL and Bcl-2. Moreover, STAT3 activation has also a immunosuppressive effect since it regulates T-cell mediated cytotoxic immune response[46], contributing to the establishment of a immunosuppressed microenvironment that would contribute to the survival and proliferation of the MM cells in the BM. On the other hand, IL-6 activation of JAK2/STAT3 pathways, also has an important role in bone destruction, a hallmark of MM. IL-6/JAK2/STAT3 axis induces the expression of the receptor activator of NFκB ligand (RANKL)[36,47] whose binding to its receptor at the surface of pre-osteoclasts, promotes their differentiation towards mature osteoclasts, activating bone resorption and thus, promoting the formation of osteolytic lesions.

It is important to highlight that the NFκB signaling pathway also has an important role in the survival of MM cells and in the maintenance of the tumorigenic microenvironment at the BM. Both canonical and non-canonical NF-kB pathways are activated by different factors present in the BM microenvironment, including IL-6, IGF-1, TNF-α or BAFF[48]. While IGF-1 is able to activate NFκB pathway, inducing the expression of anti-apoptotic, caspase-8 inhibitors FLIP and cIAP-2[49], TNF-α has a pro-survival effect through NFκB pathway mediators such as NFκB (NEMO) and IκB kinase subunit 2[44]. On the other hand, BAFF activates NFκB non-canonical pathway upregulating the expression of antiapoptotic proteins including Mcl-1, Bcl-XL, Bcl-w and Bcl-2[50]. There is also evidence indicating that IL-6 is

linked to the expression of VEGF in MM cells, being some of the VEFG isoform expression driven by the NFκB pathway[51,52].

The MEK/ERK pathway is the signaling pathway most found activated in MM patients, with a prevalence in between 43% and 53% of the patients[53]. Changes in MEK/ERK pathway have important effects in cell cycle, due to the alteration in the expression of molecules such as cyclin D1, cyclin E, Cdk2 and Cdk4 and in apoptosis prevention by the induction of the phosphorylation of the pro-apoptotic protein Bim. This phosphorylation results in the release of anti-apoptotic molecules such as Mcl-1, Bcl-XL and Bcl-2, also related to Akt pathway[54]. In the absence of mutations that activate this pathway, the stimulation of the MEK/ERK pathway in the MM cells might also occur by the action of different soluble factors present in the BM microenvironment such as BAFF, IL-6, SDF1α, VEGF or TNF-α among others[42]. As with other relevant signaling pathways that become activated in MM, the MEK/ERK is also studied as a potential therapeutic target.

PI3K/Akt signaling pathway also has a relevant role in cell proliferation, cell cycle and apoptosis. Alteration of the PI3K/Akt/mTOR pathway due to genetic modifications or its hyper-activation contributes to carcinogenesis, metastasis, invasion, proliferation and drug resistance of tumor cells. However, no activating mutations have been described in MM cells yet. Despite this fact, PI3K/Akt/mTOR pathway is important for MM cells survival[55,56].

Role of soluble factors in angiogenesis and bone homeostasis

Up to this point, we have mentioned some of the effects of the pro-tumorigenic microenvironment in the BM on the MM cell survival and growth. However, once modified by the BM microenvironment, MM cells will start to release different soluble factors that will not only perpetuate that tumorigenic microenvironment, but also will have a deep impact in angiogenesis and bone homeostasis.

Neovascularization in the bone is an essential feature for MM progression and the presence of high density of micro-vessels in the BM microenvironment is characteristic in MM. Cells residing at BM, such as BM-MSCs, osteoblasts, HSCs, or endothelial precursor cells, commonly express various angiogenic

factors, such as VEGF, FGF-2, TNF-α, HGF, IL-6, BAFF, SDF-1α, angiopoietin-1 or osteopontin (OPN). Also, MM cells are able to directly produce VEGF stablishing a VEGF autocrine loop where the produced VEGF would stimulate MM cells proliferation through the MEK-1/ERK pathway[57,58]. FGF-2 is another key pro-angiogenic molecule that would be produced by both MM cells and BM-MSCs[59]. However, contrary to VEGF, which is produced by all MM cells, FGF-2 production by MM does not seem to be a general feature in all MM cases[59]. Other molecules with pro-angiogenic activity such as MMPs[60,61] or OPN, also produced by MM cells, have also a relevant role in promoting micro-vessels formation in the BM microenvironment. The overall increase in the production of such angiogenic factors is elicited by the MM cells. The activation of angiogenesis linked to tumor progression is known as "angiogenic switch"[62] .

Bone homeostasis is a dynamic process driven by osteoclasts, osteoblast and osteocytes. Alterations in the balance between these cell types will lead to the remodeling of the bone. The characteristic bone lesions found in MM derive from the disruption of bone homeostasis initiated by the activation of JAK2/STAT3 pathway by IL-6 and the subsequent induction of RANKL expression by MM cells. Not only this but, as will be discussed later, cell-to-cell interaction of MM cells with BMSCs also induce the expression of the macrophage inflammatory protein (MIP)-1α[63]. Both RANKL and MIP-1α are mediators in the bone destruction driven by MM as they have an both in the number of osteoclasts and in their activity. MIP-1α is a chemoattractant for osteoclasts and stimulates osteoclast formation[64], while RANKL after being recognized by its receptor RANK, will induce the commitment of the macrophage/monocyte precursor cells to the osteoclast lineage[65].

Secreted by MM cell in response to the activation of the JNK pathway, Dickkopf-1 (DKK-1) is also a disruptor in bone homeostasis[66]. DKK-1 is an extracellular inhibitor of the Wnt pathway. DKK-1 interacts with membrane receptors as transmembrane proteins Kremen 1/2 and the human low-density lipoprotein receptor-related protein 5/6, thus competing with Wnt[67]. As one of the main regulatory pathways for osteogenic differentiation of BM-MSCs into osteoblasts[68], the inhibition of the Wnt/β-catenin pathway by DKK-1 will result in a reduced number of osteoblasts. By the action of these factors, RANKL, MIP-1α and DKK-1, the balance between bone formation and bone resorption driven by osteoblasts and osteoclasts is disrupted, resulting in the characteristic bone lesions present in MM patients.

A table summarizing the latest scientific evidence regarding key factors involved in MM/BM-MSCs communication and their effect is shown (Table 1).

EVs-MEDIATED COMMUNICATION BETWEEN BM-MSCs AND MM CELLS

Under non-pathological conditions, BM homeostasis is maintained by cell-to-cell contact, soluble molecules, and EVs. Whereas, over the years solid evidence has accumulated about the relevance of the first two, the involvement of EVs-mediated communication in the maintenance of BM homeostasis has started to be contemplated only in the last few decades[69]. Despite being a fairly new field, important advances have been made in the knowledge of EVs, such as their classification, in terms of their size and biogenesis, into three major categories (exosomes, micro-vesicles, and apoptotic bodies) and the fact that its content varies according to the state of their parental cells[31].

As we have previously discussed, MM cells have the capacity to alter the environment in which they reside[70] as well as the characteristics of cells present in that microenvironment. Thus, it is not surprising that the EVs produced by MM cells also play a key role in disease progression. In fact, it has recently been shown that, exosomes (a particular class of EVs) produced by both BM-MSCs and MM cells are largely responsible for MM pathogenesis[71]. This recent demonstration of the relevance of EVs in MM progression has resulted in several studies in the lats few years, however, the multitude of agents and interactions involved in the development and progression of this disease has made it difficult to fully understand the molecular mechanisms involved. In this section we aim to gather the available information so far.

Effect of MM-EVs on the BM-MSCs and bone homeostasis

As previously mentioned, osteolysis, one of the main hallmarks of MM disease, is linked to the negative effect of MM cells on cells responsible for bone homeostasis, such as MSCs, osteoblasts and osteoclasts [72]. In particular, myeloma bone disease (MBD) has a unique feature compared to other diseases that encompass bone destruction, since in MBD osteoblast activity is also severely impaired[24]. Several authors have suggested that an essential part of this bone damage is related to EVs directly produced by MM cells (MM-EVs). Zhang *et al*[73] demonstrated that the cargo of MM-EVs was enriched in various molecules which negatively regulate osteogenesis. They confirmed that MM-EVs induced high expression of miR-103a-3p in BM-MSCs, which led to impaired osteogenesis *in vitro*. Moreover, they showed that injection of MM-EVs in mouse tibia resulted in defective bone formation. Interestingly, *in vitro* assays also revealed that MM-EVs were also able to influence MM cells increasing viability and IL-6 production, known to regulate MM cell proliferation thus, establishing an autocrine feedback. MM-EVs also increased miR103a-3p expression in MM cells however, in those cells the increased prolif-

Table 1 Summary for the key soluble factors involved in multiple myeloma/bone marrow mesenchymal stem cells communication

Soluble factors	Origin	Function	Ref.
SDF1α	BMSCs	Chemoattractant of MM cell towards the BM microenvironment	[38]
IL-1β	MM cells	Act over BMSCs inducing the secretion of soluble factors, mainlyIL-6	[45]
IL-6	BMSCs	Closely related with cancer pathogenicity due to it proto-oncogenic and anti-apoptotic effect over MM cells	[46,47]
		Immunosuppressive effect over T cells	
		Also related with bone destruction by inducing the expression of RANKL by the MM cells	
VEGF	BM cells, MM cells	Promotes bone neovascularization, essential for tumour progression	[58]
RANKL	MM cells	Induce the commitment of the macrophage/monocyte precursor cells to the osteoclast lineage. Promoting indirectly bone destruction	[63]
DKK-1	MM cells	Disruptor of bone homeostasis by inhibiting BMSCs differentiation into osteoblasts	[66,67]

SDF1α: Stromal cell derived factor 1α; BM-MSC: Bone marrow mesenchymal stem cells; MM: Multiple myeloma; IL: Interleukin; RANKL: Receptor activator of NFκB ligand; VEGF: Vascular endothelial growth factor; DKK-1: Dickkopf-1.

eration of MM cells after exposures to MM-EVs does not seem to be related to miR103a-3p but to other miRNAs also present in the MM-EVs cargo, such as miR107 and miR181a-3p[24].

Among the different biomolecules found as part of the exosome cargo, long non-coding RNAs (lncRNAs) and miRNAs have been the focus of attention due to their key regulatory roles. Various miRNAs found in MM-EVs have been studied for their involvement in the disruption of osteogenesis. miR-129-5p was identified as a player in vesicle-mediated bone disease[74]. In particular, miR-129-5p seemed to inhibit the transcription factor specificity protein 1, leading to a reduction of ALPL, both at the mRNA and protein levels, during the early osteogenic differentiation of MSCs. On the other hand, the long non coding RNA Long Intergenic Non-Protein Coding RNA 461, found as part of the MM-exosomes cargo, has also been found to inhibit osteoblast differentiation by reducing the activity of Wnt/β-Catenin pathways, responsible for osteoblast proliferation, differentiation and activity[75]. Other molecules, such as soluble proteins present in the MM-EVs cargo also showed anti-osteogenic activity Faict *et al*[72] revealed that Wnt/β-Catenin inhibitor DKK-1 is present in MM-EVs and observed a lower expression of Osterix (OSX), Collagen 1A1 and alkaline phosphatase in differentiated MC3T3-E1 cells after MM-EVs treatment.

Runx2 is the master regulator of early osteogenic differentiation, and therefore a possible target for the anti-osteogenic effect of MM-EVs. In fact, lncRNA RUNX2-AS1 present in the MM-EVs cargo was identified as a bioactive molecule able to reach MSCs and form a transcriptionally repressed RNA duplex with RUNX2 premRNA, reducing the osteogenic activity[76]. In addition, a MM-EVs impact in osteoblastic differentiation through reduction of Runx2, together with OSX and OCN, has been described by Liu *et al*[77]. These authors also record increased levels of IL-6 secretion *via* APE1/NF-kB which, as aforementioned, is an important survival factor of MM cells.

Once the EVs produced by MM cells reach the BM-MSCs, their cargo modifies the BM-MSCs behaviour in the benefit of MM cells**.** A clear example of this is miR-146a which acts in a positive loop to favor disease progression[19]. Once this miRNA targets BM-MSCs, it produces an increase in the secretion of several cytokines and chemokines from those cells, including CXCL1, IL-6, IL-8, inducible protein 10 (IP-10), monocyte chemoattractant protein 1 (MCP-1), and CCL-5, which, in turn, once released into the BM microenvironment, would favor MM cell viability and migration. In addition, MM-EVs cargo miR-146a and miR-21, participate in proliferation and transformation of MSCs into cancer associated fibroblasts (CAFs). This is a type of cell which could contribute to a tumour-supportive microenvironment through secretion of cytokines, including IL-6 and TGF-β[78].

Interestingly, it has been shown that conventional chemotherapeutic agents including melphalan, and anti-proteases such as bortezomib and carfilzomib can stimulate a considerable MM-EVs release. The EVs produced under these circumstances are called "chemoexosomes". These chemoexosomes are characterized by the high presence of the heparanase enzyme in their surface. This heparanase is implied in several cellular changes leading to chemoresistance and the subsequent relapse of the patient. Heparanase EVs content is delivered in MM cells and activate ERK pathway as well as TNF-α production by macrophages, matrix degradation and migration promotion[71].

Effect of EVs produced by BM-MSCs on MM cells and MM progression

So far, we have analyzed the influence of MM-EVs on BM-MSCs, however, this communication, as previously mentioned, is bidirectional. In 2016, Wang *et al*[69] showed that BM-MSC-EVs from MM patients contained a lower level of the tumor suppressor miR-15a, and higher levels of oncogenic

proteins, cytokines, and adhesion molecules, when compared to EVs from healthy BM-MSCs. Cytokines such as IL-1ra, interferon-IP-10, MCP-1, MIP-1α, MIP-1β, and SDF1α were detected in murine BM-MSC-EVs. They confirmed that BM-MSC-EVs from MM patients act on MM cells activating proliferation, survival, and migration, as well as drug resistance to bortezomib, a widely used clinical drug for MM treatment.

In a similar study, a reduction of mir-15a levels in the cargo of BM-MSCs-EVs from MM patients was also detected. This change was shown to promote cell proliferation and dissemination or metastasis to other niches, which is a hallmark of MM. The same authors also revealed the importance of some of the proteins present in BM-MSCs-EVs cargo, as they detected higher content levels of IL-6, CCL2, γ-catenin and fibronectin, which are key to MM pathogenesis[70]. Other miRNAs cargo were also implicated in these processes. miR-483-5p was found packed in BM-MSCs-EVs and was responsible for promoting MM cell proliferation and reduced apoptosis *via* the miR-483-5p/TIMP2 axis[79]. Umezu *et al*[80] highlighted the role of miR-10a in MM disease since its transference *via* BM-MSC-EVs promoted cell proliferation in several MM cell lines (RPMI 8226, KMS-11, and U266) compared to BM-MSC-EVs with miR-10a blocked. Moreover, Gao *et al*[81] studied miR-155 present in BM-MSC-EVs cargo, which turned out to be involved in viability, stemness and drug resistance in MM cells. The role of miR-155 was underscored by the fact that incubation of the MM cells line mitochondrial pyruvate carrier 11 (MPC-11) with miR-155-mimics for 24 h resulted in a significantly reduced cell apoptosis *in vitro* and augmented expression of stemness maintenance markers OCT-4 and Nanog and drug resistance-associated proteins MRP1, ABCG2 and P-g.

As in the previous section, a table summarizing the main works referred to the relevance of communication between MM cells and BM-MSCs through EVs and the role of their cargo is shown (Table 2).

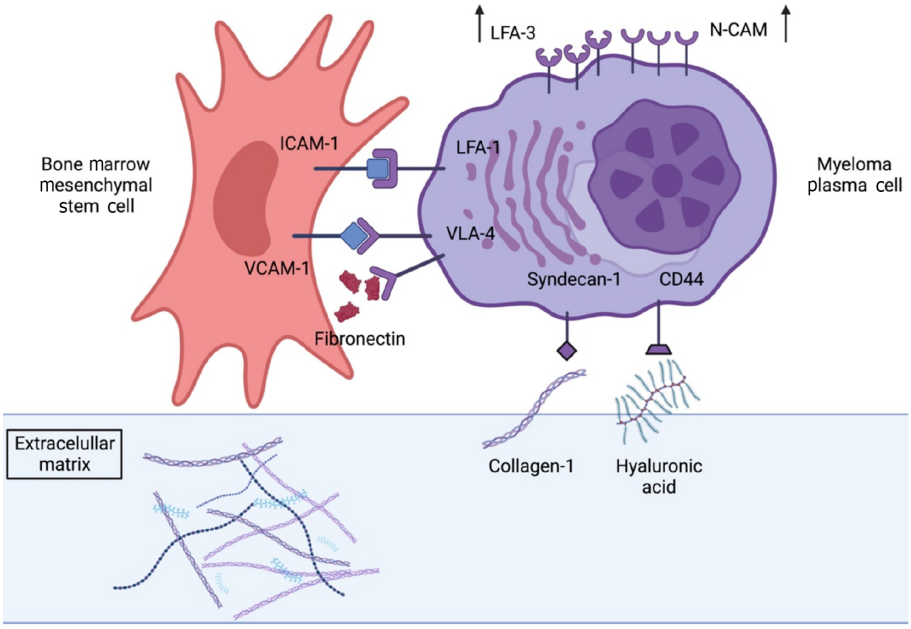
The resistance to treatment is precisely one of the major problems in MM at the clinical level, as this is directly responsible for the relapses. Some studies investigating the mechanisms behind this resistance have highlighted the implication of the activation of several signaling pathways, including p38, p53, c-Jun N-terminal kinases and Akt through the assessment of bortezomib treatment. The role of BM-MSC-EVs in interfering with the antitumor effect developed by bortezomib in MM was confirmed through different experiments. BM-MSC-EVs were able to alter apoptosis-related proteins Bcl-2, Bax, caspase-8, caspase-9, and caspase-3 promoting an antiapoptotic profile in both murine and human cells. These EVs blocked the significant reduction of Bcl-2 expression caused by bortezomib and reduced cleaved caspase-9, caspase-3, and PARP either in the absence or presence of bortezomib. Moreover, the use of GW4869, a neutral sphingomyelinase inhibitor of the formation of exosomes by the ceramide pathway, in combination with bortezomib treatment led to a significant effect on tumor load reduction[71,82].

In conclusion, the two-way communication between MM cells and BM-MSCs mediated by EVs is extremely intricate and plays a pivotal role in the progression of the disease. Since BM-MSCs-EVs have a key role in supporting MM development, this could become a key target to develop new therapies for the treatment of this hematological disease.

COMMUNICATION THROUGH CONTACT DEPENDENT MECHANISMS

As well as the already described interactions through paracrine secretion of different cytokines and EVs, MM cells also interact with BM-MSCs by direct cell-to-cell contact. These cell-to-cell interactions are not restricted to MM and BM-MSCs since MM cells also interact with other cells of the BM microenvironment such as osteoclasts and osteoblasts, endothelial cells, and lymphocytes. It is known that these contacts are also key to protect MM cells against chemotherapy, helping them to accumulate inside the BM[83], to adhere to endothelium, and to spread into the bloodstream[84], although the detailed mechanisms involved in those processes have not been completely elucidated[85].

Cell adhesion molecules in MM/BM-MSCs communication



Direct cell-to-cell adhesion and communication mechanisms have been known for more than 40 years [86,87]. These cell-to-cell communication is mediated by Cell Adhesion Molecules (CAMs), a subcategory of adhesion proteins located at the cell surface, involved in binding either to other cells, or in attaching cells to proteins of the ECM[88], suchas fibronectin, laminin or collagen (Figure 2). While it has been well documented that the ECM promotes the survival of different types of tumors, much less is known about the influence of the direct contact of BM-MSCs in their progression.

CAMs play a central role in cell communication and the maintenance of tissue homeostasis[89]. There are different superfamilies or groups of CAMs with different specificities and distributions. These families would include the Immunoglobulin superfamily CAMs (IgCAMs), integrins, cadherins and one superfamily of proteins that contain a C-type lectin-like domain (C-type lectin domain proteins or CTLDs)[89]. Following other criteria, CAMs can be classified into calcium-independent or calcium-dependent molecules[90], meaning that these molecules would need Ca^{2+} ions binding to different domains of the protein in order to rigidify their extracellular domains and enable interaction[91]. Integrins and IgCAMs belong to the calcium independent group whereas CLTDs and selectins belong to

Table 2 Summary of evidence about the relevance of different cargo molecules in the extracellular vesicles of multiple myeloma cells and bone marrow mesenchymal stem cells s to the progression of multiple myeloma

	Function	Ref.
MM-EVs cargo		
lncRNA RUNX2-AS1	Form a RNA duplex with RUNX2 premRNA, reducing the osteogenic activity in MSCs	[76]
miR-146a	Increase the secretion of several cytokines in BM-MSCs that favor MM cell viability and migration and induce CAF transformation	[78]
DKK-1	Lower expression of OSX, COL1A1 and ALP in osteoblast precusor cell line (MC3t3-E1)	[72]
MSC-EVs cargo		
mir-15a	Promote MM cell proliferation and dissemination to other niches	[70]
miR-483-5p	Induce MM cell proliferation and reduced apoptosis	[79]
miR-155	Reduce MM cell apoptosis and augment expression of stemness maintenance and drug resistance markers	[81]

EVs: Extracellular vesicles; MM: Multiple myeloma; BM-MSC: Bone marrow mesenchymal stem cells; CAF: Cancer associated fibroblast; DKK-1: Dickkopf-1; OSX: Osterix; COL1A1: Collagen 1A1; ALP: Alkaline phosphatase.

Figure 2 Schematic representation of the main cell adhesion molecules in multiple myeloma cells and bone marrow mesenchymal stem cells. The main interactions between cell adhesion molecules (CAMs) of these two types of cells as well as the interactions of these CAMs with proteins of the extracellular matrix are displayed (Created with Biorender.com). ICAM-1: Intercellular adhesion molecule 1; VCAM-1: Vascular cell adhesion molecule-1; LFA-1: Leukocyte function-associated antigen 1; N-CAM: Neural cell adhesion molecule; VLA: Very late antigen. Created with BioRender.com.

calcium dependent group[92]. Cell adhesion molecules bind to different ligands. Cadherins, selectins and IgCAMs are associated with the cell-to-cell contact, while integrins are involved in the attachment of MM cells to the ECM[93]. All these molecules are integral in modeling cellular mechanisms such as growth, contact inhibition and apoptosis. In fact, changes in cell adhesion, involving these molecules, can be the defining event in a wide range of diseases, including cancer development[94], as lower intercellular adhesiveness allows malignant cells to scape from their site, thus, destroying the architecture of the original tissue, commonly the first step leading to cancer[94].

As well as the already described interactions through paracrine secretion of different cytokines and EVs, MM cells also interact with BM-MSCs by direct cell-to-cell contact. In fact, recent studies revealed that many of the changes undergone by BM-MSCs supporting the progression of MM, are acquirable by physical contact with MM cells[95]. In MM, this cell-to-cell interactions are not restricted to MM and BM-MSCs since MM cells also interact with other cells of the BM microenvironment such as osteoclasts and osteoblasts, endothelial cells, and lymphocytes. All these interactions are regulated by CAMs. It is

known that these contacts are key to protect MM cells against chemotherapy, helping them to accumulate inside the BM[83], to adhere to endothelium, and to spread into the bloodstream[84], although the detailed mechanisms involved in those processes have not been completely elucidated[85].

The most relevant role of CAMs in MM pathophysiology is related to the homing of malignant PCs to the BM. To complete the process of homing, mediated by CXCL12, MM cells need to adhere to either ECM proteins or BM-MSCs. This is mediated by CAMs such as very late antigen (VLA)4, VLA5, CD44, leukocyte function-associated antigen 1 (LFA-1), intercellular adhesion molecule 1 (ICAM-1), MPC-1 and syndecan (Figure 2).

One way of ensuring adhesion of MM to the ECM is the binding of its integrin VLA-4 to fibronectin, a common component of the ECM. VLA-4, which is in fact a heterodimer of two integrins CD49d(a4) and CD29(b1), also mediates the interaction of MM cells with BM-MSCs, through the vascular cell adhesion molecule-1 (VCAM-1), located at the BM-MSCs[96]. This interaction activates the secretion of MIP-1α and MIP-1β in MM cells, leading to an increase of osteoclastogenic activity[97]. Moreover, the direct contact of these two types of cells through VLA-4 also induces the production of DKK-1 by MM cells, which inhibits osteoblastic differentiation of BM-MSCs. Thus, these two actions, promotion of osteoclastogenesis and inhibition of osteogenesis, would have a detrimental effect on bone structure, contributing to the typical osteolytic lesions in MM. In addition, BM-MSCs unable to undergo osteoblastic differentiation would produce higher levels of IL-6, a cytokine that would stimulate the proliferation of DKK-1-secreting MM cells[25]. Moreover, it has been observed that VLA-4–fibronectin binding is an essential step that supports the IL-6-mediated induction of PCs in normal BM, since antibodies against VLA-4 were found to inhibit the secretion of IL-6 in co-cultures of MM cells and BM-MSCs cells[96,98,99].

The interaction between MM cells and BM-MSCs is also mediated by ICAM-1 (CD54) and LFA-1 (CD11α/CD18) expressed in BM-MSCs and MM respectively. The glycoprotein ICAM-1 is the main ligand for b2 integrins and its expression is induced in response to an inflammatory microenvironment [100], such as the one resulting in the BM following the colonization by MM cells. The ICAM-1/LFA-1 interaction seems to have a key role in the progression of MM since the blocking of LFA-1 through the use of monoclonal antibodies, inhibits the production of IL-6 by BM-MSCs. Thus, this interaction is focus of various studies aimed to the development of treatments for MM[101].

Syndecan (CD138) is the principal transmembrane proteoglycan expressed in the surface of MM cells and has in fact been used as a marker for the detection of this pathology. Syndecan has multiple functions in MM. This molecule mediates de adhesion of MM cells to the collagen in the ECM through direct interaction with collagen molecules but can also mediate myeloma cell-cell adhesion[102]. Syndecan-1 also plays a broad role in cells signaling since heparan sulfate chains on syndecan-1 can bind to and sequester growth factors and cytokines, regulating their availability to cells. Also, a recent study has shown that syndecan contributes to the survival of mature MM cells by enhancing IL-6 signaling[103]. Finally, the binding of syndecan to VEGF and other angiogenic factors, has been shown to promote angiogenesis in MM[104].

Finally, CD44, a transmembrane glycoprotein, interacts mainly although not exclusively with hyaluronic acid in the ECM[105]. CD44 signaling has been shown to activate various signaling pathways in different types of cancer including PI3k/AKT, MAPK/ERK and NF-kB[106], which, as we have seen, promote MM cell survival.

Although normal PC and MM cells express basically the same set of CAMS, some of these molecules were found to be more significantly overexpressed in MM cells when compared to healthy patients. In this group we can include, leukocyte adhesion molecule LFA-3 (CD58)[107] and neural cell adhesion molecule (CD56)[108]. MM cells can also express the lymphocyte function-associated antigen LFA-1 (CD11α/CD18) which was associated with tumor growth and homotypic tumor cell adhesion or aggregation[109]. It is also worth mentioning that some homing molecules could not be detected on MPCs: Selectin molecule L-selectin and collagen receptor VLA-2[89]. Although this study provides relevant information, for this information to be biologically relevant, ligands of these receptors had to be available within the tumor environment.

Overall, given the importance of some of these CAMs in the process of MM cells homing, these molecules could be important targets for designing antitumoral treatments. Several approaches have been explored, including antibodies specifically targeting these molecules on the cell surface, as well as small molecule inhibitors that interfere with the binding of the CAMs to their ligands. Moreover, receptor-blocking antibodies against most of these CAMs (VLA-4, CD56, MPC-1, CD21) were found to partially block MM cells adhesion to the BM stroma. This partial effect could be attributed to an additional adhesion mechanism yet to be discovered[110,111].

In MM a specific type of drug resistance seems to be mediated by CAMs, the so called, CAMs mediated drug resistance[112]. CAMs can activate intracellular pathways that promote cell survival, promote cancer cell adhesion to the ECM and regulate the expression of drug transporters that could pump chemotherapy drug out of cancer cells and reduce their efficacy. It is also important to highlight that MM spreading in the last stages of the diseases also involve important changes in cell adhesion. MM can abandon de BM microenvironment and become stroma independent because of different processes involving changes in the expression levels of CAM and certain cytokines. Once this happens, cells can be found to spread extramedullary at different sites such as lungs, liver, or pleural fluid[113, 114].

Role of tunneling nanotubes in MM/BM-MSCs communication

As we have seen, communication between MM and BM-MSCs cells can take place through mechanisms that can be classified as contact-dependent and/or contact-independent mechanisms[115]. While the previous section has been dedicated to direct communication mediated by cell adhesion molecules, in this last section we will briefly discuss transport *via* tunneling nanotubes (TNTs), another form of contact-dependent interaction.

TNTs are transient intercellular structures formed by the polymerization of F-actin which provide an important and general mechanism of cell-to-cell communication[116,117] and constitute a reliable infrastructure for vesicle and protein trafficking[118]. Numerous examples of communication between MSCs and malignant hematological cells such as B cells, MM and chronic lymphocytic leukemia, are already known, as well as the effects of this communication, such as increased drug resistance. This has already been demonstrated in acute myeloid leukemia (AML), B-cell precursor acute lymphocytic leukemia (ALL) or CML[119,120]. Therefore, TNTs are considered one of the key pharmacological targets in current research.

The role of TNTs is to deliver autophagosomes, mitochondria and other lipophiles to MSCs. This induces the secretion of specific cytokines, including interferon-γ-IP-10, CXCL10, IL-8, MCP-1 and CCL2 and other growth factors which, in turn, induce tumor cell survival, enhanced growth and even drug resistance[121]. This has been checked in AML, where increased survival of cells against chemotherapy treatments is observed by means of mitochondrial transfer from MSCs routed by TNT. In this case, the mitochondrial transfer translates into an increase of up to 14% in mitochondrial mass in co-cultures of tumor cells with MSCs and a 1.5-fold increase in mitochondrial adenosine triphosphate production (ATP), making them less prone to mitochondrial depolarization and thus resulting in increased survival against chemotherapy treatments[122].

Numerous lines of treatment are currently under development for various hematological diseases that reduce the formation of TNT by blocking actin polymerization. This inhibits the cellular communication that promotes disease progression. Those treatments include cytochalasin D, cytarabine, latrunculin A and B, daunorubicin, everolimus, metformin, nocodazole CK-666, ML-141 or 6-thio-GTP [123]. In addition, vinca alkaloids or taxanes are also being targeted because of their role in the polymerization of microtubules[124].

Although the fate of mitochondria transferred into tumor cells remains unclear, there is evidence indicating that MSCs play a key role in the progression of AML, ALL, MM and mitochondrial transfer chemoresistance. It is well known that the initiation of cancer requires metabolic adjustments, since rapid proliferation cancer cells have high metabolic requirements. This mitochondrial and/or mitochondrial DNA transfer to cancer cells increases mitochondrial content and enhances the mitochondrial process of oxidative phosphorylation (Oxphos), which generates a larger quantity of ATP than glycolysis, thus, promoting cell proliferation and invasion[125]. Therefore, targeting mitochondrial respiration and Oxphos is also a treatment option, FOXM1 is known to regulate myeloma cell metabolism by increasing glycolysis and Oxphos. NB73 is a FOXM1 inhibitor that promotes FOXM1 degradation and thus growth of MM cells, making it a potential drug targeting Oxphos[126].

Studies to date have elucidated that mitochondrial transfer dynamically induced resistance occurs between MM cells and other cells in the BM microenvironment *via* TNT, providing a starting point for the development of new targeted therapies[127]. An example of this line of treatment for MM is the use of anti-CD38 monoclonal antibodies[128]. This antibodies have different mechanisms of action, including cell apoptosis[129]. Moreover, their administration in mice has shown inhibition of mitochondrial transfer, a reduction in tumor volume and, in general, increased survival[1]. However, it should be noted that, although patients who have received this treatment show increased survival, it has been observed that resistance to these treatments can be acquired in the long term.

CONCLUSION

Conditions at the BM microenvironment are essential for the establishment and progression of MM. The complex BM microenvironment encompasses hematopoietic cells, immune cells, and cells involved in bone homeostasis such as osteoclasts, osteoblasts and BM-MSCs. Thus, it is understandable that the disruption of microenvironment homeostasis by MM cells results in angiogenesis, osteolysis, immune suppression and anemia[69].

As key regulators of this microenvironment, BM-MSCs play an important role in the progression of the disease. The crosstalk between MM cells and BM-MSCs takes place at different levels, through soluble cytokines, EVs, and direct cell-to-cell contact.

The interaction between these two cell types can have both positive and negative effects on the proliferation and survival of MM cells. The communication between MM cells and BM-MSCs can promote tumor growth. The survival and proliferation of MM cells once they reach the BM is associated with immune suppression, eliminating the possibility of an effective antitumor response. Although it is the interaction between all cells in the BM what produces this immunosuppressive microenvironment, BM-MSCs have a relevant role in the construction of this particular microenvironment due not only to their

important paracrine activity, but also to their ability to establish direct communication with other cells in that microenvironment. All these direct or indirect interactions activate a pleiotropic proliferative and antiapoptotic cascades favoring disease progression.

On the other hand, the communication between MM cells and BM-MSCs can also have a negative impact on cancer cell growth and survival. BM-MSCs can secrete factors that inhibit the growth and survival of MM cells.

Currently, therapeutic advances in the treatment of this disease are based on targeted therapies using monoclonal antibodies or CAR-T. These treatments have improved patient prognosis, although long-term resistance is still observed, and further research is needed into the specific mechanisms by which cells acquire this resistance. In the quest for new effective treatments for MM, the importance of communication between MM cells and BM-MSCs cannot be overstated. Understanding the molecular mechanisms involved in this two-way communication can provide valuable insights into MM pathogenesis and help identify key targets involved in the survival and proliferation of MM cells in the BM microenvironment and thus, opening new opportunities for the design of targeted therapies to avoid disease progression.

Abstract

Head and neck squamous cell carcinoma is the seventh most common cancer worldwide with high mortality rates. Amongst oral cavity cancers, tongue carcinoma is a very common and aggressive oral cavity carcinoma. Despite the implementation of a multimodality treatment regime including surgical intervention, chemo-radiation as well as targeted therapy, tongue carcinoma shows a poor overall 5-year survival pattern, which is attributed to therapy resistance and recurrence of the disease. The presence of a rare population, *i.e.*, cancer stem cells (CSCs) within the tumor, are involved in therapy resistance, recurrence, and distant metastasis that results in poor survival patterns. Therapeutic agents targeting CSCs have been in clinical trials, although they are unable to reach into therapy stage which is due to their failure in trials. A more detailed understanding of the CSCs is essential for identifying efficient targets. Molecular signaling pathways, which are differentially regulated in the CSCs, are one of the promising targets to manipulate the CSCs that would provide an improved outcome. In this review, we summarize the current understanding of molecular signaling associated with the maintenance and regulation of CSCs in tongue squamous cell carcinoma in order to emphasize the need of the hour to get a deeper understanding to unravel novel targets.

Key Words: Head and neck squamous cell carcinoma; Cancer stem cells; Signaling; Tongue squamous cell carcinoma

Core Tip: Tongue squamous cell carcinoma is one of the most common and aggressive oral cavity carcinomas, particularly among the Indian population. Despite various treatment strategies employed, the survival rates of the patients remain poor. A rare population *i.e.*, cancer stem cells (CSCs), plays an important role in resistance, recurrence as well as metastasis which are factors responsible for the poor survival outcome. In this review, we discuss the recent findings regarding cell signaling pathways and markers associated with the CSCs and the need to gain a deeper understanding on the properties of the CSCs.

INTRODUCTION

Global cancer statistics by GLOBOCAN in 2020 showed that 2.0% of new cancer cases reported worldwide were lip and oral cavity cancers, while 1.8% of the total cancer-related deaths were of lip and oral cavity cancers. Lip and oral cavity cancers are the most commonly diagnosed cancers that are responsible for most cancer-related deaths in India[1]. Most cases of oral squamous cell carcinomas (OSCCs) are presented at advanced stages, *i.e.*, stages III or IV [tumor-node-metastasis (TNM) staging], where the 5-year survival of the patients is less than 50%. Further, 40% of the oral carcinomas are presented as tongue carcinomas[2].

Head and neck squamous cell carcinomas (HNSCCs) are carcinomas of the oral cavity, nasopharynx, oropharynx, larynx, and hypopharynx[3]. The oral cavity carcinomas comprise the anterior 2/3rd of the tongue, buccal mucosa, retromolar trigone, lower and upper alveolar ridge, hard palate, and floor of the mouth[3].

The poor survival observed in HNSCCs is primarily attributed to loco-regional/ distant metastasis and therapy resistance. Therefore, understanding the molecular mechanism underlying these properties of tumors has become very crucial. Current treatments for HNSCCs include surgery, chemo-radiotherapy, and targeted therapy.

The first evidence of cancer stem cells (CSCs) was observed in acute myeloid leukemia[4], where it was reported that only 10000 cells expressing $CD34^+/CD38^-$ could give rise to leukemia in non-obese diabetic-severe combined immunodeficient (NOD-SCID) mice. These cells possess high tumorigenic potential, which are termed as CSCs. CSCs exhibit stem cell-like properties such as self-renewal, slow cycling, and the ability to divide and differentiate into various sub-populations[5]. Further, CSCs were isolated from solid tumors such as breast cancer, HNSCCs, colorectal cancer, ovarian cancer, lung cancer, *etc*[5].

Owing to their unique properties, these CSCs escape the current treatment regimes, thereby adversely affecting patient survival. Therefore, to design an effective treatment regime in order to achieve better efficiency and treatment outcome, it is crucial to understand the molecular mechanism involved in maintaining these CSCs within the tumor. In this review, we focus on the tongue squamous cell carcinoma (TSCC) and have summarized the known molecular markers of CSCs, molecular signaling involved in the regulation of CSCs, the inhibitors used in clinics for treatment, and the ones that are in clinical trials.

CSC MARKERS FOR TSCC

CD44 and variants

CD44 is a single-chain proteoglycan transmembrane glycoprotein expressed on human embryonic stem cells at the developmental stages of cell types such as bone marrow and connective tissue. CD44 interacts with molecules such as hyaluronic acid (HA), collagen, osteopontin, fibronectin, chondroitin and serglycin/sulfated proteoglycan. CD44 has variant isoforms such as CD44, CD44s, CD44v3, CD44v6, CD44v8-10[6] with HA as the most specific ligand for CD44 and its isoforms[6].

The first report of isolation and characterization of CSCs from HNSCC showed that 5000 $CD44^+/Lin^-$ cells gave rise to *in vivo* tumors in NOD-SCID mice[7]. CD44 expression is co-related with the expression of known stem cell marker BMI-1 in HNSCC cells.

Recently, CD44v3 is reported to be overexpressed in HNSCC tumors as compared to the cut margin. Transfection of CD44v3 in the HNSCC cells increases cell migration[8]. Tumor cell growth, migration, matrix metalloproteinase activity, and lymph node metastasis in patients are associated with CD44v3

overexpression in HNSCC cells[9]. Decreased expression of CD44v9 co-relates with poor overall survival (OS) in TSCC[10]. Overexpression of CD44 co-relates with tumor invasiveness and epithelial-mesenchymal transition (EMT). Expression of CD44 in invasive margins of OSCC was associated with samples showing poor histopathological differentiation, high tumor budding activity, and single-cell invasion[11]. Further, increased expression of CD44, together with increased expression of NANOG was associated with poor survival in HNSCC patients as compared to those showing low expression of CD44 and NANOG[12].

Cells overexpressing CD44 ($CD44^+$) showed self-renewal property with high tumorigenic potential, metastasis, and chemo-resistance. Therefore, $CD44^+$ cells in HNSCC tumors are considered as CSC-rich population. CD44, paired with the overexpression of other stem cell markers, such as aldehyde dehydrogenase (ALDH) and CD133, are being used for the isolation of CSCs from HNSCC tumors[13]. In TSCC, $CD44^+/CD133^+$ cells showed stem cell-like properties such as high proliferation, invasion, and migration with high tumorigenicity[13].

There have been recent reports linking $CD44^+$ cells in HNSCC tumors to early angiogenesis[14], lymph node metastasis[15], and occult metastasis[16]. Moreover, overexpression of CD44 in adjacent normal epithelia of TSCC co-related with clinical stage and nodal metastasis in patients[17]. CD44 mRNA expression did not show any co-relation with age, sex, smoking history, size of the tumor, or 5-year survival rate[18].

ALDH

ALDH is an enzyme superfamily which converts aldehydes to carboxylic acids that are involved in drug resistance and detoxification. The human ALDH1A subfamily is involved in the retinoic acid pathway, which regulates gene expression and cell development in both normal and cancer cells. The enzymes belonging to ALDH1A subfamily viz., ALDH1A1, ALDH1A2, and ALDH1A3 are located in the cytosol that catalyze the irreversible conversion of retinaldehyde to retinoic acid.

Amongst the ALDH1A subfamily, ALDH1A1 is overexpressed in the CSCs of HNSCC. Overexpression of ALDH has co-related with overexpression of other stem cell markers such as OCT-3/4, NANOG, STELLA, SNAIL, and BMI-1 in HNSCC. $ALDH^{high}$ cells have also been shown to have increased *in vitro* sphere formation ability and *in vivo* tumorigenesis ability[19,20]. Higher expression of ALDH also co-related with poor patient survival. Importantly, 500 $ALDH^{high}$ cells isolated from HNSCC tumors showed a higher tumorigenic potential upon *in vivo* serial transplantations as compared to $ALDH^{low}$ cells[21]. High expression of ALDH1A1 in oropharyngeal carcinoma co-related with poor differentiation in tumors and poor OS patterns in patients[22]. $ALDH^{high}$ TSCC cells showed serum independency and a higher ability to form tumorospheres than $ALDH^{low}$ cells. $ALDH^{high}$ cells also exhibited overexpression of stem cell-related genes such as NOTCH2[23]. ALDH1A1 expression was directly co-related with OS and lymph node metastasis in HNSCC[24]. The study showed a co-relation of ALDH1A1 expression with TWIST1 expression in primary tumor tissues and lymph node metastases. Recent reports have demonstrated the involvement of ALDH isoforms in cisplatin resistance in HNSCC. Treating cells with ALDH inhibitors showed decreased cell viability and reduced tumor burden *in vivo* when given in combination with cisplatin as compared to only cisplatin treatment. This study also showed that treating cells with the ALDH3A1 activator along with cisplatin increased cell survival[25]. Overexpression of ALDH1A1 in HNSCC tissues co-relates with poor survival as compared to low ALDH1A1 expression[26]. Additionally, the expression of ALDH1 increased from epithelial dysplasia to oral carcinoma, that co-related with poor survival rates in OSCC patients[27]. In addition, low ALDH1A1 in the HNSCC patients showed significantly better OS as compared to high ALDH1A1 expression[25].

CD133

CD133/AC133/prominin-1 is a 97 kDa pentaspan transmembrane glycoprotein encoded by the prominin 1 (*PROM1*) gene. CD133 protein has an intracellular C-terminal domain, an extracellular N-terminal domain, and five transmembrane segments[28].

Spheroids obtained from HNSCC patient tumor cells showed higher CD133 expression than normal epithelial cells[29]. High expression of CD133 with high expression of CD44 and CD117 was observed as marker of CSCs in OSCC cells[30]. TSCC cells overexpressing CD133 showed a higher *in vitro* and *in vivo* tumorigenicity as compared to cells with low expression of CD133[31]. Recent reports showed that $CD133^+$ OSCC cells exhibit properties such as self-renewal, drug resistance, higher tumorigenic potential, and higher growth rate as compared to $CD133^-$ cells. Further, increased expression of stem cell markers such as NANOG, OCT4, SOX2, and ALDH1A1 in $CD133^+$ cells suggested that CD133 is a potential CSC marker for OSCC CSCs[32]. TSCC-derived spheroids were reported to overexpress CD133[33].

Other markers

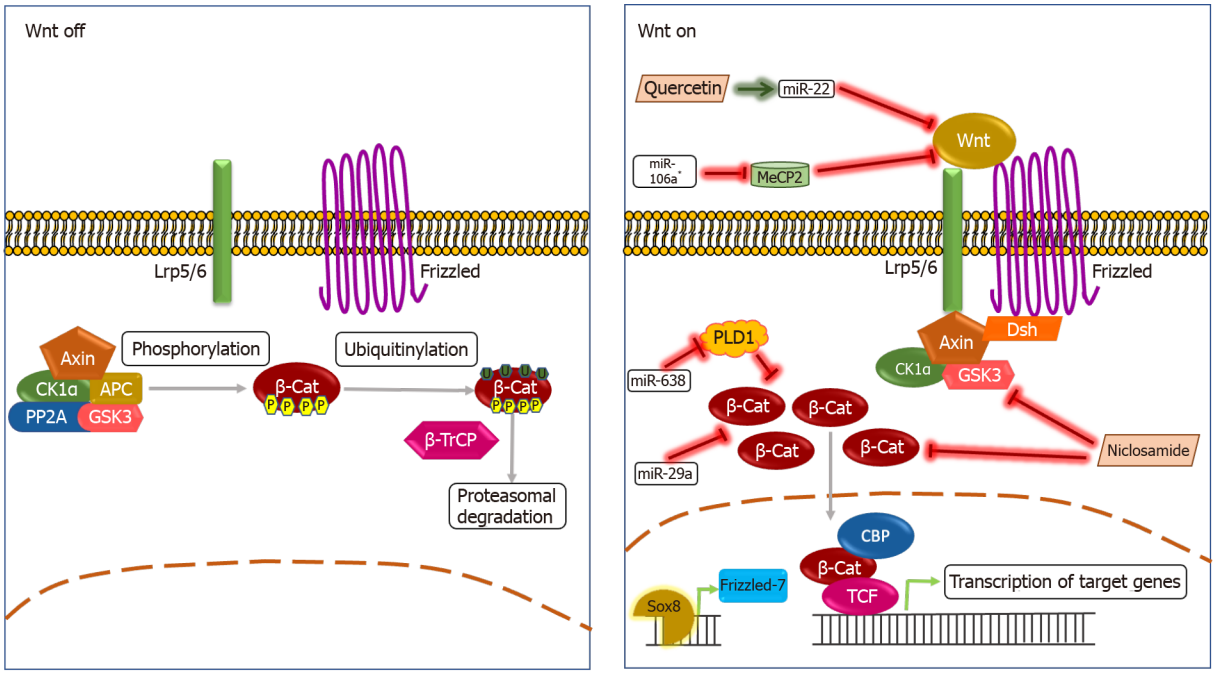
Stemness markers such as OCT-3/4, NANOG, SOX2, KLF-4, and BMI-1 have been associated with characteristics such as self-renewal, pluripotency, and development of embryonic stem cells are overexpressed in CSCs in TSCCs.

Invasive TSCC cells overexpressing CD44 and SOX9 showed a higher expression of SOX2 and OCT-4 [34]. SOX2 overexpression in TSCC tissues co-related with poor OS in patients[35]. In addition, SOX2 overexpression co-related with tumor size, cell differentiation, nodal metastasis, and clinical TNM stage. In TSCC cells, the knockdown of SOX2 showed a decrease in cell proliferation, cell migration and invasion, and colony forming, which was reversed with overexpression of SOX2[36]. Moreover, an increased SOX2 expression was associated with poor OS, disease-specific survival, and disease-free survival (DFS) in TSCC[37]. Downregulation of SOX2 by MTA-3 was reported to repress CSC properties and tumor growth in TSCCs, and patients exhibiting $MTA3^{low}/SOX2^{high}$ showed the worst prognosis [38]. Additionally, SOX2 regulated HEY1, which in turn regulates NOTCH4 expression, followed by increased EMT in HNSCC cells[39].

The expression of both OCT-3/4 and NANOG was high in side population cells that co-related with distant metastasis[40]. Also, high OCT-4 expression in TSCC samples and NANOG in adjacent cut margin tissues have been reported as indicators of lymph node metastasis and worse prognosis[12]. Furthermore, TSCC showed an association between BMI-1 overexpression and increased proliferation, nodal metastasis, and decreased OS in patients. Further, knocking down BMI-1 in TSCC cells showed a reduction in cell proliferation and migration, increased cell apoptosis, senescence, and cisplatin sensitivity[41]. Ectopic overexpression of BMI-1 increased susceptibility of tongue carcinogenesis after exposure to 4-nitroquinoline-1-oxide in mice. The ectopic expression of BMI-1 was shown to regulate the pathways such as mTOR signaling, EIF2 signaling, and p70S6K signaling[42]. Additionally, high expression of OCT4 and BMI-1, along with ALDH1, co-related with poor survival in OSCC patients[27].

The *TRIM* (tripartite motif) gene family have ubiquitin ligase function that plays an important role in various human diseases such as muscular dystrophies and atrophies and HIV infections *etc*[43]. A recent report showed that overexpression of TRIM14 induces CSC-like properties with an increased sphere formation ability and cisplatin resistance in TSCC cells. Further, on inhibition of TRIM14 by miR-15b, these characteristics were reversed, implying that TRIM14 might play an important role in the maintenance of these properties[44].

MOLECULAR SIGNALING



The Wnt pathway

The Wnt signaling consists of the Canonical (involving β-catenin) and non-canonical pathways. Canonical Wnt signaling initiates when Wnt ligand binds to FRZ receptor and low-density LRP5/6 co-receptors. In the absence of the Wnt ligand, a complex of Axin, APC, GSK3, and CK1 phosphorylates β-catenin, leading to ubiquitination and subsequent proteasomal degradation of β-catenin. When present, Wnt ligand binds to FRZ receptor leading to FRZ-induced LRP5/6 phosphorylation followed by activation of the scaffold protein DVL. Activated DVL recruits Axin to receptors, which then inhibits the phosphorylation of β-catenin. Subsequently, β-catenin translocates into the nucleus promoting the transcription of Wnt target genes by interacting with T cell-specific factor/lymphoid enhancer-binding factor. Proper functioning of the Wnt signaling pathway is important for embryonic development and self-renewal of normal stem cells[45]. Deregulated Wnt signaling is involved in the development of various cancers such as colorectal cancer, epidermal cancer[46], hepatocellular carcinoma, breast cancer, glioma, *etc*[47].

Recent studies showed that the suppression of the Wnt signaling inhibits the progression of OSCC. Micro RNAs such as miR-29a[48], miR-638[49], miR-106a*[50], *etc.*, have been shown to suppress tumor progression by regulating the Wnt signaling. The miR-638 and miR-106a* regulate Wnt through downregulating oncogenes PLD1 and MeCP2, while miR-29a caused reduction in β catenin levels. In addition, chemical compounds such as quercetin (bioactive flavonoid) and niclosamide (anthelminthic) were reported to inhibit tumor progression by affecting the Wnt signaling in OSCC. Quercetin induced miR-22 expression, thereby inhibiting the Wnt1/β catenin axis[51], while Niclosamide downregulated the expression of β-catenin, DVL2, phosphorylated GSK3β, and Cyclin D1[52]. SOX8 was shown to regulate chemo-resistance and EMT in TSCC cells by activating the Wnt pathway suggesting that it might play a crucial role in the maintenance of tongue CSCs[53]. Furthermore, the spheroid forming ability and expression of CSC markers (CD44 and ALDH) was negatively impacted in the presence of the Wnt antagonist sFRP4 in tongue carcinoma cells. In presence of the Wnt ligand, WNT3a, these properties were reverted[54]. The Wnt on and off pathway and its role in TSCC is shown in (Figure 1).

The Hedgehog pathway

The Hedgehog pathway has three different types of ligand proteins in mammals such as Sonic-Hedgehog (SHH), Indian-Hedgehog, and Desert-Hedgehog. The ligand binds to the receptor PTCH1 and removes the inhibition on the transmembrane protein Smoothened (SMO). This further leads to SMO accumulation in the cytoplasm. Subsequently, the translocation of glioma-associated oncogene (Gli) proteins into the nucleus initiates the transcription of target genes that are involved in intercellular communication, organogenesis, regeneration, and homeostasis[55].

DOI: 10.4252/wjsc.v15.i5.438 **Copyright** ©The Author(s) 2023.

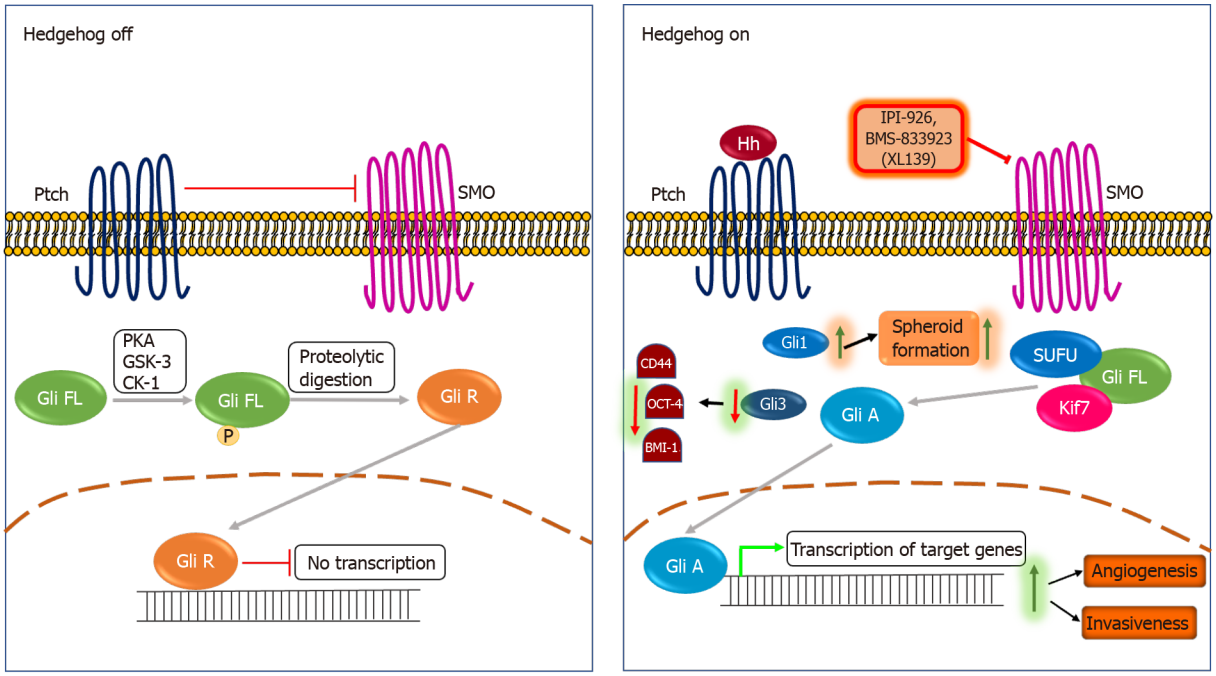


Figure 1 The Wnt signaling pathway and cancer stemness. In the absence of a Wnt ligand, in the canonical pathway,, a complex of Axin, CK1α, APC, PP2A, and GSK3 (termed destruction complex) phosphorylates β-catenin targeting it for ubiquitinylation, that leads to its proteasomal degradation. When the Wnt ligand binds to the Frizzled receptor and LRP5/6 co-receptor, the destruction complex gets localized to the receptor, preventing the degradation of β-catenin that localizes to the nucleus that further activates transcription of the target genes. It has been reported that miRNAs such as miR-29a, miR-638, and miR-106a* reduce levels of β-catenin and Wnt ligand. The miR-638 targets PLD1, a generally accepted oncogene, leading to the reduction β-catenin levels[49]. The miR-29a also directly causes a reduction in β-catenin levels in TSCC cell lines[48]. The miRNA miR-106a* causes a reduction in MeCP2 (a gene expression regulator and oncogene) levels that inhibit the binding of Wnt ligand to the receptor that in turn causes downregulation of the Wnt pathway[50]. Chemical compounds such as Quercetin and Niclosamide downregulate the Wnt signaling pathway. Quercetin causes an increase in levels of miR-22 that in turn inhibits the Wnt1/β-catenin axis [51], while Niclosamide directly binds to DVL2, phosphorylated GSK3β, and Cyclin D1 that reduces levels of β-catenin[52]. Sox8 is shown to activate the Wnt pathway by inducing the expression of Frizzled-7[53].

Hedgehog pathway activation promotes angiogenesis in OSCC. Overexpression of SHH ligand in human TSCC and expression of PTCH1, Gli1, and Gli2 proteins in microvascular cells have been observed in the tumor invasive front[56]. The involvement of Hedgehog pathway has been shown in angiogenesis by macrophages and endothelial cells[57]. Hedgehog and TGFβ signaling are involved in bone invasion and destruction. Gli2 expression is associated with bone invasion. Silencing of Gli2 showed a reduction in invasiveness in orthotopic mice models[58]. Gli3 knockdown in TSCC cells have resulted in the downregulation of the CSC markers such as CD44, OCT-4, and BMI-1 genes and a reduction in CSCs[59]. Further, increased expression of Gli1 has been shown in spheroid forming cells in TSCC cell line[60]. The Hedgehog pathway and its role in TSCC have been shown along with inhibitors in clinical trials for various cancers except for HNSCC (Figure 2).

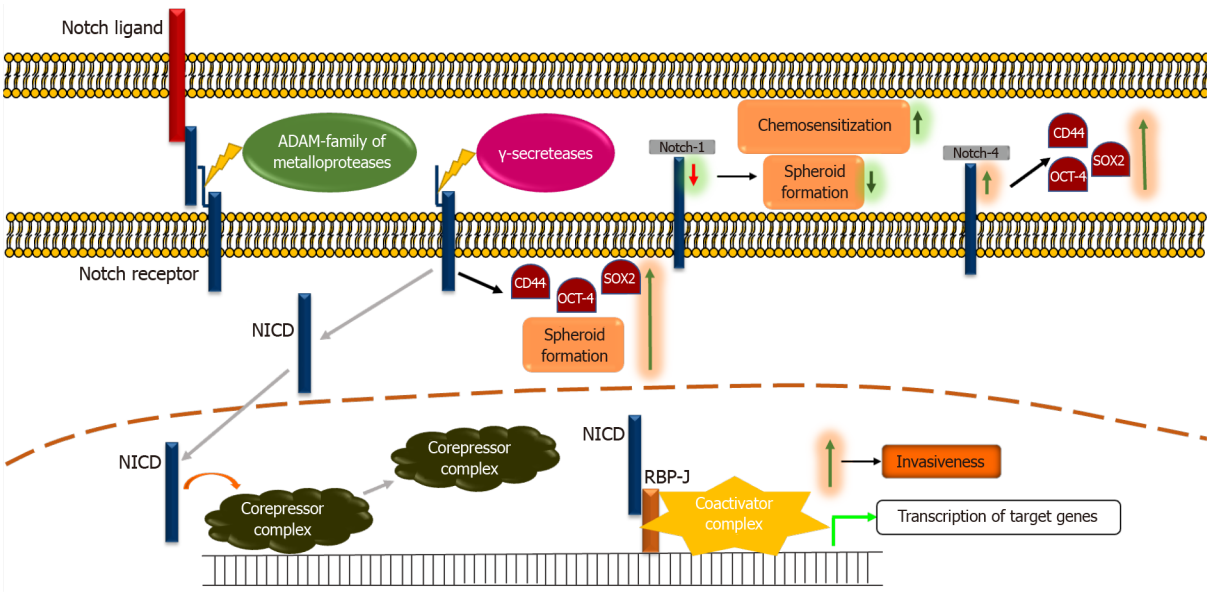
The Notch pathway

The Notch pathway has four receptors such as NOTCH 1, NOTCH 2, NOTCH 3, and NOTCH 4. The ligands are of two types, viz. Delta-like ligands (DLL1, DLL3 and DLL4) and Jagged ligands (JAG1 and JAG2). Notch pathway also involves proteolysis by metalloprotease, tumor necrosis factor-α-converting enzyme (TACE), and γ-secretase. The binding of the ligand to the receptor releases the extracellular domain by TACE activity, which then binds to the receptor on an adjacent cell, while the intracellular domain is cleaved by γ-secretase activity that further gets translocated into the nucleus, which acts like a transcriptional factor for the activation of the target genes (HES family, HEY, NF-κB, VEGF, and c-MYC) [61].

Notch signaling has been shown to induce EMT in OSCC cells. Activation of Notch signaling is directly co-related with the expression of markers such as E-cadherin and Vimentin and increased invasiveness of OSCC cells[62,63]. Decreasing NOTCH1 in the TSCC cells showed a reduction in the invasiveness of the cells and decreased expression of MMP-2 and MMP-9 (associated with metastasis and invasion) in TSCC[64]. Additionally, activation of the notch intracellular domain in TSCC cell line co-related with stemness characteristics such as spheroid formation and expression of stemness markers viz. OCT4, SOX2 and CD44. The knockdown of NOTCH1 co-related with chemo-sensitization and loss of spheroid-forming ability. Further, high expression of NOTCH1 showed a significantly poor OS as well as DFS in HNSCC patients[65]. Further, NOTCH4 expression promoted cell-cycle dysregulation,

DOI: 10.4252/wjsc.v15.i5.438 **Copyright** ©The Author(s) 2023.

Figure 2 The Hedgehog signaling pathway and cancer stemness. In the absence of Hedgehog ligand, Patched inhibits smoothened (SMO), leading to the full-length Gli protein that gets phosphorylated by PKA, GSK-3 and CK-1 and converted into Gli repressor through proteolytic digestion. The Gli repressor further inhibits the Hedgehog pathway. When the Hedgehog ligand binds to the Patched receptor, the inhibition on SMO is released, leading to the dissociation of Gli from SUFU and Kif7 that lead to the activation of the Gli protein (Gli A). Further, Gli A translocates to the nucleus that further activates transcription of target genes. Activation of the Hedgehog pathway promotes angiogenesis and invasiveness *in vivo*[57,58]. Downregulation of Gli3 reduces expression of stemness markers such as CD44, OCT-4, and BMI-1 in tongue carcinoma (TSCC) cells[59], while upregulation of Gli1 increases the spheroid formation ability of TSCC cells[60]. IPI-926 and BMS-833923 (XL139) are SMO inhibitors used to therapeutically target the Hedgehog pathway. IPI-926 is a semi-synthetic derivative of cyclopamine, while BMS-833923 (XL139) is a small molecule inhibitor of SMO. Ptch: Patched; SMO: Smoothened; Hh: Hedgehog ligand; Gli FL: Full length glioma associated oncogene; Gli A: Gli activator; Gli R: Gli repressor; IPI-926, BMS-833923 (XL139): Smoothened inhibitors.



cell proliferation, drug resistance, and inhibition of apoptosis. Elevated expression of NOTCH4 along with HEY1 co-related with OCT4, SOX2, and CD44 overexpression that showed increased migration and invasion in TSCC cells[66]. Recently, it was reported that a STAT3-activated long non-coding RNA, hepatocyte nuclear factor 1 homeobox A antisense RNA 1, promoted tumorigenesis by activating the Notch pathway in OSCC cells[67]. Further, high expression of NOTCH1 and JAG1 have been shown to be predictors of poor OS as well as DFS in oral carcinoma patients[68]. The notch signaling pathway and its role in TSCC is shown in (Figure 3).

The HGF/c-MET pathway

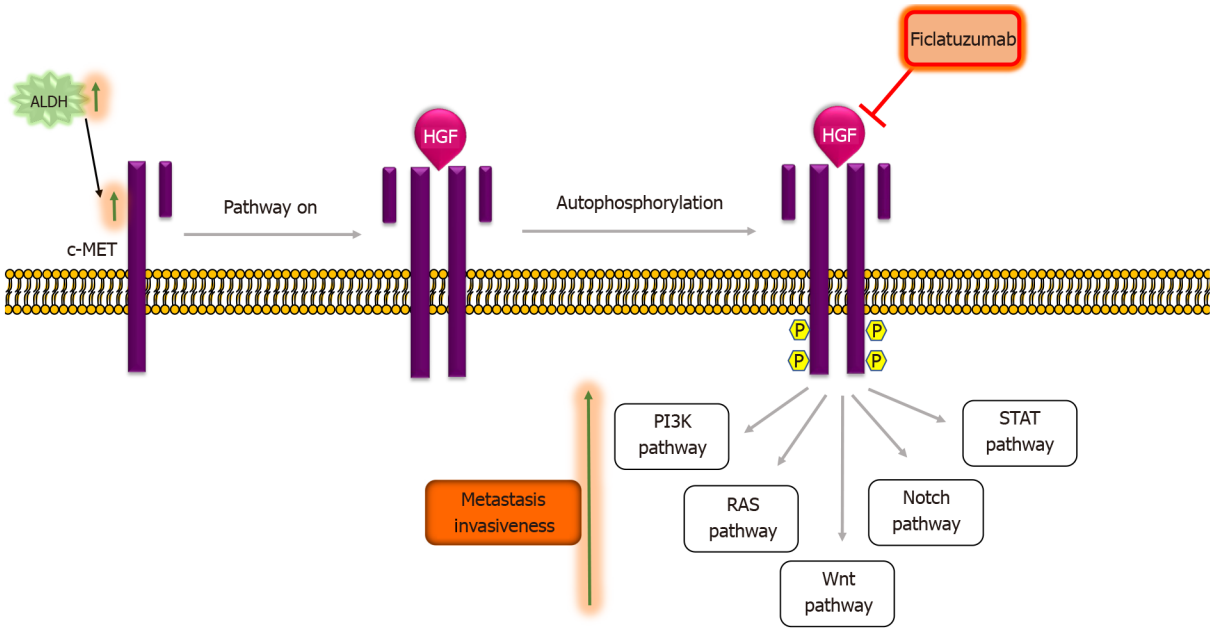
The HGF/c-MET pathway is involved in tumorigenesis in various cancers such as HNSCC, non-small cell lung cancer, hepatocellular carcinoma, ovarian cancer, bladder cancer, cervical cancer, *etc.*[69]. The binding of ligand HGF to the kinase receptor c-MET leads to the dimerization of two subunits. The dimerization results in the auto-phosphorylation of tyrosine residues in the cytoplasmic domain of the receptor, which then creates a docking site for various adaptor proteins that regulate pathways such as PI3K/AKT pathway and Wnt pathway[69].

HGF treatment has been shown to increase the expression of CSC markers and sphere forming ability of HNSCC cells, which were decreased upon c-MET knockdown. The transcriptional level of c-MET was higher in cells with high ALDH activity (one of the HNSCC CSC markers). Moreover, c-MET knockdown in the HNSCC stem-like cells resulted in better survival in *in vivo* orthotopic tongue xenograft models[70].

Significant co-relation has been observed in TSCC between the c-MET expression and tumor stage, nodal status, clinical stage, locoregional recurrence, and distant metastasis. In addition, high expression of c-MET and autocrine motility factor receptor (AMFR) was associated with worse DFS. The study suggested that c-MET and AMFR expression can be potent prognosis marker that targets to decrease metastasis in OSCC[71]. Immunostaining for the c-MET showed a significant co-relation with lymph node metastasis, recurrence, and pathological stage of TSCC[72]. High c-MET expression was co-related with lymph node metastasis, greater depth of invasion, decreased patient survival, increased invasion & migration in *in vitro* and subcutaneous *in vivo* mice model injected with TSCC cells[73]. Further, the knockdown of c-MET has shown to reduce cervical lymph node metastasis and improve survival patterns in *in vivo* models[74]. Overexpression of c-MET was shown to co-relate with occult metastasis

DOI: 10.4252/wjsc.v15.i5.438 **Copyright** ©The Author(s) 2023.

Figure 3 The Notch signaling pathway and cancer stemness. In absence of the Notch ligand, the Notch pathway is in the inactivate state. The binding of ligand to the Notch receptor leads to cleavage by ADAM-family metalloproteases releasing the extracellular domain of the receptor. Further, the receptor is cleaved by γ-secretase leading to the formation of the Notch intracellular domain (NICD), thereby activating it. The NICD then translocates to the nucleus and releases inhibition on the target genes by dissociating the corepressor complex and forms a complex with RBP-J and co-activator complex thereby activating the transcription of target genes. Further, knockdown of Notch-1 expression has been shown to increase chemo-sensitization and decrease the spheroid formation ability of tongue squamous cell carcinoma (TSCC) cells[64]. An increase in Notch-4 levels increases stemness markers such as CD44, SOX2, and OCT-4 in TSCC cells[66]. NICD activation has been shown to increase levels of CD44, OCT-4, and SOX2 in TSCC cells[65]. Activation of the Notch pathway increases the invasiveness in TSCC cells[62,63,66,67]. NICD: Notch intracellular domain.



in TSCC[75]. The HGF/c-MET pathway and its role in TSCC is shown along with inhibitor in clinical trials for various cancers except for HNSCC (Figure 4).

Other pathways

The transcription factor Nrf2 has been shown to induce the expression of genes involved in cellular antioxidant and anti-inflammatory responses. Normally, Nrf2 is located in the cytoplasm. Upon activation, it translocates to the nucleus, forming heterodimers with proteins such as c-JUN and small musculoaponeurotic fibrosarcoma protein that bind to antioxidant response element, which regulate the expression of around 200 genes that regulate anti-inflammatory and antioxidant response. Nrf2 is involved in the regulation of mitochondrial biogenesis pathways[76]. A compound named Plumbagin is shown to suppress EMT and stemness characteristics by regulating redox homeostasis and inducing reactive oxygen species (ROS) generation within the cell by suppressing the Nrf2-regulated pathways [77].

The Hippo/transcriptional coactivator with PDZ-binding (TAZ) signaling pathway is also involved in the regulation of properties such as cell proliferation, apoptosis, invasion, migration *etc.* in TSCC. When the pathway is off, the Yes-associated protein (YAP) and TAZ motif translocate to the nucleus, thereby inducing the transcription of various genes by binding to the TEA domain family proteins and other transcription factors. LATS1 is activated by MST1 with Salvador through phosphorylation, which then phosphorylates the YAP/TAZ, retaining it in the cytoplasm, which then binds to 14-3-3 and gets degraded[78]. Factors such as HIF-1α[79] and epigallocatechin-3-gallate[80] affect the Hippo pathway to modulate proliferation, apoptosis, invasion, and migration in TSCC cells.

Approximately 90% HNSCCs overexpress the EGFR pathway[81]. The EGFR is a receptor tyrosine kinase of the ErbB family. The ligands of the EGFR are EGF, heparin-binding EGF, and TGFα. Upon receptor-ligand binding, the inactive monomer of the receptor dimerizes, either with another monomer of EGFR forming a homodimer or with another ErbB family receptor forming a heterodimer. This active dimer then auto-phosphorylates the C-terminal domain of the receptor providing a docking site for the phospho-tyrosine binding domain and Src homology 2 domain resulting in the activation of several signaling pathways such as MAPK, PI3K/Akt pathway, and phospholipase Cγ pathways[82]. Stimulation of OSCC cells by EGF showed an induction of EMT in the cells, which revealed morphological changes with the downregulation of E-cadherin and the upregulation of vimentin in the cells. In addition, stimulated cells showed enrichment of stem-like population ($CD44^+/CD24^-$) with an increase in CSC markers such as ALDH1 and BMI-1, suggesting that EGF may be responsible to induce CSC properties in OSCCs[83].

Figure 4 The HGF/c-MET signaling pathway and cancer stemness. In the absence of the HGF ligand, the HGF/c-MET pathway remains inactivated. The binding of the HGF ligand to the c-MET kinase receptor results in the dimerization of two subunits that further leads to auto-phosphorylation of the tyrosine residues in the cytoplasmic domain of the receptor creating a docking site for adaptor proteins, which regulate pathways, such as PI3K, RAS, Wnt, Notch and STAT pathway. Transcriptional levels of c-MET were high in ALDH^{high} cells[70]. Activation of c-MET results in an increase in invasiveness and metastasis *in vitro* as well as *in vivo*[73, 74]. Ficlatuzumab is a humanized IgG1 monoclonal antibody targeting HGF used to therapeutically target the HGF/c-met pathway. ALDH: Aldehyde dehydrogenase; Ficlatuzumab: HGF/c-MET pathway inhibitor.

Ephrin (EPH) receptors and their ligands play important roles in controlling the actin cytoskeleton and cellular responses, including attraction/repulsion, migration, and cell positioning during developmental stages[84]. Recent report has shown regulation of the expression of stemness markers by EPHA10. EPHA10 and its ligand EFNA4 increased cell migration, sphere formation, and expression of markers such as SNAIL, NANOG, and OCT4 in OSCC cells. It was also reported that high mRNA levels of EFNA4 with NANOG or OCT4 co-related with poor survival patterns in OSCC patients[85].

CURRENT TREATMENT REGIME

The current treatment regime for HNSCCs is dependent on the TNM staging of the carcinoma based on T (tumor size considering the depth of invasion), N (nodal metastasis considering extranodal extension or ENE), and M (presence of distant metastasis)[86]. For early stage of cancer, single modality treatment, in which mostly surgery, is preferred. With the progression of disease manifested either through larger tumor dimensions or nodal metastasis, multimodality in treatment is employed, wherein surgery is followed by adjuvant chemotherapy or radiotherapy. In case of distant metastasis, where surgical intervention is difficult, chemotherapy is the preferred choice. Further, administration of adjuvant chemo or radiation therapy following surgery is shown to exhibit better patient survival[87]. Chemotherapeutic agents commonly administered are cisplatin, carboplatin, docetaxel, 5-fluorouracil, methotrexate, and paclitaxel. Radiotherapy is also employed in cycles of 1.8-2 Gy/day with a total dose of 66-72 Gy[88]. Targeted therapies, specifically acting on certain upregulated pathways, such as EGFR, are administered. For example, cetuximab targets the EGFR pathway in HNSCC patients or anti-PD1 agents for immunotherapy in HNSCC. Agents such as pembrolizumab and nivolumab, which target PD-1, have shown promising results in clinical trials[87]. Although, recent reports highlighted that owing to heterogeneity in PD-L1 expression throughout tumors and utilization of different methods and antibodies, there might arise errors in immuno-histochemical assessment of PD-L1 prior to therapy decisions[89-92]. In the course of currently existing assessment methods across various cancers, Marletta *et al*[91] observed that in HNSCC, the registration trial utilized the 22C3 clone (Dako) on Agilent autostainer link 48 while the European Medicines Agency granted administration of immunotherapy regardless of antibody, and the instrument used. The reports emphasized on the establishment of a standardized uniform protocol considering the heterogeneity of expression as well as the antibodies and platforms used for the assessment of PD-L1 before deciding whether immunotherapy should be administered to the patients[89-92].

Table 1 Clinical trials currently active for head and neck squamous cell carcinoma

Region	Drug name	Target	Phase	NCT number
Worldwide	Everolimus	Inhibitor of mTOR	I	NCT01637194
	Cetuximab	Monoclonal anti-EGFR antibody		
	Bevacizumab (with fluorouracil and hydroxyurea)	Anti VEGF-A antibody	I	NCT00023959
	Trastuzumab (with IL-12)	Monoclonal anti-EGFR antibody	I	NCT00004074
	Erlotinib	Tyrosine kinase receptor (EGFR)	I, II	NCT00101348
	Cetuximab	Monoclonal anti-EGFR antibody		
	With or without bevacizumab	Anti VEGF-A antibody		
	Erlotinib hydrochloride	Tyrosine kinase receptor (EGFR)	I, II	NCT00101348
	Cetuximab	Monoclonal anti-EGFR antibody		
	Erlotinib hydrochloride	Tyrosine kinase receptor (EGFR)	I	NCT00397384
	Cetuximab	Monoclonal anti-EGFR antibody		
	Zalutumumab (after radiotherapy)	Monoclonal anti-EGFR antibody	III	NCT00496652
	Temsirolimus	mTORC1 inhibitor	II	NCT01256385
	With or without cetuximab	Monoclonal anti-EGFR antibody		
	Cetuximab	Monoclonal anti-EGFR antibody	II	NCT00939627
	Sorafenib tosylate	Tyrosine kinase inhibitor		
	Cetuximab	Monoclonal anti-EGFR antibody	II	NCT01316757
	Erlotinib hydrochloride	Tyrosine kinase receptor (EGFR)		
	Varlilumab	Monoclonal anti-CD27 antibody	I, II	NCT02335918
	Nivolumab	Monoclonal anti-PD-1 antibody		
	MEDI7247	Monoclonal anti-ASCT2 antibody conjugated with pyrrolobenzodiazepine dimer	I	NCT03811652
	Cetuximab with lenalidomide	Monoclonal anti-EGFR antibody	I	NCT01254617
	Durvalumab	Monoclonal antibody that blocks PD-1/PD-L1 interaction	I	NCT03144778
	With or without tremelimumab	Monoclonal antibody against CTLA-4		
	Sitravitinib	Inhibitor of receptor tyrosine kinases	Early phase I	NCT03575598
	Nivolumab	Monoclonal anti-PD-1 antibody		
	Nivolumab	Monoclonal anti-PD-1 antibody	I	NCT03229278
	Pembrolizumab with trigriluzole	Monoclonal anti-PD-1 antibody		
	BKM120	PI3K inhibitor	I, II	NCT01816984
	Cetuximab	Monoclonal anti-EGFR antibody		
	FATE-NK100		I	NCT03319459
	Cetuximab	Monoclonal anti-EGFR antibody		
	Trastuzumab	Monoclonal anti-EGFR antibody		
	Nivolumab with SBRT	Monoclonal anti-PD-1 antibody	II	NCT02684253
	BYL719	PI3K inhibitor	II	NCT03292250
	Poziotinib	EGFR inhibitor		
	Nintedanib	Angiokinase inhibitor		
	Abemaciclib	CDK4 and CD6 inhibitor		
	Durvalumab	Monoclonal antibody that blocks PD-1/PD-L1 interaction		

	Tremelimumab	Monoclonal anti-CTLA-4 antibody		
	Nivolumab and tadalafil	Monoclonal anti-PD-1 antibody	Early phase I	NCT03238365
Involving Indian institutes	Gefitinib (Iressa) with cisplatin and radiotherapy	EGFR inhibitor (tyrosine kinase inhibitor)	II	NCT00229723
	Lapatinib	EGFR inhibitor (tyrosine kinase inhibitor)	II	NCT00371566
	Gefitinib with methotrexate	EGFR inhibitor (tyrosine kinase inhibitor)	III	NCT00206219
	P276-00 with EBRT	CDK inhibitor	I, II	NCT00899054
	P276-00	CDK inhibitor	II	NCT00824343
	Lapatinib with chemoradiation	EGFR inhibitor (tyrosine kinase inhibitor)	III	NCT00424255
	Lapatinib with chemoradiation	EGFR inhibitor (tyrosine kinase inhibitor)	II	NCT00387127
	MEDI4736	Monoclonal antibody blocking interaction between PD-L1 with its receptors	III	NCT02551159
	Tremelimumab with chemotherapy	Monoclonal anti-CTLA-4 antibody		

SBRT: Stereotactic radiation therapy.

Recently, a clinical trial consisting of 13 TSCC patients showed that immunotherapy of cytokine-induced killer cells after chemotherapy helped in the reversion of immunosuppression caused during chemotherapy and surgery. Twelve out of thirteen patients survived for more than 90 mo post-therapy. No immune system related toxicities were reported in the surviving patients. No other side effects of the treatment were observed except complaints of aphthous ulcers by two patients[93]. This showed that multiple modality treatments might improve the survival and quality of life of the patients. However, for further improvement in treatment, more targets specific to CSCs need to be explored.

There have been few clinical trials worldwide as well as those involving Indian institutes for newer molecules targeting EGFR pathway, immune checkpoints, PD-L1, cyclin-dependent kinases, *etc.*, as single treatment agent or in combination with other chemotherapeutic agents/radiation in HNSCC (Table 1). However, these trials are still in the early phases and do not particularly target CSCs. Therefore, further detailed study is essential in finding newer targets specific to CSCs in HNSCC.

CONCLUSION

The CSC population plays an important role in therapy resistance, recurrence, and metastasis. These factors adversely affect patients' survival. In spite of several years of research, most of the treatment regimes employed currently target the tumor bulk. CSCs possess self-renewing property, slow cycling, aberrant cell signaling, dynamic ABC transporter system, DNA repair mechanism, epigenetic modifications, and metabolic regulation, *etc.*, which enable CSCs to escape this therapy and thereby play an important role in recurrence, therapy resistance, and loco-regional/distant metastasis.

A better understanding of the aberrant signaling pathways involved in poor prognosis and maintenance of the CSC population would be more effective in improving treatment outcome. Such an understanding would also be important in the prognosis, prediction, and designing of treatment regime that not only reduce the bulk of the tumor but also effectively eliminate the CSC population thereby improving patient survival.

Molecules specifically targeting signaling pathways that regulate the CSC population administered in combination with conventional therapy or as a single treatment modality need to be studied in TSCC. Uncovering the signaling pathways for CSCs, and targeting them would enable better clinical outcomes.

Abstract

Extracellular vesicles (EVs) are nanometric particles that enclose cell-derived bioactive molecules in a lipid bilayer and serve as intercellular communication tools. Accordingly, in various biological contexts, EVs are reported to engage in immune modulation, senescence, and cell proliferation and differentiation. Therefore, EVs could be key elements for potential off-the-shelf cell-free therapy. Little has been studied regarding EVs derived from human pluripotent stem cells (hPSC-EVs), even though hPSCs offer good opportunities for induction of tissue regeneration and unlimited proliferative ability. In this review article, we provide an overview of studies using hPSC-EVs, focusing on identifying the conditions in which the cells are cultivated for the isolation of EVs, how they are characterized, and applications already demonstrated. The topics reported in this article highlight the incipient status of the studies in the field and the significance of hPSC-EVs' prospective applications as PSC-derived cell-free therapy products.

Key Words: Pluripotent stem cells; Extracellular vesicles; Exosome; Cell-free therapy

Core Tip: The research on extracellular vesicles (EVs) derived from different cell types, such as adult stem cells, has shown potential in the treatment of various pathologies. However, little has been explored regarding EVs derived from human pluripotent stem cells (hPSC-EVs). In this review, we provide an overview of studies carried out on these EVs, highlighting methodologies used for the culture of hPSCs for isolating EVs, their characteristics, and potential applications. We note the potential of hPSC-EVs as future acellular therapies. However, studies are in the infancy, and more research is needed to confirm their benefits.

INTRODUCTION

Extracellular vesicles (EVs) are nanometric particles that are enclosed by a lipid bilayer and released by all cell types. They lack a functional nucleus and are therefore unable to replicate[1]. EVs are composed of bioactive factors such as lipids, proteins, and nucleic acids, including mRNAs and non-coding RNAs [2]. EV is an umbrella term that encompasses a heterogeneous population of membrane vesicles generated through a variety of mechanisms. The two major EV subpopulations include microvesicles (MVs) and exosomes (EXOs). EXOs are intraluminal vesicles of endosomal origin released when multivesicular bodies fuse with the plasma membrane, whereas MVs or ectosomes are generated from the outer budding of the plasma membrane[3]. Due to their distinct biogenesis, MVs are generally larger (up to 1000 nm in diameter) than EXOs (less than 200 nm). However, these vesicle populations overlap not only in terms of size but also in composition[4]. Recently, other nomenclatures were described in the "Minimal information for studies of extracellular vesicles 2018" guidelines (MISEV2018) based on the physical characteristics of EVs, for example, size (< 200 nm, small EVs; > 200 nm, medium or large EVs) or density (low, middle, or high)[1].

Potential uses of EVs, such as for the diagnosis and treatment of pathologies or as potential drug carriers, have been investigated. In the field of regenerative medicine, the secretomes of adult stem cells, primarily mesenchymal stem/stromal cells (MSCs), including their EVs, are of great interest as they have been shown to act mainly in a paracrine manner rather than their potential for differentiation[5]. An interesting list of advantages and disadvantages of the use of EVs instead of stem cells has been presented by Öztürk *et al*[6]. Among the advantages of using EVs cited by them and others are low immunogenicity and toxicity; minimal risk of malign transformation; minimal risk of getting trapped in the lung or causing vasculature obstruction; avoidance of contamination with undesired cell types; avoidance of uncontrolled cell division; the ability to manipulate EVs in order to obtain potential improvements; optimization of MSC culture to obtain a higher amount of EVs; and their ability to cross the blood-brain barrier, among others[4,6]. In addition, EVs mimic the beneficial effects of MSCs in cell therapies in a wide range of animal models for different diseases[7-9].

MSC-derived EV (MSC-EV) has been extensively studied and has demonstrated several promising effects, as reviewed by Gowen *et al*[10], Tieu *et al*[11], Fuloria *et al*[12], Kou *et al*[13], and Yudintceva *et al* [14]. However, despite the high potential of MSC-EVs, several factors limit their use. Recently some reviews highlighted the difficulty of establishing criteria to define the specific characteristics of MSC-EV and discussed the great variation in the MSC-EV preparations[15,16]. Disadvantages of MSCs as a source for EVs include the variability between cells derived from different tissues, the variability between different donors, their limited ability to proliferate, the fact that they enter senescence, and genomic instability after a few passages[17]. This raises the question of whether pluripotent stem cell (PSC) derived EVs have a similar to or better therapeutic potential than adult stem cell-derived EVs.

In this context, our objective is to show, using a non-systematic search, studies that use or characterize EVs derived from human PSC (hPSC-EVs) to understand the advances in the area. We also aim to identify the conditions in which the cells are cultivated for the isolation of EVs, how these are characterized, and any demonstrated applications (*in vivo* or *in vitro*).

HPSC-EVS

Overview of hPSCs

hPSCs are characterized by unlimited proliferation and the potential to generate specialized cell lineages [18]. Human embryonic stem cells (hESC) were first isolated from human blastocysts in 1998 by Thomson *et al*[19], and to date, hundreds of hESC lineages have been established worldwide. hESC-based therapeutic technologies have applications in many diseases and conditions, such as spinal cord injuries, age-related tissue degeneration, and diabetes[20]. However, ethical issues related to using cells from embryos have hindered the application of hESCs in research and treatment, leading to the development of the induced PSC (iPSC) technology by Takahashi and Yamanaka[21] and Takahashi *et al* [22]. Since the generation of the first iPSC, many research groups have developed human iPSC (hiPSC) lineages reprogrammed from different adult cells, and obtained lineages very similar to hESC in terms of morphology and differentiation potential[23]. For more information about hPSCs, see Karagiannis *et al*[24], Liu *et al*[25], and Yamanaka[26].

Especially after the discovery of hiPSCs, pluripotent cells represented a promising alternative for regenerative medicine, transplants, disease modeling, and many other research applications[27-29]. The possibility of generating pluripotent cells from patients and, from them, differentiated cells for tissue repair may mitigate common transplant issues, such as immunologic rejection. Nevertheless, the immunogenicity of pluripotent cells remains controversial[30], and the potential for tumorigenesis hinders the wide application of these cells in clinics. The risks of contaminating the differentiated cell populations with remaining pluripotent or proliferative cells, as well as the transmission of active pluripotency transcription factors or the acquisition of mutations by the pluripotent cells during *in vitro* culture[26,31], limit the acceptance of hPSC-based therapies. Therefore, cell-free therapeutic approaches, including EVs, offer promising possibilities for applying hPSC-derived products[32].

It seems that the role of the secretomes of these cells has only recently begun to be investigated, possibly due to the difficulties still encountered in using hPSCs in the clinic. Some interesting studies show that EVs from ESCs could help with embryo implantation[33] and maintaining ESC stemness[34], while others have investigated the biogenesis of ESC-EVs[35,36], although they used murine PSCs. We will focus this review on studies with hPSCs due to their potential clinical applications.

HPSC-EVs: Isolation and characterization methodologies

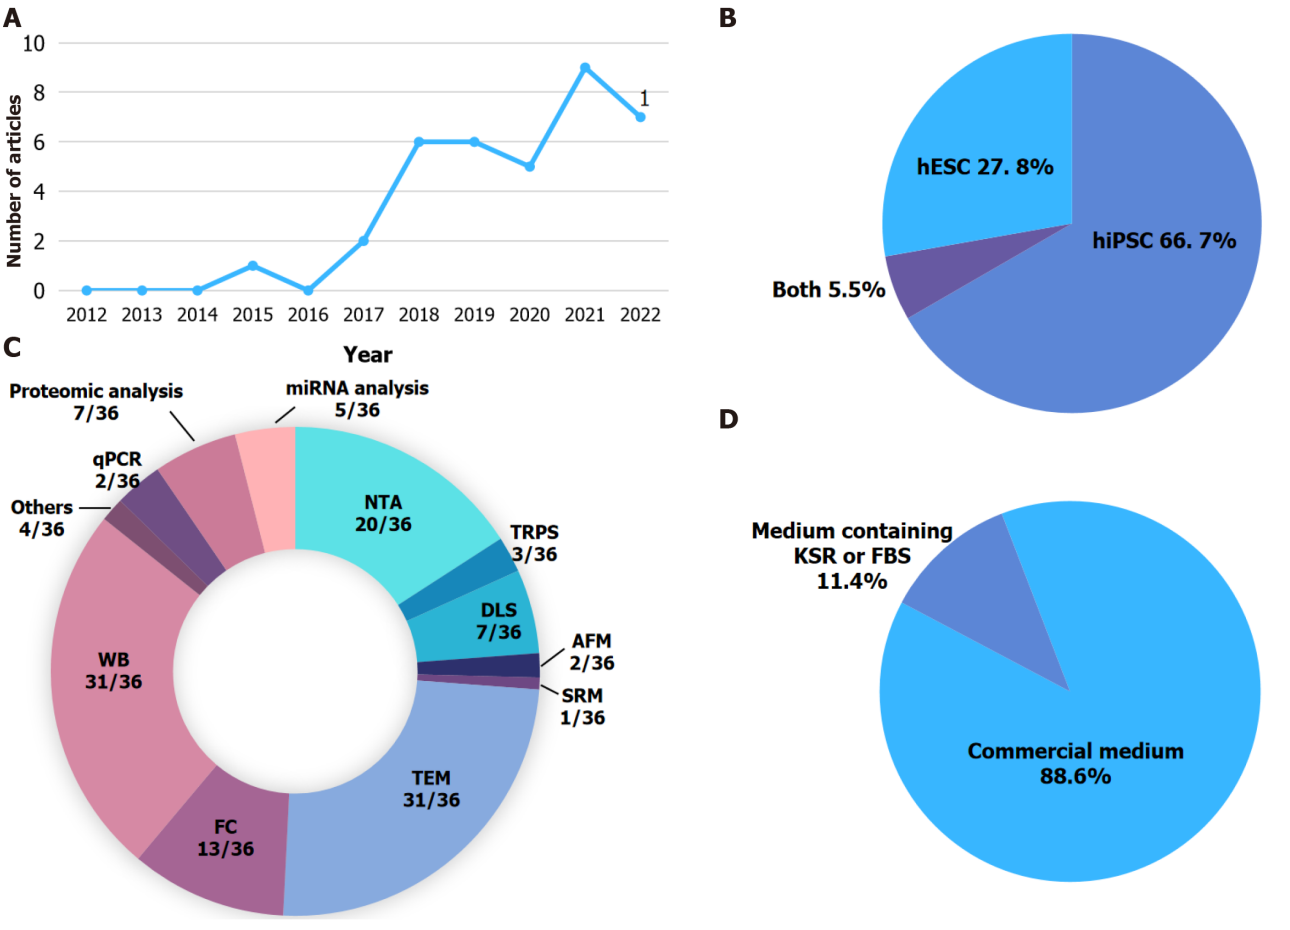
The first investigation on the isolation of EVs from hPSC dates from 2015. In this initial approach, EVs were isolated from hiPSC cultured in Essential 8™ medium using differential centrifugation (DF)/ ultracentrifugation (UC). It was shown that the hiPSC-derived EVs (hiPSC-EV) contain a variety of microRNAs (miRNAs) (such as miR-382, miR-611, and others) related to pathways such as focal adhesion, Wnt, PI3K-Akt, and MAPK signaling, as well as proteins related to processes involved in signal transduction, receptor binding, and others. In addition, the EVs positively affected the metabolism, proliferation, apoptosis rate, and differentiation capacity of cardiac MSCs. Better results were obtained when cells were exposed for only 22 h to EVs[37]. This initial attempt demonstrated how hPSC-EVs could be beneficial and of interest for future acellular therapy applications.

Despite the potential of hPSC-EVs, we observed that the number of publications in this area is still low, and most of the existing publications date from the last five years (Figure 1A, Table 1). Some studies evaluate EVs that were isolated during the differentiation process or from cells that differentiated from PSCs, such as hiPSC-derived keratinocytes[38]; hPSC-derived cardiac progenitors or cardiomyocytes[39-41]; hPSC-derived MSCs[42-44]; hiPSC-derived neurons[45-47]; and hESC-derived chondroprogenitor cells[48]. However, our review explores studies that isolated EVs from undifferentiated hPSCs.

Using a non-systematic search, we found 36 studies that isolate hPSC-EVs mainly from the hiPSC lineages (Figure 1B). Table 1 summarizes these studies, highlighting the cell culture medium used to culture the PSC, time of conditioned medium collection, EV isolation method, and EV mean size. The most common culture media were commercial, with defined components (Figure 1D). The two most common media used were mTeSR™1 (StemCell Technologies) and Essential 8™ medium (Thermo Fisher) (Table 1). A study published by Luo *et al*[49] aimed to optimize culture conditions for isolation of hiPSC-EVs. Using DMEM with different concentrations of EV-depleted KnockOut™ Serum Replacement (ED-KSR), they observed that cells remained viable at a 0.5% ED-KSR concentration and were able to isolate EVs from PSCs cultured in this condition efficiently. However, after 5 d of culture, there was a reduction in the expression of some pluripotency markers. Thus, although it may be cheaper than commercial media, it is necessary to consider the additional step of centrifugation of the KSR to remove particles, as well as the effects of the change in pluripotency-related parameters on the composition and potential of the EVs.

The biggest variations in EV isolation methods relate to the collection time of the conditioned medium: Many studies do not state the conditioning time. In most studies, however, the EVs were isolated after 24 h of cell culture or every 24 h for 3-5 consecutive days (Table 1), avoiding exceeding the 80%-90% cell confluence in the cell cultures. This collection time is possibly related to the nature of PSCs, as the culture medium must be changed daily, and cells must not reach 100% confluence to guarantee their viability and pluripotency.

Other relevant aspects of EVs are their size, morphology, and estimated particle concentrations. Most studies presented the information listed in MISEV2018, including positive and negative protein markers in EVs, usually using the western blot technique (31/36 articles) and performing a single EV analysis mainly using transmission electron microscopy (31/36 articles) to verify EV morphology and nanoparticle tracking analysis (20/36 articles) to verify their mean size and concentration (Figure 1C). The greatest number of studies used small EVs/EXOs, with sizes up to 200 nm (small EVs) (Table 1).



The most common method for hPSC-EV isolation is DF (here defined as the initial centrifugations to remove cellular debris and apoptotic bodies) followed by UC (Table 1). Although this is the most common method used, it is unsuitable for isolating EVs from large-scale experiments and clinical trials. Using a large-scale 2D culture, Andrade *et al*[69] isolated hPSC-EVs using tangential flow filtration (TFF) with or without subsequent UC (TFF + UC). The isolated EVs presented a size of approximately 100 nm, regardless of whether UC had been performed, with similar particle concentration, although TFF + UC resulted in a smaller number of proteins. The effect of different culture conditions (hypoxia - 1% O_2, physiological hypoxia - 5% O_2, and normoxia) on the therapeutic potential of hPSC-EVs was also

investigated. The results showed that EVs derived from hPSC cultured in 1% O_2 (hypoxia) had greater angiogenic potential than those derived under other conditions and that better results were achieved when obtaining EVs using TFF[69].

Another highly discussed topic about PSCs is the possible formation of teratomas, as well as the biodistribution of these cells when applied in *in vivo* models. These concerns also extend to PSC-EVs. To clarify these points, Gu *et al*[75] evaluated the safety and biodistribution of hiPSC-EVs. They used several approaches to show that PSC-EVs are safe, have no adverse effects on cells (*e.g.*, do not cause hemolysis), are not genotoxic, and can be administered by different routes (nasal, intramuscular, or intravenous) without generating adverse effects (*e.g.*, inflammation at the site or pathological changes in the organs of rats).

Potential therapeutic applications of hPSC-EVs

Although few investigations have been carried out with hPSC-EVs, we notice that almost all of them have already applied hPSC-EVs to different disease models, both *in vitro* and *in vivo*. PSC-EVs have been described as having: Protective effects in *in vitro* and *in vivo* models of ischemia-reperfusion kidney injury[64]; neural protective abilities[60]; the capacity to modulate neuroinflammation and protect against ischemic stroke through Treg cell expansion[73]; antifibrotic effects *in vivo* and in *in vivo* models of liver injury[61,72]; and reduced cartilage degradation in an osteoarthritis model[77]. They have shown improvements in wound closure, angiogenesis, and increased nerve fiber density in a wound-healing diabetic mouse model[54,79]; and improved recovery of ovarian function in a premature ovarian failure mouse model[67]. EVs were also associated with acellular nerve grafts, demonstrating their potential to repair peripheral nerve defects[80].

It was also demonstrated that MVs, but not EXOs, dedifferentiated Müller cells into retinal progenitor cells *in vitro*[71]. Other studies showed the ability of PSC-EVs to promote regeneration of diseased or damaged retinas[56] and to accelerate corneal epithelium defect healing *in vivo*[68]. Other potential uses cited for PSC-EVs are: In antitumoral activity[51,63]; in angiogenesis stimulation[69]; as a gene delivery vector[50]; to increase the functional properties of cord blood-derived hematopoietic stem and progenitor cells[70]; and to improve the number of beating EBs depending on the hiPSC origin[66].

One noteworthy effect shown in some studies is the capacity of PSC-EVs to "rejuvenate" different cell types, such as senescent endothelial cells[52,58], senescent human dermal fibroblasts[55], senescent chondrocytes[77], and others. Considering this potential, the hPSC-EVs, hESC-EVs, and hiPSC-EVs were investigated as therapeutic tools for age-related diseases. Regarding neurological diseases, the hPSC-EVs showed potential in recovery of senescent hippocampal neural stem cells in rats with vascular dementia - partially through the transfer of miRNAs that inhibit mTORC1 activation - resulting in an improvement in disease status (*e.g.*, reverse cognitive impairment)[81]. Furthermore, using mice of varying ages, hPSC-EVs were found to rejuvenate hippocampal neural stem cells partly through the transfer of SMAD proteins that activate myelin transcription factor 1 (MYT1), which is reduced in senescent cells, and activates a signaling cascade in the MYT1-Egln3-Sirt1 axis[81].

In an ischemic stroke model, hPSC-EVs reduced the expression of inflammatory cytokines and leukocyte infiltration, and increased the number of regulatory T cells and other immunomodulatory effects that alleviate neurological deficits[73]. They also reduced blood-brain barrier damage in aged stroke mice through blood-brain barrier rejuvenation, partially through the transfer of AKT1 and CALM from EVs to endothelial cells leading to activation of the endothelial nitric oxide synthase-Sirt1 axis[78]. Therefore, hPSC-EVs could be a promising cell-free therapy to treat age-related diseases associated with cellular senescence.

In order to evaluate the benefit of hPSC-EVs compared to other EVs, one interesting study demonstrated that both hiPSC-EVs and hMSC-EVs, isolated through size exclusion chromatography (Table 1), could improve the proliferation of senescent MSCs and alleviate cellular aging in a replicative aging model, possibly modulating reactive oxygen species production with peroxiredoxins presented in EVs. However, despite the similar effects, EVs derived from iPSCs enter target cells more efficiently, and the production of hiPSC-EVs was about 16-fold higher than that of MSC-EVs (using the same culture medium)[59].

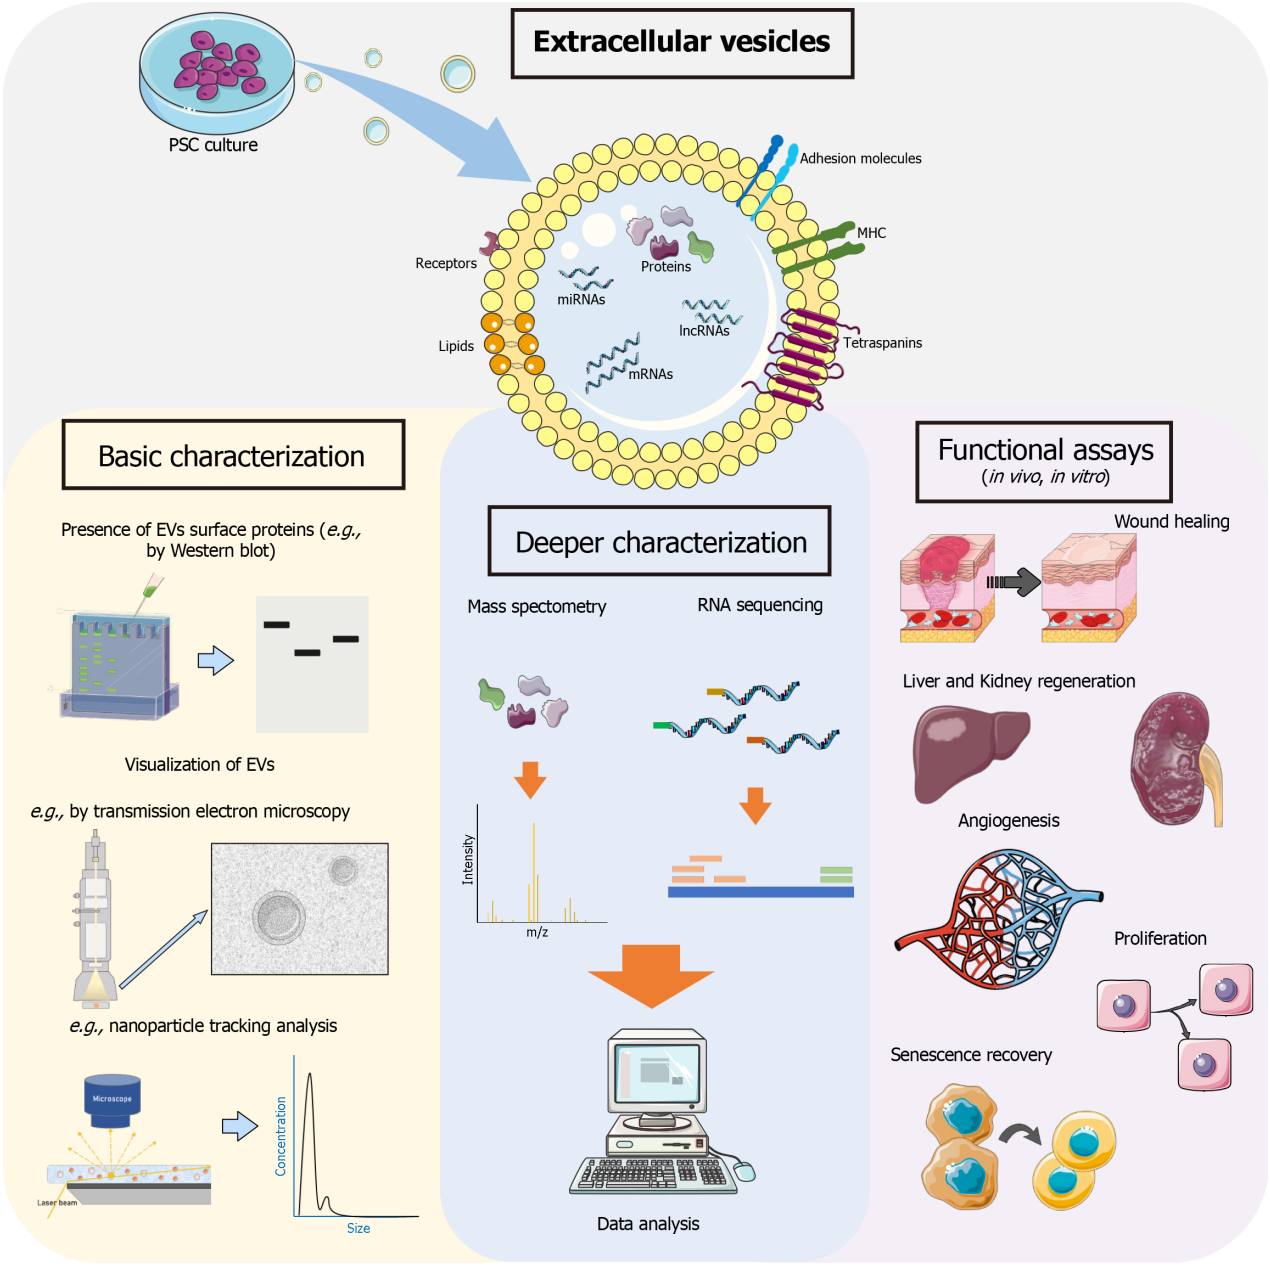
hPSC-EV composition

Even though many articles described the effects of hPSC-EVs, few made deeper characterizations of, for example, the protein and miRNA content of these EVs. Some performed proteomic analysis to help explain some of the effects[59] or as a control (time 0) to study the differentiation process[39,46]. In one interesting approach using high-density lectin microarray, Saito *et al*[57] demonstrated that rBC2LCN, a specific lectin for hPSCs, bound to hiPSC-derived EVs but not to adipose-derived stem cell-, hemodiafiltration-, or chondrocyte-derived EVs, which suggests a particular glycan-signature for hiPSC-EVs, resembling the glycome signature of the cell surface.

One recent study that provided a detailed description of the contents of hPSC-EVs was conducted by Bi *et al*[74]. The proteomics of hESC-, hiPSC-, and hMSC-EXOs showed that the main enriched proteins were related to distinct pathways between vesicles of pluripotent and multipotent cells. In hPSCs, EXO content was more focused on development, metabolism, and anti-aging properties, and in hMSCs, it was related to immune regulation. Another study in 2022 also indicated that hMSC-EV content is

strongly related to immune regulation while hPSC-EV content does not present many of the proteins related to this function[76]. Actually, 79 proteins were found to be shared between hMSC- and hPSC-EVs, yet the main biological processes related to them were DNA regulation, signal transduction and cell communication[76]. Liu *et al*[59] also compared the protein content of hiPSC-EVs and hMSC-EVs and described more than 1100 proteins shared between the different EVs, allowing to identify proteins that could be responsible for the anti-senescent effect observed in the study.

Considering the protein content of hESCs and hiPSC-EXOs, Bi *et al*[74] suggested that hESC-EXOs are more prone to regulate development and pluripotency pathways, and hiPSC-EXOs have a stronger correlation with metabolism. Regarding the most enriched miRNAs for both hPSC-EVs, it was shown that they were related to cell cycle and metabolism regulation. Interestingly, miRNAs found in both hESC-EXOs and hiPSC-EXOs were involved in cell differentiation, development, and cell cycle, even though the hiPSC-EXO set of miRNAs seemed to play a less significant role in these functions than the hESC-EXO set[74].



In order to explore whether apoptosis-linked gene 2-interacting protein X (ALIX), a protein present in the endosomal sorting complex required for the transport and biogenesis of EXOs, could regulate the protein content of EV, Sun *et al*[62] isolated EVs from hiPSCs in which ALIX was overexpressed (using lentiviral transduction) or were knocked out (using CRISP-Cas9 system). EVs isolated from these cell lineages were of similar size, although EVs generated from knockout cells were slightly larger. The evaluation of protein content in EVs showed that those derived from knockout cells had fewer proteins, while EVs from overexpressing cells presented a higher number of proteins. These differences could be related to the differences demonstrated in functional assays, *e.g.*, cell viability, apoptosis inhibition, and formation of capillary-like structures, where EVs from overexpressing cells had better effects. So, EVs with different protein profiles could have different therapeutic applications.

CONCLUSION

Although hPSC cultivation has been carried out for some time, the requirements for *in vitro* culture of these cells are very specific, as many factors are necessary to maintain them in their undifferentiated state. This, together with the cost, could be one of the reasons why secretomes and isolation of hPSC-EVs have not been extensively studied so far. Commercial media are now defined with a few components that are no longer as expensive as before, which may have contributed to the increase in publications in recent years.

An overview of the hPSC-EV studies is shown in Figure 2, which illustrates the potential use of these EVs for regenerative medicine. Regarding EV characterization, we observed in the publications that hPSC-EVs follow the basic requirements described in MISEV2018. However, despite the recent increase in research in this area, further characterization of the content of these EVs needs to be carried out. In addition, studies with modified cells aimed to enrich the content of EVs with some specific protein or miRNA may be of great interest. One interesting approach requiring more extensive discussion is the possible use of hPSC-EVs in reprogramming adult cells into PSCs. A recent study used EVs derived from ESCs undergoing cardiac differentiation to transdifferentiate fibroblasts to cardiomyocyte-like cells with relatively high efficiency[82].

Our review shows that hPSC-EVs have therapeutic potential, although no publications demonstrate that they are effectively better than other EVs, such as hMSC-EVs. hPSC can be obtained from different sources (embryonic or reprogrammed from adult cells) and, despite showing some heterogeneity between lineages, they are highly similar in their main characteristics: They are pluripotent and with a high proliferative capacity. The latter makes it possible to obtain a large number of EVs. It should be noted that PSC-EV derived from different hPSC lineages may show some variability in their content. But considering the fact that we can isolate EVs from a single source (a homogenous culture), this can possibly bring less variability between batches compared to other common EV sources. However, studies in this area are still needed as current results are highly variable. Alternatives to EVs include the use of cell-engineered nanovesicles generated by serial extrusion of hiPSCs, as described by Lee *et al*[83], which presented similar results to PSC-EVs, but with higher production yield. However, more studies are needed to verify the viability of this method for future applications. Thus, challenges that remain are the large-scale production of EVs, which in the case of hPSC cultivation can be expensive, and the investment in efficient methodologies for EV isolation that could be used in good manufacturing practices for future acellular therapies.

Abstract

The corneal epithelium is composed of stratified squamous epithelial cells on the outer surface of the eye, which acts as a protective barrier and is critical for clear and stable vision. Its continuous renewal or wound healing depends on the proliferation and differentiation of limbal stem cells (LSCs), a cell population that resides at the limbus in a highly regulated niche. Dysfunction of LSCs or their niche can cause limbal stem cell deficiency, a disease that is manifested by failed epithelial wound healing or even blindness. Nevertheless, compared to stem cells in other tissues, little is known about the LSCs and their niche. With the advent of single-cell RNA sequencing, our understanding of LSC characteristics and their microenvironment has grown considerably. In this review, we summarized the current findings from single-cell studies in the field of cornea research and focused on important advancements driven by this technology, including the heterogeneity of the LSC population, novel LSC markers and regulation of the LSC niche, which will provide a reference for clinical issues such as corneal epithelial wound healing, ocular surface reconstruction and interventions for related diseases.

Key Words: Cornea; Limbal stem cells; Single cell RNA sequencing; Heterogeneity; Novel markers; Niche regulation

Core Tip: Limbal stem cells (LSCs), a cell population that resides at the limbus in a highly regulated niche. With the advent of single-cell RNA sequencing, our understanding of LSC characteristics and their microenvironment has grown considerably. This review focuses on the current research on single cell sequencing in LSCs. We highlight the heterogeneity, novel specific markers and niche regulation of LSCs.

INTRODUCTION

The cornea is a unique transparent tissue in the human body exposed to the external environment and is the window for sight[1,2]. Specifically, the corneal epithelium acts as a protective barrier on the ocular surface and is constantly regenerating. This unique property of the corneal epithelium is dependent on self-renewing epithelial stem cells located at the limbus, known as limbal stem cells (LSCs)[3-5]. LSCs reside in the "palisades of Vogt" (also known as limbal epithelial crypts) and are critical for corneal epithelial regeneration and wound healing. LSCs respond to corneal epithelial cell renewal or wound healing by differentiating to produce limbal progenitor cells (LPCs) and transient amplifying cells (TACs), which then migrate to the central cornea to replenish the corneal epithelium[6-9]. This process was summarized as the XYZ hypothesis[10] and explained the balance of cell numbers and homeostasis in the corneal epithelium maintained by LSCs.

Like the stem cells in other tissues, the surrounding microenvironment or limbal niche strictly supports and regulates the functional behaviors of LSCs[11,12]. The limbal niche has unique characteristics and components, including mesenchymal cells, immune cells, melanocytes, vascular cells, extracellular matrix and signaling molecules (*e.g.*, growth factors and cytokines)[13-16]. Significant pathology involving any component of the limbal niche can lead to the dysfunction of LSCs or even result in limbal stem cell deficiency (LSCD), a disease that is characterized by impaired wound healing or blindness[17,18].

Various studies have identified numerous markers of LSCs but identifying definitive molecular signatures to distinguish LSCs and other corneal epithelial cells is still challenging. The unclear internal heterogeneity of the LSC population can increase the difficulty in efficiently isolating pure LSCs for clinical transplantation. In addition, emerging evidence supports that reconstruction of the limbal niche may be introduced to treat LSCD. Therefore, understanding the function and niche regulation of LSCs is needed to discover novel therapies for ocular surface disease.

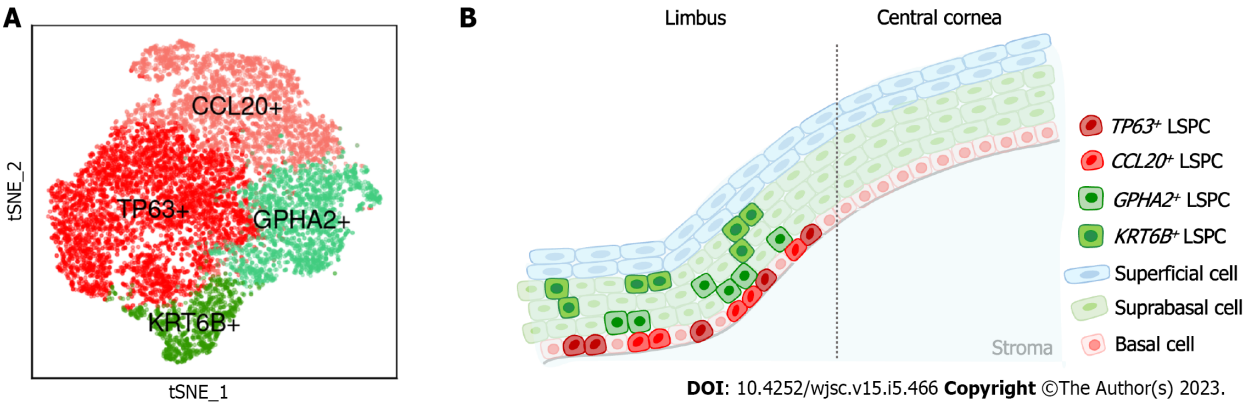
With the development and maturity of sequencing technology, more and more genomic, transcriptomic, epigenetic and proteomic sequencing technologies have been applied to studying eye tissues [19-22]. In recent years, single-cell RNA sequencing (scRNA-Seq) technology has provided a powerful tool for discovery of new cell types and for dissecting their potential heterogeneity in unprecedented resolution[23-25]. For multicellular organisms, cell heterogeneity is defined by differences in genetic background, transcriptomic and proteomic profiles[26]. Compared to other traditional techniques for detecting the average expression of genes in multiple cells, single-cell sequencing can detect differential signals between individual cells, improve the resolution of research from the tissue to the cellular level [27-29]. A single-cell atlas has been compiled for several ocular tissues, such as the uvea[30], retina[31-34], iris[35,36], sclera[37,38] and human cornea[39,40]. In this review, we summarize the current advances on LSCs derived from single-cell studies to better understand the features and functions of LSCs and the precise cellular and molecular mechanisms of niche regulation. Overall, this review presents key points from recent discoveries to enrich our knowledge on LSC biology and ocular surface homeostasis reconstruction or other clinical problems.

HETEROGENEITY OF THE LSC POPULATION

LSCs are located in the basal layer of the corneal epithelium. As previously mentioned, they are characterized by a high proliferative potential, small size, high nucleoplasmic ratio and slow cell cycle[41,42]. LSCs are scarce, and finding bona-fide markers to distinguish them from other basal epithelial cells is challenging. In addition, few studies have investigated the heterogeneity and hierarchy of LSCs. Understanding the heterogeneity of LSCs is important for comprehending the function to effectively

isolate them for clinical transplantation.

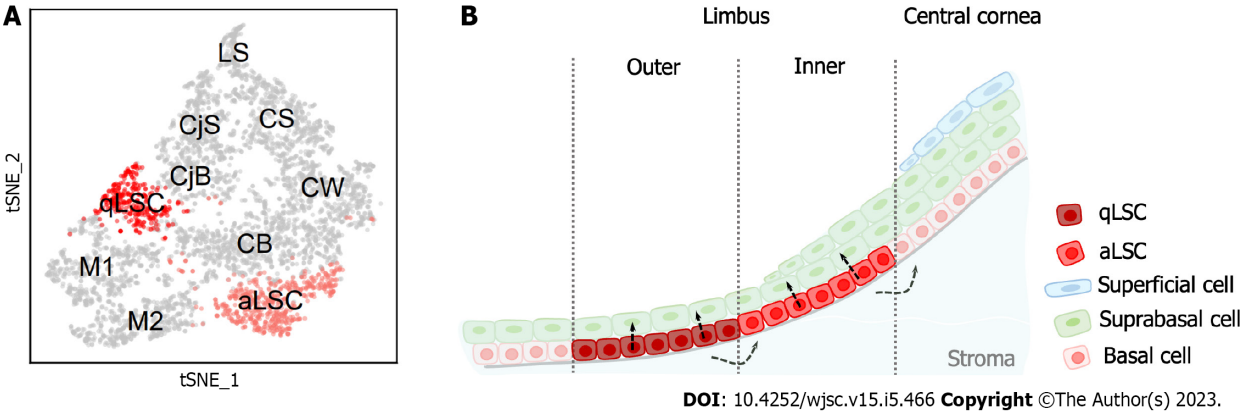
Dou *et al*[43] performed scRNA-Seq on human limbal tissues and identified four subclusters of stem/progenitor cells after single-cell transcriptome analysis. In this study, the authors annotated eight cell types, including prominent limbal epithelial cells, stromal cells and other rare cell populations. The authors then subclustered limbal epithelial cells and resolved their heterogeneity, including limbal stem/progenitor cells (LSPCs), limbal suprabasal cells and limbal superficial cells. To further explore the LSC population, the authors then subclustered LSPCs and obtained four subpopulations (Figure 1) including: (1) A subpopulation with the classical LSC marker *TP63*[44]; (2) A subpopulation with high expression of *CCL20*, which is a chemokine that can induce cell migration and proliferation[45]; (3) A subpopulation with specific expression of *GPHA2*, a marker recently identified in quiescent LSCs (qLSCs) from humans and mice[46,47]; and (4) A subpopulation with high expression of *KRT6B*, which is associated with rapid keratinocyte division and contributes to inhibiting the migration of mitotic cell populations from the basal layer[48]. The authors then investigated the differences in stemness and differentiation status and observed that *TP63*$^+$ and *CCL20*$^+$ cells presented a high stemness state, whereas *GPHA2*$^+$ and *KRT6B*$^+$ showed a high differentiation state.



Another study by Li *et al*[49] annotated five subtypes from the limbal basal epithelium of the human cornea. They characterized terminally differentiated cells (TDCs), post-mitotic cells, TACs, LPCs and LSCs. Furthermore, the authors discovered that these five subtypes represented the major stages and trajectories of human LSC proliferation and differentiation (from LSCs, LPCs, TACs and post-mitotic cells to TDCs), and they were spatially situated in different regions from the limbus to the central cornea. In TDCs, corneal epithelium-specific differentiation markers and keratinocyte keratinization markers were expressed at the highest levels, while the LSC differentiation markers had the lowest expression.

LSCs in mice are also heterogeneous and behave differently than human LSCs. Altshuler *et al*[46] combined scRNA-Seq and quantitative lineage tracing for in-depth analysis of mouse limbal epithelium. The authors revealed the presence of two distinct subpopulations of mouse LSCs that were in separate and well-defined spatial locations called the "inner" and "outer" limbus (Figure 2). The inner limbus contains active LSCs, which maintain the homeostasis of the corneal epithelium. The outer limbus contains qLSCs that have a significantly lower rate of division and are involved in wound healing and border formation. Spectral tracking experiments displayed that qLSCs can quickly exit the dormant state and enter the cell cycle in response to injury, suggesting that qLSCs are a reservoir for tissue regeneration. In addition, their circumferentially extended clonal growth model and continuous localization on the border highly indicates that these cells play a crucial role in border maintenance. Notably, this finding was also confirmed by a study utilizing the two-photon live imaging approach [50]. Collectively, LSCs are highly heterogeneous in both humans and mice, unlike stem cells in other tissues. Further studies are needed to investigate the self-renewal and differentiation mechanisms of LSCs.

NOVEL MARKERS FOR LSCS



Since 1989, when LSCs were discovered[4], a series of markers have been found to identify these cells, such as *TP63, KRT3, KRT12*. However, the marker pattern typically labels the broad limbal basal cell population. Accurately distinguishing LSCs from other epithelial cells is still challenging and is still an active area of research. Altshuler *et al*[46] discovered a novel set of markers to accurately identify LSCs. They applied *in situ* hybridization probes for *Krt4* and *Krt12* to label mouse conjunctival and corneal basal and suprabasal cells, respectively. *Gpha2* staining could obviously demarcate the outer LSCs (also known as qLSCs), while the inner LSCs (also known as active LSCs) were labeled as *Atf3*$^+$. Then, they used immunofluorescence staining to confirm that the outer limbal epithelial basal cells were *Krt15*$^+$/*Ifitm3*$^+$/*Cd63*$^+$, and the inner limbal epithelial basal cells were *Atf3*$^+$/*Mt1-2*$^+$. Next, the authors explored the correlation between mouse and human LSC markers. Immunofluorescence images revealed that *KRT15*, *IFITM3* and *GPHA2* were expressed in human limbus epithelial basal cells. *Ifitm3* was found to be restricted to cellular vesicles in the cytoplasm of undifferentiated limbal cells, which was consistent with a previous study's findings[51]. *Ifitm3* knockdown led to a differentiation phenotype and a reduced colony-forming capacity. These experiments suggest that *Ifitm3* and *Gpha2* can be used to identify LSCs, and *Ifitm3* mediates the undifferentiated state.

Gpha2 has been frequently studied in human LSCs. Dou *et al*[43] explored the four subclusters of LSPCs, which were identified by *TP63*, *CCL20*, *GPHA2* and *KRT6B*. Collin *et al*[47] identified several novel genes, one of which was *GPHA2*, using an unbiased approach to recognize marker genes that were highly expressed in human LSCs relative to other corneal epithelial cells. High and specific expression of *GPHA2* was observed in the limbus crypts, which was consistent with the findings of Altshuler *et al*[46]. Moreover, the authors used RNA interference (RNAi) to downregulate *GPHA2* and observed a significant reduction in cell proliferation and differentiation efficiency, indicating an important role of GPHA2 in maintaining the undifferentiated state of human LSCs. The authors also performed flow activated cell sorting analysis with colony forming efficiency assays to confirm the

RNAi data.

Other LSC markers have also been identified. Li *et al*[49] identified *TSPAN7*$^+$ and *SOX17*$^+$ cells distributed in a scattered pattern in human limbus epithelium basal cells. The authors established an *in vitro* model of epithelial cells and discovered *TSPAN7* and *SOX17* were not strongly expressed in human limbal epithelial cells. However, mRNA and protein expression levels were significantly activated after injury, especially during cell migration and growth. The authors also utilized RNAi to downregulate *TSPAN7* and *SOX17* and observed inhibited cell proliferation and significantly delayed epithelial regeneration during wound healing. Overall, the discovery of novel markers of LSCs (Table 1) can help us to better distinguish LSCs from other cells to further understand the function and state of LSCs and provide a more effective strategy for the isolation, culture and clinical application of LSCs.

NICHE REGULATION OF THE LSCS AT THE LIMBUS

LSC proliferation, migration and differentiation are inseparable from the regulation of the limbal niche microenvironment. The stem cell niche is the local microenvironment directly promoting or protecting stem cell populations[52-54]. The LSC niche provides a sheltered environment that protects LSCs from stimulation[55-58]. If the LSC niche is involved in pathological damage, then LSC dysfunction can occur. Therefore, the study of the LSC niche is essential.

Collin *et al*[47] investigated the interaction between LSCs and the limbal niche by single-cell analysis. The authors combined scRNA-Seq and ATAC-Seq and performed CellPhoneDB analysis[59]. They identified multiple significant interactions between human LSCs and regulatory factors of immune cells such as proinflammatory cytokines [tumor necrosis factor, interleukin (IL)-1β, IL-6, IL-17A, interferon γ, and oncostatin M], proinflammatory cell surface receptor (triggering receptor expressed on myeloid cells 1), proinflammatory cytokine expression (adaptor complexes 1) and regulators of inflammatory

Table 1 Novel limbal stem cell markers identified by single-cell RNA sequencing

LSC subtype	Marker	Species	Ref.
LSPC with high stemness	*TP63, CCL20*	Human	[43]
LSPC with high differentiation	*GPHA2, KRT6B*	Human	
LSC	*TSPAN7, SOX17, SELE, ECSCR, RAMP3, RNASE1, NPCD1, NNMT, SLC2A3, KLF2, PDK4*	Human	[49]
Limbal progenitor cell	*DCN, PLIN2, DEGS1, MMP10, IFITM3, SLC6A6, LTB4R, SLP1*	Human	
qLSC	*Gpha2, Cd63, Ifitm3*	Mouse	[46]
aLSC	*Atf3, Socs3, Mt1, Prdm1*	Mouse

responses (nuclear factor kappa B, RELA, colony-stimulating factor 2, phosphoinositide 3-kinase, extracellular signal-regulated kinase 1/2, and F2). The authors verified that limbal epithelial cells were significantly reduced in cell culture medium containing tumor necrosis factor-α and IL-1β. This suggested that proinflammatory cytokines produced by immune cells were involved in the apoptosis of limbal epithelial cells[60], thus mimicking the central corneal defect and stimulating the proliferation of LSCs[61]. This was also consistent with other reports showing that the addition of proinflammatory factors to limbal epithelial cell cultures can directly affect the expression of LSC markers and their colony forming efficiency capacity[60,62-64].

Dou *et al*[43] systematically explored intercellular communication between LSPCs and other cell populations based on ligand-receptor analysis. By correlating the corresponding receptor-ligands in human LSPCs and their niche cells, the authors observed that LSPCs were regulated by the limbal niche as well as by other cells in the limbal niche. The Notch signaling pathway was also involved in cell-cell interaction between LSPCs and their niche cells. NOTCH1-4 receptors were expressed in LSPCs, and their relevant ligands were primarily identified in niche cells, such as Schwann cells, stromal cells, pericytes and LSPCs. Likewise, the WNT7A, WNT7B and WNT5A ligands, which participate in the Wnt/β-catenin signaling pathway, were detected on LSPCs. Their corresponding receptors were primarily detected on limbal epithelial cells, stromal cells, immune cells, Schwann cells and LSPCs. The presence of multiple chemokines, such as CCL4, CCL4L2, IL-1β and IL-24, on LSPCs and their paired receptors indicated that immune cell interactions may potentially regulate LSPCs.

Altshuler *et al*[46] revealed that T cells acted as niche cells and served its function in the maintenance of quiescence, epithelial thickness control and wound healing. By studying the limbus of the severe combined immunodeficiency (SCID) and non-obese diabetic SCID mice, which are unable to make mature T and B lymphocytes, it was observed that the GPHA2 protein was substantially decreased to almost undetectable levels. In contrast, the expression of *Ifitm3* did not rely on the existence of immune cells, implying that it was regulated by other niche cells. When T cells were inhibited by topical application of the corticosteroid dexamethasone, LSCs showed a dramatic reduction in *Cd63* and *Gpha2* expression levels and increased cell proliferation, demonstrating that T cells played a crucial role in regulating qLSCs. Finally, corneal epithelial debridement followed by epithelial closure by fluorescein dye infiltration revealed delayed epithelial wound healing in mice lacking T cells.

In addition, other niche cells were determined to be important for the microenvironment regulation of LSCs. Oxidative stress can lead to a variety of eye diseases, such as keratitis, cataracts and retinal diseases, which are subject to varying degrees of oxidative damage[65,66]. Recently, studies found that melanocytes in the limbal niche (as antioxidant systems) protected LSPCs from UV-induced oxidative damage and reduced oxidative stress through the transfer of melanosomes[67,68]. Moreover, by ligand analysis, Dou *et al*[43] identified the intercellular communications between melanocytes and LSCs. NAMPT, as a ligand, was highly expressed in melanocytes and had been reported to act as a critical switch in melanoma cells. CD44 acted as a receptor and was also highly enriched in melanocytes.

Vascular endothelial cells are also one of the important niche cells of LSCs. It has been reported that vascular endothelial cells were highly correlated with the classic Wnt signaling pathway involved in the regulation of the corneal limbal niche[69,70]. Furthermore, Dou *et al*[43] performed a differential expression analysis with the integration of the scRNA-Seq datasets from the limbus and the skin and observed that the vascular endothelial cells from the limbus highly expressed anti-vascular factors compared to that from the skin, consistent with characteristics of corneal angiogenic privilege. Above all, these studies have shown that the regulation of the LSC niche (Figure 3) occupies a key role in the growth, development, proliferation and differentiation of LSCs.

CONCLUSION

The first Drop-Seq experiments were performed on mouse retina in 2015[23]. Since this revolutionary experiment, single-cell sequencing technology has been widely used in many fields, including ophthalmology, and gene expression has been studied at an unprecedented resolution in multiple ocular tissues. Corneal transparency is essential for normal vision; thus, comprehension of the mechanisms related to corneal wound healing and regeneration is crucial for the treatment of patients suffering from corneal disease. Currently, corneal epithelial regeneration is a relatively satisfactory approach and has the potential to treat corneal superficial scars. However, for multiple corneal basal scars or endothelial disease, corneal transplantation remains the only option to restore clear vision[71-73]. Unfortunately, corneal clouding remains one of the leading causes of blindness worldwide due to the lack of corneal donor tissue or the limited availability of corneal surgery[74,75]. Although most studies support corneal regeneration through LSC therapies[76,77], the study of LSCs is particularly important.

This review focused on the current research on single-cell sequencing in LSCs. We highlighted the heterogeneity of LSCs and presented several novel specific markers of LSCs and the role of niche regulation of LSCs. LSCs can be identified in both humans and mice, and several markers, such as *GHPA2* and *IFITM3*, can be highly and specifically expressed on LSCs. Moreover, both T cell regulation in mice studied by Altshuler *et al*[46] and immune cell regulation in humans studied by Collin *et al*[47] and Dou *et al*[43] suggest that niche regulation is of vital importance for LSCs.

Future research can still benefit from RNA-Seq technology as it can aid in acquisition of further knowledge on the functions and characteristics of LSCs, including in the discovery of more novel highly specific expression markers and more niche regulated components that can promote or inhibit the proliferation and differentiation of LSCs. These discoveries should be translated into better prevention and treatment strategies to treat blindness and improve the clinical prognosis of patients with LSCD and other LSC-related diseases.

Abstract

BACKGROUND

Wound healing impairment is a dysfunction induced by hyperglycemia and its effect on endothelial precursor cells (EPCs) in type 2 diabetes mellitus. There is increasing evidence showing that exosomes (Exos) derived from adipose-derived mesenchymal stem cells (ADSCs) exhibit the potential to improve endothelial cell function along with wound healing. However, the potential therapeutic mechanism by which ADSC Exos contribute to wound healing in diabetic mice remains unclear.

AIM

To reveal the potential therapeutic mechanism of ADSC Exos in wound healing in diabetic mice.

METHODS

Exos from ADSCs and fibroblasts were used for high-throughput RNA sequencing (RNA-Seq). ADSC-Exo-mediated healing of full-thickness skin wounds in a diabetic mouse model was investigated. We employed EPCs to investigate the therapeutic function of Exos in cell damage and dysfunction caused by high glucose (HG). We utilized a luciferase reporter (LR) assay to analyze interactions among circular RNA astrotactin 1 (circ-Astn1), sirtuin (SIRT) and miR-138-5p. A diabetic mouse model was used to verify the therapeutic effect of circ-Astn1 on Exo-mediated wound healing.

RESULTS

High-throughput RNA-Seq analysis showed that circ-Astn1 expression was increased in ADSC Exos compared with Exos from fibroblasts. Exos containing high concentrations of circ-Astn1 had enhanced therapeutic effects in restoring

EPC function under HG conditions by promoting SIRT1 expression. Circ-Astn1 expression enhanced SIRT1 expression through miR-138-5p adsorption, which was validated by the LR assay along with bioinformatics analyses. Exos containing high concentrations of circ-Astn1 had better therapeutic effects on wound healing *in vivo* compared to wild-type ADSC Exos. Immunofluorescence and immunohistochemical investigations suggested that circ-Astn1 enhanced angiopoiesis through Exo treatment of wounded skin as well as by suppressing apoptosis through promotion of SIRT1 and decreased forkhead box O1 expression.

CONCLUSION

Circ-Astn1 promotes the therapeutic effect of ADSC-Exos and thus improves wound healing in diabetes *via* miR-138-5p absorption and SIRT1 upregulation. Based on our data, we advocate targeting the circ-Astn1/miR-138-5p/SIRT1 axis as a potential therapeutic option for the treatment of diabetic ulcers.

Key Words: Adipose-derived mesenchymal stem cells; Circular RNA astrotactin 1; Diabetic; Exosomes; Angiogenesis

INTRODUCTION

Diabetes affects 30 million children as well as adults in the United States, *i.e.* one out of every eleven people in the United States, which leads to $327 billion costs each year. Consequently, it is important to develop a new method of diabetes treatment. Interventions that improve healing rates and decrease diabetic ulcer size could lower the infection incidence, amputation rate, and care cost[1]. Diabetic foot (DF) is a severe complication of type 2 diabetes mellitus (T2D). DF infection is the main reason for DF development and deterioration, and controlling infection plays an important role in disease treatment. Previous studies have found that diabetes is associated with hyperglycemia, one of the most important causes of oxidative stress. Endogenous antioxidants are able to destroy the reactive species and create a balance between antioxidants and free radicals[2,3]. The impaired function and senescence of endothelial progenitor cells (EPCs) and high glucose (HG)-induced reactive oxygen species likely exacerbate DFs[4].

Accumulated evidence shows that mesenchymal stem cell (MSC)transplantation promotes angiogenesis and accelerates diabetic wound healing[5,6]. Adipose-derived mesenchymal stem cells (ADSCs) therapy provides potentially new therapeutic options to improve diabetic wound healing[7], and autologous stem cell transplantation reduces the cost of drug development, which in turn reduces financial costs. However, the mechanism is not clear.

Stem cells live in niches, which are complicated microenvironments that exert important functions in directing the division, differentiation, and activity of stem cells. However the direction of differentiation is affected by hypoxia, cytokines, trophic factors, chemical and pharmacological agents, and physical factors[8]. Considering the safety of *in vivo* transplantation, some investigations have suggested that exosomes (Exos) from ADSCs play a similar functional role to ADSCs in promoting diabetic wound healing. Exos are tiny endosomal membrane-bound vesicles, 50–200 nm in length, that have a variety of contents including protein and nucleic acids which vary with cell or tissue origin. They play their full role by fusing with selected cells and releasing their cargo that could contain bioactive molecules including lipids, proteins, non-coding-RNA (ncRNA)[9-11] and mRNAs. Previous studies have found that Exos can regulate the epithelial–mesenchymal transition and disease progression in different cancers[12,13]. Exos secreted from ADSCs attenuate diabetic nephropathy by promoting autophagy flux

and by inhibiting apoptosis in podocytes[14]. Exos from nuclear factor erythroid 2–related factor 2-overexpressing ADSCs accelerate cutaneous wound healing by promoting vascularization in a DF ulcer [4]. Exos from linc00511-overexpressing ADSCs accelerate angiogenesis in healing DF ulcers by suppressing progestin and adipoQ receptor family member 3-induced Twist1 degradation[15]. However, it remains largely unknown if Exos from ncRNA-modified ADSCs can improve wound healing.

The ncRNAs include circular RNA (circRNA), long non-coding RNA (lncRNA), and microRNA (miRNA). circRNA activity is indispensable during the regulation of gene expression, demonstrating that circRNAs function not only as candidate therapeutic agents but also as diagnostic markers. circRNA 5′ and 3′ extremities are linked to form an integrated circular structure, which makes circRNAs more resistant to RNA exonuclease degradation. as well as more stable 8than linear RNAs[16,17]. A previous study found that circRNAs possess activity and potential clinical benefits in skin wound healing[18].

To identify relevant circRNAs as therapeutic targets, we used high-throughput sequencing detection to identify the function of mmu_circ_0000101 (circ-Astn1), which acts as the key factor in delivery by ADSC Exos. Exos from circ-Astn1-modified ADSCs improve wound repair in diabetic rats through miR-138-5p/SIRT1 pathway regulation. The present study verified the effect of treatment with Exos from circ-Astn1-overexpressing ADSCs on HG-induced EPC dysfunction. The abundance and simple methods of sampling of ADSC-Exos make it safer in terms of trauma and other adverse reactions.

MATERIALS AND METHODS

Ethics statement

The Animal Care and Use Committee of Peking Union Medical College Hospital approved the investigation protocol (No: XHDW-2020-01; Beijing, China). We carried out all postoperative animal care along with surgical interventions following the National Institutes of Health Guidelines for the Care and Use of Laboratory Animals. All surgeries and euthanasia were performed under sodium pentobarbital anesthesia (30 mg/kg) by intraperitoneal injection, and all efforts were made to minimize suffering.

High-throughput and strand-specific RNA sequencing library construction

Total RNA from ADSCs and fibroblast Exos was isolated using TRIzol reagent (Invitrogen, Carlsbad, CA, United States). Our team prepared about 3 μg total RNA *per* sample using the VAHTS Total RNA-seq (H/M/R) Library Prep Kit from Illumina (Vazyme Biotech Co., Ltd., Nanjing, China) to isolate the ribosomal RNA and remove other RNAs such as ncRNA and mRNA. We then performed RNA purification using RNase R (Epicenter, 40 U, 37 °C for 3 h) followed by TRIzol. An RNA sequencing RNA-Seq) library was prepared using the KAPA Stranded RNA-Seq Library Prep Kit (Roche, Basel, Switzerland) and they were exposed in order following extensive codifying with Illumina HiSeq 4000 from Aksomics, Inc. (Shanghai, China).

Cell treatment

To investigate endothelial precursor cell (EPC) dysfunction as well as apoptosis, we cultivated EPCs at 37 °C with 5% carbon dioxide in EPC medium (Gibco, Carlsbad, CA, United States) and processed them after 1 d using 5.5 or 30 mmol/L glucose. We harvested EPCs for detection of apoptosis as well as to test their response to Exo therapy. In order to study the protective function of Exos on EPCs, we added 100 μg/mL Exos to cultures following 80% EPC fusion to evaluate the protective function against damage caused by prior HG treatment with various glucose concentrations.

ADSC isolation and identification

We isolated ADSCs from adipose tissue following the method used in a previous study[4]. We observed no uninduced differentiation in cultural expansion. We induced osteogenic differentiation *via* a 3-wk culture of ADSCs in Dulbecco's Modified Eagle Medium (DMEM) supplemented with 10% fetal bovine serum (FBS), 0.1 μM dexamethasone, 50 μM ascorbate-2-phosphate, and 10 mmol/L β-glycerophosphate. We induced adipogenic differentiation through culturing ADSCs for 2 weeks in DMEM supplemented with 10% FBS, 10 μM insulin, 0.5 mmol/L isobutylmethylxanthine, 200 μM indomethacin, and 1 μM dexamethasone. We also investigated the osteogenic or adipogenic differentiation of ADSCs through Oil-Red O and alkaline phosphatase staining.

Identification and isolation of ADSC-derived Exos

We isolated ADSC-derived Exos when cells reached 80%-90% confluence. Our team rinsed ADSCs from various groups with phosphate-buffered saline (PBS), and then cultured them in FBS-free endothelial cell growth medium (EGM)-2MV, which was supplemented with 1 × serum replacement solution (PeproTech, Rocky Hill, NJ, United States) for another 2 d. Then, we collected conditioned culture medium and centrifuged it at 300 × *g* for 10 min to remove cells and at 2000 × *g* for another 10 min to

remove apoptotic cells and cellular debris. Following centrifugation at 10000 × *g* for 30 min, we filtered the supernatant through a 0.22 μm filter (Millipore, Billerica, MA, United States), then transferred 15 mL supernatant to the Amicon Ultra-15 Centrifugal Filter Unit (100 kDa) and centrifuged it at 4000 × *g* to concentrate to approximately 1 mL. The ultrafiltration unit was washed twice with PBS centrifuged it again at 100000 × *g*, and the supernatant was aspirated. All processes were conducted at 4 °C. We resuspended the Exo pellets obtained in 500 μL PBS. Finally, the Exo protein content was evaluated using the Pierce bicinchoninic acid assay (BCA) Protein Assay Kit (Thermo Fisher Scientific, Waltham, MA, United States). We stored Exos at -80 °C until subsequent use for experiments and identified Exos by western blotting and transmission electron microscopy.

Diabetic wound induction

We utilized Balb/c mice and induced diabetes through a single intraperitoneal injection of 60 mg/kg streptozotocin (STZ) dissolved in 0.1 M citrate buffer (pH 4.5). Three days after STZ administration, we confirmed diabetes development by measuring fasting blood glucose levels in blood samples obtained from the tail vein. We considered a mouse with fasting blood glucose levels > 250 mg/dL diabetic, which we maintained for 1 mo and employed for subsequent analyses of posterior blood glucose stabilization. Following diabetes validation, we anesthetized mice through intramuscular injection with ketamine hydrochloride and xylazine cocktail at 80 and 10 mg/kg, respectively. Once anesthesia was established, hair was shaved from the dorsal leg area and the region was sterilized using povidone iodine solution. A sterile biopsy punch was used to generate a full-thickness 4 mm excisional wound. Then we allocated mice randomly to subcutaneous injection with 100 μL PBS containing 200 μg ADSC Exos or equivalent amount of PBS without Exos at four sites near the wound (25 μL/site). We euthanized mice and harvested skin specimens for histopathological validation.

RNA overexpression or interference

RNA overexpression or interference was induced by transfection of miR-138-5p mimics or inhibitor, circ-Astn1 and SIRT1 overexpression vector, and siRNA against circ-Astn1 (si-circ-Astn1) obtained from RiboBio (Guangzhou, China). Our team performed transfection using Lipofectamine 2000 (Thermo Fisher Scientific) following a method previously described[19].

Quantitative polymerase chain reaction

We isolated total RNA from skin tissue or cells from wounds using a TRIzol reagent kit. Our team synthesized cDNA to amplify with TaqMan miRNA Reverse Transcription Kit. Our team then performed quantitative polymerase chain reaction (qPCR) using a TaqMan Human miRNA Assay Kit, using the $2^{-\Delta\Delta CT}$ approach to detect fold changes with respect to expression. We used *U6* and glyceraldehyde-3-phosphate dehydrogenase (*GAPDH*) as internal references. Primers utilized were: Circ-Astn1, F: 5′-CTGGACCCTTGTGAACACCAATG-3′, R, 5′-GGATCATCACCAGGCACAAGATG-3′; FOXO1, F: 5′-AAGGCCATCGAGAGCTCAGC-3′, R, 5′-GATTTTCCGCTCTTGCCTCC-3′; miR-138-5p, F: 5′-GCTGGTGTTGTGAATCAG-3′, R: 5′-GAACATGTCTGCGTATCTC-3; U6, F: 5′-AGTAAGCCCTTGCTGTCAGTG-3′, R: 5′-CCTGGGTCTGATAATGCTGGG-3′; GAPDH: F: 5′-GTCTCCTCTGACTTCAACAGCG-3′, R: 5′-ACCACCCTGTTGCTGTAGCCAA-3′, and were designed by Gene Pharma (Shanghai, China).

Apoptosis detection

To assess apoptosis, we collected cells into centrifuge tubes and centrifuged them at 1000 rpm for 5 min. We resuspended cells in PBS at 4 °C and removed the supernatant following centrifugation. We resuspended the cell pellet at 1–5 × 10^6/mL in 1 × binding buffer, then 100 μL cell suspension was mixed with 5 μL Annexin V/fluorescein isothiocyanate in the dark at room temperature for 5 min. Lastly, we added 10 μL propidium iodide (PI) and 400 μL PBS to stain the cells. We analyzed data using the FlowJo package.

Immunofluorescence and immunohistochemical assays

We fixed skin tissue samples in 10% formalin solution, embedded them in paraffin, and sectioned them at 5 μm. Our team stained tissue sections with hematoxylin and eosin (HE) for histological detection, and cluster of differentiation 31 (CD31) immunofluorescence staining was used to detect histopathological changes associated with angiogenesis. We performed terminal deoxynucleotidyl transferase dUTP nick end labeling (TUNEL) to identify apoptotic cells. Our team visualized sections using fluorescence (Nikon, Tokyo, Japan) or light microscope (Zeiss, Oberkochen, Germany), and photographed them using a digital camera.

Western blot analysis

Skin tissues were lysed, and lysates were centrifuged at 12000 rpm at 4 °C following addition of a protease inhibitor. The protein concentration was determined using the Pierce BCA kit (Thermo Fisher). Proteins were separated by 10% sodium dodecyl sulfate-polyacrylamide gel electrophoresis and electrotransferred to PVDF membranes. The primary antibodies used to assay protein expression were SIRT1

(1:600), forkhead box O1 (FOXO1) (1:600) (all from Santa Cruz Biotechnology, Santa Cruz, CA, United States), and anti-GAPDH (1:1000; Sigma-Aldrich, St. Louis, MO, United States), followed by a horseradish peroxidase-conjugated secondary antibody (1:1000; Abcam, Cambridge, MA, United States). An enhanced chemiluminescence kit (Millipore, Burlington, MA, United States) was used to read the bands.

Luciferase reporter assay

We created and cloned wild-type (WT) and 3'-UTR mutant (MUT) *SIRT1*, as well as WT and MUT *circ-Astn1* into pMIR firefly luciferase-expressing vectors. We co-transfected the vectors into HEK293T cells once they reached 70% confluence, using 500 ng pMIR-SIRT1-wt/pMIR-SIRT1-Mut or pMIR-*circ-Astn1*-wt/pMIR-*circ-Astn1*-Mut combined with 50 nM miR-138-5p mimics using a Lipofectamine 2000 Transfection Kit for the luciferase assay. We assayed luciferase activity using a Dual-Luciferase Reporter System (Promega, Madison, WI, United States). We performed five independent assays.

Tube formation assay

We performed an EPC tube formation assay using Matrigel (BD Biosciences, Franklin Lakes, NJ, United States). Matrigel solution was mixed with ECMatrix diluent buffer then spread on μ-Slide plates and incubated at 37 °C for 1 h for the matrix solution to solidify. Next, we added various treatments to the EPCs (2×10^4 cells/well) to wells containing solid matrix and cultured them with EGM-2 medium at 37 °C for a period of 12 h. Our team detected tube formation under an inverted light microscope (100 ×) and evaluated three independent representative fields from each well to determine mean tube number.

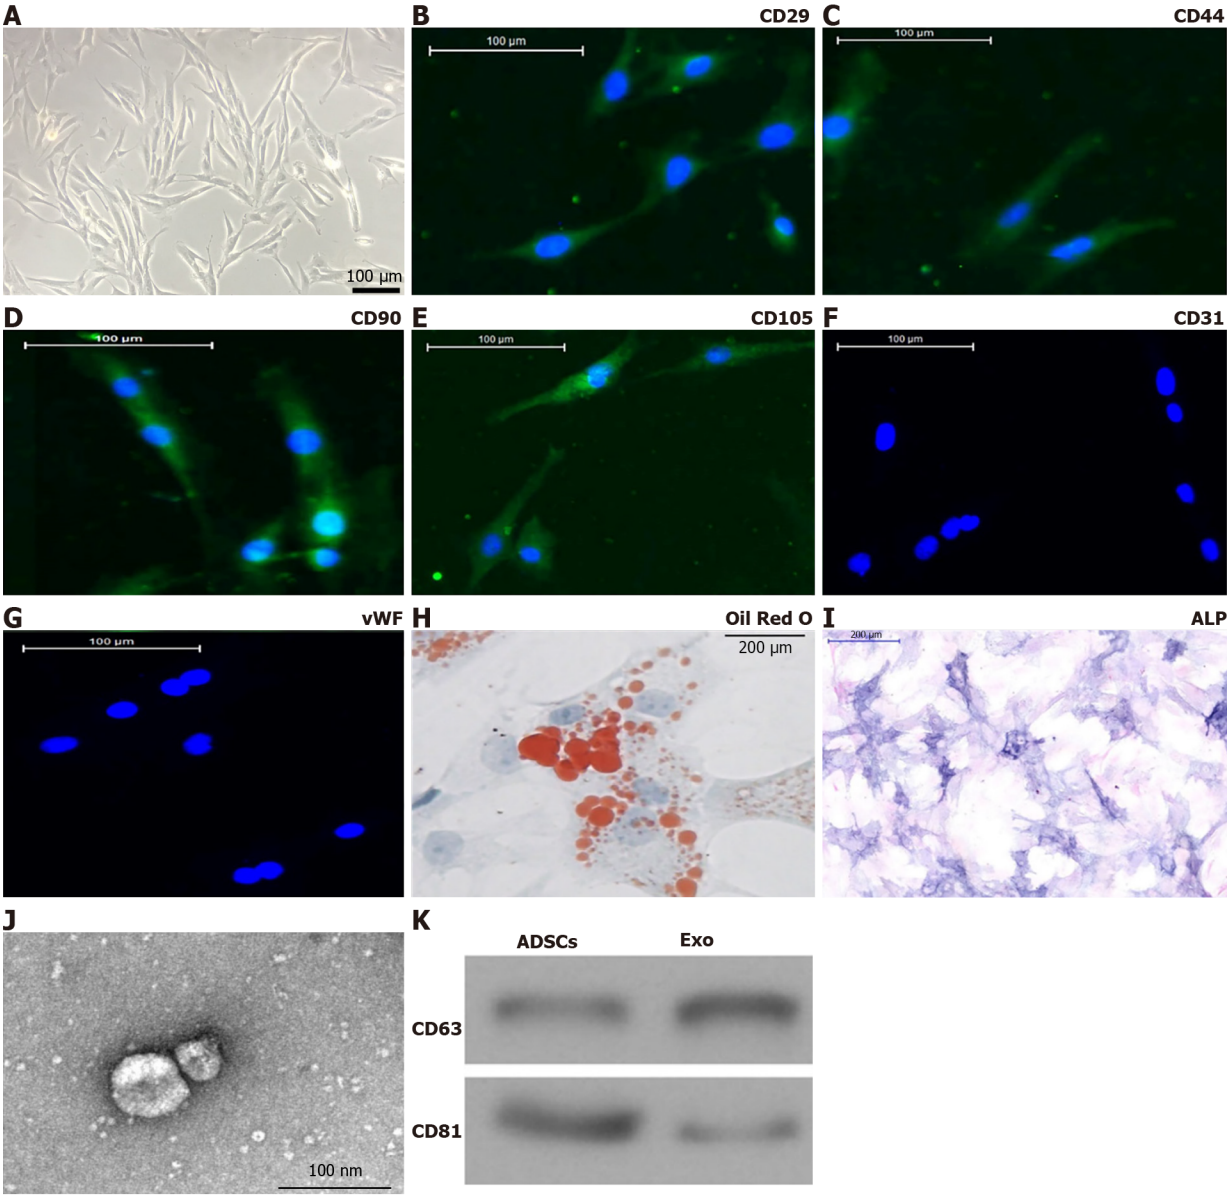
Cell Counting Kit (CCK)-8 assay

EPC proliferation was evaluated using the Cell Counting Kit-8 (CCK-8) (BD Biosciences). Our team cultivated transfected cells in 96-well plates with Exos in HG conditions for 1 d in wells to which 10 μL CCK-8 reagent and 90 μL fresh culture medium was previously added. Absorbance was detected at 450 nm using a microplate reader following incubation at 37 °C for 2 h.

Statistical analyses

We denoted continuous parameters by the mean ± SD and employed one-way variance of analysis (ANOVA) to compare data using GraphPad Prism (GraphPad, La Jolla, CA, United States). $P \leq 0.05$ indicated a statistically significant difference.

RESULTS



ADSC and Exo characterization

Isolated ADSCs have classical cobblestone-like morphology (Figure 1A). Immunofluorescence staining showed that ADSCs from mouse adipose tissue samples were positive for expression of the mesenchymal cell surface markers CD29 (Figure 1B), CD44 (Figure 1C), CD90 (Figure 1D), and CD105 (Figure 1E), but negative for expression of the endothelial cell marker CD31 (Figure 1F) as well as von Willebrand Factor (Figure 1G). The results of Oil Red O staining (Figure 1H) together with alkaline phosphatase staining (Figure 1I) verified that isolated ADSCs possessed both osteoblastic and adipocytic differentiation capacity. We concluded that ADSCs have the potential for multidirectional differentiation[20].

Exos were isolated by ultra-high-speed centrifugation. Transmission electron microscopy revealed that ADSC Exos had spherical or cup-shaped morphology with a diameter ranging from 50 to 120 nm (Figure 1J) as previously reported[21]. Western blotting suggested that ADSC Exos were positive for the Exo markers CD81 and CD63, which are cellular components (Figure 1K).

Exos derived from circ-Astn1-modified ADSCs play important roles in the restoration of EPC function by decreasing apoptosis under HG conditions

To determine the role of circRNAs in ADSC Exo-mediated restoration of EPC function under HG conditions, circRNA expression in ADSCs and fibroblast Exos was explored by RNA-Seq. The results verified that the contents of mmu_circ_0000101, mmu_circ_0008040, mmu_circ_0008061, and mmu_circ_0008099 were all significantly upregulated in ADSC Exos compared with fibroblast Exos (Figure 2A). RT-qPCR analysis confirmed that mmu_circ_0000101, mmu_circ_0008040, mmu_circ_0008061 and mmu_circ_0008099 expression in EPCs decreased after exposure to HG conditions (Figure 2B), with expression of mmu_circ_0000101 in particular decreasing most significantly. Consequently, mmu_circ_0000101 was selected for subsequent study. Mmu_circ_0000101 originated from *Astn1* gene exon 5, so mmu_circ_0000101 was also known as circ-Astn1. The entire mature spliced sequence length was 967 bp. The gene is on chromosome 1: 160432178-160441253 (Figure 2C).

Figure 1 Characterization of adipose-derived mesenchymal stem cells and exosomes. A: Adipose-derived mesenchymal stem cells (ADSCs) showed a typical cobblestone-like morphology. Scale bar: 100 μm; B–G: Immunofluorescence staining of cell surface markers. ADSCs exhibited positive expression of cluster of differentiation 90 (CD90), CD29, CD44, and CD105, but not von Willebrand factor or CD34. Scale bar: 100 μm; H and I: The differentiation potential of ADSCs assessed by Oil Red O (H) and alkaline phosphatase (I) staining. Scale bar: 200 μm; J: Transmission electron micrographs demonstrated ADSC exosome morphology. Scale bar: 100 nm; K: Western blotting detection of CD81 and CD63 expression in exosomes and ADSCs.

Flow cytometry investigations have shown that HG (30 mmol/L glucose) treatment promotes EPC apoptosis. Treatment with Exos from WT ADSCs suppressed HG-induced EPC apoptosis, and treatment with Exos from ADSCs overexpressing circ-Astn1 had a more significant effect in suppressing HG-induced apoptosis of EPCs than Exos from WT ADSCs (Figure 2D and E), suggesting that circ-Astn1 played an important role in ADSC-Exo-mediated EPC protection under HG conditions. CCK8 detection confirmed that treatment with Exos containing high levels of circ-Astn1 had a greater effect in restoring the proliferative ability of EPCs under HG conditions (Figure 2F). We used tubule formation by EPCs in Matrigel-coated culture wells as an *in vitro* angiogenesis model, and evaluated their potential by counting the branch numbers formed. HG conditions suppressed angiogenesis, and treatment with Exos containing high levels of circ-Astn1 was more effective in promoting angiogenesis of EPCs under HG conditions (Figure 2G-J).

The circ-Astn1-mediated miR-138-5p/SIRT1/FOXO1 signaling pathway protects EPCs under HG conditions by promoting angiogenesis

Bioinformatics data showed that circ-Astn1 regulates SIRT1 expression *via* inhibition of miR-138-5p. SIRT1 functions critically in promoting angiogenesis by activating the FOXO1 signaling pathway[22]. To

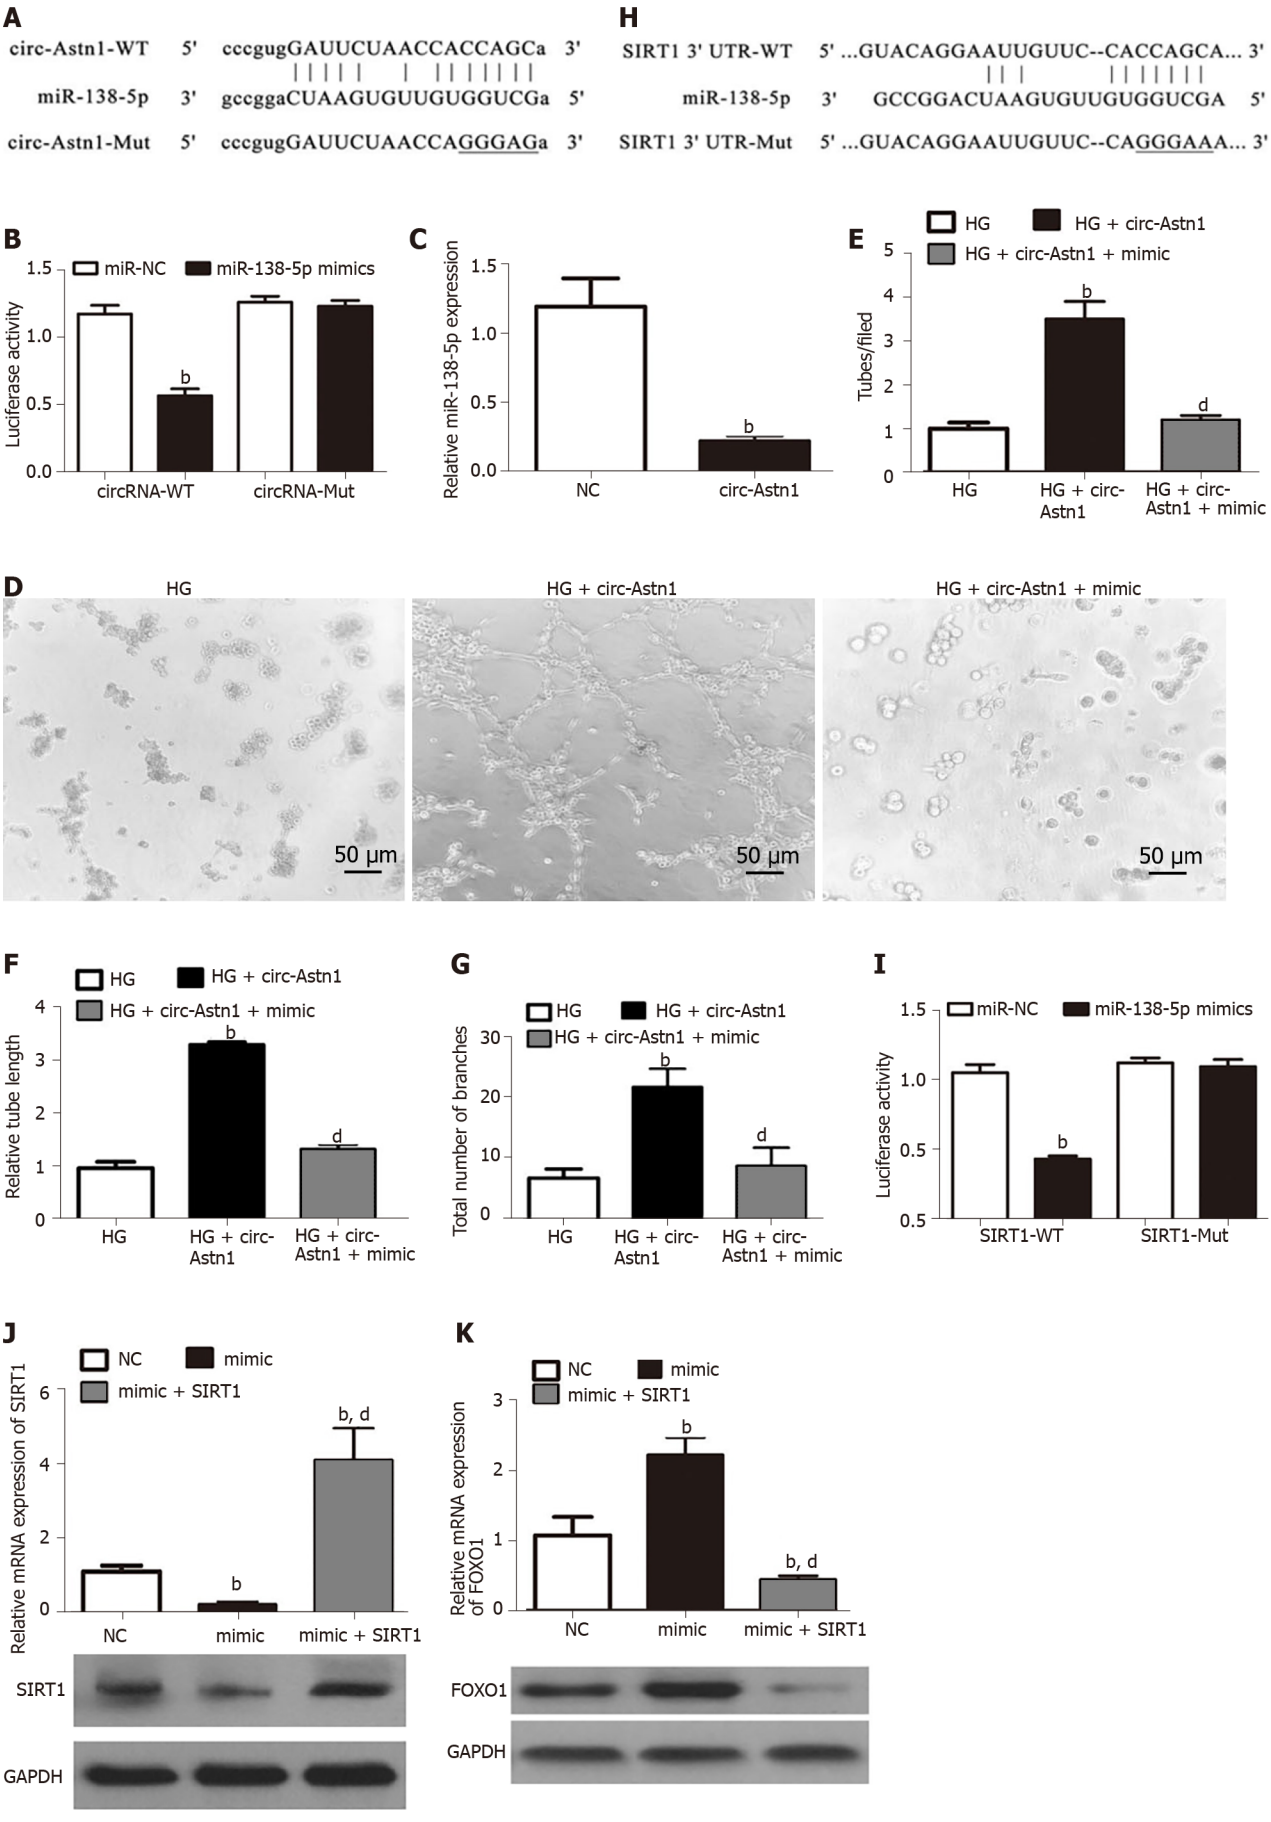
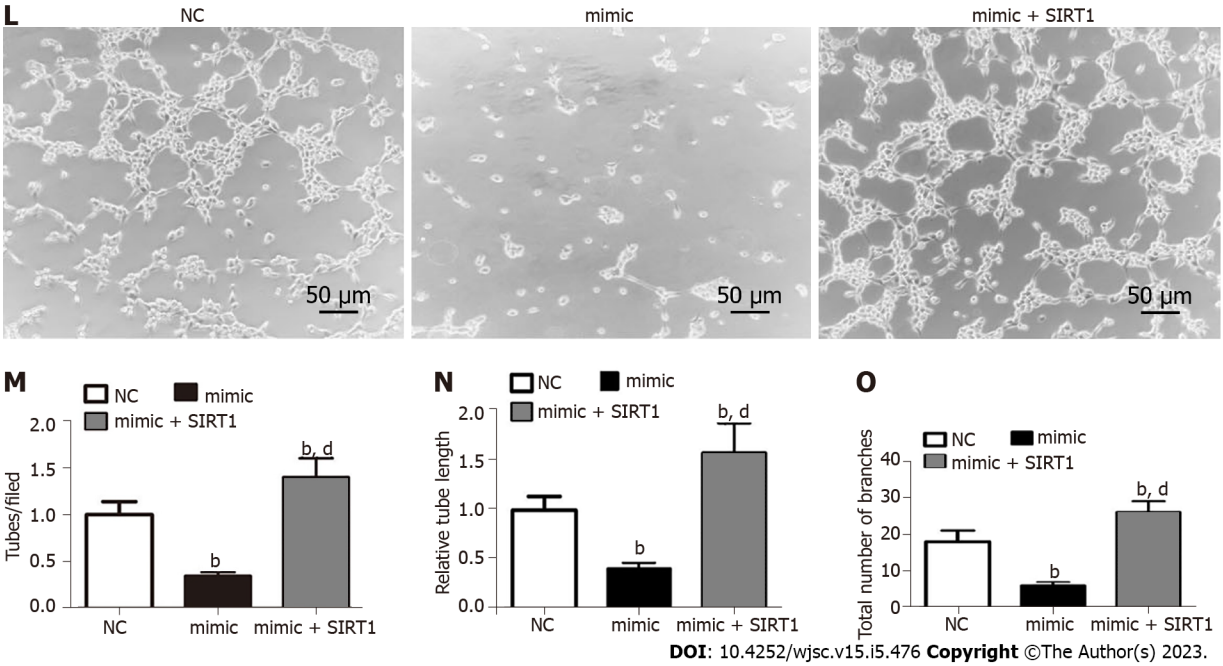
validate the interaction among circ-Astn1, SIRT1, and miR-138-5p, we created a luciferase reporter (LR) vector. The candidate miR-138-5p-binding sites on circ-Astn1 as well as sites with point mutations inserted to prevent binding are shown in Figure 3A. Luciferase activity assay using 293T cells, which we transfected with MUT or WT circ-Astn1, verified that miR-138-5p suppressed circ-Astn1 activity (Figure 3B). RT-qPCR analysis suggested that circ-Astn1 overexpression suppressed miR-138-5p expression in EPCs (Figure 3C). Meanwhile the tubule formation assay showed that upregulation of circ-Astn1 restored angiogenic differentiation ability under HG conditions, but miR-138-5p overexpression destroyed the protective effect of circ-Astn1 (Figure 3D-G).

Next, we created the LR vector. Candidate miR-138-5p-binding sites on SIRT1 3'-UTR and those with point mutations inserted to prevent binding were constructed (Figure 3H). We transfected 293T cells with MUT or WT SIRT1 3'-UTR, which verified that WT miR-138-5p suppressed SIRT1 activity (Figure 3I). RT-qPCR analysis illustrated that miR-138-5p overexpression suppressed FOXO1 and SIRT1 expression at both mRNA and protein levels relating to EPCs (Figure 3J and K). However, overexpression of SIRT1 promoted SIRT1 and downregulated FOXO1 expression even after miR-138-5p overexpression. Analysis of tubule formation verified that miR-138-5p upregulation decreased angiogenic differentiation ability, but overexpression of SIRT1 restored the angiogenic differentiation ability of EPCs (Figure 3L-O).



Exos from circ-Astn1-modified ADSCs possess high therapeutic effect, enhancing wound healing



We investigated the influence of ADSC Exos on wound healing in full-thickness cutaneous wounds in mouse feet in a model of STZ-induced diabetes. Mice were treated by subcutaneous injection of Exos from WT or circ-Astn1-modified ADSCs, or an equivalent volume of PBS Exo diluent. Exos with high circ-Astn1 concentration accelerated wound closure significantly compared to PBS-treated control mice. The wounds treated with high circ-Astn1-containing Exos were almost closed by 14 d, while large areas of scarring were visible in both controls and circ-Astn1-knockdown-Exo-treated wounds (Figure 4A). Immunofluorescence with CD31 staining verified that microvascular development was more extensive with Exo treatments, specifically with high-circ-Astn1-containing Exos compared with the control group. However, circ-Astn1-knockdown suppressed the therapeutic effect of Exos (Figure 4B and C). TUNEL staining suggested that circ-Astn1 Exos significantly suppressed skin tissue apoptosis compared with control treatment, but circ-Astn1-knockdown suppressed the therapeutic effect of Exos (Figure 4D and E). Hematoxylin and eosin staining also showed that circ-Astn1 Exos treatment significantly promoted skin tissue wound healing compared with control treatment, but circ-Astn1-knockdown suppressed the therapeutic effect of Exos (Figure 4F). RT-qPCR analysis confirmed that circ-Astn1 Exos significantly suppressed miR-138-5p expression (Figure 4G) but promoted SIRT1 (Figure 4H) and decreased FOXO1 (Figure 4I) expression at both the mRNA and protein levels compared with controls.

DISCUSSION

Vascular deficits are fundamental factors regarding diabetes-related traits. Although former investigations have revealed that the proangiogenic wound healing phase is blunted by diabetes, detailed knowledge of factors regulating skin revascularization as well as capillary stabilization in diabetic wounds was missing[23]. Previous investigations revealed that Exos derived from ADSCs promote diabetic wound healing by regulating the disease microenvironment[4,20]. There is also evidence that circRNAs belong to a new RNA family that has been found to be broadly expressed, and have indispensable biological activities in regulating skin wound healing[18]. In this study, we found a series of circRNAs, which RNA-Seq detection showed were abnormally expressed in ADSC Exos compared with fibroblast Exos. Among the abnormally expressed circRNAs, expression of mmu_circ_0000101 (circ-Astn1), mmu_circ_0008040, mmu_circ_0008061, and mmu_circ_0008099 was all increased significantly in ADSC Exos. Further study showed that circ-Astn1 decreased more significantly in EPCs after exposure to HG conditions. This suggesting that ADSC Exos protected EPCs from HG-induced damage related to circ-Astn1 delivery.

Our *in vitro* experiments revealed that HG conditions promoted EPC apoptosis and destroyed the ability of EPCs to differentiate into blood vessels. Transplantation of ADSC Exos exerted a protective effect in reversing HG-induced EPC damage. Increasing the circ-Astn1 content of Exos increased the protective effect. Bioinformatics analyses identified miR-138-5p as the circ-Astn1 downstream target, and this was confirmed by luciferase reporter (LR) experiments. A previous study revealed that overex-

pression of miR-138 aggravates HG-induced vascular cell damage[24]. Our current investigation also found that circ-Astn1 overexpression decreased miR-138-5p expression. Meanwhile miR-138-5p overexpression reduced vascular EPC differentiation, suggesting that circ-Astn1 protected against HG-induced EPC damage by miR-138-5p adsorption.

Additional bioinformatics results showed that SIRT1 was also a miR-138-5p downstream target and this was verified by LR experiments. SIRT1 is a highly conserved nicotinamide adenosine dinucleotide (NAD)-dependent deacetylase, which plays a regulatory role in metabolism and aging[25]. miR-138-5p overexpression reduced SIRT1 expression. Overexpression of SIRT1 restored vascular differentiation of EPCs after miR-138-5p upregulation. Previous studies have suggested that the SIRT1/FOXO1 pathway activity improves the stress microenvironment[26-28]. SIRT1 correlates to and deacetylates FoxO1. Moreover, previous studies have confirmed that SIRT1, a deacetylase that suppresses FoxO1 acetylation which is a crucial negative blood vessel development regulator, restrains anti-angiogenic activity[22,29,30]. Recently, it was reported that oxidative stress induces FoxO1 nuclear translocation which plays an important role in apoptosis regulation[26]. *In vivo* experiments have confirmed that Exos originating from circ-Astn1-modified ADSCs function indispensably in restoring EPC function and promoting wound healing by promotion of angiogenesis and suppression of apoptosis. RT-qPCR analysis demonstrated that treatment with Exos containing high levels of circ-Astn1 reduced miR-138-5p expression and promoted SIRT1. This increase in SIRT1 level suppressed FOXO1 expression, suggesting that Exos derived from circ-Astn1-modified ADSCs enhanced wound healing in a diabetic mouse model *via* miR-138-5p/SIRT1/FOXO1 axis regulation.

CONCLUSION

In conclusion, our research indicated that Exos derived from circ-Astn1-modified ADSCs enhanced wound healing in a diabetic mouse model *via* miR-138-5p/SIRT1/FOXO1 axis induction. Our study verified the therapeutic effects of circ-Astn1-Exos on an STZ-induced diabetic wound healing model. However, more in-depth studies are required to determine the actual role of miR-138-5p/SIRT1/FOXO1 in wound healing.

ARTICLE HIGHLIGHTS

Research background

Wound healing impairment is a dysfunction induced by hyperglycemia and its effect on endothelial precursor cells (EPCs) in type 2 diabetes mellitus. There is increasing evidence showing that exosomes (Exos) derived from adipose-derived mesenchymal stem cells (ADSCs) exhibit the potential to improve endothelial cell function along with the wound healing process.

Research motivation

The potential therapeutic mechanism of ADSC Exos in wound healing in diabetic mice remains unclear.

Research objectives

To verify the effect of treatment with Exos from circular RNA astrotactin 1 (circ-Astn1)-overexpressing ADSCs on high glucose (HG)-induced EPC dysfunction.

Research methods

In this study, Exos from ADSCs and fibroblasts were used for high-throughput RNA sequencing (RNA-Seq). ADSC-Exo-mediated healing of full-thickness skin wounds in a diabetic mouse model was investigated. We utilized EPCs to investigate the therapeutic function of Exos in cell damage and dysfunction caused by HG. We utilized a luciferase reporter (LR) assay to detect interactions among circ-Astn1, SIRT1 and miR-138-5p. We employed diabetic mice to verify the therapeutic effect of circ-Astn1 on Exo-mediated wound healing.

Research results

High-throughput RNA-Seq detection showed that circ-Astn1 expression was increased in ADSC Exos compared with Exos from fibroblasts. Exos containing high concentrations of circ-Astn1 had enhanced therapeutic effect in restoring EPC function under HG conditions by promoting SIRT1 expression. Circ-Astn1 expression enhanced SIRT1 expression through miR-138-5p adsorption, which was validated by LR assay along with bioinformatics analyses. Exos containing high concentrations of circ-Astn1 had better therapeutic effect on wound healing *in vivo* compared to wild-type ADSC Exos. Immunofluorescence and immunohistochemical investigations suggested that circ-Astn1 enhanced angiopoiesis through Exo treatment of wounded skin as well as suppressing apoptosis through promotion of SIRT1 and decreased FOXO1 expression.

Research conclusions

In summary, we concluded that circ-Astn1 promoted the therapeutic effect of ADSC-Exos and thus improved wound healing in diabetes *via* miR-138-5p absorption and SIRT1 upregulation. Based on our data, we advocate targeting the circ-Astn1/miR-138-5p/SIRT1 axis as a potential therapeutic alternative for treatment of diabetic ulcers.

Research perspectives

More in-depth studies are required to determine the actual role of miR-138-5p/SIRT1/FOXO1 in wound healing.

FOOTNOTES

Author contributions: Wang Z and Wang YB designed the project and drafted the paper based on feedback from the other authors; Feng C, Liu H, and Meng T performed all experiments and analyses; Huang WQ and Song KX took part in the analyses and draft revision.

Supported by The Beijing Municipal Natural Science Foundation, No. 7192160.

Institutional animal care and use committee statement: The Animal Care and Use Committee of Peking Union Medical College Hospital approved the investigation protocol (No: XHDW-2020-01). We carried out all postoperative animal care along with surgical interventions following the NIH Guide for Care and Use of Laboratory Animals. All surgery and euthanasia were performed under sodium pentobarbital anesthesia (30 mg/kg) by intraperitoneal injection, and all efforts were made to minimize suffering.

Conflict-of-interest statement: The authors have no conflicts of interest to declare.

Data sharing statement: The datasets used or/and analyzed during the current study are available from the corresponding author on reasonable request.

ARRIVE guidelines statement: The authors have read the ARRIVE Guidelines, and the manuscript was prepared and revised according to the ARRIVE Guidelines.

Open-Access: This article is an open-access article that was selected by an in-house editor and fully peer-reviewed by external reviewers. Abstract

BACKGROUND

Mesenchymal stem cells (MSCs) have been applied to treat degenerative articular diseases, and stromal cell-derived factor-1α (SDF-1α) may enhance their therapeutic efficacy. However, the regulatory effects of SDF-1α on cartilage differentiation remain largely unknown. Identifying the specific regulatory effects of SDF-1α on MSCs will provide a useful target for the treatment of degenerative articular diseases.

AIM

To explore the role and mechanism of SDF-1α in cartilage differentiation of MSCs and primary chondrocytes.

METHODS

The expression level of C-X-C chemokine receptor 4 (CXCR4) in MSCs was assessed by immunofluorescence. MSCs treated with SDF-1α were stained for alkaline phosphatase (ALP) and with Alcian blue to observe differentiation. Western blot analysis was used to examine the expression of SRY-box transcription factor 9, aggrecan, collagen II, runt-related transcription factor 2, collagen X, and matrix metalloproteinase (MMP)13 in untreated MSCs, of aggrecan, collagen II, collagen X, and MMP13 in SDF-1α-treated primary chondrocytes, of glycogen synthase kinase 3β (GSK3β) p-GSK3β and β-catenin expression in SDF-1α -treated MSCs, and of aggrecan, collagen X, and MMP13 in SDF-1α-treated MSCs in the presence or absence of ICG-001 (SDF-1α inhibitor).

RESULTS

Immunofluorescence showed CXCR4 expression in the membranes of MSCs. ALP stain was intensified in MSCs treated with SDF-1α for 14 d. The SDF-1α treatment

promoted expression of collagen X and MMP13 during cartilage differentiation, whereas it had no effect on the expression of collagen II or aggrecan nor on the formation of cartilage matrix in MSCs. Further, those SDF-1α-mediated effects on MSCs were validated in primary chondrocytes. SDF-1α promoted the expression of p-GSK3β and β-catenin in MSCs. And, finally, inhibition of this pathway by ICG-001 (5 μmol/L) neutralized the SDF-1α-mediated up-regulation of collagen X and MMP13 expression in MSCs.

CONCLUSION

SDF-1α may promote hypertrophic cartilage differentiation in MSCs by activating the Wnt/β-catenin pathway. These findings provide further evidence for the use of MSCs and SDF-1α in the treatment of cartilage degeneration and osteoarthritis.

Key Words: Stromal cell-derived factor-1α; Mesenchymal stem cells; Chondrogenic differentiation; Wnt/β-catenin; C-X-C chemokine receptor 4

Core Tip: In this study, we investigated the effect of stromal cell-derived factor-1α (SDF-1α) on the differentiation of bone marrow mesenchymal stem cells (MSCs) and primary chondrocytes *in vitro*. We demonstrated that SDF-1α promotes the chondrogenic differentiation of MSCs, and similar results were observed in primary chondrocytes. In addition, SDF-1α also activates the Wnt/β-catenin pathway to regulate chondrocyte hypertrophy and maturation in MSCs.

INTRODUCTION

Osteoarthritis (OA) is a chronic, multifactorial disease characterized by progressive degradation of articular cartilage[1]. The underlying molecular mechanism responsible for the pathogenesis of OA is not yet fully elucidated; as such, a disease-modifying therapy remains elusive[2], although a potential therapeutic strategy of cell-based cartilage regeneration using mesenchymal stem cells (MSCs) has been proposed[3,4]. It is known that following cartilage injury, MSCs undergo proliferation to form new cartilage and repair damage. During this process, chemokines play a role in targeted cell recruitment[5]. The chemokine stromal cell-derived factor-1α [SDF-1α, also known as C-X-C chemokine ligand (CXCL) 12 α][6] binds to the CXC receptor 4 (CXCR4) present in synovial fluid and cartilage tissues[7]. SDF-1α plays an important role in the targeted recruitment and chemotaxis of MSCs[8], and increased SDF-1α levels promote the entry of CXCR4-positive MSCs into damaged cartilage[9]. In addition, MSC recruitment mediated by the SDF-1α/CXCR4 axis has been shown to play an important role in other tissue repair processes[10]. Indeed, a previous study showed that intra-articular injection of meniscus progenitor cells promoted cartilage regeneration and improved OA *via* the SDF-1α/CXCR4 axis and by inducing progenitor cell homing[11]. Earlier, Hitchon *et al*[12] had reported the finding of upregulated expression levels of CXCR4 mRNA and protein in chondrocytes of rats with post-traumatic OA, while Kanbe *et al*[13] reported high SDF-1α expression in human chondrocytes of rheumatoid arthritis and OA joint fluid. This latter study also indicated that synovectomy significantly reduced SDF-1α and matrix metalloproteinase (MMP) concentrations in serum. Finally, Xiang *et al*[14] reported their study of human OA cartilage and *in vitro* SDF-1-induced OA chondrocytes, which demonstrated that inhibition of SDF-1α signaling was able to attenuate OA.

MSCs can differentiate into chondrocytes, which are characterized by SRY-box transcription factor 9 (Sox9), aggrecan, and collagen II expression[15]. *In vivo*, human MSCs used for cartilage repair undergo hypertrophic differentiation, which is characterized by an increase in cell volume and in the expression levels of several markers of hypertrophy, including runt-related transcription factor 2 (RUNX2), collagen X, MMP13, Indian hedgehog homolog, and alkaline phosphatase (ALP)[16]. Under physiological conditions *in vivo*, hypertrophic chondrocytes exhibit endochondral ossification. Furthermore, SDF-1α mediates several changes in the bone and cartilage[17], with roles in both physiologic and pathogenic processes. For example, SDF-1α/CXCR4 signaling regulates the bone morphogenetic protein-2-induced chondrogenic differentiation of MSCs and enhances chondrocyte

proliferation and maturation[18]. However, it also increases the expression of MMP3 in chondrocytes, leading to mechanical destruction of the bound matrix[19]. Therefore, despite its role in MSC recruitment, the direct effect of SDF-1α on cartilage differentiation by MSCs requires further clarification.

The present study focused on the direct role of SDF-1α in chondrocyte differentiation and demonstrated that SDF-1α participated in chondrocyte differentiation in MSCs. In addition, the Wnt/β-catenin pathway mediated the effects of SDF-1α on cartilage differentiation.

MATERIALS AND METHODS

MSC isolation and culture

MSCs were obtained from Sprague-Dawley (SD) rats. Ten male 4-8-wk-old SD rats weighing 150-200 g were housed in standard housing conditions with a 12-h light/dark cycle. The rats were euthanized using 20 mg/kg of ketamine intraperitoneally. Bone marrow was flushed from femurs of the SD rats using a 10-mL injector filled with Dulbecco's modified eagle medium (DMEM) and Ham's F12 medium containing 10% fetal bovine serum (all from Gibco; Thermo Fisher Scientific, Inc., Waltham, MA, United States), 100 IU/mL penicillin, and 100 IU/mL streptomycin (Boster Biological Technology, Pleasanton, CA, United States). The cultures were maintained at 37 °C in an atmosphere of 5% CO_2. The cells were grown for 48 h, and the medium was replaced. The cells were allowed to reach 70%-80% confluence and passaged by trypsinization using 0.05% trypsin/ ethylene diamine tetraacetic acid (Boster Biological Technology). The culture medium was replaced every 2 d. Rat MSCs cultured to passage 3 were used for the experiments.

Isolation and culture of primary chondrocytes

Ten male 3-d-old SD rats were euthanized by intraperitoneal ketamine, and their cartilage samples were soaked in a beaker containing 75% alcohol for 15 min. The cartilage surface of the proximal tibia was removed to a depth of 1.0-1.5 mm^3 using the micro-shear method and digested with 0.25% trypsin at 37 °C for 30 min. Following 10 min of centrifugation at 500 × *g*, the tissue pieces were collected and incubated with 0.25% collagenase II (Beijing Solarbio Science & Technology Co., Ltd., Beijing, China) at 37 °C for 24 h. After a second centrifugation, the chondrocytes were cultured under the same conditions as described for the MSCs.

Multilineage differentiation of MSCs

To confirm that the isolated cells were MSCs, their differentiation into bone, cartilage, and adipose cell lineages was induced. For bone differentiation, passage 3 cells were cultured with osteogenic medium (RASMX-90021; Cyagen Biosciences, Inc., Santa Clara, CA, United States). After 21 d, the cells were stained with 0.5% alizarin red S at room temperature. In brief, the cells were washed twice with phosphate-buffered saline (PBS), fixed with 4% paraformaldehyde for 15 min at room temperature, and then stained with alizarin red S solution for 30 min at room temperature. Morphology was evaluated using an inverted microscope (Leica DM IRM; Leica Microsystems, Wetzlar, Germany). Chondrogenic differentiation was achieved by pelleting 2.5 × 10^5 passage 3 cells in a 15-mL centrifuge tube at 500 × *g* for 5 min then resuspending the cells in 0.5 mL of chondrogenic induction medium [DMEM high-glucose, 100 nmol/L dexamethasone, 10 ng/mL transforming growth factor (TGF)-β 3, 50 mg/mL ascorbic acid 2-phosphate, 100 mg/mL sodium pyruvate, 40 mg/mL proline and insulin transferrin selenous acid-supplement][20]. The medium was replaced every 3 d. After 21 d, the pellets were fixed with 4% paraformaldehyde for 1 h at room temperature, then embedded in paraffin, cut into 5-μm sections, and stained with Alcian blue. Adipogenesis of MSCs was induced by culturing the cells in 6-well culture plates containing adipogenic medium (Cyagen Biosciences, Inc.). After 21 d, the cultures were fixed with 4% paraformaldehyde, stained with oil red O working solution (60% of 0.5% oil red O/ isopropanol in distilled water) for 1 h at room temperature, and observed using light microscopy (Leica DM IRM; Leica Microsystems).

Fluorescence staining

MSCs cultured in 12-well plates were prepared for immunofluorescence analysis (performed at room temperature). First, MSCs were fixed with 4% paraformaldehyde for 15 min at room temperature. The fixed cells were then permeabilized by incubating in 0.1% Triton (Boster Biological Technology, Inc.) in PBS for 10 min. After the cells were blocked with 3% bovine serum albumin (BSA; Boster Biological Technology, Inc.) in 0.1% Triton/PBS for 1 h at room temperature. The cells were initially incubated with anti-CXCR4 antibody (1:200; Abcam, Cambridge, United Kingdom) overnight at 4 °C and subsequently with an fluorescein isothiocyanate-labeled goat anti-rabbit IgG antibody (H + L) (1:200; Beyotime Institute of Biotechnology, Jiangsu, China) for 30 min at room temperature. The labeled cells were mounted with 4',6-diamidino-2-phenylindole (DAPI) at room temperature and observed by fluorescence microscopy.

MSC micromass culture

MSCs were first resuspended in F12-DMEM medium containing 10% fetal bovine serum, 0.25% penicillin-streptomycin, and 0.25% L-glutamine, and plated at a density of 2.5 × 10^5 cells/10 μL. After incubation for 4 h, a micromass culture medium supplemented with 1 mmol/L β-glycerophosphate and 0.25 mmol/L ascorbic acid with or without SDF-1α (PeproTech, Inc., Rocky Hill, NJ, United States) was added. The cells were cultured in chondrogenic induction medium that was replaced every other day. On day 7, the cells were stained with Alcian blue, and the absorbance of the supernatant was measured at 600 nm.

Chondrogenic differentiation assays

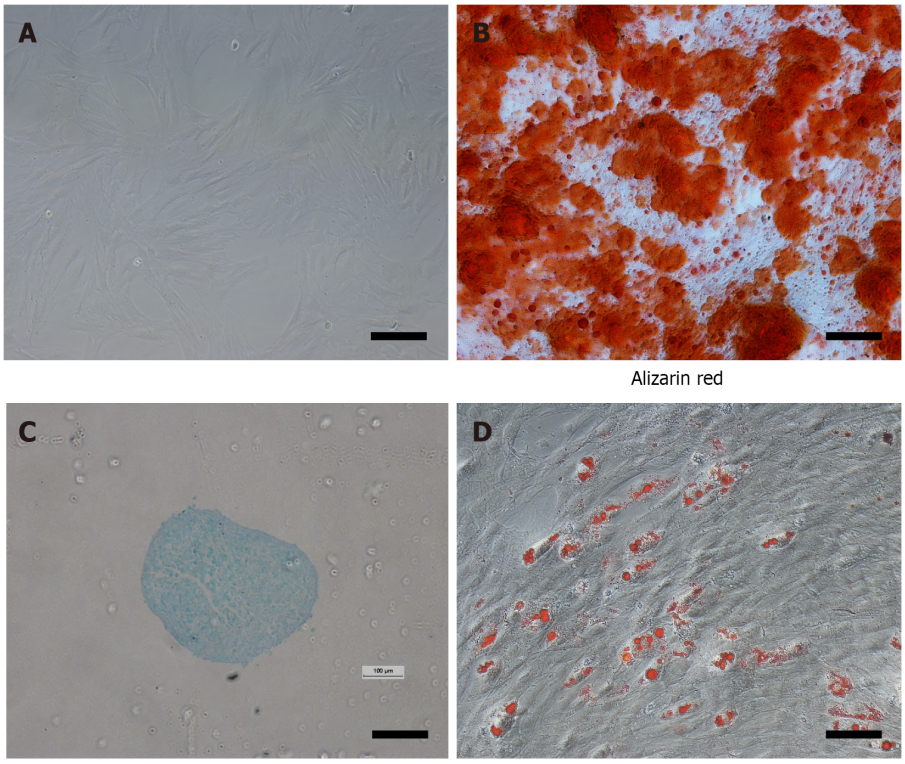
MSCs and primary chondrocytes were seeded in 6-well plates containing the chondrogenic induction medium. The following three conditions were assessed: Control (cytokine-free); 50 ng SDF-1α; and 100 ng SDF-1α[21]. The expression levels of collagen II, collagen X, aggrecan, MMP13, Sox9, and RUNX2 were determined. The expression levels of Wnt/β-catenin were measured in cells incubated for 24 h with 100 ng SDF-1α and ICG-001, an inhibitor of the Wnt/β-catenin pathway in MSCs.

Protein isolation and western blotting

Collagen II (1:2000), collagen X (1:2000), aggrecan (1:2000), MMP13 (1:1000), Sox9 (1:5000), and RUNX2 (1:2000) antibodies were purchased from Abcam, whereas the p- glycogen synthase kinase 3β (GSK3β) (1:2000), GSK3β (1:2000) and β-catenin (1:2000) antibodies were purchased from Cell Signaling Technology, Inc. (Danvers, MA, United States). Secondary mouse IgG (1:10000) or rabbit IgG (1:10000) antibodies were purchased from Abcam, and the anti- glyceraldehyde-3-phosphate dehydrogenase (GAPDH) (1:1000) antibody was from Boster Biological Technology. Protein was extracted from the cells using 100 mL radio immunoprecipitation assay buffer (Boster Biological Technology, Inc.) supplemented with protease and phosphatase inhibitors. After microcentrifugation for 20 min at 10000 × *g*, the lysates were prepared as described above. The cell protein concentration was detected with a bicinchoninic acid kit (Boster Biological Technology, Inc.). Briefly, a total of 20 μg of cellular protein *per* sample was loaded onto a 10% Bis-Tris gel according to the protocol provided by the manufacturer. The separated proteins were then transferred to polyvinylidene fluoride membranes (Thermo Fisher Scientific), which were blocked for 1 h at room temperature with 5% BSA (Boster Biological Technology, Inc.) in Tris-buffered saline containing 0.1% Tween-20 (TBST). The blots were probed overnight at 4 °C with rabbit antibodies against GAPDH, collagen II, collagen X, aggrecan, MMP13, Sox9, RUNX2, p-GSK3β, GSK3β and β-catenin. Following three washes with TBST, the blots were incubated for 1 h at room temperature with anti-mouse or anti-rabbit IgG-horseradish-peroxidase-labeled secondary antibodies and washed three times with TBST. Finally, immunoreactivity was detected with enhanced chemiluminescence, and densitometry was performed using Quantity One software (Bio-Rad Laboratories, Inc., Hercules, CA, United States).

Statistical analysis

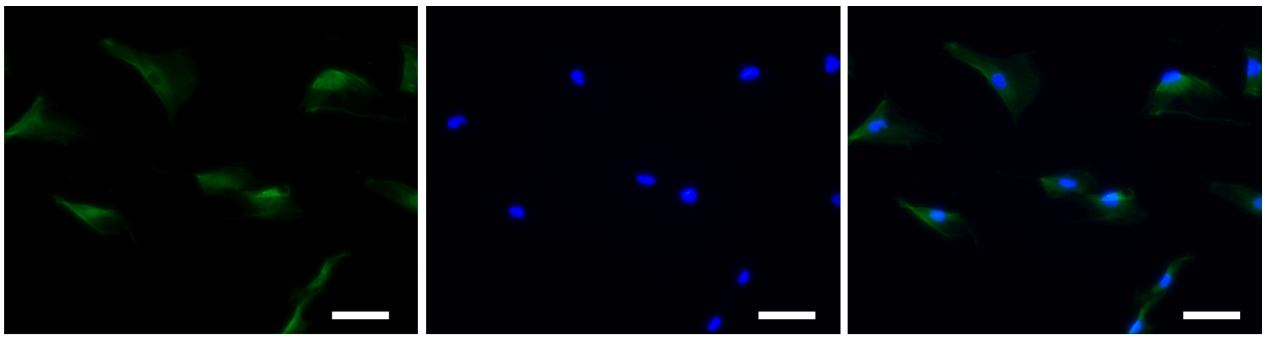
Statistical analysis was performed using GraphPad Prism 6.0 software (GraphPad Software, Inc., La Jolla, CA, United States). The results were summarized as mean ± standard deviation. Every experiment contained ≥ 3 replicate and was performed three independent times, unless otherwise stated. One-way analysis of variance and Fisher's least significant difference post hoc test were performed to compare differences between multiple groups. $P < 0.05$ indicated a statistically significant difference. we use 1 to express $P < 0.05$ and 2 to express $P < 0.01$.



RESULTS

MSC culture and multilineage differentiation potential

The cells were initially quiescent but began to proliferate rapidly after day 3. Growth yielded a monolayer structure, composed of fibroblasts (Figure 1A). At passage 3, the isolated cells were successfully differentiated into the three skeletal cell lineages: Bone, cartilage, and adipose tissue. After culture in the osteogenic medium, nodules formed that were positive for alizarin red S staining, indicating calcium-bearing mineral deposits (Figure 1B). After culture with cartilage induction medium, cartilage microspheres were positive for Alcian blue staining. Blue granules were also noted in MSCs (Figure 1C). After culture in the adipogenic induction medium, lipid accumulation in the form of lipid droplets was noted in some of the cells, which were stained red by oil red O (Figure 1D).



Expression of CXCR4 in rat MSCs

CXCR4 expression was detected in the membrane of the rat MSCs, while DAPI staining was confined to the nuclei of the MSCs (Figure 2).

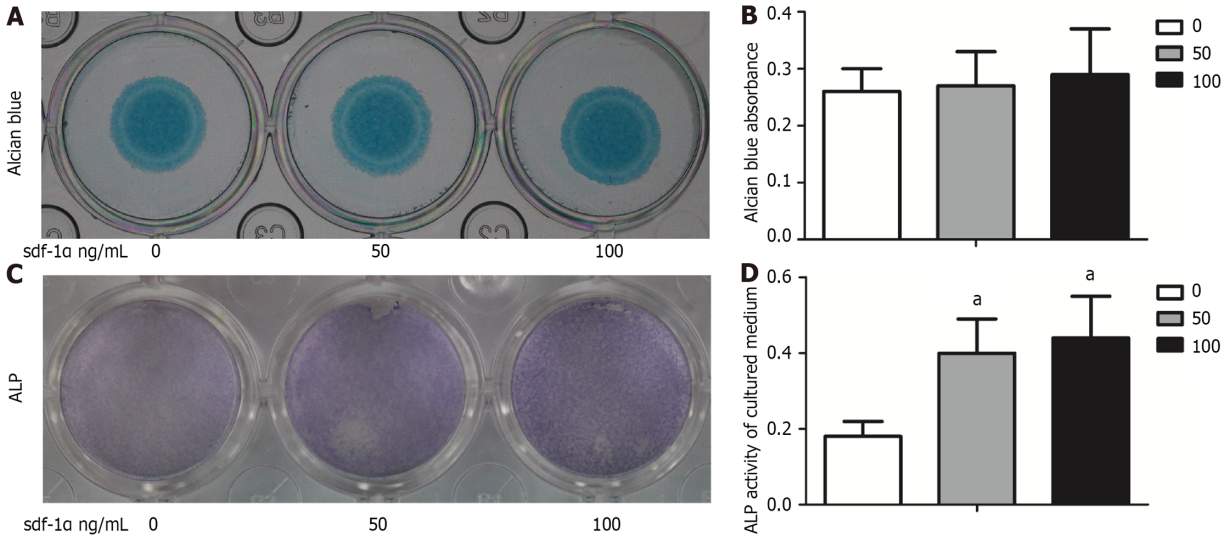

Figure 2 Expression of C-X-C chemokine receptor type 4 on rat mesenchymal stem cells. Representative image of the expression of C-X-C chemokine receptor type 4 (green fluorescence) on mesenchymal stem cell membranes. CXCR4: C-X-C chemokine receptor type 4; DAPI: 4',6-diamidino-2-phenylindole.

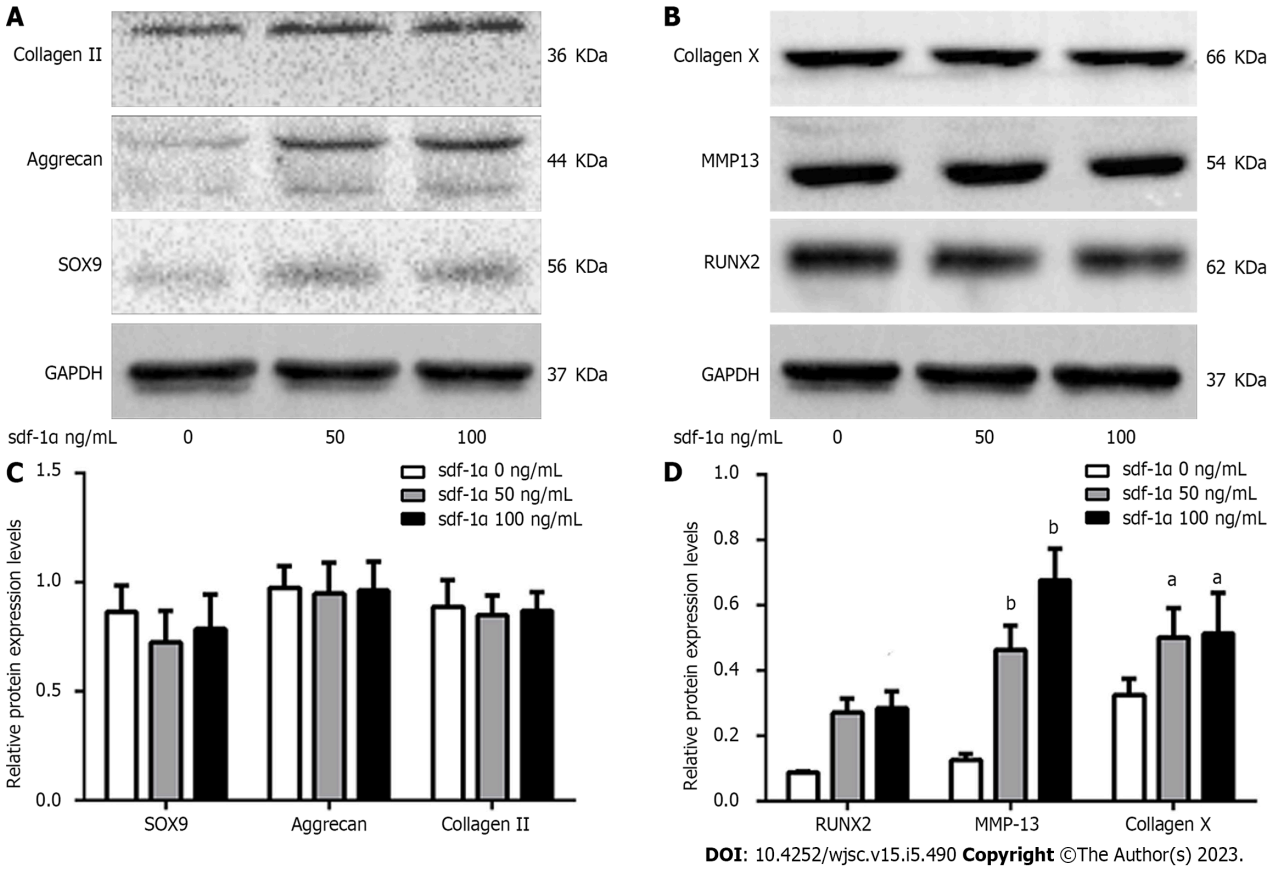
SDF-1a exerted no effect on early cartilage formation of MSCs but enhanced hypertrophic differentiation

No significant differences were noted between control (untreated) cells and cells treated with 50 ng SDF-1α or 100 ng SDF-1α in regards to the size of the cartilage micelles or the absorbance of Alcian blue (Figure 3A and B). ALP expression and activity levels were increased after 14-d SDF-1α treatment compared to control cells (Figure 3C and D).



Effect of SDF-1a on MSCs during cartilage differentiation

Western blotting indicated no significant differences in the expression levels of early chondrocyte differentiation markers (Sox9, aggrecan, and collagen II) between MSCs treated with SDF-1α and untreated MSCs on day 7 (Figure 4A). On day 14, however, the expression levels of chondrocyte hypertrophy markers (RUNX2, collagen X, and MMP13) were increased in a dose-dependent manner in the SDF-1α-

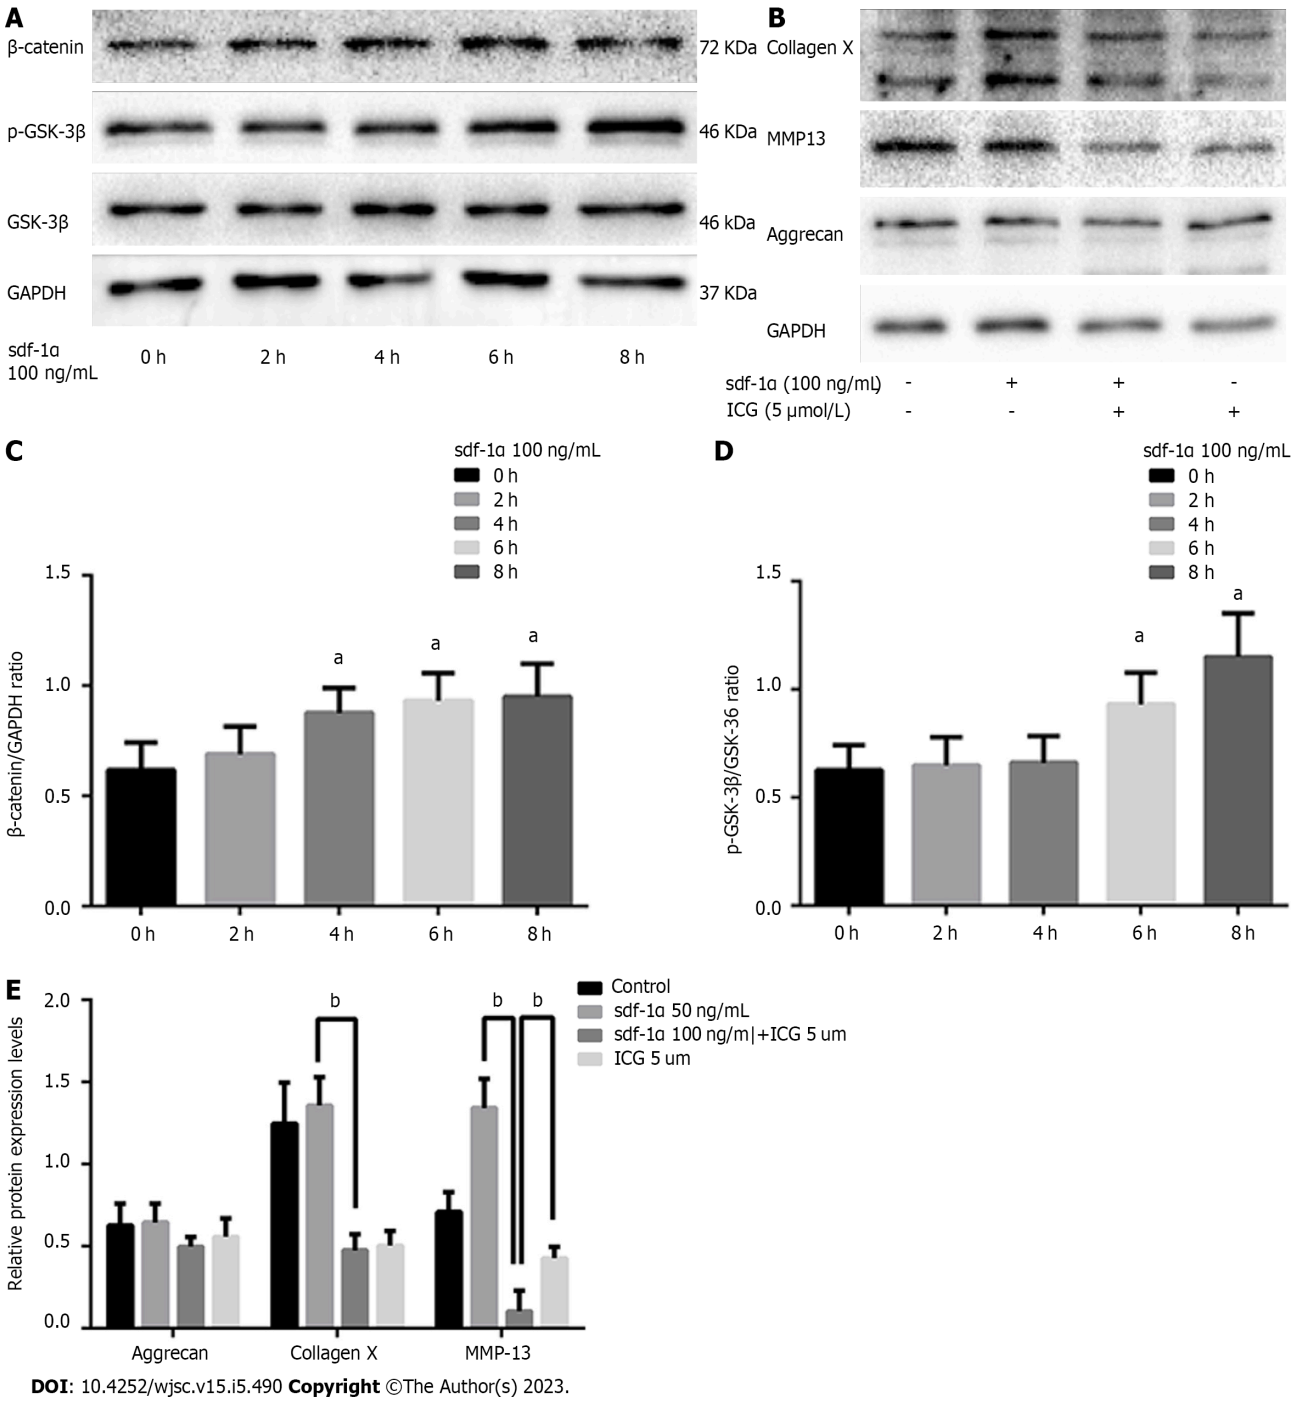
treated group (Figure 4B).

Effects of SDF-1a on the cartilage phenotype of primary chondrocytes.

Western blotting showed that SDF-1α treatment did not affect the expression levels of collagen II and aggrecan in primary chondrocytes, whereas it significantly increased the expression levels of collagen X and MMP13 in the MSCs (Figure 5).



Wnt/β-catenin pathway was involved in the effect of SDF-1a on cartilage differentiation.

SDF-1α promoted the expression of p-GSK3β, decreased degradation of β-catenin, and a gradual increase in β-catenin expression were demonstrated (Figure 6A). Upon blockade of the Wnt/β-catenin pathway *via* ICG-001, the SDF-1α-mediated increase in the expression levels of collagen X and MMP13 was neutralized (Figure 6B).

DISCUSSION

In the present study, rat MSCs, which were successfully differentiated into the three skeletal cell lineages and were positive for the expression of the CXCR4 receptors on the cell membrane, were used to assess the effects of SDF-1α on cartilage formation. The results indicated that the size of the cartilage micromass, the absorbance of Alcian blue, and the expression levels of Sox9, aggrecan, and collagen II did not significantly change in response to SDF-1α. However, the expression and activity levels of ALP and the expression levels of RUNX2, collagen X, and MMP13 were significantly increased. These results demonstrated that SDF-1α promoted hypertrophic cartilage differentiation in MSCs, while not affecting the early differentiation of cartilage. Similar results were obtained in primary chondrocytes. The data further indicated that SDF-1α caused a gradual increase in the expression levels of p-GSK-3β *in vitro* and activated the Wnt/β-catenin pathway, leading to increased collagen X and MMP13 expression levels. These findings demonstrated that the SDF-1α/CXCR4 axis was required in the cartilage differentiation process. Previous studies have implicated other chemokine types, including CXCL8 and CXCL1, as capable of promoting chondrocyte hypertrophy and calcification[22,23].

The Wnt/β-catenin pathway is a classical Wnt signaling pathway involved in tissue development and cell proliferation, differentiation, and apoptosis[24,25]. The signal transduction of the Wnt/β-catenin pathway is well defined and proceeds as follows. Initially, the extracellular Wnt proteins (Wnt-3a, Wnt-4, Wnt-8c, and Wnt-9a) combine with the frizzled and LRP proteins on the cell membrane to form an activation complex. Subsequently, the phosphorylation of GSK-3β blocks the phosphorylation and

Figure 6 Wnt/β-catenin pathway involvement in the effects of stromal cell-derived factor-1α on cartilage differentiation. A: Expression levels of β-catenin, p-glycogen synthase kinase 3β (p-GSK-3β), and GSK-3β by western blotting; B: Blockage of the Wnt/β-catenin pathway with ICG-001 inhibited the expression levels of collagen X and matrix metalloproteinase 13; C: Relative β-catenin protein expression; D: Ratio of relative protein expression of p-GSK-3β to relative protein expression of GSK-3β (p-GSK-3β/GSK-3β); E: Relative aggrecan, collagen X, and MMP13 protein expression. $^{1}P < 0.05$, $^{b}P < 0.01$, Student's *t*-test. p-GSK-3β: p-glycogen synthase kinase 3β; GSK-3β: Glycogen synthase kinase 3β; MMP13: Matrix metalloproteinase 13; GAPDH: Glyceraldehyde-3-phosphate dehydrogenase; sdf-1α: Stromal cell-derived factor-1α.

degradation of β-catenin. Finally, β-catenin enters the cell nucleus and modulates T cell factor/Lymphoid enhancer factor binding, which initiates the transcription of downstream genes, thus causing biological changes[26-30]. Several Wnt signaling components regulate the hypertrophic maturation of chondrocytes. Specifically, Wnt can induce the accumulation of β-catenin, which then enters the nucleus and binds to cell factor/lymphoid enhancer-binding factor to promote the transcription of the collagen X and MMP13 genes. Ultimately, P-GSK3β can add phosphate groups to the serine/threonine residues at the β-catenin N terminus to promote its degradation[4.31].

Overexpression of the Wnt receptor frzb-1 was shown to hinder chondrocyte maturation and mineralization[32]. In a subsequent study, knock-out of the secreted frizzled-related protein 1, a Wnt signaling antagonist, led to a reduced height of the growth plate and increased calcification of

hypertrophic areas, indicating that activation of the Wnt signaling pathway accelerated endochondral ossification[33]. The findings of the present study are consistent with the collective previous results indicating that the SDF-1α/CXCR4 axis activates the Wnt/β-catenin signaling pathway in MSCs, which in turn increases the production of collagen X and MMP13. Conversely, when we treated the MSCs with the Wnt/β-catenin inhibitor ICG-001, the effects of SDF-1α were no longer observable, which confirmed the regulatory role of Wnt/β-catenin. Thus, the present study indicates that SDF-1α does not promote the early stages of cartilage differentiation nor increase the expression of Sox9, which is similar to the results of Kim *et al*[34].

Hypertrophic differentiation of chondrocytes is the primary barrier preventing the use of MSCs in therapeutic cartilage repair[35,36]. Hypertrophy is sometimes noted in OA[37,38]. However, SDF-1α also mediates MSC recruitment and can exert a positive role in OA[31]. The identification of cytokines that block cartilage hypertrophy caused by SDF-1α, promote physiological endochondral ossification, prevent mineralization of the extracellular matrix, and mediate chondrocyte apoptosis will contribute to an improved understanding of the pathogenesis of OA and provide targets for development of future treatment strategies for this disease[39].

There were some limitations in this study, which must be considered when seeking to generalize our findings. First, measuring the stimulation with SDF-1α in MSCs is challenging because the only verification technique is overexpression or knockdown of the CXCR4 receptor. Second, this study primarily used cell experiments and lacked an *in vivo* perspective to the experimental research. Regardless, through this study, we were able to adequately demonstrate effects of SDF-1α on cartilage differentiation in MSCs and primary chondrocytes.

CONCLUSION

The present study demonstrated a role of SDF-1α in promoting hypertrophic cartilage differentiation in MSCs and primary chondrocytes *in vitro*. SDF-1α activated the Wnt/β-catenin pathway in MSCs. Identification of the novel molecular mechanism by which SDF-1α promotes cartilage differentiation in MSCs suggests a therapeutic approach to OA and cartilage repair.

ARTICLE HIGHLIGHTS

Research background

Stromal cell-derived factor-1α (SDF-1α) has a chemotactic effect on mesenchymal stem cells (MSCs), and SDF-1α and MSCs are used together to treat cartilage degeneration and cartilage defects. The specific effects of SDF-1α on cartilage differentiation in MSCs need to be clarified.

Research motivation

Understanding the effects of SDF-1α on MSCs will provide a new theoretical basis for the use of MSCs in the repair of cartilage degeneration.

Research objectives

To explore the role and mechanism of SDF-1α on cartilage differentiation in MSCs and primary chondrocytes.

Research methods

MSCs were treated with SDF-1α and subsequently stained for alkaline phosphatase and with Alcian blue to demonstrate chondrogenic differentiation. Western blot analysis was used to examine the expression of cartilage differentiation-related and Wnt/β-catenin pathway proteins in MSCs and primary chondrocytes.

Research results

After extraction and incubation with the appropriate differentiation media, MSCs differentiated into the three skeletal lineages. SDF-1α exerted no effect on early cartilage formation but enhanced hypertrophic differentiation in MSCs. SDF-1α had no effect on the expression of SRY-box transcription factor 9, aggrecan, and collagen II but increased the expression of runx family transcription factor 2, collagen X, and matrix metalloproteinase 13 in MSCs and primary chondrocytes. SDF-1α increased the expression of p- glycogen synthase kinase 3β and β-catenin.

Research conclusions

SDF-1α enhanced hypertrophic differentiation in MSCs and primary chondrocytes. This effect was achieved by activating the Wnt/β-catenin pathway.

Research perspectives

These findings provide a new theoretical basis for the treatment of cartilage degeneration with MSCs.

ABOUT COVER

Editorial Board Member of *World Journal of Stem Cells*, Luminita Labusca, MD, PhD, Senior Researcher, National Institute of Research and Development in Technical Physics Iasi, 47 D Mangeron Boulevard, Iasi 70050, Romania. drlluminita@yahoo.com

AIMS AND SCOPE

The primary aim of *World Journal of Stem Cells* (*WJSC*, *World J Stem Cells*) is to provide scholars and readers from various fields of stem cells with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJSC* publishes articles reporting research results obtained in the field of stem cell biology and regenerative medicine, related to the wide range of stem cells including embryonic stem cells, germline stem cells, tissue-specific stem cells, adult stem cells, mesenchymal stromal cells, induced pluripotent stem cells, embryonal carcinoma stem cells, hemangioblasts, lymphoid progenitor cells, *etc*.

INDEXING/ABSTRACTING

The *WJSC* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Journal Citation Reports/Science Edition, PubMed, PubMed Central, Scopus, Biological Abstracts, BIOSIS Previews, Reference Citation Analysis, China National Knowledge Infrastructure, China Science and Technology Journal Database, and Superstar Journals Database. The 2022 Edition of Journal Citation Reports cites the 2021 impact factor (IF) for *WJSC* as 5.247; IF without journal self cites: 5.028; 5-year IF: 4.964; Journal Citation Indicator: 0.56; Ranking: 12 among 29 journals in cell and tissue engineering; Quartile category: Q2; Ranking: 86 among 194 journals in cell biology; and Quartile category: Q2. The *WJSC*'s CiteScore for 2021 is 5.1 and Scopus CiteScore rank 2021: Histology is 17/61; Genetics is 145/335; Genetics (clinical) is 42/86; Molecular Biology is 221/386; Cell Biology is 164/274.

Abstract

Mesenchymal stem cells (MSCs) can differentiate into various tissue cell types including bone, adipose, cartilage, and muscle. Among those, osteogenic differentiation of MSCs has been widely explored in many bone tissue engineering studies. Moreover, the conditions and methods of inducing osteogenic differentiation of MSCs are continuously advancing. Recently, with the gra-dual recognition of adipokines, the research on their involvement in different pathophysiological processes of the body is also deepening including lipid metabolism, inflammation, immune regulation, energy disorders, and bone homeostasis. At the same time, the role of adipokines in the osteogenic differentiation of MSCs has been gradually described more completely. Therefore, this paper reviewed the evidence of the role of adipokines in the osteogenic differentiation of MSCs, emphasizing bone formation and bone regeneration.

Key Words: Mesenchymal stem cells; Adipokines; Adipose tissue; Osteogenic differentiation; Osteogenesis; Bone regeneration

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Bone tissue supports and protects the organs of the human body. There is a close relationship between the immune system and bone homeostasis. Adipose tissue is an essential accessory tissue around bone tissue, which regulates bone homeostasis through the secretion of adipocytokines. There are many types of adipokines, but only some have been studied in detail. Different adipokines affect the behavior and differentiation of mesenchymal stem cells under different local microenvironments and surrounding inflammation, thus coordinating and participating in the regulation of bone homeostasis.

INTRODUCTION

Adipose tissue is currently considered an endocrine organ[1] and comprises adipose cells, endothelial cells, fibroblasts, and immune cells[2]. Adipokines are factors secreted by adipose tissue and have multiple functions[3] involving various biological processes including immune responses, inflammation, glucose metabolism, insulin secretion, sensitivity regulation, regulation of blood pressure and myocardial contractility, blood vessel growth, and lipid metabolism[3,4]. Therefore, adipokines regulate different biological processes in different organs including the brain, liver, muscles, blood vessels, heart, and pancreas[5]. The function, characterization, molecular targets, and potential clinical disease correlation of adipokines are still unclear and the main focus of future adipokine research.

Mesenchymal stem cells (MSCs), pluripotent stem cells derived from the mesoderm, were identified by surface markers such as CD29, CD37, CD44, CD90, CD105, and CD166[6]. MSCs can be readily extracted from many tissues including bone marrow, umbilical cord, placenta, fat, liver, and skin[7]. However, the most well-studied source is bone marrow. MSCs have been shown to differentiate into mature cells of various tissues including cartilage, bone, tendon, ligament, and adipose tissue[8]. Due to its multipotential nature, MSCs have been used to treat many diseases including tumors, central nervous system disease, liver disease, graft-versus-host disease, inflammation, immune system disease, and bone regeneration[9-12]. In this review, we focus on the osteogenic differentiation of MSCs.

Bone is a rigid organ that supports and protects the other vital organs in the body. In adults, bones are renewed approximately every 7 years[13], and bone formation by osteoblasts and bone resorption by osteoclasts play a significant role. Osteoclasts originate from hematopoietic stem cell precursors, and osteoblasts originate from MSCs[14]. The dynamic balance of the two processes maintains the stability of bone metabolism, whereas the destruction of balance leads to various diseases including osteoporosis [15], osteopenia[16], and bone nonunion[17]. Osteoblasts promote the deposition of calcium salts in the bone matrix and stimulate bone remodeling and osteoblast differentiation of MSCs. It can be verified by the detection of runt-related transcription factor 2 (RUNX2), alkaline phosphatase (ALP), and osteopontin (OPN). Therefore, the biological characteristics of MSC osteogenic differentiation have been widely used in bone tissue engineering to treat bone defects caused by trauma, infection, and tumor surgery[18-20]. As a common progenitor of both adipocytes and osteoblasts, MSCs are in a delicate equilibrium state during differentiation, whereas adipose-inducing factors inhibit the osteogenic differentiation of MSCs. In contrast, bone-inducing factors inhibit the adipogenic differentiation of MSCs[6]. As an important active secretion of fat, the position and role of adipokine in the osteogenic differentiation of MSCs are worth further consideration. Therefore, we reviewed the role of adipokines in the osteogenic differentiation of MSCs.

CYTOKINE AND CYTOKINE-LIKE PROTEINS

Interleukin (IL) is an essential inflammatory adipokine that plays a vital role in the differentiation of MSCs in the early stage of bone reconstruction[21]. Lacey *et al*[22] found that low-dose IL-1β (0.001-1 ng/mL) inhibited ALP activity, reduced RUNX2 and procollagen expression, and inhibited the degree of mineralization of MSCs in mice. IL-6 is a multifunctional lymphoid factor with pro-inflammatory and anti-inflammatory effects[23]. At the same time, it can be secreted by osteoblasts to stimulate the secretion of osteoclasts and participate in bone homeostasis. IL-6 induces osteogenic differentiation in human bone marrow-derived MSCs (BMSCs) *via* mitogen-activated protein kinase signaling[24]. IL-10 can reduce the synthesis of pro-inflammatory cytokines and chemokines and inhibit the expression of IL-1 and tumor necrosis factor alpha (TNF-α)[25]. In mice, IL-10 inhibits the osteogenic differentiation of MSCs prior to ALP expression[26]. IL-17 cytokines act by binding to the IL-17 receptor family[27]. In the early stage of bone injury, IL-17 secretion increases, promoting the transformation of MSCs into bone

progenitor cells or osteoblasts. In some cases, IL-17 can also act as an anti-osteoblast factor, leading to bone loss[28,29].

TNF-α is a pro-inflammatory cytokine that can bind to the TNF receptor superfamily and participate in the regulation of a variety of biological processes. Different doses of TNF-α showed different osteogenic differentiation activity of MSCs. Wang *et al*[30] showed that a high dose of TNF (50 ng/mL) could stimulate the upregulation of some osteogenic factors in MSCs, including vascular endothelial growth factor and insulin growth factor. Lacey *et al*[22] cultured BMSCs with different doses of TNF-α and found that low-dose TNF-α (0.1-10 ng/mL) inhibited the mineralization and activation of ALP and OPN in cultured MSCs.

Monocyte chemotactic protein 1 (MCP-1), also known as C-C motif chemotactic factor ligand 2, can influence monocyte migration and subsequent macrophage polarization[31]. Xie *et al*[32] showed that in the process of osteogenic differentiation, MSCs from patients with ankylosing spondylitis secreted more MCP-1 than MSCs from healthy people. Enhanced MCP-1 secretion promoted monocyte migration, increased classical macrophage polarization, and enhanced TNF-α secretion[32]. Other adipokine-related cytokines, such as progranulin and resistin, have not been reported to correlate with MSC osteogenic differentiation.

Transforming growth factor β (TGF-β) has a unique correlation with the differentiation of adult MSCs [33]. Through the precise matching of ligands, receptors, and cell signaling molecules, TGF-β is involved in the lineage transformation process of the differentiation of various stem cells such as lipids, osteoblasts, chondrogenic and myogenic cells[34]. Tang *et al*[35] confirmed that TGF-β1 induced the migration of MSCs to the bone resorption site of mice by activating the activin receptor-like kinase 5-Smad2/3-Smad4 pathway and restricted the further recruitment of osteoclasts but did not induce osteogenic differentiation. However, other studies have reported that TGF-β inhibits osteogenic differentiation through Wnt signaling interactions and inhibits RUNX2 through the activation of Smad3[36,37]. However, TGF-β has also been reported to promote the osteogenic differentiation of MSCs[38,39]. However, further research needs to be carried out in the future.

Chemerin is a secreted protein derived from adipocytes and liver cells involved in physiological processes including inflammation, angiogenesis, and calcium mobilization[40,41]. Epidemiological studies have reported that patients with osteoporosis have higher circulating chemerin[42], and the knockout of chemerin or its receptor CMKLR1 inhibits lipogenesis and promotes the osteogenic differentiation of MSCs[43]. Li *et al*[41] showed that chemerin promoted the osteogenic differentiation of C3H10T1/2 cells and MSCs through Akt/Gsk3β/β-catenin signaling. However, Akt inhibitors (MK2206) inhibited chemerin's promotion of osteogenic differentiation and active β-catenin.

PROTEINS OF THE FIBRINOLYTIC SYSTEM

Plasminogen activator inhibitor-1 (PAI-1) is a serine protease inhibitor of the fibrinolytic system[44]. Adipose-derived PAI-1 is associated with various pathologic conditions including inflammation, diabetes, cancer, and obesity[44]. Takafuji *et al*[45] studied the role of PAI-1 in the osteogenic differentiation of MSCs using wild-type and PAI-1-deficient mice and found that the loss of PAI-1 significantly weakened the expression of BMSC osteogenic genes, such as bone morphogenetic protein 2 (BMP-2) and ALP.

Tissue factor, another adipokine that plays a crucial role in the clotting process[46], whose overexpression in the body can lead to multiple forms of thrombosis[47]. In a study aimed at improving coagulation activity, Rangasami *et al*[48] found that pluronic micelle-mediated tissue factor silencing could effectively induce the higher differentiation of MSCs in osteogenic and lipid-forming media.

COMPLEMENT AND COMPLEMENT-RELATED PROTEINS

Adipsin was the first adipocyte-secreted protein to be identified[49] and is currently named complement factor D[50]. Fat cells produce it through the activation of peroxisome proliferator-activated receptor gamma[51]. More recently, adipsin was shown to promote insulin secretion by pancreatic β cells and prevent β-cell death[52]. By activating Wnt signaling, adipsin initiates adipogenesis from BMSCs[53]. Experiments on BMSCs of adipsin knockout mice showed the increased expression of mineralized nodules and osteoblast markers including RUNX2, COL1A1, and osteocalcin compared with MSCs of normal origin[53].

Complement and complement-related proteins from adipose tissue include complement component 1q and TNF-related protein family, complement factor B, and acylating simulation protein[3,54]. However, it has not been reported whether they induce or inhibit the osteogenic differentiation of MSCs.

ADIPOKINES

Leptin, a hormone derived from adipose tissue, is involved in pathophysiological processes such as food absorption, energy metabolism, inflammation, immunity, and bone homeostasis[55-58]. Leptin binds to its leptin receptor, a marker specific to BMSCs[59]. Leptin has been shown to cross-regulate BMP-9 signaling through the JAK/STAT signaling pathway in MSCs, thereby enhancing BMP-9-induced osteogenesis[60].

Adiponectin plays a vital role in anti-inflammation, glucolipid metabolism, and insulin resistance regulation[61,62]. Wang *et al*[63] reported that adiponectin regulates BMSC osteogenic differentiation and osteogenesis through the Wnt/β-catenin pathway. Similar results have also been reported in other studies[64-66].

Visfatin is commonly produced by visceral adipose tissue and is also known as nicotinamide phosphoribosyltransferase (Nampt) or pre-B cell cluster enhancer. It is strongly expressed in osteogenic differentiation[67] and promotes the proliferation and mineralization activity of osteoblasts[68]. Visfatin induces the secretion of IL-6, IL-8, and MCP-1 during the osteogenic differentiation of MSCs and significantly increases matrix mineralization during osteogenic differentiation, while the expression of type I collagen is decreased[69].

Nicotinamide adenine dinucleotide (NAD) is involved in energy metabolism and protein modification[70]. Nampt has recently been identified as a novel adipokine[71]. Nampt is a rate-limiting enzyme and participates in all-around MC3T3 E1-osteogenesis prior to the cell differentiation process of NAD salvage pathways. Knocking out Nampt, or adding its specific inhibitor, Fk866, resulted in decreased intracellular NAD concentration and decreased osteogenic ability[67]. Thus, Nampt can be used as a specific marker for the osteogenic differentiation of MSCs[72].

Visceral adipose tissue-derived serine protease inhibitor (vaspin), an adipose-derived hormone, attenuates osteogenic differentiation of the preosteoblast cell line MC3T3-E1[73] and antagonizes the osteogenic differentiation of rat osteoblasts. However, the role of vaspin in the osteogenic differentiation of MSCs has not been reported[74].

BMPs, the largest component of the TGF-β ligand family, regulate multiple organogenetic pathways, fat formation, and energy metabolism[75,76]. BMP-2, BMP-3, BMP-4, BMP-5, BMP-6, and BMP-7 all strongly promote osteogenesis. Short-term addition of BMP-2 increases osteocalcin expression[77], and BMP-7 induces the increased expression of ALP, a marker of osteoblast differentiation, and accelerates calcification[78]. The absence of BMP-2 and BMP-4 results in severely impaired osteogenic function, but the limb skeleton still develops normally without BMP-4[79]. BMP-3 regulates adult bone mass by limiting the differentiation of bone progenitor cells into mature osteoblasts[80]. It is important to note that BMP-7 has been marketed and used in surgery to aid fracture healing, with no reported local or systemic adverse events[81]. The effects of BMP-5[82,83] and BMP-6[84,85] on the osteogenic differentiation of MSCs have also been reported.

Nesfatin-1 is a novel anorexia polypeptide that has a wide range of biological effects including energy metabolism, gastrointestinal function, anxiety and depression, and the regulation of cardiovascular and reproductive function[86-88]. The role of nesfatin-1 in the osteogenic differentiation of MSCs has not been reported, but it can promote the expression of osteogenic genes such as ALP and RUNX2 in newly derived rat stem cells[89]. Therefore, we speculate that Nesfatin-1 has a similar role in the osteogenic differentiation of MSCs, but this conclusion still needs to be confirmed by further studies.

Cathepsins are an important category of enzymes located within the lysosomes[90]. Cathepsins are produced by various tissues, which also include adipose tissue[91]. Cathepsin K is a crucial enzyme in the degradation of the organic bone matrix, and its expression in bone formation-related cells, including fibroblasts, osteoblasts, and MSCs, has also been confirmed[92,93]. Zhang *et al*[94] showed that knockout or inhibition of cathepsin K can promote the regeneration of BMSCs of jaw bone through glycolysis, thus promoting alveolar bone regeneration. Similarly, cathepsin S deficiency alters the balance between adipocyte and osteoblast differentiation, increases bone turnover, and alters bone microstructure[95].

Apelin is an endogenous ligand of the G protein-coupled apelin receptor[96]. Besides being an adipokine, apelin is also expressed in skeletal muscle, the central nervous system, the heart, and other tissues, and is involved in lipolysis, glucose metabolism, cell proliferation, and angiogenesis[97]. Exogenous addition of apelin protein or overexpression of apelin promotes postpositional MSC osteoblast differentiation by activating the Wnt/β-catenin signaling pathway[98].

Omentin-1 is the adipokine most commonly expressed in omental adipose tissue and is also abundant in plasma[99]. Omentin-1 is involved in the physiological processes of inflammation, insulin, and cardiovascular functions[99,100]. For bone effects, a study of postmenopausal women found a negative correlation between omentin-1 levels and lumbar bone density[101]. Tang *et al*[102] found that omentin-1 has a dose-dependent effect on the viability of MC3T3-E1 cells, which can significantly increase the expression of members of the TGF-β/Smad signaling pathway, and also significantly increase the expression levels of BMP-2, RUNX2, OPN, osteocalcin, and other proteins, thus promoting osteogenesis.

Lipocalin 2 (LCN2) is a protein involved in host defense, autoimmunity, insulin resistance, skin healing, tumor, and infection[103,104]. LCN2 disrupts osteoclast formation in bone tissue by negatively regulating the proliferation and differentiation of osteoclast precursors[105]. As a secretory bone factor,

LCN2 positively affects the osteogenic differentiation and *in vivo* osteogenesis of MC3T3-E1[106].

Melatonin is an indoleamine that is synthesized and secreted primarily by the pineal gland in mammals but is also secreted by adipose tissue[107]. Melatonin mainly affects the circadian rhythm and sleep-wake cycle and is also involved in immune regulation and inhibition of tumor growth[108,109]. Melatonin is also involved in MSC differentiation, which is involved in developing and regenerating bone, muscle, and fat tissues. In BMSCs, melatonin enhances osteogenesis and inhibits lipogenesis. Melatonin also differentiates bone marrow progenitors from adipocytes to osteoblasts[110,111].

Gremlin-1 is a highly conserved glycoprotein, mainly distributed in the extracellular matrix, with a small amount in the endoplasmic reticulum[112]. As an adipokine, gremlin-1 plays an important role in adipose tissue homeostasis[113]. At the same time, studies have shown that gremlin-1 is a BMP protein inhibitor, which can inhibit their binding to BMP receptors on the cell membrane by binding to BMP-2, BMP-4, and BMP-7[112]. Specific overexpression of gremlin-1 in mouse bone tissue results in severe osteoporosis; however, conditional knockout of gremlin-1 increases trabecular volume and bone formation[114]. Gremlin-1 has also been shown to inhibit the viability and osteogenic differentiation of human BMSCs[115].

LIPID TRANSPORT

Apolipoprotein E (ApoE), one of the main components of plasma very low-density lipoprotein[116], regulates lipid homeostasis by regulating lipid transport between tissues and cells. ApoE4 is associated with hyperlipidemia and hypercholesterolemia, leading to coronary heart disease, stroke, and atherosclerosis[117-119]. BMP-2 can upregulate the ApoE level of the mouse mesenchymal progenitor cell line (C3H10T1/2), leading to enhanced osteogenic differentiation. At the same time, ApoE is also expressed *in vitro* in mouse cranial primary osteoblasts with advanced osteoblast sequences[120].

ENZYMES

Dipeptidyl peptidase 4 (DPP-4) is a protein secreted in the salivary glands, prostate, seminal vesicles, endometrium, small intestine, and decidual membrane, and has recently been identified in adipose tissue as well[121]. DPP-4 is an important drug target in type 2 diabetes and directly induces insulin resistance in adipocytes and skeletal muscle[121]. DPP-4 not only reflects but also promotes adipose tissue dysfunction. Choi *et al*[122] found that DPP-4, when overexpressed, could restrict the induction of osteogenic differentiation of heart artery flap-derived mesenchymal cells by the autocrine insulin-like growth factor-1 signaling pathway, but this result has not been verified on MSCs.

Tissue inhibitors of metalloproteinases (TIMPs) have four main members, TIMP-1, TIMP-2, TIMP-3, and TIMP-4, and are primarily responsible for degrading most proteins in the extracellular matrix[123,124]. TIMPs are generally considered to be inhibitors of matrix metalloproteinases (MMPs) through the action of their terminal N-domain[125]. Meanwhile, TIMPs exist in the extracellular matrix in a soluble form and preemptively bind to the extracellular matrix, thus inhibiting the effect of MMPs[126]. TIMPs can selectively inhibit different MMPs, metalloproteinase and a disintegrin and metalloproteinase with thrombospondin motifs[125,126]. Inhibition of endogenous TIMP-1 can inhibit the proliferation, metabolic activity, and osteogenic differentiation ability of MSCs by activating Wnt/β-catenin signaling [127]. However, Liang *et al*[128] found in the process of MSC osteogenic differentiation that TIMP-1 knockdown increased the deposition of calcium nodules, ALP activity, and the expression of osteocalcin protein by activating Wnt/β-catenin signaling. The conclusions here are contradictory and need further confirmation by other studies. Studies targeting TIMP-3 have shown that increased expression of TIMP-3 can significantly promote osteogenic differentiation of MSCs in the fracture model of diabetic rats [129].

CONCLUSION

The formation and regeneration of bone tissue usually require regulation of the local microenvironment. The balance between bone resorption and bone regeneration is essential for bone tissue regeneration. Adipokines are exogenous immune regulatory substances secreted by adipose tissue, and are widely involved in pathophysiological processes of surrounding tissues, including bone homeostasis and bone regeneration. Not all human adipokines have been identified, but the current literature has revealed that the surface adipose tissue secretes more than 600 factors or proteins involving many processes of human pathophysiology[130]. There are many types of adipokines, including cytokines[22], fibrinolysin[44], complement and related proteins[49], enzymes[121], lipid transport systems[116], endocannabinoids [131], and angiotensinogen[132] (Table 1).

Table 1 Key activities of factors released by adipose tissue

Classification	Appellation	Mechanism	Ref.
Cytokine and cytokine-like proteins	Interleukin	IL-6 induces osteogenic differentiation in human bone marrow-derived MSCs *via* MAPK signaling. IL-10 inhibits osteogenic differentiation of MSCs prior to ALP expression. IL-17 promoting the transformation of MSC into bone progenitor cells or osteoblasts	[24,26,28]
	TNF-α	High dose of TNF could stimulate the upregulation of some osteogenic factors in MSCs, including VEGF and insulin-like growth factor. Low-dose TNF-α inhibited the mineralization and activation of ALP and OPN in cultured MSCs	[22,30]
	MCP-1	Influencing monocyte migration and subsequent macrophage polarization	[31]
	TGF-β	Through the precise matching of ligands, receptors, and cell signaling molecules, TGF-β is involved in the lineage transformation process of the differentiation of various stem cells, such as lipid, osteoblast, chondrogenic, and myogenic	[34]
	Chemerin	Chemerin promotes lipogenesis and inhibits osteogenic differentiation of MSCs	[42]
Proteins of the fibrinolytic system	PAI-1	Loss of PAI-1 significantly weakened the expression of bone marrow-derived MSC osteogenic genes, such as BMP-2 and ALP	[45]
	Tissue factor	Tissue factor silencing could effectively induce higher differentiation of MSCs in osteogenic and lipid-forming media	[48]
Complement and complement-related proteins	Adipsin	Adipsin initiates adipogenesis from bone marrow MSCs by activating Wnt signaling	[53]
Adipokines	Leptin	Leptin has been shown to cross-regulate BMP-9 signaling through the JAK/STAT signaling pathway in MSCs, thereby enhancing BMP-9-induced osteogenesis	[60]
	Adiponectin	adiponectin regulates BMSC osteogenic differentiation and osteogenesis through the Wnt/β-catenin pathway	[63]
	Visfatin	Promoting the proliferation and mineralization activity of osteoblasts	[68]
	Nicotinamide	Nampt is a speed-limit enzyme and participates in the all-around MC3T3-E1. Osteogenesis prior to the cell differentiation process of NAD salvage pathways	[67]
	Visceral	Attenuating the osteogenic differentiation of preosteoblast cell line MC3T3-E1	[73]
	Bone morphogenetic proteins	BMP-7 induced increased expression of ALP, a marker of osteoblast differentiation, and accelerated calcification. The absence of BMP-2 and BMP-4 resulted in severely impaired osteogenic function. BMP-3 regulates adult bone mass by limiting the differentiation of bone progenitor cells into mature osteoblasts	[78-80]
	Nesfatin-1	Promoting the expression of osteogenic genes such as ALP and RUNX2 in rats' newly derived stem cells	[89]
	Cathepsins	Knockout or inhibition of cathepsin K could promote the regeneration of bone marrow MSCs of jaw bone through glycolysis. Cathepsin S deficiency alters the balance between adipocyte and osteoblast differentiation, increases bone turnover, and alters bone microstructure	[94,95]
	Apelin	Promoting postpositional MSC osteoblast differentiation by activating the Wnt/β-catenin signaling pathway	[98]
	Omentin-1	Increasing the expression of BMP2, RUNX2, OPN, and osteocalcin	[102]
	Lipocalin 2	Disrupting osteoclast formation in bone tissue by negatively regulating the proliferation and differentiation of osteoclast precursors	[105]
	Melatonin	Differentiating bone marrow progenitors from adipocytes to osteoblasts	[111]
	Gremlin-1	BMP protein inhibitor	[112]
Lipid transport	ApoE	Enhancing osteogenic differentiation of the mouse mesenchymal progenitor cell line	[120]
Enzymes	DPP-4	Restricting the induction of osteogenic differentiation of heart artery flap-derived mesenchymal cells by the autocrine insulin-like growth factor-1 signaling pathway	[122]
	Tissue inhibitors of metallo-	Inhibition of endogenous TIMP-1 can inhibit the proliferation, metabolic	[127]

proteinases	activity, and osteogenic differentiation ability of MSCs by activating the Wnt/β-catenin signal

ALP: Alkaline phosphatase; ApoE: Apolipoprotein E; BMP-2: Bone morphogenetic protein 2; DPP-4: Dipeptidyl peptidase 4; IL: Interleukin; JAK: Janus kinase; MAPK: Mitogen-activated protein kinase; MCP-1: Monocyte chemotactic protein 1; MSC: Mesenchymal stem cell; Nampt: Nicotinamide phosphoribosyltransferase; OPN: Osteopontin; PAI-1: Plasminogen activator inhibitor-1; RUNX2: Runt-related transcription factor 2; TIMP-1: Tissue inhibitors of metalloproteinase; TGF-□: Transforming growth factor beta; TNF: Tumor necrosis factor; VEGF: Vascular endothelial growth factor.

In summary, this paper reviewed the current research on the regulation and influence of adipokine in the osteoblast differentiation of MSCs. However, this review did not include all currently discovered adipokines but only included published studies involving osteogenic differentiation of MSCs. Most of the included studies were conducted in BMSCs, with a small number involving osteoblast precursor cells, progenitor cells, and a small number of other tissue-derived stem cells. Our review suggests that different adipokines have different effects on the outcome of osteogenic differentiation, bone regeneration, and bone remodeling of MSCs. The progress of related research provides a good reference for subsequent preclinical and clinical studies and a new reference for treating osteogenic disorders and diseases of osteoblastic homeostasis.

Abstract

Cancer stem cells (CSCs) are a small proportion of the cells that exist in cancer tissues. They are considered to be the culprit of tumor genesis, development, drug resistance, metastasis and recurrence because of their self-renewal, proliferation, and differentiation potential. The elimination of CSCs is thus the key to cure cancer, and targeting CSCs provides a new method for tumor treatment. Due to the advantages of controlled sustained release, targeting and high biocompatibility, a variety of nanomaterials are used in the diagnosis and treatments targeting CSCs and promote the recognition and removal of tumor cells and CSCs. This article mainly reviews the research progress of nanotechnology in sorting CSCs and nanodrug delivery systems targeting CSCs. Furthermore, we identify the problems and future research directions of nanotechnology in CSC therapy. We hope that this review will provide guidance for the design of nanotechnology as a drug carrier so that it can be used in clinic for cancer therapy as soon as possible.

Key Words: Cancer stem cells; Nanotechnology; Nanoparticles; Nanodrug delivery systems; Drug resistance; Therapy

Core Tip: Cancer stem cells (CSCs) have the potential to self-renew, proliferate, and differentiate. CSCs play a key role in the occurrence, development, recurrence, and metastasis of tumors. Due to the good compatibility and biodegradability of nanomaterials, they are applied to target CSCs for drug delivery, photothermal therapy, and magnetic hyperthermia to treat cancer.

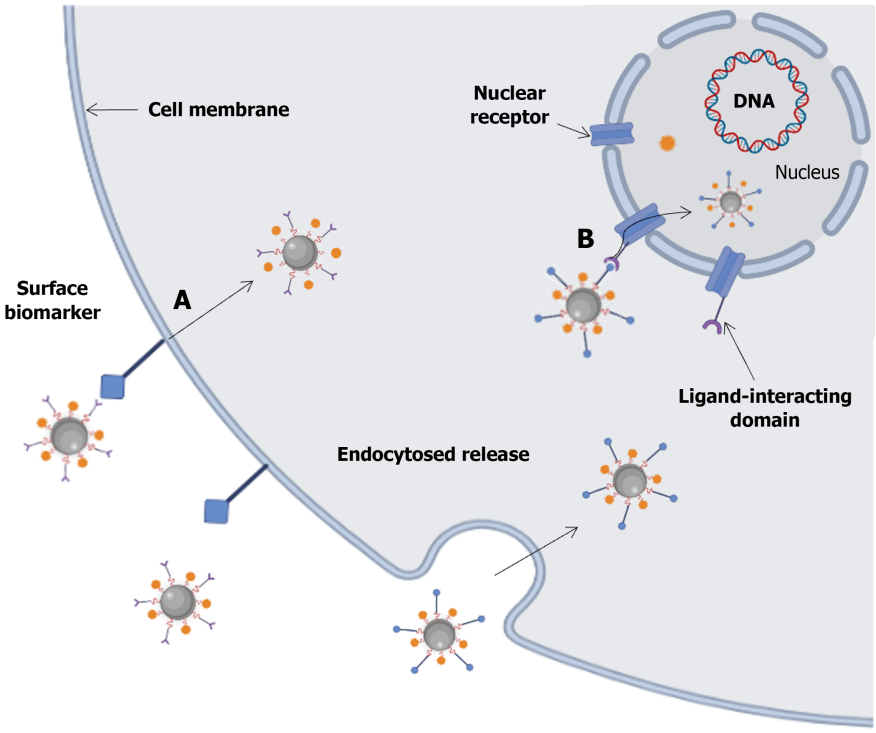
INTRODUCTION

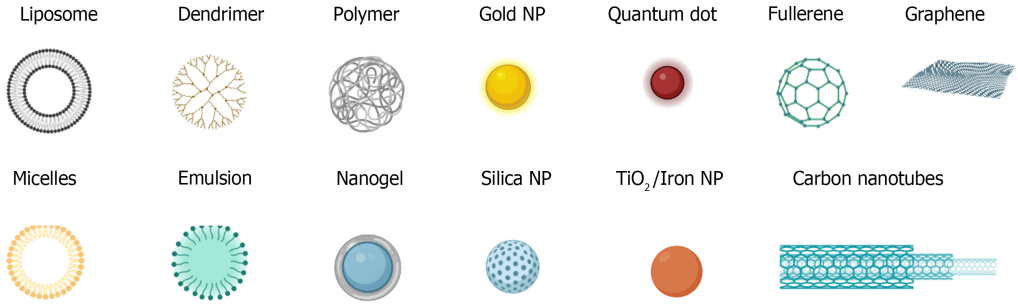
Cancer is a major threat to people's health and life worldwide[1]. One of every eight deaths is caused by cancer[2,3]. Current cancer treatments mainly include surgical intervention, radiation therapy, and chemotherapy, which often kill healthy cells and are harmful to patients. Therefore, researchers are seeking better ways to eliminate cancer cells, with less side effects. Some researchers are working on the use of various macrocyclic ligands for cancer therapy, making ruthenium an ideal choice over other transition metals due to its special chemical properties[4]. However, what plagues most cancer treatments is the presence of a small number of cancer stem cells (CSCs) in tumor tissues[5,6], which have the potential for self-renewal, unlimited proliferative capacity, and multidirectional differentiation [5,7]. These cells are in the G0 phase and hypoxic microenvironment and play a key role in tumorigenesis, progression, recurrence, and metastasis. The presence of CSCs in solid tumors such as breast cancer (BC)[8,9], human leukemia[10,11], colorectal cancer[12,13], glioblastoma multiforme (GBM)[14], and ovarian cancer[15] has been reported, and it has been confirmed that CSCs play an important role in the development of tumors.



CSCs have inherent properties such as phenotypic plasticity, drug efflux transporters, overexpression of antiapoptotic proteins, an efficient DNA repair system and a persistent stemness profile that make them resistant to conventional therapies such as chemotherapy and radiation[16-18]. In general, CSC resistance mainly occur through stem cell pathways including the hedgehog[19,20], Notch[21,22], Wnt/β-linked protein[23,24], Nanog[25,26], nuclear factor kappa B (NF-*k*B)[27], and epidermal growth factor receptor pathways[28]. They express ATP-binding cassette (ABC) transporter proteins that can abrogate potential drug damage. CSCs also activate DNA repair capacity within tumor cells and are resistant to cell death[29], which helps to prevent the recruitment of apoptotic factors[5,30]. Therefore, the development of effective anticancer strategies to specifically kill tumor cells and tumor stem cells will be central to cancer therapy.

In recent years, the popularity of nanotechnology has promoted the development of nanodrug delivery systems (NDDS), and various nanodrug carriers have been applied to the treatment of tumors. Due to their small size, biocompatibility, and biodegradability, nanoparticles (NPs) help to fully exploit the function of NDDSs as drug delivery systems/drug carriers, including as imaging agents and for photothermal therapy (PTT), recognition, and drug and gene delivery[31]. As the carrier of active drugs in the drug delivery model, NDDSs can ensure the specific release of active drugs in the patient's body, improve drug solubility and bioavailability and prolong maintenance to improve drug efficacy[32]. Nanocarriers offer remarkable specificity in targeted delivery through active and passive targeting mechanisms (Figure 1)[33,34]. In active targeting, NPs are conjugated to antibodies, peptides, aptamers, and other small molecules[34]. Drug delivery using NP targeting reduces toxicity in healthy cells, prevents drug degradation, and has the advantages of better specificity, biocompatibility, less cytotoxicity, extended half-lives, controlled drug release, and high drug loading capacity for NP-based cancer treatments compared to traditional chemo-cancer treatments[35]. In passive targeting, enhanced permeability and retention (EPR) effects result in NPs circulating slowly in the tumor microenvironment and being more concentrated there than in healthy tissue[36]. Some commonly used nanocarriers (Figure 2) include lipid and micelle-based NPs, polymer/non-polymer NPs, nanobinding, carbon nanotubes (CNTs), graphene oxide (GO), nanocapsules, dendritic macromolecules, polymer micelles, and quantum dots (QDs), which are used to enhance the effectiveness of therapeutic interventions by delivering nontoxic large payloads[37-39]. Recent advances in nanotherapeutics have led to the development and exploration of various nanomaterial carriers for efficient drug/therapeutic delivery.

CSCs have been identified as playing a central role in the setbacks currently faced in clinical trials and research. Therefore, designing a system that can target them at the cellular and system levels is the most promising avenue in the evolution of therapeutic design. By reviewing the application of nanotechnology in CSCs, we hope to provide guidance for the design and in-depth study of nanotechnology drug carriers so that they can be applied in clinic to treat cancer.



NANOTECHNOLOGY FOR CSC SORTING

To better understand the molecular basis of the contribution of CSCs to tumor progression, metastasis, and treatment resistance, many studies have identified biomarkers on the surface of CSC populations to distinguish them from the majority of tumor cells. Magnetic-activated cell sorting (MACS) is a CSC

sorting technique. Magnetic NPs have unique magnetic activity and are one of the most actively studied NPs, usually ranging in diameter from 1 to 100 nanometers. Basically, magnetic NPs are classified as magnetically manipulated substances, consisting mainly of iron oxides or other metals (iron, nickel, or cobalt). MACS microbeads are superparamagnetic particles coupled to highly specific monoclonal antibodies. The cell surface-specific antigens are combined with stem cell markers such as CD44, CD133, and epithelial cell adhesion molecule (EpCAM), connected to the magnetic bead, and the cells labeled with the conjugated magnetic bead is separated by providing a uniform magnetic field to sort out the corresponding CSC population (Figure 3).

KINDS OF NANODRUG DELIVERY SYSTEMS

To date, nanomedicine has been focused on identifying alternatives to tumor therapy, with researchers focusing on the design of various nanocarriers, which have been used to load various anticancer drugs and herbal medicines to target tumor cells. In fact, according to the National Institutes of Health, there have been clinical trials involving the use of nanotechnology in CSC therapy (Table 1). Because the mechanisms of multidrug resistance are very complex and varied, targeting one mechanism alone does not address clinical needs. Nanocarriers have good stability, a high encapsulation rate and a high drug

loading rate and have been proven to be effective carriers for genes and drugs delivered to tumor cells. This delivery induces apoptotic pathways and inactivates resistance genes for targeting tumor tissue to eliminate CSCs. According to the classification of nanotechnology used to target CSCs, they can be divided into Polymeric NPs(PNPs), liposomes, gold (Au) nanorods (GNRs), QDs, CNTs, GO, PTT, and magnetic fluid hyperthermia (Table 2).

PNPs

PNPs can enhance the therapeutic effects of drugs, reduce the drug resistance of CSCs, and improve the therapeutic effects of chemotherapy drugs. The following is a summary of the classification of PNPs through different antibody-ligand recognition (Figure 4), mesoporous silica ($mSiO_2$) NPs (MSNs), and other nanodrug delivery systems.

CD44

CD44[40,41] is a non-kinase transmembrane glycoprotein that is overexpressed in several cell types, including CSCs. Hyaluronic acid (HA) has become a research hotspot in drug release due to its simple chemical structure and inherent properties of targeting CD44. Kesharwani *et al*[42] designed a novel HA copolymerized styrene maleic acid and the effective anticancer agent 3,4-difluoromethylcurcumin to form nanomicelles. CD44+/CD133+/EpCAM+ pancreatic CSCs showed better uptake of HA-engineered nanomicelles and a better anticancer effect on CD44+ pancreatic CSCs. Furthermore, these nanomicelles significantly inhibited the expression of NF-κB, thereby reducing its proliferation and invasion. Debele *et al*[43] conjugated HA with hydrophobic 6-mercaptopurine (MP) and introduced doxorubicin (DOX) into colon cancer cells and colon CSCs through ligands. The inhibitory effect of the synthesized bisensitive polymer drug conjugate (HA-SS-MP) micelles on tumor growth was significantly higher than that of free drugs. In *vitro* cytotoxicity of HA-SS-MP and DOX-loaded HA-SS-MP micelles was great for CSCs (HCT116-CSCs). Gu *et al*[44] prepared mineralized HA-SS-tetracylecyl nanocarriers (M-HA-SS-TA) from oily, hydrophobic, and unstable sulforaphane (SFN), which showed a good response to highly reduced and weakly acidic tumor niches. The SFN nanomaterials (SFN/M-HA-SS-TA) can release SFN rapidly. Compared to free SFN, SFN/M-HA-SS-TA rapidly releases SFN in response to tumor niches, showing stronger inhibition of breast CSC (BCSC)-like properties (invasions, self-renewal, and tumor growth) *in vitro* and *in vivo*. However, magnetic fluid hyperthermia (MFH) mediated by anti-CD44 antibody-modified superparamagnetic iron oxide NPs (SPIONPs) can kill CSCs, and significantly inhibit the growth of transplanted Cal-27 tumors in mice[45].

CD133

The CD133 antigen is a five-fold transmembrane single-chain glycoprotein that exists on the surface of tumor stem cells. It is a key molecule that regulates the fate of stem cells and a functional marker of stem cells. It can be used to detect and isolate CSCs in various solid tumors[46]. NPs with SN-38 (anti-CD133 antibody-conjugated SN-38-loaded nanoparticles (CD133Ab-NPs-SN-38)), a topoisomerase inhibitor conjured by anti-CD133 antibody, targets CD133+HCT116 cells and inhibits colony formation. The CD133-targeted NP delivery system can eliminate CD133-positive cells[47]. The Wnt/β-catenin pathway plays critical roles in CSC generation and maintenance as well as in normal stem cells. Integrin subunit alpha 5-targeting NPs attenuate β-catenin and significantly reduce triple-negative BC (TNBC) metastasis and may provide a facile and unique strategy of specially attenuating β-catenin *in vivo* for treating metastatic TNBC[48]. Codelivery of DOX and salomycin (SAL) REDOX-triggered double-targeted liposomes CEP-LP@S/D can be used for the synergistic treatment of liver cancer. The system is based on the binding of CD133- and EpCAM-targeting peptides to form Y-shaped CEP ligands that anchor to the liposome surface and allow selective targeting of CD133EpCAMlCSC[49].

EpCAM

EpCAM, considered to be a homogenous cell-cell adhesion glycoprotein, is expressed in epithelial and circulating tumor cells (CTCs), as well as CSCs[50], and is involved in the regulation of cell adhesion, proliferation, migration, dryness, and the epithelial-to-mesenchymal transition (EMT) of cancer cells. Locatelli *et al*[51] coloaded GNRs and adriamycin (Adr) to label EpCAM by targeting the surface of CSCs and killed CSCs under laser ablation. Ishiguro *et al*[52] used RNA nanotechnology to pair milk source nanocapsules (MNVs) with synthetic oligonucleotide aptamers that could bind to EPCAM with high affinity and specificity and loaded small interfering RNA (siRNA) onto β-catenin. The EpCAM-targeted (ET) therapeutic MNV has been prepared. These ET-TMNVs can target EPCAM-positive stem cell populations and effectively release siRNAs within cells that inhibit β-catenin expression and tumor growth. For polymer nanomicelles (GNRS-1/curc@Pms) made from biocompatible poly(L-lactide-co-

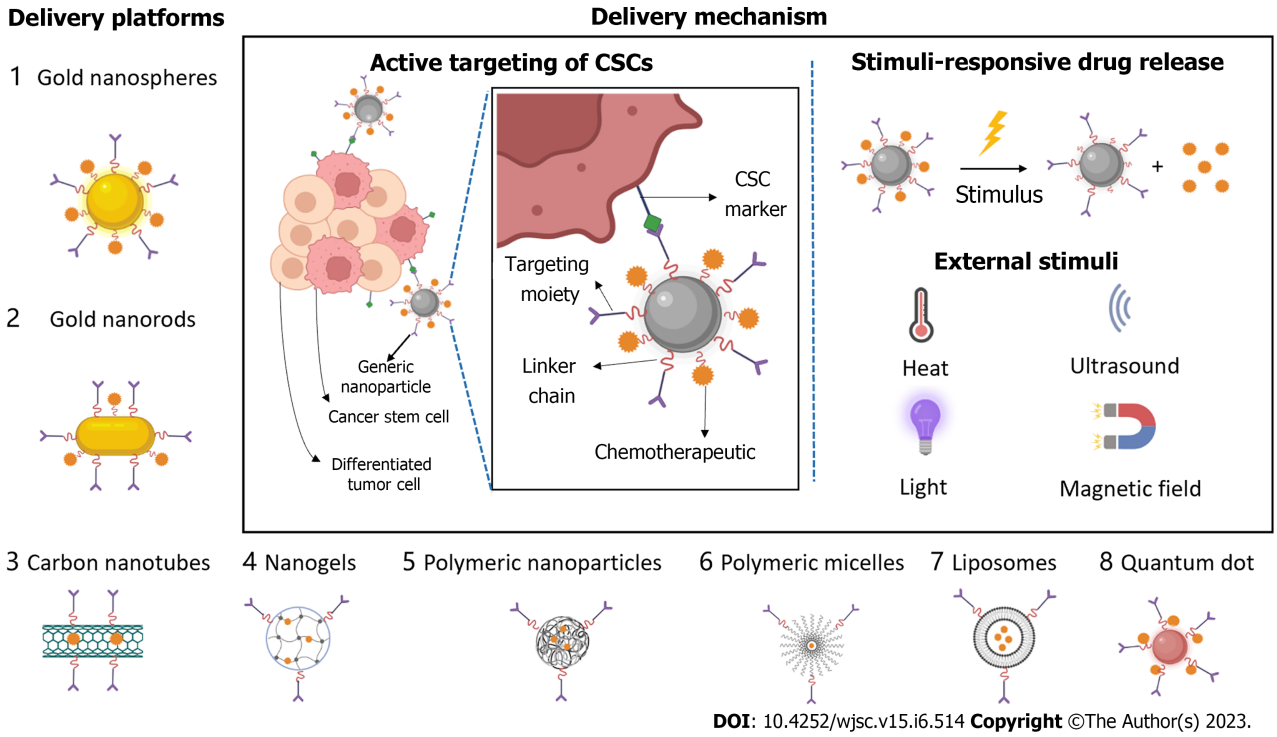

Figure 4 Nanoparticle-mediated targeted drug delivery to cancer stem cells (created with BioRender). CSCs: Cancer stem cells.

glycolide)-block-poly(ethylene glycol) (PLGA-b-PEG) copolymer as drug carriers for Adr and GNRs, when Adr/GNRs@Pms-antiEpCAM with EpCAM antibodies are modified, they are delivered to specific tumor stem cells and increase the drug concentration at the tumor site, thereby killing the entire tumor stem cell population[51].

MSN

MSN drug loading[53] can significantly enhance the cytotoxicity of anticancer drugs with low potency. Therefore, the positive polymer polyethylenimine (PEI) is usually coated and chemically modified to introduce a positive charge on the surface of MSNs, which can effectively bind the DNA structure, siRNAs, and other nucleic acids, thus enhancing their uptake by cells. The PEI-modified MSN was used for double delivery of the chemotherapy drug cisplatin, and the DNA encoding the hepatocyte nuclear factor 4 alpha transcription factor was used for gene therapy of liver cancer. This therapy inhibited the proliferation of CD133+ HUH7 cells, reduced the proportion of CSCs, and reduced the expression of dry-related genes. The nuclear targeting system of MSNs by Li *et al*[54] can directly target CSCs and enter the nucleus through anti-CD133 surface modification and heat-triggered exposure of the TAT polypeptide under an alternating magnetic field (AMF). Combined with hyperthermia and hypoxia-activated chemotherapy, the release of nuclear-targeted drugs eventually leads to complete apoptosis of CSCs. CSC-specific targeting of $mSiO_2$-dendritic polyglycerol (dPG) nanocarriers delivered the chemotherapy drug DOX and the P-glycoprotein (P-gp) inhibitor tariquidar (Tar) to reverse multidrug resistance (MDR) and enhance chemotherapy efficacy in bCSCs[55]. A targeted theranostic nano vehicle (TTNV) was designed using manganese-doped MSNs with an ideal surface area and pore volume for loading optimized ratios of antitumor DOX and the drug efflux inhibitor Tar. This strategically framed TTNV, which is chemically coupled with folic acid and HA, as a dual-targeted entity to promote folate receptor (FR)-mediated cancer cells and CD44-mediated CSC uptake, respectively[56].

Other nanodrug delivery systems

The N-(2-hydroxypropyl) methylacrylamide (HPMA) cyclopamine delivery system, as a selective macromolecular therapy for CSCs, has improved drug solubility and reduced systemic toxicity, allowing it to effectively remove CD133+ tumor stem cells in prostate tumors. HPI-1 was loaded with PLGA-PEG NPs to solve the problem of poor water solubility and effectively eliminate CD133+ CSCs in pancreatic and liver cancer[57,58].

GBM stem cells (GSCs) are the leading cause of chemotherapy failure in GBM. PLGA NP-encapsulated disulfiram effectively inhibited *in situ* and subcutaneous GSC xenografting in mouse models[59]. Although we are increasingly understanding GBM at the molecular level, treatment options are still limited. We have developed bioreducible poly(β-aminoester) NPs that exhibit high intracellular delivery efficacy and low cytotoxicity that have the ability to escape from endosomes and facilitate the

release of cytoplasmic environment-triggered cargo for the delivery of microRNAs to tumor-reproducing human CSCs[60]. In the study by Wang *et al*[61], a high temperature thermal breakdown approach was used to create composite magnetic nanocubes modified by PEI and HA. The ferric oxide nanocubes recognized hepatocellular carcinoma (HCC) stem cells *via* receptor-ligand binding of HA and CD44 (HA receptor), while loading small molecule LDN193189 inhibited the expression of stemness-related genes octamer-binding transcription factor 4 and Nanog. Double pH-sensitive polymeric drug-conjugated NPs showed enhanced inhibition of the progression of drug-resistant SK-3 CSCs, whereas AuNPs conjugated to Adr *via* nitrogen reduction bonds overcame resistance by avoiding P-gp efflux, thereby delivering more DOX to tumor stem cells. This mechanism resulted in the elimination of all tumor cell subpopulations and prevented the potential reaggregation of CSCs[62]. Tran *et al*[63] inhibited the transfer of MCF-7-SCs by inhibiting the EMT process, revealing the potential role of nanozinc sulfide in inhibiting the migration and invasion of bCSCs, which opened up a new way of thinking and provided a potential approach for the treatment of BC.

It has also been shown that the constructed amphiphilic polymer, HA-cystine-PLGA, can be used to deliver DOX and cyclopamine to CD44-high-expressing bCSC subpopulations and a large number of BC cells, and allow on-demand release. The dual delivery particles effectively reduce the number and size of tumor spheroids, and HA shows targeting effects on bCSCs[64].

Gao *et al*[65] proposed a novel intravenous photodynamic therapy (PDT) platform based on stem cell simulation of SUCNPs@mSiO2 for tumor targeting and enhanced PDT efficacy. Due to the coating of the stem cell membrane, the prepared nano SUCNPs@mSiO2 has good stability and biocompatibility. Moreover, it has the ability to be intravenously injected and escape immunity, extend the blood circulation time, and improve the tumor targeting function of stem cells, paving the way for the development of photosensitizers with bioactive cell components, such as SUCNPs@mSiO2, as a platform for targeting PDT. Sorafenib and glucose oxidase were integrated into the N-acetylgalactosamine-modified zeolite imidazolate framework (ZIF-8), designated SG@GR-ZIF-8, and this nano preparation exhibited significant antimetastatic HCC activity against C5 WN1 cells, a liver CSC-like cell line with tumorigenic and lung metastatic activity[66]. PT chemotherapy synergy was achieved by loading crocodile-based PT agents with natural cytotoxic heat shock protein (HSP) inhibitors that had high potency biradical characteristics into a redox-sensitive chitosan (CHI) matrix. Within solid tumors, PEG shells that prevent nano-assembled mono nuclei from phagocytosing were cleared quickly to expose the positively charged CHI, and the isolated peptide iRGD was further activated. This step drives tumor penetration of CHI NPs and allows CSC targeting by selective identification of CD44 proteins. Due to the inhibition and chemosensitization of HSPs, the designed nano assembly can completely eliminate CSCs and non-CSCs, thereby inhibiting tumor growth and metastasis[67]. Chen *et al*[68] used PLGA/d-alpha-tocopherol PEG 1000 succinate (TPGS) NPs for the first time with the combination of chemotherapy drugs and ATP-binding cassette (ABC) transporter inhibitors (ATIs) and used TPGS and PLGA to prepare NPs. Due to the overexpression of ABC transporters in CSCs, the combination of ATIs and chemotherapy drugs can overcome the multidrug resistance of CSCs. PLGA/TPGS NPs were prepared for the codelivery of DOX and extracellular lipopeptide composite to reach the tumor site with an optimized synergistic ratio, and resveratrol NP reduces cancer activity and decreases inflammation in CSC-rich oral cancer[69]. In addition to active targeting strategies, relying on intelligent changes in nanodrug size to penetrate deep into tumor tissues and improve the clearance rate of CSCs is also an important strategy for efficient reversal of MDR. On this basis, a special morphologically tunable nanodrug was developed, which integrated chemotherapy and immune checkpoint blocking therapy for large tumor cells and CSCs into drug delivery systems. As NPs are transferred from circulation to tumor tissue, particle size shrinks, favoring pharmacokinetics and cellular uptake while enabling sequential drug release when needed. The nanomedicine reduced the proportion of CSCs and enhanced the therapeutic effect on tumors, thereby prolonging the survival time of mice[70].

Liposomes

Liposomes are spherical vesicles consisting of one or more concentric phospholipid bilayer layers that enclose a water core. Liposomes are both nontoxic and biodegradable, making them powerful drug delivery systems. They improve the therapeutic effect of drugs by stabilizing compounds, overcoming barriers to cell and tissue uptake, and increasing the biological distribution of drugs at target sites in the body while minimizing systemic toxicity[71].

Tumor necrosis factor-associated apoptosis-inducing ligands (TRAILs) have received much attention for their favorable ability to activate apoptosis in cancer cells by interacting with death receptors (DRs). However, CSC-like cells lack or express low levels of the death receptor DR and are highly resistant to apoptosis mediated by TRAIL, limiting therapeutic efficacy. The liposomal component of the plasmid DNA encoding TRAIL and SAL enables cancer cells to express TRAIL as protein generators, and more importantly, to upregulate DR expression through SAL-induced CSCs, making drug-resistant CSCs sensitive to TRAIL-triggered apoptosis. This liposome-based programmable drug codelivery system shows the potential to effectively eliminate CSCs and inhibit CSC-rich tumor growth in mouse models of colon tumors *in situ*[72].

Gong *et al*[73] prepared and characterized SAL-loaded nanoliposomes (SLNs), DOX-LNs (DLNs) and SAL and DOX simultaneously delivered nanoliposomes (SAL/DOX). Novel SDLNs and SLN-DLNs are used to deliver SAL and DOX to HCC cells and CSCs. Hybrid lipo plastids (HLs) are nanosized liposome particles that can be prepared by the ultrasonic mixing of capsule and micelle molecules in buffer solution. The inhibitory effect of HLs on the growth of the CSC subpopulation of HCC cells (HepG2) has proven that HLs are a new type of nanomaterial that can be used to target CSCs in the treatment of HCC[74]. Dual-targeted liposomes CEP-LP@S/D selectively target CD133EpCAMlCSCs. Upon arrival at CSCs, CEP-LP@S/D liposomes undergo cytoplasmic endocytosis, in which high concentrations of glutathione break the disulfide bonds, thereby degrading the liposomes[75]. The combination of docetaxel liposome (DTXPL) and telmisartan (TEL) increased the cytotoxicity of H460 WT 3D cells two-fold. In H460 WT and DTX-resistant CD133+ xenograft tumor models, tumors treated with the combination of DTXPL and TEL showed reduced tumor volume, increased apoptosis, and downregulated CSC marker expression[76].

Lipid nanocapsule (LNC) encapsulated with paclitaxel and SAL can induce apoptosis in bCSCs, which is enhanced by the codelivery of paclitaxel and SAL. Synergistic cytotoxic effects on cells, non-bCSCs, and bCSCs, as well as effective reduction in tumor mammary globular growth by encapsulating both paclitaxel and SAL, suggest that LNCs have potential for the treatment of BC[77].These studies demonstrate the great potential of nanoliposome-targeted drug delivery to tumor stem cells.

GNRs and QDs

GNRs are pseudo-one-dimensional rod-like NPs, which have become one of the emerging materials of interest in recent years due to their anisotropic shape and adjustable plasma properties[78]. QDs, also known as nanocrystals, are NPs composed of II-VI or III-V elements that are rich in energy electrons and quantum-confined holes[79]. QDs are widely studied as biomedical imaging probes due to their unique optical and electronic properties. They are usually nanoscale semiconductor microcrystals and are widely used to improve the efficacy of fluorescent markers in bioimaging[80].

PKF118-310 (PKF) and vorinostat (SAHA) loaded on GNP corona Protein corona (PC), a AuNP system with protein corona coating for simultaneous delivery of PKF and SAHA resulted in a reduction of stem cell populations and Snail marker in MCF7 bCSCs[81]. Coloaded with GNRs and Adr, EpCAM was labeled by targeting the surface of CSCs to kill CSCs under laser ablation[54]. A novel fluorescent on nano aptamer sensor for the quantitative detection of CD133 has also been designed. By hybridization of CD133-targeting aptamers modified on the surface of QDs and AuNPs with partially complementary paired RNA (single-stranded RNA), the distance between the QDs and AuNPs is shortened, resulting in fluorescence resonance energy transfer between them so that the fluorescence of the QDs is quenched by AuNPs. The QD fluorescence recovery aptamer sensor is a sensitive and reliable sensor for the detection of CD133, providing a simple and promising detection tool for CSC markers[82]. Inhibition of glutamine decomposition may be an effective anti-CSC strategy. The glutaminase 1 (GLS1) inhibitor telaglenastat (CB-839) was loaded into Au pegylated NPs (Au-PEG-CD133-CB-839) equipped with covalently coupled CD133 aptamer. In an *in vitro* exposure to a CD133-positive brain tumor model, Au-PEG-CD133-CB-839 reduced the activity of CD133-positive cancer cells in a dose-dependent manner [83]. Glucose-installed-targeted NPs (Glu-NPs) demonstrated higher cellular uptake of siRNA payload in globular BC (MBA-MB-231) cell cultures compared to glucose-uncoupled control NPs (MeO-NPs). Glu-NPs, a promising nanocarrier design for CSC-targeted cancer therapy, caused significantly enhanced gene silencing in CSC-rich MDA-MB-231 tumor tissue in situ after systemic administration to tumor-bearing mice[84]. Liu *et al*[85] reported that SAL was conjugated with biocompatible AuNPs coated with PEG showed specific targeting ability and high antitumor efficacy against CD24 Low/CD44high subsets in BC cells. The biodegradable naturally negatively charged polysaccharide HA is used to synthesize AuNPs, while HA can act as a capping agent based on its hydroxyl group, thereby stabilizing newly produced AuNPs. HA-functionalized AuNPs exhibit excellent physical properties and high cell uptake and have a strong inhibitory effect on MDA-MB-231 cells and CSCs. In particular, synergistic chemothermal therapy with HA-capped AuNPs combined with NIR irradiation has shown more effective therapeutic results in terms of cytotoxicity, apoptosis, and necrosis compared with chemotherapy alone[86].

The disadvantage of metallic nanomaterials lies in their toxicity. Reactive oxygen species(ROS) generation, influence on cell structures and other characteristics of metallic NPs toxicity are similar to other NPs, and the toxicity is related to size, shape, dimensionality, surface charge. Therefore, metallic NPs should be carefully examined before used in clinic.

CNTs

The high surface-to-volume ratio, enhanced electrical conductivity, strength, biocompatibility, ease of functionalization, and optical properties of CNTs have led to their consideration as novel drug and gene delivery vehicles. CNTs are cylindrical tubes formed from sp2 hybrid carbon atoms, which can range in size from 1 nanometer to several microns. CNTs can be divided into single-walled CNTs (SWCNTs) and multiwalled CNTs (MWCNTs) according to the number of layers formed in them[87].

BCSCs have strong resistance to traditional hyperthermia, while PTT mediated by amino-modified multiwalled CNTs on the surface can effectively kill bCSCs[88]. CD133 is a currently recognized CSC marker for GBM. CNTs can be targeted to CD133-positive cells of GBM (GBM-CD133+) through a CD133 antibody. Wang *et al*[89] grafted a CD133 monoclonal antibody onto CHI-modified CNTs. Then, CSCs were effectively killed by PTT. The gastric CSC-specific targeted drug delivery system (SAL-SWNT-CHI-HA complex) is also based on CHI-coated SWCNTs loaded with SAL and functionalized with HA to selectively eliminate gastric CSCs[90]. SWCNTs facilitate active targeting due to their needle shape, significant transmembrane penetration, EPR effects, high drug loading capacity, and ease of functionalization of biological agents (*i.e.* antibodies). Surface functionalization with polymers such as PEG helps overcome the limitations of the original NTs, providing good water solubility, prolonging blood circulation, and reducing the toxic effects of SWCNT-based nanocarriers. The potential therapeutic effect of the combination of paclitaxel and SAL in BC and CSCs is mediated by a pH-responsive release mechanism near the acidic tumor microenvironment *via* a hydrazone junction[91].

GO

Driven by the achievements of CNTs, graphene, and GO are new types of drug nano carriers used to support a variety of therapeutic drugs, anticancer drugs, insoluble drugs, antibiotics, antibodies, *etc.*

GO is alleged to specifically target CSCs rather than normal cells and to induce CSC differentiation and inhibit tumor sphere formation in multiple cell lines, including breast, ovarian, prostate, lung, pancreas, and GBM cell lines, by inhibiting several key signaling pathways, including the Wnt, Notch, and signal tranducer and activator of transcription signaling pathways[92].

Choi *et al*[93] synthesized reduced graphene-silver nanocomposites (rGO-Ag) using the R-phycoglobin biomolecular mediated method. These composites have a toxic effect on ovarian CSCs (OvCSCs) and can reduce the survival rate of OvCSCs by decreasing the mitochondrial membrane potential and expression of apoptotic genes, leading to mitochondrial dysfunction and possibly apoptosis. RGO-Ag may be a novel nanotherapeutic molecule for specifically targeting highly tumorigenic ALDH+CD133+ cells and clearing CSCs.

PTT

PTT uses metal NPs to eradicate CSCs and stimulate a hyperthermal physiological response by converting light into heat[94]. MSNs under an alternating magnetic field eliminate CSCs by blocking the hypoxia signaling pathway and heating, thus effectively inhibiting tumor growth[56,95]. Burke *et al*[86] found that bCSCs have strong resistance to traditional hyperthermia, and PTT mediated by amino-modified multiwalled CNTs on the surface can effectively kill bCSCs. Wang *et al*[87] grafted CD133 monoclonal antibody onto CHI-modified CNTs. CD133 is currently recognized as a CSC marker for GBM, and CNTs can be targeted to GBM-CD133+ through the CD133 antibody. Then the CSCs were effectively killed by PTT. NPs loaded with bimodal metal cages and photodynamic therapys (PDT) PDTs target CSCs by reducing cell mobility under laser irradiation[96]. Researchers developed a CSC-specific-targeted, retinoic acid (RA)-loaded Au nanostar-dPG nanoplatform for the efficient eradication of CSCs. The nanocomposites possess good biocompatibility and exhibit effective CSC-specific multivalent-targeted capability due to HA decorated on the multiple attachment sites of the bioinert dPG. With the help of CSC differentiation induced by RA, the self-renewal of bCSCs and tumor growth were suppressed by the high therapeutic efficacy of PTT in a synergistic inhibitory manner[97]. Based on PTT properties of CNTs and metallic materials, nanoplatform functions with chemotherapy and PTT can be designed to produce synergistic effects.

Researchers have utilized MnO_2@Ce6 NPs and a PDT-based approach that improved tumor microenvironment-related therapeutic resistance by modulating the tumor microenvironment with excess hydrogen protons and water, resulting in subsequent radiation of CSCs[98]. Haldavnekar R *et al*. introduced nickel-based functionalized nanoprobe-facilitated surface-enhanced Raman scattering for the prediction of cancer dissemination by CSC-based surveillance[99]. MoS_2 nanosheets and a moderate PTT treatment were applied to target a CSC surface receptor (*i.e.* CD44) and modulate its downstream signaling pathway. The treatment showed attenuated self-renewal capacity, more response to anticancer drugs, and less invasiveness[100].

Although PTT can inhibit tumor growth by eliminating tumor stem cells, it is usually difficult to completely eradicate tumors due to the limited penetration depth of near-infrared (NIR) light. Therefore, combining PTT with other therapies is expected to overcome these challenges.

Magnetic fluid hyperthermia

MFH uses the good magnetic thermal conversion ability of magnetic NPs under the influence of an external alternating magnetic field to rapidly heat the internal tumor, forming a high-temperature zone, to kill tumor cells or induce their apoptosis[101].

When anti-CD44 antibody-modified SPIONPs are prepared, SPIONP-mediated hyperthermia can kill CSCs, and MFH significantly inhibits the growth of transplanted Cal-27 tumors in mice[59]. Nuclear targeting systems coated with MSNs of superparamagnetic iron oxide-based NPs can directly target CSCs and can be used to combine thermotherapy and hypoxia-activated chemotherapy with nuclear-

targeted drug release under an alternating magnetic field, ultimately leading to complete apoptosis of CSCs[73]. Biomimetic magnetic NPs induce apoptosis of stress-escape CSCs and inhibit their proliferation and metastasis *in vitro* and *in vivo* by the combined therapeutic effects of DOX chemotherapy and magnetic MSNs MFH under the action of an alternating magnetic field[102]. Antibody-modified NPs targeting lung CSCs enhance cellular uptake *in vitro* and prolong tumor accumulation *in vivo*. Due to the combined effects of hyperthermia and chemotherapy treatment, up to 98% of lung CSCs are killed by AMF within 30 min of application outside the body. In *in vivo* models, this combination therapy significantly inhibited tumor growth and metastasis in mice carrying lung CSC xenografts with minimal side effects and adverse reactions[103]. In summary, MFH shows great potential in targeting tumor stem cells.

FUTURE PERSPECTIVES AND CHALLENGES

The discovery of CSCs has made us gradually realize the complexity of tumors. CSCs are the roots of tumor occurrence, drug resistance, and postoperative recurrence. Therefore, the eradication of CSCs is of great significance for the treatment of cancer. At present, theoretical research on tumor stem cells is still in the initial stage, and many problems have not been solved. For example, CSCs and normal stem cells have very similar self-renewal, multidirectional differentiation, signaling pathways, and cell surface markers. How to effectively kill CSCs without damaging normal stem cells needs further research. Some regulatory mechanisms and biological behaviors of tumor stem cells have not been fully clarified. It is believed that with the continuous deepening of CSC research, more targets and a theoretical basis will be provided for clinical treatment.

In addition to effective drugs targeting CSCs, it is also necessary to consider the heterogeneity of CSCs to eliminate tumor cells and CSCs more effectively, inhibit recurrence and improve the survival rate of patients. Although great progress has been made in research on the molecular mechanism of cancer, cancer detection and treatment, and the treatment methods have been continuously improved, there is still a lack of effective treatments for cancer. The targeting, slow release, good biocompatibility, and stability of nanomaterials will play a huge role. In addition, nanotargeting technology is used to track the biological characteristics of CTCs[104]. The physical and chemical properties of each component of the tumor microenvironment are different from those of normal tissues, and the tumor microenvironment plays a huge role in the process of tumor occurrence and development, which makes the tumor microenvironment an important target for nanomaterial-targeted therapy[105]. Although there are still several difficulties in the wide application of nanomaterials in clinical practice, the most important of which is biosafety, there is still no convincing evidence that nanomaterials can be effectively metabolized in the body without accumulation and causing toxic side effects. In addition, how to improve the linking efficiency of targeted molecules and nanomaterials, the activity of targeted molecules after linking, the stability of the binding of targeted substances and drug carriers, and the metabolic pathways and toxicity of nanomaterials *in vivo* have not yet been solved. However, the strong ability shown in the early stages makes us hypothesize that nanomaterials for CSC-targeted therapy have broad prospects as a new generation of tumor treatment. With the continuous deepening of CSC research and the rapid development of nanotechnology, these fields will potentially overlap and provide a strong guarantee for cancer treatment.

CONCLUSION

Cancer is a huge barrier for researchers due to its high mortality rate and resistance to treatments. For example, multidrug resistance, recurrence, and the spreading nature of cancer cells make cancer extremely difficult to treat. CSCs are the main reason for inducing the characteristics of drug resistance and the regenerative ability of tumor cells. Therefore, the targeted system of cancer treatment began to turn to stem cell research. As an emerging field, nanotechnology is mainly applied to materials and carrier structures with diameters between 1 and 100 nanometers. Because nanomaterials have similar dimensions, they differ in composition, structure, hydrophobicity, magnetism, immunogenicity, and other properties. CSC therapies based on these unique properties have been extensively studied, but only a few have entered clinical trials. To better improve clinical translation, further research on targeted drug delivery of nanocarriers is needed to reduce toxicity, enhance permeability and retention, and minimize the shielding effect of the protein corona. By rationally designing and constructing new NDDS to accurately target CSCs that have developed drug resistance, the efficiency of reversing multidrug resistance and inhibiting tumor growth can be effectively improved, providing a tremendous opportunity to improve cancer treatment or prognosis, which will ultimately improve the survival rate of cancer patients.

Abstract

Brain diseases affect 1 in 6 people worldwide. These diseases range from acute neurological conditions such as stroke to chronic neurodegenerative disorders such as Alzheimer's disease. Recent advancements in tissue-engineered brain disease models have overcome many of the different shortcomings associated with the various animal models, tissue culture models, and epidemiologic patient data that are commonly used to study brain disease. One innovative method by which to model human neurological disease is *via* the directed differentiation of human pluripotent stem cells (hPSCs) to neural lineages including neurons, astrocytes, and oligodendrocytes. Three-dimensional models such as brain organoids have also been derived from hPSCs, offering more physiological relevance due to their incorporation of various cell types. As such, brain organoids can better model the pathophysiology of neural diseases observed in patients. In this review, we will emphasize recent developments in hPSC-based tissue culture models of neurological disorders and how they are being used to create neural disease models.

Key Words: Induced pluripotent stem cells; Astrocytes; Oligodendrocytes; Microglia; Brain organoids; Assembloids

INTRODUCTION

Human pluripotent stem cells (hPSCs) include both human embryonic stem cells (hESCs) and human-induced PSCs (hiPSCs). Current *in vitro* disease models that use hiPSCs begin with skin or blood cells that have been reprogramed with the four transcriptional elements octamer-binding transcription factor 4, SRY-box 2, Krüppel-like factor 4, and MYC[1]. Through differentiation, these hPSCs are the starting material to create models for different organs including the brain[2], kidney[3], liver[4,5], lung[6], and pancreas[7]. These models are able to simulate a "disease-in-a-dish", mimicking different disease phenotypes *in vitro*[8,9]. Both genetically modified hiPSCs and patient-derived hiPSCs can generate disease models[10-12]. These models are advantageous because of their accessibility, quick processing, and species-specific human attributes. Patient-derived hiPSCs can also be used to test personalized medicine approaches to effectively model gene mutations and chromosomal abnormalities. To study neurological diseases, scientists have generated multiple neural cell types from hPSCs including neurons[13], astrocytes[14], and oligodendrocytes (OLs)[15]. In the past decade, advancements in disease modeling and tissue engineering have also led to the "brain organoid" model[16]. Brain organoids are self-assembled structures that resemble the fetal human brain and are composed of progenitor, neuronal, and glial cells. A related system is the spheroid, a circular aggregate of cells that may reflect biological properties of an organ system but ultimately lacks structural complexity. Perhaps the most cutting-edge form of modeling technology in stem-cell research is the assembloid, which are three-dimensional (3D) structures made by fusing and integrating two or more cell types or organoids from different organ culture protocols[17]. These assembloids can model the organ crosstalk interactions that occur across physiological systems in the human body.

In this review, we discuss recent advancements in the field of disease modeling using hiPSC-derived neural cell types as well as organoids. We also discuss challenges that exist with current approaches, in addition to considerations for possible improvements that will further advance the field of disease modeling.

NEURAL CELL TYPE DIFFERENTIATION FROM HPSCS

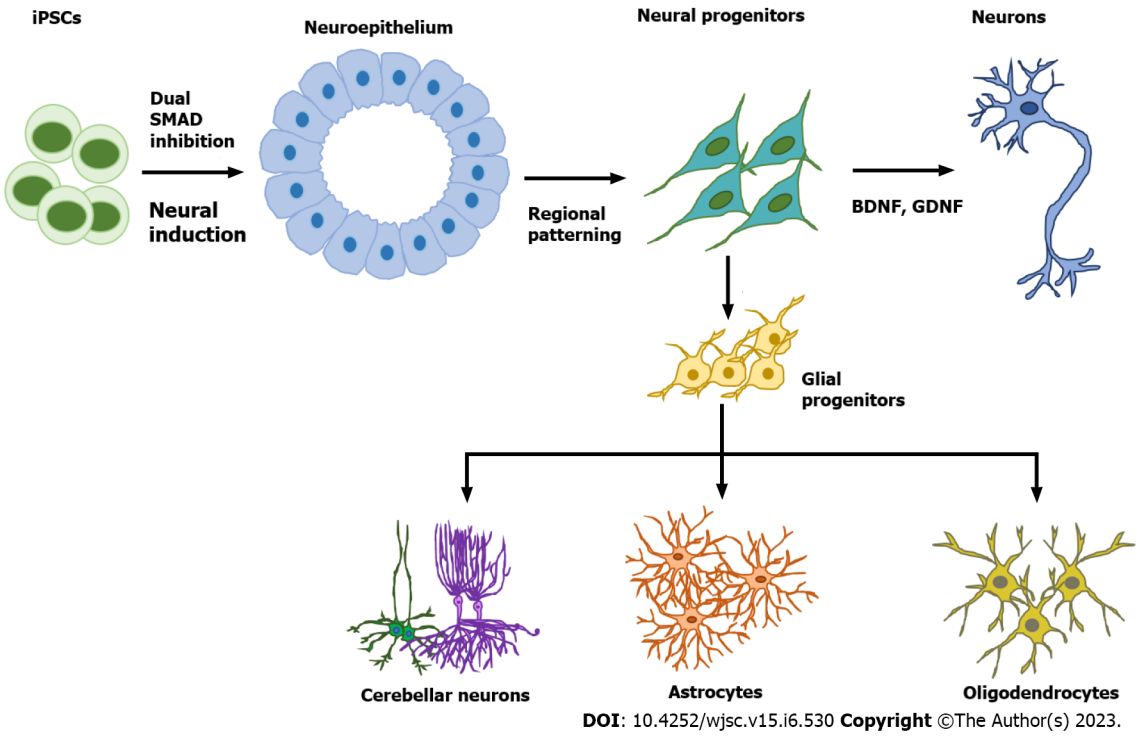
Neural progenitors

The development of the mammalian brain initially occurs at the gastrula stage when the ectoderm differentiates to form the neural tube. This process is called neural induction, wherein neural tube cells become neural progenitors[18,19]. These progenitors subsequently give rise to specific neuronal subtypes along the rostral-caudal axis and dorsal-ventral axis[20]. Protocols for neural progenitor differentiation from hPSCs have been developed that reflect this neural induction principle (Table 1). In 2001, the first protocol of neural progenitor differentiation from hPSCs was developed using the embryoid body (EB) method, which was a combined two-dimensional (2D) monolayer and 3D suspension culture [21]. Without extrinsic factors, the EB method mainly derived dorsal forebrain cortical neurons. In 2008, advances in the EB method eventually gave rise to a complete 3D culture system called the serum-free floating culture of EB-like aggregates with quick aggregation (SFEBq)[22]. The SFEBq method generated neural tissues with self-organized structure using hPSCs, paving the way for the development of more complex systems such as brain spheroids and organoids. Following this advance, in 2009 the dual SMAD inhibition method was developed, which successfully directed over 80% of hESCs to induce neural differentiation[23]. The dual SMAD inhibition method was initially intended for 2D monolayer culture by inhibiting the bone morphogenetic protein (BMP) and transforming growth factor beta (TGF-β) signaling pathways, but it has been widely applied to 3D culture for neural progenitor differentiation

Table 1 Comparison of methods for neural induction from human pluripotent stem cells

Method	Neural induction outcomes	Significance	Ref.
Embryoid bodies; selected neural rosettes; 2D and 3D culture	Neural tube-like rosettes stained with Nestin, Musashi-1 and NCAM; positive neuronal markers MAP2 and TUJ1 expression	First study of neural progenitor differentiation from hPSCs	Zhang *et al*[22], 2001
SFEBq aggregate; sorting cells; 3D culture	Self-organized structure with four distinct zones: ventricular, early and late cortical-plate, and Cajal-Retzius cell zones	Pure 3D culture, provides the basis for the brain organoid method	Eiraku *et al*[23], 2008
Dual SMAD inhibition; 2D monolayer culture	Complete neural conversion of > 80% of hESCs	Mostly wild used method; also enables neural induction in 3D culture	Chambers *et al*[24], 2009
Dual SMAD inhibition combined with retinoid signaling; 2D monolayer culture	More than 95% of hPSCs were PAX6 and OTX1/2 cortical progenitor cells in 15 d	Improved the dual SMAD inhibition protocol and higher neural induction efficiency	Shi *et al*[62], 2012
Cortical organoid/spheroid; 3D culture	Form layered structure tissues partially mimicking human cerebral cortex	Mostly brain-like tissue with some functions	Lancaster *et al*[17], 2013; Paşca *et al*[26], 2015; Qian *et al*[27], 2016
Dual SMAD inhibition combined with Wnt, FGF and Notch inhibition	Generate functional cortical neuron in 16 d	Improved the dual SMAD inhibition protocol and accelerated neural induction	Qi *et al*[28]

EB: Embryoid body; FGF: Fibroblast growth factor; hPSCs: Human pluripotent stem cells; MAP2: Microtubule-associated protein 2; NCAM: Neural cell adhesion molecule; OTX: Orthodenticle homeobox; PAX6: Paired box 6; SFEBq: Serum-free floating culture of EB-like aggregates with quick aggregation.



from hPSCs. It is worth noting that both the SFEBq and dual SMAD inhibition methods can enable the generation of cortical spheroids and organoids[24-26]. In 2017, Studer's group modified the dual SMAD inhibition protocol to also block mitogen-activated protein kinase (MAPK), fibroblast growth factor (FGF), and Notch signaling, thereby accelerating forebrain cortical neuron derivation[27]. Although these protocols yield primarily deep-layer cortical neurons, deriving upper layer cortical neurons such as L2/3 and L4 cells is still a challenge.

Astrocytes

Astrocytes are star-shaped populations of glial cells that help maintain homeostatic balance and support neuron growth within the central nervous system. There are two distinct groups of astrocytes: The highly branching protoplasmic astrocytes of the grey matter and the fibrous astrocytes found in the white matter that interact with OLs and axons[28]. Activated astrocytes can release neuroinflammatory cytokines and chemokines that mediate intercellular communication with microglia and invoke various neuroinflammatory responses. Similar to neurons, there are many subtypes of astrocytes depending on their location, morphology, molecular signature, and physiological function. The differentiation of glia cells from hPSCs usually takes more time and is more complicated than differentiating a neuron (Figure 1).

During brain development, astrocytes differentiate from radial glia or neural progenitors at the subventricular zone. It is currently unknown what signaling regulates the regional identity of astrocytes. The differentiation of astrocytes is usually initiated by inhibition of dual SMAD signaling using small molecules or by the EB method to generate neuroepithelial cells. Glial progenitors expressing nuclear factor IA (NFIA), S100β, and cluster of differentiation 44 (CD44) are derived from these neuroepithelial cells[29]. Ultimately, mature astrocytes are generated from radial glia by activating the signal transducer and activator of transcription 2 signaling pathway using ciliary neurotrophic factor. The most common marker for astrocytes is glial fibrillary acidic protein (GFAP)[30]. Mature astrocytes express aldehyde dehydrogenase family 1 member L1, aldolase C, glutamate transporter-1, and aquaporin 4[31]. In 2011, the first reported protocol for hPSC-derived astrocytes in a chemically defined system required long-term culture of up to 6 mo[29,32]. This protocol used the EB method and supported differentiation through the addition of the factors FGF2 and epidermal growth factor (EGF). To attenuate the culture time, shorter 4-6 wk long accelerated protocols for generating functional astrocytes through overexpression of the transcription factors SOX9 and NFIB were developed[33,34]. In 2017, the Pasca lab found a method to derive functional astrocytes using 3D cortical organoids. However, this protocol required up to 590 d, limiting its application[30]. The majority of recent studies use commercially available astrocyte differentiation medium to differentiate astrocytes from neural progenitor cells[35,36].

Astrocytopathies including Alexander disease[37,38], Aicardi-Goutières syndrome (AGS)[39], and vanishing white matter disease[40] can be effectively modeled with hiPSC-derived astrocytes[41]. Neurodegenerative diseases including Alzheimer's disease (AD)[36], Parkinson's disease (PD)[42], and Huntington's disease have also been modeled using similar methods. The familial presenilin-1 (*PS1*)

DOI: 10.4252/wjsc.v15.i6.530 **Copyright** ©The Author(s) 2023.

Figure 1 Neural cell subtype differentiation from human pluripotent stem cells. The first step of neural cell differentiation is neural induction to generate neuroepithelial cells, usually by the dual SMAD inhibition method. Specific neural progenitors can be generated by tuning different signaling pathways such as Sonic Hedgehog, Wingless/integrated, retinoic acid, and bone morphogenetic protein. Neural progenitors can then be directed to become mature neurons through induction with neurotrophic factors such as brain-derived neurotrophic factor and glial cell line-derived neurotrophic factor or derived into glial progenitors through treatment with the growth factors fibroblast growth factor 2 and epidermal growth factor. Glial progenitors can give rise to either astrocytes or oligodendrocytes. BDNF: Brain-derived neurotrophic factor; GDNF: Glial cell line-derived neurotrophic factor.

mutation along with PD familial leucine-rich repeat kinase 2 (*LRRK2*) G2019S mutations were both modeled using hiPSC-derived astrocytes. The results showed the crucial role of astrocytes in the disease pathogenesis of AD and PD, respectively[36,42]. When co-cultured with neurons, astrocytes generated from Huntington's disease patient-derived hiPSCs displayed decreased electrophysiological activity and diminished neuroprotection consistent with Huntington's disease[43]. Regarding *in vitro* stroke modeling, ischemia-like conditions can be simulated by replacing normal oxygen (O_2)/carbon dioxide (CO_2) conditions with nitrogen (N_2)/CO_2 and subjecting cells to glucose deprivation[44,45]. However, cultures in 2D cannot effectively model stroke due logistical difficulties in restricting oxygenation as well as maintaining nutrition deprivation. However, Wevers *et al*[46] used neurovascular unit on-a-chip, which included a triculture of brain vascular cells, hiPSC-astrocytes, and hiPSC-neurons to model ischemic stroke. The study used antimycin-A, an inhibitor of complex III of the electron transport chain, to induce hypoxic conditions[45]. Modeling the motor neuron pathology linked to amyotrophic lateral sclerosis (ALS) was achieved using hiPSC-derived astrocytes from a patient who had the C9ORF72 mutation[46,47]. Recent studies also reported generation of ventral spinal cord-like astrocytes, which better reflect ALS pathophysiology[48]. Zika virus targeting of astrocytes has also been studied using hiPSC-derived astrocytes, which corroborated the reactive oxygen species imbalance, mitochondrial abnormalities, and DNA damage observed after Zika virus infection[49]. Astrocytes derived from hiPSCs are also beneficial in modeling neurodevelopment disorders including Down's syndrome[50-53], Rett syndrome[54-57], and schizophrenia[58,59]. Rare genetic diseases such as the lysosomal storage disorder Gaucher disease can be modeled using patient hiPSC-derived astrocytes[60,61] (Figure 1, Table 1).

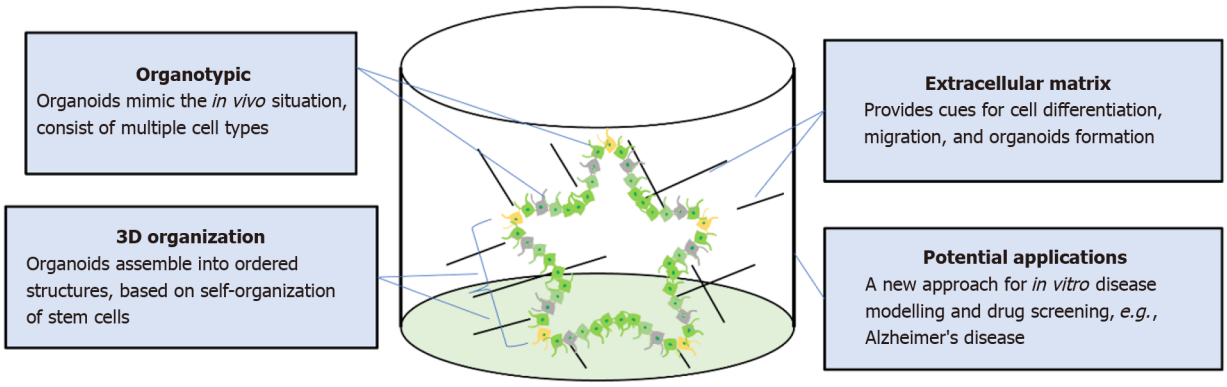
Oligodendrocytes

Protocols to differentiate hiPSCs into pre-OL progenitors were first established in 2012[62]. Retinoic acid (RA) and purmorphamine, a small-molecule agonist of Sonic Hedgehog (Shh) signaling, were used to make pre-OL progenitors that express the markers oligodendrocyte transcription factor 2 (OLIG2) and NK2 homeobox 2. Pre-OL progenitors were then further differentiated into bipotential OL progenitor cells (OPCs) that expressed markers SOX10 and platelet-derived growth factor receptor alpha (PDGFRA) using PDGF-AA, triiodothyronine, and neurotrophin-3. The OPCs at this stage were further developed into either $O4^+$ and myelin basic protein-positive (MBP^+) human-induced OLs or $GFAP^+$ astrocytes. OPCs ameliorate neurological deterioration and support survival of *shiverer* mice after engraftment[62]. However, this protocol requires a lengthy 120-d culture period. Efficient and robust

generation of hiPSC-derived OPCs in 95 d has been achieved more recently[63,64]. Improved differentiation of myelinating OLs was obtained using brain extracellular matrix from decellularized human brain tissue[65]. Fast and efficient OL generation has additionally been achieved with SOX10 overexpression, either by introducing lentiviral vectors at the neuroepithelial stage or by direct transfection of hiPSCs prior to differentiation[66,67].

Shaker *et al*[68] published a 42-d protocol to derive organoids containing myelinating human OLs and astrocytes. Differentiated OLs that were produced using hiPSCs from primary progressive multiple sclerosis patients were found to be functional and supported *in vivo* myelination in *shiverer* mice[63]. Death of OLs is a hallmark of Pelizaeus-Merzbacher disease, an X-linked leukodystrophy caused by mutations in proteolipid protein 1 (PLP1)[63]. Human-induced OLs from individuals with PLP1 mutations have helped to identify important subgroups based on cell-intrinsic phenotypes and to elucidate the pathogenesis of various PLP1 mutations[15,68]. Involvement of OLs in neurodegenerative diseases, including AD and PD as well as multiple system atrophy[69], have also been studied using human-induced OLs.

OTHER CELL TYPES OF THE CENTRAL NERVOUS SYSTEM



Microglia

Although murine models have been the main tool for studying the genetics and function of microglia, there are important distinctions between murine microglia and human microglia when it comes to aging and associated diseases[70,71]. Historically, viable microglia cells have been obtained by extracting them from brain tumors or epileptic foci removed from surgery, but this procedure is logistically very challenging. These hurdles were reduced when multiple methods to differentiate microglia from hPSCs were developed[70-75]. Muffat *et al*[73] published the first protocol by producing microglia-like cells from regular and patient hESCs and hiPSCs. This method used serum-free neuroglial differentiation media, which contained various components with concentrations adjusted to biologically match human cerebrospinal fluid. Abud *et al*[76] described a two-step method to successfully derive microglia-like cells (iMGLs) from 10 different hiPSC lines in 5 wk. The transcriptome profile of the derived iMGLs was strikingly similar to that of both adult human and fetal microglia[75]. Most microglial directed differentiation protocols involve hematopoiesis[73,75,76]. Some reported studies use chemically-defined protocols to generate human microglia through the formation of myeloid progenitors in 30 d[77]. Ionized calcium binding adapter molecule 1, a protein that belongs to the calcium-binding protein family, is one of the main markers of microglia[78]. It is primarily involved in rearranging cytoskeleton and has been used as a marker for the 3D reconstruction of microglial cells[79,80]. Other general markers used for microglial identification are CD45 and CX3C motif chemokine receptor 1. In a recent study, Dräger *et al*[81] described an effective 8-d protocol for generating induced transcription factor microglia-like cells (iTF-Microglia) based on the inducible expression of six transcription factors (human MAF BZIP transcription factor B, CCAAT enhancer-binding protein, interferon regulatory factor (IRF8) PU.1, and IRF5).

The risk of developing late-onset AD is linked to several genes, including triggering receptor expressed on myeloid cells 2 (*TREM2*) and *CD33* expressed by microglia. Microglia accumulate around amyloid plaques during AD and exacerbate pathophysiology by secreting cytokines and chemokines that induce inflammation. Microglia that have been generated using hiPSCs can be effectively used to model neurological diseases *in vitro*[80,81]. Alternatively, microglia derived from patient hiPSCs have also been used for modeling neurodegenerative diseases. Recently, patient hiPSCs expressing the AD-linked R47Hhet *TREM2* variant was used to elucidate the signal transduction deficit observed during AD progression[82]. Another study using microglia derived from AD patient hiPSCs reported that dysregulated peroxisome proliferator-activated receptor gamma (PPARγ)/p38 MAPK signaling causes the phenotypic deficits observed in *TREM2* variants. The results of this study concluded that the activation of PPARγ/p38MAPK signaling can ameliorate metabolic deficits within these cells and consequently rescue critical microglial cellular functions such as β-amyloid phagocytosis[83].

BRAIN ORGANOID DEVELOPMENT FROM HPSCS

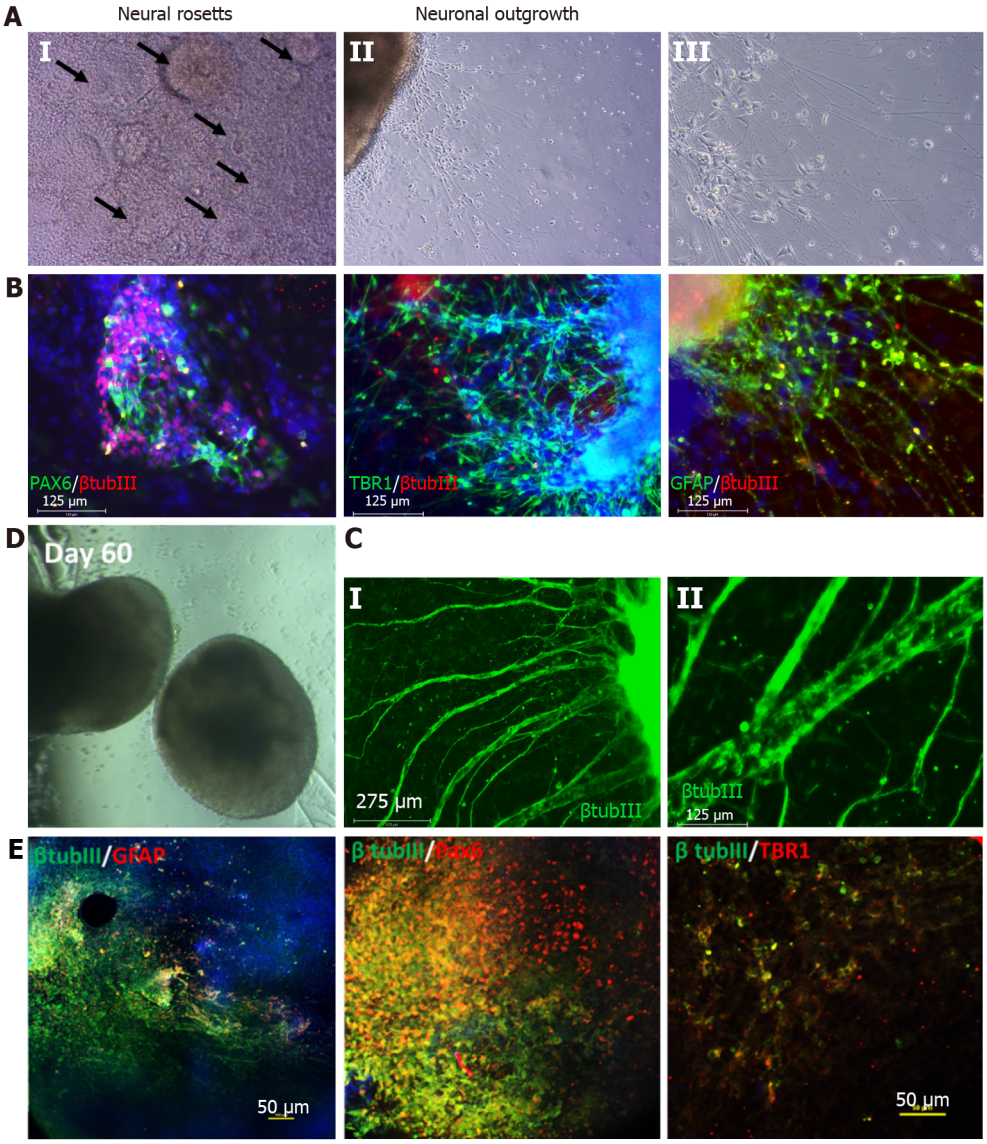
Protocols for producing brain organoids were derived from the EB and SFEBq methods for neural induction. The formation of brain organoids is based on the self-organization and self-renewal of stem cells to generate a mixed cell population in 3D suspension culture (Figure 2). In 2013, the first study on brain organoids was reported to generate whole brain tissues with regional specific structures using an EB-based culture involving Matrigel support in a spinning bioreactor[24]. The organoids were used to model microcephaly, a neurodevelopmental disease whose pathologic features are difficult to recapitulate using animal models. This was the first work done to generate brain-like tissue *in vitro* and apply them to study human pathological disorders. In the following years, a simpler method was

DOI: 10.4252/wjsc.v15.i6.530 **Copyright** ©The Author(s) 2023.

Figure 2 Self-organization of brain organoids. Human brain organoids are generated based on the self-organizing properties of stem cells. Organoids usually contain multiple cell types including mature neurons and immature neural progenitors. The key to organoid regeneration is the extracellular matrix that is used to support stem cell growth and differentiation. Brain organoids have been widely utilized to model neurological pathology in disease such as Alzheimer's disease and microcephaly.

developed to generate cortical spheroids in 3D static culture without Matrigel and agitation[25]. This method first derived neural progenitors using dual SMAD inhibition and then induced regional specific patterning by supplementing culture with the growth factors FGF2 and EGF. The last step of this protocol extended cultivation of brain aggregates and replaced the growth factors with the neurotrophic factors brain-derived neurotrophic factor (BDNF) and glial cell line-derived neurotrophic factor (GDNF) for up to 3 mo. The generated cortical spheroids exhibited a cortical layer-like structure and were developmentally comparable with the human fetal cortex. Brain spheroids and organoids have been widely used to model human brain development and neurological diseases *in vitro* and have provided a promising platform for drug screening[84] (Table 2, Figure 2).

Forebrain organoids



The areas of the brain originating from the telencephalon and diencephalon are referred to as the forebrain. The telencephalic region consists of the cerebral cortex and cerebellum, whereas the diencephalon includes the thalamus, hypothalamus, and pituitary glands. Self-organized cortical organoids or dorsal forebrain organoids were first reported using the SFEBq method. Multiple cortical layer tissues were generated through inhibition of TGF-β and Wnt signaling, resulting in dorsal-ventral patterning[22,85]. Lancaster *et al*[17] reported the first 3D culture system for deriving cortical organoids from hPSCs. Later, the Pasca lab generated more complex cortical spheroids and organoids from hPSCs, containing both neurons and astrocytes[25] (Figure 3). In following years, several groups attempted to develop protocols to derive cortical organoids from hPSCs. However, a common problem faced by many of these approaches was the presence of multiple ventricular subtypes within each organoid[26,86-91]. Cortical organoids derived from familial AD patient hiPSCs show increased levels of phosphorylated Tau and cytoplasmic neurofibrillary tangle-like deposits[92,93] (Table 1). Recent studies have shown that culture variations have an impact on the AD phenotypes seen in cerebral organoids and should be considered when using these models[94]. Cortical organoids were also used in stroke modeling to study the effects of oxygen-glucose deprivation (OGD), neuronal death that followed, and damaged neural networks[95]. These models use 2-8 h of OGD with O_2 (0.1%), CO_2 (5.0%), and N_2 (95.0%) gas levels and deoxygenated glucose-free medium to induce ischemia[95]. It has also been discovered that hypoxic conditions can reduce the number of progenitors and impair the differentiation of immature neurons during the development stage of brain organoids[96,97]. Ventral forebrain tissue-like medial ganglionic eminence (MGE) organoids are usually patterned by high Shh and low Wnt signals[85,98]. These MGE organoids contain diverse GABAergic interneurons subtypes including somatostatin, parvalbumin, calretinin, and calbindin. These MGE organoids were assembled to model the migration of human interneurons towards the cerebral cortex[98-100]. In 2020, the Pasca lab reported a method to generate striatal organoids expressing medium spiny neuron markers such as DARPP32 using activin A, IWP-2, and SR11237[101]. Brain organoid technology has also been utilized to generate organoids that can model other regions of forebrain tissue including thalamic organoids[102], hypothalamic organoids[103-105], and hippocampal organoids[106,107].

The hippocampus plays a significant role in learning, memory, and emotion. Hippocampal atrophy or hyperexcitability can cause neurological disorders such as schizophrenia and neurodegenerative diseases like AD. Hippocampal spheroids can be derived from hiPSCs using dual SMAD inhibition, Shh, and Wnt pathway inhibition followed with Wnt activation[107,108]. Commonly reported hippocampal markers include zinc finger and BTB domain-containing 20 and prospero homeobox 1. Hippocampal spheroids can be used to model AD pathology either by the exogenous addition of

Table 2 Comparison of methods for brain organoids generation from human pluripotent stem cells

Organoid type or brain region modeled	Method brief description	Model application	Ref.
EB-like aggregates; cerebral cortex	SFEBq, static suspension culture with cell sorting	Form self-organized structure mimicking the early cortiogenesis	Eiraku *et al*[23], 2008
Cerebral organoid; whole brain	Spinning bioreactor with Matrigel supporting	Form pyramidal identities with spatial separation mimicking the developing human brain at early stage; modeling microcephaly	Lancaster *et al*[17], 2013
Cortical neuroepithelium; cerebral cortex	Improved SFEBq, in 40% oxygen in Lumox plates	Inside-out layer pattern for human cortex	Kadoshima *et al*[86], 2013
Cortical spheroid; cerebral cortex	Static suspension culture with FGF-2 and EGF	Generated laminated cerebral cortex-like structure with some functions	Paşca *et al*[26], 2015
Cerebellar-plate-like neuroepithelium; cerebellum	Static suspension culture with FGF-19 and SDF-1	Mimicking the early development of human cerebellum	Muguruma *et al*[129], 2015
Telencephalic organoids; forebrain	Static suspension culture after neural rosettes isolation manually	Modeling autism spectrum disorder	Mariani *et al*[130], 2015
Dorsomedial telencephalic-like tissue; hippocampus	Improved SFEBq, in 40% oxygen	Modeling the development of human hippocampus	Sakaguchi *et al*[107], 2015
Forebrain organoids; cerebral cortex	Miniaturized spinning bioreactor	Zika virus exposure	Qian *et al*[27], 2016

Figure 3 Characterization of cortical organoids for neural and astrocyte marker expression. A: Brightfield images showing the neural rosettes and neuronal outgrowth from the organoids replated to an attachment plate at day 35 of differentiation; B: Resulting immunocytochemistry analysis of neural marker paired box 6 (PAX6), cortical deep layer VI marker T-box brain transcription factor 1 (TBR1), astrocyte marker glial fibrillary acidic protein (GFAP) co-stained with common neural marker β tubulin III, scale bar 125 μm; C: Immunostaining at later stage of the replating showing thick axon like extensions from the organoids, scale bar: 275 μm; D: Brightfield images of the day 60 cortical organoids; E: Confocal images of the day 60 organoids showing astrocyte marker GFAP, neural marker PAX6, cortical deep layer VI marker TBR1 co-stained with common neural marker β tubulin III, scale bar: 50 μm.

amyloid beta 42 oligomer[107,108] or by using amyloid precursor protein/PS1 variant hiPSCs. Current hippocampal organoids reflect the early stages of embryonic hippocampus development and successfully can create dentate gyrus granule and carbonic anhydrase 3 (CA3) pyramidal-like neurons, but are unable to produce CA1 pyramidal-like neurons.

Midbrain organoids

The protocol to differentiate human midbrain-like organoids (hMLOs) employs several molecules to mediate the differentiation of neuroepithelial cells. These factors include hBDNF, hGDNF, dibutyryl cyclic adenosine monophosphate, ascorbic acid, TGF-β3, and 1 purmorphamine[109,110]. The presence of dopamine transporter tyrosine hydroxylase as well as the expression of G-protein-regulated inward-rectifier potassium channel 2 are both characteristics of midbrain dopaminergic (mDA) neurons in hMLOs. Common midbrain genes including engrailed, nuclear receptor 4A2, LIM homeobox

transcription factor 1 beta (*LMX1B*), *LMX1A*, monoamine oxidase B, calbindin 1, tyrosine hydroxylase, catechol-O-methyltransferase, and dopa-decarboxylase have also been detected in these organoids. Additionally, neurons in hMLOs have been found to exhibit action potentials with large sag currents, indicating the existence of mDA neurons[111] (Figure 3).

According to single cell sequencing studies, hMLOs replicate early embryonic neurodevelopment and recapitulate disease characteristics[112,113]. However, the methods to generate midbrain organoids can take a significant amount of time, and can vary from batch to batch. To scale up the generation of midbrain organoids, Mohamed *et al*[114] recently published microfabricated disk technology using eNUVIO EB-Disks. Another study found that the use of recombinant spider-silk microfibers functionalized with full-length human laminin produced similar ventral midbrain organoids with lower inter-organoid variability[114,115]. Alternatively, an automated approach, termed automated midbrain organoids, was published by Renner *et al*[116] that produced high-throughput 3D midbrain organoids. The high-throughput production of hMLOs from hPSCs in spinner flasks was also reported using TH-TdTomato reporter hPSC lines as well[116].

As the second most prevalent neurodegenerative disease worldwide[117], PD is frequently studied using hPSC-derived hMLOs[87,111,112,115,118-120]. The disease is characterized by the loss of dopaminergic neurons in the substantia nigra and is mainly caused by mutations in glucocerebrosidase and LRRK2 genes in addition to α-synuclein (α-syn; *SNCA*) gene triplications[111,121,122]. The hMLOs generated from patients with these mutations display PD traits such as oligomeric and fibrillar α-syn aggregates, loss of mDA neurons, and Lewy body-like inclusions[111,118,119]. Since hPSCs can be edited using clustered regularly interspaced short palindromic repeats (CRISPR)/CRISPR-associated protein 9 technology, *SNCA* gene genome correction has been demonstrated to revert PD patient hPSCs back to wild-type phenotypes[119,123]. These hMLOs have also been successfully generated from hiPSCs carrying the *LRRK2*-G2019S mutation[124]. Biallelic pathogenic variations in the phosphatase and tensin homolog-induced kinase 1 gene that controls mitochondrial function is also connected to the etiology of PD[125]. Human Parkinsonism can also have a more direct cause such as the toxicity of some drugs including 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine, which has also been modeled using hMLOs[126-128] (Table 2)[129-138].

Hindbrain organoids

The medulla, pons, and cerebellum make up the hindbrain region, which is developed from the metencephalon and myelencephalon. Methods to generate hindbrain organoids commonly involve purmorphamine-mediated Shh signaling activation to convert neuroepithelial cells into ventral identity neurons. RA is used as a potent caudalizing agent to promote the fate of hindbrain cells instead of Wnt signaling activation, which is required for midbrain patterning[138]. Markers of hindbrain neurons include serotonergic neuron marker serotonin, human fifth Ewing variant, gastrulation brain homeobox 2, choline acetyltransferase (ChAT), and HB9. Due to their location, cerebellar neurons cannot be easily studied at the cellular or molecular level. Thus, using hiPSC-derived technologies is advantageous in this situation. The cerebellum can be divided into inhibitory GABAergic neurons known as Purkinje cells, which are derived from pancreas-specific transcription factor 1α progenitors, and excitatory glutamatergic neurons known as granule cells, which are descended from atonal homolog 1 (also known as MATH1) progenitors[139].

The first published granule cell differentiation protocol using hiPSCs involved several factors including FGF8B, Wnt proteins, BMPs, and RA. This method recapitulates anteroposterior and dorsoventral patterning and thereby induces *MATH1*-expressing mitotic neural progenitors, which can later be differentiated into cerebellar granule cells. Purkinje cells derived from hiPSCs initially had an immature phenotype, and thus needed to be co-cultured with mouse cerebellar granule cell precursors to allow for maturation[129,140]. However, cells made using this approach had substantial functional variability. Silva *et al*[141] recently published a protocol that generates mature cerebellar neurons without the need of such a co-culture system. This method involves stimulating the development of cerebellar precursors with FGF19, followed by self-organization and differentiation using stromal cell-derived factor 1 and BDNF/GDNF. Cerebellar neurons derived from hiPSCs are also helpful for modeling diseases, particularly cerebellar ataxia, a neurodegenerative disease that affects cerebellar neurons and eventually leads to motor incoordination. Cerebellar neurons derived from hiPSCs of either healthy human participants or ataxia patients were used in several recent studies to create an *in vitro* disease model. Spinocerebellar ataxia type 6 patient hiPSC-derived Purkinje cells have been used to model both thyroid hormone depletion-dependent degeneration and downregulation of the transcriptional targets TATA-Box Binding Protein Associated Factor 1 and BTG anti-proliferation factor 1, indicating their potential as a pathogenesis tool[141].

Recently, protocols for generating brain stem organoids have also been published, offering a new tool for evaluating the pathophysiology of disorders that impact the brainstem. Human brain stem organoids express the medullary marker ChAT, the pons marker hydroxylase, and the mature and functioning excitatory and inhibitory neuron markers vesicular glutamate transporter 1 and glutamic acid decarboxylase 67 in addition to various other relevant markers[142]. Both $OLIG2^+$ and MBP^+ OLs, as well as $S100^+$ astrocytes, are expressed in brain stem organoids[142].

Assembloids

Assembloids are systems that combine one type of spheroid or organoid with another type of spheroid or organoid. For example, assembloids can be produced by combining the dorsal and ventral forebrain, the cerebral cortex with the thalamus, or the cerebral cortex with any other non-neural cell type such as microglia, immunological cells, pericytes, and endothelial cells. The Pasca lab published the first assembloid study in 2017, in which human cortical spheroids were mixed with human subpallium spheroids[98]. The assembloids were created using human subpallium spheroids and cortical spheroids differentiated from hiPSCs from timothy syndrome (TS) patients with mutations in the α1c subunit of the L-type calcium channel (*CACNA1C*) gene. The two types of spheroids were combined in simple conical tubes and left undisturbed for 3 d to produce assembloids. The interneurons within the assembloids migrated, suggesting high potential for the study of certain aspects of migratory disorders such as TS. These patient-derived assembloids showed less effective interneuron movement, which was reversed by the administration of L-type calcium channel blockers.

Since then, many labs have sought to use assembloids to elucidate the interactions that occur between different physiological systems. The Knoblich lab reported the use of fused cerebral organoids that combined dorsal and ventral forebrain tissue cultures. They showed migration of C-X-C chemokine receptor type 4-dependent GABAergic interneurons from the ventral forebrain to the dorsal forebrain, which had a more MGE identity[143]. Assembloids of cortical organoids with integrated pericyte-like cells which express angiotensin-converting enzyme 2 have also been shown to enhance severe acute respiratory syndrome coronavirus 2 infection, suggesting the involvement of multiple cell types[100]. Another study employed cortico-striatal assembloids to recapitulate neurodevelopmental disorders that impair the cortico-striatal pathway, including schizophrenia, obsessive-compulsive disorder, and autism spectrum disorder[144-146]. These cortico-striatal assembloids were developed from patients with Phelan-McDermid Syndrome, a severe developmental disorder also known as 22q13.3DS. It is important to note that these patient-derived assembloids had a higher number of calcium spike events than striatal organoids, offering a better representation of altered neural activity. Interneuron migration has also been reported in a separate assembloids study that fused human MGE organoids with human cortical organoids[147].

CURRENT LIMITATIONS AND POTENTIAL ADVANCEMENTS

The extended culture times required by current methods to produce neural cell types as well as organoids restrict their application. Another consideration is the cell-line-to-cell-line and batch-to-batch variabilities of hiPSC differentiation. Therefore, accelerated protocols with less variable outcomes should be developed. For hiPSC-derived astrocytes, the major drawback is their lack of regional identity. Most protocols derive astrocytes with cortical identity, which may not be useful for modeling disease pathophysiology affecting the ventral part of the brain. Therefore, it is essential to employ experimental approaches that can produce astrocyte subtypes with the appropriate rostro-caudal and dorso-ventral identities. In the case of hiPSC-derived OLs, the lack of advanced OL disease models created using genetically-modified hiPSCs also limits their application. Finally, the lack of vascularization in current organoid and assembloid systems prevents the important study of cell-type crosstalk. Therefore, incorporating vasculature as well as reducing culture time would benefit multiple methods of neural lineage disease modeling.

CONCLUSION

Research in hPSCs has proven to be extremely helpful in creating disease models that can corroborate results gleaned from animal models and overcome their associated limitations. Distinct brain cell types can be produced using hPSCs including neurons, astrocytes, OLs, microglia, in addition to more advanced heterogeneous systems such as brain organoids. These systems have contributed to the development of models for neurological diseases such as AD, PD, and many others. Current models that employ hPSCs have certain shortcomings related to the absence of vasculature as well as microglia. However, developing research in the field of tissue engineering that use cocultures, organ-on-chip and assembloids may be able to get around these limitations in the years to come.

ACKNOWLEDGEMENTS

The VA Tennessee Valley Healthcare System provided resources and facilities for the research that was reported in this article. Images were obtained with the resources of the Vanderbilt Cell Imaging Shared Resource.

FOOTNOTES

Author contributions: Yuan Y and Bejoy J wrote the manuscript; Qian ES and Woodard LE edited the manuscript; all authors have read and approved the final manuscript.

Abstract

Osteoarthritis (OA) is a common degenerative joint disease that often involves progressive cartilage degeneration and bone destruction of subchondral bone. At present, clinical treatment is mainly for pain relief, and there are no effective methods to delay the progression of the disease. When this disease progresses to the advanced stage, the only treatment option for most patients is total knee replacement surgery, which causes patients great pain and anxiety. As a type of stem cell, mesenchymal stem cells (MSCs) have multidirectional differentiation potential. The osteogenic differentiation and chondrogenic differentiation of MSCs can play vital roles in the treatment of OA, as they can relieve pain in patients and improve joint function. The differentiation direction of MSCs is accurately controlled by a variety of signaling pathways, so there are many factors that can affect the differentiation direction of MSCs by acting on these signaling pathways. When MSCs are applied to OA treatment, the microenvironment of the joints, injected drugs, scaffold materials, source of MSCs and other factors exert specific impacts on the differentiation direction of MSCs. This review aims to summarize the mechanisms by which these factors influence MSC differentiation to produce better curative effects when MSCs are applied clinically in the future.

Key Words: Osteoarthritis; Mesenchymal stem cells; Differentiation; Hypoxia; Dexamethasone; Cell therapy

Core Tip: Several reviews have summarized the current status of mesenchymal stem cells (MSCs) in the treatment of osteoarthritis (OA). These studies usually focus on the paracrine function of MSCs. However, the differentiation function of MSCs also plays an important role in the treatment of diseases. This is the first review to report the factors that may affect the differentiation direction of MSCs in the treatment of OA and aims to provide guidance for more accurate regulation when MSC therapy is applied in the future.

INTRODUCTION

Osteoarthritis (OA) is one of the most common degenerative joint diseases, and its incidence increases with age[1]. With the rapid growth of the aging population, the prevalence of OA is increasing[2]. At present, there are more than 300 million OA patients worldwide[3]. The major symptoms of OA are pain and joint dysfunction, which seriously affect the quality of life of patients. Intra-articular microenvironment changes occur as OA develops. Due to tissue injury, severe hypoxia occurs in the joint cavity, and the expression level of hypoxia inducible factor 1 alpha increases significantly[4]. Many inflammatory cytokines infiltrate joints with OA, including interleukin-1 and tumour necrosis factor alpha (TNF-α). The expression of transforming growth factor-beta (TGF-β) in cartilage is significantly lower than that in healthy joints, which can lead to metabolic disorders of chondrocytes[5].

OA is an incurable disease at present, and cartilage degeneration and subchondral bone remodeling are considered the main pathogenic mechanisms of OA. There are no drugs that can delay the progression of OA[6]. The goal of clinical treatment is to relieve symptoms such as pain and loss of function[7]. The common treatments for OA include physiotherapy, pain relievers and nonsteroidal anti-inflammatory drug administration, intra-articular glucocorticoid injection and surgery. When OA progresses to the advanced stage, the only treatment option for most patients is total knee replacement surgery, which causes patients great pain and anxiety[8]. Some innovative new treatment options have been proposed, including mesenchymal stem cell (MSC) therapy.

Mesenchymal stem cells are a branch of stem cells, with the stem cell characteristics of self-renewal and differentiation potential[9]. MSCs can repair tissue damage after injury by differentiating into different tissue cells, so they can play an important role in disease treatment. In 1968, Professor Friedenstein[10] first discovered the existence of MSCs in bone marrow and established an adherent method to isolate and culture MSCs *in vitro*. Pittenger *et al*[11] proved for the first time that MSCs have multidirectional differentiation ability. Since then, MSCs have been widely studied and applied to the treatment of clinical diseases. In 2006, the International Society for Cell Therapy (ISCT)[12] established three minimal criteria for defining MSCs unequivocally: (1) The cells must have the ability to adhere to plastic surfaces when cultivated in standard conditions; (2) they must express CD105, CD73, and CD90, but not CD45, CD34, CD14/CD11b, CD79a/CD19, or HLA-D; and (3) they must have the ability to differentiate into at least the following cell types *in vitro*: Osteoblasts, adipocytes, and chondroblasts.

MSCs can be isolated from various tissues, such as bone marrow, adipose tissue, cord blood and placenta. MSCs from different sources have different characteristics[13]. At present, bone marrow MSCs (BMSCs) and adipose MSCs (ADSCs) are the most commonly used. Heo *et al*[14] found that only BMSCs and ADSCs have the ability to differentiate into three lineages, including osteoblasts, adipocytes and chondrocytes, to meet the minimum MSC standard proposed by the ISCT[15]. However, Beeravolu *et al*[16] believe that MSCs from the human umbilical cord and fetal placenta can also differentiate into three lineages.

At present, there are approximately 1519 studies on "mesenchymal stem cells" registered, according to clinicaltrials.gov (April 2023). MSCs have been used as cellular therapy for various degenerative, inflammatory and autoimmune diseases in a large number of clinical trials. These clinical trials include diseases of the musculoskeletal system, respiratory system, blood system and cardiovascular system and have already shown the effectiveness and safety of MSCs. These cells are most commonly used for the treatment of OA in the musculoskeletal system. At present, the pathogenesis of OA is not completely clear. A large number of studies have shown that subchondral bone destruction[17,18] and cartilage degeneration[19-21] participate in pathogenesis. Osteogenesis and chondrogenesis of MSCs play a key role in the treatment of OA.

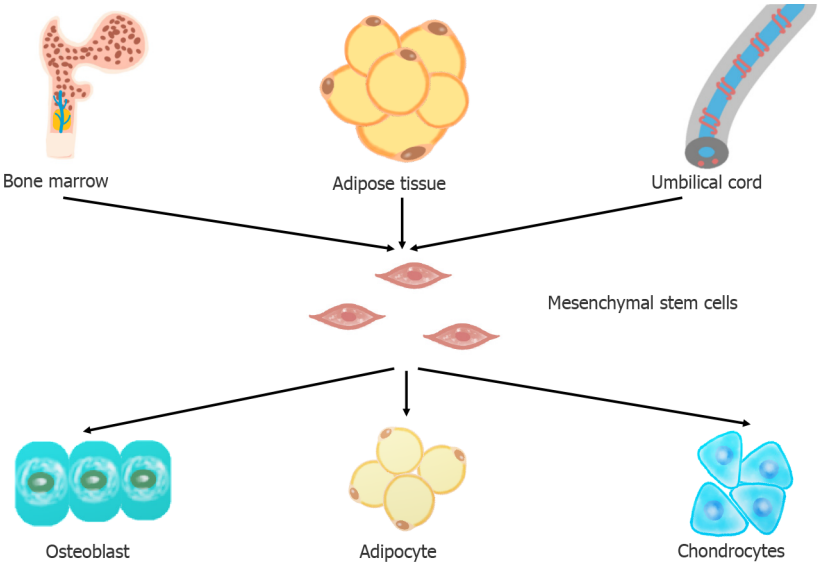
Lamo-Espinosa *et al*[22] recruited 30 patients with OA and injected MSCs into the experimental group and hyaluronic acid (HA) into the control group. After 12 mo, magnetic resonance imaging (MRI) showed that the experimental group receiving the high dose of MSCs had a greater cartilage thickness, which is an indicator of the regeneration of cartilage in OA patients, than the control group. Tang *et al*

[23] injected MSCs into rabbit models of OA. Nine weeks later, the knee joints of the rabbits were collected and analyzed. They found that when MSCs were injected, the articular cartilage of the rabbit showed characteristics of good reconstruction, such as a regular surface, restored cartilage thickness, nearly normal chondrocyte morphology, and uniformly distributed red Safranin O staining in the articular cartilage. At present, no experiment has been performed on the differentiation of MSCs in isolated subchondral bone tissue. However, many similar studies that applied MSCs to bone defects have been performed and proved the feasibility of osteogenic differentiation of MSCs *in vivo*. For example, in the treatment of femoral head necrosis in the same hypoxic environment, after MSCs are implanted, the expression of bone-related genes is improved, and alkaline phosphatase and type I collagen are increased, which are indicators of bone formation[24]. MSCs are considered promising candidates for bone and cartilage repair and regeneration in OA. But the differentiation of transplanted MSCs is influenced by the microenvironment. Therefore, this article reviews the factors affecting the osteogenesis and chondrogenesis of MSCs (Figure 1).

MECHANISM OF OSTEOGENIC AND CHONDROGENIC DIFFERENTIATION OF MSCS

The differentiation of MSCs depends on a number of factors, including chemical, physical and biological factors. These factors activate different signaling pathways and transcription factors that regulate MSC differentiation into different cells[25]. The differentiation of MSCs is precisely controlled by various signaling pathways[26]. These signaling pathways activate lineage-specific transcription factors[27].

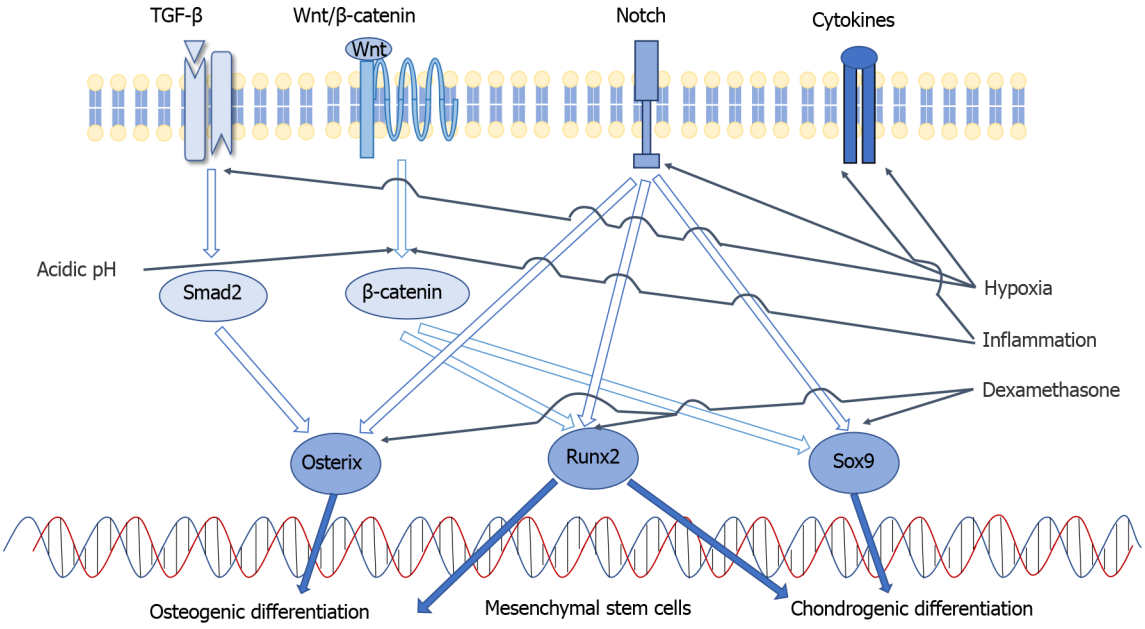
Chondrogenesis and osteogenesis of MSCs are interrelated processes. There are two ways for MSCs to form bone: Endochondral or intramembranous ossification. In endochondral ossification, MSCs first differentiate into chondrocytes and secrete cartilage matrix, and then they are stimulated by osteoblasts to form bone. In contrast, in intramembranous ossification, MSCs differentiate into osteoblasts directly [28]. Therefore, there are some common signaling pathways and transcription factors involved in the osteogenic differentiation and chondrogenic differentiation of MSCs.



TGF-β signaling, Wnt/β-catenin signaling and Notch signaling are the key pathways involved in chondrogenic differentiation of MSCs. The key cytokines include Sox9, Runx2, TGF-β, FGF and others [29]. Sox9 plays an essential role during chondrogenic differentiation and is considered an early sign of chondrocyte formation. Complete deletion of Sox9 can prevent the formation of cartilage. When it is overexpressed, it significantly inhibits the proliferation of chondrocytes[30]. Sox9 is a regulator of the type II collagen (*ColII*) gene, which is a specific marker of cartilage formation. The expression of *ColII* in chondrocytes has been found to be in direct proportion to the concentration of Sox9[31]. TGF-β can promote the differentiation of MSCs into chondrocytes and inhibit the terminal differentiation of chondrocytes into mast cells[32]. The differentiation of chondrocytes induced by TGF-β is mainly mediated by the Smad signaling pathway[33], which can upregulate the expression of Sox9 transcription factors and promote the synthesis of collagen and proteoglycan.

The main paracrine signaling pathways involved in the osteogenic differentiation of MSCs include bone morphogenetic protein (BMP) signaling, Wnt signaling, and Notch signaling[28,34-36]. The key transcriptional regulatory factors include Runx2, β-catenin, and osterix[27]. Runx2 is indispensable for the osteogenic differentiation of MSCs because it is a common convergence point for many signaling pathways[25,37]. It leads to the differentiation of MSCs into osteoblasts and inhibits the differentiation of adipogenesis and chondrogenesis. Runx2 promotes the differentiation of MSCs into osteoblasts in the early stage and promotes the maturation and mineralization of osteoblasts in the later stage by regulating extracellular matrix proteins, such as ColI and alkaline phosphatase (ALP). When Runx2 is absent, neither periosteal nor endochondral ossification occurs[38]. BMP2 is also an effective osteogenic induction factor that promotes the expression of Runx2, thus promoting the differentiation and maturation of osteoblasts[28]. Osterix is an osteoblast-specific transcription factor that is only expressed in osseous tissue and plays a decisive role in the differentiation of MSCs into osteoblasts[39]. Activation of the Wnt signaling pathway induces osterix expression. Overexpression of osterix in MSCs leads to osteogenic differentiation and an enhanced bone regeneration ability of MSCs[40]. The activity of β-catenin is also regulated by Wnt signaling. β-catenin can facilitate the shift of MSC fate to osteoblasts and enhance endochondral ossification. Its deficiency hinders the osteogenesis of MSCs and promotes the formation of cartilage and fat[41,42] (Figure 2).

FACTORS AFFECTING THE OSTEOGENIC AND CHONDROGENIC DIFFERENTIATION OF MSCS IN THE MICROENVIRONMENT OF OA



Oxygen concentration

The effect of oxygen concentration on MSCs has been studied for over twenty years (hypoxia promotes murine bone marrow-derived stromal cell migration and tube formation). Although there are still some controversies, a large number of studies have proven that low oxygen tension (hereinafter "hypoxia")

Figure 2 Signaling pathways involved in osteogenic and chondrogenic differentiation of mesenchymal stem cells and the mechanism of certain factors. TGF-β: Transforming growth factor-beta.

exerts a significant impact on the differentiation of MSCs. Hypoxia often occurs in the stem cell microenvironment, which induces beneficial signals, such as upregulation of pluripotency markers, for MSCs to maintain their functions[43]. In the general microenvironment *in vivo*, the oxygen concentration is usually low. For example, the oxygen concentration in healthy bone marrow is only 1.3% to 7.0%[44], and that in articular cartilage is only 2% to 5%[45]. In particular, OA often occurs in a hypoxic environment. Nitric oxide synthase and hypoxia-inducible factor-1 are often upregulated in OA and aggravate the hypoxic environment[46]. Although the oxygen concentration in the microenvironment of MSCs is low, a 21% O_2 concentration (hereinafter "normoxia") is routinely used in cell culture.

Ciapetti *et al*[22] isolated and cultured BM-MSCs under 2% O_2. They observed a higher tendency of osteogenic differentiation of these cells compared with the cells cultured in standard normoxia. Significant changes in the MSC immunophenotype, such as increased CD73 and CD90 expression, were observed, but CD105 expression was reduced. MSCs cultured under hypoxia have better mineralization, higher mineral density and higher calcium matrix deposition than those cultured under normoxia.

Alizarin red S staining is a convenient method for detecting calcium salt deposition. The positive area observed in hypoxic cultured MSCs was greater than that in cells cultured in normoxia, which means that osteoblast differentiation was enhanced[47,48]. Fennema *et al*[49] found that hypoxic culture increased the levels of osteogenic genes, such as osteopontin, osteocalcin, ALP and ColI[50]. Hypoxia activates the Notch signaling pathway, increases the expression of CBF-1α, and promotes the osteogenic differentiation of MSCs[51,52].

Similarly, hypoxic conditions increased the chondrogenic differentiation efficiency compared to normoxic conditions. Chondrogenic differentiation of MSCs can be quantitatively assessed by Safranin O staining[53,54], and the positive area increases after hypoxic culture. Immunohistochemistry demonstrated that the expression of *ColII* increased[50]. Hypoxia may enhance the chondrogenic differentiation capacity of MSCs by enhancing the expression of chondrogenic genes[55]. This may be manifested as increased mRNA expression of glycosaminoglycans, aggrecan, transcription factor and Sox9[56,57]. The level of cartilage oligomeric matrix protein is higher under hypoxic conditions[53]. These factors play crucial roles in chondrocyte differentiation. Hypoxia affects the overall cellular response through TGF-β, leading to upregulation of cartilage molecular markers, such as *ColII* and Sox9 [58]. However, some studies have shown that hypoxia can enhance chondrogenesis and inhibit osteogenesis of MSCs[59,60]. These differences between studies may be due to differences in culture conditions and sources of MSCs and therefore larger sample sizes and more precise experiments are required to fully elucidate the effect of hypoxia on MSC differentiation.

Inflammation

OA was once referred to as noninflammatory arthritis, but it is now considered a persistent low-grade inflammatory disease, and many inflammatory cells are involved[61]. Chronic inflammation activates the Wnt/β-catenin pathway, which leads to mitochondrial damage and further impairs the differentiation of MSCs[62]. Interferon-gamma (IFN-γ) and TNF-α are two important inflammatory cytokines involved in OA inflammation[63]. Li *et al*[64] pretreated MSCs with IFN-γ and TNF-α to simulate the inflammatory microenvironment. They found that the inflammatory microenvironment promoted chondrogenic differentiation of MSCs and inhibited their osteogenic differentiation.

Acidic pH

Inflammation decreases the extracellular pH and makes the OA joint cavity a weakly acidic microenvironment[65]. The pH of joints with OA (6.40 ± 0.08) was obviously lower than that of normal joints (7.01 ± 0.26)[66]. Decreasing pH was shown to inhibit the proliferation and metabolism of MSCs in culture. Furthermore, the activity of alkaline phosphatase was reduced, which means that the osteogenic differentiation of MSCs was decreased[67]. At physiologic pH (8.0), MSCs exhibit the strongest osteogenic differentiation potential[68]. A pH of 8.0 is recommended for a greater therapeutic effect of MSCs in OA.

Osmolar pressure

The osmolar pressure in the joint cavity of healthy adults is 404 mOsm/L ± 57 mOsm/L, while that in OA patients is 297.0 mOsm/L ± 16.9 mOsm/L. The joint cavity of OA patients is exposed to a hypoosmotic environment[69,70]. At present, there is little research on the effect of osmotic pressure on the osteogenic and chondrogenic differentiation of MSCs. Some studies have demonstrated that hyperosmolarity promotes the chondrogenic differentiation of MSCs and cartilage repair[71-73]. No study on the effect of hypo-osmotic stress has been conducted.

Cytokines

In contrast to normal bone, subchondral bone in advanced OA is characterized by osteosclerosis, including a higher bone volume fraction, a greater number of trabecular bones in the load-bearing area, and an increase in the thickness of the original trabeculae. This may be due to the overexpression of growth factors in the joints of patients with OA, such as insulin-like growth factor 1 and TGF-β[74]. Both of these cytokines have been shown to promote osteogenic and chondrogenic differentiation of MSCs [75,76]. The local expression of basic fibroblast growth factor (bFGF) in the joints of patients with OA is significantly higher than that in healthy people[77]. bFGF has been proven to be an important growth factor for maintaining the stemness of MSCs[78].

OTHER COMMON INFLUENCING FACTORS IN THE TREATMENT OF OA

Glucocorticoids

Dexamethasone is a member of the glucocorticoid class, and it is considered to be the mildest corticosteroid drug used for OA treatment[79]. Intra-articular injection of glucocorticoids is one of the treatment methods for OA[80], and dexamethasone can also be used as an immunosuppressive agent for MSC transplantation. Moreover, dexamethasone is generally considered one of the main components that induces MSCs to differentiate toward osteogenic, adipogenic and chondrogenic lineages[81]. The

osteogenic differentiation of MSCs mainly relies on osteogenic induction medium, which is usually composed of dexamethasone, ascorbic acid and β-sodium glycerophosphate. Dexamethasone induces increased expression of Runx2, osterix, and bone matrix proteins. Furthermore, it can induce osteogenic differentiation by inhibiting Sox9 expression[82]. Ascorbic acid and β-sodium glycerophosphate increase the content of ColI and stimulate the formation of a mineralized matrix[11]. Human MSCs need dexamethasone to produce ALP, a marker used to distinguish osteoblasts in culture[83,84]. The chondrogenic differentiation medium often includes dexamethasone, ascorbic acid and TGF-β3. Dexamethasone enhances the expression of the cartilage-specific gene Sox9[85]. The adipogenic differentiation medium often contains dexamethasone, ascorbic acid, 3-isobutyl-1-methylxanthine, insulin and other components[86]. Although the detailed mechanism of differentiation induced by dexamethasone is currently unknown, dexamethasone clearly affects the direction of MSC differentiation [87].

Doi *et al*[88] found that dexamethasone had certain effects on the osteogenic differentiation of MSCs. The effect of dexamethasone on inducing MSCs to differentiate into osteoblasts depends on the dosage and exposure time of the drugs[89]. It has been reported that short-term use of low-dose (10^{-8}, 10^{-7} mol/L) dexamethasone can stimulate the osteogenesis of MSCs and significantly increase the formation of mineralized nodules and the expression of osteogenic markers (BSPII and Runx-2) in cells[90,91]. It has also been reported that high concentrations of dexamethasone (10^{-6} mol/L) can inhibit the osteogenic differentiation of MSCs and induce them to differentiate into adipocytes. A high dose can reduce the osteogenic differentiation-related surface phenotype, as indicated, for example, by decreased surface expression of CD73. The higher concentration of dexamethasone resulted in enhanced lipid droplet formation and higher expression of lipid-forming markers (PPAR-γ and CEBP-α) in cells. In addition, a high concentration of dexamethasone exacerbates apoptosis of MSCs, inhibits MSC proliferation, and promotes senescence of MSCs[83]. A concentration of dexamethasone up to 10^{-6} mol/L imposes toxic effects on MSCs[89,92]. When the concentration of dexamethasone was lower than 10^{-8} mol/L, no differentiation of osteoblasts was detected[93,94]. Therefore, 10^{-7} mol/L is considered the most appropriate concentration for inducing MSCs to differentiate into bone[91].

Similarly, dexamethasone can also promote chondrogenic differentiation of MSCs[93]. Tangtrongsup *et al*[95] found that chondrogenic differentiation was suppressed in dexamethasone-free cultures. It can increase the proteoglycan content and collagen type II intracellular content. Dexamethasone may not function as a specific chondrogenic factor to directly promote cartilage differentiation, rather, it may promote it by inducing cells to upregulate cartilage factors, such as Runx2 and Noggin[96]. Its influence is mainly dependent on the context[97].

In addition to the dosage, the duration of dexamethasone treatment also affected the differentiation of MSCs. Dexamethasone is commonly used in bone trauma to relieve edema and pain, but long-term use may lead to osteoporosis through bone loss and bone marrow lipogenesis. Some studies suggest that long-term exposure of MSCs to dexamethasone may negatively impact their differentiation[91]. Others found that a lack of dexamethasone inhibits the differentiation of MSCs, so continuous delivery *in vivo* should be given priority[95]. Moreover, Song *et al*[98] found that within 4 wk, as exposure time increased, stimulation of osteogenic differentiation by dexamethasone strengthened, and calcium deposition increased. According to some authors, the sensitivity of MSCs to dexamethasone depends on the stage of cell maturation. Dexamethasone mainly acts on early stem cells, so it should be applied in the early stage[84]. It has also been suggested that early exposure to dexamethasone has little effect on MSC differentiation, and thus, continuous exposure for at least one week is required[89]. At present, there is little research on the effect of the duration of dexamethasone exposure on MSC differentiation, and more accurate experiments are needed to verify this hypothesis. As a glucocorticoid, dexamethasone is not suitable for systematic use to regenerate local tissue defects due to possible negative effects on healthy tissues and organs. Therefore, the application of local controlled release devices of dexamethasone in MSC therapy is reasonable.

Scaffolds

MSCs can be injected directly into the damaged site or differentiate into target cells together with the tissue engineering scaffold. Many tissue engineering experiments have proven that biological scaffolds can enhance the osteogenic and chondrogenic differentiation of MSCs. HA is often used to form a stable 3D environment for MSC chondrogenesis *in vitro*, which allows for better provision of oxygen and nutrients to MSCs. HA can promote the osteogenic process of endochondral ossification of MSCs[99]. Three-dimensional nanofibrous scaffolds, such as poly-((D,L)-lactide-ε-caprolactone)dimethacrylate scaffolds and poly(-caprolactone) nanofibrous scaffolds, have been shown to enhance chondrogenic differentiation of MSCs[100,101]. The combination of MSCs with biomaterials can improve the differentiation ability of MSCs. These studies have demonstrated that better efficacy can be achieved by injection of scaffolds loaded with MSCs.

Sources of MSCs

The source of MSCs also significantly impact their differentiation. By reviewing clinical trials, we found that bone marrow-derived MSCs (BM-MSCs), adipose tissue-derived MSCs (AD-MSCs) and umbilical cord-derived MSCs (UC-MSCs) are mainly used in OA research. MSCs from different sources have

different characteristics and differentiation potentials[102].

BM-MSCs offer the advantages of strong differentiation ability, mild implantation reaction and strong expansion ability *in vitro*. However, BM-MSCs need to be obtained from the patient's bone marrow, and bone marrow collection is a painful and invasive process. The number of BM-MSCs derived *in vivo* is quite low and requires *in vitro* amplification. Moreover, the differentiation potential and proliferative capacity of BM-MSCs decrease with the age of the donor[103]. Adipose tissue was first identified as an alternative source of MSCs in 2001[104,105]. AD-MSCs offer the advantage that they can be obtained in large quantities in a simple, minimally invasive manner. They can be extracted from excess adipose tissue that is discarded as waste during liposuction, avoiding immunogenicity and ethical concerns. The quantity and quality of MSCs from adipose tissues were significantly higher than those of other tissues [106]. Some studies have suggested that the differentiation potential of AD-MSCs depends on the source of adipose tissue[107]. MSCs from visceral adipose tissues have greater osteogenic differentiation capacity[108,109]. UC-MSCs exhibit superior clonogenic, proliferation and migration capacities[43,110]. They can secrete relevant chondrogenic factors[111,112]. Furthermore, UC-MSCs are less mature, which makes them a better choice for allogeneic therapy[113]. Wharton's jelly (WJ) is the most frequently used source of umbilical cord tissue[114]. WJ-MSCs are relatively novel for cell and tissue engineering therapy and are considered promising candidates for the development of cell-based therapies[113,115].

Many studies have shown that BM-MSCs have higher osteogenic and chondrogenic differentiation potential[116,117]. They exhibit a relatively high incidence of bone and cartilage formation[50], and they can generate more mature bone tissue and more compact cartilage pellets[118]. BM-MSCs express high levels of CD90, which means that they are more suitable for bone repair and regeneration[119].

AD-MSCs are more inclined to differentiate into adipocytes, and their potential for osteogenic differentiation and chondrogenic differentiation is relatively low[107]. Some studies hypothesize that the chondrogenic potential of MSCs derived from adipose tissue is higher than that of MSCs derived from UC sources[120]. However, other studies have suggested that AD-MSCs and UC-MSCs show similar chondrogenic potential[110].

Although BM-MSCs have stronger differentiation ability, AD-MSCs and UB-MSCs perform better for pain relief and functional improvement in OA[121]. AD-MSCs are considered the most effective MSCs in relieving pain, while UC-MSCs are considered the most effective MSCs in improving function in OA patients[122]. Therefore, AD-MSCs and UC-MSCs showed better anti-arthritis efficacy than BM-MSCs [123].

CONCLUSION

In this review, we summarize the common factors that affect the differentiation of MSCs in the OA microenvironment. MSCs can differentiate into different lineages, and these processes are precisely regulated by signaling pathways. Many factors can affect the differentiation direction of MSCs by acting on these signaling pathways. The multidirectional differentiation potential and tunability of MSCs make them a promising treatment for OA and other diseases. A large number of studies have confirmed their safety and effectiveness.

At present, a large number of studies focus on the paracrine effect of MSCs. However, the differentiation function of MSCs can also play an important role in disease treatment. Chemical, physical and biological factors can affect the differentiation of MSCs. Therefore, there are many conditions that can affect the efficacy of MSCs. To control the differentiation of MSCs more precisely to improve their efficacy in the treatment of diseases, it is necessary to understand how various influencing factors work. However, there are few studies on the factors that affect the differentiation direction of MSCs, and we are still at a preliminary stage in understanding how these factors determine the fate of MSCs. More research is needed on the differentiation of MSCs, which is of great value for developing novel therapies for diseases and applying MSCs to clinical practice.

Abstract

The high incidence and disability rates of stroke pose a heavy burden on society. Inflammation is a significant pathological reaction that occurs after an ischemic stroke. Currently, therapeutic methods, except for intravenous thrombolysis and vascular thrombectomy, have limited time windows. Mesenchymal stem cells (MSCs) can migrate, differentiate, and inhibit inflammatory immune responses. Exosomes (Exos), which are secretory vesicles, have the characteristics of the cells from which they are derived, making them attractive targets for research in recent years. MSC-derived exosomes can attenuate the inflammatory response caused by cerebral stroke by modulating damage-associated molecular patterns. In this review, research on the inflammatory response mechanisms associated with Exos therapy after an ischemic injury is discussed to provide a new approach to clinical treatment.

Key Words: Mesenchymal stem cell-derived exosome; MicroRNA; Inflammation; Ischemic stroke; Adipose-derived stem cell; Toll-like receptor

Core Tip: Mesenchymal stem cell-derived exosome (MSC-Exos) transplantation is a novel treatment method for ischemic stroke that exhibits certain achievements in trials. Here, we review the strategies developed for MSC-Exos in the neuroinflammatory response of patients with stroke and provide potential therapeutic targets. These methods provide new insights for the future clinical application of MSC-Exos in the treatment of ischemic stroke.

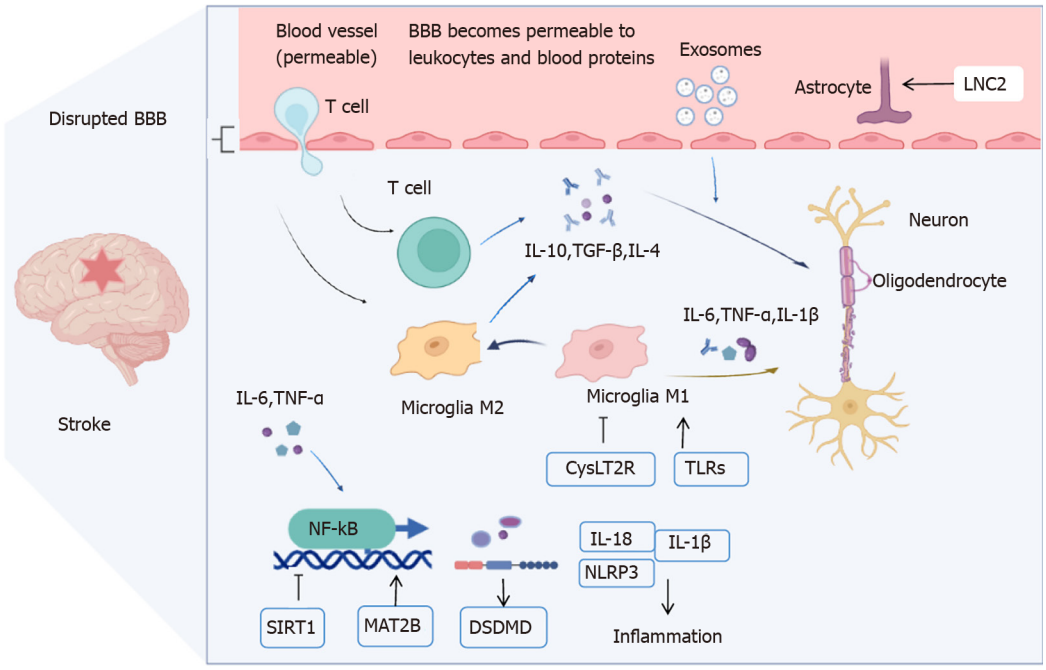
INTRODUCTION



Stroke is a common clinical condition that frequently occurs in middle-aged and elderly people and is a global public health problem with high disability and mortality rates; it ranks third in the list of diseases affecting human lifespan[1]. The main goals of stroke treatment are vascular recanalization and reduction of cerebral ischemic injury. At present, the main recanalization methods are intravenous thrombolysis and endovascular mechanical thrombectomy; however, owing to the restricted time window and various comorbidities, few patients can benefit from these procedures[2,3]. Increasing evidence has suggested that inflammatory cytokines promote the migration of immune cells to damaged tissues through the blood-brain barrier (BBB) after stroke, aggravating the inflammatory response and leading to nerve cell injury[4,5]. However, the exact molecular mechanisms underlying the inflammatory response after stroke remain unclear, hindering the development of effective and specific treatments.

The effectiveness of stem cell transplantation, which can regulate the immune-inflammatory response and the permeability of the BBB, in the treatment of ischemic stroke (IS) has been verified[6,7]. However, pluripotent stem cells are obstructed by the BBB and cannot effectively enter the central nervous system, leading to risks, such as tumorigenicity, thrombosis, and pulmonary embolism, limiting their clinical application. It has been suggested that the therapeutic mechanism of mesenchymal stem cells (MSCs) may involve secreted exosomes (Exos) rather than the direct replacement of brain cells[8]. MSC-derived extracellular vesicles (MSC-EVs) possess the biological characteristics of cells and can penetrate the BBB, reduce the risk of tumors and pulmonary embolism, considerably improve therapeutic efficiency, and reduce complications, thereby having broad therapeutic prospects. MSC-derived Exos (MSC-Exos) reduce inflammatory responses after stroke[9-12]. However, the specific mechanism by which Exos alleviate the inflammatory response after stroke has not yet been explored.

Therefore, in this review, we present the current progress in research on the unique biological characteristics of MSC-Exos and the specific mechanism of action of MSC-Exos in the neuroinflammatory response after stroke. This review aims to explore the role of Exos in the neuroinflammatory response in stroke and provide potential therapeutic targets, with the expectation of offering a reference for future clinical treatments.

PATHOLOGICAL CHANGES AFTER CEREBRAL ISCHEMIA

Brain cell death after stroke can lead to a series of pathological processes including cell energy failure, neuronal apoptosis, leukocyte infiltration, inflammatory immune responses, tight junction (TJ) protein breakage and degradation, BBB destruction, and increased permeability[13,14]. The main goals of IS treatment are to restore blood flow and improve functional outcomes as soon as possible[15]. In addition, methods of regulating immune inflammation and oxidative stress responses, anti-apoptosis, and promotion of angiogenesis and neurogenesis are of great significance for the treatment of cerebral apoplexy in ischemic and hypoxic injured brain tissues[16]. The BBB controls the inflow and outflow of biological substances necessary for metabolic activity and neuronal function in the brain; therefore, its structural and functional integrity is essential for maintaining the brain microenvironment. The BBB is mainly comprised of vascular endothelial cells, pericytes, the basement membrane, astrocytes, neurons, and microglia, which exchange substances that connect the central and peripheral nervous systems. The mechanisms of BBB injury after stroke include modification of TJ proteins, regulation of transporter expression, and inflammatory damage[17]. The intravascular inflammatory response marks the beginning of BBB disruption and leukocyte infiltration in ischemic brain tissue[18]. The inflammatory response after stroke is an important factor in BBB disruption and nerve cell edema, leading to damage to mental function and even death (Figure 1).

DOI: 10.4252/wjsc.v15.i6.561 **Copyright** ©The Author(s) 2023.

Figure 1 Pathological changes after stroke. Blood-brain barrier (BBB) disruption after stroke is permeable to leukocytes and blood proteins. Microglia are stimulated, and these activated microglia (M1), in turn, release tumor necrosis factor-α, interleukin (IL)-6, and IL-1β, which activate the nuclear factor kappa-B inflammatory response of reactive astrocytes (A1) and further amplify this effect. Exosomes can penetrate BBB, promote microglial M1 polarization to M2 and T cell activation, mediate lipocalin-2, sirtuin 1, methionine adenosyl transferase 2B, pyrin domain-containing protein, cysteinyl leukotriene receptor 2, and other signaling pathways to promote the release of anti-inflammatory cytokines IL-10, transforming growth factor-β, and IL-4. By BioRender.com. BBB: Blood-brain barrier; CysLT2: Cysteinyl leukotriene receptor 2; IL: Interleukin; LNC2: Lipocalin-2; MAT2B: Methionine adenosyl transferase 2B; NF-κB: Nuclear factor kappa-B; SIRT1: Sirtuin 1; TLRs: Pyrin domain-containing protein; TNF-α: Tumor necrosis factor-α.

Microglia are the resident immune cells of the brain that polarize into different phenotypes (M1 or M2)[19]. M1 inflamed microglia lead to BBB dysfunction and vascular 'leakage,' whereas M2 microglia have inflammation-inhibiting, immune-regulating, tissue-repair, and damage-eliminating functions; they also protect the BBB[20]. Activated M1 microglia release the pro-inflammatory factors tumor necrosis factor-α (TNF-α), interleukin (IL)-1, and IL-6, which activate the nuclear factor kappa-B (NF-κB)-mediated inflammatory response of reactive astrocytes (A1s) and further amplify this effect[21]. Owing to inflammatory response stimulation, the structure of the neurovascular unit (NVU) changes, which inhibits central nervous system restoration. This change in the microenvironment stimulates M2 microglia to initiate phagocytosis and secrete transforming growth factor-β (TGFβ), IL-4, and IL-10, and the engulfment of immune cells, indirectly protecting against inflammation-induced BBB disruption [22]. M2 polarization promotes the release of anti-inflammatory cytokines and tissue repair, including neurogenesis, axonal remodeling, angiogenesis, and oligodendrogenesis[21,23]. Activated matrix metalloproteinase (MMP)-2 and MMP-9 by microglia after stroke degrade the basement membrane and TJ proteins, resulting in BBB disruption, leukocyte infiltration, and angioedema, thus aggravating brain injury[17,24,25]. Pericytes also release cytokines that play vital roles in maintaining the structural integrity of the BBB. Under pathological conditions, dysfunctional pericytes can cause basement membrane degradation or alter NVU coordination, leading to BBB instability[17]. In addition, BBB injury along with the activation of TGFβ signaling in astrocytes may be a mechanism to disrupt NVU structure, as TGFβ overproduction affects the function of pericytes and vascular smooth muscle cells[26,27]. Microglial polarization is closely related to stroke progression; M1 microglia promote astrocyte differentiation to the A1 phenotype through a variety of signaling pathways, including the immune inflammatory response, angioedema, BBB disruption, neuronal apoptosis, and glutamate excitotoxicity, thereby exacerbating brain injury caused by IS[28,29]. The inflammatory reaction of the nervous system is closely related to the polarization of microglia, pericyte-secreted factors, astrocyte differentiation, and leukocyte species. However, the underlying mechanism of action of Exos in the treatment of neuroinflammation in stroke remains unclear.

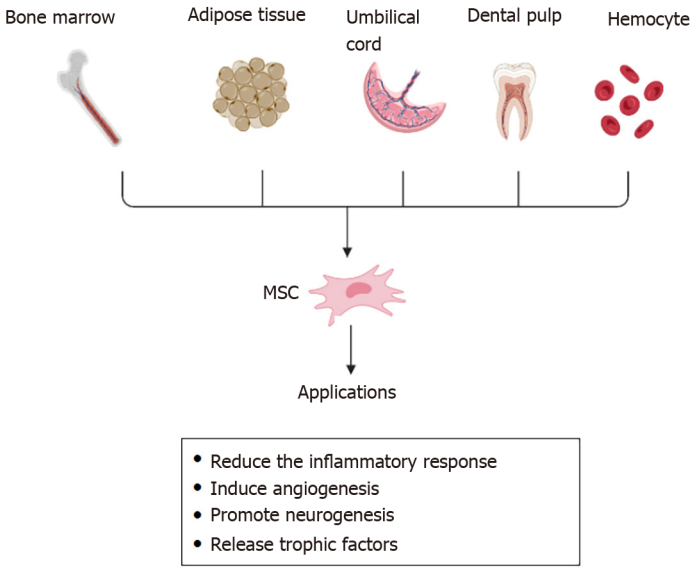
BIOLOGICAL CHARACTERISTICS OF MESENCHYMAL STEM CELL EXOSOMES

MSCs are pluripotent stem cells with self-renewal, differentiation, secretion, and homing properties. They were first discovered in the bone marrow, where they are abundant and easily extractable, and are

also found in the dental pulp, umbilical cord, hemocytes, and adipose tissue (such as bone marrow MSCs, dental MSCs, umbilical cord-derived MSCs, adipose-derived MSCs, and hematopoietic stem cells)[30,31]. To overcome the problems with primary MSCs, human pluripotent stem cells (hPSCs), including human embryonic stem cells (hESCs) and pluripotent stem cells (iPSCs), represent a promising solution[32]. MSCs can differentiate into lipogenic, chondrogenic, osteoblastic, endothelial, neural, and epithelial lineages, both *in vivo* and *in vitro*[33,34]. MSCs can reduce inflammatory responses, release trophic factors to promote therapeutic effects, induce angiogenesis, promote neurogenesis, reduce infarct volume, and replace damaged cells *via* immunomodulation[10,35,36]. Extracellular vesicles secreted by MSCs can be divided into three types based on their size and intracellular origin: Apoptotic bodies, microvesicles, and Exos. Apoptotic bodies are ≥ 1000 nm and microvesicles are 100–1000 nm in diameter. Exos (30–100 nm in diameter) originate from multivesicular bodies and are released by exocytosis, which is dependent on cytoskeletal reorganization, but independent of intracellular Ca^{2+} concentration[37,38]. When multivesicular bodies fuse with the cell membrane, Exos are released from the cells. Previously, these vesicles were considered waste products actively excreted by cells; however, studies have shown that Exos have key functions, such as transmitting information between cells, tissue regeneration, and immune regulation[39] (Figure 2).

Exos are released upon fusion with the cell membrane and trigger the release of different cellular substances. Exos can carry the same bioactive substances as their source cells and are vital for information transmission between cells, such as immune regulation and promotion of cell migration, proliferation, differentiation, and matrix synthesis[40]. Moreover, the exogenous Exos of stem cells express specific surface markers (CD9, CD63, CD81, and CD92), express specific phenotypes of stem cells (CD29, CD44, CD73, and CD90)[41], and carry heat shock proteins (HSP) proteins (HSP8, HSP60, HSP70, and HSP9), signal transduction proteins, and multivesicular production-related proteins. More importantly, they can directly transfer bioactive molecules, including non-coding regulatory microRNAs (miRNAs), messenger RNAs (mRNAs), and proteins from donor cells to recipient cells. MiRNAs are short (approximately 22 nucleotides), single-stranded, non-coding RNAs transcribed in the nucleus by RNA polymerase II from one gene or between two different genes to regulate different cellular processes such as differentiation, proliferation, metabolism, inflammation, stress response, angiogenesis, and signaling transduction[42]. miRNAs mainly affect gene expression by degrading the corresponding miRNAs or suppressing translation[43]. Alexander *et al*[44] showed that exosomal miRNAs participate in regulating inflammatory responses; miR-146a-containing Exos can inhibit inflammation, whereas miR-155-containing Exos promote inflammation following exposure to the same inflammatory stimulus.

Exos contain a variety of active substances that form the basis for disease treatment. These bioactive substances carried by Exos can target specific cells for information transmission and enter the cytoplasm by fusion with receptor cell membranes or endocytosis, thereby changing the target cell function by transmitting proteins, lipids, and nucleic acids[45]. Exos can be effectively isolated from donor cells and protect their contents from the external environment, ensuring the complete transmission of effective information[46]. Exos act as mediators that facilitate intercellular communication and influence the recipient cell activity by delivering content. DiR-labeled MSC-Exos were injected into a rat model of stroke *via* the caudal vein, and the *in vivo* tracer showed that Exos could penetrate the BBB and reach the brain tissue. The fluorescence signal peaked on the third day and then gradually decreased[47]. Matsumoto *et al*[48] also demonstrated that Exos can increase long-term neuroprotective effects after stroke, modulate peripheral immune responses, and increase angiogenesis and axonal dendritic remodeling. Therefore, the use of Exos for the treatment of neurological diseases has great potential[49, 50]. These results suggest that Exos is an important therapeutic target for the treatment of stroke (Figure 3).



MSC-EVS REGULATE INFLAMMATORY RESPONSE IN IS TREATMENT

The potential therapeutic mechanisms of stem cell Exos involve promoting dendritic and axonal growth, repairing nerves, and promoting angiogenesis through direct actions[51,52]. Through indirect action, it can promote the secretion of inflammatory factors by cells by exogenously producing Exos that appear to interact with recipient brain cells, thereby stimulating them to release their own Exos and playing a role in anti-inflammation and neurological repair. Transplantation of MSC-Exos improves inflammatory responses in IS, maintaining BBB function, decreasing brain edema, regulating energy metabolism, and promoting antioxidant, anti-inflammatory, and anti-apoptotic effects[53]. In IS, miRNAs are involved in a variety of cellular functions, such as injured tissue repair and remodeling, and different neuronal activities. Their target genes play a crucial regulatory role in the inflammatory process of post-ischemic reperfusion injury, which explains their potential use as therapeutic targets in IS and is the focus of Exos research[54,55]. According to current research, the main signaling pathways mediated by Exos after cerebral ischemia are as follows (Table 1)[12,41,56-63].

Table 1 Application of stem cell exogenous exosomal miRNA in treatment of ischemic stroke

MicroRNA	Source	Model(s)	Functional effects	Pathway(s)	Ref.
miR-21a-5p	MSCs	OGD microglia	Induces microglial M2 polarization by targeting STAT3	STAT3	Xin *et al*[12], 2022
miR-138-5p	BMSCs	MCAO mouse, OGD astrocytes	Promotes astrocyte proliferation and inhibits inflammatory response	LCN2	Deng *et al*[41], 2019
miR-542-3p	MSCs	MCAO mice, OGD human glial cells	Suppresses inflammation and prevents cerebral infarction	TLR4	Cai *et al*[56], 2021
miR-146a-5p	HUMSCs	MCAO mouse, OGD microglia	Anti-inflammation	IRAK1/TRAF6	Zhang *et al*[57], 2021
miR-223-3p	MSCs	MCAO Rats, OGD microglia	Anti-inflammation	CysLT2R	Zhao *et al*[58,59], 2020
miR-21-3p	MSCs	MCAO rats	BBB protection, anti-inflammation, anti-apoptosis	MAT2B	Li *et al*[60], 2019
miR-26a-5p	HUMSCs	I/R mice, OGD microglia	Inhibits microglial M1 polarization	TLRs	Li *et al*[61], 2020
miR-150-5p	BMSCs	MCAO rats	Decelerates neuronal apoptosis, reduces inflammation	TLR5	Li *et al*[62], 2022
miR-30d-5p	ADSCs	Patients, MCAO rats, OGD microglia	Promotes M2 microglial/macrophage polarization	Inflammatory mediators	Jiang *et al*[63], 2018

Figure 2 Sources and potential function for stroke of mesenchymal stromal cells. These cells are found in bone marrow, dental pulp, umbilical cord, hemocyte, and adipose tissue. Mesenchymal stromal cells reduce the inflammatory response, release trophic factors, induce angiogenesis, and promote neurogenesis in stroke. By BioRender.com. MSC: Mesenchymal stem cell.

NF-kB signaling pathway

The transcription factor NF-κB regulates many aspects of innate and adaptive immunity and plays an important role in the inflammatory response. It is also involved in the migration of immune effector cells to the inflammatory system, thereby allowing the secretion of pro-inflammatory cytokines[64]. Han *et al*[65] showed that MSCs-Exos protect MCAO-injured rats, possibly by regulating the AMP-activated protein kinase (AMPK) and JAK2/STAT3/NF-κB signaling pathways. NF-κB is a central inflammatory mediator responding to many immune receptors. NF-κB mediates the induction of pro-inflammatory

Figure 3 Exosomes. Extracellular vesicles are classified into three types: Apoptotic bodies, microvesicles, and exosomes (Exos). Apoptotic bodies are ≥ 1000 nm, microvesicles are 100–1000 nm, and Exos are 30–100 nm in diameter. The contents carried by the Exos are mainly DNA, mRNA, microRNA, functional proteins, and other active substances. The membrane structure can express a variety of antigens and antibody molecules. The surface markers of the Exos mainly include CD63, CD81, CD9, and heat shock protein 70. By Figdiaw. MSCs: Mesenchymal stem cells.

cytokines, such as TNF-α, IL-1, and IL-6, in monocytes/macrophages[66]. Fann *et al*[67] confirmed the involvement of NF-κB signaling in the activation of pyrin domain-containing inflammasomes following IS. Preconditioning MSCs with lithium modifies EV secretion patterns, enhancing the therapeutic potential of the derived EVs (Li-EVs) and significantly increasing the resistance of cultured astrocytes, microglia, and neurons to hypoxic injury compared with control and native EVs. Li-EVs reduce the abundance of post-hypoxic and post-ischemic TLR4 (leading to activation of the NF-κB signaling pathway) and decrease proteasomal activity, which together contribute to reduced levels of poststroke encephalitis[68]. The miRNAs carried by Exos play a significant physiological role. Cai *et al*[56] confirmed that MSC-derived exosomal microRNA-542-3p (miR-542-3p) prevented ischemia-induced glial cell inflammatory responses by inhibiting TLR4. Interleukin-1 receptor-associated kinase 1 (IRAK1) and tumor necrosis factor receptor-associated factor 6 (TRAF6) may be parts of an NF-κB-induced negative feedback loop[69]. Zhang *et al*[57] found that injected Exos produced by human umbilical cord MSCs (HUMSC-Exos) enter the site of ischemic injury and be internalized by cells, both *in vivo* and *in vitro*. *In vitro*, HUMSC-Exos treatment attenuates microglial inflammation induced by oxygen-glucose deprivation (OGD). *In vivo*, HUMSC-Exos treatment significantly reduced infarct volume, alleviated behavioral deficits, and improved microglial activation 3 d after transient cerebral ischemia. MiR-146a-5p from HUMSC-Exos can attenuate microglial-mediated neuroinflammation through the IRAK1/TRAF6 pathway and ensuing neurological deficits after IS. NF-κB signaling pathway activation is a 'master regulator' of inflammation and is associated with the generation of free radicals and the activation of proteolytic enzymes and pro-inflammatory cytokines, playing an important role in regulating apoptosis after stroke[70,71]. Taken together, these results show that NF-κB signaling is essential for the regulation of brain tissue inflammasomes under ischemic conditions. In addition, MSC-Exos treatment decreased the activation of the NF-κB signaling pathway, thereby attenuating inflammasome expression and activation under ischemic conditions. These findings suggest that therapeutic interventions targeting neuroinflammasome activation may provide new opportunities for the treatment of IS.

NOD-like receptor family pyrin domain-containing 3 signaling pathway

NOD-like receptor family pyrin domain-containing 3 (NLRP3) plays an important role in mediating the inflammatory responses during cerebral IS[72]. The NLRP3 inflammasome is a multiprotein complex comprising NLRP3 and pyroptosis-related factors (ASC and caspase 1)[73]. The NF-κB and mitogen-activated protein kinase (MAPK) pathways play a major role in the expression and activation of NLRP1 and NLRP3 inflammasomes in primary cortical neurons[67]. Bone marrow MSC-Exos (BMSC-Exos) can reduce brain infarct area and cerebral edema, thus improving neurological function. MSC-Exos can downregulate the expression of NLRP3 inflammasome and pyroptosis-related proteins on the surface of neurons[74]. Moreover, it improved the transition from M1 to M2 phenotype both *in vivo* and *in vitro*. BMSC-Exos relieve cerebral ischemia/reperfusion (I/R) injury by suppressing NLRP3 inflammasome-mediated inflammation and pyroptosis *via* modulation of microglial polarization[74]. Sarmah *et al*[75] came to similar conclusions by treating a rat MCAO model with intra-arterial injections of MSCs; the levels of NLRP-1 and NLRP-3 inflammasomes and their related components IL-1β, caspase-1, and ASC were significantly reduced. NLRP3 apoptotic bodies are involved in astrocyte and microglial

polarization and are closely related to the development of the inflammatory cascade after stroke, and BMSC-Exos reduce the inflammatory response after stroke by inhibiting NLRP3 activation.

Sirtuin signaling pathway

Sirtuins (SIRTs) are NAD+-dependent deacylases with multiple roles in energy metabolism regulation, cell survival, transcriptional regulation, inflammation, circadian regulation, and DNA repair[76]. SIRT-1 and SIRT-3 are both associated with the inflammatory response in stroke patients. Xin *et al*[12] used an *in vivo* neonatal male mouse model of hypoxic-ischemic (HI) injury and induced *in vitro* hypoxia-glucose deficiency, thus simulating microglial BV-2 cells to deliver miR-21a-5p (miR-21a-5p) as a therapeutic intervention through MSC-Exos. Treatment of BV-2 cells with MSC-EVs increased cell viability and miR-21a-5p levels, which were decreased after glucose-oxygen deprivation. In both *in vitro* and *in vivo* models of HI injury, the effects on microglial polarization and STAT3 phosphorylation decreased when miR-21a-5p levels were reduced in MSC-Exos. These results suggest that MSC-Exos attenuate HI brain injury in neonatal mice by delivering miR-21a-5p, which induces microglial M2 polarization by targeting STAT3. Adipose-derived MSC-derived miR-22-3p reduces infarct volume and apoptosis in a stroke model[77]. Sarmah *et al*[75] demonstrated that intraarterial MSCs increase SIRT-1 to inhibit the NF-κB pathway, reducing inflammasome signaling and apoptosis, thereby exerting a neuroprotective effect. SIRT1 may be an independent risk factor for cerebral infarction, and a high concentration of SIRT1 in cerebral infarction may be associated with disruption of the BBB[78].

Cysteinyl leukotriene signaling pathway

Cysteinyl leukotrienes (CysLTs), including leukotriene C4 (LTC4), leukotriene D4 (LTD4), and leukotriene E4 (LTE4), are derived from 5-lipoxygenase metabolites of arachidonic acid after cell necrosis and are effective mediators of inflammation[79]. The effects of CysLTs are mainly mediated by the CysLT1 and CysLT2 receptors (CysLT1R and CysLT2R), which are active in various cell types during pathological brain injury. CysLT2 is expressed in the cerebral cortex, hippocampus, substantia nigra, and lateral ventricle[80]. Zhao *et al*[58,59] showed that the overexpression of miR-223-3p (miR-223-3p) in MSC-Exos can reduce MCAO-induced infarction, improve neurological deficits, and promote learning and memorization. MiR-223-3p inhibits the expression of pro-inflammatory factors and promotes the secretion of anti-inflammatory factors in the ischemic cortex and hippocampus. Western blot and quantitative real-time PCR analyses also showed that exosomal miR-223-3p reduced the mRNA and protein expression of CysLT2R *in vitro* and *in vivo*. Exosomal miR-223-3p from MSCs alleviated cerebral I/R injury by inhibiting the pro-inflammatory response mediated by M1 polarization of microglia, which may be related to the inhibition of CysLT2R by exosomal miR-223-3p.

Lipocalin-2

Lipocalin-2 (LCN2), a 25 kDa protein, is a neutrophil gelatinase-associated protein that affects different cellular processes during stroke. The pro-inflammatory mediator LCN2 plays a key role in I/R injury [81]. Genetic or pharmacological inhibition of these pro-inflammatory mediators (iNOS, IL-6, CCL2, and CCL9) provides neuroprotection against stroke and reduces the expression of inflammatory factors by down-regulating LCN2[41]. Deng *et al*[41] used a mouse MCAO model to explore the effects of BMSC-derived exosomal miR-138-5p in IS *in vivo*. Overexpression of miR-138-5p promoted cell proliferation and inhibited apoptosis of OGD-damaged astrocytes, accompanied by decreased expression of inflammatory factors. This was achieved by downregulating LCN2, and the expression of LCN2 protein was subsequently detected by Western blot analysis. More importantly, BMSCs attenuated neuronal injury in IS mice by delivering miR-138-5p to astrocyte Exos. Therefore, the exogenous exosomal miR-138-5p from BMSCs promotes astrocyte proliferation and inhibits the inflammatory response after IS by targeting LCN2, thereby reducing neurological impairment, which may provide a new target for IS treatment.

Methionine adenosyl transferase 2B

Methionine adenosyl transferase (MAT) is an enzyme involved in cell cycle regulation. Mammals have three major MAT genes: MAT1A, MAT2A, and MAT2B[60]. TNF-induced activation of MAT2B promotes tumor growth through the NF-κB pathway in hepatoma cells[81]. MiR-21-3p antagomir can control the inflammatory response by inhibiting NF-κB signaling; these functions of miR-21-3p are exerted by directly targeting MAT2B[82]. This interaction forms the basis of the function of miR-21-3p/MAT2B in regulating inflammation. Li *et al*[60] found that miR-21-3p expression was elevated in the MCAO model, and the inhibition of exogenous adipose-derived stem cell Exos miR-21-3p could inhibit the expression of MAT2B in neural cells, thereby improving the BBB status and inhibiting apoptosis and inflammatory responses. MiR-21-3p antagomir could inhibit the expression of pro-inflammatory cytokines (TNF-α, IL-1β, and IL6) and promote the expression of anti-inflammatory cytokines (IL-10). Thus, miR-21-3p can protect neural cells by inhibiting the expression of MAT2B and thus inhibiting apoptosis and inflammatory responses.

Toll-like receptors (TLRS)

Evidence suggests that Toll-like receptors (TLRs) play important roles in the development of ischemic brain injury in adults[83]. TLRs, comprising 13 members (TLR-1 to TLR-13), are type 1 integral membrane proteins responsible for detecting invading pathogens and initiating immune responses[84, 85]. The microglial TLR pathway is activated following cerebral ischemia and inhibition of TLR signaling by exosomal miR-26a-5p decreases cholesterol 25-hydroxylase protein expression, which in turn inhibits microglial M1 polarization and relieves nerve injury after brain injury[61]. The gene expression of many inflammatory mediators, such as TNF-α, IL-1, and IL-6, can reduce the development of nervous system inflammation by inhibiting TLR4 transduction pathway downregulation[86]. Upregulation of miR-326 attenuates IL-10, IL-1β, and TNF-α pro-inflammatory cytokine expression in response to lipopolysaccharide stimulation by targeting TLR4[87]. TLR5 activates NF-kB and MAPK pathways that regulate the transcription of genes encoding immune mediators[88]. Qiao *et al*[89] elucidated that TLR5 downregulation is accompanied by alleviated neurological deficits, reduced infarct volume, and reduced edema after IS[90]. Li *et al*[62] validated that BMSC-Exos can improve neurological function and pathological changes, decelerate neuronal apoptosis, and reduce inflammatory factors in MCAO rats. Exosomal miR-150-5p from BMSCs mitigates cerebral I/R injury by inhibiting TLR5 expression. These studies showed that TLRs and their related miRNAs are associated with inflammation after IS.

Inflammatory mediators

Dabrowska *et al*[91] transplanted human bone marrow stem cells and their secreted Exos into a rat model of local brain injury. The results showed that monocyte chemoattractant protein-1 (MCP-1) expression increased locally after brain injury, whereas MCP-1 expression decreased in the transplanted HUMSCs and Exos groups. In addition, they observed that the infusion of pro-inflammatory cytokines and chemokines with HUMSCs or EVs in rats with untreated focal brain injury was associated with reduced microglial/macrophage and astrocyte activation. MSC-Exos therapy can reduce the expression of the inflammatory cytokines TNF-α and IL-6, increase the expression of the cytokines IL-4 and IL-10, and reduce brain injury. Exos from stem cells can enhance the activation of CD4+ and CD8+ lymphocytes, decrease the number of dendritic cells, regulate peripheral immunosuppression caused by stroke[9], and pass antigens to the immune system through the BBB[92]. IL-4, CD206, and IL-10 are markers of M2 microglial secretion, whereas TNF-α, IL-6, and iNOS are markers of M1 microglial secretion[93]. Yang *et al*[94] found that the MCAO model also verified that Exos intervention reduced the infarct volume and promoted the polarization of microglia to M2 phenotype. These results demonstrate that adipose-derived stem cell Exos can prevent stroke by shifting microglia from an M1 to M2 phenotype in the hippocampus[94].

Microglial polarization

Microglia are macrophages of the central nervous system and are important components of innate and adaptive immune responses[95]. The microglial M1 type can secrete pro-inflammatory factors, whereas the M2 type can secrete anti-inflammatory factors; therefore, the fact that MSCs and Exos can promote the polarization of microglia to M2 is notable for the treatment of IS. The M2 type protects nerve cells mainly by engulfing debris and promoting the repair and regeneration of brain tissue. In contrast, inflammatory factors of the M1 phenotype aggravate post-stroke symptoms. Therefore, the microglial response after stroke is an important prognostic factor[96]. Different miRNAs transported by Exos contribute to the differentiation of microglia into distinct phenotypes. Increased levels of miR-124-3p in microglial Exos promote M2 microglial polarization, reduce brain damage, and improve stroke outcomes[97]. Adipose-derived MSCs (ADMSCs) participate in the repair process of tissues through paracrine effects after relieving nerve injury; ADMSCs have similar biological characteristics to MSCs. Stimulation of AMSC-derived Exos with inflammatory factors was found to convert M1 microglia into M2 microglia, suggesting that AMSC-derived Exos promote microglial polarization by activating pro-inflammatory microenvironment signals[98]. miRNAs are critical regulators of genes involved in various biological processes; miR-146a-5p-enriched BMSC-Exos directly target IRAK1 and nuclear factor-activated T cell 5 (NFAT5), which contributes to inflammatory responses and polarize M1 microglia/macrophages[99]. Exos containing miR-216a-5p, miR-124, miR-155, miR-182, miR-17-5p, miR-30d-5p, and miR-223-3p were found to promote microglial M2 polarization[63,100-103]. BMSC-Exos promote microglial polarization from M1 to M2, inhibit inflammation-related signaling pathways, and reduce endothelial cell injury and neurological impairment caused by IS[104-106]. Although astrocytes may play a role in brain inflammation, little is known about their role in stroke pathology[107].

Activated regulatory T cells

Changes in regulatory T cell (Treg) numbers and function after stroke are accompanied by a decrease in immunosuppressive function, which affects stroke prognosis[108]. The immunosuppressive function of Tregs is largely impaired during stroke and Treg-derived anti-inflammatory factors, including transforming growth factor-beta (TGF-b) and IL-10, are reduced[109,110]. MiRNAs delivered by stem cell Exos can induce anti-inflammatory polarization as important regulators of Treg homeostasis and

function[111,112]. MSC-Exos induce anti-inflammatory IL-10 and TGF-β transcription, attenuate pro-inflammatory factors IL-1β, IL-6, and TNF-β, and inhibit the differentiation and activation of Tregs[113, 114]. Furthermore, MSC-Exos are absorbed by endothelial cells, impair T-cell function by inhibiting T-cell proliferation *in vitro*, and increase endothelial cell proliferation, migration, and capillary formation in a dose-dependent manner[115]. Wang *et al*[116] showed that the intravenous injection of MSC-EVs reduced neurological deficits, cerebral infarct volume, brain edema, and neuronal injury in both young and old mice. The neuroprotective and anti-inflammatory effects of MSC-EVs were demonstrated through a decrease in leukocyte infiltration and, specifically, polymorphonuclear neutrophil, monocyte, and macrophage infiltration, in the cerebral ischemic areas of aged mice. In addition, MSC-EVs significantly decreased the number of monocytes and activated Tregs. The expression and phosphorylation of signal transducer and activator 1 (STAT1) are increased in mice with miR-146a deficient Tregs, and miR-125a is involved in the differentiation of Tregs[117]. Exosomal miR-16 and miR-21, derived from bone marrow stem cells, can increase the production of Tregs and exert anti-inflammatory effects[118]. Although breakthroughs have been made in elucidating the working mechanism of Tregs over the past decade, the mechanism by which this minor population of peripheral immune cells has a significant beneficial effect after stroke injury remains largely unknown[108].

CONCLUSION

Brain injury after stroke is a complex pathological process. This review summarizes the recent studies on the mechanism of action of MSC-Exos in regulating inflammatory responses during IS treatment. MSC-Exos regulate microglial polarization through various pathways such as NF-κB, NLRP3, and STATs, indicating that microglial M1 to M2 phenotype polarization is closely related to the inflammatory response after IS.

However, some essential questions remain unanswered. Stroke-induced brain injury involves multiple mechanisms that cannot be explained by a single one. Immune inflammation plays a crucial role in this process, especially the NF-κB, NLRP3, and other signaling pathways. After immune inflammation, microglia, leukocytes, and other inflammatory cells are activated and release many pro-inflammatory factors. Additionally, nerve cells are affected by varying degrees of damage caused by ischemia and hypoxia after stroke.

However, these studies have some limitations. MSC-Exos can mediate different signaling pathways to reduce inflammatory responses after stroke in animal models. However, these results have not been translated into clinical practice. Most studies have focused on exosomal miRNAs, indicating that they play an important role in regulating cellular functions. However, research on other bioactive molecules contained in Exos, such as miRNAs, mRNAs, and proteins, is limited. This does not mean that this mechanism of action of miRNAs can explain how Exos attenuate post-stroke inflammation. The dosage, mode of administration, and duration of action of the Exos should be elucidated. Exos are considered ideal biomarkers and drug delivery vehicles, with great potential for overcoming the limitations of stem cell therapy[119]. The use of Exos as drug-loaded systems will facilitate breakthroughs in the research and development of targeted drugs for clinical treatment. Moreover, new directions and methods will be provided for stroke treatment.

Abstract

Lung cancer is the major cause of cancer-related deaths worldwide, it has one of the lowest 5-year survival rate, mainly because it is diagnosed in the late stage of the disease. Lung cancer is classified into two groups, small cell lung cancer (SCLC) and non-SCLC (NSCLC). In turn, NSCLC is categorized into three distinct cell subtypes: Adenocarcinoma, squamous cell carcinoma, and large cell carcinoma. NSCLC is the most common lung cancer, accounting for 85% of all lung cancers. Treatment for lung cancer is linked to the cell type and stage of the disease, involving chemotherapy, radiation therapy, and surgery. Despite improvements in therapeutic treatments, lung cancer patients show high rates of recurrence, metastasis, and resistance to chemotherapy. Lung stem cells (SCs) are undifferentiated cells capable of self-renewal and proliferation, are resistant to chemotherapy and radiotherapy and, due to their properties, could be involved in the development and progression of lung cancer. The presence of SCs in the lung tissue could be the reason why lung cancer is difficult to treat. The identification of lung cancer stem cells biomarkers is of interest for precision medicine using new therapeutic agents directed against these cell populations. In this review, we present the current knowledge on lung SCs and discuss their functional role in the initiation and progression of lung cancer, as well as their role in tumor resistance to chemotherapy.

Key Words: Lung cancer; Cancer stem cells; Biomarkers; Chemoresistance

Core Tip: Lung cancer stem cells (CSCs) could have a functional role in primary tumor initiation, invasion and metastasis, resistance to chemotherapeutic drugs, and recurrence in lung cancer. To improve lung cancer treatments, it is necessary to identify and characterize CSCs populations in lung tissue and develop targeted therapies against these cell types. This review discusses the current knowledge on CSCs in lung tissue and future perspectives in lung cancer treatment.

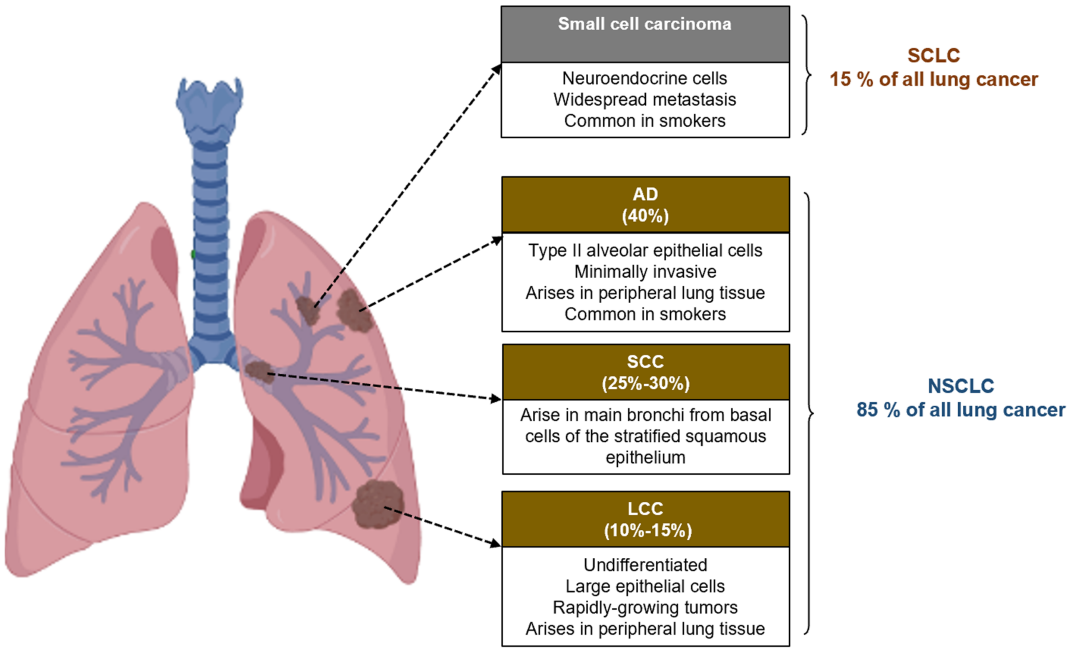
INTRODUCTION

Lung cancer is the leading cause of cancer death worldwide, in both men and women. Lung cancer is classified into two histological types, small cell lung cancer (SCLC) derived from cells of the neuroendocrine lineage and non-SCLC (NSCLC) derived from epithelial cells. The latter is the most frequent type of lung cancer in the population, since represents approximately 85% of all lung tumors, while SCLC represents the remaining 15%[1].

Based on the morphology of the transformed cells, NSCLC is classified into three subtypes: Squamous cell carcinoma (SCC), adenocarcinoma (AD), and large cell carcinoma (LCC). AD arises in peripheral lung tissue from type II alveolar epithelial cells that line the small alveoli, while SCC arises in the central lung region from cells of the stratified squamous epithelium that line the airways from the trachea to the main bronchi. LCC is a heterogeneous group of tumors that lack the morphological characteristics of AD and SCC sub-types or SCLC and arise from epithelial cells that line the lungs[1,2].

SCLC arises from lung epithelial cells from the main bronchi to the terminal alveoli. Their histologic features correlate with the site of origin and reflect epithelial variations of the airways[2]. The classification and main characteristics of lung cancer are shown in Figure 1.

All forms of lung cancer have a poor prognosis, mainly SCLC and SCC, which are typically seen in smokers. SCLC is the most aggressive lung cancer because it grows quickly and spreads to other tissues, generating metastases in the liver, brain, bones, and adrenal glands[3]. LCC has a better prognosis, which depends on the cell subtype. The poor prognosis is generally associated with the ability of the cells to metastasize and the late diagnosis of the disease, since the symptoms and signs do not usually appear in the early stages[4]. People with lung cancer may have chest pain, frequent coughing, blood in the mucus, trouble breathing, swallowing or speaking, loss of appetite and weight, and tiredness[5].



The prevalence of lung cancer worldwide is 13%, with an incidence of 1.8 million new cases per year. Lung cancer is responsible for about 20% of all cancer-related deaths worldwide and has one of the lowest 5-year survival rates (7% in SCLC and 11-17% in NSCLC, depending on the subtype and stage of the cancer[6].

The main cause of lung cancer is long-term smoking, with a 25-fold increase in the risk of developing the disease. However, there are other risk factors such as genetic factors, long-term menopausal hormone replacement therapy, exposure to radon, asbestos, metals (arsenic, cadmium, and chromium), organic chemicals found in smoke coal, and a history of lung disease such as tuberculosis, emphysema, or chronic bronchitis[7]. Smoking can cause all types of lung cancer, but is most strongly linked to SCLC and SCC, while AD is the most common type of lung cancer in patients who have never smoked. In the first two, cancer development frequently occurs in people 60 to 70 years of age with a long-term history of tobacco smoking, while AD occurs in younger people[7].

In this review, we update knowledge about the properties of SCs and their participation in the initiation and progression of lung cancer, pointing out the biomarkers that may be useful in therapeutic strategies or as a prognosis of the disease. In addition, we discuss the role of SCs in the resistance to therapeutic treatments.

SOMATIC MUTATIONS IN LUNG CANCER

Lung carcinogenesis is a chronic process that involves multiple genetic, cellular, and tissue alterations as a consequence of mutations in genes that regulate growth, differentiation, and apoptosis. Cancers are caused by the accumulation of mutations in critical genes, specifically those that control cell growth and division or the repair of damaged DNA. These changes allow cells to grow and divide uncontrollably to form a tumor. In almost all cases of lung cancer, these genetic changes, which are present only in certain lung cells, are acquired during life as a result of exposure to carcinogens, long-term hormone therapy, or chronic lung disease[8].

Figure 1 Classification and main characteristics of lung cancer. Lung cancer is classified into two histological types, small cell lung cancer (SCLC) derived from cells of the neuroendocrine lineage and non-SCLC (NSCLC) derived from epithelial cells. NSCLC is classified into three subtypes: Adenocarcinoma, squamous cell carcinoma, and large cell carcinoma. SCLC: Small cell lung cancer; NSCLC: Non-SCLC; AD: Adenocarcinoma; SCC: Squamous cell carcinoma; LCC: Large cell carcinoma.

The most frequently mutated genes in lung cancer are *epidermal growth factor receptor* (*EGFR*), *Kirsten rat sarcoma virus* (*KRAS*) and *tumor protein 53* (*TP53*)[9,10]. The proteins encoded by these genes participate in signaling pathways that contribute to lung tumorigenesis. Mutations in the *EGFR* gene cause the expression of receptors on the cell membrane that are constitutively activated, triggering signaling pathways within cells involved in lung tumorigenesis. Binding of epidermal growth factor (EGF) to EGFR induces receptor phosphorylation at tyrosine residues and activates multiple downstream signaling pathways, such as the Ras-Raf-MAPK, PI3K, and STAT pathways, which induce proliferation and cell invasion, angiogenesis, inhibition of apoptosis and metastasis. The constitutive activity of EGFR has been observed in more than 60% of patients with NSCLC and is due to different mutations present in the receptor[11]. *KRAS* was first identified as a viral oncogene in the Kirsten RAt Sarcoma virus. The *KRAS* gene encodes the Ras proteins, low molecular weight enzymes with guanosine triphosphate hydrolase (GTPase) activity located on the inside of the plasma membrane. Ras GTPases are activated in response to the binding of ligands to several receptors such as EGF, platelet-derived growth factor, integrin, and cytokine receptors. Mutations in the *KRAS* gene cause loss of the ability of Ras to hydrolyze GTP to guanosine diphosphate leading to constant activation of Ras[12]. Similar to constitutive activation of EGFR, mutated Ras stimulates multiple signaling pathways relevant to tumor development. Mutations in the *KRAS* gene are of high frequency in NSCLC but are also present in other types of cancer such as colorectal and pancreatic cancer[13]. Another protein associated with the onset of lung cancer is the p53 tumor suppressor protein encoded by the *TP53* gene. This tumor suppressor responds to several cellular stresses to regulate expression of target genes, thereby inducing DNA repair or cell cycle arrest and apoptosis[14]. Mutations in the *TP53* gene synthesize a non-functional p53 protein, causing accumulation of damaged DNA in cells and dysregulation of the cell cycle. Mutations in the *KRAS* and *TP53* genes have been found in up to 30% of patients with lung cancer and have been considered as predictors of poor prognosis[9]. Mutations in other genes such as *CDKN2A*, *STK11*, *BRAF*, *PIK3CA*, *RB1*, *PTEN* or *MET* have been associated with the onset of lung cancer, although they showed a lower mutation rate than the *EGFR*, *KRAS* or *TP53* genes. Most of them are involved in the regulation of cell proliferation, differentiation, or apoptosis[9].

Lung tumor tissue is characterized by a heterogeneity of cell types with different phenotypic characteristics and properties as a result of the accumulation of gene mutations and differential cell signaling in the tumor microenvironment. However, it has been shown that only a small fraction of cells in tumor tissue have the ability to form tumor spheroids *in vitro* and develop tumors when they are transplanted into immunodeficient animals. These observations raise the need to study which are the cell populations in the tumor with tumorigenic potential.

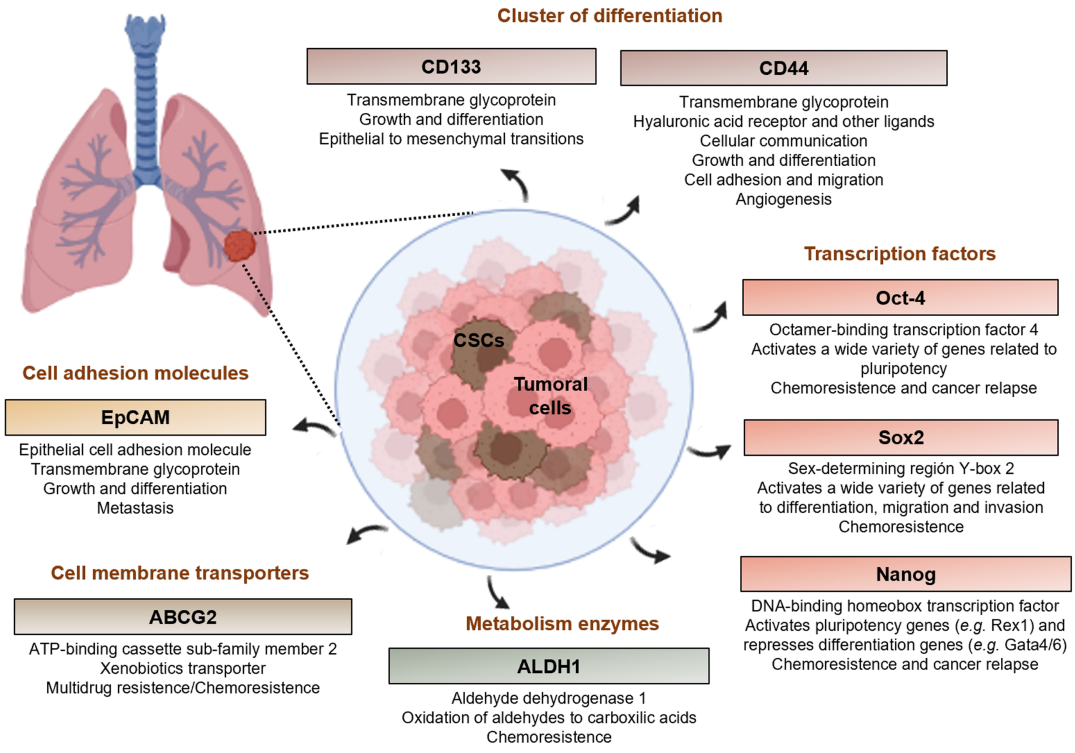
ROLE OF STEM CELLS IN TUMORIGENESIS

Cancer stem cells (CSCs) are defined as a subpopulation of tumor cells residing in the tumor with SCs characteristics. CSCs have the ability to self-renew, generate identical daughter cells with stem cell properties, differentiate into multiple cancer cell lineages, facilitate tumor growth and survival, and metastasize to distal sites. In addition, they could be the cause of evasion of the immune system, resistance to chemotherapy and radiation therapy, and cancer relapse[15]. CSCs differ from normal tissue-specific SCs only in their uncontrolled growth and altered genotypes[16].

The seminal proposition that CSCs could be responsible for tumor initiation was introduced by the end of XIX century[17], however the first conclusive evidence for CSCs in acute myeloid leukemia was demonstrated in 1997 by Bonnet and Dick[18]. These authors isolated a subpopulation of CD34+/CD38- leukemic cells capable of initiating tumors in non-obese diabetic/severe combined immunodeficiency disease (NOD/SCID) mice histologically similar to the donor. In recent years, CSCs have been identified in several tumors, including breast, brain, colon, and lung cancer[19].

CSCs are a small proportion of the cell population of a tumor (less than 1%) that exhibit high tumorigenic potential. This is supported by experiments where thousands of tumor cells need to be inoculated into syngeneic or immunodeficient animals for a solid tumor to develop. Some years ago, this requirement was thought to be due to the loss of viability of tumor cells during transfer or the absence of a suitable niche for tumor growth. The new paradigm indicates that only CSCs (a small fraction of the transplanted cells) has the potential to generate a tumor[20]. This hypothesis can be reinforced by the fact that metastases are histologically heterogeneous and similar to the primary tumor, which implies that the cell that gave rise to it has the potential to differentiate into multiple cell types, such as a SCs[19].

Several questions have been raised about the origin of CSCs in tumor tissue. The first hypothesis is that CSCs could originate from tissue-specific normal SCs that have dysregulated cell growth. In this sense, it has been shown that all tissues harbor SCs that play an essential role in tissue repair[16]. These normal SCs could be transformed into CSCs due to the accumulation of gene mutations or the action of chemical mediators released under conditions of tissue damage[21]. This hypothesis is accepted for tissues with a high degree of cell renewal, such as intestinal epithelium or skin, but it is controversial for tissues that are quiescent or that renew slowly, such as lung epithelium. In this sense, some authors have identified a fraction of cells in active division (less than 1.3%) located in specific niches of the tracheal and bronchiolar epithelium with characteristics of SCs that could become CSCs[22,23]. The second hypothesis is that CSCs could originate from more differentiated progenitor cells that have acquired the capacity for self-renewal or differentiated tumor cells (called CSCs-like cells) due to mutations in genes that regulate the cell cycle, hypoxia, or chemical mediators of the tumor microenvironment such as nitric oxide or certain interleukin[24].



STEM CELL MARKERS IN LUNG CANCER

Tumor tissue is heterogeneous, showing different cell populations that have their own signaling pathways, leading to more complex therapeutic strategies. Factors contributing to intratumoral heterogeneity include genetic mutations, epigenetic changes, interactions with the microenvironment and CSCs[25]. CSCs represent only a small group of cells within the heterogeneity of tumor tissue. SCs trigger specific signaling pathways, such as Notch, Hedgehog, and Wnt, that allow them to self-renew and proliferate in tissue repair processes. These pathways are tightly controlled, but their aberrant activation in CSCs can induce the expression of tumor molecular markers, leading to tumorigenicity and chemoresistance[26].

CSCs have been identified in several types of cancer through proteins that are differentially expressed in these cells. These proteins include cell membrane receptors, cell adhesion molecules, cell membrane transporters, enzymes involved in metabolism, and transcription factors. Its are used as biomarkers to predict the prognosis of the disease, evaluate the most appropriate chemotherapy treatments and the efficacy of the therapies in tumor remission[15].

Biomarkers that have been identified in lung cancer include cluster of differentiation-133 (CD133), cluster of differentiation-44 (CD44), epithelial cell adhesion molecule (EpCAM), aldehyde dehydrogenase 1A1 (ALDH1A1), ATP-binding cassette sub-family G member 2 (ABCG2) and the transcription factors octamer-binding transcription factor 4 (Oct-4), sex-determining region Y-box 2 (Sox2), and Nanog[15,26]. Although these biomarkers have different structures and functional roles, its are linked to the SCs properties and uncontrolled proliferation of tumor cells. The biomarkers identified in lung CSCs are shown in Figure 2.

Biomarkers are not specific for lung CSCs and may be expressed in other types of cancer, such as breast, brain, colon or liver cancer. Since a single marker is not sufficient to accurately identify CSCs, combinations of several markers are used to identify and isolate CSCs in tumor tissue[27].

Figure 2 Stem cell biomarkers in lung cancer. Biomarkers identified in cancer stem cells in lung tissue include clusters of differentiation, cell adhesion molecules, cell membrane transporters, enzymes of cell metabolism, and transcription factors. CSCs: Cancer stem cells; ABCG2: ATP-binding cassette subfamily G member 2; ALDH: Aldehyde dehydrogenase.

Cluster of differentiation

CD133: CD133, also known as prominin-1, is a transmembrane glycoprotein involved in cell growth and differentiation through its involvement in multiple signaling pathways[27,28]. It has been identified as the main biomarker of SCs in normal tissue and of stemness in tumor tissue from patients with NSCLC or SCLC.CD133 expression is essential to maintain CSCs characteristics such as tumor cell proliferation, migration, and invasion, and the ability to resist chemotherapy[27].

In lung cancer, the high level of expression of CD133 has been correlated with epithelial to mesenchymal transitions and the formation of metastases in lymph nodes and other tissues, which reveals that CD133 is a biomarker of tumor aggressiveness and poor prognosis of the pathology[29-31]. The molecular mechanisms involved in CD133-mediated cell growth and resistance to chemotherapy are still under study, but appear to be associated with the Wnt/catenin, PI3K-AKT and SRC-FAK signaling pathways[32,33]. Furthermore, CD133 has been shown to directly interact with vascular endothelial growth factor (VEGF), stimulating angiogenesis and leading to tumor growth[34]. CD133 is also used as diagnostic, predictive, or therapeutic biomarkers in other types of cancer including breast, stomach, liver, prostate, colorectal, pancreatic, and renal[28].

CD44: CD44 is a transmembrane glycoprotein of high structural and functional diversity due to alternative splicing processes and post-translational modifications. It can bind to a wide variety of ligands on the cell surface, including hyaluronic acid (HA), and trigger multiple cellular processes such as cell-cell signaling, cell growth and differentiation, cell adhesion and migration, angiogenesis, or cell survival[26].

CD44 regulates several signaling pathways to promote cancer progression, including Notch, Hedgehog, and Wnt pathways[26]. In addition, it can act as a co-receptor and heterodimerizes with growth factor receptors [EGFR, fibroblast growth factor receptor (FGFR), hepatocyte growth factor receptor, VEGF receptor, transforming growth factorβ receptor] and leads to activation of the PI3K-AKT and MAPK pathways[15]. It is hypothesized that CD44 could play an important role in tumorigenesis mediated by the constitutive activation of EGFR, whose expression is frequently mutated in patients with NSCLC. In this last sense, CD44 could be an important marker to predict the efficacy of chemotherapy using EGFR-specific tyrosine kinase inhibitors in patients with lung cancer[15].

CD44 is expressed in almost all tumor types, but it has been identified as the main CSCs biomarker in lung ADs and in SCC. Its expression is associated with a more aggressive tumor phenotype, with the ability to metastasize and resist chemotherapy[35].

Cell adhesion molecules

EpCAM: EpCAM is a transmembrane protein and acts as an adhesion molecule on the lung epithelium. It is a potential biomarker for lung tumors of epithelial origin[36]. EpCAM expression in lung tumor epithelium is upregulated by metastasis-associated protein 1 and leads to increased metastatic capacity of tumor cells[36]. The co-expression of EpCAM with CD44 and CD166 in NSCLC indicates a greater self-renewal capacity, clonal heterogeneity and stemness. These biomarkers in lung tumor tissue indicate a poor prognosis for the disease[37].

Cell membrane transporters

ABCG2: ABCG2 is a transporter of xenobiotic compounds into the extracellular space, which has been implicated in the development of multidrug resistance (MDR) in cancer. The wide variety of ABCG2 substrates includes several antitumoral drugs such as paclitaxel, doxorubicin, cisplatin, topotecan, mitoxantrone and irinotecan. ABCG2 also expels the fluorescent dye Hoechst 33342 out of the cell, a property that is unique to SCs and is used for identification of these cells[38]. The expression of ABCG2 in SCs has been conserved in many tissues, such as the pancreas, lung, heart, testis, liver, brain, prostate, and embryonic tissue, demonstrating the importance of this transporter for cell survival[39]. In lung cancer, increased expression of ABCG2 has been found in SCs, associated with the upregulation and activity of the transcription factors Sp1, Sp3, YAP1 and Nrf2[40-42]. Its expression in lung CSCs is associated with cancer relapse and poor prognosis[42].

Enzymes involved in metabolic pathways

ALDH1: ALDH1 is an enzyme that participates in cellular metabolism through the oxidation of aldehydes to carboxylic acids and is a marker of SCs of normal and tumor tissue[43]. It has three main isotypes, ALDH1A1, ALDH1A2 and ALDH1A3, but its activity is mainly attributed to the ALDH1A1 isotype[43].

Increased expression of ALDH has been found in NSCLC overexpressing a subpopulation of CD44+/EpCAM+ cells[44]. Overexpression of the ALDH1 and CD133 markers was found exclusively in SCC and AD[45]. ALDH1A1 overexpression is associated with an aggressive chemotherapy-resistant tumor phenotype. Despite this, ALDH1 could be a useful therapeutic target for tumors growing in tissues that do not normally express high levels of ALDH1A1, such as the lung, breast, colon, and stomach[43].

Transcription factors

Otherwise, the transcription factors involved in the normal activity of SCs could be deregulated in cancer, and activate cellular pluripotency genes and suppress differentiation genes, triggering signaling pathways responsible for the characteristics of CSCs. Transcription factors that regulate the functions of lung CSCs, such as Oct-4, Sox2, and Nanog, have been identified.

Oct-4: Oct-4 also known as POU5F1, is a member of the POU transcription factor family that contains a binding domain to the ATGCAAAT sequence in target genes[15]. The *Oct-4* gene encodes four protein isoforms called Oct4A, Oct4B-190, Oct4B-265, and Oct4B-164. Of these, Oct4A is known to transcribe a wide variety of genes that regulate SCs stemming. Several Oct-4A target genes have been identified in CSCs of lung cancer, including Fgf4, Utf1, Opn, Rex1/Zfp42, and Fbx15[15].

Oct-4A transcriptional activity is upregulated by post-translational modifications, through phosphorylation at residues Ser229, Ser236 and tyr327 or sumoylation at residue Lys118. Its expression is high in SCs, however Oct-4 is ubiquitinated and degraded by the proteasome in the cell differentiation process[15].

In lung cancer, Oct4 activity is associated with chemotherapy resistance, cancer relapse, and worse outcomes[15].

Sox2: Sox2 is a member of the high mobility group (HMG) box gene family encoded by the sex-determining region Y-box gene. HMG is a sequence of 80 amino acids that acts as a DNA-binding domain in several target genes related to the maintenance of pluripotency in embryonic SCs and CSCs [46]. Sox2 is closely associated with early embryonic development, neuronal differentiation, bronchial morphogenesis, and airway epithelial maturation[46].

In lung cancer, Sox2 can regulate the transcription of the c-MYC, Wnt and Notch oncogenes and increase metastatic capacity through the FGFR-ERK1/2-SOX2 signaling pathway[47]. In SCC, Sox2 can induce expression of tumor-related factors p63 and keratin 6 and lead to cancer differentiation, migration, and invasion. In SCLC, Sox2 is crucial in the PI3K-Akt-Sox2 signaling pathway and may mediate chemoresistance[47]. In addition, Sox2 together with Oct-4 increase its expression under hypoxia in tumor tissue, which induces the expression of the CD133 marker and the self-renewal and maintenance of lung CSCs[48].

Sox2 transcriptional activity can be increased by phosphorylation at amino acid residue Thr118 or methylation at Arg113, which inhibits its proteasome degradation or promotes its homodimerization, respectively[49].

Sox2 and Oct4 have been located in the cell nucleus of SCLC and lung AD, but not in their paracancerous tissues or benign tumor tissues, pointing to the importance of Sox2 and Oct4 as potential markers for cancer therapies[50].

Nanog: Nanog, a DNA-binding homeobox transcription factor, may promote cell proliferation, renewal, and stem properties. Nanog can regulate cell pluripotency through two mechanisms of action. Thus, Nanog can repress the transcription of genes essential for cell differentiation, such as Gata4 and Gata6, or it can activate the transcription of genes necessary for self-renewal, such as Rex1[15].

Nanog expression is upregulated by Nr5a2 promoting CSCs properties and tumorigenesis in NSCLC [51]. Nanog is highly expressed in pluripotent cells and its expression is downregulated during differentiation. Its transcriptional activity is increased by phosphorylation at amino acid residues Ser52, 65 and 71 and Thr287, which abolishes its ubiquitination and degradation by the proteasome[52].

Nanog is increased in many types of carcinomas, including lung cancers, and is associated with chemoresistance, cancer relapse, and poor prognosis[15,52].

STEM CELL MARKERS AS THERAPEUTIC TARGETS FOR THE TREATMENT OF LUNG CANCER

Most clinical trials involve the use of drugs whose targets of action are protein tyrosine kinases, regulators of the cell cycle or cell signaling pathways. Several chemotherapy drugs are not effective in controlling tumor growth and metastases. Thus, novel therapeutic agents directed against CSCs are a hope for patients who do not respond to conventional therapies or who relapse after cancer treatment. These therapies include the use of synthetic or natural inhibitors, monoclonal or bispecific antibodies (BsAb), antibodies-drug conjugates, aptamer-drug conjugates, or chimeric antigen receptor T (CAR-T) therapies. Novel therapies using stem cell biomarkers as pharmacological targets are summarized in Table 1.

Inhibitory drugs

Salazosulfapyridine in combination with cisplatin and pemetrexed is under phase I study for advanced NSCLC (Trial registration-UMIN 000017854). This drug inhibits the intracellular uptake of cysteine by the cysteine-glutamate antiporter in CSCs that overexpress CD44 marker, preventing the synthesis of the antioxidant GSH, essential for cellular redox homeostasis, and leading to the inhibition of tumor growth[53].

Phase II trial using disulfiram in combination with cisplatin plus vinorelbine have shown to be effective for the treatment of metastatic NSCLC (Trial registration-NCT 00312819)[54]. *In vitro* studies in NSCLC cell lines treated with cisplatin have shown the growth of chemoresistant ALDH1+ cell subpopulations. These cells were sensitive to the cytotoxic effects of cisplatin after treatment with diethylaminobenzaldehyde and disulfiram, inhibitors of ALDH1 activity[55]. In xenograft models in NOD/SCID mice, it has been shown that disulfaran inhibits the activity of ALDH1A1 and the expression of Sox2, Oct-4 and Nanog, reducing the size of tumors derived from ALDH+ CSCs and cancer recurrence [56].

ABCG2 transporter is one of the main CSCs markers under study due to its role in MDR. It has been found that the secalonic acid D, a metabolite of marine-derived mangrove endophytic fungus, can down-regulate the expression of ABCG2 by activation of Calpaina 1, a protease that shortens the half-life of the transporter[57]. In addition, Verteporfin, an inhibitor of the YAP1 transcription factor, was found to down-regulate the expression of the ABCG2 transporter in lung CSCs[41].

A-803467, a tetrodotoxin-resistant sodium channel blocker, inhibits ABCG2 transporter activity, increasing the sensitivity to chemotherapeutic drugs such as topotecan, doxorubicin and mitoxantrone in multidrug resistant cells. A combination of A-803467 and ABCG2 substrates may potentially be a novel therapeutic treatment in tumors overexpressing the ABCG2 protein[58].

FL118, a topoisomerase 1 inhibitor similar to camptothecin analogues (such as irinotecan or topotecan) used in the clinic, selectively inhibits the expression of several members of the proapoptotic protein family such as Survivin, Xiap, CIAP2 and BCL-2. It has also been found that FL118 down-regulate the expression of ABCG2, ALDH1A1 and Oct-4. FL118 improves sensitivity to chemotherapy and inhibits the growth of CSCs and metastases. Moreover, FL118 is effective for human tumors that acquire irinotecan, topotecan and cisplatino resistance due to its ability to bypass the drug resistance induced by ABC transporters[59].

Monospecific and Biespecific antibodies

mAbMEM-85 is a monoclonal antibody of therapeutic interest since it inhibits the growth of lung cancer cells in murine models. It has been shown that mAbMEM-85 recognizes the hyaluronate binding site in the C-terminal region of CD44 in lung cancer SCs[60].

Axitinib is a monoclonal antibody that inhibits the activity of the ABCG2 transporter in CSCs, and reverses MDR. Studies in A549 human lung cancer cells and nude mice bearing S1-M1-80 xenografts

Table 1 Potential therapeutic strategies targeting lung cancer stem cell markers

Stem cell marker-target	Therapeutic strategies in clinical trials and preclinical studies
Differentiation cluster	
CD133	Docetaxel-loaded liposomes conjugated to anti-CD133 aptamers
	Gefitinib-loaded nanomicelles conjugated to anti-CD133 aptamers
	Salinomycin sodium-loaded nanoparticles conjugated to anti-CD133 antibody
	CD133-specific CAR-T cells plus anti-PD-1 antibody and a CD73 inhibitor
CD44	Salazosulfapyridine plus cisplatin and pemetrexed (Phase I clinical trial for the treatment of advanced non-squamous NSCLC)
	mAb MEM-85 (monoclonal antibody)
	HA-Cisplatin conjugated
	HA-Irinotecan conjugated (Phase II study for treatment of SCLC)
	HA-Apoferritin conjugated
	HA-conjugated cisplatin-loaded nanoparticles
Cell adhesion molecules	
EpCAM	Doxorubicin-loaded nanoparticles conjugated to EpCAM aptamer
	Catumaxomab BsAb anti-human EpCAM/CD3 T-cell antigen (Phase I study for treatment of NSCLC)
	MT110 BsAb anti-EpCAM/CD3 T-cell antigen (Phase I clinical trial for treatment of lung adenocarcinoma)
	MuS110 BsAb anti-human EpCAM/CD3 T-cell antigen
	2C11x4-7 BsAb anti-murine EpCAM/CD3 T-cell antigen
Cell membrane transporters	
ABCG2	Secalonic acid D
	Axitinib in combination with topotecan or mitoxantrone
	FL118 (topoisomerase 1 inhibitor) in combination with irinotecan, topotecan or cisplatino
	A-803467 (tetrodotoxin-resistant sodium channel blocker) in combination with topotecan, doxorubicin or mitoxantrone
	Verteporfin (YAP1 inhibitor)
Metabolic enzymes	
ALDH	Disulfiram in combination with cisplatin plus vinorelbine (Phase II clinical trial for the treatment of NSCLC)
	Disulfiram alone or in combination with diethylaminobenzaldehyde and cisplatin
	FL118 in combination withirinotecan, topotecan or cisplatino
Transcription factors and signaling pathway	
Oct-4	FL118 in combination with irinotecan, topotecan or cisplatino
Notch-signaling pathway	BsAb-5 directed against c-MET and CTLA-4 in CD166+ NSCLC

mAb: Monoclonal antibody; HA: Hyaluronic acid; BsAb: Bispecific antibody; CAR-T: Chimeric antigen receptor T; c-MET: Cellular mesenchymal-to-epithelial transition factor; CTLA-4: Cytotoxic T-lymphocyte-associated protein 4; NSCLC: Non-small cell lung cancer; ABCG2: ATP-binding cassette subfamily G member 2; CD133: Cluster of differentiation-133; CD44: Cluster of differentiation-44; EpCAM: Epithelial cell adhesion molecule; ALDH: Aldehyde dehydrogenase; Oct-4: Octamer-binding transcription factor 4.

that overexpress ABCG2 have shown that axitinib increases tumor cell apoptosis induced by chemotherapeutic drugs such as topotecan and mitoxantrone without causing additional toxicity[61].

BsAb target two different epitopes or antigens simultaneously. One of the Fab fragments recognizes epitopes on cytotoxic drugs or CD8+ T or NK immune cells, while the other Fab fragment can bind epitopes on CSCs. Then, BsAbs can selectively direct effector cells or chemotherapeutic drugs towards CSCs, promoting their destruction. BsAb have been extensively explored in translational and clinical studies in lung cancer.

Catumaxomab is a BsAb with binding sites directed to human EpCAM and CD3 T-cell antigen. A phase I study has shown that catumaxomab is safe and tolerable when administered intravenously in patients with NSCLC[62]. Other anti-CD3-EpCAM BsAbs have been studied in immunocompetent mice bearing lung tumors, showing potent inhibition of local and disseminated tumor growth[63]. MT110 BsAb targeting EpCAM/CD3 T-cell antigen has been tested in patients with colorectal, gastric, and lung cancer[64]. MuS110 BsAb was found to have similar *in vitro* characteristics and *in vivo* antitumor activity as MT110[65].

BsAb-5 target cellular mesenchymal-to-epithelial transition factor (c-MET) and cytotoxic T-lymphocyte-associated protein 4 in CD166+ lung CSCs with high affinity and specificity. BsAb-5 has been shown to reduce tumor size in mouse models by a mechanism that involves inhibition of the c-MET-Notch pathway in CSCs and the up-regulating effector T cells. BsAb could be a possible drug for the treatment of human NSCLC[66].

Drugs conjugated to specific ligands of CSCs

The extracellular domain of CD44 contains a HA binding site, a property that is used for the development of HA-conjugated antitumor drugs. Preclinical studies have shown that HA can be effectively used to deliver chemotherapy and selectively decrease CD44+ lung CSCs. Thus, a phase II clinical trial (ACTRN 12611000520932) using HA-irinotecan has shown to be effective in the treatment of SCLC[67]. Other studies show that cisplatin or apoferritin conjugated to HA are effective in eliminating lung CSCs[68,69].

Drugs-loaded nanoparticles

In recent years, nanoparticulate systems have been developed to encapsulate antitumor drugs. The efficacy of these systems in the treatment of cancer has been improved by the conjugation of the nanoparticles to specific ligands, antibodies or aptamers directed against SC markers. In this sense, it has been shown that the intratracheal administration of HA-conjugated cisplatin-loaded nanoparticles attenuated lung cancer growth in mice[70]. Other systems such as salinomycin sodium-loaded nanoparticles conjugated to anti-CD133 antibody, doxorubicin-loaded nanoparticles conjugated to EpCAM aptamer and gefitinib or docetaxel-loaded liposomes conjugated to anti-CD133 aptamers have been shown to be effective in inhibiting tumor growth[71-74].

CAR-T therapies

CAR-T cell is a new therapeutic approach that involves the development of a receptor expressed in T cells that recognizes certain specific antigens on the membrane of cancer cells, triggering an antitumor immune response. The efficacy of specific CAR-T therapy against the AC133 epitope of CD133 has been studied in a mouse model with orthotopic xenograft. AC133-specific CAR-T cells reduced tumor size and prolonged survival in the humanized orthotopic SCLC model but were unable to eliminate tumors completely. However, the combination of AC133-specific CAR-T cells with an anti-PD-1 antibody and a CD73 inhibitor was able to eliminate chemoresistant CSCs[75].

CONCLUSION

Current chemotherapies for lung cancer involve the use of drugs whose targets of action are protein tyrosine kinases, regulators of the cell cycle or cell signaling pathways. Despite improvements in treatments, some patients do not respond to therapies or have cancer relapses months or years after treatment. It is hypothesized that one of the main causes of cancer relapse is the ineffectiveness of anticancer drugs to eliminate CSCs in tumor tissue. Chemotherapy and radiotherapy induce senescence of tumor cells. Factors released by senescent cells into the tumor microenvironment could activate signaling pathways that induce phenotypic and functional changes in SCs, increasing their plasticity and uncontrolled growth. In addition, CSCs could be chemoresistant due to the expression of transporters in cell membranes that expel xenobiotic compounds into the extracellular space.

In lung cancer, several biomarkers have been identified in CSCs associated with the maintenance of tumorigenicity, metastasis and chemoresistance. These biomarkers could be useful as targets for the effective treatment of lung cancer. Thus, new drugs directed against CSCs include the use of inhibitors, monoclonal and BsAb, antibody-drug conjugates or aptamer-drug conjugates, and CAR-T therapies. These therapies are a hope for patients who do not respond to conventional treatments or relapse in lung cancer.

Abstract

BACKGROUND

Accumulating evidence suggests that the maxillary process, to which cranial crest cells migrate, is essential to tooth development. Emerging studies indicate that *Cd271* plays an essential role in odontogenesis. However, the underlying mechanisms have yet to be elucidated.

AIM

To establish the functionally heterogeneous population in the maxillary process, elucidate the effects of *Cd271* deficiency on gene expression differences.

METHODS

p75NTR knockout (*Cd271*$^{-/-}$) mice (from American Jackson laboratory) were used to collect the maxillofacial process tissue of p75NTR knockout mice, and the wild-type maxillofacial process of the same pregnant mouse wild was used as control. After single cell suspension, the cDNA was prepared by loading the single cell suspension into the 10x Genomics Chromium system to be sequenced by NovaSeq6000 sequencing system. Finally, the sequencing data in Fastq format were obtained. The FastQC software is used to evaluate the quality of data and CellRanger analyzed the data. The gene expression matrix is read by R software, and Seurat is used to control and standardize the data, reduce the dimension and cluster. We search for marker genes for subgroup annotation by consulting literature and database; explore the effect of p75NTR knockout on mesenchymal stem cells (MSCs) gene expression and cell proportion by cell subgrouping, differential gene analysis, enrichment analysis and protein-protein interaction network analysis; understand the interaction between MSCs cells and the differentiation trajectory and gene change characteristics of p75NTR knockout MSCs by cell communication analysis and pseudo-time analysis. Last we verified the findings

single cell sequencing *in vitro*.

RESULTS

We identified 21 cell clusters, and we re-clustered these into three subclusters. Importantly, we revealed the cell–cell communication networks between clusters. We clarified that *Cd271* was significantly associated with the regulation of mineralization.

CONCLUSION

This study provides comprehensive mechanistic insights into the maxillary- process-derived MSCs and demonstrates that *Cd271* is significantly associated with the odontogenesis in mesenchymal populations.

Key Words: *Cd271*; Mesenchymal stem cells; Single cell RNA sequencing; Osteogenesis; Mineralization; Tooth development

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Our study reveals the following findings: (1) High cellular heterogeneity and molecular details; (2) Significant functional and signaling differences between cell types; (3) Novel subclusters of mesenchymal stem cells; and (4) Crucial cell-cell interactions of mesenchymal subpopulations. We provided new insights into the biological features of mesenchymal stem cells at the single cell level. Our findings contribute to thorough exploration of the mechanism of *Cd271* in regulating odontogenesis and osteogenesis which add to the theory of tooth development.

INTRODUCTION

During the early stage of embryogenesis, cranial neural crest cells migrate throughout the maxillary and mandibular processes, which are defined as ecto-mesenchymal stem cells (MSCs)[1,2]. Ecto-MSCs were regarded as the primitive dental cells in the classical theory of tooth development. To date, in-depth studies of the odontogenesis and osteogenesis of MSCs are still lacking.

Cd271 (low-affinity nerve growth factor receptor, p75 neurotrophic receptor) is a member of the tumor necrosis factor receptor superfamily, and is implicated in various biological functions[3]. It is used as a specific cell surface marker for purifying and identifying MSCs[4]. Previous studies focused on cellular physiological functions in processes, such as migration, proliferation, differentiation, survival and apoptosis[5-8]. *Cd271* is involved in the regulation of morphogenesis and the development of various tissues, including nerves, fat, liver and teeth[9-13]. In addition to these features, emerging studies indicate that *Cd271* plays a critical role in initiating tooth development, differentiation and mineralization of odontogenic stem cells. Mitsiadis *et al*[14] indicated that *Cd271* surrounded the developing tooth germ within nerve fibers and was highly expressed in the epithelium and mesenchyme in the early stages of odontogenesis within the cells of origin[14]. The spatial–temporal expression of *Cd271* was similar to the mineralization factor *Runx2* during the early development of tooth germ[15], which was supported by other studies[16,17]. These studies indicate that *Cd271* is involved in the physiological processes of tooth development and biomineralization. However, the molecular mechanisms of *Cd271*, as a transmembrane signaling molecule, in the morphogenesis and development of teeth remains largely unknown.

Conventionally, MSCs were considered a unified group of fusiform cells. Nevertheless, accumulating evidence suggests that MSCs are functionally and morphologically heterogeneous in essence[18,19]. High-throughput single cell RNA sequencing (scRNA-Seq) is powerful for disclosing the complexity and diversity of cells and relationships among genes involved in tissues, and offers an opportunity to explore unbiased gene expression profiling of cells[20]. scRNA-Seq also provides insights into specific changes in cell lineages, trajectory inference, and the identification of biomarkers[21,22]. scRNA-seq has been used to study MSCs derived from adipose tissue, bone marrow, endometrium, placenta and dental pulp[23-27]. However, application of scRNA-seq in maxillary-process-derived MSCs is still absent.

Herein, we used the maxillary process from mouse embryos as a model to understand the development of maxillary-process-derived MSCs. We applied scRNA-Seq analysis to elucidate the cellular heterogeneity and explore molecular details better compared with conventional methods. Our study provides novel insights into the biological features of MSCs at the single cell level and the mechanism of *Cd271* in regulating odontogenesis and osteogenesis.

MATERIALS AND METHODS

Animal preparation and tissues dissection

Cd271 knockout (*Cd271*$^{-/-}$) and wild-type (*Cd271* $^{+/+}$) mice were used in this study. The *Cd271*$^{-/-}$ mice were gifts from The Jackson Laboratory (Bar Harbor, ME, United States). These mutant mice that exhibit the targeted deletion of exon III of the *Cd271* locus do not express functional full-length *Cd271*. All animal experiments were performed according to the protocols approved by the Medical Ethics Committee of Wenzhou Medical University (No. wydw2019-0224). We completed experimental steps under ethical guidelines. The animal protocol was designed to minimize pain or discomfort to the animals. The animals were housed to laboratory conditions (23 °C, 12 h/12 h light/dark, 50% humidity, ad libitum access to food and water) prior to experimentation. The homozygotes of *Cd271* $^{+/+}$ and *Cd271*$^{-/-}$ mice were mated to produce heterozygous offspring. The heterozygous mice were mated to generate three types of genotype embryos, *Cd271*$^{+/+}$ and *Cd271*$^{-/-}$and *Cd271*$^{+/-}$. We obtained embryos through abdominal surgery, and chose homozygous embryos from embryonic day 16.5. The embryos were placed in a 6-cm Petri dish and washed with Phosphate buffer saline (PBS). We cut the amniotic membrane with ophthalmic scissors to separate the fetal mice and washed them with PBS again. After cutting the head of the fetus, we cut the maxillary process tissue under a stereomicroscope. After the removal of nonpurpose tissues like blood stains and fatty layers, we rinsed the tissue twice in PBS. The genotype of wild-type and *Cd271* knockout mice was confirmed with a one-step genotyping kit (Vazyme, Nanjing, China).

Single cell isolation and library preparation

Maxillary processes were dissociated into single cells in dissociation solution (0.35% collagenase IV5, 2 mg/mL papain, and 120 U/mL DNase I) in 37 °C water bath with shaking for 20 min at 100 rpm. Single cell suspensions were washed and resuspended to load to the 10X Chromium platform. More than 25000 single cells were captured and subjected to 10X Chromium Controller machine to generate gel beads-in-emulsion (GEMs). mRNA was prepared using the 10X Genomics Chromium Single Cell 3′ Reagent Kit V2 (10X Genomics, Pleasanton, CA, United States). Cells were divided by partitions into the GEMs along with GelBeads coated with oligos in this step. These oligos utilized poly-dT sequences to capture mRNAs and cell-specific and transcript-specific barcodes. The following cDNA amplification generated adequate quantities for library construction according to the standard protocol. Libraries were sequenced on an Illumina NovaSeq 6000 sequencing system (paired-end multiplexing run, 150 bp) by the LC-Bio Technology (Hangzhou, China) at a minimum depth of 20000 reads per cell.

scRNA-Seq data processing

We processed sequencing reads using CellRanger (version 6.0.1). Then we created objects by Seurat (version 4.0.5) R package, and merged data using the function of Merge[28]. The ratio of mitochondrial genes to all genetic material was used to judge whether a cell was in a steady state. Generally, it was thought that a cell might be in a state of stress when it had a higher proportion of mitochondrial genes. Therefore, we filtered cells with > 10% mitochondrial gene content. Considering potential cellular diploidy, we filtered cells with < 1000 or > 6000 genes. After the above steps, we finally obtained 17426 cells.

Data were normalized using the log-normalization method. After controlling for the relationship between mean expression and dispersion, we identified highly variable genes in individual cells. We input variable genes to perform principal component analysis (PCA) and identified significant principal components based on the function of JackStraw[29]. A total of 20 principal components were selected as statistically significant inputs to the Uniform Manifold Approximation and Projection (UMAP). We examined the distribution of UMAP and PCA between these samples. The data showed correlations. We compared the mean expression of genes between samples and found an excellent Pearson correlation between them. We divided the cells clustered by the FindCluster into 21 clusters.

Cell annotation

We identified cell types based on specific maker genes. The MSCs lineage was identified by *Col1a1* and *Col3a1*. *Lgals7* and *Krtdap* marked the epithelial cell lineage; muscle cell marker genes included *Actc1* and *Tnnt1*; macrophage marker genes included *Pf4* and *C1qb*; glial marker genes included *Dct* and *Ptgds*; T cell marker genes included *Cma1* and *Cpa3*; endothelial cell marker genes included *Egfl7* and *Cdh5*; and perivascular cell marker genes included *Rgs5* and *Ndufa4 L2*. The FindAllMarkers function was

used to find differentially expressed genes between each cell type.

Gene set enrichment analysis

Gene set enrichment analysis (GSEA) can identify whether predefined gene sets show significant differences between biological processes by a computational method. Typically, GSEA is used to estimate expression in dataset samples. To study differences in the biological processes between the two groups, we downloaded the reference gene set c2.cp.kegg.v7.4.entrez.gmt from the MSigDB database on the basis of the gene expression profiling dataset[30]. We used GSEA included in the R package ClusterProfiler to perform enrichment analysis and visualization of the dataset. The cut-off standards were set as nominal $P < 0.05$, FDR q < 0.25 and normalized enrichment score (NES) > 0.6.

MSCs reclustering

On account of our main focus on MSCs, we extracted a subpopulation of MSCs. Based on hierarchical clustering and defined marker genes, we reclustered the MSCs using the FindClusters function and assigned the MSCs to 13 cell subpopulations. The progenitor subpopulation was identified by *Cdk1* and *Dkk1*, the osteoblasts subpopulation was identified by *Runx2* and *Sp7*, and the fibroblasts subpopulation was determined by maker genes *Dlk1* and *Shox2*. We next counted the proportions and number of these cell subpopulations in wild-type or *Cd271* knockout mice.

Gene ontology functional enrichment analysis and protein–protein interaction network

Gene Ontology (GO) is an approach for functional enrichment analysis of genes in diverse levels and dimensions. GO analysis comprises three levels: Biological process, molecular function and cellular components. The Wilcoxon rank-sum test was used to identify genes differentially expressed in MSCs between wild-type and *Cd271* knockout samples (logFC > 0.25, $P < 0.05$). Differentially expressed genes that were identified between wild-type and *Cd271* knockout samples were subjected to GO functional annotation by the ClusterProfiler (version 4.2.0) R package to identify the significantly enriched biological processes[31].The enrichment results were visualized in the form of a lollipop plot, and the significance threshold for the enrichment analysis was set at a corrected $P < 0.05$.

The STRING online database (https://string-db.org/) analyzed the interaction between the marker genes. We constructed a protein–protein interaction (PPI) network for the results obtained by Cytoscape (3.9.0). The functional interactions between the proteins expressed by the genes were mapped, including direct physical interactions and indirect functional correlations.

Pseudotemporal analysis

Cell differentiation of MSCs (progenitors, osteoblasts and fibroblasts) was inferred by the Monocle (2.22.0) R package and default parameters recommended by the developers[32]. The integrated gene expression profiling of each cell type was exported from Seurat into Monocle to establish the cellular gene dataset. The variable genes were defined by the process of DispersionTable, and the cells were sorted with the function of setOrderingFilter. The DDRTree method was used to reduce the dimension, and the orderCells function was used to estimate the cell arrangement along the trajectory. Based on clustering characteristics and marker gene analysis, we obtained the trajectory map of the differentiation time of MSCs. The study of each trajectory used a standard protocol with default parameters.

Cell–cell communication analysis

We identified the underlying interactions between MSCs and other cell populations by CellChat (version 1.1.3) (http://www.cellchat.org/) R package, which is commonly used to analyze cell–cell communication networks from single cell transcriptome sequencing profiling[33]. Taking advantage of CellChat, we inferred the scRNA-Seq data quantitatively and researched cell–cell communication networks. We predicted the main ingoing and outgoing signal patterns by network analysis and pattern recognition methods, as well as the coordination function between cells and signals. We counted all the important receptor–ligand pairs in the intercellular signal transmission by bubble chart, and we selected the signaling with a higher contribution to the cell for network centrality analysis.

Cell culture and mineralization induction

MSCs were isolated from embryonic maxillary processes. After washing with high-glucose Dulbecco's modified Eagle's medium (DMEM; Gibco, United States) three times, the cells were digested with trypsin–EDTA (Gibco) at 37 °C for 10 min, and centrifuged at 1000 rpm for 5 min. The cells were resuspended in a growth medium with DMEM, 10% fetal bovine serum (FBS) (Gibco), and 1% antibiotics (100 mg/mL penicillin and 100 μg/mL streptomycin) to generate primary MSCs. We maintained the cells at 37 °C in a 5% CO_2 humidified incubator and replaced the medium every 3 d.

For mineralization induction, cells were seeded in DMEM supplemented with 10% FBS at 4×10^4 cells per well in 24-well plates. At 75%–80% confluence, we changed the medium to mineralization induction medium, which consisted of DMEM with 10% FBS, 100 IU/mL penicillin, 100 IU/mL streptomycin, 0.1 μM dexamethasone, 10 mmol/L β-glycerol phosphate (Sigma–Aldrich, St. Louis, MO, United States) and 50 μM ascorbic acid (Sigma–Aldrich). We cultured the cells for up to 7 d, and replaced the medium

every 3 d.

Alkaline phosphatase activity and staining

The alkaline phosphatase (ALP) activity kit (Nanjing Jiancheng Biotech, China) was used to detect intracellular ALP activity. Cells were lysed in RIPA lysis buffer (Beyotime, China) without protease and phosphatase inhibitors to induce mineralization for 7 d. We centrifuged the lysate at 12000 rpm and 4 °C for 30 min, and incubated the supernatant with reaction buffer at 37 °C for 15 min. We stopped the color development and measured the absorbance at 520 nm. We measured the protein concentration of the lysate with a Bicinchoninic Acid Assay (BCA) protein assay kit (Beyotime). The ALP staining assay was performed with a Beyotime kit. On day 7 of induction, the cells were fixed for 30 min and stained with Alkaline Phosphatase Assay Kit (Beyotime, China) in the dark for 30 min. The cells were observed and imaged for histochemical detection of ALP with a Nikon microscope.

Alizarin Red staining and quantification

After osteogenic inducting for 14 d, the cells were fixed with 4% paraformaldehyde for 30 min. They were stained with 1% Alizarin Red (pH 4.3) (Beyotime) for 20 min at room temperature and washed three times with deionized water. We observed and imaged the calcium deposits under a Nikon microscope. To quantify calcium deposits, we destained the stained cells with 10% cetylpyridinium chloride monohydrate (Sigma–Aldrich) in 10 mmol/L sodium phosphate (pH 7.0) for 30 min. We transferred a 200-μL aliquot to a 96-well plate to measure the absorbance at 550 nm by a Varioskan Flash Spectral Scanning Multimode Reader (ThermoFisher Scientific, United States).

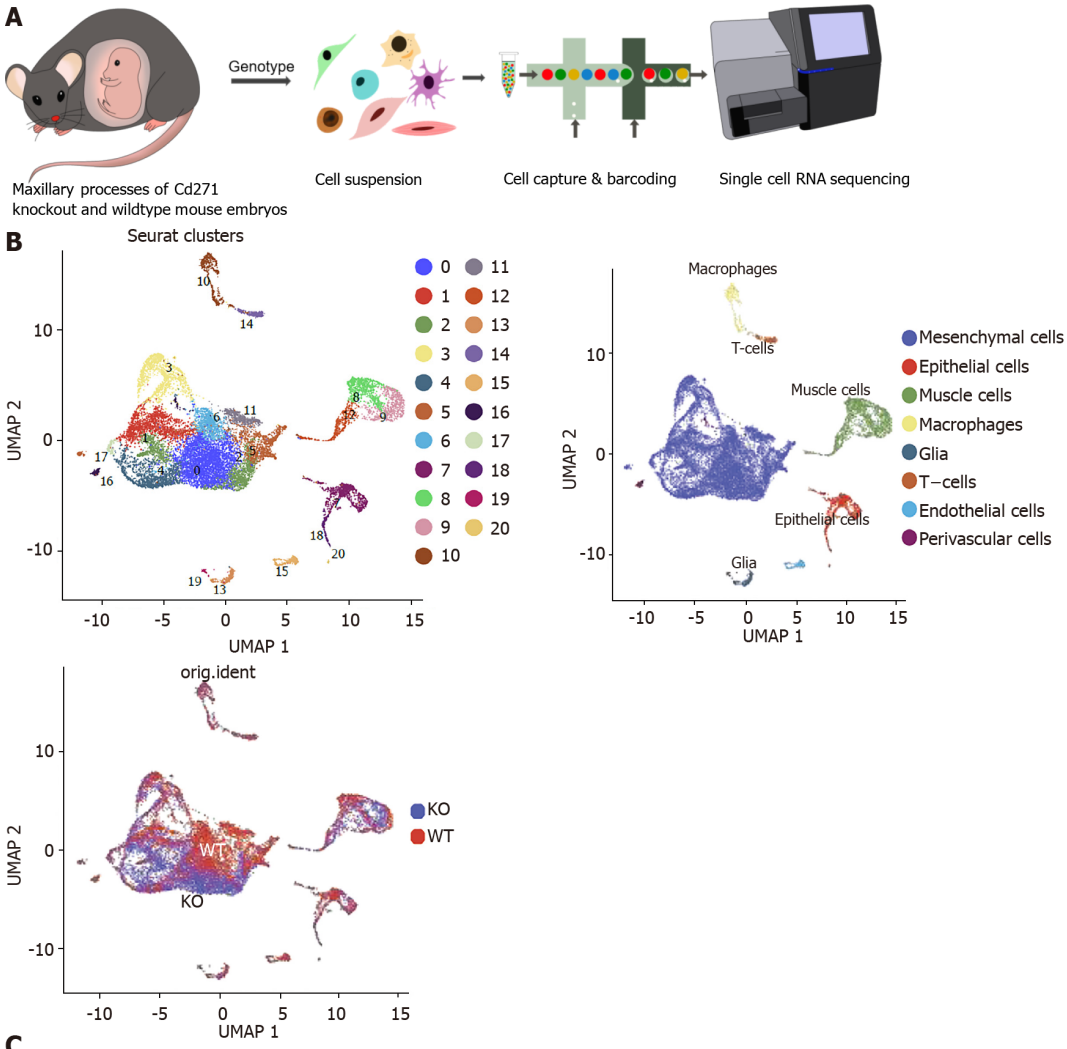
Quantitative real-time polymerase chain reaction

Total RNA was isolated from the cells by an RNA prep pure Cell Kit (TIANGEN, Beijing, China). cDNA was synthesized following the instructions for the HiScript® III RT Super Mix for quantitative real time polymerase chain reaction (qPCR) kit (Vazyme, Nanjing, China). Quantitative real-time polymerase chain reaction (PCR) was performed with ChamQ Universal SYBR qPCR Master Mix kit (Vazyme) and Real-Time PCR Detection System (Quantstudio5, United States). Gene-specific primer pairs are show in Supplementary Table 1.

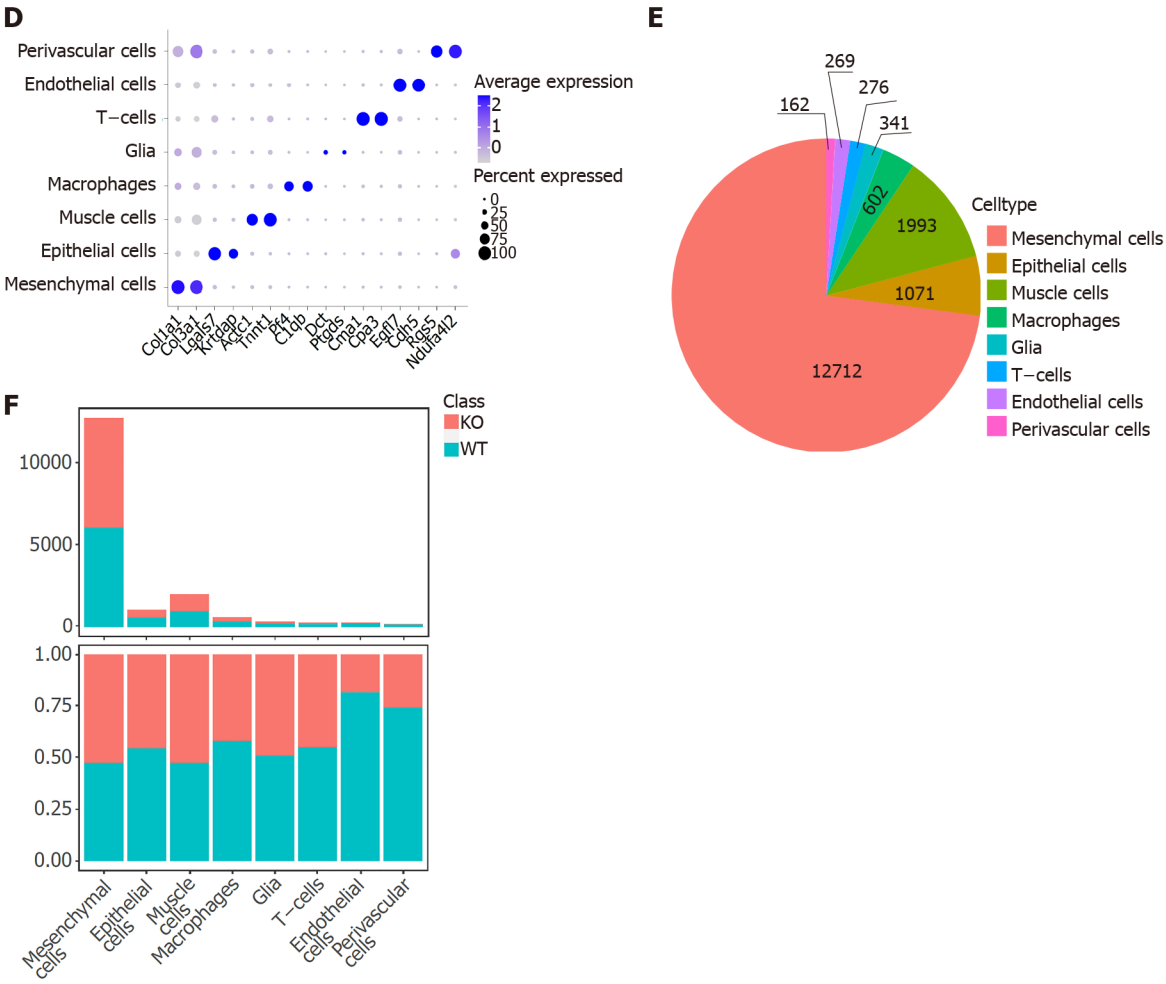
Cell Counting Kit-8 proliferation

Cell Counting Kit-8 (CCK-8; Dojindo Kagaku, Japan) was used to investigate the proliferation rate of E16.5d *Cd271* knockout and wild-type MSCs. The cells were seeded at 2 × 10^3 cells/well in a 96-well plate. After mixing the CCK-8 solution, the cells were cultured at 37 °C for 2 h in the dark. Absorbance was detected for 7 d continuously by a microplate reader at 450 nm.

Statistical analysis



Except the scRNA Seq, all the experiments were repeated more than three times. A one-way analysis of variance (ANOVA) or t test (GraphPad Prism 9.0 software, La Jolla, CA, United States) was used to identify significant differences. $P < 0.05$ was considered statistically significant.



RESULTS

scRNA-Seq analysis showed high cellular heterogeneity of murine maxillary process

To reveal cellular heterogeneity, we performed scRNA-Seq with murine maxillary processes from wild-type and *Cd271* knockout embryo tissues (Figure 1A and Supplementary Figure 1). After quality controlling and normalizing scRNA-Seq data, we obtained transcriptomes of 17426 cells (Supplementary Figure 2). UMAP clustering divided the cells into 21 independent clusters. Based on established lineage-specific marker genes, these 21 clusters were assigned to eight cell lineages (Figure 1B). We identified differentially expressed genes by comparing the gene expression profiles of one cluster with the others (Figure 1C). The MSC lineage was identified by *Col1a1* and *Col3a1*, and epithelial cells were marked by *Lgals7*. Based on these established lineage-specific maker genes, we assigned these clusters to eight cell types and plotted them (Figure 1D). We identified nine mesenchymal clusters (0–6, 11 and 17), a total of 12712 cells, which constituted the majority of sequenced cells by > 72.94%. Clusters 7, 18 and 20 were annotated as epithelial cells with a relative proportion of 6.14%. Muscle cells consisted of clusters 8, 9 and 12 with a relative proportion of 11.43%, while cluster 10 accounted for 3.11% as macrophages. Clusters 13 and 19 were annotated as glial cells (341, 1.95%). Clusters 14–16 were annotated as T cells (276, 1.58%), endothelial cells (269, 1.54%), and perivascular cells (162, 0.92%), respectively (Figure 1E).

We also analyzed the single cell sequence profiling from wild-type and *Cd271* knockout mice to establish the distribution of different types of cells and the source of samples. We counted the number and proportion of each cell type using histograms (Figure 1F). MSCs occupied most of the cell transcriptomes from the maxillary process, and the proportion of these cells between *Cd271* knockout

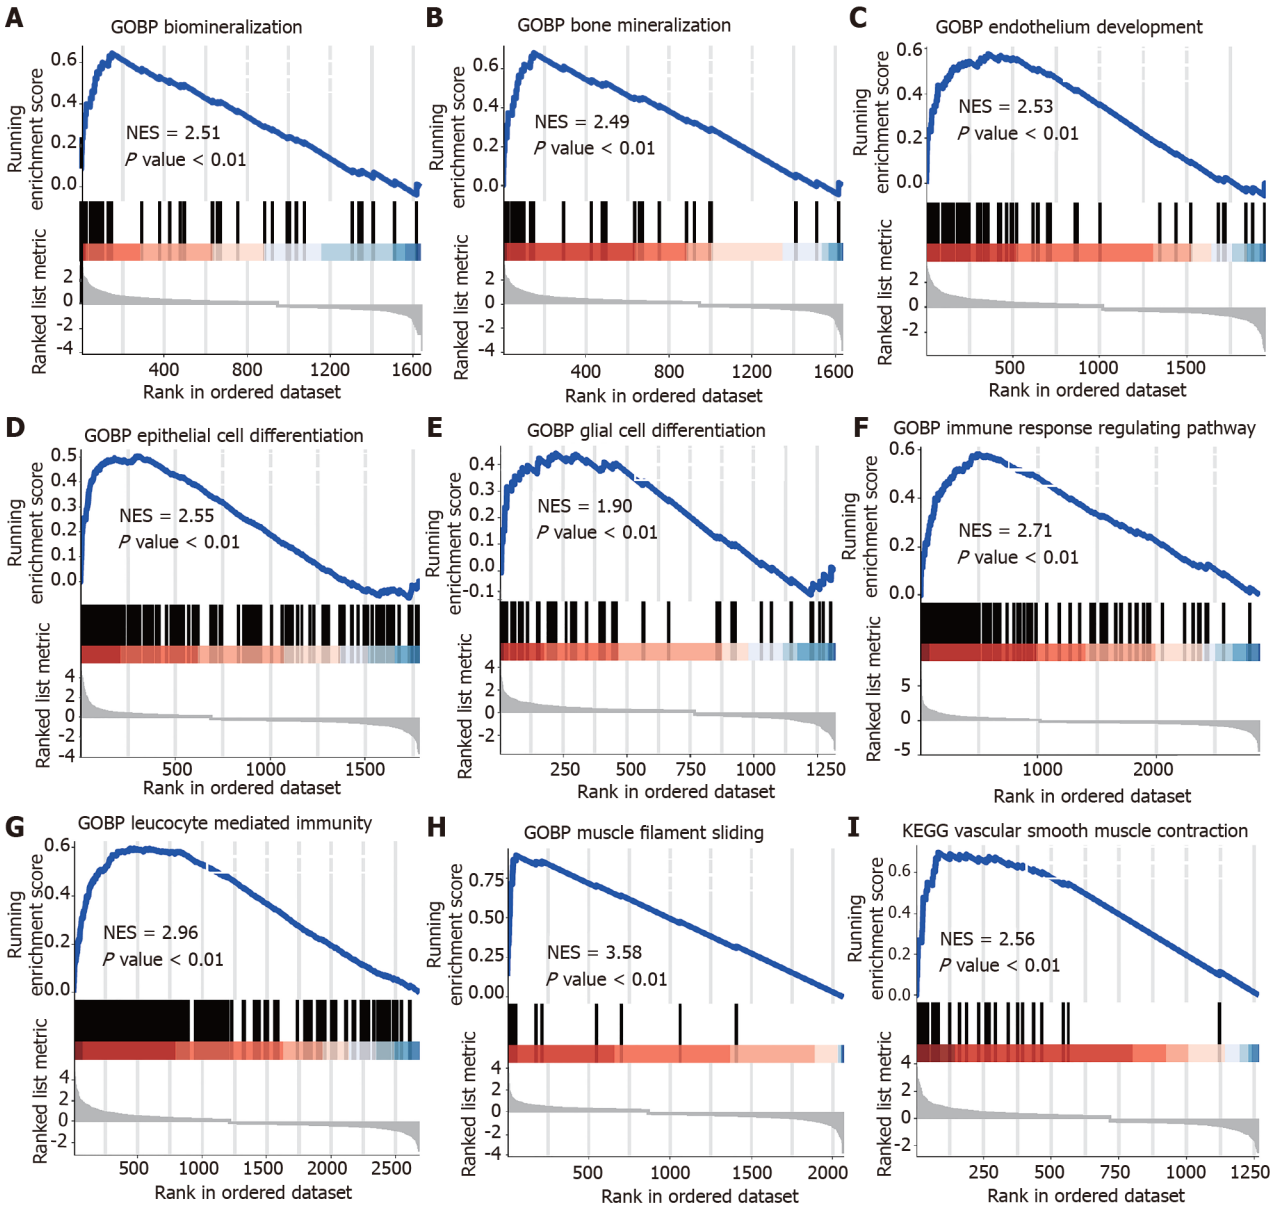
Figure 1 Single cell RNA sequencing analysis of maxillary processes from wild-type and *Cd271* knockout mice. We identified 21 clusters of cells, and the single cell RNA sequencing data were characterized. A: Schematic representation of the experimental workflow. The *Cd271* knockout and wild-type maxillary processes were collected from mouse embryos at 16.5 d. After genotyping, cells were suspended as single cells, and the cDNA library was constructed and sequenced; B: Cells extracted from the samples were subjected to Uniform Manifold Approximation and Projection hierarchical clustering and color-coded by cluster grouping, predominant cell type, and sample origin; C: Heatmap showing expression levels of differentially expressed genes in each cluster; D: Dot plot showing prominent marker genes for each cell type (mesenchymal cells, epithelial, muscle cell, macrophage, glial, T cell, endothelial, and perivascular); E: Pie chart showing the number of each cell type; F: Histogram showing the number and proportion of cells from wild-type and *Cd271* knockout mice. UMAP: Uniform Manifold Approximation and Projection; KO: Knockout; WT: Wild-type.



and wild-type was similar.

GSEA showed significant functional and signaling differences between cell types

To identify the relevant molecular mechanisms and possible pathways, we subjected all expressions to GSEA. The results showed a high correlation with MSCs and a close relationship with biomineralization. The results suggested that biomineralization (NES = 2.51, $P < 0.01$) and bone mineralization (NES = 2.49, $P < 0.001$) associated pathways enriched in MSCs (Figure 2A and B). GSEA also revealed that the differentially expressed genes enriched endothelial development, epithelial and glial cell differentiation, immune response, myofilament sliding and vascular smooth muscle contraction (Figure 2C–I).

Unsupervised clustering revealed novel subclusters of MSCs

As MSCs contribute much to embryogenesis and are essential in odontogenesis and osteogenesis, we performed unsupervised reclustering of MSCs. We performed the Subcluster analysis to investigate the heterogeneity within the mesenchymal populations. We observed further heterogeneity in subclusters 0–12 (Figure 3A). We used the published markers to identify the subclusters in MSCs. For instance, *Cdk1* and *Dkk1* marked progenitors, *Runx2* and *sp7* marked osteoblasts, and *Dlk1* and *Shox2* marked fibroblasts. We scored these marker genes in MSC clusters (Figure 3B). In this way, MSC clusters could also be identified into three subpopulations: Progenitors, fibroblasts and osteoblasts. We counted the cell proportions of the MSCs subclusters from wild-type and *Cd271* knockout maxillary processes. The

results showed that the numbers of subclusters 1, 3 and 10 were lower, while the other subclusters were higher in *Cd271* knockout compared with wild-type mice (Figure 3C).

Cd271 knockout MSCs exhibited weaker proliferation and osteogenic differentiation potential

We compared MSCs between wild-type and *Cd271* knockout maxillary processes. GO functional enrichment analysis revealed that differentially expressed genes were enriched in ossification, myeloid cell differentiation and biomineralization cell proliferation-related signaling (Figure 4A). To compare the differences in proliferation and osteogenic differentiation between wild-type and *Cd271* knockout MSCs, we investigated the potential for MSC proliferation. As the CCK-8 assay showed, the *Cd271* knockout MSCs exhibited weaker cell proliferation (Figure 4B). We induced the cells with an osteogenic induction medium and performed the mineralization assay. ALP staining and a quantitative assay revealed a lower and lighter mineralization level of *Cd271* knockout than wild-type MSCs. Lighter and fewer mineralized nodules were observed by Alizarin Red staining in *Cd271* knock out MSCs (Figure 4C). These results indicated more inadequate osteogenic differentiation potential in *Cd271* knockout MSCs. We selected several differentially expressed genes with considerable interaction by

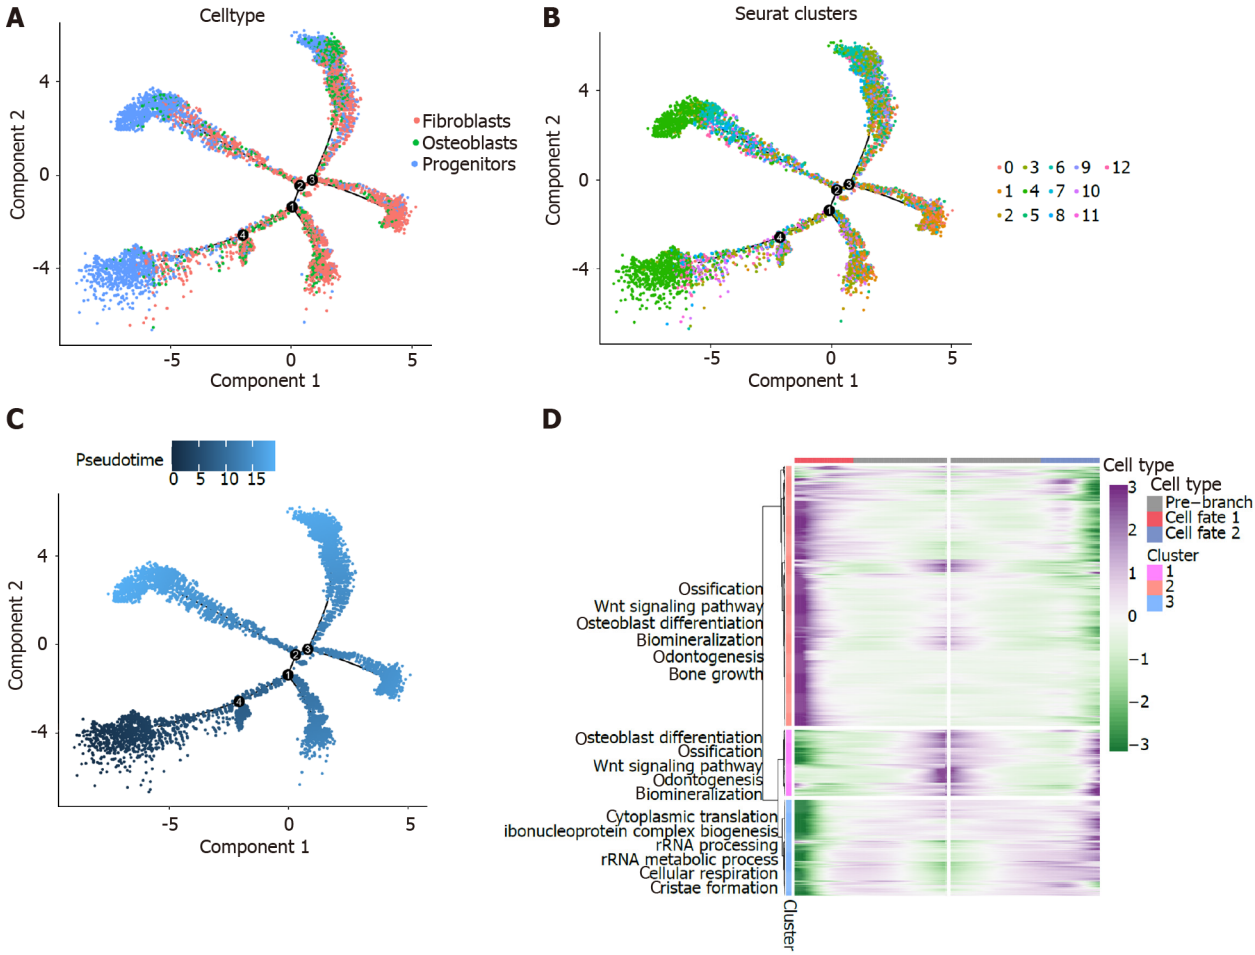
Cytoscape, and measured the gene expression by real-time quantitative PCR (Figure 4D). Proliferation, ossification and osteoblast differentiation-related genes, such as *Col4a1*, *Col6a1*, *Sparc*, *Vim*, *Col1a1* and *Col3a1*, were significantly decreased in *Cd271* knockout MSCs (Figure 4E). *Cd271* was involved in regulating osteogenic differentiation in MSCs, and our results implied a weaker potential of proliferation and osteogenic differentiation in *Cd271* knockout MSCs.

Different sets of genes appeared to shift along the differentiation trajectory

We selected MSCs to institute a pseudotemporal trajectory map that contained terminals consistent with distinct cell fates. The progenitor cells aggregated at the root and branches, indicating a good cell cycle of the progenitor cells. Osteoblasts and fibroblasts were scattered in various branches, showing high invasive potential (Figure 5A–C). We extracted differentially expressed genes over pseudotemporal changes and plotted heatmaps. Different sets of genes were also found to be shifted during the progression of MSCs, stressing the actional change of the progenitor cells, which managed the cell fate transition in the mesenchyme. We clustered the differentially expressed genes into three and performed GO analysis. Clusters 1 and 2 were significantly enriched in biological processes of osteoblast differentiation, biomineralization and odontogenesis, while cluster 3 was mainly enriched in cell metabolism (Figure 5D).



Cell–cell interactions of mesenchymal subpopulations were crucial in the maxillary process

The dataset of scRNA-Seq provided an opportunity to analyze intercellular communication mediated by

ligand–receptor interactions. To gain insights into potential signaling interactions between different cellular subpopulations, we interrogated our data with CellChat (version 1.1.3) (http://www.cellchat.org/) R package, which could predict the ligand and receptor interactions at single cell resolution[33]. We found dense communication between MSCs and other cells, and the most concentrated interactions occurred in the mesenchymal subpopulation (Figure 6A and B). It revealed the importance of mesenchymal interaction signaling. We detected 30 signaling pathways in eight cell groups, including MK, PTN, ncWNT, IGF, PDGF, WNT and VEGF signaling pathways. We compared the contribution of efferent (or afferent) signaling between cells, confirming that MSCs had higher interaction than other cell types while acting as outgoing signaling pathways (Figure 6C). We analyzed the potential signaling of MSCs, revealing a series of signaling pathways, such as odontogenesis-related signaling such as WNT, BMP and HH signaling (Figure 6D).

We explored ligand–receptor signals broadcast by MSCs, which revealed that MSCs might affect other cells in the ligand–receptor interaction of MK and PTN signaling (Figure 6E). We performed network centrality analysis on MK and PTN signaling, which confirmed that MSCs were important signal senders in intercellular communication (Figure 6F and G). The expression of *Mdk* and *Ptn* in wild-type and *Cd271*$^{-/-}$ MSCs exhibited significant differences by quantitative real-time PCR assay. The expression of *Mdk* and *Ptn* was higher in the *Cd271* knockout MSCs (Figure 6H). These results disclosed underlying ligand–receptor interactions and suggested that MK and PTN signaling may be influenced by *Cd271* in mesenchymal subpopulations.

DISCUSSION

Although MSCs have been extensively studied, there is still a lack of knowledge about the key

mechanisms in tooth development. Researchers have found that the maxillary process included various cell subpopulations with diverse phenotypic and functional characteristics[34]. How this heterogeneity appears in osteogenesis and odontogenesis remains unclear. *Cd271* used to be a marker of the MSCs, and it had been reported that *Cd271* promotes differentiation in MSCs[35-37]. Hence, we used *Cd271* knockout mouse embryos to investigate what happens to MSCs in their initial developmental stage. We constructed a single cell profiling of representative mouse embryo maxillary processes and selected MSCs to explore their characteristics and critical regulatory mechanism *Cd271* related.

Maxillary-process-derived MSCs are recognized as primitive odontogenic stem cells. For instance, researchers obtained the MSCs from the first branchial arch of mice and the maxillary process tissue of rats in succession, and revealed the pluripotency of MSCs[38,39]. Wen *et al*[40] found that $p75^{+/+}$ MSCs have good multidirectional differentiation potential[40]. We identified nine MSC clusters among 21 clusters identified using scRNA-Seq in mouse embryo maxillary processes. MSC clusters accounted for the majority, suggesting that MSCs contribute much to embryogenesis. Emerging studies have revealed that the marker genes of MSCs, *Col1a1* and *Col3a1*, promote collagen production and influence odontogenesis or osteogenesis[41-43]. The decreased expression of these two genes in *Cd271* knockout MSCs compared to wild-type, suggested that *Cd271* was related to MSC regulation of odontogenesis or osteogenesis.

In the past, several studies concentrated on the whole population of MSCs rather than the relationships among the subclusters. Our subcluster analysis disclosed that these MSC clusters could be separated into three subpopulations: Fibroblast, progenitors and osteoblast, which had not been separated before. One of the characteristics of MSC clusters is the expression of osteoblast differentiation-associated genes such as *Runx2*, *Sox9*, *Msx1* and *Omd*[44-47]. Previous studies showed that proteins such as Runx2 and Sox9 were positively regulated by *Cd271* in MSCs[48-50]. However, these studies did not show the heterogeneity of MSCs, or which subpopulations of MSCs these proteins derived from. Our results revealed that these proteins were mainly expressed in the osteoblast subpopulation. The number of osteoblast subpopulations decreased while progenitor subpopulations increased. This suggested that some progenitors were hindered from differentiating into osteoblasts in the *Cd271* knockout MSC clusters. Consistently, GO enrichment analysis and GSEA verified significant enrichment of the ossification, biomineralization and bone mineralization pathways in the *Cd271* knockout and wild-type cells. Based on our scRNA-Seq data, we gained differentially expressed genes between two groups for the first time. We picked out several differentially expressed genes with extensive interactions; for instance, *Sparc*, *Vim*, *Col4a1*, *Col6a1*, *Col1a1* and *Col3a1*. These genes are considered to relate to cell proliferation, bone mineralization and multipotent differentiation[41-43,51-54]. In *Cd271* knockout MSCs, we verified by quantitative real-time PCR that these differentially expressed gene clusters had lower expression. Functional experiments also demonstrated a weaker odontogenic and osteogenic differentiation and proliferation in the *Cd271* knockout MSCs. Consistent with previous studies, our results confirmed that the MSC clusters had an essential role in odontogenesis and osteogenesis and *Cd271* possibly regulated it.

Pseudotemporal analysis uncovered a developmental trajectory among these three subpopulations. Significantly, the progenitor subpopulation was found to develop into the osteoblast and fibroblast subpopulations. We concluded that the progenitors were the base subpopulation and increasingly transformed into the osteoblast and fibroblast subpopulations in MSCs. Consistent with our GO and GSEA findings, the differentially expressed genes that emerged in pseudotemporal analysis showed a significant relation with ossification and osteoblast differentiation in MSCs. Collectively, our results revealed that MSCs were progressively diversified and determined to the odontogenic fate. Thus, the mesenchyme in the maxillary process provides a remarkable model to study the development of maxillary-process-derived MSCs.

It is known that the interactions between dental mesenchyme and epithelium play a crucial part in the integral tooth developmental process. Nevertheless, the cell–cell interactions within the maxillary process have not been extensively studied[55]. In our study, scRNA-Seq offered the opportunity to identify communicating pairs on the basis of the expression of their cell-surface receptors and ligands. CellChat showed that the most concentrated interactions occurred between mesenchymal and other cells. It indicated that MSCs play a vital role in cell communication. It is worth noting that MSCs mainly participated in MK, PTN, ncWNT, WNT and BMP signaling. Previous studies reported that *Cd271* might regulate the odontogenic differentiation of MSCs through the BMP, WNT and PI3K pathways[17,49,56]. However, there are no reports that MDK signaling participates in regulating MSCs. In the CellChat, the receptor interactions of MDK and PTN appeared to be obvious. It reminded us that the *Mdk* and *Ptn* might play a primary role in the developmental process of MSCs. *Mdk* and *Ptn* expression notably increased in *Cd271* knockout cells during induction of mineralization for 7 d. Our subsequent study will explore the molecular mechanism of how *Cd271* regulates *Mdk* to influence osteogenesis.

Although our studies revealed several significant discoveries, there were some limitations. First, different clustering can generate different results; thus, further groupings are needed to perform future analysis. Second, the current study was based on scRNA-Seq. Therefore, we did some biological observation but did not illustrate the direct mechanisms of *Cd271* involved in tooth development. Therefore, further studies about direct mechanisms and *in vivo* studies are needed.

CONCLUSION

Our study reveals high cellular heterogeneity, molecular details and cell-cell interactions in MSCs. It provides a valuable resource for understanding the development of maxillary-process-derived MSCs. And it enables the maxillary process to serve as an excellent model to explore tooth development and

cell fate determinations. Furthermore, we have found significant functional and signaling differences between *Cd271* knockout and wildtype MSCs. We have clarified that *Cd271* is significantly associated with the regulation of mineralization. We tentatively propose that *Mdk* signaling is involved in the regulatory mechanism of mineralization. These findings contribute to thorough exploration of the mechanism of *Cd271* in regulating odontogenesis and osteogenesis which add to the theory of tooth development.

ARTICLE HIGHLIGHTS

Research background

Tooth loss has become a common problem in human life. Compared with traditional denture restoration, dental tissue engineering has become the most ideal means to solve this problem, and it is also one of the most active research fields of stomatology in recent years. The tooth development involves complex signal pathways. Ecto-mesenchymal stem cells (MSCs) were regarded as the primitive dental cells in the classical theory of tooth development. To date, in-depth studies of the odontogenesis and osteogenesis of MSCs are still lacking.

Research motivation

We contribute to thorough exploration of the mechanism of odontogenesis and osteogenesis to add to the theory of tooth development.

Research objectives

Our study provides novel insights into the biological features of MSCs at the single cell level and the mechanism of *Cd271* in regulating odontogenesis and osteogenesis.

Research methods

We used the maxillary process from mouse embryos as a model to understand the development of maxillary-process-derived MSCs. We applied single cell RNA sequence analysis to elucidate the cellular heterogeneity and explore molecular details. And we verified the findings from single cell sequencing *in vitro* by lab experience such as cell staining, cell counting and quantitative real time polymerase chain reaction.

Research results

Our study reveals: (1) High cellular heterogeneity and molecular details; (2) Significant functional and signaling differences between cell types; (3) Novel subclusters of mesenchymal stem cells; and (4) Crucial cell-cell interactions of mesenchymal subpopulations. Besides, we contribute to thorough exploration of the mechanism of *Cd271* in regulating odontogenesis and osteogenesis.

Research conclusions

Our study reveals high cellular heterogeneity, molecular details and cell-cell interactions in MSCs. We found significant functional and signaling differences between *Cd271* knockout and wildtype MSCs. We clarified that *Cd271* is significantly associated with the regulation of mineralization.

Research perspectives

We need illustrate that *Mdk* signaling is involved in the regulatory mechanism of mineralization in future research. And direct mechanisms of *Cd271* involved in tooth development are needed in further studies.

Abstract

BACKGROUND

Timing of passaging, passage number, passaging approaches and methods for cell identification are critical factors influencing the quality of neural stem cells (NSCs) culture. How to effectively culture and identify NSCs is a continuous interest in NSCs study while these factors are comprehensively considered.

AIM

To establish a simplified and efficient method for culture and identification of neonatal rat brain-derived NSCs.

METHODS

First, curved tip operating scissors were used to dissect brain tissues from new born rats (2 to 3 d) and the brain tissues were cut into approximately 1 mm^3

sections. Filter the single cell suspension through a nylon mesh (200-mesh) and culture the sections in suspensions. Passaging was conducted with TrypL™ Express combined with mechanical tapping and pipetting techniques. Second, identify the 5th generation of passaged NSCs as well as the revived NSCs from cryopreservation. BrdU incorporation method was used to detect self-renew and proliferation capabilities of cells. Different NSCs specific antibodies (anti-nestin, NF200, NSE and GFAP antibodies) were used to identify NSCs specific surface markers and muti-differentiation capabilities by immunofluorescence staining.

RESULTS

Brain derived cells from newborn rats (2 to 3 d) proliferate and aggregate into spherical-shaped clusters with sustained continuous and stable passaging. When BrdU was incorporated into the 5th generation of passaged cells, positive BrdU cells and nestin cells were observed by immunofluorescence staining. After induction of dissociation using 5% fetal bovine serum, positive NF200, NSE and GFAP cells were observed by immunofluorescence staining.

CONCLUSION

This is a simplified and efficient method for neonatal rat brain-derived neural stem cell culture and identification.

Key Words: Neonatal rats; Brain-derived neural stem cells; Culture; Identification

Core Tip: How to harvest sufficient neural stem cells (NSCs) is a basic requirement for the study and clinical application of NSCs. This study describes a simplified and efficient method for neonatal rat brain-derived NSC culture and identification comprehensively considering the influencing factors including timing of passaging, passage number, passaging approaches and methods for cell identification. It demonstrates that combination of TrypL™ Express and mechanical tapping and pipetting techniques makes a more efficient way of passaging. The optimal timing for NSC passage is on the fourth to fifth day of primary or passage NSC culture.

INTRODUCTION

Spinal cord injuries (SCIs) are associated with high morbidity, disability and medical costs around the world[1-3]. Prevention, treatment and rehabilitation of SCIs remains one of the global health issues. Pathophysiological basis for sensory, motor and sphincter dysfunction below the neurological level of injury is the substantial variations, necrosis and loss of neurons along with ruptured tracts of spinal cord as well as demyelination induced by primary and/or secondary SCIs[4,5]. Therefore, the research fucus on the key to promoting recovery of function following SCIs falls on how to replenish the lost neurons and boost the regeneration of axis cylinder and myelin sheath. It should be noted that neural stem cells (NSCs) have the capacity to self-renew and proliferate, and differentiate into nerve cells of central nervous system including neuron, astrocyte and oligodendrocyte[6]. Hence, by replenishing neurons, forming axis cylinder, increasing oligodendrocyte and reconstructing medullary sheath and then remolding the injured structure and function of spinal cord, NSCs replacement as a possible therapeutic approach could bring hope to SCI patients. In view that rapid and simplified accesses to a large number of pure NSCs for research are needed, it is necessary to develop a method for NSC amplification, culture, purification and identification *in vitro* to provide sufficient-necessary condition for further investigation of NSCs.

The present study cultured, passaged and harvested large amounts of high pure NSCs with growth factor containing serum-free medium using TrypLE™ Express digestion method combined with mechanical disassociation method[4,7,8], which provide the platform for the further study of NSCs.

MATERIALS AND METHODS

Rats

In this study, Brain-derived NSCs were abstracted from several two-to-three-day old newborn SD rats provided by Southwest Medical University Animal Resource Center.

Reagents

Hyclone DEME/F12 (1:1); Hyclone standard fetal bovine serum; Peprotech EGF (20 μg); Peprotech bFGF (10 μg); Gibco B27 Plus Supplement (50×); Gibco TrypL™ Express (1×); rabbit anti-nestin polyclonal antibody (Wuhan Boster Biological Technology, Ltd.); mouse anti-NSE monoclonal antibody and mouse anti-GFAP monoclonal antibody (Wuhan Boster Biological Technology, Ltd.); RBITC-labeled goat anti-mouse IgG (Beijing Biosynthesis Biotechnology Co., Ltd.); RBITC-labeled goat anti-rabbit IgG (Beijing Biosynthesis Biotechnology Co., Ltd.).

Preparation of serum free medium for NSC culture

Take 100 mL of DMEM/F12 (1:1) and add EGF (20 ng/mL), bFGF (20 ng/mL), B27 Plus Supplement (2%), glutamine (2 mmol/L) and 1 mL of penicillin-streptomycin solution (100 U/mL). NaOH filtered with 0.22 μm microporous membrane filter were used to adjust PH of the solution between 7.2 and 7.4. After preparation, the medium was stored at 4°C. Serum free medium (SFM) should be kept fresh. A weekly dosage of 100 mL for on preparation is generally recommended.

Primary culture, passage, cryopreservation, resuscitation and identification of NCSs

Preparation of extracts and primary NSC culture: Newborn SD rats (2–3 d old) were selected and immersed in 75% alcohol for 10 min for disinfection. In supine position, the rats were fixed to foam board and placed on the clean bench with cranial cavity exposed. Brain tissues were isolated and placed in sterilization incubators containing phosphate-buffered saline (PBS) (0.01 M, PH 7.2, pre-warmed to 37°C, 10 min, the same below) for washing to remove blood stains on the surface. Then pia mater as well as choroid plexus tissues were removed under a dissecting microscope. The dissected brain tissues were washed and transferred to a new sterilization incubator. Using curved tip operating scissors, dissected brain tissues were cut into approximately 1 mm^3 sections and were transferred to centrifuge tubes (10 mL, the same below) using sterile pipettes. Centrifuge the sections at 1000 rpm for 1 min and remove the supernatant. Save the cerebral cortex in three separate tubes, each containing 1 mL of mixed enzyme, shake them gently for 5 min in a 37°C water-bath and centrifuge them at 1000 rpm for 5 min, and then remove the supernatant. Add 5% fetal bovine serum, pipette and tap gently 10 times using pipettes, shake gently in a 37°C water-bath, centrifuge for 5 min at 1800 rpm, and remove the supernatant. Then add DMEM/F12 (1:1), pipette and tap gently 20 times using pipettes, filter using stainless-steel cell strainers (200-mesh), centrifuge for 5 min at 1000 rpm and remove the supernatant. Use 0.5 mL of SFM to resuspend cells. Pipette and tap the cells gently and form single-cell suspensions. Seed the cells at a rate of 1 × 10^6/mL (cell density determined by trypan blue method excluding dead cells) in 25 mL glass culture flasks and cultured in carbon dioxide constant temperature incubators (stable temperatures of 37°C, saturated humidity, a CO_2 level of 5%). Centrifuge the cells for 5 min at 1000 rpm every other day or every two days depending on how the cells developed and refresh half of the media with fresh growth media. Approximately, four or five days later, initiate passaging. Observe and record cell growth status under inverted phase contrast microscope every day including medium color, impurities in medium, cell refraction, density, size of neurosphere formation and neurosphere refraction.

Passaging of NSCs: After four to five days of primary culture, which is dependent on the growth process of cell and neurospheres, gather all neurospheres and culture solution and place in a 15 mL cone shaped tube, centrifuge for 5 min at 1000 rpm and remove the supernatant. Add 1 mL of TrypLE™, pipette cells gently using pipettes, shake them gently for 5 min in a 37°C water-bath and centrifuge them at 1800 rpm for 5 min, and then remove the supernatant. Add 0.5 mL of SFM to resuspend cells. Using 1000 μL pipettes, tap the cells gently 10 times (for 200 μL pipettes, approximately 20 times). Seed the cells at a rate of 1 × 10^6/mL (cell density determined by trypan blue method excluding dead cells) in a 25 mL glass culture flask and cultured in the above described constant temperature incubators (stable temperatures of 37°C, saturated humidity, a CO_2 level of 5%).

Cryopreservation and resuscitation of NSCs: Add 1 mL of freshly prepared cell freezing medium (DMEM/F12:fetal bovine serum:DMSO = 7:2:1) to the single-cell suspensions. Adjust the cell density to 5×10^6/mL, and preserve the suspension in a 4°C refrigerator for three hours. Place the cryovials in a small plastic storage box and keep the box immediately in a −80°C gas-phase liquid nitrogen freezer overnight and finally cryopreserve the cryovials in a liquid-phase liquid nitrogen freezer. For cell resuscitation, remove cryovials from the liquid-phase liquid nitrogen freezer and place the cryovials in a 37°C water-bath for rapid melting. Transfer the cells to centrifuge tubes and add 4 mL of basal media. Centrifuge the cells for 5 min at 1000 rpm and remove the supernatant. Add SFM and resuspend cells. Seed the cells at a rate of 1 × 10^6/mL (cell density determined by trypan blue method excluding dead cells) in 25 mL glass culture flasks and cultured in the above described constant temperature incubators.

Identification of NCSs: Identify the 5th generation of passaged NSCs and the revived NSCs from cryopreservation. Use bromodeoxyuridine (BrdU) incorporation method to detect the self-renew and proliferation abilities of cells. Use diverse neurocyte-specific antibodies such as anti-nestin, anti-NF200, anti-NSE and anti-GFAP antibodies to examine NSC specific surface markers and muti-differentiation capabilities by immunofluorescence staining.

BrdU incorporation method for the detection of the proliferation of NSCs: (1) At 24 h after the culture of 5th generation of passaged NSCs, add BrdU to SFM to make BrdU reach a concentration of 10 μmol/L. Continue to culture the cells for five days and seed the NSCs cultured in suspensions at a rate of 1 × 10^6/mL (500 μL) in a carbon dioxide constant temperature incubator containing 24-well culture plates with polylysine coated coverslips (stable temperatures of 37°C, moderate saturated humidity, a CO_2 level of 5%) for four hours; (2) Draw the solution and gently wash 3 × 5 min with PBS (0.01 mol/L, PH7.2); (3) Add 4% paraformaldehyde for a fixation for 15 min at room temperatures; (4) Draw the stationary fluids and wash 3 × 5 min with PBS (0.01 mol/L, PH7.2); (5) Use 37°C blocking buffer (10% sheep serum and 0.3% Triton) for 1 h closed incubation (150 μL per well, almost spread the coverslips) and then draw the stationary fluids. Add 150 μL of mouse anti-BrdU primary monoclonal antibody (dilute the fluids with PBS to adjust the concentration to 1:200) and cover coverslips. Use PBS (0.01mol/L, PH7.2) as positive control to replace mouse anti-BrdU primary monoclonal antibody. Continue to culture the cells in a 37°C constant temperature incubator for two hours; (6) Blot fluids in the last step and wash 3 × 5 min with PBS (0.01 mol/L, PH7.2); (7) Add FITC labeled goat anti-mouse IgG second antibody (dilute the fluids with PBS to adjust the concentration to 1:40) (cells should be protected against exposure to light for each of the following steps). Continue to culture the cells in a 37°C constant temperature incubator for one hour; (8) Blot the second antibody and wash 3 × 5 min with PBS (0.01 mol/L, PH7.2); (9) Add 20 μL of anti-fluorescence quencher over the slide; and (10) Lift the coverslip using a self-made right-angled tip needle and then press it with the side containing the cells down avoiding creating air bubbles. View the cells under a fluorescence microscope, take photos and make records.

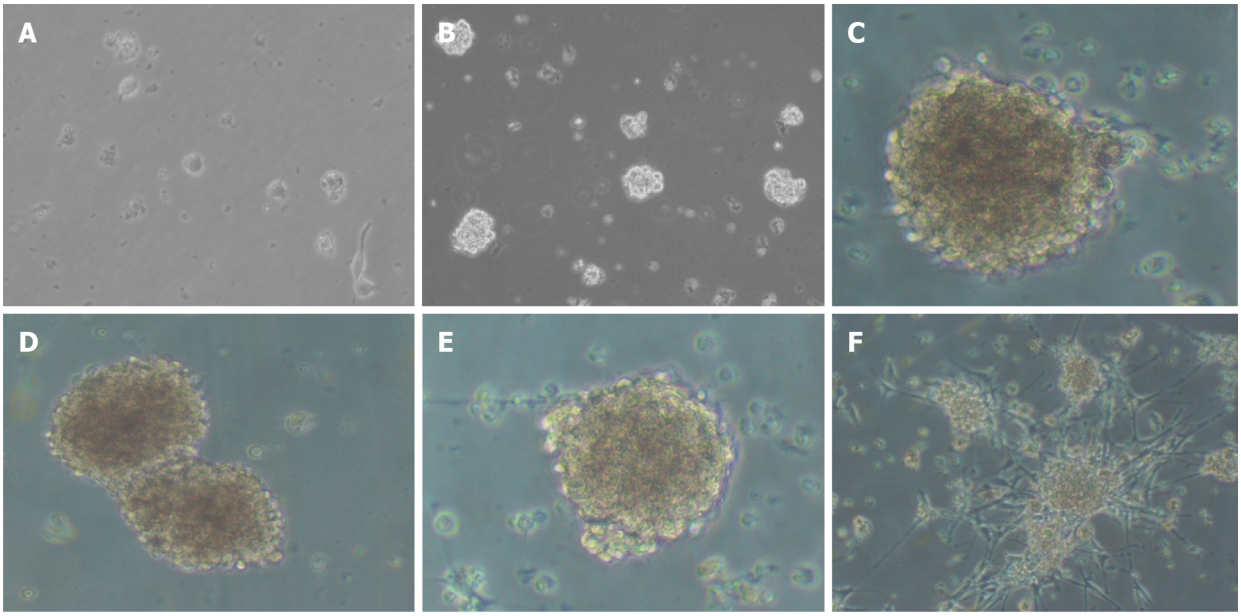
Nestin immunofluorescence staining: (1) Take a small amount of 5th generation of cultured neurosphere containing NSCs and seed them in a carbon dioxide constant temperature incubator containing 24-well culture plates with polylysine coated coverslips (stable temperatures of 37°C, moderate saturated humidity, a CO_2 level of 5%) for four hours; (2) Discard the solution and wash gently 3 × 5 min with PBS; (3) Add 4% paraformaldehyde for a stationary phase for 15 min at room temperatures; (4) Discard the stationary liquid and wash gently 3 × 5 min with PBS; (5) Use 37°C blocking buffer (10% sheep serum and 0.3% Triton) for 1 h closed incubation (150 μL per well, almost spread the coverslips) and then blot the stationary fluids. Add rabbit anti-nestin monoclonal primary antibody (dilute the fluids with PBS solution to adjust the concentration to 1:200). The primary antibody was substituted for PBS solution as a negative control. Continue to culture the cells in a 37°C constant temperature incubator for two hours; (6) Discard the liquid used in the last step and gently wash 3 × 5 min with PBS (0.01 M, PH7.2); (7) Add RBITC labeled goat anti-rabbit IgG second antibody (dilute the fluids with PBS solution to adjust the concentration to 1:40) (avoid light exposure for each of the following steps). Then culture the cells in a 37°C constant temperature incubator for one hour; (8) Blot the second antibody. Wash 3 × 5 min with PBS (0.01 mol/L, PH7.2); (9) Add DAPI staining solution (150 μL per well, almost spread the coverslips) for 3 min at room temperatures and then blot the DAPI staining solution. Wash 3 × 5 min with PBS (0.01mol/L, PH7.2). Add 20 μL of anti-fluorescence quencher over the slide; and (10) Lift the coverslip and then press it with the side containing the cells down on the slide containing 20 μL of anti-fluorescence quencher (Be careful to avoid creating air bubbles).

Observe the cells under a fluorescence microscope, take photos and make records. Differentiation of NSCs and immunofluorescence staining of GFAP, NF200 and NSE. (1) Using SFM containing 5% fetal bovine serum, seed the 5th generation of NSCs in 24-well culture plates with polylysine coated coverslips and culture the cells for 5 d; Repeat steps (2), (3) and (4) in the section of BrdU incorporation method for the detection of the proliferation of NSCs or in nestin immunofluorescence staining; (5) Use 37°C blocking buffer (0.3% Triton X-100 and 10% sheep serum) for 1 h closed incubation (150 μL per well, almost spread the coverslips, similarly hereinafter) and then discard the stationary fluids. Add mouse anti-GFAP monoclonal antibody, mouse anti-NSE monoclonal antibody and mouse anti- NF200 monoclonal antibody, respectively (all as primary antibody, dilute the fluids with PBS to adjust the concentration to 1:200), and the primary antibody was substituted for prepared PBS solution as a negative control and then cultured in the above described constant temperature incubators for two hours; (6) Discard the liquid in the last step, and wash 3 × 5 min with prepared PBS; (7) Add RBITC-labeled goat anti-mouse IgG secondary anti-body (dilute the fluids with PBS to adjust the concentration to 1:40), and incubate the cell in a above mentioned incubator for 1 h; Repeat steps (8), (9) and (10) in the section of BrdU incorporation method for the detection of the proliferation of NSCs or in nestin immunofluorescence staining.

RESULTS

Development and identification of NSCs

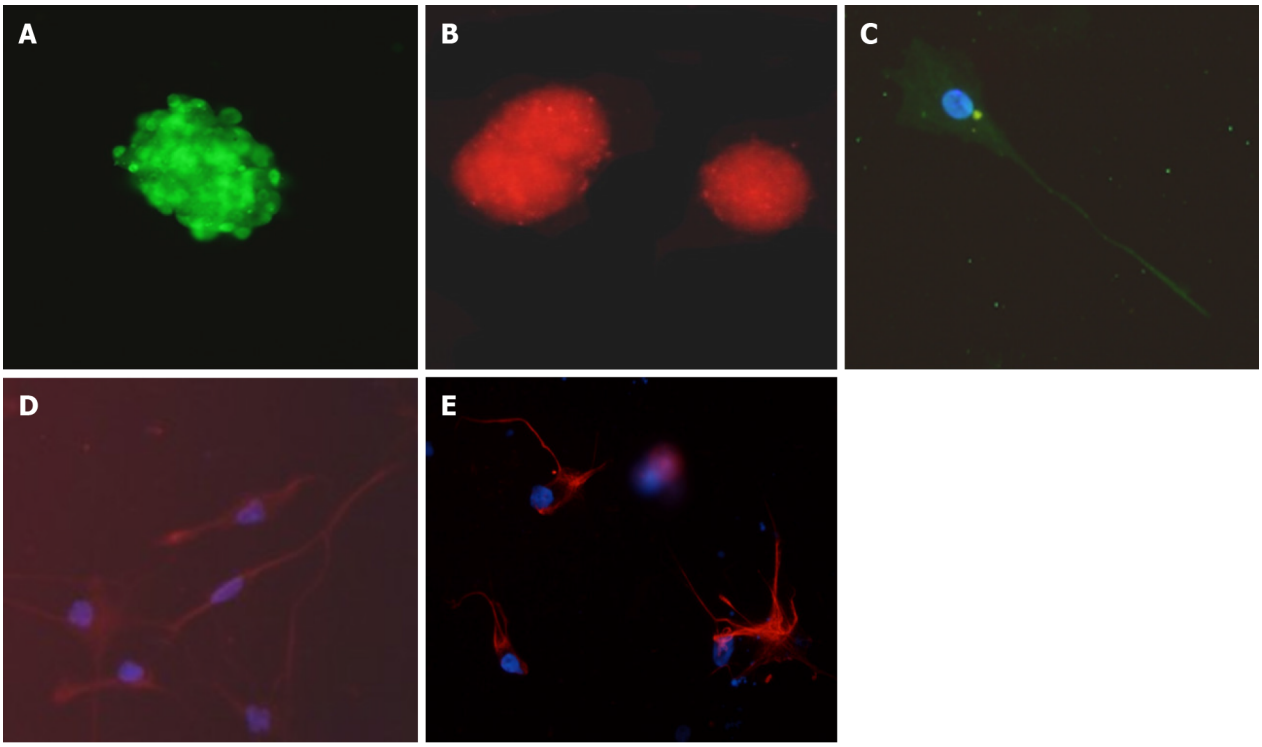
The first-generation cells derived from newborn SD rats appear small, equal sized, glossy spheres. At 24 h after the primary culture, larger amounts of cells aggregate in the middle of potion of the growth medium. These single floating cells can differentiate and renew (Figure 1A). There are also plenty of glossy, spherical-shaped, adherent single cells at the bottom of the culture bottle. Moreover, many structural looseness, highly refractile, spherical-shaped clusters and membraniform flocculation also exist in the culture medium, which are considered as clumps of dead cells and uneliminated tissues such as blood vessels and pia mater, respectively. At 2 to 3 d after the primary culture, several and even dozens of translucent, highly refractile, spherical-shaped or thyrsiform cell clusters are discovered (Figure 1B). What's more, only a small amount dead cell clusters were left in the culture medium. At four to five days after the primary culture (Figure 1C), the cell mass bulks up to a spherical shape when large numbers of cell clusters aggregate and form translucent slippery spheres under an inverted phase-contrast microscope. However, refractivity at the center of the sphere decreases and few aggregated dead cells are observed. Compared with that of neurospheres at five days after the primary culture, the volume of neurospheres at eight days after the primary culture is obviously big and the refractivity is poor and it shows dark brown in most parts of the sphere center (Figure 1D). Passaging conducted at that time only dissociates neurospheres into smaller cell clumps and few single floating cells rather than single-cell suspensions. It is speculated that this is associated with tight cell-cell junction around the neurospheres. Moreover, many small sized adherent cells are observed at two days after the passaging with small quantity of low density single floating cells. Adherent differentiation occurs in plenty of large volume neurospheres during the continuous culture.



Generally, there are two methods of cell dissociation: mechanical and enzymatic. It is discovered that it is hard to control enzyme concentration and time, which easily lead to cell death. Comparatively, TrypLE™ Express digestion method combined with mechanical disassociation method can harvest sufficient normomorph, uniform size single floating cells with glossy cytoplasm and there are relatively few cell debris and impurities in the culture medium. In addition, medium-sized cloned neurospheres in good shape can be observed in the passaged NSC culturation (Figure 1E). At four hours after the induction of dissociation of 5th generation of passaged NSCs using 5% fetal bovine serum, adherent neurospheres and gradual migration of cells away from neurospheres are observed. At approximately five days after the induction of dissociation, spheres become flattened and form various shaped cells surrounding the neurospheres. At approximately five days after the induction of dissociation, the spheres flatten and make up lots of various shapes of cells. These cells connect to each other into a mesh-structure (Figure 1F).

Identification of NCSs

The incorporation of BrdU into the 5th generation of passaged cells showed positive after BrdU immunofluorescence staining (green fluorescence, Figure 2A) and nestin immunofluorescence staining (red fluorescence, Figure 2B). At five days after the induction of dissociation of 5th generation of passaged cells using 5% fetal bovine serum, NF200 (green fluorescence, DAPI nucleic acid stain revealed the blue fluorescent cell nucleus, Figure 2C), NSE (red fluorescence, blue fluorescent obtained with DAPI nucleic acid stain, Figure 2D) and GFAP (red fluorescence, DAPI nucleic acid stain revealed the blue fluorescent cell nucleus, Figure 2E) positive immunoreactivities were found.



DISCUSSION

Since 1990s, many researchers have demonstrated that NSCs are widely present in central nervous system (CNS) including spinal cord[6,9-17]. NSCs not only have the probabilities of division, regeneration proliferation and multidirectional differentiation (differentiate into nearly all types of CNS nerve cells such as neuron and glial cell), but also exhibit low immunogenicity and good histocompatibility[6,9-17]. This refutes the theory that the damaged cells are unable to be regenerated and repaired following the injuries to the nerve and the spinal cord, and provides new hope to the reconstruction of structure and function in CNS disorders such as SCIs and cerebral injuries[6,18]. NSCs, as the seed cells enhancing CNS regeneration, spontaneously become cores and foundation of neurological research. Efficient approaches for enhancing pure NSC yield in the research thus becomes crucial. The present study established a method for NSC amplification, culture, purification and identification *in vitro* to provide sufficient-necessary condition for further investigation of NSCs. Cell culture technology is the basic premise for the investigation of NSCs. Mature techniques for the isolation and culture of NSCs have been developed. In addition to proving the presence of NSCs and its potential of self-renewal and multidirectional differentiation, Reynolds and Weiss *et al*[9] also demonstrated that NSCs could proliferate massively *in vitro*, which establish crucial conditions for future investigation of NSCs. However, application of methods for *in vitro* amplification of stem cells is currently restricted to CNS. By contrast, cloning of monolayer cells[6,19] offers an alternative approach for NSC culture. This

approach is widely used because using this approach we can not only derive an abundant amount of pure NSCs in a short time but also determine the differentiation capacity for a single NSC or its precursor cells.

For the timing of NSC passaging, the present study found that although passaging at two-to-three-day primary culture could facilitate the dissociation of neurospheres and formation of single-cell suspensions, the number of single cells derived was unsatisfactory at low densities which was not conductive to amplification and proliferation of NSCs after passage. Passaging performed when primary NSCs are cultured for seven to eight days could only dissociate neurospheres into small clusters of cells with a small amount of single floating cells instead of single-cell suspensions, which was presumably related to the tight junctions between peripheral neurosphere cells[20]. Moreover, small clusters of adherent cells with small portion of low density single floating cells were discovered after only two days of passage. Differentiation of adherent large neurospheres occurred after a continued cultivation. The observation of nine-to-ten-day primary NSC culture revealed that differentiation occurred in plenty of adherent large neurospheres with lots of dead cells, which also inhibits passaging. Comparatively, when passaging was performed after four to five days of primary culture, it not only promotes easy generation of single-cell suspensions dissociated from neurospheres but also harvests sufficient single floating cells with fewer dead cells and improved amplification and proliferation capabilities of NSCs. It follows that the optimal timing for NSC passage is after four-to-five-day primary or passage NSC culture. During the progress of *in vitro* culture, junctions can be formed between NSCs, which assemble to form neurospheres, through cytoskeletal protein and calnexin induced cell-cell adhesion mediation[20]. For neurospheres formed through primary culture or passage culture carried out for two to three days, the junction between NSCs is relatively loose making dissociation and formation for single floating cells easy. However, an analysis of the grow curve over this period displayed that passaging which is carried out when NSCs entered the logarithmic growth phase from the incubation phase might destroy the rapid amplification of NSCs resulting in passaged NSCs' repeated incubating and missing the optimal timing for amplification and at last failure to yielding sufficient NSCs in a short time. On the fourth to fifth day of primary culture or subculture, the number of NSCs increased significantly, the volume of neurospheres grew bigger and cell-cell junctions became tight when the junctions were still able to be dismantled by some means to obtain single cells comfortably. Notably, cell culture gradually reached a plateau period with anchoring cell-cell junctions over time. Oppositely, when the primary or passage culture last for seven to eight days, cell-cell junctions would become so tight that it was difficult to cleave or dissociate. Forced disconnection might end up with NSC damage, dissolution, death, adherence and differentiation. Furthermore, it was observed that the number of neurospheres decreased with their increasing volume suggesting the bulked volume of neurospheres might arise from neurosphere fusion instead of large amplification of NSCs. This can be interpreted as with the increasing volume of neurospheres, it is difficult for the cells within the spheres to contact the culture medium, which then prevents cells within the spheres from absorbing nutrition and affecting the process of metabolism, causing decline in the proliferation abilities of cells within the neurospheres, death of a large number of cells and generation of necrotic cores[21]. From this view, balance should be reached between easy dissociation of neurospheres into single cells and rapid amplification of NSCs without damaging the proliferation abilities of cells within spheres by the excessive volume of neurospheres or causing death during the choice of timing for NSC passage. After summarizing the results of experiments, it is believed that the optimal timing for NSC passage is on the fourth to fifth day of primary or passage NSC culture.

Currently, the commonly used methods for passaging are enzymatic digestion method and mechanical method. After analyzing the investigations[4,7,8], the present study discovered that: (1) Although mechanical method alone is easy to operate and needs a very few of centrifugation, the force and times of tapping and pipetting is difficult to control and it increases the probability of mechanical damage to cells, which is not conducive to the experimental operation; (2) for enzymatic digestion method, trypsin is mainly used. However, the effect of trypsin in digestion is likely to cause chemical damage to NSCs. Moreover, usage of serum or enzyme inhibitor to counteract the digestive effect of trypsin may reduce the vitality and proliferation rate of NSCs and then influence the experimental results; (3) concerning the combination of enzymatic digestion method and mechanical tapping and pipetting method, in spite of a very few of blasting is needed and small scale of blasting can dissociate neurospheres into single-cell suspensions, it does not elevate the number of single cells while the amplification capability of NSCs and number of neurospheres decrease significantly; and (4) in terms of TrypL™ Express digestion method combined with mechanical tapping and pipetting method, TrypL™ Express, a high purity recombinant enzyme, has trypsin-like property, which cleaves peptide bonds on the C-terminal sides of lysine and arginine. TrypL™ Express has high thermostability compared with trypsin. There is no need to use serum or enzyme inhibitor to compromise its digestive effect. Instead, the effect of TrypL™ Express is mild with less toxicity. However, the action of TrypL™ Express should not last long. This study used TrypL™ Express combined with mechanical tapping and pipetting methods as the passaging method. Using this passaging method, sufficient regular shaped, even sized sheen floating single cells were harvested. What's more, cell culture medium is clear with few fragments and elemental impurities, and NSCs holds vigorous growth and proliferation abilities. After observing the process of NSC culture post passaging, it discovered proper sized and good shaped colony-like neurospheres. Based on this, this study recommend using TrypL™ Express combined with mechanical tapping and pipetting method as the method for NSCs passaging.

Additionally, immunofluorescence staining was used to identify whether the cultured cells derived from newborn rats' brains were NSCs. The 5th generation of passaged cells showed positive after both BrdU immunofluorescence staining and nestin immunofluorescence staining. BrdU, a thymidine analog, can incorporate into newly synthesized DNA during the S-phase of the cell cycle[22]. Its property of continuous self-replication and self-reproduction by stem cells makes it take in labeled Brdu during replication. Thus, when immunocytochemical detection is carried out, BrdU positive suggests the cells are in the division and proliferation phrase. Accordingly, NSCs' potential of division and proliferation can be identified by Brdu detention. Nestin, also called NES, is a major cytoskeletal protein in stem cells in the mammalian CNS and its expression is inversely associated with cell differentiation[23-25]. Nestin is a specific biomarker for NSCs and functions as one of factors to identify NSCs. However, nestin is also expressed in pancreatic progenitor cells and endodermal cells. Therefore, nestin positive cells are not necessarily NSCs. The identification of NSCs cannot only based on a certain feature. Apart from nestin immunofluorescence staining, specific biomarkers for NSC differentiation should be considered. The present study selected neuron-specific biomarkers NF200 and NSE and astrocyte-specific biomarker GFAP respectively for the identification of muti-differentiation of NSCs. This study used immunofluorescence staining for the detection of cultured cells derived from newborn rat brains in respect of the above described some characteristics of NSCs. It was observed that the 5th generation of passaged culture cells showed BrdU positive after BrdU immunofluorescence staining and nestin positive after nestin immunofluorescence staining. NF-200, NSE, GFAP positive cells were discovered following immunofluorescence staining at five days after induction of dissociation was performed in 5% fetal bovine serum. This implied that the cultured cells fulfil the criteria for NSC identification - expression of nestin, abilities of differentiation, renewal and proliferation and moreover the capabilities of dissociation. The composition of all these factors can demonstrate the cultured cells are NSCs.

There still are limitations on the development of methodologies to efficiently isolate, culture, and identify NSCs *in vitro*, and evaluating these obtained NSCs is the precondition for its clinical application. Further studies should try to find relevant influencing factors behind these issues.

CONCLUSION

Above all, the approaches used in this study yields sufficient purified NSCs, which then are employed for the further study of NSCs.

ARTICLE HIGHLIGHTS

Research background

The present study explores to establish a simplified and efficient method for culture and identification of neural stem cells (NSCs) derived from newborn rats in the aspects of timing of passaging, passage number, passaging approaches and methods for cell identification.

Research motivation

The study of NSCs is crucial for it will provide important insight into understanding and treating brain disorders. Efficient way to harvest sufficient neural stem cells will facilitate the use of NSCs in clinical scenarios.

Research objectives

This study aimed to explore a more effective protocol for culturing and identifying NSCs derived from newborn rats.

Research methods

Passaging of brain tissues sections dissected from new born rats (2 to 3 d) was conducted using TrypL™ Express combined with mechanical tapping and pipetting techniques. After five passages, NSCs as well as the revived NSCs from cryopreservation were identified. BrdU incorporation method was used to detect self-renew and proliferation capabilities of cells. Different NSCs specific antibodies (anti-nestin, NF200, NSE and GFAP antibodies) were used to identify NSCs specific surface markers and muti-differentiation capabilities with immunofluorescence staining.

Research results

With TrypL™ Express combined with mechanical tapping and pipetting techniques, spherical-shaped cell clusters were successfully obtained. When BrdU was incorporated into the 5th generation of passaged cells, positive BrdU cells and nestin cells were observed by immunofluorescence staining. After induction of dissociation using 5% fetal bovine serum, positive NF200, NSE and GFAP cells were

observed by immunofluorescence staining.

Research conclusions

The present study developed a simplified and efficient method for neonatal rat brain-derived neural stem cell culture and identification.

Research perspectives

First, there still are limitations on the development of methodologies to efficiently isolate, culture, and identify NSCs *in vitro*. Second, evaluating these obtained NSCs is the precondition for its clinical application. Further studies should try to find relevant influencing factors behind these issues.

Abstract

BACKGROUND

Bone marrow-derived mesenchymal stem cells (MSCs) show podocyte-protective effects in chronic kidney disease. Calycosin (CA), a phytoestrogen, is isolated from *Astragalus membranaceus* with a kidney-tonifying effect. CA preconditioning enhances the protective effect of MSCs against renal fibrosis in mice with unilateral ureteral occlusion. However, the protective effect and underlying mechanism of CA-pretreated MSCs ($MSCs^{CA}$) on podocytes in adriamycin (ADR)-induced focal segmental glomerulosclerosis (FSGS) mice remain unclear.

AIM

To investigate whether CA enhances the role of MSCs in protecting against podocyte injury induced by ADR and the possible mechanism involved.

METHODS

ADR was used to induce FSGS in mice, and MSCs, CA, or MSCs^{CA} were administered to mice. Their protective effect and possible mechanism of action on podocytes were observed by Western blot, immunohistochemistry, immunofluorescence, and real-time polymerase chain reaction. *In vitro*, ADR was used to stimulate mouse podocytes (MPC5) to induce injury, and the supernatants from MSC-, CA-, or MSCs^{CA}-treated cells were collected to observe their protective effects on podocytes. Subsequently, the apoptosis of podocytes was detected *in vivo* and *in vitro* by Western blot, TUNEL assay, and immunofluorescence. Overexpression of Smad3, which is involved in apoptosis, was then induced to evaluate whether the MSCs^{CA}-mediated podocyte protective effect is associated with Smad3 inhibition in MPC5 cells.

RESULTS

CA-pretreated MSCs enhanced the protective effect of MSCs against podocyte injury and the ability to inhibit podocyte apoptosis in ADR-induced FSGS mice and MPC5 cells. Expression of p-Smad3 was upregulated in mice with ADR-induced FSGS and MPC5 cells, which was reversed by MSC^{CA} treatment more significantly than by MSCs or CA alone. When Smad3 was overexpressed in MPC5 cells, MSCs^{CA} could not fulfill their potential to inhibit podocyte apoptosis.

CONCLUSION

MSCs^{CA} enhance the protection of MSCs against ADR-induced podocyte apoptosis. The underlying mechanism may be related to MSCs^{CA}-targeted inhibition of p-Smad3 in podocytes.

Key Words: Calycosin; Mesenchymal stem cells; Focal segmental glomerulosclerosis; Apoptosis; Smad3

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Calycosin (CA)-pretreated mesenchymal stem cells (MSCs^{CA}) enhanced the protective effect of MSCs against adriamycin (ADR)-induced podocyte injury *in vitro* and *in vivo* by inhibiting apoptosis, accompanied by more reversal of the upregulated expression of p-Smad3 after ADR induction. Smad3 overexpression eliminated the inhibitory effect of MSCs^{CA} on podocyte apoptosis, suggesting that MSCs^{CA} inhibit podocyte apoptosis by targeting p-Smad3. These results broaden our understanding of the potential of MSCs pretreated with herbal extract and provide new theories for possible therapeutic mechanisms for ADR-induced focal segmental glomerulosclerosis.

INTRODUCTION

Focal segmental glomerulosclerosis (FSGS) is the most common primary glomerulopathy and the dominant pathological type of chronic kidney disease (CKD)[1,2], associated with high albuminuria and end-stage renal disease (ESRD) with a poor prognosis[3,4]. FSGS is linked with injury or even depletion of podocytes, manifested by the gradual disappearance of podocyte-specific markers such as podocin[5, 6]. As podocyte injury plays a critical role in FSGS progression, protecting podocytes is promising to prevent ESRD in patients with FSGS[7].

Apoptosis of podocytes has been widely studied in previous studies[8-10], and inhibition of podocyte apoptosis has been reported to delay FSGS progression[11]. Podocyte apoptosis is characterized by the loss of Bcl-2 protein and the increase of Bax protein[12,13]. Recently, Smad3-related pathways have been reported to be involved in podocyte apoptosis[14]. However, the underlying mechanism remains unclear, and no specific effective treatment can prevent podocyte apoptosis.

Mesenchymal stem cells (MSCs) are multipotent stem cells that exhibit varying potential for multilineage cell differentiation as well as the capacity for self-renewal[15]. Therefore, using MSCs to treat various diseases is worth exploring[16-18]. MSCs treat diabetic nephropathy by protecting podocytes[19-21], and bone marrow-derived MSC (BMSC) transplantation can attenuate FSGS progression in a rat model of FSGS[22,23]. In addition, the protective effects of MSC derivatives or exosomes on podocytes have also been reported[24,25]. However, the application of MSCs is also

limited. For instance, MSCs may be losing their biological function after being isolated and cultured for a long time. After infusion, MSCs must face harsh environments with various stressors such as inflammation, hypoxia, high acidity, or reduced energy reserve. On this account, preconditioning, genetic modification, and delivering MSCs with biomaterials have been developed[26]. Thus, it is important to explore how MSCs can overcome adverse microenvironments to enhance their therapeutic benefits.

Calycosin (CA), a phytoestrogen with a kidney-tonifying effect, is isolated from *Astragalus membranaceus*. It has been reported that CA is the top component of potentially active compounds for the treatment of nephrotic syndrome[27]. Moreover, CA has also been found to be an active ingredient in the treatment of adriamycin (ADR) nephropathy using network pharmacology combined with transcriptomics[28]. Our research group used Ca-pretreated MSCs to treat mice with unilateral ureteral occlusion (UUO) and found that they improved renal fibrosis and inhibited necrosis of renal tubular epithelial cells more than normal MSCs did[29]. However, the protective effect on podocytes and their mechanism of action remain unknown.

In rodents, ADR can induce rapid podocyte injury characterized by massive foot process effacement and glomerulosclerosis, which serves as a model of FSGS[30,31]. In the present study, we compared the antiapoptotic efficacy of CA-pretreated MSCs ($MSCs^{CA}$) to that of MSCs or CA in a mouse model of FSGS induced with ADR and *in vitro*, as well as the possible mechanisms of action involved.

MATERIALS AND METHODS

Animal experiments

The C57BL/6 mice utilized in this investigation were bought from Chengdu Dashuo Biotechnology Co., LTD. in China. They were male, 8 wk old, and weighed 22-25 g. All the mice were kept in a specific disease-free space with 12 h of light and dark cycles and had free access to water and food. The mice were randomly divided into the following six groups: Normal control group; ADR injection group; ADR with Dulbecco's modified Eagle's medium (DMEM; 200 μL) injection (ADR + DMEM); ADR with 200 μL MSCs (10^6 cells/mL) (ADR + MSCs); ADR with 200 μg/mL CA (10^6 cells/mL) (ADR + CA); and ADR with MSCs preconditioned with 200 μg/mL CA (10^6 cells/mL) (ADR + $MSCs^{CA}$). For ADR-induced FSGS, the mice were injected with 10 mg/kg ADR (Shenzhen Main Luck Pharmaceuticals Inc.) *via* the tail vein. The normal control mice were injected with vehicle (saline). MSCs, CA dissolved in DMEM, and $MSCs^{CA}$ were injected *via* the tail vein 4 wk after ADR injection once weekly. Since both MSCs and CA are soluble in DMEM, mice in the ADR + DMEM group were given an equal volume of normal DMEM as the solvent control. All mice were killed at 8 wk after ADR injection. All animal experiments were carried out in accordance with the recommendations of the Institute of Nutrition and Health's Animal Care and Utilization Committee, and were approved by the Southwest Medical University's Animal Ethics Committee (No. 20210223-024).

Isolation of MSCs

As previously described, MSCs were isolated from the leg bone marrow of male C57BL/6 mice aged 6-8 wk[32]. Briefly, cells were grown at 37 °C and 5% CO_2 in DMEM Petri plates with 10% fetal bovine serum (FBS, Gibco, Carlsbad, CA, United States), 1 g/L glucose, and 1% penicillin-streptomycin (Beyotime, Shanghai, China). At 24 h, the medium was changed to remove the non-adherent cells. The MSCs were passed once 90% confluence was reached. As described previously[26], anti-CD29 (102205; Biolegend), anti-CD90 (ab24904; Abcam, Cambridge, MA, United States), and anti-CD11b (101205; Biolegend, San Diego, CA, United States) antibodies were used to label MSCs, and the purity of the MSCs was analyzed using a BD FACSVerse (Becton, Dickinson and Company, Franklin Lakes, NJ, United States).

CA pretreatment of MSCs

CA (≥ 94% purity) was purchased from Cayman Chemical Company (Ann Arbor, MI, United States). The stoste used for MSC pretreatment included full medium and CA (200 g/mL) dissolved in DMEM as previously described[29]. After incubation for 72 h, the MSCs and $MSCs^{CA}$ were injected into mice, and the supernatants were used to treat mouse podocytes (MPC5) for 48 h.

Urine albumin-creatinine ratio

Random urine samples were collected, followed by determining the albumin concentration with a mouse albumin ELISA kit (Sangon Biotech, China) and creatinine with a creatinine assay kit (Nanjing Jiancheng, Jiangsu Province, China). The urine albumin-creatinine ratio was calculated by dividing the urine albumin concentration by the creatinine concentration.

Hematoxylin-eosin staining

Mouse kidneys were fixed in 4% neutral formaldehyde followed by paraffin embedding. The paraffin sections were rehydrated in a graded ethanol series and subjected to hematoxylin-eosin (HE) staining

(Beyotime, Shanghai, China) as previously described[33].

Immunohistochemistry

The sections underwent antigen retrieval in 0.01 M citric acid solution (pH 6.0) in a microwave oven for 10 min after deparaffinization and rehydration. To inhibit endogenous peroxidase, the slices were incubated with 5% H_2O_2 for 15 min. The sections were then further blocked for 30 min at room temperature with 5% bovine serum albumin (BSA), and then incubated overnight at 4 °C with anti-p-Smad3 antibody (C25A9; Cell Signaling Technology, Danvers, MA, United States). The slices were treated with secondary antibodies for 1 h at room temperature following PBS washing. Images were recorded with a light microscope (Eclipse 80i; Nikon, Japan).

TUNEL assay

TUNEL assay was used to evaluate podocyte apoptosis in the kidneys after ADR induction, as previously described[34]. After the mouse kidneys were fixed in 4% neutral formaldehyde followed by paraffin embedding, the paraffin sections were used for staining. Podocyte apoptosis was measured through the utilization of a One-step TUNEL In Situ Apoptosis Assay Kit (AF488; Green) (E-CK-A321; Elabscience, China). The images were captured with an orthotopic fluorescence microscope (DM4B; Leica, Germany).

Cell culture and treatment

Prof. San-Tao Ou (Department of Nephrology, Southwest Medical University) kindly donated the conditionally immortalized MPC5 cell line. The cells were grown at 33 °C in RPMI-1640 medium supplemented with 10 IU/mL recombinant interferon and 10% FBS. After the MPC5 cells were cultured at 37 °C for 14 d to induce differentiation, the differentiated cells were treated with different concentrations of ADR for 24 h. A Smad3 overexpressing MPC5 cell line was established with the Smad3 overexpression plasmid pcDNA3.1-Smad3 which was described previously[35].

Immunofluorescence

After treatment, the MPC5 cells or frozen sections were fixed with 4% paraformaldehyde for 10 min, permeabilized with 0.25% Triton X-100 (in PBS), and blocked with 5% BSA for immunofluorescence. After that, the frozen sections or MPC5 cells were incubated with anti-podocin (BA0290; Boster, Wuhan, China), anti-Bax (AF0120; Affinity, United States), and anti-Bcl-2 (AF6139; Affinity) antibodies at 4 °C overnight. After washing with PBS, the frozen sections or MPC5 cells were incubated with Alexa Fluor 594 Donkey anti-mouse/rabbit secondary antibodies (Thermo Fisher Scientific, Waltham, MA, United States) for 1 h at room temperature. The nuclei were stained with 4¢,6-diamidino-2-phenylindole (Sangon Biotech). Images were captured with a fluorescence microscope (EVOS FL Auto, Thermo Fisher Scientific, United States).

Real-time quantitative polymerase chain reaction

TRIzol reagent (Invitrogen, Carlsbad, CA, United States) was used to separate total RNA from cells or kidneys, and a Reverse Transcription Kit (Promega, Madison, WI, United States) was used to obtain cDNA. Using Master Mixture (TaKaRa, Dalian, China) and LightCycler 480 equipment (Roche, Germany), the podocin mRNA expression levels were assessed. The internal control used was GAPDH. Using $2^{-\Delta\Delta Ct}$ analysis, the relative expression of the target gene was standardized to GAPDH expression. The primer sequences used are shown in Supplementary Table 1.

Western blot analysis

Using RIPA lysis buffer (Beyotime), total proteins were extracted from kidneys or cells. The protein concentrations were determined with a BCA protein assay kit (Beyotime). Proteins were transferred onto polyvinylidene difluoride membranes after being separated by 12% SDS-PAGE. Then the membranes were incubated with anti-podocin (BA0290; Boster), anti-p-Smad3 (C25A9; Cell Signaling Technology), anti-Smad3 (C67H9; Cell Signaling Technology), anti-Bax (AF0120; Affinity), anti-Bcl-2 (AF6139; Affinity), and anti-GAPDH (AB0037; Abways, China) antibodies at 4°C overnight. The membranes were treated with the relevant secondary antibody at room temperature for 1 h after being rinsed with Tris-buffered saline with Tween (TBST). The protein bands were depicted with an enhanced ECL kit (Boster) and a chemiluminescence imaging system (ChemiScope 6200; Clinx, China). ImageJ software (NIH, Bethesda, MD, United States) was used to calculate the band gray intensity.

Apoptosis detection by flow cytometry

The cells were digested with trypsin-EDTA solution (C0201; Beyotime), collected in a centrifuge tube, and centrifuged for 5 min at 1800 rpm, and the supernatant was discarded. The cells were resuspended with 1 mL precooled PBS. According to the Annexin V-FITC/PI Apoptosis Detection kit's instructions (Vazyme, Nanjing, China), the prepared propyl iodide staining solution was added to the cells and incubated at 37 °C for 10 min without light. Red fluorescence was detected at an excitation wavelength of 488 mm and light scattering was detected with a BD FACSVerse (Becton, Dickinson).

Statistical analysis

The mean and standard deviation of the data are displayed. Using SPSS 21.0 software (IBM Corp., Chicago, IL, United States), one-way analysis of variance was used to compare the data. $P < 0.05$ was considered statistically significant.

RESULTS

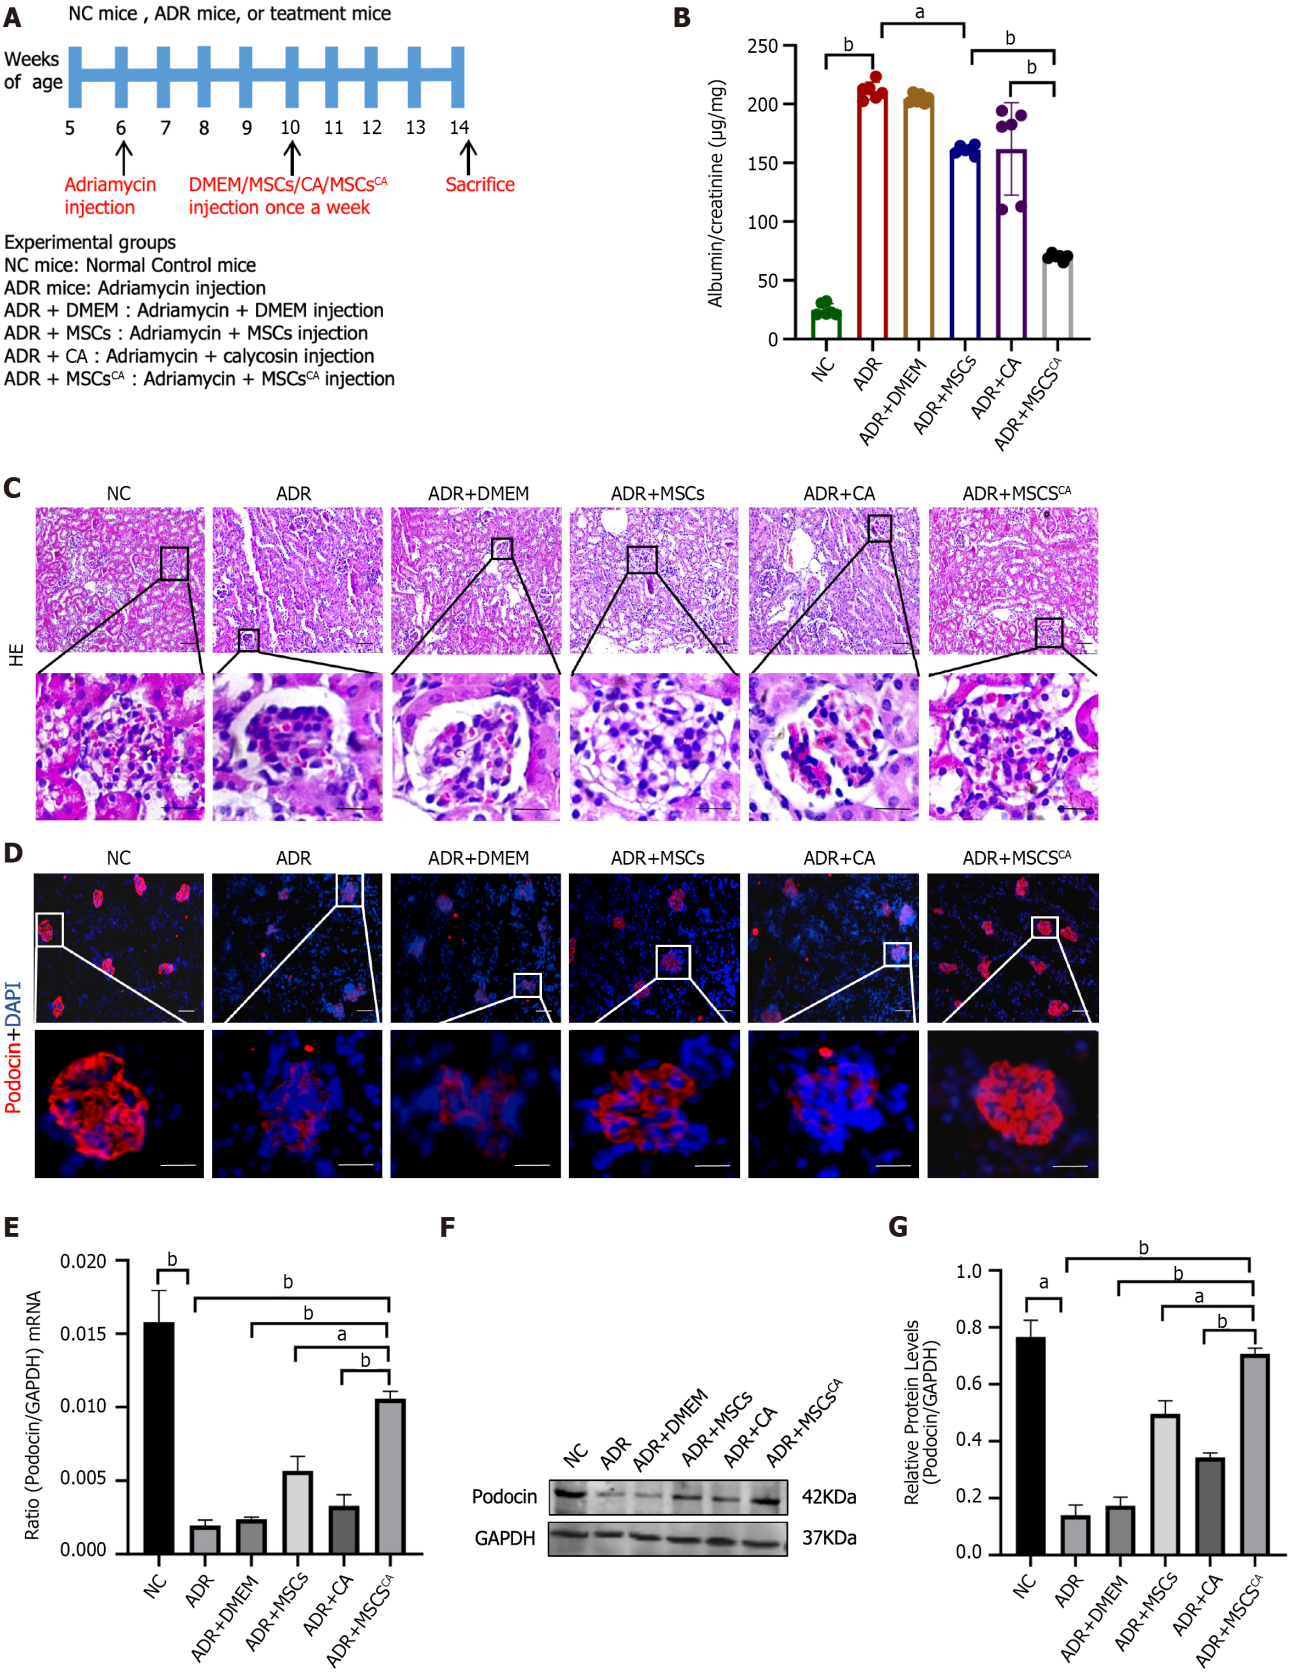
MSCs^{CA} enhance the protective effect of MSCs on podocyte injury in ADR-induced FSGS

To investigate whether CA pretreatment enhances the protective effect of MSCs on podocyte injury in ADR-induced FSGS mice, we treated mice with MSCs, CA, or MSCs^{CA}. Due to MSCs, CA, and MSCs^{CA} being dissolved in DMEM, a DMEM group was separately designed as the solvent control group to exclude the protective effect of DMEM-containing nutrients on podocytes (Figure 1A). The identification of MSCs, the chemical formula of CA, and its appropriate concentration can be found in our previous research[26]. Eight weeks after ADR injection, increased urinary albumin excretion was detected in ADR-treated mice, and MSCs^{CA} reversed this more significantly than MSCs or CA alone. However, there was no difference between the DMEM group and the model group (Figure 1B). HE staining showed that glomerular atrophy and FSGS were prominent in the ADR and DMEM groups, but MSCs^{CA} treatment reversed this change and was superior to MSCs and CA treatment (Figure 1C). Immunostaining, real-time quantitative polymerase chain reaction (RT-PCR), and Western blot analysis showed that the expression of podocin, a podocyte-specific marker, was significantly reduced in the ADR and DMEM groups; however, MSCs^{CA} treatment best restored its expression (Figure 1D-G). The above evidence indicated that MSCs^{CA} treatment better protected podocytes from ADR injury in FSGS mice.

The capacity of MSCs to prevent apoptosis in ADR-induced FSGS is improved by CA pretreatment

To determine the effect of MSCs^{CA} on renal cell apoptosis, Western blot and TUNEL assay were performed. Expression of Bax protein as an apoptosis marker was significantly increased in the ADR and DMEM groups compared with the normal group, and their levels were reduced after MSC or CA treatment (Figure 2A and B). MSCs^{CA} reduced ADR-induced Bax protein expression more significantly than MSCs or CA. The changing trend in Bcl-2 protein expression was opposite to that of Bax in each group (Figure 2A and C). TUNEL assay showed an obvious increase in the brightness and range of green fluorescence in the ADR group, which was weakened by MSCs^{CA} treatment (Figure 2D). The above data indicated that MSCs^{CA} enhanced the antiapoptotic effect of MSCs on kidney cells of ADR-induced FSGS mice.

P-Smad3 is upregulated in podocytes of ADR-induced FSGS mice and reversed after MSCs^{CA} treatment

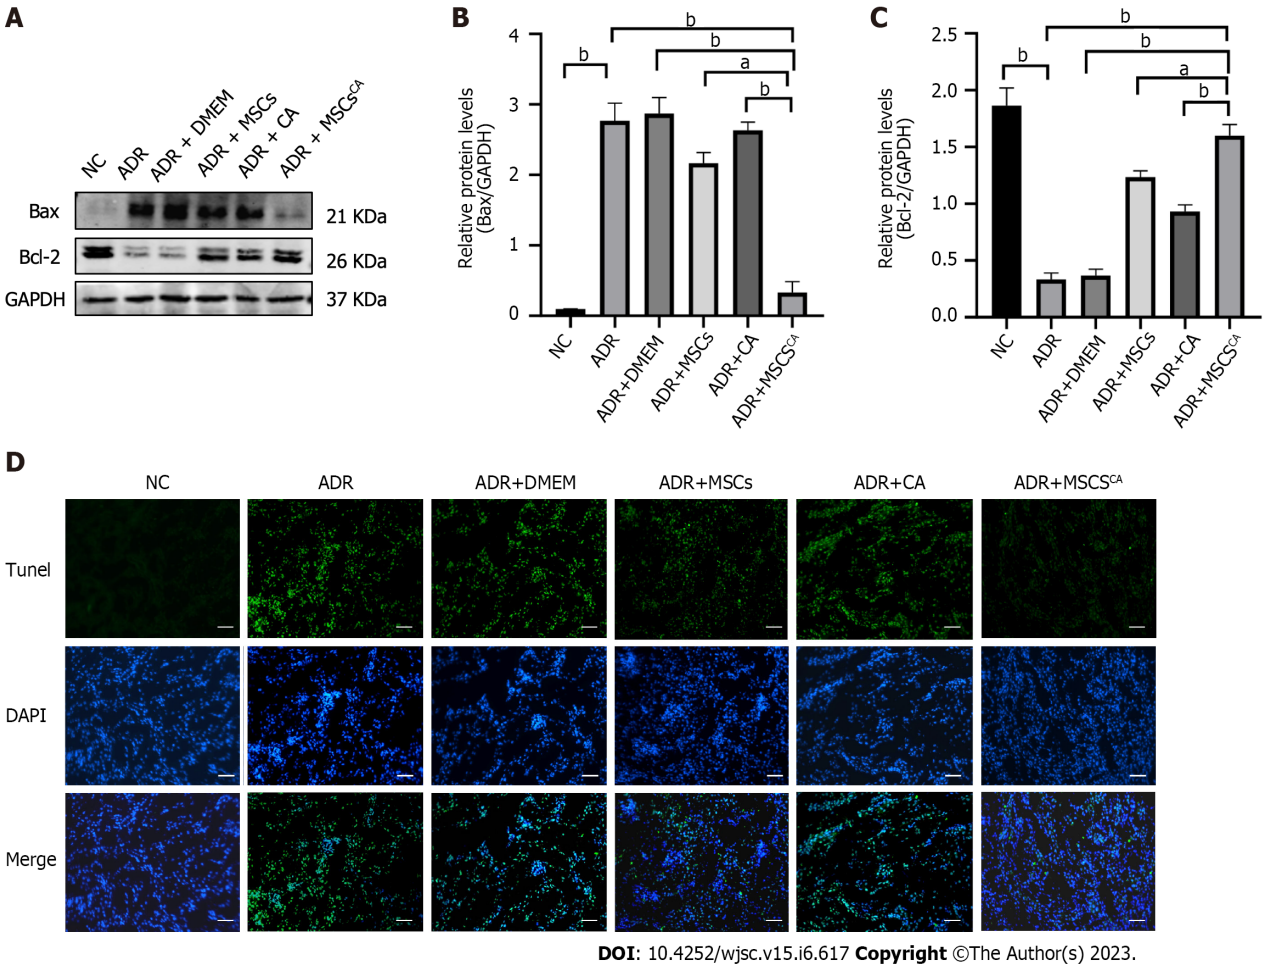


It has been reported that the Smad3 protein is involved in podocyte apoptosis[13], so we examined the effect of MSCs^{CA} on the expression of Smad3 and p-Smad3 proteins. As expected, we found by Western blot and immunohistochemistry that MSCs^{CA} treatment significantly reversed the upregulation of p-Smad3 in ADR-treated mouse renal podocytes, and the effect was superior to that of MSC and CA treatment (Figure 3). The above evidence suggested that p-Smad3 was involved in the ADR-induced injury of podocytes and the recovery after MSCs^{CA} treatment.

The capacity of MSCs to reduce the injury caused by ADR-stimulated MPC5 cells in vitro is improved by CA pretreatment

To further demonstrate the enhanced potential of MSCs^{CA} to protect podocytes from ADR injury, we cultured and treated MPC5 cells. Immunofluorescence staining, RT-PCR, and Western blot showed that 1.2 μM/mL ADR decreased the expression of podocin mRNA and protein, while the expression was significantly promoted by treatment with conditioned medium from MSCs, or CA. Importantly, conditioned medium from MSCs^{CA} further elevated the expression of podocin mRNA and protein compared with the ADR group (Figure 4). Therefore, MSCs^{CA} protected podocytes from ADR injury better than MSCs or CA alone.

CA pretreatment enhances the ability of MSCs to inhibit apoptosis in ADR-stimulated MPC5 cells



Immunofluorescence staining and Western blot demonstrated that the protein level of Bax was upregulated in MPC5 cells treated with ADR, but its expression was significantly inhibited by treatment with a conditioned medium from MSCs, or CA alone (Figure 5). The effects of the conditioned medium from MSCs^{CA} were more pronounced. The trend for Bcl-2 protein expression was the opposite. These findings revealed that Ca-pretreated MSCs enhanced the inhibitory effect of MSCs on podocyte apoptosis.

MSCs^{CA} improve ADR-induced podocyte apoptosis by targeting p-Smad3 expression

As described previously, p-Smad3 is involved in ADR-induced FSGS mice. Further experiments were conducted to explore whether MSCs^{CA} inhibit podocyte apoptosis by targeting p-Smad3. Expression of p-Smad3 in MPC5 cells was markedly elevated by ADR stimulation and subsequently significantly downregulated by MSCs^{CA} treatment. The upregulated expression of p-Smad3 was also reversed by MSCs or CA, but to a lesser extent (Figure 6A and B). When Smad3 accompanied by p-Smad3 in MPC5 cells was overexpressed, Bax protein expression was upregulated but Bcl-2 protein expression was downregulated. Meanwhile, MSCs^{CA} treatment no longer showed a protective effect against ADR-induced podocyte apoptosis compared with the group without Smad3 overexpression (Figure 6C-G). Flow cytometry was used to detect apoptosis, and it was found that the apoptosis rate of MPC5 cells was significantly increased after ADR induction compared with the normal group, and MSCs^{CA} reversed this increase. However, after overexpression of Smad3, the apoptosis rate was increased compared with the normal group and the model group regardless of whether MSCs^{CA} were administered. This means that treatment with MSCs^{CA} did not improve the apoptosis of podocytes with Smad3 overexpression (Figure 6H-L). The graphical abstract (created in BioRender.com) is shown in Figure 6M. The above evidence suggested that MSCs^{CA} improved podocyte apoptosis through targeted inhibition of p-Smad3.

DISCUSSION

Increasing evidence has shown that MSCs and derived extracellular vesicles can ameliorate renal deterioration in CKD[36,37]. However, because of a hostile environment with several stresses such as inflammation, high acidity, hypoxia, and depleted energy reserve, few MSCs survive *in vivo* after intravenous or direct local injection[38-40]. The question of whether preconditioning BMSCs can shield them from the damaging environment at the injury site and enhance their functionality has drawn more attention in research. These pretreatments involve the application of supportive materials, cytokines, and natural or synthetic chemicals[41-44]. Researchers have been investigating the preconditioning of MSCs using Chinese herbal medicine or its primary monomer components. There is evidence that resveratrol-pretreated adipose-derived stem cells show increased regenerative capacity in a rat model of diabetes-induced cardiomyopathy[45]. Further research has shown that preconditioning MSCs obtained from umbilical cords with the active ingredient of a Chinese herb, triptolide, primed MSCs to be activated and inhibited the immune response before being delivered[46]. Previous results from our group have also shown that CA-pretreated BMSCs show enhanced antifibrotic activity in UUO mice and inhibit tubular epithelial cell necrosis[29]. Therefore, we investigated whether MSCs^{CA} enhance podocyte protection. Similar to previous studies, MSCs^{CA} protected podocytes from ADR-induced apoptosis, both *in vivo* and *in vitro*, which means that they may be a potential therapy for FSGS.

CA is the top ingredient in *Astragalus*, which is one of the most widely used herbs in Chinese medicine to treat kidney disease[47-49]. The effectiveness of CA in CKD has been confirmed in recent years[50-52]. However, whether its combination with MSCs can enhance their efficacy in treating CKD remains to be seen. It has been shown that human MSCs are stimulated to enhance osteogenesis and mineralization by CA-7-O-glucoside obtained from *Astragalus membranaceus*[53]. This result gave us confidence and we also identified the advantages and potential of MSCs^{CA} in the treatment of FSGS, which extends the application of CA and MSCs in FSGS.

The main pathological manifestations of FSGS are podocyte injury and the therapeutic options for FSGS are limited, requiring further research and exploration. Therefore, we explored the mechanism of podocyte injury. Podocyte apoptosis is the main type of podocyte injury, which includes podocyte dedifferentiation, autophagy, and epithelial-mesenchymal transformation[54]. Podocyte apoptosis is caused by many factors, including drugs, infection, and immune disorders[55-57]. ADR is one of the

drugs that causes podocyte apoptosis due to its pharmacological action and distribution[58]. However, how to protect podocytes from ADR needs further research to find more effective targeted drugs.

Smad3 is involved in apoptosis, and podocytes are no exception[59,60]. Activation of Smad3 and its related pathway proteins induces podocyte apoptosis[14,61]. The canonical Smad pathway is a crucial regulatory route in the etiology of renal inflammation and fibrosis, according to earlier research. Major receptor-associated Smads include Smad2 and Smad3. Mad-homology 2 domain is located at the C-terminus of Smad3, which has unique phosphorylation sites and sequences triggered by transforming growth factor (TGF)-β1. The binding of phosphorylated Smad3 to TGF-β1 signaling receptors promotes fibrosis[62]. Our study showed that MSCs^{CA} significantly downregulated the expression of p-Smad3 in the kidneys of ADR-induced FSGS mice and ADR-induced MPC5 cells. Subsequently, we overexpressed Smad3 in MPC5 cells and confirmed that MSCs^{CA} targeted inhibition of p-Smad3 to improve podocyte apoptosis using rescue experiments. This provides a new possible mechanism and target for preventing podocyte apoptosis by MSCs^{CA}.

There were some limitations to this study. Although we have revealed that MSCs^{CA} improve podocytes apoptosis by inhibiting Smad3 signaling, this study still has certain limitations and the underlying mechanism deserves further exploration. First, how does MSCs^{CA} intervene in the Smad3 signal, directly or indirectly? We speculate that CA may activate the anti-apoptotic activity of MSCs or affect the differentiation, mobilization, and homing of BMSCs as well as the abundance of beneficial exosomes, but the main mechanism and responsible factors are still unknown. Second, it is still unclear which molecules in podocytes respond to the activity of MSCs and what are their potential relationship with Smad3. Understanding these mechanisms is conducive in expanding the application of MSCs^{CA}, and we will answer each question one by one in future research.

CONCLUSION

This study showed that MSCs^{CA} improve ADR-induced podocyte apoptosis by targeting Smad3 inhibition, and are superior to MSCs or CA. Thus, our study provides a new perspective on the synergistic application of MSCs and a new theory for the mechanism of improvement of podocyte apoptosis.

ARTICLE HIGHLIGHTS

Research background

Focal segmental glomerulosclerosis (FSGS) has become a global public health problem due to its high incidence and lack of treatment. Prevention of podocyte apoptosis is essential in the treatment of FSGS. Bone marrow-derived mesenchymal stem cells (BMSCs) have been found to protect podocytes, but have some limitations, such as low survival rate *in vivo* and poor homing function. In our previous study, calycosin (CA)-pretreated BMSCs enhanced the antifibrotic activity in kidneys compared with BMSCs. Therefore, CA-pretreated MSCs are expected to be a new method to protect podocytes in the treatment of FSGS.

Research motivation

Although MSCs have been confirmed to improve podocyte apoptosis in mice, their availability and effectiveness *in vivo* are limited. Currently, there is still a lack of effective therapeutic methods for FSGS, and their mechanism of action is not clear.

Research objectives

To evaluate the therapeutic effect of CA-pretreated BMSCs in a mouse model of adriamycin (ADR)-induced FSGS *in vivo* and MPC5 cells *in vivo*.

Research methods

MSCs^{CA} were compared with MSCs or CA to observe their inhibitory effects on podocyte apoptosis in mice with ADR-induced FSGS *in vivo* and ADR-treated MPC5 cells *in vitro*, to explore the possible mechanism by which MSCs^{CA} improves podocyte apoptosis.

Research results

In vivo results showed that MSCs^{CA} reduced podocyte apoptosis, improved podocyte injury and depletion, alleviated glomerulosclerosis and albuminuria, and downregulated p-Smad3 expression in ADR-induced FSGS mice, which were superior to MSCs and CA. Similar to *in vivo* studies, MSCs^{CA} alleviated ADR-induced apoptosis of MPC5 cells more significantly than MSCs and CA. Through rescue experiments, we found that the potential of MSCs^{CA} to protect podocytes may be realized through targeted inhibition of p-Smad3 expression.

Research conclusions

MSCs^{CA} improve ADR-induced podocyte apoptosis by targeting Smad3 inhibition, which are superior to MSCs or CA.

Research perspectives

Our findings provide a new potential strategy for the treatment of FSGS.

Abstract

BACKGROUND

Induced pluripotent stem cells (iPSCs) show great ability to differentiate into any tissue, making them attractive candidates for pathophysiological investigations. The rise of organ-on-a-chip technology in the past century has introduced a novel way to make *in vitro* cell cultures that more closely resemble their *in vivo* environments, both structural and functionally. The literature still lacks consensus on the best conditions to mimic the blood-brain barrier (BBB) for drug screening and other personalized therapies. The development of models based on BBB-on-a-chip using iPSCs is promising and is a potential alternative to the use of animals in research.

AIM

To analyze the literature for BBB models on-a-chip involving iPSCs, describe the microdevices, the BBB *in vitro* construction, and applications.

METHODS

We searched for original articles indexed in PubMed and Scopus that used iPSCs to mimic the BBB and its microenvironment in microfluidic devices. Thirty articles were identified, wherein only 14 articles were finally selected according to the inclusion and exclusion criteria. Data compiled from the selected articles were organized into four topics: (1) Microfluidic devices design and fabrication; (2) characteristics of the iPSCs used in the BBB model and their differentiation conditions; (3) BBB-on-a-chip reconstruction process; and (4) applications of BBB

microfluidic three-dimensional models using iPSCs.

RESULTS

This study showed that BBB models with iPSCs in microdevices are quite novel in scientific research. Important technological advances in this area regarding the use of commercial BBB-on-a-chip were identified in the most recent articles by different research groups. Conventional polydimethylsiloxane was the most used material to fabricate in-house chips (57%), whereas few studies (14.3%) adopted polymethylmethacrylate. Half the models were constructed using a porous membrane made of diverse materials to separate the channels. iPSC sources were divergent among the studies, but the main line used was IMR90-C4 from human fetal lung fibroblast (41.2%). The cells were differentiated through diverse and complex processes either to endothelial or neural cells, wherein only one study promoted differentiation inside the chip. The construction process of the BBB-on-a-chip involved previous coating mostly with fibronectin/collagen IV (39.3%), followed by cell seeding in single cultures (36%) or co-cultures (64%) under controlled conditions, aimed at developing an *in vitro* BBB that mimics the human BBB for future applications.

CONCLUSION

This review evidenced technological advances in the construction of BBB models using iPSCs. Nonetheless, a definitive BBB-on-a-chip has not yet been achieved, hindering the applicability of the models.

Key Words: Induced pluripotent stem cells; Cell differentiation; Blood-brain barrier; Neurovascular unit; Organ-on-a-chip; Microfluidic device

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: This systematic review provided a current perspective on the applicability of induced pluripotent stem cells within blood-brain barrier (BBB)-on-a-chip with high technology advances in commercial chips and promotion of an efficient human neurovascular unit, able to screen for drugs, mimic brain dysfunctions, such as stroke and Huntington's disease, and suitable for future personalized therapeutic approaches. However, the composition and construction of the BBB models lack consensus in the literature.

INTRODUCTION

Induced pluripotent stem cells (iPSCs) have been largely studied for their numerous applications in drug screening, toxicological studies, cell therapy, and disease modeling[1]. Their relevance may be justified by their resemblance to embryonic stem cells, given their ability to differentiate into any one of the three germ layers: ectoderm, mesoderm, and endoderm[1,2], making them attractive candidates for cell therapy-based regenerative medicine[3].

Different from primary cells, iPSCs are easily attainable and able to mature into almost any desired cell type. In general, they can be formed by reprogramming cells obtained from a tissue biopsy or from more accessible sources such as peripheral blood, renal epithelial cells, or dental pulp[4,5]. These characteristics, as opposed to primary cells, have promoted more reliable models for complex human structures such as the blood-brain barrier (BBB)[6].

The BBB secures the brain with a homeostatic environment, controlling the interaction, communication, and molecular and ion exchange between the central nervous system (CNS) and the peripheral blood[7]. The neurovascular unit (NVU) is generally composed of brain microvascular endothelial cells (BMECs), astrocytes (ACs), and pericytes (PCs), being directly involved in regulating CNS blood flow, and consequently, neuronal activity[8].

Recreating the BBB microenvironment *in vitro* allows for the investigation of barrier dysfunction in neurodegenerative diseases, and drug delivery to the CNS, in addition to the evaluation and screening

of the permeability of substances across the BBB[9,10]. In this regard, classic BBB *in vitro* models have traditionally utilized Transwell® technology, which enables the construction of multicellular models with paracrine interactions between the co-cultures of ECs and ACs or PCs. Notwithstanding its usefulness, Transwell® technology lacks a key element for the *in vivo*-like functioning of ECs: Laminar flow[6,9]. Moreover, many of the existing BBB models employ primary BMECs, immortalized BMECs, or human umbilical vein ECs (HUVECs) as EC-layer cultures. Even though they can constitute fair BBB constructs, access to primary cell sources can be difficult for ethical purposes and immortalized lines often fail to mimic the actual BBB function found *in vivo*[6,9].

In the building of *in vitro* BBB mimics, iPSC-derived BMECs (iBMECs) present improved barrier properties compared to primary BMECs, allowing for the modeling of genetic diseases and personalized therapy approaches[2]. These properties become more apparent when iBMECs are cultured in a complex environment. The traditional *in vitro* culture model, despite being simple and reproducible, fails to mimic cell-cell and cell-extracellular matrix (ECM) interactions[11]. Animal models, which present ideal barrier permeability, transport mechanisms, and morphological characteristics, present low reliability given that 80% of clinical trials fail in drug-delivery tests[12]. These limitations may be overcome with the development of organs-on-a-chip that simulate complex morphology in a three-dimensional (3D) culture[13].

The construction and applications of BBB-on-a-chip using microfluidic devices provide a lower-cost alternative with an impact on ethical issues, allowing for the reduced use of animals, reagents, and sample volume, and also permitting real-time microscopic analysis, with shortened reaction and analysis times, high throughput, automation, and portability[14,15]. Furthermore, from a morphological point of view, the microdevices assure a compatible reproduction of the BBB model due to the presence of laminar flow and shear stress, which convey better maintenance of barrier functions, homeostasis, and transport. This model has already been applied to several studies of neurological disorders such as Alzheimer's disease, stroke, infectious diseases, and brain cancer[15]. Despite being the best alternative for simulation and in-depth study of the BBB, studies involving microfluidic devices lack clear protocols for large-scale manufacturing and adequate liquid perfusion, making the process imprecise and hard to operate, in addition to the difficulty in collecting channel material for detailed assessments[16].

Regarding the construction of BBB *in vitro* models on-a-chip using iPSCs, the literature still lacks a consensus on the best conditions to mimic BBB dysfunction upon CNS disorders and to screen for drugs and other therapeutic approaches. In view of these gaps, this systematic review searched the current literature for examples that meet the abovementioned criteria, that is, iPSCs, BBB models, and microfluidic devices.

MATERIALS AND METHODS

Search strategy

The articles used in this review were identified through searches performed in the PubMed and Scopus databases following the PRISMA guidelines[17]. The following selected criteria of interest, keyword strings ((Induced Pluripotent Stem Cell) AND (Microfluidic Device) AND (Blood-Brain Barrier)) and Boolean operators (DecS/MeSH) were used:

PubMed: (((((((“organs-on-chips”[Title/Abstract]) OR (“organs-on-a-chip”[Title/Abstract])) OR (“microfluidic device”[Title/Abstract])) OR (“lab-on-chips”[Title/Abstract])) OR (microfluidics[Title/Abstract])) AND ((((“blood-brain barrier”[Title/Abstract]) OR (“Brain Blood Barrier”[Title/Abstract])) OR (“Blood Brain Barrier”[Title/Abstract])))) AND ((((“Induced Pluripotent Stem Cell”[Title/Abstract]) OR (“Induced pluripotent stem cells”[Title/Abstract])) OR (iPSC[Title/Abstract])))) NOT (review[Publication Type]);

Scopus: ((TITLE-ABS-KEY (ipsc) OR TITLE-ABS-KEY (“induced pluripotent stem cell”) OR TITLE-ABS-KEY (“induced pluripotent stem cells”))) AND (((TITLE-ABS-KEY (“organs-on-chips”) OR TITLE-ABS-KEY (“organs-on-a-chip”) OR TITLE-ABS-KEY (“microfluidic device”) OR TITLE-ABS-KEY (“lab-on-chips”) OR TITLE-ABS-KEY (microfluidics) OR TITLE-ABS-KEY (“lab-on-chip”))) AND ((TITLE-ABS-KEY (“blood brain barrier”) OR TITLE-ABS-KEY (“brain blood barrier”) OR TITLE-ABS-KEY (“blood-brain barrier”)))) AND (LIMIT-TO (LANGUAGE, “English”)) AND (LIMIT-TO (DOCTYPE, “ar”)).

Inclusion and exclusion criteria

Only original full-text articles written in English have been included, without publication year limit, containing: (1) iPSCs; (2) microfluidic devices; and (3) simulation of the BBB by specialized cells. From the perspective of the Problem, Intervention, Comparison, and Outcome criterion, the addressed Problem was unclear literature on the best conditions to mimic the BBB using microfluidic device technology (BBB-on-a-chip) and IPSCs; the Intervention was to analyze the conditions for BBB-on-a-chip manufacture regarding the design and material for an adequate construction of the NVU with a functional environment for testing; the Comparison was related to conventional analyses; and the Outcome was a microdevice that mimics the BBB applied in neurological conditions or not. The

exclusion of articles followed the following criteria: (1) Book chapters; (2) reviews; (3) duplicate articles in the databases; and (4) a study that did not report the use of iPSCs in the BBB-on-a-chip.

Data extraction

The selected articles under evaluation were analyzed under four topics, which were represented in three tables and one figure that addressed the following characteristics: (1) Microfluidic devices design and fabrication; (2) characteristics of the iPSCs used in the BBB models and their cultivation conditions; (3) iPSC differentiation process into iBMECs for reconstruction of the BBB-on-a-chip model; and (4) applications of BBB microfluidic 3D models using iPSCs.

Data compilation and review

In this systematic review, the preselection of titles was performed by authors Alves ADH and Gamarra LF from the defined search strategies. The ten authors (Alves ADH, Nucci MP, Ennes do Valle NM, Missina JM, Rego GNA, Mamani JB, Dias OFM, Garrigós MM, de Oliveira FA, Gamarra LF), in pairs, independently, and randomly reviewed and analyzed the eligibility of the articles according to the selection criteria mentioned above. In case of discrepancy in study selection between two authors, the criteria were discussed with a third reviewer and resolved.

Ennes do Valle NM and Mamani JB searched for the fabrication and characteristics of microfluidic devices; Alves ADH, Nucci MP, Ennes do Valle NM, Missina JM, and Rego GNA searched for differentiation and characterization protocols for iPSCs; Alves ADH, Nucci MP, Ennes do Valle NM, Missina JM, and Gamarra LF searched for the insertion and manipulation of cells in the microfluidic device; de Oliveira FA, Mamani JB, Dias OFM, and Garrigós MM searched for the objectives and applications of the selected studies. Analyses of data extracted from tables and flowcharts were performed by full peer consensus, respecting the above distribution. In this review, all authors wrote the entire text.

Risk of bias assessment

The selection of articles was performed in pairs and a third independent author decided if the articles should be included. The data selected in the tables were divided by the authors into the groups already described above, and data verification was carried out by the following group. The final inclusion of studies into the systematic review was by agreement of all reviewers.

Data analysis

The variables grouped in the tables and charts were distributed in percentages or range of distribution and used to characterize and illustrate the most frequently used results in this review.

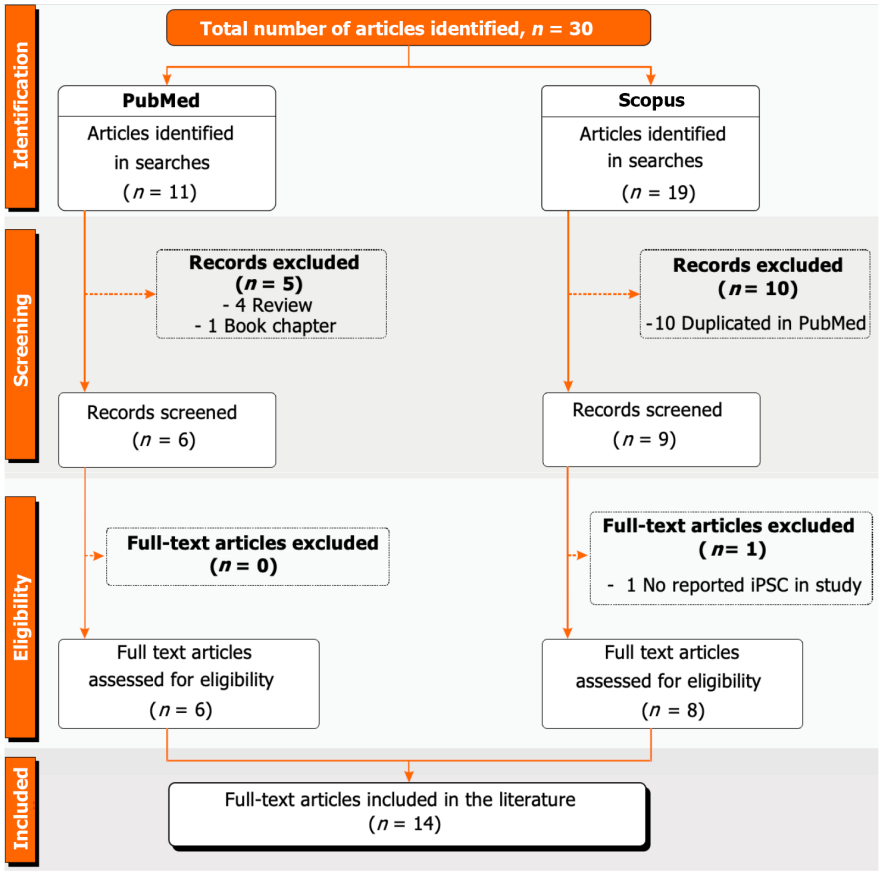
RESULTS

Overview of the reviewed literature

A search was performed based on the abovementioned selection strategy and keywords, resulting in 30 original articles in English: 11 from PubMed and 19 from Scopus. Following the exclusion criteria, 5 of the 11 articles from PubMed were excluded: 4 under the "review article" criterion and 1 under the "book chapter" criterion. Regarding the studies found in Scopus, 10 were manuscripts duplicated by the other database. After the eligibility analysis, only two articles were withdrawn: One for not having reported a study using iPSCs, and the other for not involving BBB functionality. Finally, this systematic review included 14 articles[18-31] that met all selection and inclusion criteria established by the authors (Figure 1).

Microfluidic device design and fabrication

The main theme of this review has been studied in current years (2017-2022), as shown in Table 1. The latest studies were performed in commercial chips[18-21], whereas older studies were performed using chips manufactured in-house[22-31]. In general, the studies with commercial chips did not detail the type of polymer[18-20] or the technology or mold used[18-21]. Only one of them specified the use of polydimethylsiloxane (PDMS), a well-known polymer for manufacturing microfluidic chips[21]. The majority of studies that manufactured the chip in-house used PDMS (57%)[22,25-29,31], but two studies adopted the less than usual materials polymethylmethacrylate (PMMA)[23] and Objet VeroClear® photopolymer[30]. Most of the chips fabricated in-house were molded by soft lithography[24-29,31], except the study by Choi *et al*[23], which employed computer numerical control; and the study by Wang *et al*[30], which used a 3D object printer. Details about mold material and fabrication were seldom explored in soft lithography applications; however, the mainly reported material was SU-8 made by photolithography[25-27].



Half of the articles evaluated displayed membrane-free microfluidic chips[18-20,24,25,29,31], as shown in Table 1. The remaining studies reported the presence of a membrane dividing the channels within the chip: Three (21%) made of PDMS[21,26,27], one made of polyethylene terephthalate (PE)[28],

DeStefano *et al* [31], 2017	In house	PDMS	Soft lithography	Material: Aluminum mold. Fabrication: NR	Membrane-free	390 μm, 450 μm, 550 μm, and 770 μm (different width)

3D: Three-dimensional; CNC: Computer numerical control; hBMECs: Human brain microvascular endothelial cells; HUVEC: Human umbilical vein endothelial cells; NA: Not applied; NR: Not reported; PDMS: Polydimethylsiloxane; PC: Porous polycarbonate; PE: Polyethylene terephthalate; PETE: Polyester track-etched; PMMA: Poly(methyl methacrylate); SU-8: Negative photoresist.

two made of polyester (PETE)[22,23], and one of porous polycarbonate (PC)[30]. Almost all microfluidic chips with membranes were designed to comprise a top and a bottom channel[21-23,26-28]. An exception was found in the study by Wang *et al*[30], whose chip design was more complex, containing four parts that were stacked to compose the BBB model. Five studies (36%) presented three-channel microfluidic chips: Two side channels that were generally used to perfuse medium, and one middle channel where the cells were generally cultured[18-20,25,29]. The remaining studies employed simpler chip designs that comprised a single[24] or multiple channels[31] parallel to each other. Channel

Figure 1 PRISMA flow chart of the study selection process applied in this systematic review. iPSC: Induced pluripotent stem cell.

dimensions were largely variable (from 160 μm to 2200 μm) among the selected articles, defined according to the desired use of the chip.

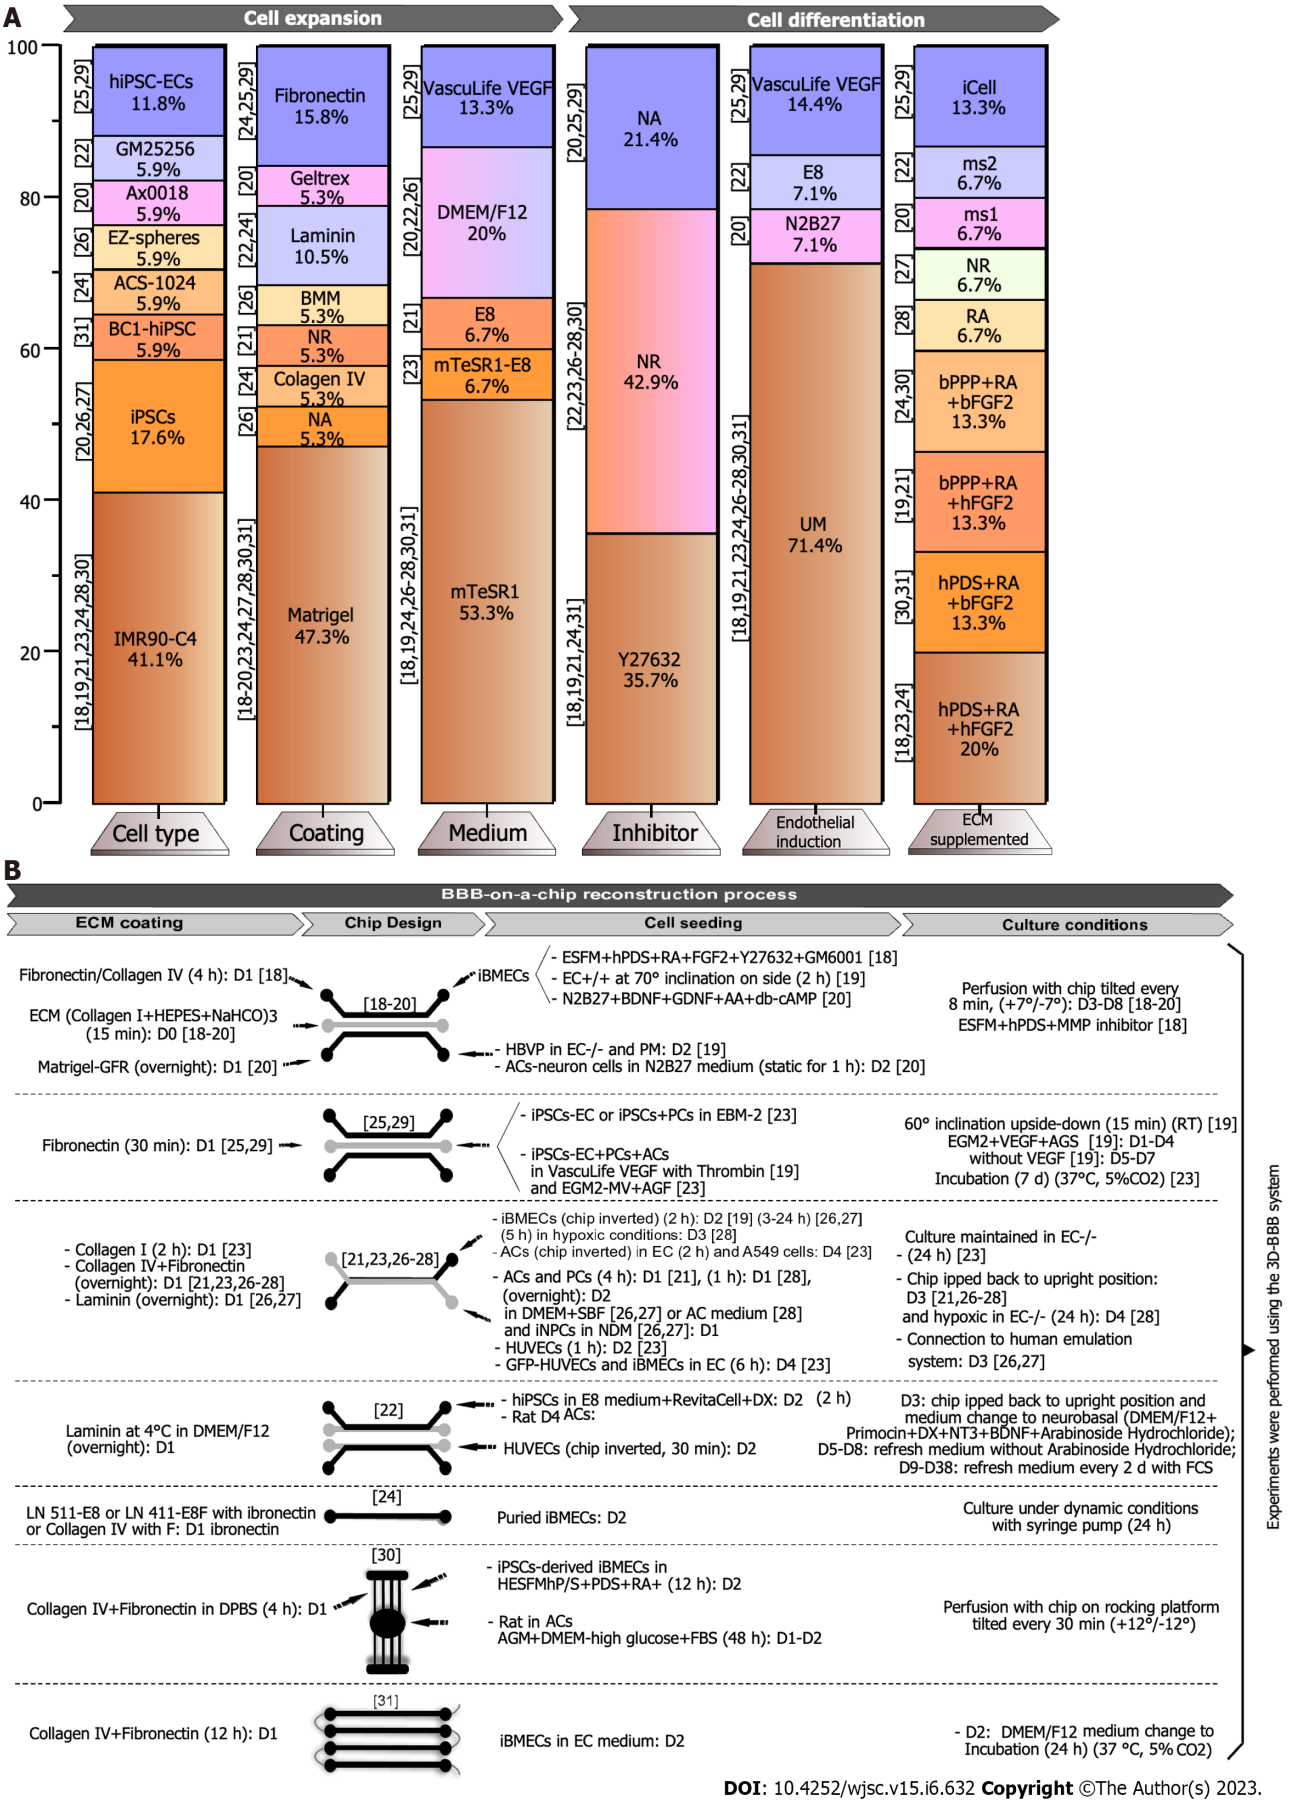
Characteristics of the iPSCs used in the BBB models and their cultivation and differentiation conditions

To build the BBB, as shown in Table 2 and Figure 2A, IMR90-C4 from human fetal lung fibroblasts was the main iPSC line used (41.1%)[18,19,21,23,24,28,30], commonly cultivated in Matrigel-coated flasks. Few studies (17.6%) have reported the use of different iPSC lines[20,26,27], one of which used nine different types of iPSCs[27] that were extracted from skin fibroblasts or the peripheral blood of healthy (5) or unhealthy donors (2). Two of these skin fibroblast lines from unhealthy donors were modified by clustered regularly interspaced short palindromic repeat (CRISPR)[27]. These diverse cell lines were useful in modeling BBB dysfunctions and their corrections[27].

Concerning the coating applied for culturing the iPSC lines, fibronectin was selected for cultivation of human iPSC (hiPSC)-ECs (11.8%)[25,29]. Other particular iPSC lines, such as Ax0018 (neural stem cells)[20] and BC1-hiPSC (bone marrow)[31], were cultured on Matrigel, whereas GM25256 (skin fibroblast)[22], and ACS-1024 (bone marrow)[24] were cultured on laminin. The ECM on which EZ-Spheres (neural progenitors) were grown was not defined[26]. Interestingly, the study by Motallebnejad *et al*[24] compared cultivation of the ACS-1024 line on different laminin isoforms (LN511 and LN411), or on collagen IV associated with fibronectin[24]. Overall, Matrigel was the coating of choice in the majority of the selected studies (47.4%)[18-20,23,24,27,28,30,31]. The least common coatings, such as basement membrane matrix coating[26] and geltrex[20], appeared in 5.3% of the analyzed articles (Figure 2A and Table 2).

The iPSCs generally go through a complex differentiation process, involving multiple medium replacements with the addition of supplements and composition changes. Most iPSC cultivation protocols were undertaken in mTeSR1 medium (53.3%) associated[23] or not[18,19,24,26-28,30,31] with essential medium 8 (E8, 6.7%) for about 3 d, mainly for culturing the IMR90-C4 cell line. Part of these studies (35.7%)[18,19,21,24,31] added the Rho-associated, coiled-coil containing protein kinase inhibitor (Y27632) to the cultures overnight to inhibit cell proliferation before differentiation[32,33]. Unconditioned medium (UM), normally composed of Dulbecco's modified Eagle medium (DMEM)/F12 supplemented with knockout serum replacement + non-essential amino acids (NEAA) or minimum essential medium (MEM) with NEAA (MEM-NEAA) + glutamax or L-glutamine + β-mercaptoethanol, was used

Table 2 Characteristics of the induced pluripotent stem cells used in the blood-brain barrier model, their cultivation and differentiation conditions



Ref.	Cell origin	Cell differentiation				BBB components model	
		iPSCs line	Flask coating	Medium	Supplement	Differentiated cell/medium	Co-culture/medium
Kurosawa *et al* [18]	Human fetal lung fibroblast	IMR90-C4	Matrigel	Day 3-2: mTeSR1-cGMP	Day 3: With Y27632 Day 2: Without Y27632	iBMECs (10^7) in ESFM	NA

in 71.4% of the studies[18,19,21,23,24,26-28,30,31] to promote differentiation to ECs (for 6 d on average), followed by a change to human endothelial serum-free medium containing diverse substances, such as retinoic acid (RA), platelet-poor-derived bovine serum (bPPP) or human serum from platelet-poor human plasma (hPDS), and basic fibroblast growth factor, to induce BMEC formation (Figure 2A and Table 2).

Few studies have described different processes to generate iBMECs. Lee *et al*[25] used solely vasculife vascular endothelial growth factor medium with iCell media supplement[29]. The study by Wevers *et al* [20] used DMEM/F12 and N2B27 supplemented with brain-derived neurotrophic factor (BDNF) + glial cell line-derived neurotrophic factor + ascorbic acid + 2′-O-Dibutyryladenosine-3′,5′-cyclic monophosphate. Finally, the study by Middelkamp *et al*[22] utilized DMEM/F12 supplemented with primocin + doxycycline (DX) + N2 + MEM-NEAA + neurotrophin-3 (NT3) recombinant human protein + BDNF recombinant human protein, followed by a change to E8 supplemented with revitacell + DX, and a later change to neurobasal medium supplemented first with primocin + B27SF + glutamax + DX + NT3 + BDNF, in addition to arabinoside hydrochloride for 24 h, followed by the addition of fetal calf serum. DX induced the overexpression of neurogenin *2* in GM25256 iPSCs, being one of the key factors for the differentiation of GM25256 into iNeurons (Table 2).

All of the abovementioned processes were described for iPSC differentiation on a plate, with the exception of the study by Campisi *et al*[29], whose cell differentiation step occurred inside the microfluidic chips. Furthermore, two studies used hypoxic conditions during the cell differentiation process[23,28].

BBB-on-a-chip reconstruction process

To build the BBB-on-a-chip model, the microdevices must first receive a coating layer to sustain 3D cell growth, as depicted in Figure 2B. From this perspective, diverse coating substances and different cell-seeding strategies have been described, depending on the chip design. As seen in Figure 2B, previously to cell culture on-a-chip, fibronectin was the principal ECM component coating the microfluidic channels (39.3%)[18,21,23-26,28-31], among which 28.6% corresponded to a mixture of fibronectin + collagen type IV. More recent studies have applied an ECM composed of collagen type I + 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid + sodium bicarbonate (10.7%)[18-20]. Laminin coating was used in 14.3% of the analyzed studies[22,26,27], wherein a mixture of different types of laminin + fibronectin was employed in the study by Motallebnejad *et al*[24]. Additionally, one study utilized only Matrigel[20], and another utilized collagen type I[23] as channel coating. The mentioned coatings were carefully selected for each channel, depending on the desired environment and cultured cell type.

Regarding cell seeding, five studies have described an iBMEC single culture[18,19,24,29,31], in which two studies applied a selective cell expansion step before seeding[19,24]. A co-culture of iBMEC + ACs was reported in three studies[20,23,30], one of which used PCs in the co-culture[29]. Yet, most studies have built their BBB models based on an approach involving more than two cell types in co-culture, normally associating ACs and PCs with other ECs such as HUVECs[22], iBMECs[21,28], and iPSC-ECs [25], with the exception of Jagadeesan *et al*[26] and Vatine *et al*[27], who associated neural progenitor cells with ACs and PCs in the brain-side, and iBMECs in the blood-side of their BBB model (Figure 2B).

The particular aspects of cell culture inside the chips are displayed in Figure 2B. Among the observed aspects, we highlight the inversion or inclination of the chip to seed the cells[21-23,25-28], maintenance of the chip under hypoxic conditions[28], and tilting of the chips for gravity-dependent bidirectional medium flow[18-20,30].

Applications of BBB microfluidic 3D models using iPSCs

Regarding the general objective of the studies (Table 3), the great majority of the articles (roughly 80%) [18-21,23,24,26-30] were aimed at developing a microfluidic BBB model, as well as assessing the convenience of the manufactured model by quantifying common molecular markers that are normally expressed in cells that make up the BBB *in vivo*. Five of these studies (35.7%) analyzed drug transport for BBB characterization purposes[18,19,27,28,30]. Only two studies described actual applications for their models: Wevers *et al*[20] used their developed chip to model BBB disruption upon ischemic stroke, and Lee *et al*[25] tested the permeability of their model to commercial and synthesized polymer nanoparticles (NPs). Middelkamp *et al*[22] compared a 2D Transwell BBB model to one built on-a-chip, whereas DeStefano *et al*[31] evaluated the effect of shear stress on their BBB microfluidic chips.

The characterization of the BBB model was performed by means of structural and functional analyses. Concerning structural analyses, the expression of tight junction proteins was evaluated in 85.7% of the studies using immunocytochemistry (85.7%)[18-21,23-31]. Part of these studies also performed quantitative polymerase chain reaction (qPCR) (42.9%)[23-25,29,31]. Less frequently used techniques were fluorescence (F-actin staining)[24], transcriptional analysis[27], mass spectrometry (MS) (proteomics)[28], and western blot analysis[31]. Transport protein and receptor expression was evaluated in 57.1% of the cases[18,20,21,23,26-28,31] by immunocytochemistry (42.9%)[18,21,23,26-28], qPCR (21.4%)[18,20,31], fluorescence (permeability glycoprotein inhibition, 14.3%)[20,21], transcriptional analysis (7.1%)[27], and MS (7.1%)[28]. Two studies (14.3%) characterized neuronal differentiation by immunocytochemistry[22,26], one of which also applied RNA sequencing and transcriptomic analysis to further characterize the HUVECs[22]. Structural characterization of ACs and PCs was performed by immunocytochemistry by Campisi *et al*[29]. Lastly, DeStefano *et al*[31] used microscopic techniques to structurally and functionally characterize ECs seeded on-a-chip[31] (Table 3).

Functional characterization of the BBB model was more varied, with the use of diverse techniques. Tight junction functionality (71.4%) was mostly analyzed by fluorescence (50%)[18-20,22,24,26,30] using diverse fluorescent markers[18,23,24,26,28-30] such as zonula occludens-1 (ZO-1), claudin-5[21,22,26,28], occludin (OCLN)[21,22], glucose transporter type 1[21,24,26], platelet/EC adhesion molecule-1 (PECAM-1)[22,24,26,27], and vascular endothelial (VE)-cadherin[22]. Other techniques used to evaluate tight junction functionality were transepithelial electrical resistance (TEER) measurements (42.9%)[19,20,24,27,28,30], enzyme-linked immunosorbent assay (21.4%)[19,27,28], (ultra or high performance) liquid chromatography with tandem MS (LC-MS/MS) (21.4%)[18,27,30], immunocytochemistry[23,27] (14.3%), transendothelial migration of cancer cells[23], electron transmission microscopy (7.1%)[28], and transmitted light microscopy (7.1%)[27]. Microvessel permeability (57.1%)[19-21,25,27-30] and microvessel integrity (7.1%)[19] were assessed by fluorescence (57.1%)[19-21,25,27-30]. Transport protein function was evaluated by 21.4% of the studies[18,27,28] by fluorescence (14.3%)[27,28] and high-performance LC-MS (7.1%)[18]. Neuronal functionality was evaluated by calcium fluorescence imaging (14.3%)[20,27] and immunocytochemistry (7.1%)[27]. Mitochondrial membrane potential was analyzed by luminescence and ATP quantification (7.1%)[20]. In a diverse approach, the study by Vatine *et al*[27], among other evaluations, perfused whole human blood through the chip channels to perform a whole-blood neuronal toxicity assay using a colorimetric technique, focusing on the quantification of lactic dehydrogenase[27] (Table 3).

Overall, the analyzed studies were successful in building structural and functional BBB models on-a-chip using iPSCs. Most of them highlighted the future use of their models for drug screening tests, in addition to mimicking physiological conditions found in healthy and unhealthy individuals, wherein one of the studies reported the applicability of their device for modeling cancer cell invasion and migration through the BBB. The studies also focused on the potential for the development of personalized therapies, mainly in conditions of disease. Some interesting outcomes have reported long-lasting BBB function for the developed chips, with an average BBB function duration of 7 d[21,28] to 10 d[30] (Table 3).

DISCUSSION

This systematic review showed that this theme, BBB models with iPSCs in microdevices, is quite novel in the scientific literature; without setting a time limit, only articles from 2017 to 2022 were found. Furthermore, the articles published in the last 2 years have already shown great technological advances in BBB-on-a-chip in commercial devices[18-21]. Curiously, the same chip by MIMETAS® was used in three studies by different labs around the world (Japan[18], the Netherlands[19], and Germany[20]), and another commercial BBB-on-a-chip was also used by an American lab[21]. These advances in technological on-chip manufacturing allow the scientific community to direct further efforts to apply the developed BBB-on-a-chip to model pathological conditions, such as stroke[21], and design personalized therapeutic approaches.

Among the developed BBB models on a microdevice, some showed distinctive features, mainly for the chips fabricated in house. For example, the study by Choi *et al*[23] described a BBB microchip whose functionality was based on a track-etched 10 μm pore polyester membrane covered with a collagen type

Table 3 Applications of blood-brain barrier microfluidic three-dimensional models using induced pluripotent stem cells

Ref.	Application	Characterization	Evaluation technique	Outcomes
Kurosawa *et al*[18]	Build and evaluate a BBB 3D *in vitro* model	Capillary structure formation and tight junction proteins expression	Immunocytochemistry	Formation of the capillary structure, functional tight proteins; lower expression of ABC transporters than levels found *in vivo*, except for BCRP; expression of functional SLC transporters
		Transport proteins and receptors expression	Immunocytochemistry	
			qPCR	
		Tight junction functionality	Fluorescence (lucifer yellow and antipyrine)	
			HPLC-MS/MS (test-drug transport)	
		Transport proteins function	HPLC-MS/MS (test-drug transport)	
Fengler *et al*[19]	Build and evaluate a BBB 3D *in vitro* model	Tight junction proteins expression	Immunocytochemistry	Capillary diameter CA. 40 times larger than *in vivo* brain vessels; physiologically relevant TEER values; physiologically similar localization of BCRP and GLUT-1 proteins. Promising BBB model for future drug screening tests
		Microvessel integrity	Fluorescence (DEX-A647 and sodium fluorescein)	
		Microvessel permeability	Diazepam, Emricasan, Ac-YVAD-CMK, Z-DEVD-FMK, ZVAD (OH)-FMK, Staurosporine, and IL-1β	
		Tight junction functionality	ELISA (Diazepam)	
			TEER measurements	
Wevers *et al*[20]	Build and evaluate a BBB 3D *in vitro* model	Tight junction proteins expression	Immunocytochemistry	Barrier functionality similar to that found *in vivo*; microfluidic model suitable for evaluating disruption of the BBB; successful ischemic stroke modeling. Potential use for modeling the BBB under sub-optimal conditions (disease) and for evaluating potential therapies
		Tight junction functionality	TEER measurements	
		Microvessel permeability	Fluorescence (sodium fluorescein)	
		Transport proteins expression	Fluorescence: P-gp inhibition	
			qPCR	
		Neuronal functionality	Calcium fluorescence imaging	
	Ischemic stroke modeling	Microvessel permeability	Fluorescence (FITC-dextran)	
		Mitochondrial membrane potential	Luminescence (CellTiter-GLO)	
			ATP quantification	
Noorani *et al*[21]	Build and evaluate a BBB 3D *in vitro* model	Tight junction proteins expression	Immunocytochemistry	BBB functionality remains intact for up to 7 d and is similar to that found *in vivo*; a more physiologically relevant BBB model; shear stress contributes positively to BBB tightness
		Microvessel permeability	UPLC-MS/MS: [$^{13}C_{12}$] sucrose and [$^{13}C_6$] mannitol	
		Transport proteins expression	Immunocytochemistry	
			Fluorescence: P-gp inhibition	
Middelkamp *et al*[22]	Compare 2D cultures to microfluidic chip cultures	Neuronal differentiation and characterization of HUVECs	Immunocytochemistry	Culture in microfluidic chips promotes gene expression that more closely resembles that found *in vivo*
			RNA sequencing	
			Transcriptomic analysis	
Choi *et al*[23]	Build and evaluate a BBB 3D *in vitro* model	Tight junction proteins expression	Immunocytochemistry	cECMTE membrane with 10 m pores in microfluidic device were successful in mimicking the *in vivo* BBB, also allowing for cancer cell tissue migration. Promising BBB model for studying cancer metastasis, cell communication, and migration
			qPCR	
		Tight junction functionality	Fluorescence (lucifer yellow)	
			Transendothelial migration of cancer cells (CellMask)	
			Immunocytochemistry	
		Transport proteins expression	Immunocytochemistry	

Motallebnejad *et al*[24]	Build and evaluate a BBB 3D *in vitro* model	Tight junction proteins expression	Immunocytochemistry	LM511-E8 ECM contributes to long-lasting endothelial cell and BBB function, in addition to promoting better shear stress responses. Authors recommend the use of LM511-E8 ECM for future studies involving BBB function
			Fluorescence (F-actin staining)	
			qPCR	
		Tight junction functionality	TEER measurements	
			Fluorescence (rhodamine B-labeled neutral dextran)	
Lee *et al*[25]	BBB permeability to polymer nanoparticles	Tight junction and transport proteins expression	qPCR	Fast analysis of polymer nanoparticles permeability; physiologically reliable BBB model
		Permeability to polymer nanoparticles	Fluorescence (polymer nanoparticles and FITC-dextran)	
			3D fluorescence intensity maps	
Jagadeesan *et al*[26]	Build and evaluate a BBB 3D *in vitro* model	Tight junction proteins expression	Immunocytochemistry	Successful fabrication of BBB model personalized for different human individuals; BBB models were able to mimic physiological differences between healthy and ill individuals
		Tight junction functionality and microvessel permeability	Fluorescence: FITC-dextran	
		Transport proteins expression	Immunocytochemistry	
		Neuronal differentiation		
Vatine *et al*[27]	Build and evaluate a BBB 3D *in vitro* model	Tight junction proteins expression	Immunocytochemistry	Successful fabrication of BBB model personalized for different human individuals; BBB models were able to mimic physiological differences between healthy and ill individuals
			Transcriptional analysis	
		Microvessel permeability and tight junction functionality	Fluorescence (FITC-dextran and 2NDBG)	
			ELISA (human albumin, IgG and transferrin)	
			LC-MS/MS (T_3, colchicine, levetiracetam and retigabine)	
			Transmission light microscopy	
			TEER measurements	
			Immunocytochemistry	
		Transport proteins expression	Immunocytochemistry	
			Transcriptional analysis	
		Transport protein function	Fluorescence (rhodamine-123)	
		Whole-blood neuronal toxicity	Colorimetric assay (quantification of lactic dehydrogenase)	
		Neuronal functionality	Immunocytochemistry	
			Calcium fluorescence imaging	
Park *et al*[28]	Build and evaluate a BBB 3D *in vitro* model	Tight junction proteins expression	Immunocytochemistry	BBB functionality remains intact for up to 7 d. Promising BBB model for future drug and antibody transport studies
			Multiplex qPCR	
			MS (proteomics)	
		Tight junction functionality and microvessel permeability	Electron transmission microscopy	
			TEER measurements	
			Fluorescence (dextrans, cetuximab, angiopep-2, MEM75, 13E4)	
			ELISA (dextrans, cetuximab)	
		Transport proteins expression	Immunocytochemistry	
			MS	
		Transport proteins function	Fluorescence (rhodamine-123 and doxorubicin)	

Campisi *et al*[29]	Build and evaluate a BBB 3D *in vitro* model	Tight junction proteins expression	Immunocytochemistry	Tri-culture of human iPSC-derived endothelial cells, astrocytes and pericytes spontaneously arranged into a BBB-like model. Promising BBB model for future preclinical experiments
			qPCR	
		Tight junction functionality and microvessel permeability	Fluorescence (FITC-dextran)	
		Characterization of astrocytes and pericytes	Immunocytochemistry	
Wang *et al*[30]	Build and evaluate a BBB 3D *in vitro* model	Tight junction proteins expression	Immunocytochemistry	Pumpless media perfusion system that resembles the blood residence time within brain tissues; physiologically relevant TEER values maintained for up to 10 d. Promising BBB model for future drug permeability studies
		Tight junction functionality and microvessel permeability	TEER measurements	
			Fluorescence: FITC-dextran and doxorubicin	
			LC-MS/MS (caffeine and cimetidine)	
DeStefano *et al*[31]	Evaluate BBB upon shear stress	Characterization of iPSC-derived endothelial cells morphology and function	Microscopy (time-lapse imaging analysis using ImageJ)	BBB endothelial cells display unique features that differ from endothelial cells from other tissues; shear stress plays a key role in BBB-like function in microfluidic models
		Tight junction proteins expression	Immunocytochemistry	
			Western blot	
			qPCR	
		Transport proteins expression	qPCR	

2NDBG: 2-deoxy-2-[(7-nitro-2,1,3-benzoxadiazol-4-yl)-amino]-D-glucose; 3D: Three-dimensional; Ac-YVAD-CMK: Caspase-1 inhibitor; ATP: Adenosine triphosphate; UPLC-MS/MS: Ultra-performance liquid chromatography-mass spectrometry (tandem); BBB: Blood-brain barrier; BCRP: Breast cancer resistance protein; cECMTE: Condensed extracellular matrix track-etched; CellTiter-GLO: Luminescent cell viability assay; DEX-A647: Dextran conjugated to Alexa 647; ECM: Extracellular matrix; ELISA: Enzyme-linked immunoassay; FITC-dextran: Fluorescein isothiocyanate dextran; GLUT-1: Glucose transporter 1; hBMEC: Human brain microvascular endothelial cells; HPLC-MS/MS: High-performance liquid chromatography-mass spectrometry (tandem); HUVEC: Human umbilical vein endothelial cell; iBMEC: Induced pluripotent stem cell-derived brain microvascular endothelial-like cell; IgG: Immunoglobulin G; IL-1β: Interleukin 1 beta; iPSC: Induced pluripotent stem cell; LC-MS/MS: Liquid chromatography-mass spectrometry (tandem); LM511-E8: Fragment E8 of laminin 511; MS: Mass spectrometry; P-gp: Permeability glycoprotein; qPCR: Quantitative polymerase chain reaction; RNA: Ribonucleic acid; SLC: Solute carrier protein; TEER: Trans-epithelial electrical resistance; Z-DEVD-FMK: Caspase-3 inhibitor; ZVAD (OH)-FMK: Pan-caspase inhibitor.

I ECM. This study reported that the ECM-covered membrane with a larger pore size allowed for better modeling of the communications between neural cells and ECs, in addition to enabling the evaluation of cancer cell metastasis through the BBB[23]. Other articles also based their 3D BBB models on microfluidic channels separated by porous membranes of various materials - PDMS[21,26,27], PC[30], PE[28], PETE[22,23] - and various pore sizes that ranged from 0.4 mm to 7 mm. Nevertheless, none of these studies focused on the importance of the membrane material or pore size to the envisaged BBB function.

However, half of the selected articles, and curiously, the most recent ones, showed similar geometries with straight membrane-free channels. The advantage of the presence of a membrane is controversial in the literature regarding its role in the BBB model. Due to the relatively greater thickness of the artificial membrane compared to the basal lamina *in vivo*, cell-cell interactions are limited[34,35]. More recent articles use the diffusible factors produced by the cells in culture themselves for indirect communication between ACs and the BBB endothelium, without the physical restriction imposed by the artificial membrane[35].

Organs-on-chips are a currently sought alternative due to the possibility of physiologically relevant 3D *in vitro* single- or pluricellular culture and, more importantly, due to the possibility of laminar medium flow, mimicking the environment and shear stress found in capillary vessels. Also, the microchip culture of neural cells has shown more *in vivo*-like results, with more mature neurons and ACs[22]. However, the establishment of laminar flow might be cumbersome, given the need for apparatuses such as syringes, capillary tubes, and peristaltic pumps adapted for the sterile environment required for cell culture. Some studies have attempted to overcome this problem with creative alternatives, such as rocking platforms that allow the bidirectional flow of media within the microchips[18-20,30]. Regardless, the cerebral tissue is rather complex and involves a multitude of interacting cell types and ECM proteins. *In vitro* modeling at such a level is already challenging *per se*, whether or not the laminar flow is involved.

Regarding the material used for chip fabrication, conventional PDMS was used in most cases (57%)[22,25-29,31]. One of the studies adopted PMMA[23], which consists of the least hydrophobic material

utilized in microfabrication. In addition, this material is ideal for mass production, and it is stiffer than PDMS. However, rapid prototyping is somewhat complicated by the fact that PMMA bonding is more difficult than the straightforward bonding of PDMS[36,37]. Conversely, PDMS may nonselectively adsorb proteins and hydrophobic molecules, which could possibly interfere with the characterization process of the BBB-on-a-chip and future drug screening applications[38]. Hence, some studies have presented alternatives to tackle this issue, such as covering the microchip surface with bovine serum albumin[39], grafting with anti-fouling molecules[40], or silanization[41].

For construction of the *in vitro* NVU, the cell cultures have been classically established in Transwell plates, mainly using primary brain ECs isolated from animal and human sources, which retain very tight barriers *in vitro* and may be useful tools for studying paracellular permeability[42,43]. Immortalized EC lines, such as HUVECs, have also been used in these BBB models, although they do not provide the permeability profile or the protein expression typically present in the human BBB[44]. Moreover, there is great difficulty in obtaining primary human brain ECs from healthy individuals[45].

The aforementioned drawbacks have been recently addressed with the use of iPSCs. After going through a complex differentiation protocol, these stem cells have shown *in vivo*-like barrier function [27]. Their BBB phenotype can be further enhanced by co-cultivation with other cells that exert barrier function *in vivo*, such as ACs and PCs[24,27]. In view of this aspect, we found in this systematic review a great diversity of iPSC commercially available cell lines from human sources, such as the IPS cell line IMR90-C4 from human fetal lung fibroblasts[18,19,21,23,24,28,30]. We further verified that one study used an iPSC line from unhealthy donors, with the advanced purpose of verifying BBB dysfunction in a pathological model and an attempt to correct this dysfunction through gene editing (CRISPR)[27]. In addition, building BBB models from human-derived iPSCs may be a valuable tool for personalized medicine, wherein a patient's CNS disease could be precisely modeled *in vitro*, enabling the evaluation of personalized treatment.

On the other hand, iPSC-based BBB models have shown short-lived BBB function, which is generally maintained for up to 2 d[21]. Current efforts have been aimed at extending the BBB profile of these cultures[21,28,30]. 3D BBB on-a-chip devices form more physical and physiologically accurate morphologies. The cell-cell and cell-matrix interactions produced in microfluidic models generally provide a robust BBB function, with permeability to different substances (drugs, antibodies, proteins) that resemble that observed *in vivo*[18,19,27,28].

Most of the studies featured in this review (86%) differentiated their iPSCs into BMECs. This is expected since BMECs are the specialized cells in the CNS vasculature that show barrier properties. On the other hand, four studies differentiated the iPSCs into neural cells (neurons and ACs)[20,22,26,27]. The NVU, which makes up the BBB, is mainly composed of strict interactions among BMECs, the ECM, basal lamina, PCs, ACs, and adjacent neurons[11,46]. Even though neurons are indeed considered to be part of the BBB, they are physiologically positioned farther from the microvessels that make up the NVU (10 μm to 20 μm) than ACs or PCs[47]. The studies that reported co-culture of ECs with neurons mentioned in the current review did not clearly state the reasons for using neurons in their BBB models, but some studies stated that co-culture of iBMECs with neurons induces the upregulation of membrane transporters typical of the BBB, promoting a more robust function[29,48], as reported in a study by Wevers *et al*[20]. Microfluidic chips co-cultured both with iBMECs and neural cells showed a more robust phenotype regarding BMECs and strong indicators of epithelial cell barrier integrity and permeability (TEER from 1000 to 4000 Ω × cm^2)[18,19,21,27,30].

Although studies have pointed out drawbacks using primary BMECs or iBMECs in the EC monolayer in BBB-on-a-chip, they still constitute a more reliable model. One of the biggest challenges in using iBMECs in BBB research is the difficulty in producing an *in vivo*-like BMEC phenotype *in vitro* following the currently available protocols, which generally result in more epithelial-like phenotypes with the suboptimal expression of membrane transporters[6,20,26,27,49]. A recent meta-analysis study showed that iPSCs could only be reliably differentiated into BMECs through exposition to endothelial ETS transcription factors ETS variant transcription factor 2, Friend leukemia integration 1 transcription factor, and Ets-related gene[49]. Nevertheless, the differentiation of iPSCs into iBMECs can further benefit from co-culture with neural cells, such as ACs and neurons[27,50]. While a more robust differentiation protocol is not established, some studies make use of alternative ways to make an EC layer, such as the use of HUVECs[22], primary BMECs[20], or even immortalized lines[10]. On the other hand, the isolation of human primary BMECs is a challenge, since they comprise less than 0.1% of the cells in the CNS and tend to de-differentiate in culture[27,51]. Studies with HUVECs generally point out some limitations, such as the formation of an incomplete EC monolayer[22]. Immortalized cells, despite being easily commercialized, generally constitute BBB models with poor barrier properties[27,52].

Fully iPSC-based chips were useful in modeling BBB disruptions from diseased patients, such as the alterations found in Huntington's disease and in monocarboxylate transporter 8 deficiency[26,27]. Wevers *et al*[20] and Middelkamp *et al*[22] also differentiated the iPSCs into neurons, albeit not providing further justifications for doing so. With the exception of Vatine *et al*[27], who observed improved barrier functions with a fully iPSC-derived BBB chip, the other studies considered in this review have not versed on whether their obtained outcomes were positive or negatively dependent on the use of iPSCs.

Normally the microfluidic chips receive a coating made of collagen type IV/fibronectin before cell seeding[21,23,24,26-28,30,31]. These coating agents improve cell adhesion to the chip substrate through micropatterning, offering a fibrous base to guide cell differentiation and cell-to-cell contacts[16]. Motallebnejad *et al*[24] considered that the *in vivo* brain endothelial basement membrane is made up of laminins. Keeping this in mind, they compared the characteristics of the iPSC-derived ECs grown on an ECM based on E8 fragments of laminin 411 or laminin 511 (laminin511-E8) to ECs grown on the common collagen IV/fibronectin ECM. The authors found that the ECM made of laminin511-E8 presented more significant results, with the iPSC-ECs grown on this ECM exhibiting a longer-lasting EC phenotype and improved barrier stability compared to cells grown on the collagen IV/fibronectin ECM. iPSC-ECs grown on laminin511-E8 presented higher expression levels of junctional proteins such as claudin-5, VE-cadherin, and PECAM-1. Curiously, three other articles used a laminin ECM coating[22,26,27], but on the "brain side" channel of their microfluidic devices. One of the aforementioned studies also used the laminin coating on the "blood side" channel for culturing HUVECs, but without mentioning the importance of the laminin ECM[22].

Another important aspect of microfluidic device analyses in many studies is perfusion, whether by culture media or other biologically-relevant liquids, due to the shear stress and their important advantage in *in vitro* studies[10,16,53]. For BBB models, the role of shear stress on BBB function remains inconclusive. Among the studies selected for this review, eight (57%) considered shear stress[19-22,24,27,30,31], whereas two[22,30] designed their BBB mimics to minimize shear stress. Vatine *et al*[27] reported an increase in the expression of tight junction genes, such as tight junction protein 1/*ZO-1*, *OCLN*, *PECAM-1,* and cadherin 5/VE-cadherin, even under shear stress as low as 0.01 or 0.5 dyne/cm^2. A study by Noorani *et al*[21] found ambiguous results for cultures under shear stress; perfusion did not induce changes in tight junction gene expression but decreased the permeability levels of sucrose and mannitol. In turn, the work by DeStefano *et al*[31] focused solely on the effect of increasing shear stress (0, 4, or 12 dyne/cm^2) on the genotype and phenotype of iPSC-derived ECs. The authors found no correlation between the presence of shear stress and the expression of a more robust EC phenotype, since tight junctions are already formed under static conditions. Some authors considered that perfusion makes a bigger difference in BBB models made of non-iPSC-derived EC cultures such as HUVECs or primary ECs[31,54], whereas iPSC-derived ECs do not experience drastic changes in BBB markers upon shear stress[21,31]. Motallebnejad *et al*[24] gathered evidence that culturing iPSC-derived ECs on laminin511-E8 ECM improves the response of ECs to shear stress, wherein the cells exhibit changes in morphology, surface area, and the upregulation of tight junction proteins.

Regarding BBB applications, the specialized literature has not yet been able to establish a consistent microfluidic BBB model that can cover a broad range of applications, from modeling CNS disorders, including cancer metastasis, to screening for drugs able to permeate the BBB to treat such maladies. This is reflected in the goals of most studies selected to be part of this review. The great majority of the articles (roughly 80%) were aimed at developing a microfluidic BBB model, as well as assessing the convenience of the manufactured model by quantifying common molecular markers that are normally expressed in cells that make up the BBB *in vivo*[18-21,23,24,26-30]. Only one of the studies focused not on the BBB model itself but on the permeation potential of either commercial or synthesized polymer NPs through the *in vitro* 3D BBB mimic[25]. The BBB is a significant obstacle to the effective transport of large molecules for the treatment of brain disorders, and a study by Lee *et al*[25] showed that iPSC-ECs are appropriate for generating the 3D *in vitro* BBB model[25]. Surface modification of NPs with ligands for specific binding to BBB cells enhances NP accumulation in the brain through receptor-mediated endocytosis, providing good conditions to explore personalized therapies[25].

Another different application for the 3D BBB model was reported in a study by Wevers *et al*[20], which employed hypoxia together with hypoglycemia and lack of perfusion to successfully mimic ischemic stroke on-a-chip[20]. This hypoxic condition was also used to improve the iPSC differentiation to BMECs inside the microfluidic device by Park *et al*[28]. Based on the hypoxic environment found during the embryological development of the BBB *in vivo*, the whole differentiation step of iPSCs into ECs, both on a plate and in the microfluidic chip, was performed under low oxygen (5% O_2). For the cells cultured under hypoxia, the authors observed the upregulation of diverse tight junction proteins and membrane transporters, contributing to a more robust BBB function. Moreover, they found that the differentiated ECs produce hypoxia-inducible factor 1α, a molecular marker whose presence was found to improve the function and durability of the BBB model[28].

Concerning the characterization techniques, the structural evaluation of the BBB model was mainly targeted by immunocytochemistry, whereas functional aspects have been mainly assessed using fluorescence techniques. Immunocytochemistry assays are the golden standard for identifying proteins related to the BBB, as well as for identifying different stages of BBB maturation (early, intermediate, and late phases of BBB development)[55]. Fluorescence assays are easily accessible and generally offer a vast array of markers that can be used for various purposes, from evaluating BBB permeability and integrity to neuronal functionality. Many studies mentioned TEER measurements as an important method to characterize BBB function[20,21,24,27,28,30,56]. However, they pose a number of disadvantages. The TEER values across BBB culture models are frequently influenced by disregarded physical and technical factors such as temperature, viscosity, and current density, generated by various electrode types, surface size, circumference, and porosity of the insert membrane, leading to severalfold differences within the

same biological model[57]. Additionally, these TEER values can vary according to cell type (primary, immortalized, iPSC-derived), cell source (animal or human), and culture type (2D, 3D culture, co-culture)[58]. Therefore, the comparison of TEER values among different studies is highly discouraged in the relevant literature.

This systematic review highlights the main aspects of the current literature on BBB models on-a-chip, from iPSC differentiation to the NVU formation and characterization inside the microfluidic devices, also considering the functional duration of the proposed models by diverse approaches, focusing on future applications. However, the lack of uniform nomenclature and protocols made it a challenge to deeply analyze and comprehend all the steps in the processes involved.

The construction of BBB-on-a-chip still faces numerous challenges in producing feasible, reproducible, and reliable models. This becomes apparent in that, among the 14 articles studied in this review, 12 focused on the development of a robust *in vitro* model[18,19,21-24,26-31], and only 2 focused on the application of a model to study BBB disruption following ischemic stroke[20] and study the BBB permeability to polymer NPs[25]. Even though the use of iPSCs in microfluidic systems poses an advancement in these BBB constructs, there remain obstacles in the use of this type of cells, especially related to differentiation protocols, which need to be further developed in order to result in more dependable cell phenotypes. Moreover, on-chip technology remains a costly *in vitro* alternative, and the in-house manufacture of microfluidic devices is hampered by the need for a clean room and specialized equipment and personnel.

The integration of sensors to monitor barrier permeability and neuronal response to drug exposure is an important aspect scarcely addressed. The addition of such sensors could enable more precise and real-time measurements of drug transport across the BBB and its effects in brain cells. In terms of potential impacts, this technology can accelerate the development of new drugs by allowing for faster and more accurate screening of compounds that cross the BBB for therapeutic effects on the brain. One important step towards this scenario was already taken in the study by Vatine *et al*[27], who were successful in perfusing whole human blood through their microfluidic device, creating promising conditions to evaluate disease[27]. Moreover, more reliable BBB-on-a-chip constructs may help to better understand the *in vivo* functioning of the BBB across different individuals, representing a significant impact on personalized medicine.

CONCLUSION

Despite the well-known literature on iPSCs, microfluidic devices, and BBB *in vitro* models in isolation, the combination of the three subjects is a currently relevant theme, already presenting with advanced technology in the use of commercial microdevices for modeling the BBB. The BBB-on-a-chip models, in spite of their particularities in each study, have shown to be efficient for reconstructing the NVU *in vitro*, being able to reproduce the characteristics found *in vivo* in terms of structure and function. They have displayed promising qualities for investigating barrier disorders, drug delivery, mimicking disease, and personalized medicine.

ARTICLE HIGHLIGHTS

Research background

Induced pluripotent stem cells (iPSCs) offer a potential alternative to building blood-brain barrier (BBB)-on-a-chip models that more closely resemble the structure and functions found *in vivo*.

Research motivation

iPSC-derived BBB models on-a-chip are a promising field that still lacks improvements and uniformity within the specialized literature.

Research objectives

To search the literature and analyze the selected data on the cultivation of iPSCs within microfluidic environments to mimic the human BBB.

Research methods

A literature search using the PRISMA approach using the following terms: “iPSC,” “BBB,” and “microfluidic device,” wherein 14 studies were selected based on the inclusion and exclusion criteria, and data were organized into three tables and one flow chart.

Research results

Studies have been found from 2017 to 2022, wherein the microdevices were either commercially

available or manufactured in-house using soft-lithography. iPSCs were differentiated into endothelial or neural cells and seeded in the chips individually or in co-culture onto an extracellular-matrix layer mainly made of collagen IV/fibronectin. The selected studies focused principally on the structural and functional design of the human BBB model on-a-chip, displaying future application potential for drug screening and disease modeling.

Research conclusions

Despite the lack of consensus in protocols, the studies analyzed herein were able to efficiently reproduce a human microfluidic BBB *in vitro* making use of iPSCs.

Research perspectives

The developed BBB models on-a-chip have shown great potential to study physiopathological conditions related to the central nervous system, to apply advanced technology approaches for novel therapies (drug delivery through nanoparticles), and to develop genetic modification therapies for BBB dysfunctions through clustered regularly interspaced short palindromic repeats methodologies.

FOOTNOTES

Author contributions: Alves ADH, Nucci MP, Ennes do Valle NM, Missina JM, and Gamarra LF conceived and designed this study; Alves ADH, Nucci MP, Ennes do Valle NM, Rego GNA, and Gamarra LF performed the literature review; Alves ADH, Nucci MP, Ennes do Valle NM, Rego GNA, Mamani JB, and Missina JM performed the data extraction and critical review; Alves ADH, Nucci MP, Ennes do Valle NM, Missina JM, de Oliveira FA, and Mamani JB interpreted and analyzed the collected data; Alves ADH, Nucci MP, Ennes do Valle NM, Missina JM, Dias OFM, Garrigós MM, and Gamarra LF wrote this review; All authors reviewed and approved the final manuscript as submitted.

ABOUT COVER

Editorial Board Member of *World Journal of Stem Cells*, Giovanni Di Bernardo, BSc, PhD, Associate Professor, Department of Experimental Medicine, Biotechnology and Molecular Biology Section, University of Campania Luigi Vanvitelli, Naples 80138, Italy. gianni.dibernardo@unicampania.it

AIMS AND SCOPE

The primary aim of *World Journal of Stem Cells* (*WJSC*, *World J Stem Cells*) is to provide scholars and readers from various fields of stem cells with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJSC* publishes articles reporting research results obtained in the field of stem cell biology and regenerative medicine, related to the wide range of stem cells including embryonic stem cells, germline stem cells, tissue-specific stem cells, adult stem cells, mesenchymal stromal cells, induced pluripotent stem cells, embryonal carcinoma stem cells, hemangioblasts, lymphoid progenitor cells, *etc*.

INDEXING/ABSTRACTING

The *WJSC* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Journal Citation Reports/Science Edition, PubMed, PubMed Central, Scopus, Biological Abstracts, BIOSIS Previews, Reference Citation Analysis, China National Knowledge Infrastructure, China Science and Technology Journal Database, and Superstar Journals Database. The 2023 Edition of Journal Citation Reports® cites the 2022 impact factor (IF) for *WJSC* as 4.1; IF without journal self cites: 3.9; 5-year IF: 4.5; Journal Citation Indicator: 0.53; Ranking: 15 among 29 journals in cell and tissue engineering; Quartile category: Q3; Ranking: 99 among 191 journals in cell biology; and Quartile category: Q3. The *WJSC*'s CiteScore for 2022 is 8.0 and Scopus CiteScore rank 2022: Histology is 9/57; Genetics is 68/325; Genetics (clinical) is 19/90; Molecular Biology is 119/380; Cell Biology is 95/274.

Abstract

Acute pancreatitis (AP) often leads to a high incidence of cardiac injury, posing significant challenges in the treatment of severe AP and contributing to increased mortality rates. Mesenchymal stem cells (MSCs) release bioactive molecules that participate in various inflammatory diseases. Similarly, extracellular vesicles (EVs) secreted by MSCs have garnered extensive attention due to their comparable anti-inflammatory effects to MSCs and their potential to avoid risks associated with cell transplantation. Recently, the therapeutic potential of MSCs-EVs in various inflammatory diseases, including sepsis and AP, has gained increasing recognition. Although preclinical research on the utilization of MSCs-EVs in AP-induced cardiac injury is limited, several studies have demonstrated the positive effects of MSCs-EVs in regulating inflammation and immunity in sepsis-induced cardiac injury and cardiovascular diseases. Furthermore, clinical studies have been conducted on the therapeutic application of MSCs-EVs for some other diseases, wherein the contents of these EVs could be deliberately modified through prior modulation of MSCs. Consequently, we hypothesize that MSCs-EVs hold promise as a potential therapy for AP-induced cardiac injury. This paper aims to discuss this topic. However, additional research is essential to comprehensively elucidate the underlying mechanisms of MSCs-EVs in treating AP-induced cardiac injury, as well as to ascertain their safety and efficacy.

Key Words: Acute pancreatitis; Cardiac injury; Mesenchymal stem cells; Extracellular vesicles; Inflammation; Therapeutic strategies

Core Tip: Acute pancreatitis (AP) often causes cardiac injury, leading to poor prognosis. Mesenchymal stem cells (MSCs) and their extracellular vesicles (EVs) possess anti-inflammatory properties and have been studied as a potential therapy for inflammatory diseases. Although preclinical studies on the use of MSCs-EVs for AP-induced cardiac injury are lacking, research has demonstrated their positive effects in various inflammatory diseases such as sepsis-induced cardiac injury and cardiovascular diseases. Therefore, MSCs-EVs may represent a promising strategy for treating AP-induced cardiac injury.

INTRODUCTION

Acute pancreatitis (AP) often results in important extra-pancreatic organ damage, including the lungs, kidneys, heart, liver, and intestines[1-3]. Cardiac injury associated with AP frequently manifests with non-specific symptoms, or is overshadowed by symptoms caused by AP itself, making it easy to be overlooked and leading to the misconception that cardiac injury is uncommon in AP[4]. However, studies have reported a 100% incidence rate of cardiac injury in all cases of AP, with cardiac injury occurring earlier than damage to organs such as the lungs and kidneys[5,6]. The severity of cardiac injury is closely related to the severity of AP, with severe acute pancreatitis (SAP) having the highest occurrence rate of severe cardiac injury, which can reach up to 60.5%, and in some severe cases, SAP can even lead to cardiac dysfunction[7,8]. Retrospective analysis has also confirmed significantly elevated serum cardiac injury markers in SAP patients upon admission[6]. Among SAP patients who succumbed to multiple organ dysfunction syndrome, approximately 86.4% experienced cardiovascular failure[9]. Cardiac injury is a significant contributing factor to the challenges in curing and increased mortality rates of SAP, with approximately 10%-30% of SAP fatalities attributed to SAP-induced cardiac injury[7]. Therefore, it is crucial to give adequate clinical attention to AP-induced cardiac injury. However, the exact mechanisms underlying AP-induced cardiac injury are complex, involving multiple factors, and the precise mechanism remains unclear, posing a significant challenge in the development of effective treatments.

Mesenchymal stem cells (MSCs) are among the most readily accessible types of stem cells, which can be extracted from sources such as bone marrow, adipose tissue, umbilical cord, and dental pulp. They possess unique characteristics of self-renewal and multi-directional differentiation, allowing them to differentiate into various cell types. MSCs participate in various inflammatory diseases through the paracrine secretion of bioactive molecules and can also promote tissue repair [10,11]. Moreover, MSCs can regulate the phenotype of immune cells and alleviate inflammatory responses[12]. However, the long preparation period required for MSCs transplantation makes it unsuitable for emergency situations. Additionally, MSCs carry the risks of immunogenicity and tumorigenicity, which to some extent limits their application [13].

The various biological functions of MSCs are primarily carried out through the secretion of bioactive molecules, encompassing a diverse range of chemical factors, cytokines, immunomodulatory factors, extracellular matrix components, as well as several other proteins, nucleic acids, and lipids[14]. MSCs also release extracellular vesicles (EVs) that serve as the principal mediators for MSCs to exert their immune and inflammatory regulatory effects. MSCs-EVs act as carriers, transporting bioactive molecules such as growth factors, cytokines, chemokines, mRNA, miRNA, lncRNA, *etc.*, which they transmit through paracrine or endocrine secretion[15]. EVs have been identified as effective therapeutic vehicles capable of delivering various proteins and regulatory genes to target organs. MSCs-EVs are believed to possess similar anti-inflammatory and other biological effects as MSCs, while offering advantages over MSCs such as smaller size, targeted transport, and low immunogenicity[16]. Therefore, MSCs-EVs hold the potential to replace MSCs in exerting therapeutic effects on certain diseases.

MSCS-EVS HAVE EMERGED AS A PROMISING TREATMENT OPTION FOR VARIOUS INFLAMMATORY DISEASES

With the increasing focus on the immunomodulatory effects of MSCs, extensive research has been conducted to investigate their mechanisms in inflammatory diseases. MSCs-EVs, which possess similar anti-inflammatory effects as MSCs and the ability to avoid potential risks associated with cell transplantation, have been widely studied in the context of inflammatory diseases. Multiple studies have demonstrated the efficacy of MSCs-EVs in improving inflammatory responses in animal models of various diseases, including brain ischemia-reperfusion injury, acute lung injury/acute respiratory distress syndrome (ARDS), inflammatory bowel disease, acute liver injury, acute kidney injury, sepsis, AP, myocardial ischemia-reperfusion injury, and acute myocardial infarction[17]. For instance, MSCs-EVs can regulate inflammatory and immune responses following brain ischemia by modulating the central nervous system, peripheral immune system, and immune regulatory molecules, thereby promoting neurological function recovery[18]. By transmitting miRNA, MSCs-EVs can reduce the secretion of pro-inflammatory cytokines, oxidative stress, and prevent

lung tissue infiltration by inflammatory cells, thereby alleviating ventilator-associated lung injury[19]. Moreover, MSCs-EVs can regulate gene expression and inhibit the production of inflammatory cytokines by transmitting miRNA or other bioactive molecules, thereby reducing neutrophil infiltration, improving lung inflammation and oxidative damage, and promoting the survival, proliferation, and differentiation of alveolar epithelial cells and endothelial cells. This, in turn, facilitates lung tissue repair, regeneration, and improvement of lung function[19-22]. In acute liver failure, MSCs-EVs can inhibit inflammasomes, reduce levels of inflammatory factors, and alleviate inflammatory response, thus improving acute liver injury[23].

MSCs-EVs for the treatment of sepsis and sepsis-induced cardiac injury

MSCs-EVs have shown promise in treating sepsis by modulating the immune response and mitigating inflammatory damage through various mechanisms. These mechanisms include regulating cytokine production, reducing oxidative stress, and promoting immune cell proliferation and differentiation[24]. In septic mice, MSCs-EVs have demonstrated the ability to decrease pro-inflammatory cytokine levels while promoting the production of anti-inflammatory cytokines, thus improving survival rates[25]. Furthermore, MSCs-EVs have been discovered to alleviate sepsis-induced acute lung injury by suppressing the mitogen-activated protein kinase (MAPK)/nuclear factor-κB (NF-κB) pathway. This regulation leads to the modulation of immune cell activity, reduction of oxidative stress levels, and promotion of cell survival and regeneration[26]. Additionally, MSCs-EVs can also improve the severity of sepsis-induced renal injury by directly delivering biologically active molecules, such as circRNA[27]. Moreover, through the delivery of miRNA and other biologically active molecules, MSCs-EVs can inhibit macrophage apoptosis, regulate macrophage polarization, and induce macrophage M2 polarization. These actions help to modulate immune responses and inflammation, promote tissue repair, and ultimately alleviate sepsis-induced acute lung and kidney injury[28-31].

Between 40% and 60% of sepsis patients experience cardiac injury[32]. Numerous studies have demonstrated the potential of MSCs-EVs in alleviating sepsis-induced cardiac injury. For example, MSCs-EVs carrying miR-223 can prevent myocardial cell apoptosis and suppress the inflammatory response by inhibiting the NF-κB signaling pathway, which in turn can help to prevent sepsis-induced cardiac injury[33]. MSCs-EVs enriched with miR-146a-5p can promote cell proliferation and survival by regulating Myb-like protein 1 expression, thus protecting septic myocardial cells or tissue[34]. In addition, the delivery of miR-223-3p by MSCs-EVs can suppress sepsis-induced cardiac inflammation, pyroptosis, and dysfunction[35]. Moreover, MSCs-EVs containing miR-141 can activate β-catenin by targeting phosphatase and tensin homolog deleted on chromosome 10 (PTEN), thereby mitigating septic mouse myocardial injury[36]. Furthermore, MSCs-EVs can also deliver circRTN4 to inhibit cardiac fibrosis and inflammation through the miR-497-5p/mitsugumin 53 signaling axis, thus preventing sepsis-induced cardiac injury[37]. Finally, the presence of PTEN-induced putative kinase 1 in MSCs-EVs can restore mitochondrial $_{m}Ca^{2+}$ efflux, thereby preventing septic myocardial cell mitochondrial calcium overload[38].

MSCs-EVs can be used for the treatment of AP

Limited studies have been conducted on the role of MSCs-EVs in AP. Some studies have demonstrated the potential of human umbilical cord MSCs-EVs in reducing the severity of traumatic pancreatitis by colonizing injured pancreatic tissue, which in turn regulates inflammatory cytokine levels and inhibits acinar cell apoptosis[39]. Furthermore, human umbilical cord MSCs-EVs have shown promise in improving the inflammatory response in mild to moderate traumatic pancreatitis by suppressing inflammation, increasing cell proliferation, and inhibiting pancreatic acinar cell apoptosis. These effects promote the repair of pancreatic tissue, leading to effective relief of traumatic pancreatitis[40]. In addition, MSCs-EVs derived from hair follicles have also been found to promote pancreatic tissue repair and enhance pancreatic function by reducing inflammation in pancreatic cells and inhibiting cell pyroptosis-related signaling pathways[41]. These findings suggest that MSCs-EVs have therapeutic potential in treating AP and may offer a promising alternative to traditional treatments.

Table 1 presents a summary of the factors delivered by MSCs-EVs in inflammatory diseases, the signaling pathways that these factors mediate, and the ultimate effects of MSCs-EVs on inflammation or immunity.

RESEARCH PROGRESS OF USING MSCS-EVS FOR TREATING AP-INDUCED CARDIAC INJURY

In recent years, there has been growing recognition of the therapeutic potential of MSCs-EVs in the treatment of inflammatory diseases. Sepsis and AP, which are closely associated with inflammatory reactions, can result in cardiac and other organ injuries due to the amplification of the inflammatory response during their course. MSCs-EVs, on the other hand, have been shown to have potential therapeutic effects for both conditions.

Although research on the use of MSCs-EVs for AP-induced cardiac injury is limited, several studies have confirmed their potential in treating sepsis-induced cardiac injury, as well as their potential as a therapeutic strategy for various cardiovascular diseases. For instance, MSCs-EVs have been demonstrated their ability to improve myocardial inflammation, reduce cell apoptosis, and promote cardiac remodeling and function following acute myocardial infarction. This is achieved by inhibiting the activation of the NF-κB signaling pathway through the transmission of miR-302d-3p[42]. Additionally, MSCs-EVs have been found to alleviate myocardial ischemia-reperfusion injury by suppressing M1 polarization of macrophages through the inhibition of Toll-like receptor 4 (TLR4) *via* the transmission of miR-182[43]. Based on these findings, it is reasonable to speculate that MSCs-EVs may also exert therapeutic effects on AP-induced cardiac injury.

Table 1 Therapeutic potential of MSCs-EVs in inflammation disease

Cell model/animal model	Target cells in tissue	Source of MSCs	Cargo of MSCs-EVs	Factors or pathways involved	Therapeutic effects and mechanisms	Ref.
ALI						
Mouse BMDMs stimulated with LPS/C57BL/6 mouse with LPS-induced ALI	Alveolar macrophages	Human AT-MSCs	miR-27a-3p	NF-κB1	*In vitro*: MSCs-EVs facilitated M2 polarization of BMDMs through the inhibition of NF-κB1 expression; *in vivo*: Systemic or intratracheal administration of MSCs-EVs reduced NF-κB1 expression in alveolar macrophages *via* miR-27a-3p delivery, promoting macrophage M2 polarization and alleviating LPS-induced ALI	[20]
Mouse MLE-12 cells (lung epithelial cells) barrier model/ICR mouse with sulfur mustard-induced ALI	Lung epithelial cells	Mouse BM-MSCs	Not detected	GPRC5A/YAP axis	*In vitro*: MSCs-EVs dose-dependently inhibited sulfur mustard-induced lung epithelial cell apoptosis and promoted the repair of adherens and tight junction integrity through the regulation of the GPRC5A/YAP axis, ultimately facilitating the recovery of epithelial barrier function; *in vivo*: Administration of MSCs-EVs protected lung epithelial cells from apoptosis and epithelial barrier damage by regulating the GPRC5A/YAP axis, promoting the restoration of barrier function and exerting a protective effect against pulmonary edema in ALI	[21]
HLMVECs injured by a mixture of IL-1β, TNF-α, and interferon-γ which were often used as a surrogate for ALI pulmonary edema fluid/-	-	Human BM-MSCs	Ang1 mRNA	Not detected	*In vitro*: MSCs-EVs partially increased Ang1 secretion in injured HLMVECs through the transfer of Ang1 mRNA, subsequently promoting the secretion of anti-permeability factors, restoring intercellular junctions, and preventing the formation of "actin stress fiber", thereby dose-dependently restoring protein permeability across HLMVECs during ALI; *in vivo*: -	[22]
Sepsis						
-/BALB/C mouse with LPS-induced sepsis	Not detected	Human UC-MSCs	Not detected	Not detected	*In vitro*: -; *in vivo*: Administration of MSCs-EVs effectively mitigated the destructive effects of inflammation caused by sepsis by reducing inflammatory factors, thereby alleviating tissue damage	[25]
-/C57BL/6 mouse with CLP-induced sepsis-induced ALI	Not detected	Human UC-MSCs	Not detected	MAPK/NF-κB pathway	*In vitro*: -; *in vivo*: MSCs-EVs can inhibit the phosphorylation and activation of the MAPK/NF-κB pathway, increase heme oxygenase 1 expression, enhance nuclear factor erythroid 2-related factor 2 expression, and upregulate antioxidant enzyme levels, thereby suppressing the infiltration of polymorphonuclear neutrophils to alleviate lung inflammation, improving pulmonary microvascular permeability to mitigate pulmonary edema, ultimately enhancing the survival rate of mice with sepsis-induced ALI	[26]

-/C57BL/6N mouse with CLP-induced sepsis-induced renal injury	Not detected	Hypoxia pretreated mouse AT-MSCs	mmu_circ_0001295	Not detected	*In vitro*: -; *in vivo*: EVs secreted by hypoxia-pretreated MSCs can mitigate the elevated levels of plasma chemokines and cytokines induced by sepsis through the delivery of mmu_circ_0001295, thereby improving renal microvascular dysfunction, suppressing renal vascular leakage, and ultimately mitigating sepsis-induced renal dysfunction to enhance the survival rate of septic mice	[27]
Mouse RAW264.7 cells (monocytes/macrophages) stimulated with LPS/C57 mouse with LPS-induced sepsis	BMDMs	Mouse BM-MSCs	miR-17	BRD4/EZH2/TRAIL axis	*In vitro*: MSCs-EVs suppressed the inflammation caused by RAW264.7 cells under LPS stimulation by delivering miR-17 to regulate the BRD4/EZH2/TRAIL axis; *in vivo*: MSCs-EVs, through the delivery of miR-17 to regulate the BRD4/EZH2/TRAIL axis, decreased serum levels of pro-inflammatory cytokines and suppressed their expression in BMDMs, ultimately improving LPS-induced sepsis in mice and enhancing survival rates	[28]
Mouse BMDMs stimulated with LPS/C57BL/6 mouse with CLP-induced sepsis	Liver macrophages	IL-1β pretreated mouse MSCs (source not mentioned)	miR-21	PDCD4	*In vitro*: MSCs-EVs induced M2-like polarization of macrophages, and IL-1β-pretreated MSCs-derived EVs exhibited an enhanced capacity to promote macrophage polarization towards an M2-like phenotype; *in vivo*: MSCs-EVs, by delivering miR-21, suppressed the effects of PDCD4 and induced M2-like polarization of macrophages, resulting in reduced inflammation, alleviated symptoms, prevented the progression of sepsis, and ultimately improved the survival rate	[29]
-/C57BL/6 mouse with CLP-induced sepsis-induced ALI or LPS-induced ALI	Alveolar macrophages	Mouse BM-MSCs	SAA1	LPS	*In vitro*: -; *in vivo*: MSCs-EVs delivering SAA1 induced LPS internalization by mouse alveolar macrophages, leading to a decrease in inflammatory cytokine levels and ultimately alleviating sepsis-induced ALI	[30]
Mouse MH-S cells (alveolar macrophages) stimulated with LPS/C57BL/6 mouse with LPS-induced ARDS	Alveolar macrophages	Mouse BM-MSCs	Not detected	HIF-1α/glycolysis-related protein	*In vitro*: MSCs-EVs suppressed M1 polarization and promoted M2 polarization of alveolar macrophages by inhibiting cellular glycolysis, thereby exerting anti-inflammatory effects; *in vivo*: Intratracheal administration of MSCs-EVs attenuated the LPS-induced inflammatory response by suppressing glycolysis in alveolar macrophages *via* regulation of HIF-1α, leading to improved lung pathology, reduced lung edema, increased PaO_2/FiO_2 ratio, and therefore enhancing survival rate	[31]
Mouse RAW264.7 cells (monocytes/macrophages) or primary cardiomyocytes stimulated with LPS respectively/C57BL/6 mouse with LPS-induced sepsis-induced cardiac injury	Cardiomyocytes	Mouse BM-MSCs	miR-223, STAT3 and Sema3A proteins	STAT3, Sema3A	*In vitro*: MSCs-EVs suppressed the release of inflammatory cytokines in LPS-induced macrophages through the delivery of miR-223 and reduced LPS-induced cardiomyocyte apoptosis and cell death; *in vivo*: MSCs-EVs	[33]

					carrying miR-223 suppressed the expression of STAT3 and Sema3A, resulting in reduced serum levels of TNF-α, IL-1β, and IL-6, which in turn decreased cardiomyocyte apoptosis, improved cardiac function, and conferred cardio-protection in sepsis, ultimately reducing mortality. Additionally, by inhibiting miR-223 to pre-treat MSCs, the protein cargo within the secreted EVs can be reprogrammed, leading to an increased delivery of Sema3A and STAT3 proteins that exert detrimental effects on recipient cells	
Rat H9c2 cells (cardiomyocytes) stimulated with LPS/C57BL/6 mouse with LPS-induced sepsis-induced cardiac injury	Myocardium	Rat BM-MSCs	miR-146a-5p	MYBL1	*In vitro*: MSCs-EVs, by delivering miR-146a-5p, suppressed MYBL1 to inhibit the progression of LPS-induced cardiomyocyte inflammation, promoting cell proliferation, and inhibiting cell apoptosis; *in vivo*: MSCs-EVs administration can ameliorate cardiac injury and improve survival rates in septic mice	[34]
Human HL-1 cells (cardiomyocytes) model of cardiac dysfunction induced by LPS/C57BL/6 mouse with LPS-induced myocarditis	Cardiomyocytes	Mouse BM-MSCs	miR-223-3p	FOXO3/NLRP3 axis	*In vitro*: MSCs-EVs inhibited LPS-induced inflammation and pyroptosis in cardiomyocytes by delivering miR-223-3p, which targeted FOXO3 to suppress NLRP3 expression; *in vivo*: MSCs-EVs restricted myocardial tissue infiltration of inflammatory cells and inflammatory response, decreased cardiomyocyte pyroptosis, thus improving cardiac dysfunction by shuttling miR-223-3p, which targeted the FOXO3/NLRP3 axis	[35]
-/KM mouse with CLP-induced sepsis-induced cardiac injury	Cardiomyocytes	Mouse BM-MSCs	miR-141	PTEN/β-catenin axis	*In vitro*: -; *in vivo*: MSCs-EVs ameliorated myocardial impairment and improved cardiac function by attenuating myocardial inflammatory infiltration and cell apoptosis in septic mouse myocardial tissues through the delivery of miR-141 and regulation of the PTEN/β-catenin axis	[36]
RAT H9c2 cells or human AC16 cells (cardiomyocytes) stimulated with LPS respectively/wistar rat with CLP-induced sepsis-induced cardiac injury	Cardiomyocytes	Human MSCs (source not mentioned)	circRTN4	miR-497-5p/MG53 axis	*In vitro*: MSCs-derived exosomal circRTN4 improved cell survival and suppressed apoptosis in LPS-stimulated cardiomyocytes by targeting the miR-497-5p/MG53 axis; *in vivo*: MSCs-EVs, administered through injection into three different sites around renal tissue for three consecutive days after CLP, delivered circRTN4 to suppress oxidative stress, reduce inflammation factors, and alleviate apoptosis, resulting in the mitigation of cardiac injury	[37]
Human AC16 cells (cardiomyocytes) stimulated with LPS/C57BL/6 mouse with CLP-induced sepsis-induced cardiac injury	Cardiomyocytes	Human UC-MSCs	PINK1 mRNA	PKA/NCLX axis	*In vitro*: MSCs-EVs mediated the delivery of PINK1 mRNA to regulate cardiomyocyte $_{m}Ca^{2+}$ efflux through the PKA/NCLX axis; *in vivo*: MSCs-EVs mediated the transfer of PINK1	[38]

					mRNA, leading to the maintenance of normal $_{m}Ca^{2+}$ efflux, alleviation of mitochondrial calcium overload, and subsequent mitigation of cardiomyocyte injury caused by mitochondrial damage, resulting in improved cardiac function and increased survival rate	
AP						
-/SD rat with impactor-induced traumatic AP	Pancreatic tissue	Human UC-MSCs	Not detected	Not detected	*In vitro*: -; *in vivo*: MSCs-EVs inhibited the apoptosis of pancreatic acinar cells, controlled the systemic inflammatory response, and thereby attenuated pancreatic tissue injury and facilitated the repair of pancreatic tissue	[39, 40]
Mouse MPC-83 cells (pancreatic acinar cells) stimulated with caerulein/C57BL/6J mouse with caerulein-induced AP	Pancreatic acinar cells	Mouse HF-MSCs	Not detected	Pyroptosis-related protein	*In vitro*: MSCs-EVs enhanced cell viability, mitigated inflammation, and attenuated the expression of pyroptosis-related proteins in caerulein-stimulated pancreatic acinar cells; *in vivo*: Intraperitoneal or intravenous administration, especially intravenous injection, of MSCs-EVs, can mitigate pancreatic acinar cell pyroptosis, alleviate the inflammatory response and oxidative stress in AP, thus reducing the severity of pancreatic injury	[41]
Cardiovascular diseases						
Mouse HL-1 cells (cardiomyocytes) hypoxia model/C57BL/6J mouse with LAD ligation-induced AMI	Cardiomyocytes	Mouse BM-MSCs	miR-302d-3p	BCL6/MD2/NF-κB axis	*In vitro*: MSCs-EVs carrying miR-302d-3p improved the viability of hypoxic cardiomyocytes, suppressed inflammation, and inhibited apoptosis by targeting the BCL6/MD2/NF-κB axis; *in vivo*: Intramyocardial injection of MSCs-EVs carrying miR-302d-3p near the infarcted area attenuated cardiomyocyte apoptosis and cardiac inflammation by targeting the BCL6/MD2/NF-κB axis, leading to reduced infarct size and myocardial fibrosis, thereby suppressing post-AMI cardiac remodeling and improving cardiac dysfunction	[42]
Mouse RAW264.7 cells (monocytes/macrophages) stimulated with LPS/C57BL/6J mouse with LAD ligation-induced ischemia-reperfusion injury	Cardiac macrophages	Mouse BM-MSCs	miR-182	TLR4/NF-κB/PI3K/Akt signalling cascades	*In vitro*: MSCs-EVs carrying miR-182 facilitated the polarization of macrophages from an M1 to M2 phenotype in an inflammatory environment by inhibiting the TLR4/NF-κB signaling pathway and activating the PI3K/Akt signaling pathway through cross-talk between them; *in vivo*: MSCs-EVs carrying miR-182 regulated myocardial inflammation and reduced infarct size, thereby attenuating myocardial ischemia-reperfusion injury and improving cardiac function in mice through the promotion of macrophage M2 polarization *via* targeting the TLR4/NF-κB/PI3K/Akt signaling cascades	[43]

MSCs: Mesenchymal stem cells; EVs: Extracellular vesicles; BM-MSCs: Bone marrow-derived MSCs; AT-MSCs: Adipose tissue-derived MSCs; UC-MSCs: Umbilical cord-derived MSCs; HF-MSCs: Hair follicle-derived MSCs; Akt: Protein kinase B; ALI: Acute lung injury; AMI: Acute myocardial infarction; Ang1: Angiopoietin-1; AP: Acute pancreatitis; BCL6: B-cell leukemia/lymphoma 6; BMDMs: Bone marrow-derived macrophages; BRD4: Bromodomain-containing protein 4; CLP: Cecal ligation and puncture; EZH2: Enhancer of zeste homolog 2; FOXO3: Forkhead box protein O3; GPRC5A: G protein-coupled receptor family C group 5 member A; HIF-1α: Hypoxia-inducible factor-1α; HLMVECs: Human lung microvascular endothelial cells; IL-1β: Interleukin-1β; LAD: Left anterior descending coronary artery; LPS: Lipopolysaccharide; MAPK: Mitogen-activated protein kinase; MD2: Myeloid differentiation protein 2; MG53: Mitsugumin 53; MYBL1: Myb-like protein 1; NCLX: Mitochondrial Na^+/Ca^{2+} exchanger; NF-κB: Nuclear factor-κB; NF-κB1: Nuclear factor-κB subunit 1; NLRP3: NOD-like receptor thermal protein domain associated protein 3; PDCD4: Programmed cell death 4; PI3K: Phosphatidylinositol 3-kinases; PINK1: PTEN-induced putative kinase 1; PKA: Protein kinase A; PTEN: Phosphatase and tensin homolog deleted on chromosome 10; SAA1: Serum amyloid A1; Sema3A: Semaphorin 3A; STAT3: Signal transducers and activators of transcription 3; TLR4: Toll-like receptor 4; TNF-α: Tumor necrosis factor-α; TRAIL: Tumor necrosis factor-related apoptosis-inducing ligand; YAP: Yes-associated protein.

In a study conducted by Chen *et al*[44], MSCs-EVs were found to be effective in reducing oxidative stress and inflammatory damage in cardiac tissue, decreasing cell apoptosis, improving cardiac function, and ultimately increasing the survival rate of rats with SAP. These beneficial effects were attributed to the activation of the protein kinase B (Akt)/nuclear factor erythroid 2-related factor 2 (Nrf2)/heme oxygenase 1 (HO-1) signaling pathway. In our own research[45], we delved into the potential protective effects and mechanisms of MSCs-EVs in SAP-induced cardiac injury. Our findings suggest that MSCs-EVs can downregulate the high mobility group box-1/TLR4 signaling axis and activate the Akt signaling pathway by delivering miR-29a-3p. This, in turn, helps improve myocardial inflammation, enhance myocardial cell vitality, reduce cell apoptosis, and ultimately alleviate myocardial damage while preserving cardiac function. Therefore, we hypothesize that MSCs-EVs may play a crucial role in the onset and progression of SAP-induced cardiac injury.

IS THERE POTENTIAL FOR USING MSCS-EVS IN THE TREATMENT OF AP-INDUCED CARDIAC INJURY?

Studies have demonstrated that injecting EVs derived from MSCs overexpressing macrophage migration inhibitory factor into the infarcted area of the heart can enhance myocardial angiogenesis, reduce cell apoptosis, decrease cardiac remodeling, and thereby improve cardiac function[46]. Pre-treatment of bone marrow-derived MSCs with fibronectin type III domain-containing protein 5 can promote the secretion of more EVs, which can inhibit the secretion of pro-inflammatory cytokines, increase anti-inflammatory cytokine levels, and promote M2 polarization of macrophages *via* NF-κB signaling pathway and Nrf2/HO-1 axis[47]. Furthermore, when bone marrow-derived MSCs are pre-treated with lipopolysaccharide, the EVs secreted by these MSCs can inhibit M1 polarization of macrophages, promote M2 polarization, alleviate inflammation and cell apoptosis, and thereby facilitate tissue repair in various inflammatory diseases[48]. These studies highlight the potential of MSCs-EVs for targeted interventions, as the cargo and level of bioactive molecules loaded in EVs can be modulated according to the specific therapeutic goals. The *In vitro* plasticity of MSCs-EVs suggests a promising avenue for their utilization in the treatment of specific diseases.

The potential of using MSCs-EVs for clinical therapy is being explored in the initial stages. A Phase I clinical trial has been conducted on MSCs-EVs containing KrasG12D siRNA for the treatment of metastatic pancreatic cancer, and Phase I and II clinical trials on MSCs-EVs transfected with miR-124 for the treatment of stroke have been initiated[49]. Encouraging results have been reported in some clinical studies. A Phase I clinical trial confirmed the safety and efficacy of intravenous injection of placenta-derived MSCs-EVs for treating complex anal fistula in non-Crohn's disease patients [50]. In another Pilot Randomized Clinical Trial, placenta-derived MSCs-EVs were injected intraparenchymally to patients who underwent decompressive craniectomy after malignant middle cerebral artery infarction, and no significant adverse events were observed[51].

Due to the membrane of MSCs-EVs can be modified with specific ligands or peptides, they can be engineered to effectively target specific tissues or cells[52]. Additionally, MSCs-EVs can be stored for extended periods of time. Therefore, when compared to cell-based therapies, MSCs-EVs offer several advantages, including lower risks of immune rejection and tumorigenesis, lower costs, and on-demand availability. As a result, MSCs-EVs may present a promising potential as a viable strategy for treating AP-induced cardiac injury. However, there are still challenges to overcome in optimizing the separation and characterization of EVs, ensuring their purity and potency, and determining appropriate doses and delivery routes for MSCs-EVs in the treatment of AP-induced cardiac injury. Furthermore, potential safety concerns associated with the use of MSCs-EVs, such as the risk of thrombosis formation, immunogenicity, and potential tumorigenicity due to targeted delivery failure, must be carefully evaluated in clinical trials.

CONCLUSION

In conclusion, AP poses a significant global health threat, particularly when accompanied by cardiac injury, as it can complicate the treatment of SAP and worsen prognosis. Although there is currently limited preclinical research on the effectiveness of MSCs-EVs in treating AP-induced cardiac injury, multiple studies have demonstrated their ability to mitigate inflammation in various inflammatory diseases, including AP, regulate the immune response, promote tissue

regeneration, and improve sepsis-induced cardiac injury and various cardiovascular diseases. Therefore, we postulate that MSCs-EVs may hold promise as a potential treatment for AP-induced cardiac injury. However, further experimental research is necessary to explore their mechanisms, clarify treatment targets, and identify intervention pathways.

Abstract

In recent years, mesenchymal stem cells (MSC) have been considered the most effective source for regenerative medicine, especially due to released soluble paracrine bioactive components and extracellular vesicles. These factors, collectively called the secretome, play crucial roles in immunomodulation and in improving survival and regeneration capabilities of injured tissue. Recently, there has been a growing interest in the secretome released by retinal cytotypes, especially retinal pigment epithelium and Müller glia cells. The latter trophic factors represent the key to preserving morphofunctional integrity of the retina, regulating biological pathways involved in survival, function and responding to injury. Furthermore, these factors can play a pivotal role in onset and progression of retinal diseases after damage of cell secretory function. In this review, we delineated the importance of cross-talk between MSCs and retinal cells, focusing on common/induced secreted factors, during experimental therapy for retinal diseases. The cross-link between the MSC and retinal cell secretomes suggests that the MSC secretome can modulate the retinal cell secretome and vice versa. For example, the MSC secretome can protect retinal cells from degeneration by reducing oxidative stress, autophagy and programmed cell death. Conversely, the retinal cell secretome can influence the MSC secretome by inducing changes in

MSC gene expression and phenotype.

Key Words: Secretome; Mesenchymal stem cells; Retinal cells; Extracellular vesicles; Retinal diseases

Core Tip: Recently, the mesenchymal stem cell secretome, a solution rich with paracrine bioactive factors and extracellular vesicles, acquired a significant role in immunomodulation and survival induction of damaged tissues. A secretome is also released by retinal cells, physiologically or following pathological stimuli. One of the most promising therapeutic frontiers is represented by a possible "cross-talk" between mesenchymal stem cells and retinal cells through the secretomes in order to improve the knowledge on released factors mechanisms of action during their potentially beneficial role.

INTRODUCTION

In recent years, mesenchymal stem cells (MSCs) have been indicated as the most effective source for cell-based therapy, particularly in regenerative medicine. In particular, MSCs produce major therapeutic effects releasing soluble paracrine bioactive components and extracellular vesicles (EVs) constituting the so called secretome. These secreted factors play crucial roles in modulating immunity and improving survival and regeneration capabilities of injured tissue[1].

Secreted trophic factors are also key to preserving the morphofunctional integrity of the retina, regulating biological pathways involved in survival, function and response to injury[2]. Additionally, these factors can play a fundamental role in onset and progression of retinal diseases after damage of cell secretory functions[3]. In this review, we discussed the link between the secretome of MSCs to the retinal cell secretome, in order to highlight the current knowledge of secreted factor involvement in retinal diseases.

Main features of MSCS

One of the most recent fields of therapy research concerns MSCs, multipotent non-hematopoietic stem cells that originate from the mesoderm. They can reach a pathological site following the release of different biologically active immunomodulatory and regenerative factors related to different diseases[4]. There are multiple sources of MSCs, including umbilical cord blood, placenta, adipose tissue, skin and bone marrow tissue, with the latter representing the most widely used source[5]. Isolation of different types of MSCs, such as adipose tissue-derived mesenchymal stromal/stem cells (ASCs), is a non-invasive process, and this represents a fundamental advantage from an ethical and/or legal point of view[6]. The key point for MSC use is their low immunogenicity, permitting allogeneic trans-plantation in the medical setting[7].

Moreover, recent studies have shown that MSCs can produce an immune response, mediated by T cells regulated by IFN-γ[8]. When activated, MSCs can reach the correct pathological site to exert reparative functions, triggered by a huge number of secreted factors from the injured cells, such as cytokines, chemokines and growth factors[9]. Among the latter, placental growth factor plays a pivotal role, along with VEGF, EPO, SDF-1, ANG2, G-CSF, stem cell factor, PDGF, EGF, HGF and IGF-1[10]. Regarding cytokines and chemokines, the former include TNF-α and interleukins such as IL-1b, IL-2, IL-3, IL-6 and IL-8, and the latter includes, among others, CCL5 and CCL22[11].

Various studies have confirmed that human MSCs evade allorecognition, affect T lymphocytes and dendritic cell activities and produce a local immunosuppressant microenvironment by releasing the already cited cytokines[12]. Moreover, MSCs can be easily genetically manipulated, with elevated metabolic activity and low mutation rate, and can efficiently secrete a wide number of proteins[13]. Today, preclinical and clinical trials using MSCs, especially human bone marrow-derived MSCs (hBMMSCs) and human adipose mesenchymal stem cells (hADSCs), have been performed in different kinds of pathologies with promising results, such as autoimmune disease, joint reconstruction, vascular disease, nerve injury, organ transplantation, degenerative disease and severe infection[14].

In particular, one of the fields with the highest number of ongoing clinical trials is represented by eye diseases (Table 1). The protective activity of MSCs was initially linked to their direct differentiation and replacement of injured tissues, as evidenced by human MSCs becoming hepatocyte-like cells or rat MSCs turning into neuron-like cells[15]. However, today the protective action of MSCs is well known to be primarily mediated through paracrine properties, exerted by what is defined as the MSC secretome.

MSC secretome

The secretome released by MSCs consists of a conditioned medium (CM) made up of soluble elements (cytokines and growth factors) and a vesicular part made up of exosomes and microvesicles, which are fundamental for protein and genetic material transfer towards other cells[16]. The most recent *in vitro* and *in vivo* studies on the features of the MSC

Table 1 Ongoing clinical trials on eye diseases based on the use of mesenchymal stem cells

secretome have highlighted its role in facilitating cell survival, proliferation, differentiation and physiological processes [17]. A huge number of secreted growth factors are well known today, including VEGF, SDF-1, TGF-β, IGF-1, fibroblast growth factor (FGF), nerve growth factor-beta (NGF-β), HGF, G-CSF and EGF[18]. With regard to MSC secreted cytokines and chemokines, the most investigated are CCL2, CCL5 and CXCL12 (SDF-1)[19].

One of the most useful aspects of the MSC secretome is the possibility to tailor or modify its composition depending on the desired cell-specific therapeutic effects. This promising possibility depends on MSC tissue sources or on the number of passages, allowing the creation of distinct secretory profiles and exosomal compositions[20]. However, several controversial studies have already been published. It was shown, for example, that the impact of MSCs extracted from adipose tissue was more noticeable on axonal growth than MSCs coming from bone marrow, while cell passaging did not influence the secretome content/activities supporting postnatal neuronal survival and axonal growth[21]. During the last few years, it has been revealed that MSCs are able to modify the microenvironment by releasing EVs, primarily distinct into apoptotic bodies, microvesicles and exosomes[22] (Table 2). The latter subtype consists of a bilayered lipid film of 30-120 nm, originating from convex membranes in late endosomes, determining the production of multi-alveolar bodies[23].

Different and various proteins are typical markers of exosomes, such as tetraspanin (CD9, CD63, CD81), annexin, heat shock proteins, caveolin and clarins as well as protein characteristics of source cells[24]. Furthermore, exosomes present specific lipids, comprising lipid raft portions, ceramides, sphingomyelin, cholesterol, GM1 ganglioside and phosphatidylserine. Additionally, they can contain nucleic acids, mRNA and ncRNA[25]. MSC-derived exosome biosynthesis and secretion are complex pathways that differ in microenvironmental stimuli, like inflammation or hypoxia[26]. The mTOR and Wnt pathways seem to play a pivotal role in exosome release[27]. Interestingly, recent studies have shown that MSC-derived exosomes may be involved in antigen presentation and immunologic response, coagulation, angiogenesis and apoptosis, as confirmed by the expression of antigens such as CD9, CD44 and CD89 on their surface [28]. Thus, the secretome obtained from the culture of MSCs would appear to promote tissue repair and modulate immune response *in vitro* and *in vivo*, showing a translational impact on regenerative medicine[29]. The use of CM could present diverse advantages if compared to the original MSC implantation, such as: (1) Removal of the inherent risks of cell transplantation; (2) Simpler storage, transport and conservation requirements; and (3) Possible application as a ready-to-go biologic product[30].

Secretome preconditioning modulated by the MSC cultural microenvironment

In recent years, it has been shown how preconditioning approaches for improving paracrine secretion, such as hypoxia, biochemical stimuli and 3D microenvironment, can increase the viability, proliferation and paracrine features of MSCs, thus expanding the therapeutic potential of these cells and their derived products[31]. In detail, dynamic culture conditions, such as 3D aggregate culture and fluid flow, could noticeably impact cellular behavior[32]. Boosted levels of growth factors and cytokines were detected in 3D MSC cultures grown on rotatory orbital or shaking platforms, in stirred systems, such as stirred tank reactors or spinner flasks, and in microgravity bioreactors[33]. Nevertheless, little is still known about the dynamic culture conditions and procedures for 3D aggregate MSC cultures as a scalable and reproducible plan for secretome production. However, the possibility of culturing cells under 3D conditions in a way to better mimic the *in vivo* environment has emerged[34].

A dynamic cross-talk between the cells could permit them to constantly modify their secretome following received stimuli, generating a microenvironment able to promote secretome enrichment for specific applications. Additionally, enhancing the manufacturing process allows MSC cell populations to be obtained that can be cryopreserved for clinical applications to expand clinical efficacy[35]. Recently, the use of matrix-conjugated hydrogel cell culture materials normalized a culture of induced pluripotent stem cell-derived MSCs (iPSC-MSCs), leading to a well-defined secretory profile able to promote enhanced neovascularization both *in vitro* and *in vivo*[36]. Using such innovative biomaterials, it was possible to stimulate reproducible secretion of proangiogenic and immunomodulatory cytokines from iPSC-MSCs that improved tubulogenesis of endothelial cells in Geltrex and neovascularization in chick chorioallantoic membranes [37].

Treatment with both IFN-γ and TNF-α permitted optimization of the MSC secretome. Recently, a unique supernatant of MSCs from human umbilical cord-derived MSCs, pretreated with TNF-α, was discovered to be more powerful in promoting macrophage migration, M2 polarization and pha-gocytosis, due to the induced high levels of CCL2 and IL-6 [38]. Another way to overcome the expansion limitation of MSCs is to work with MSCs derived from human-induced pluripotent MSCs, serving as a reproducible and sustainable cell source. In a way similar to hBMMSCs, human-induced pluripotent MSCs can release EVs with *in vitro* immunomodulatory properties, with an increased expression of well-known immunomodulatory genes, such as *HLA-DRA*, *IDO1* and *CXCL8/IL8* and at least another 100 regulated by NFKB signaling, known to play a pivotal role in immune response[39].

Interestingly, it has recently been shown that hypoxic preconditioning appears to induce the ASC secretome to release a secretome with enhanced anti-apoptotic effects by promoting the autophagic process of ASCs[40]. Furthermore, the specific content of EVs can be modulated by hypoxia, with their source cell responding by triggering HIF at low oxygen levels. The pleiotropic effects of HIF regulate the expression of many genes involved in pathways such as inflammation, angiogenesis, migration, differentiation, metabolism, proliferation and apoptosis. Expression of these genes is reflected in the interior of secreted EVs, which showed a greater regenerative ability than those achieved under normal oxygen conditions[41]. Moreover, the preconditioning of MSCs in an oxidative stress (OS) environment provides the release of

Table 2 Secretome and extracellular vesicle features

Type	Dimension	Origin	Collection	Content
Medium-size EVs (microvesicles)	200-1000 nm	Plasma membrane shedding	Filtration, ultracentrifugation, chromatography, precipitation, immunoaffinity	Similar to exosomes + cytosolic/plasma membrane/post-translational modified proteins
Small-size EVs (exosomes)	Up to 200 nm	Multivesicular bodies pathway	Filtration, ultracentrifugation, chromatography, precipitation, immunoaffinity	Receptors, transcription factors, enzymes, proteins, lipids, nucleic acids (DNA, mRNA and miRNA)
Soluble factors	Up to 5 nm	Protein synthesis	Protein extraction methods	Proteins, growth factors, chemokines, cytokines, enzymes
Secretome	From protein size to 1000 nm	Cell secretion/shedding	Cell culture media (concentration is possible)	The combination of the other components

EV: Extracellular vesicle; miRNA: MicroRNA.

many proteins, growth factors, cytokines and exosomes that could increase the antioxidant ability of MSCs against OS, enforcing the secretome as an encouraging, novel, cell-free tissue regeneration approach[42].

Characterization of MSC secretome EVs

A detailed analysis of the secretome structure might contribute to the improvement of secretome application for regenerative purposes and allow the discovery of novel biomarkers circulating in patient blood, improving pathology diagnosis and discovering new therapeutics targets[43]. As already anticipated, secretome fractions consist of lipids, proteins and non-coding RNAs able to impact the physiology of target cells. MSC-EVs were shown to contain a significant number of microRNAs (miRNAs), such as miR-210, miR-200b-3p and miR-4732-3p, involved in improving myocardial function[44]. BM-MSC-EVs, PD-L1-MSC-EVs and human umbilical cord-derived MSC-EVs also exhibited a healing role in autoimmune conditions[45]. miR-146a and miR-27a/b, upregulated in ASC-derived EVs, were able to induce neoangiogenesis pathways, while miR-122-5p, miR-27a, miR-206 and lncRNA MALAT1 played a relevant role in osteogenic regenerative processes[46].

Other studies identified specific factors from the secretome released by tumor cells that might be actively involved in cancer progression, thus representing optimal biomarkers[47]. Additionally, a customized secretome could be rich in proapoptotic factors that are helpful against cancer or higher levels of proangiogenic and pro-osteogenic factors suitable for regenerative applications. An interesting case is represented by human fetal MSCs, producing a secretome rich in anti-apoptotic factors as well as proangiogenic and antiangiogenic and osteogenic differentiative proteins[48]. On the contrary, the multipotent fetal dermal cell secretome is enriched in upregulated proteins involved in wound healing processes, angiogenesis and cellular metabolism[49]. Such data underlined that the fetal MSC secretome could be more beneficial for regenerative purposes if compared to the adult MSC secretome. In agreement with reports on the secretome derived from 3D cultured cells, fetal cells cultured under 3D conditions might further improve the therapeutic abilities of their secretome[50].

Unique immunomodulatory properties emerged for amniotic MSCs. Their secretome was able to reduce the polarization of T cells toward inflammatory helper T cell subgroups, inducing regulatory T cells, to decrease the proliferation of activated peripheral blood mononuclear cells, to affect monocyte polarization to antigen-presenting cells stimulating the synthesis of anti-inflammatory macrophage (M2) markers and to reduce the activation of B lymphocytes into plasma cells[51]. The most intriguing aspect of secretome EV fractions is the functional mitochondria release from human mesenchymal stromal cells[52]. Recent studies in non-orthopedic tissues proposed that MSCs can rescue damaged cells by donating mitochondria, repairing mitochondrial activity in target cells, preserving cell viability and stimulating tissue repair. To obtain this goal, MSCs might be able to package mitochondria for export into EVs, and these "mitoEVs" could provide a delivery approach for cell-free mitochondria-targeted therapy[53].

Therapeutic role of the secretome in central nervous system pathologies

The MSC secretome is a significant element of the paracrine and autocrine cell signaling mechanism, playing a crucial role in the regulation of many physiological and pathological processes. In particular, its effects on immunomodulation, neuronal survival and regeneration, due to the action of soluble and vesicular factors, are pivotal in reducing or even arresting neuronal disease evolution and in promoting repair[54]. Thus, the various MSC secreted factors and vesicles seem to be an effective tool for the protection and survival of neuronal and glial cells[55]. Traumatic brain injury (TBI) is determined by external mechanical forces able to cause physical, cognitive and emotional impairments[56]. In this case, the MSC-derived secretome may be used to control the secondary injury mechanisms of TBI, modulate the abnormal inflammatory cascade, reduce proinflammatory cytokines and stimulate neural stem cell proliferation and differentiation [57]. Moreover, EVs released by MSCs reduced neuroinflammation and supported neurogenesis and angiogenesis, rescuing spatial learning and motor damage in TBI animal models[58].

Spinal cord injury is characterized by long-term functional deficits following the loss of neurons and glial cells, inflammation and demyelination[59]. The paracrine factors secreted into the lesion site by MSCs, such as HGF, BDNF and NGF could promote immunomodulation, glial scar reduction, axonal regeneration and neurite outgrowth. Additionally, the

ASC-derived secretome reduced the production of TNF-α by M1 macrophages while it improved TGF-β1 and IL-10 production by M2 macrophages[60]. MSC exosomes could stimulate anti-inflammatory and proangiogenic effects and axonal regeneration and suppress glial scar formation and cell apoptosis, reducing lesion size and improving functional recovery after traumatic spinal cord injury[61].

Ischemic stroke is a cerebrovascular pathology induced by blood vessel occlusion or injury, leading to a blood supply defect, determining focal tissue loss and endothelial and neuronal cell death[62]. The use of MSC secreted factors such as IGF-1 and BDNF could induce neuroprotection by impeding neuronal damage and tissue loss and reduce astrocyte injury by GFAP downregulation[63].

Parkinson's disease (PD) is a neurodegenerative pathology characterized by the progressive degeneration of dopaminergic neurons. In PD, it has already been seen that the addition of the MSC secretome can promote a partial reversion of PD histological impairments and gains in animal motor ability by the secretion of immunomodulatory, anti-inflammatory, neurogenic, neurodevelopmental, neurorescuing or antiapoptotic factors[64]. Recent evidence highlighted the particular ability of the MSC secretome to reduce one of the hallmarks of the disease, the alpha-synuclein aggregates, through an MMP-2-based mechanism[65].

MAIN FEATURES OF RETINAL CELLS

Even if peripherally localized, the retina represents an important part of the central nervous system. Though it presents the same types of functional elements and neurotransmitters sited in other portions of the central nervous system, the retina includes five classes of neurons: photoreceptors (rods and cones); bipolar cells; amacrine cells; horizontal cells; and ganglion cells. Light absorption by the photopigment in the outer segment of rods and cones, the two photoreceptors, starts a cascade of events that changes the receptor membrane potential and the quantity of neurotransmitter released by the rod and cone synapses onto the adjacent bipolar cells, in the outer plexiform layer. Then, in the inner plexiform layer, the short axonal processes of bipolar cells realize a synapse with the dendritic processes of ganglion cells whose axons form the optic nerve. Horizontal and amacrine cells, instead, present their cell bodies within the inner nuclear layer and are mainly involved in lateral interactions between already described retinal cells, impacting the sensitivity of the visual system to light contrast over a wide range of intensities. The amacrine cell processes, which ramify laterally in the inner plexiform layer, are postsynaptic to bipolar cells and presynaptic to ganglion cells, while the processes of horizontal cells instead extend in the outer plexiform layer. The existence of different subgroups of amacrine cells that play a distinct role within visual pathways is relevant. Furthermore, the neural retina and the choroid are connected by a monolayer of cells constituting the retinal pigmented epithelium (RPE). Light absorption, epithelial transport, spatial buffering of ions, visual cycle regulation and phagocytosis of rod and cone outer segment membranes represent the main functions exerted by the RPE[66].

RPE cell secretome and retinal diseases

The RPE is characterized by a polarized nature, with molecules expressed by these cells either secreted to the apical or basolateral membrane by the Na^+/K^+-ATPase associated channel or by the anion channel, respectively. These products, mainly growth, anti/proangiogenic and neurotrophic factors, are critical for the correct functioning of the neuroretina and choroid. Among them, the most characterized are VEGF[67,68], TGF-β[67,69], PEDF[70], MMPs[71], NGF[72], FGF-1, FGF-2, and FGF-5[73], IGF-1[74], BDNF[75], PDGF[76], CTGF[77], LEDGF[78], interleukins[79], tissue inhibitor of matrix metalloproteases[80], PIGF[81], angiogenin[82], EPO[83], somatostatin[84] and apolipoprotein A1[85]. These factors could also play a fundamental role in the etiology of several retinal diseases such as diabetic retinopathy (DR), age-related macular degeneration (AMD) and retinopathy of prematurity[86].

Deep proteomic analyses of RPE cells cultivated in these pathological condition microenvironments suggested that previously described molecules could be involved in membrane and cytoskeleton dynamics, mitochondrial trafficking, protection/induction of cellular stress, apoptosis, differential modulation of multidrug resistance-associated proteins and in other metabolic events already during the first stages of the diseases[87]. In physiological conditions, RPE cells release EVs characterized by proteins associated with biological pathways involved in AMD etiology, including drusen composition. Recently, it was shown that drusen-associated proteins are secreted as cargo of EVs produced by RPE cells in a polarized apical to basal way. Remarkably, drusen-associated proteins revealed differential regulation of polarized secretion in homeostatic conditions and in response to AMD stressors[88]. Findings suggested that a finely-tuned mechanism is pivotal to regulate directional sorting and secretion of drusen-associated proteins *via* RPE secretome EVs, supporting the influential role of vesicles as a strategic source of drusen proteins and critical elements to drusen development[89].

OS changed the release of several factors implicated in neovascularization and AMD, stimulating a proangiogenic microenvironment by increasing the secretion of VEGF, PTN and CRYAB and reducing the production of anti-PEDF and CFH. Apical secretion was influenced more than basolateral for PEDF, CRYAB and CFH, while directional secretion was impacted more for VEGF, which may have implications for choroidal neovascularization[90]. VEGF-A is an important proangiogenic factor released by different retinal cytotypes (endothelial cells, Müller cells, ganglion cells and pericytes) but primarily by the basolateral side of RPE in homeostatic conditions, shifting to apical during pathological conditions [91].

In particular, VEGF overexpression was highlighted in hypoxic and hyperglycemic conditions, by both *in vitro* and *in vivo* studies, demonstrating that in pathological conditions VEGF causes alteration of tight junction proteins and transepithelial resistance[92]. It has been confirmed that VEGF R2, placed in the apical side of RPE cells, can induce

disruption of the RPE barrier by promoting VEGF signaling[93]. Considered together, such findings led to the development of anti-VEGF therapies to treat retinal neovascularization in patients with DR and other related diseases. However, many associated complications are still present, such as repeated injection requirements, increased ocular pressure, macular edema, subconjunctival hemorrhage, pain, uveitis and the compromised viability of RPE, photoreceptors, choriocapillaris and Müller glia[94].

One of the most interesting relates to splice variants of VEGF, such as VEGF165b, expressed by RPE cells. It can appear to act as a powerful antiangiogenic isoform of VEGF with significant results in treating induced choroidal neovascularization and was decreased in DR[95]. Nevertheless, while inner retinal barrier and Müller cell association with VEGF is well known, the outer retinal barrier properties of RPE in relation to VEGF in diabetes and other ocular neovascularization-related diseases should be better investigated. One of the most significant glycoproteins of the RPE secretome is PEDF, a serine protease inhibitor with neuroprotective, antiangiogenic and anti-inflammatory features. In homeostatic conditions, PEDF is apically released from the RPE and preserves retinal and choriocapillaris integrity by preventing endothelial cell proliferation[96]. It was seen that PEDF was downregulated in human hyperglycemic RPE cells as well as in patients affected by proliferative DR (PDR), diabetic macular edema (DME), retinopathy of prematurity, retinitis pigmentosa and leber congenital amaurosis[97]. Thus, PEDF is primarily considered for its therapeutic potential, showing positive effects in photoreceptor survival, morphology and function while reducing vascular permeability in correlation with reduced levels of angiogenic factors (VEGF, VEGFR-2), cytokines and chemokines[98]. Additionally, recent animal studies have proven that in an oxygen-induced retinopathy model and in a rat model of choroidal neovascularization, PEDF upregulation blocked retinal neovascularization and inflammation[99].

Another prosurvival cytokine able to stimulate fibroblast chemotaxis/proliferation and preserve pericyte viability and physiological vascularization of the retina is PDGF. Similar to VEGF, it can promote pathologic neovascularization in PDR and DR and in a hypoxia-regulated microenvironment[100]. PDGF receptor activation suggests an autocrine mechanism in epiretinal membrane development and retinal wound repair[101]. Today, one of the most promising research fields is understanding the cross-talk of PDGF with other signaling pathways in order to identify the best molecular targets for combinatorial therapies. This idea arose from several animal studies that established that antagonism to PDGF-BB (a homodimeric form of the PDGF family), together with anti-VEGF, enhanced the arrest of retinal neovascularization[102].

An important cofactor of VEGF is PlGF. It can alter retinal fibrovascular integrity and RPE permeability by interaction with VEGF and activation of Akt and HIF-1 pathways[103]. Thus, it was found at high levels in AMD and PDR patients [104]. The use of anti-PlGF monoclonal antibody in different animal models revealed reduced inflammation and vascular leakage with no adverse effects in retinal ganglion cell (RGC) viability[105]. However, novel strategies that avoid the weaknesses observed in repeated intraocular injections should consider PlGF as a valid therapeutic target. RPE cells cultured in high glucose medium also showed an elevated expression of CTGF, one of the main fibrogenic factors involved in fibroblast proliferation and extracellular matrix synthesis, which could control the microenvironment around the distal retinal/RPE/Bruch's membrane complex and protect against neurodegenerative diseases[106]. Increased retinal CTGF levels might play an essential role in DR, probably by reducing VEGF levels[107]. Thus, the combined use of anti-CTGF and anti-VEGF in treating complications of DR could exert more beneficial effects than a monotherapy drug[108].

CTGF is corroborated in its activity by the more well-known FGF, which plays a crucial role in stimulating vascularization, angiogenesis and cell survival and acting as autocrine factors. FGF1, FGF2 and FGF5 are principally released in the RPE, reaching their highest levels in non-proliferative retinopathy, PDR with active proliferative retinopathy and diabetic conditions, respectively[109]. Recently, targeting of retinal FGFs exhibited worthy results in improving visual acuity of DME and exudative AMD patients, even if further studies are mandatory to determine long-term effects[110]. The secretome produced by human RPE cells also contained IGF-1 and IGF-2, natural proteins promoting growth and insulin-like metabolic effects, together with their receptor (IGF-R) and binding protein (IGFBP-2)[111]. Both growth factors seem to play a pivotal role for RPE autocrine/paracrine-mediated modulation of proliferation[112]. Recent evidence showed that another IGFBP family member, IGFBP-3, was able to reduce DR by considerably decreasing TNF-α levels and proapoptotic markers[113].

Among secreted factors, TGF-β represents one of the main elements that can modulate main cellular physiological processes, like growth, differentiation, proliferation and apoptosis[114]. However, there is scant information on its efficacy and potential mechanisms in relation to retinal homeostasis or pathology. In detail, comparable secretion levels of TGF-β from polarized RPE, differentiated from human embryonic stem cells and human RPE, promoting retinal homeostasis and sustaining the potential of human embryonic stem cell-RPE in replacement therapies, have recently been highlighted[115]. Human stem cell-derived RPE treated with reactive oxygen species for 1 wk or 3 wk released more than 1000 proteins, many of which showed relevant changes due to induced stress.

In particular, secreted APOE and TGF-β were decreased 4-fold, and urotensin-II, one of the most effective vasoconstrictors, doubled, similar to BMP1[116]. The glycoprotein EPO represents one of the most promising molecules found in the RPE secretome. It acts as an erythropoiesis regulator with different additive features such as vessel integrity, recruitment of endothelial progenitor cells, neuroprotection and antioxidative properties[117]. High levels of EPO were recently found in DR, PDR and DME patients[118]. Especially in hyperglycemic conditions, EPO seems to protect the RPE barrier, reducing retinal vasculogenesis, downregulating VEGF and VEGFR expression and protecting tight junctions by increasing the flow of Ca^{2+} ions in blood-brain barrier animal models[119]. However, the administration of EPO in the late stage of a hypoxia-induced murine retinopathy model worsened retinal neovascularization, suggesting that EPO might play a protective role in early DR and a pathologic one in late DR[120]. This dual nature of EPO could be related to its action mechanism, whose first step is its hypoxia-modulated binding to cell surface receptor EPOR. Thus, it can be predicted that in the first stages of DR, EPO exerts neuroprotective functions, while in the advanced stage of DR EPO acts as a neovasculogenesis inducing molecule that is regulated by hypoxia[121].

MMPs, apically secreted by RPE, are calcium-dependent endopeptidases involved in angiogenesis and are fundamental for ocular extracellular matrix and photoreceptor outer segment homeostasis[122]. Recently, it has been seen that basolateral secretion of MMP is related to AMD, and increased levels of MMP-2 and MMP-9 were also observed in the Bruch's membrane of AMD and DR patient eyes[123]. Thus, inhibitors of both cited MMPs might also exert an advantageous role by blocking capillary cell apoptosis, growth of vessels and reduce inflammatory-mediated permeability[124].

In addition to angiogenic and antiangiogenic factors, numerous inflammatory chemokines and cytokines were elevated in retinal diseases, such as PD and PDR. Among them, the most investigated were MCP-1, IL-6 and IL-8. It was seen that MCP-1 and IL-8 secretion levels are directly correlated to blood glucose levels, suggesting a crucial role in altered blood retinal barrier (BRB) activities of DR affected patients[125]. MCP-1 carries out chemoattractant activity for monocytes and lymphocytes to promote endothelial proliferation and may limit the impairment of neurosensory retina[126]. IL-6 and IL-8, were overexpressed in cultured RPE cells stimulated with IL-1b or TNF-β, suggesting that polarized release of growth factors/cytokines is favored in retinal diseases[127].

Additionally, it is interesting to cite the recently discussed role of somatostatin as a neuromodulator of retinal homeostasis, as hypothesized by its downregulation in the RPE of diabetic eyes[128]. Finally, several substrates of the serine protease HTRA1 were found in the RPE secretome, proposing a link between it and complement modulation and amyloid deposition in AMD etiopathogenesis. In detail, a cleavage of fibromodulin (90%), CLU (50%) and vitronectin (54%) involved in regulation of the complement pathway was seen, along with a cleavage of 2-macroglobulin (55%) and ADAM9 (54%) related to amyloid deposition as well as some cell surface protein cleavages including talin-1 (21%), fascin (40%) and chloride intracellular channel protein 1 (51%)[129].

Müller glia cell secretome and retinal diseases

Regarding the RPE, Müller cells can modulate trophic secretion depending on the healthy or pathological status of the retina[130]. The Müller cell physiological secretome mainly contains molecules that are crucial to increase BRB tightness, like thrombospondin-1 and PEDF[131]. In pathological circumstances, factor synthesis and secretion both shift towards an inflammatory environment. Under hyperglycemic conditions, IL-1b release by Müller cells is increased, leading to vascular impairment and cell death *via* a paracrine mechanism. Thus, by inhibiting IL-1b or knocking down its receptor, it was possible to decrease inflammation and photoreceptor/retinal vessel disruption in murine models, exerting a possible therapeutic role for ocular dystrophies related to chemokine expression and/or diabetes[132]. Furthermore, the proinflammatory IL-6 and TNF-α can be secreted by Müller cells, determining a possible promotion of both vascular dysfunction and angiogenesis, even if IL-6 may exert protective effects toward photoreceptor cells[133].

Stimulation of porcine and human Müller cells with IL-4, IL-6, IL-10, VEGF, INF-γ, TGF-β1, TGF-β2, TGF-β3 and TNF-α resulted in a primarily proinflammatory phenotype with release of cytokines and factors of the complement system[134]. Additionally, Müller cells expressed proteins linked to biosynthesis and maturation of phagosomes. These findings underline the relevance of Müller cell signaling in chronic retinal inflammation[135]. Additionally, under hyperglycemia and hypoxic conditions, Müller cells shift PEDF secretion to VEGF, contributing to ocular vascular diseases[136]. Therefore, inhibition or knockdown of Müller cell-derived VEGF could reduce ischemia-induced impairment of the BRB, prevent ischemia-induced retinal neovascularization and decrease vascular leakage[137].

Recent evidence highlighted that in the diabetic retina expression of VEGF could be regulated by increasing the activity of the receptor for retinoic acid alpha, which also stimulates the expression of glial cell line-derived neurotrophic factor, with a final significant decrease of vascular leakage[138]. Nevertheless, in recent years, the neuroprotective effects of VEGFR-2 in Müller glia have also been described, suggesting its significance for cell survival and consequential viability of neuronal cells in the diabetic retina[139]. Interestingly, the secretome of Müller cells also contains increased levels of MMP-2 and MMP-9 in patients with PDR and AMD, respectively[140]. It was proposed that the stabilization of HIF-1a could raise the level of VEGF, inducing MMP-2 expression in neighboring endothelial cells, with consequent retinal neovascularization[141]. As MMPs regulate crucial cellular pathways through angiogenesis and apoptosis, their targeting could represent an important therapeutic strategy for ocular diseases. Moreover, new evidence has proven that Müller glia release neurotrophic factors, such as CLU, osteopontin and basigin, that support RGC survival. The latter two significantly enhance RGC survival *in vitro*, suggesting that the survival-promoting activity of the Müller cell secretome is multifactorial[142].

Recently, it was shown that human iPSC-derived multinucleated giant cells (hiMGCs) could represent an alternative to primary MGCs in understanding glial cell involvement in retinal disorders, including DR. Under culture with palmitate, a major free fatty acid with elevated plasma levels in diabetic patients, hiMGCs and primary MGCs expressed low transcript levels of *AQP4*, *RLPB1*, *SLC1A3*, *KCNJ1* and *KCJN10*. Furthermore, the analysis of the palmitate-treated hiMGC secretome evidenced an upregulation of proangiogenic factors powerfully related to DR, including ANG2, endoglin, IL-1b, CXCL8, MMP-9, PDGF-AA and VEGF[143]. One of the most interesting pieces of evidence regarding the Müller cell secretome was linked to the production of different EVs from endfeet and microvilli of retinal Müller cells in adult mice. In particular, VAMP5 was identified as a Müller cell-specific snap receptor member that is part of EVs and responsive to ischemia, with relevant changes between the secretomes of Müller cells and neurons *in vitro*[144].

Other glial cell secretome and retinal diseases

Undifferentiated rat RGC line RGC-5 can secrete numerous protein markers of RGCs, even if they are unable to react to glutamate or N-methyl-D aspartate. Furthermore, it has recently been highlighted that human nonpigmented ciliary epithelial (HNPE) cells could release several neuroproteins located in the aqueous humor, many of which can influence the activity of neuronal cells. Recent works identified about 130 unique proteins from the HNPE cell-conditioned SF-medium, most of which are involved in cell differentiation. These results led to the hypothesis that a differentiation

system of HNPE cell-conditioned SF-medium with RGC-5 cells can promote a differentiated phenotype in RGC-5 cells, functionally close to primary cultures of rat RGCs[145].

The secretome of retinoblastoma, the solid malignancy of the developing retina, is immunosuppressive and induces a protumoral phenotype. This conclusion was the result of complex analyses that identified the cytokine extracellular matrix metalloproteinase inducer and macrophage migration inhibitory factor, both characterized by detected immunosuppressive activity and secreted at high levels in retinoblastoma primary cell cultures. In addition, macrophages derived from peripheral blood mononuclear cells increased the expression of M2-like polarization markers following exposure to retinoblastoma-conditioned medium or recombinant migration inhibitory factor[146].

CROSS-LINK BETWEEN RETINAL AND MESENCHYMAL SECRETOMES: DIFFERENT MSC-DERIVED SECRETOMES AS INNOVATIVE APPROACHES FOR RETINAL DISEASES

The MSC secretome is currently studied extensively for the treatment of several retinal diseases. Its therapeutic potential lies in its richness of immunomodulatory, antiangiogenic and neurotrophic factors, preventing retinal degeneration and improving retinal morphology and function. Additionally, exosomes secreted by MSCs showed anti-inflammatory and antiapoptotic effects (Figure 1 and Table 3). Based on MSC origins and their particular secreted factors, several promising preclinical and clinical studies were initiated to explore the potential advantages of MSC secretome for the treatment of retinal diseases.

Novel evidence on the role of MSC secreted factors in retinal disease etiopathogenetic pathways

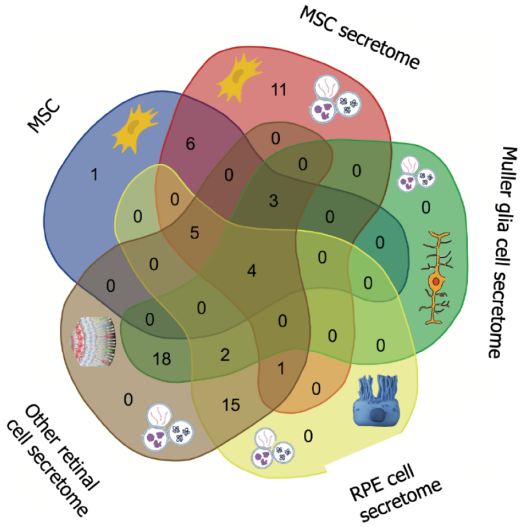
Novel evidence showed that MSC conditioned media inhibits abnormal neovascularization and decreases vaso-obliteration (promoting revascularization) in retinopathies by restoring neuronal Sema3E levels, which reduce pathological concentrations of IL-17A (and associated proinflammatory factors, such as IL-1b) in myeloid cells[147]. Among MSC released factors, PDGF secretion may play a crucial role in MSC-mediated RGC neuroprotection. These results were obtained from the arrest of PDGF signaling by small molecule PDGF inhibitors, neutralizing antibody or downstream phosphatidylinositol 3 kinase, which blocked RGC neuroprotection conferred by MSC co-culture. Furthermore, intravitreal injection of PDGF led to relevant optic nerve neuroprotection *in vivo* after experimental induction of high intraocular pressure[148]. Application of conditioned media obtained from MSCs protected against Aβ 1-42 oligomer-induced retinal pathology in RGCs of both rat and ARPE-19 cells, due to proteins associated with SIRT1/pAKT/pGSK3β/β-catenin, tight junction proteins and the apoptosis pathway[149]. Furthermore, in recent years, the administration of EVs in models of neurological disorders has highlighted a relevant improvement of neurological dysfunction. In particular, miRNAs from MSC-EVs, as one of the central mediators that control various genes and decrease neuropathological change, have been identified in various neurological pathologies[150].

Bone marrow MSC-derived secretome regulates retinal cell neuroprotection

The BMMSC secretome protects retinal morphology, regulates autophagy-, proapoptotic– and pronecroptotic–related gene and protein expression and promotes the activation of antioxidant machinery, exerting a neuroprotective ability during retinal degeneration[151]. A recent expression analysis of about 1000 proteins exhibited high levels of paracrine factors secreted by hBMMSCs that might be fundamental in the neuroprotective effect of the stem cell secretome over *in vitro* retinal degeneration. These results support the hypothesis that the paracrine effect of hBMMSCs may slow photoreceptor death and be a therapeutic possibility in retinal photoreceptor degenerative diseases[152]. Additionally, rat BMMSCs cultured with the secretome from neonatal rat retinal cells were able to differentiate into RGC-like cells, exhibiting protein expression patterns similar to those of isolated RGCs such as Map2, nestin and Thy1.1[153].

Adipose MSC-derived secretome regulates retinal cell regeneration

Recent evidence showed an important therapeutic effect of hADSCs and its secretome on an *in vivo* model of sodium iodate retinal neurodegeneration. The studies highlighted that the hADSC secretome effects were particularly striking, especially in terms of photoreceptor regeneration and retinal function, as underlined by increased expression of retinal regeneration markers such as Pax6, Chx10, S-Opsin (Opn1sw), Nrl, Crx and GFAP[154]. Oxidatively stressed ARPE-19 cells treated with adipose MSC conditioned media and/or combined with nicotinamide, vasoactive intestinal peptide or both factors showed an improved recovery from the damaged status. Additionally, the same treatment could determine better protection of the neuroretinal architecture, mainly rods and cones, and a lower degree of glial cell activation[155].



The preclinical efficacy of adipose-derived stem cell concentrated conditioned medium (ASC-CCM) was recently tested in repetitive ocular blast injury mice, highlighting a significant rescue from retinal injury and a significant restoration of visual function, also associated with a significant reduction of neuroinflammation markers, retinal GFAP and OS. Furthermore, *in vitro*, oxidatively stressed Müller cells pre-incubated with ASC-CCM exhibited normalized levels of GFAP, viability and catalase activity[156]. Intravitreal injection of ASC-CCM was safe and efficient against the visual impairments of mild TBI. Blast mice treated with ASC-CCM exhibited improved vision at 5 mo but minimal effects at 10 mo, associated with alterations of GFAP and proinflammatory gene expression in retina. Thus, the unchanged glial response and the risk of retinal injury with live cells suggested that ASC-CCM might have better safety and efficacy than live cells for visual dysfunction therapy[157].

Table 3 Key molecules of the mesenchymal secretome derived from different cell types in the treatment and regeneration of retinal cells

MSC	MSC secretome	Müller glia cell secretome	RPE cell secretome	Other retinal cell secretome

MSC: Mesenchymal stem cell; RPE: Retinal pigment epithelium; FGF: Fibroblast growth factor; NGF: Nerve growth factor.

DOI: 10.4252/wjsc.v15.i7.665 **Copyright** ©The Author(s) 2023.

Figure 1 Common factors released by retinal and mesenchymal cell secretomes. Both groups of cells can release different clusters of factors that are able to influence the microenvironment by paracrine mechanisms. The most common factors are highlighted in the cytotypes. More details are available in Table 3. MSC: Mesenchymal stem cell; RPE: Retinal pigment epithelium.

Human uterine cervical and Wharton's jelly MSC-derived secretomes regulate retinal cell immunomodulation

The treatment of oxidatively stressed ARPE-19 cells with human uterine cervical stem cells-conditioned medium evidenced a significant increase of *VEGFA*, *HO-1*, *HSPB1*, *GCLC*, *PDGFA* and *PDGFB* mRNA expression, highlighting a potential stimulation of detoxifying genes, protection from damage by OS and better vascularization[158]. Recent studies demonstrated that RPE cell viability and the expression of anti-apoptotic Bcl2 were reduced significantly in conditioned media secreted by human Wharton's jelly MSC (WJMSCs)-treated RPE cells, while expression of proapoptotic biomarkers Bax and IL-1b was not significantly changed. WJMSCs are a subgroup of MSCs isolated from the Wharton jelly of the umbilical cord characterized by a high potential of proliferation and a secretome rich in trophic factors and immunomodulatory cytokines. Moreover, previously described experiments showed that the WJMSC secretome could induce apoptosis in RPE cells through activating apoptosis pathways, being a potential therapeutic target for pathologies like proliferative vitreoretinopathy[159].

CONCLUSION

The crosslink between mesenchymal cell and retinal cell secretomes is a topic of interest for regenerative medicine, as both types of cells secrete trophic factors that can modulate cellular pathways involved in survival, function and response to injury. The mesenchymal cell secretome is a collection of molecules secreted by MSCs and have a positive effect on re-establishing the intra-articular homeostasis and stimulating regeneration by different growth factors, cytokines and miRNA that are contained within the EVs of the secretome. The retinal cell secretome is mainly composed of the secreted factors from the RPE and Müller cells, which are key to maintain the structural and functional integrity of the retina. The crosslink between these two types of secretomes could potentially enhance the neuroprotective effect of the MSC

secretome on retinal degeneration, by modulating OS, autophagy and programmed cell death. This scenario could be of particular interest especially for MSC secretome-only factors, such as FGF, CXCL12, CCL511, NGF-, described miRNAs and the lncRNA MALAT, whose complementary action might play a functional compensation role towards retinal cell alterations.

However, many challenges still exist, including the specific characterization of secretome released factors to further target therapy to the pathology profile, better manipulation of the retinal secretome or from other cell sources for noteworthy therapeutic effect, improving methods for intraocular administration of secretome factors and developing personalized combinations of trophic factors involved in different pathological pathways (inflammation, reactive oxygen species, angiogenesis, proliferation) to evaluate the collective therapeutic potential. Nevertheless, the possible improvement of new efficient pharmaceutical formulations related to the secretome of MSCs and retinal cells, with the addition of exogenous factors or drugs without the necessity to deliver cells into the eye may represent a novel milestone towards a personalized approach to retinal disease.

Abstract

Parkinson's disease (PD), characterized by loss of nigrostriatal dopaminergic neurons, is one of the most predominant neurodegenerative diseases affecting the elderly population worldwide. The concept of stem cell therapy in managing neurodegenerative diseases has evolved over the years and has recently rapidly progressed. Neural stem cells (NSCs) have a few key features, including self-renewal, proliferation, and multipotency, which make them a promising agent targeting neurodegeneration. It is generally agreed that challenges for NSC-based therapy are present at every stage of the transplantation process, including preoperative cell preparation and quality control, perioperative procedures, and postoperative graft preservation, adherence, and overall therapy success. In this review, we provided a comprehensive, careful, and critical discussion of experimental and clinical data alongside the pros and cons of NSC-based therapy in PD. Given the state-of-the-art accomplishments of stem cell therapy, gene therapy, and nanotechnology, we shed light on the perspective of complementing the advantages of each process by developing nano-stem cell therapy, which is currently a research hotspot. Although various obstacles and challenges remain, nano-stem cell therapy holds promise to cure PD, however, continuous improvement and development from the stage of laboratory experiments to the clinical application are necessary.

Key Words: Parkinson's disease; Synuclein; Neural stem cells; Nanomaterials; Nano-stem cell therapy

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core tip: Neural stem cell (NSC) transplantation is a groundbreaking therapy with therapeutic effects for many neurodegenerative diseases. Parkinson's disease (PD) is the second most common neurodegenerative movement disorder. The ability of NSCs for neural differentiation has been suggested as an effective mechanism in PD subjected to cell transplantation. Here, the potential therapeutic mechanisms, challenges, nanobased support, and manifestations of NSCs in PD are discussed, along with examples of preclinical and clinical studies.

INTRODUCTION

Parkinson's disease (PD), with a global prevalence of > 6 million, is the second most common neurodegenerative movement disorder. Currently, no disease-modifying cure is available, and occurrence of PD has been projected to double over the next generation[1]. PD is an age-related disorder affecting about 5% of the population by the age of over 85 years.

The primary pathological property of PD is the presence of abnormal α-synuclein (ASN) in the form of neural inclusions called Lewy bodies, whose toxic effect is hypothesized to contribute to progressive degeneration and cell loss [2,3]. Dopaminergic (DAergic) neurons in the substantia nigra pars compacta specifically undergo degeneration leading to dopamine (DA) and several other biochemical deficits in the nigrostriatal system, resulting in the development of motor symptoms, including bradykinesia, resting tremor, muscular rigidity, and postural instability[4]. Moreover, loss of other types of neurons and the presence of Lewy pathology in many parts of the central, enteric, and autonomic nervous systems have been demonstrated that probably contribute to non-motor manifestations, such as autonomic dysfunction, olfactory impairment, and mood, cognitive or sleep disturbances present in PD patients[5,6].

Dopamine replacement therapy (DRT) is the gold standard treatment for alleviating PD symptoms. However, as the disease progresses, compensatory mechanisms for denervation affect the duration and delay the alleviating effect of DRT in a nonlinear manner[7]. Surgical procedures are also used, including stereotactic ablations or deep brain stimulation. Nevertheless, these approaches only partially manage the severe motor symptoms and alleviate DAergic desensitization supporting DRT in advanced PD patients[8,9]. Aggregation of ASN, besides the gain-of-toxic function, can also result in loss of function, thereby decreasing its functions[10]. Since ASN exerts physiological activity towards newly formed neurons by promoting the development and maturation of dendrites and the spine, depending on the expression level [11], the intraneuronal inclusions of ASN contribute to the PD pathogenesis by also affecting neurogenesis[12]. Therefore, stimulation of endogenous neurogenesis or cell-replacement therapy is considered a therapeutical option against PD neurodegeneration[13]. Accordingly, strategies aiming at rebuilding the pathway and reshaping the brain have been developing[14].

Endogenous neural stem cells (NSCs) exist throughout life and are found in specific areas of the human brain. NSCs exhibiting abilities to self-renew and differentiate into neurons, astrocytes, or oligodendroglia are responsible for restoring brain function under normal circumstances. The regeneration of DAergic neurons from stem cells is considered an alternative treatment for PD[15].

In the early phase of preclinical and clinical studies, foetal ventral midbrain tissues were grafted into the striatum of rats[16,17] and PD patients[18-23]. The foetal DAergic neuron transplants survived, released DA, and improved behavioural deficits in animal models of PD[16,17] and individuals[20,21]. However, apart from these benefits, in some patients, dyskinesia developed[22,23]. Moreover, independent postmortem examinations revealed that the healthy neurons grafted into the brains of PD patients acquired Lewy bodies several years after transplantation[18,19] due to a prion-like mechanism with permissive templating of synucleinopathy progression[1,6]. In this context, DA neuron-based transplant approaches are not curative; nevertheless, they offer a competitive therapeutic effect[5]. The rapid development of cell- and molecular-based research opens new perspectives for cell therapy approaches in managing PD [5]. During the last decade, cumulative research on using different types of stem cells as starting material supports the potential of stem-cell-based DAergic neuron replacement therapy for PD[5]. The considered candidates are NSCs, embryonic stem cells (ESCs), induced pluripotent stem cells (iPSCs), and mesenchymal stem cells (MSCs)[24]. Importantly, translation into the clinic of the stem cells transplantation approach requires avoidance of adverse immunological response and proliferation and related risk of tumorigenesis[5].

This review focuses on the therapeutic potential of NSCs in PD. Accordingly, we give an overview of their use in experimental studies and clinical trials and discuss challenges related to their application, alongside the pros and cons of NSC-based therapy in PD. Given the state-of-the-art accomplishments of stem cell therapy, gene therapy, and nanotechnology, we shed light on the perspective of complementing the advantages of each process by developing nano-stem cell therapy, also using genetically engineered NSCs.

EMERGENCE OF NSCS IN ADULT BRAIN AND ALTERNATIVE SOURCES OF NSCS

NSCs are an important central nervous system (CNS) element. NSCs exist in the embryonic brain and adult nervous system during human life and are found in two specific brain regions (Figure 1A). The subgranular region of the dentate gyrus and the lateral wall of the subventricular zone both contain a significant number of adult endogenous NSCs[25]. These cells have a few key features, including self-renewal, proliferation, and multipotency, which make them a major component in the CNS, maintaining the cell pool of nervous tissues[15]. NSCs can differentiate into neurons, astrocytes, or oligodendrocytes and may replace the loss of DAergic neurons in PD[13]. Moreover, NSCs can encourage endogenous repair mechanisms as they can migrate near the site of damage to increase neuroblasts and promote tissue repair. NSCs can have immunomodulatory effects such as cytokine, chemokines, and chemokine receptors secretion and T cell proliferation inhibition[26,27] (Figure 1B). Neurotransmitters, neuropeptides, cytokines, metabolites, extracellular matrix proteins, and accessory cells control NSCs proliferation[13].

The alternative sources of NSCs are foetal and adult nervous system tissues, umbilical cord blood, bone marrow, peripheral blood, amniotic fluid, Wharton jelly, skin- or adipose-derived MSCs, or iPSCs[28] (Figure 1A). In the transplantation procedure, these stem cells are either *in vitro* pre-differentiated or, according to the concept that signals in the injured tissue will recruit the stem cells and induce their differentiation *in situ*, NSCs are applied directly in the undifferentiated state[28]. Recently, trans-differentiation, especially chemically induced, whereby somatic cells are reprogrammed into patient-specific neuronal cells by skipping an intermediate proliferative pluripotent stem cell stage, offers perspectives on alternative autologous cell therapeutic strategies for PD[29]. By producing the desired type of CNS cells, these sources have all been used to demonstrate their potential for treating various neurodegenerative diseases[30].

EXPERIMENTAL APPROACHES TO NSC TRANSPLANTATION

Several preclinical studies have shown that different types of human NSCs, after their transplantation, could migrate, survive, and proliferate in specific brain sites. Immunohistochemical examinations support evidence that the transplanted human NSCs could transform into functional neurons and integrate into neural circuits[31]. In *in vivo* studies, it has been demonstrated that NSCs transplantation was an efficient therapeutic method for PD (Table 1). Yang *et al*[32] have shown that the clonal line C17.2 of NSCs grown *in vitro* under control conditions and transplanted into intact or 6-hydroxydopamine (6-OHDA)-lesioned rats spontaneously developed into neuronal-like cells, expressed traits of a DA phenotype, and integrated into the host brain[32]. Svendsen *et al*[33] have demonstrated that expanded populations of human CNS progenitor cells maintained in a proliferative state in culture and can migrate and differentiate into both neurons and astrocytes following intracerebral grafting into the striatum of adult rats with unilateral DAergic lesions[33]. NSCs, secreting *in vitro* nerve growth factor and neurotrophin-3, engrafted into the 6-OHDA lesioned striatum of rats, have been reported to survive and partially differentiate into tyrosine hydroxylase (TH)-positive cells. A significant rotational behaviour improvement accompanied these effects[33].

The ability of NSCs for neural differentiation and to exert a trophic effect by secreting nerve growth factor and neurotrophin-3 on dying DA neurons in the striatum has been suggested as an effective mechanism against behavioural deficits in PD rats subjected to cell transplantation[34]. A high-throughput quantitative proteomic study revealed that the protein profile of the subventricular zone severely distorted in mice by 6-OHDA injection was normalized and striatal astrocytes were activated after human NSC transplantation accompanied by an increase in neurotrophic factors. In addition, the grafted mice exhibited improved behavioural performance. The changes in the proteome have been suggested to result from the stimulation of host nigral DAergic neurons and their nigrostriatal projections rather than their replacement[35]. To increase trophic factor secretion, genetically engineered human NSCs were developed[36]. Stereotaxic transplantation of human NSCs (HB1.F3 clone) secreting stem cell factor into the 6-OHDA-lesioned striatum of rats has been demonstrated to result in functional improvements and ameliorated Parkinsonian behavioural symptoms. It was accompanied by the activation of endogenous neurogenesis in the subventricular zone, alongside the preservation of TH-positive cells of the nigrostriatal pathway[37]. Similarly, human olfactory bulb NSCs genetically engineered to express human nerve growth factor ameliorated the cognitive deficits associated with 6-OHDA-induced lesions in PD model rats. Transplanted cells exhibiting enhanced survival and differentiation rate migrated to damaged areas to promote repair or neuroprotection through cell replacement, integration, and/or neuroprotection[38]. Foetus-derived human NSCs (hVM1 clone 32) transplanted in their undifferentiated state protected against motor and nonmotor deficits in middle-aged parkinsonian mice, although degeneration of the nigrostriatal pathway was not significantly improved. Thus, the multifactoriality of NSCs was suggested[39]. Yoon *et al*[40] have reported that although the human-brain-derived NSCs injected into the striatum of rats with the 6-OHDA-induced lesion of the nigrostriatal pathway differentiated into DAergic neurons, no functional or behavioural improvements were observed[40]. Transplantation of human-brain-derived NSCs in the form of cell aggregates with a pre-established cell network into the striatum of 6-OHDA-injected rats appeared to be more effective than single-cell transplantations. The transplanted cells not only survived but also exerted a therapeutic effect attributed to secreting DA[41].

Nonhuman primate models of PD represent the highest clinical translational value due to close-to-human similarities in physiology, anatomy, and immunology and are used to validate therapeutical strategies at preclinical stages[42]. Successful transplantation of undifferentiated human NSCs into the substantia nigra of 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP)-challenged primates promoted homeostatic adjustments attributed to normalization of endogenous neuronal number-to-size ratios and protection of host nigrostriatal circuitry that resulted in behavioural improvement. In addition, the percentage of cells containing ASN inclusion dropped from 80% to 20% upon human NSC transplantation.

Table 1 Experimental studies on the therapeutic role of neural stem cells in Parkinson's disease models

Cells type	Model	Effects	Ref.
Undifferentiated NSCs line C17.2	6-OHDA rat model	Striatum deposition ↑ Expression of β-tubulin III, NSE, NeuN ↑ TH- and AADC-positive cells ↓ Motor behaviour deficits	Yang *et al*[32]

6-OHDA: 6-hydroxydopamine; AADC: Aromatic L-amino decarboxylase; DA: Dopamine; DAergic: Dopaminergic; DAT: Dopamine transporter; GIRK2: G Protein-activated inward rectifier potassium channel 2; hNSCs: Human NSCs; hbNSCs: Human brain-derived NSCs; hfNSCs: Human fetal-derived NSCs; hGFAP: Human glial fibrillary acidic protein; hNFG-GFP-OBNSCs: Olfactory bulb neural stem cells (OBNSCs) genetically engineered to express hNGF and GFP; hpNSCs: Human parthenogenetic stem cell-derived NSCs; HuC: Very early neuronal marker; HuD: Postmitotic neuronal marker; MAP2:

Microtubule-associated protein 2; MPTP: 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine; NSE: Neuron-specific enolase; NeuN: Matured neuronal marker; NPCs: Neural progenitor cells; TH: Tyrosine hydroxylase; TNF-α: Tumor necrosis factor- α.

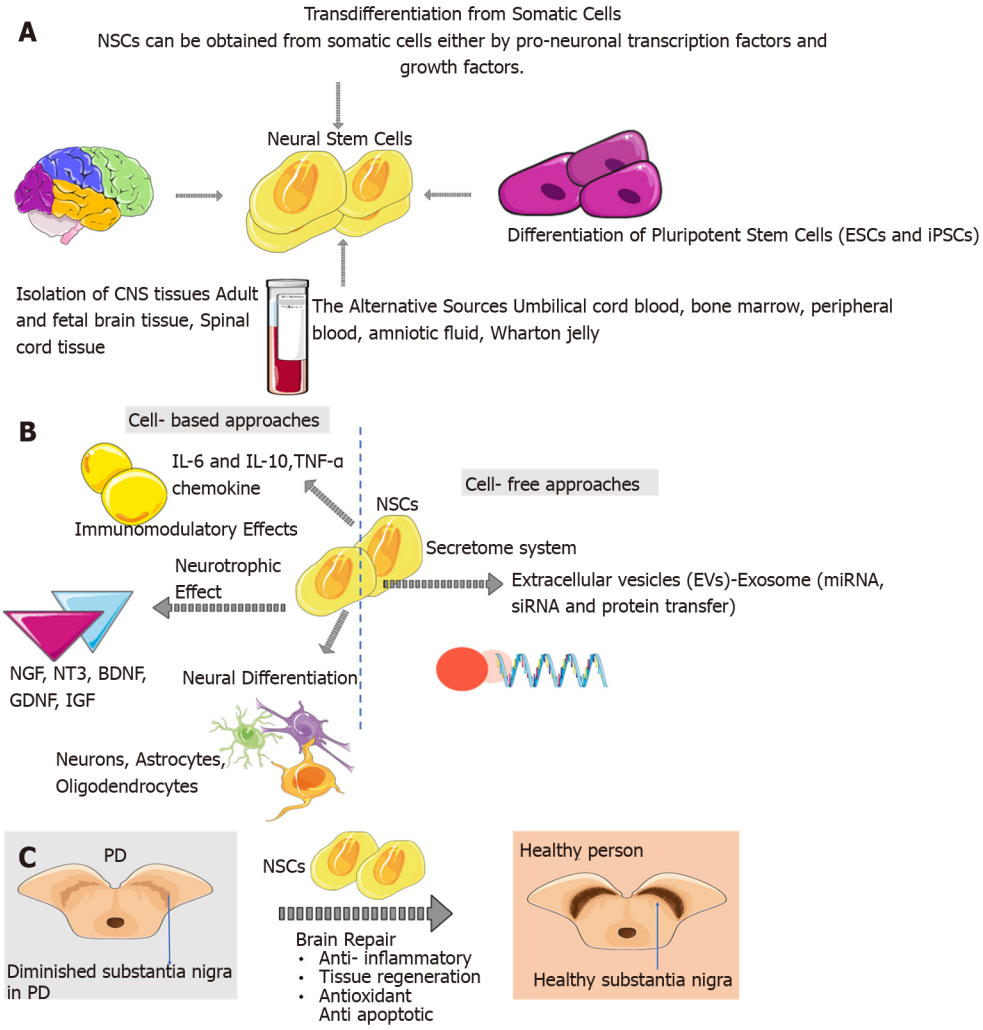

Figure 1 Emergence of neural stem cells in the adult brain and alternative sources of neural stem cells. A: The sources of neural stem cells (NSCs) are embryonic stem cells and induced pluripotent stem cells, adult/foetal brain tissue and spinal cord tissue. Also, NSCs can be obtained from somatic cells either by transcription factors and growth factors. The alternative sources of NSCs are foetal and adult nervous systems, umbilical cord blood, bone marrow, peripheral blood, amniotic fluid, Wharton jelly; B: NSCs can have immunomodulatory effects such as cytokine, chemokines, and chemokine receptors secretion and T cell proliferation inhibition. NSCs can have neurotrophic effects such as nerve growth factor, neurotrophin-3, brain-derived neurotrophic factor, and glial cell line-derived neurotrophic factor. NSCs can target secretome and paracrine effects *via* extracellular vesicles like exosomes. Also, NSCs play a role in neural differentiation; C: NSCs after their transplantation, could migrate, survive, and proliferate in specific brain sites. And NSCs play a role in brain repair mechanisms such as antiapoptotic, anti-inflammatory, and antioxidant. CNS: Central nervous system; BDNF: Brain-derived neurotrophic factor; ESCs: Embryonic stem cells; EVs: Extracellular vesicles; GDNF: Glial cell line-derived neurotrophic factor; iPSCs: Induced pluripotent stem cells; NGF: Nerve growth factor; NT-3: Neurotrophin-3; NSCs: Neural stem cells; TFs: Transcription factors; PD: Parkinson's disease; TGF: Transforming growth factor. Importantly, no tumours, overgrowth, or inappropriate stem cell migration in the transplanted primates were observed [43]. Gonzalez *et al*[44] evaluated the safety and efficacy of two doses of human parthenogenetic stem-cell-derived NSCs injected in the striatum and substantia nigra of MPTP-lesioned monkeys with moderate to severe PD symptoms. They found that human parthenogenetic NSCs engrafts promoted behavioural recovery accompanied by raised striatal DA concentration, fibre innervation, and several DA neurons. Increased expression of genes and pathways downregulated in PD has been observed. Importantly, the 12 mo post-transplantation of human parthenogenetic NSCs was safe and well tolerated by the animals with no serious adverse events[44]. This safety aspect is significant as the potential for inappropriate stem cell migration and tumour formation must be minimized before cell transplantation[5].

Stem cell therapeutic strategies for PD not only deal with the direct replacement of damaged or lost cells but also target secretome and paracrine effects on neurotrophic and growth factors and endogenous neural precursor cell activity[45,46] (Figure 1B). The heterogeneous population of membrane-bound exosomes and extracellular vesicles (EVs) is a part of the

secretome system[45]. Nanosized EVs derived from human iPSC (hiPSC)-NSCs have been suggested as a safer alternative to NSCs. Upadhya *et al*[47] demonstrated that EVs exhibited similar neuroreparative properties as NSCs, and they could be administered noninvasively as an autologous or allogeneic off-the-shelf product. EVs comprising miRNAs and/or proteins promoting synaptogenesis, synaptic plasticity, and better cognitive function have been demonstrated to incorporate well into neurons, microglia, and astrocytes of rodents after intranasal treatment, resulting in enhancement of hippocampal neurogenesis and an anti-inflammatory effect[47]. The results hold the promise of using stem-/progenitor-cell-derived EVs, or EVs loaded with bioactive molecules such as DA, catalase, curcumin, and siRNAs, to alleviate parkinsonian symptoms[48]. Specifically, exosomes biologically active EVs, with high miR-133b, which are lacking in PD patients, can promote the growth of neurites[49]. Lee *et al*[50] have demonstrated that NSC-derived EVs *via* a paracrine signalling-based mechanism exerted antioxidant, antiapoptotic, and anti-inflammatory effects, thereby protecting against loss of neuronal population and function of target cells, both *in vitro* and *in vivo* PD models[50]. Nevertheless, isolation, characterization, and testing of the biological properties of EVs retain critical issues for translation[47]. An emerging alternative to the cell-based approach is the nanotechnology approach for the targeted delivery of growth factors aiming to support and expand resident CNS stem cells for endogenous repair[51].

PROS AND CONS OF THE USE OF NSCs IN PD

Injected neural progenitor cells (NPCs) accumulate in the brain and integrate with the injured zone; however, in only a small percentage, most of the cells remained undifferentiated. The promotion of tissue survival is associated with anti-inflammatory and antiapoptotic effects at both mRNA and protein levels and increased secretion of growth factors[52] (Figure 1C). Additionally, NPCs cooperate with nearby immune and resident cells of the CNS to modulate the focal release of stem cell regulators and aid in the functional recovery from CNS injuries[53,54]. As Marsh and Blurton-Jones [55] have reviewed, there is strong evidence that NSC-mediated changes in neurotrophies resulting in increased synaptic plasticity, long-term potentiation, and neuronal survival contribute to the improvement of cognitive and motor performance observed *in vivo*. Thus, NSCs providing neurotrophic support to affected neuronal populations and synapses is a promising approach for treating neurodegenerative diseases such as PD[55]. Safety, including a potential tumorigenic effect, raised concerns. Amariglio *et al*[56] (2009) have reported a donor-derived brain tumour in a boy with ataxia telangiectasia following intracerebellar and intrathecal injection of human foetal NSCs[56]. Moreover, the complex issue of the immune rejection of transplanted cells in the brain has been demonstrated[5]. Therefore, the development of stem-cell-derived neuronal transplant therapies in PD requires consideration of this safety aspect alongside the effectiveness ones, which can be managed by addressing issues related to type and source of cells, their reproducible generation, accurate zone of transplantation and maintenance of function and viability of these grafted cells should be considered[5].

Considering transplantation safety, protocol standardisation, and the ethical aspect, approaches with the use of ESCs and IPSCs for making DAergic neurons are being developed[5,14].

ESCs, undifferentiated pluripotent cells derived from mammalian blastocysts, can make all types of cells in the body. Also, iPSCs, laboratory-generated counterparts of ESCs, that are generated from adult somatic cells, possess similar properties and can differentiate into any other cell. ESCs and iPSCs are used in many clinical trials are going on globally and have wide applications in regenerative medicine for specific diseases and conditions. The results of these trials do not, however, reach the general population because of the long and complex time frame needed to complete the clinical trials and publish the data obtained[57].

iPSCs have some advantages, such as obtaining the reprogrammed cells directly from the patients, thus potentially reducing the risk of transmissible infections and immune reactions. Additionally, they can change into any type of cell approach to treating PD[58]. Using iPSCs for treating PD is ethically permissible because patients' somatic cells can be differentiated into a pluripotent state to produce DAergic neurons implanted into the brain. Several investigations elucidated the promising role of iPSCs in regenerating DAergic neurons for treating PD. Transplantation of iPSCs ameliorated PD symptoms[58]. iPSCs have some disadvantages, such as powerful pluripotency; hence the risk of tumour development of iPSCs may be greater than other stem cells. The heterogeneity of iPSCs for clinical therapy could lead to potential tumorigenicity risks *in vivo*. Additionally, iPSCs made from autologous PD patients may contain pathogenic gene mutations that impact the outcome of cell replacement therapy[59]. Although grafted autologous iPSCs cells are considered immune-privileged, they can still be recognized as foreign (allogeneic) by the patient's immune system in some situations. Cell preparation protocol and transplantation site have been suggested to influence iPSC-derived cell immunogenicity[60]. Hence, decreasing the heterogeneity and increasing the controllability of iPSCs and cell preparation through isolation, purification, amplification, and modification of stem cells is necessary to decrease the tumorigenicity and immunogenicity potentials[61].

Although these scalable and traceable sources with well-established protocols and the efficacy in preclinical PD models have made ESCs and iPSCs promising candidates for cell-based therapy (Table 2), the risks of tumour development and immunosuppression have not been eliminated. These sources are still not ethically neutral, especially ESCs, as the embryo is used in the persevering protocol[5,14].

Despite these great efforts, there is still a gap between experimental therapeutic approaches and their translation into clinical practice. Although several clinical trials (Table 3) have been studied using cell-based treatments for PD (Clinical Trials. gov; NCT03119636[62], NCT05635409[63], NCT02452723[64], NCT03815071[65], UMIN000033564[66], NCT-03128450[67], NCT03309514[68], NCT01898390[69], NCT02795052[70], NCT00976430[71], NCT03724136[72], NCT03684122[73]) these days, the main obstacles restricting the clinical use of stem cells refer mainly to ethical concerns,

Table 2 Experimental studies on the therapeutic role of alternative stem cell sources in Parkinson's disease models

Stem cells source	Model	Effects	Ref.

immune response, tumorigenesis, and toxicity[31].

PROSPECTS FOR NSC-BASED THERAPY

From the short review above, several challenges for NSC-based therapy emerge, which can be identified at every stage of the neurosurgical procedure, including preoperative cell preparation and quality control, perioperative procedures, and postoperative graft preservation, adherence, and overall success of the therapy[74].

Strict quality control and safety assessments of the relevant cells must be in place at the preoperative stage. To achieve the optimal number of DAergic neurons, the required number of implanted cells in the final graft should be achieved [74]. The DA neurons can be derived from different stem cells or directly from NSCs. The use of foetus-derived NSCs has shown outstanding potential in rodent models of PD, and the possibility for tumorigenicity is minimal[75]. Safety issues related to the risk of tumorigenesis by grafted stem cells need to be evaluated for the long-term survival and phenotype stability of stem-cell-derived neurons in the graft following transplantation to identify the appropriate stem cell type. In addition, cell dose, case selection, and delivery route are also necessary as a precondition for the clinical use of cell-based therapies[76]. Patients receiving treatment with NSCs products are at risk for safety issues related to delivery methods, immune and allergic reactions to the medication, tumour development, heterotopic neuronal differentiation with functional disruption, and viral and microbial contamination[26]. Therefore, the fundamental concern of cell-based therapies is that before entering the clinic, transplantable cell populations must be differentiated and characterized according to good manufacturing practice regulations both *in vitro* and *in vivo*[77]. This, in turn, requires access to a large pool of differentiated cells stored in a tissue bank. However, providing sufficient *in vitro* differentiation of neurons from NSCs is challenging[78]. Cell origin is a significant problem that must be considered in treating PD by NSC transplantation as the high concentration of NSCs is needed to treat diseases[79].

Table 3 Clinical trials for cell-based therapy in Parkinson's disease

Study identifier	Cell type	Aim of the study
NCT03119636[62]	hESC-NPCs	Safety and efficacy evaluation of intracerebral transplantation
NCT05635409[63]	hESC-DA neurons	Safety and tolerability evaluation of intraputamenal transplantation
NCT02452723[64]	ISC-hpNSC®	Safety evaluation of intracerebral transplantation
NCT03815071[65]	iPS-NSCs	Safety and efficacy evaluation
UMIN000033564[66]	iPSC-derived dopaminergic progenitors	Safety and efficacy of transplantation into the corpus striatum
NCT03128450[67]	hNSCs	Safety and efficacy evaluation of nasal delivery
NCT03309514[68]	NSC-derived neurons	Safety and efficacy evaluation of intracerebral injection
NCT01898390[69]	hVMT	Safety and efficacy evaluation
NCT02795052[70]	BMSC	Efficacy evaluation of intravenous and intranasal delivery
NCT00976430[71]	BMSC	Safety and efficacy evaluation
NCT03724136[72]	BMSC	Efficacy evaluation of intravenous and intranasal delivery on cognitive impairment
NCT03684122[73]	Umbilical cord derived MSCs differentiated into NSCs	Safety evaluation of intrathecal and intravenous injections

BMSC: Bone-marrow-derived stem cell; iPS-NSC cells: Pluripotent stem-cell-derived neural stem cells; ISC-hpNSC®: Human parthenogenetic stem-cell-derived neural stem cells developed by international stem cell corporation; hNSCs: Human neural stem cells; hVMT: Human ventral mesencephalon tissue; hESC-NPCs: Human embryonic stem cells-derived neural precursor cells.

For the promotion of the behaviour of NSCs, the fabrication of culture surfaces is developed. In this context, nanomaterials, with their nano size, unique physicochemical properties, and capability for surface functionalization, offer the potential for designed manipulation of cell behaviour. Fabricating the extracellular matrix with biocompatible nanomaterial-based scaffolds with topology simulating the microenvironment *in vivo* seems to be a promising strategy. Pandanaboina *et al*[78] demonstrated successful differentiation of embryonic rat NSCs on the nanocellulose coupled with lysine scaffold as 87% of the cells attached to the surface, and more than half of the NSCs had differentiated into functional neurons[78]. Previously they found that plasmonic gold nanorods integrated into growth surfaces tuneable stimulated and modulated embryonic rat NSCs[80]. A robust scaffold for culturing NSCs *in vitro* is three-dimensional graphene (3DG) foam, which behind supporting their growth, maintains cells in an active proliferative state through the modulation of metabolism and several metabolic processes. 3DG-stimulated pathways are involved in amino acid incorporation and glucose metabolism[81] (Figure 2).

As NSCs are regulated by a specialized vasculature during adult neurogenesis, transplanted, they may be importantly affected by the adjoining vasculature and endothelial cells[76]. Chou *et al*[82] have shown the importance of establishing an appropriate neurovascular microenvironment to deliver NSCs to replace lost DA neurons. This study indicated the molecular and cellular signalling involved in forming vasculature-like structures and increased neuronal differentiation through endothelial signalling[82]. The ability to properly locate and track transplanted NSCs is necessary to develop the efficacy of NSC therapies and ensure the treatment's safety[25].

A critical step for efficient NSCs therapy is the survival and integration of the grafted DAergic neurons, due to the lack of both stromal and growth factor support of the cells and the risk of ischaemic stress and an innate immune response [51]. Prion-like transmission synucleinopathy to the healthy neurons grafted into the brains of PD patients should be considered[18,19,21]. Nanomaterials capable of suppressing oxidative stress[83], neuroinflammation[84], or even toxic protein aggregation[85] can act as bioactive nanomedicines addressing the limitations of cell-based therapy for PD. The strategy of combining nano-enabled therapy with stem-cell-based therapy shows potential for the treatment of PD[46]. Accordingly, NSCs isolated from human olfactory bulb human coengrafted with carbon nanotubes (CNTs) restored cognitive deficits and neurodegenerative changes in the trimethyl-induced rat model of neurodegeneration. Moreover, the CNTs supported engrafted NSCs by stimulating differentiation into neurons rather than glial cells[86]. To support individual cells over the first few weeks at the postgrafting stage, attached growth-factor-loaded nanoparticles (NPs) are directly to the cell before grafting has been developed[51]. Nanomaterial carriers can be designed into "intelligent" nanodrug delivery systems functionalised with targeting ligands with the controlled release of loaded drugs/genes/cells for effective transport of them to inaccessible and specific brain areas[46]. Preclinical data have supported the safety and efficacy of the surrogate NPs stroma as no adverse effects after injection of stroma/cell constructs into the brain were evident, and human foetal ventral mesencephalic cell survival *in vivo* was increased fourfold[87]. At the postoperative stage, monitoring the injected/transplanted cells is critical for the optimisation of the neurosurgical procedure. Nanomaterials, with their unique optical properties, cellular uptake, surface functionalisation, and good biocompatibility, are

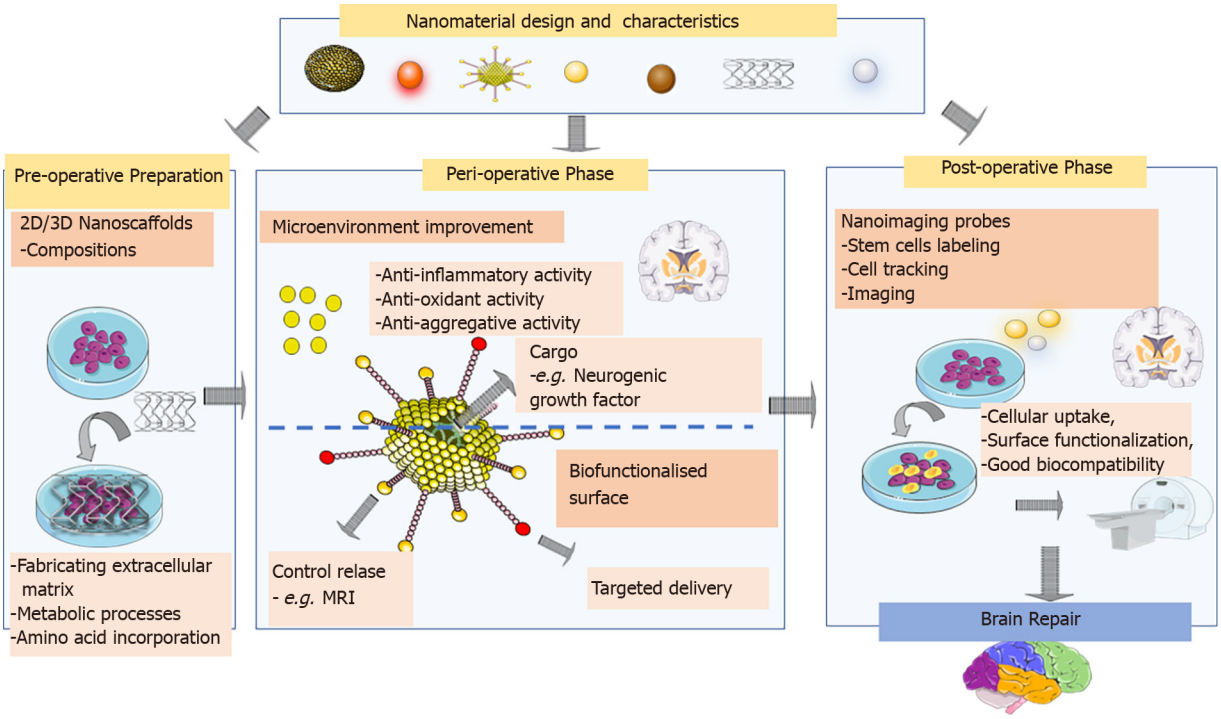

Figure 2 Application of nanomaterials in stem cell therapy of Parkinson's disease. Preoperative preparation: Nanomaterials, with their small size, unique physicochemical properties, and capability for surface functionalisation, offer the potential for designed manipulating cell behaviour. A promising strategy is that fabricating the extracellular matrix with biocompatible nanomaterial-based scaffolds with topology simulating the microenvironment. Preoperative phase: nanomaterials capable of suppressing oxidative stress, neuroinflammation, and toxic protein aggregation can act as bioactive nanomedicines addressing the limitations of cell-based therapy for Parkinson's disease. Moreover, "intelligent" nano-drug delivery systems functionalised by targeting ligands with the controlled release of loaded molecules like growth factor aims to support and expand stem cells for brain repair. At the postoperative stage, nanomaterials, with their unique optical properties, cellular uptake, surface functionalisation, and good biocompatibility, are promising candidates for cell tracking and imaging. MRI: Magnetic resonance imaging. Citation: The parts of the figures were drawn using pictures from Servier Medical Art. promising candidates for cell tracking and imaging[46] (Figure 2).

Advances in the development of stem cell and gene therapies create new opportunities. The combination of stem cell and gene therapy could be a technical breakthrough that increases the therapeutic effectiveness of stem cells. Engineered cells overexpressing genes involved in DA synthesis or neurotrophic factors might increase their functional capability and solve differentiation and survival issues, thus improving gene therapy's efficacy[88]. Taking into account the safety of cell-based therapy the cells can be reprogrammed to avoid as many adverse effects as possible, including immune reactions and tumours[89].

CHALLENGES FOR NANO-STEM CELL THERAPY

Nano-stem cell therapy can face many challenges, mainly related to the safety profile of NPs, including potential cytotoxicity and unknown impact on stem cell differentiation and biodegradability. There is ample scope for further research for understanding mechanisms by which cells interact with nanomaterials, the biotransformation of NPs, and their influence on cell functions, making it challenging to control the safety and effectiveness of nano-cell therapy[46,90]. Since the activity of NPs strongly depends on their sizes, structures, shapes, and surface chemistry and is cell type dependent[91], several problems related to methods for the synthesis, bio-functionalisation, characterisation, and tailoring of 3D nanostructures in tissue engineering should be addressed[46,90].

Given the challenges and state-of-art accomplishments of nanotechnology, it can be expected to lead to the development of nano-stem cell therapy for PD. It is supported by recently merged multifunctional nanotheragnostic approaches for effective stem cell therapy in managing brain cancers[92].

CONCLUSION

PD significantly affects society because it carries a mounting socioeconomic burden, while no cure is currently available. The studies discussed in this review have shown the potential of NSC-based therapy for PD (Figure 1C). Although NSCs present major promise in treating this neurodegenerative disease, they raise significant concerns. They may form a

tumour, which is a more devastating condition than PD. Moreover, immunological rejection, ethical issues, limited cell sources, and complications related to skill to maturation into desired neuronal cell types and proper differentiation are important reasons for further research to facilitate NSC therapy in PD.

Currently, combining stem cell therapy, including genetically engineered cells, with nanotechnology approaches to complement each other's advantages provides new insights into the improving the therapy protocol and efficacy. The safety profile and the efficacy of nano-stem cell therapy in treating neurodegenerative diseases is a research hotspot. It is believed that future advancements in new nanomaterials will surely benefit NSCs-based therapy from this technology.

In conclusion, although various obstacles and challenges remain, nano-stem cell therapy holds promise to cure PD. Clearly, its continuous improvement and development from the stage of laboratory experiments to the clinical application are necessary.

Abstract

BACKGROUND

Mesenchymal stromal cells (MSCs) are multipotent cell populations obtained from fetal and adult tissues. They share some characteristics with limb bud mesodermal cells such as differentiation potential into osteogenic, chondrogenic, and tenogenic lineages and an embryonic mesodermal origin. Although MSCs differentiate into skeletal-related lineages *in vitro*, they have not been shown to self-organize into complex skeletal structures or connective tissues, as in the limb. In this work, we demonstrate that the expression of molecular markers to commit MSCs to skeletal lineages is not sufficient to generate skeletal elements *in vivo*.

AIM

To evaluate the potential of MSCs to differentiate into skeletal lineages and generate complex skeletal structures using the recombinant limb (RL) system.

METHODS

We used the experimental system of RLs from dissociated-reaggregated human placenta (PL) and umbilical cord blood (UCB) MSCs. After being harvested and reaggregated in a pellet, cultured cells were introduced into an ectodermal cover

obtained from an early chicken limb bud. Next, this filled ectoderm was grafted into the back of a donor chick embryo. Under these conditions, the cells received and responded to the ectoderm's embryonic signals in a spatiotemporal manner to differentiate and pattern into skeletal elements. Their response to differentiation and morphogenetic signals was evaluated by quantitative poly-merase chain reaction, histology, immunofluorescence, scanning electron microscopy, and *in situ* hybridization.

RESULTS

We found that human PL-MSCs and UCB-MSCs constituting the RLs expressed chondrogenic, osteogenic, and tenogenic molecular markers while differentially committing into limb lineages but could not generate complex structures *in vivo*. MSCs-RL from PL or UCB were committed early to chondrogenic lineage. Nevertheless, the UCB-RL osteogenic commitment was favored, although preferentially to a tenogenic cell fate. These findings suggest that the commitment of MSCs to differentiate into skeletal lineages differs according to the source and is independent of their capacity to generate skeletal elements or connective tissue *in vivo*. Our results suggest that the failure to form skeletal structures may be due to the intrinsic characteristics of MSCs. Thus, it is necessary to thoroughly evaluate the biological aspects of MSCs and how they respond to morphogenetic signals in an *in vivo* context.

CONCLUSION

PL-MSCs and UCB-MSCs express molecular markers of differentiation into skeletal lineages, but they are not sufficient to generate complex skeletal structures *in vivo*.

Key Words: Human mesenchymal stromal cells; Recombinant limbs; Mesenchymal stromal cell morphogene-sis; Mesenchymal stromal cell *in vivo* differentiation; Skeletal tissues

Core Tip: Human mesenchymal stromal cells (MSCs) from umbilical cord blood or placenta can differentiate into osteogenic and chondrogenic lineages in culture systems and have been used in regenerative medicine. Here, we used the recombinant limb (RL) model to provide evidence that MSCs do not have the ability to generate skeletal structures *in vivo*. MSCs received and responded to the ectoderm's embryonic spatiotemporal signals in this RL system. However, the expression of differentiation markers of skeletal lineages was not sufficient to generate skeletal structures *in vivo*.

INTRODUCTION

The limbs have an intricate anatomy that results from highly coordinated morphogenesis and cellular differentiation processes, which establish the correct position and shape of muscles, bones, cartilage, tendons, skin, and nerves[1]. During embryonic development, limb bud mesodermal cells (LBMCs) form a bud covered by a layer of ectodermal cells. The morphogenesis and differentiation of limb tissues are controlled by the response to signals that emanate from three signaling centers: The apical ecto-dermal ridge (AER), which controls the proximodistal axis; the zone of polarizing activity, which directs the anteroposterior axis; and the ventral and dorsal LB ectoderms, which control the dorsal-ventral axis[1,2]. Fibroblast growth factor 8 (FGF8) and Wnt family member 3a signals emanate from the AER and maintain the MCs in an undifferentiated and proliferative state. Once cells stop receiving AER signals, they begin the differentiation process toward the chondrogenic and tenogenic lineages, followed by endochondral ossification to form the skeletal elements[1,2]. As development progresses, the coordination between signals is essential for patterning and differentiation to fully develop the skeletal elements of a functional limb[1,2].

SRY-box transcription factor 9 (SOX9) is the earliest molecular marker of chondrogenic commitment[3]. Besides, SOX9 induces the expression of extracellular matrix proteins such as collagen type 2 (Col2α) and aggrecan (ACAN)[4]. On the other hand, growth differentiation factor 5 (GDF5) promotes cell condensa-tion and cell adhesion during the initial stages of chondrogenesis[5,6]. By contrast, hypoxia-inducible factor alpha (HIF-1α) is critical in maintaining the chondrogenic environment[7]. Once cartilage anlagen is formed, ossification begins by expressing Runt-related transcription factor 2 (RUNX2)[8-10]. At the same time, the dorsal and ventral margins of early embryonic LB initiate tendon specification by express-ing the earliest known marker of tenocyte progenitors, scleraxis (SCX)[11,12]. SCX induces the transcription of major structural collagens and the glycoprotein tenomodulin[13]. Mohawk (MKX) is involved in tendon maturation by

maintaining SCX expression, which restricts cells to the tenogenic lineage[13,14].

Regenerative medicine has emerged as an alternative treatment for degenerative diseases or an adjuvant therapy[15,16]. To this end, the potential use of mesenchymal stromal cells (MSCs) has garnered great interest. Because MSCs share characteristics with LBMCs and have the potential to differentiate into osteogenic or chondrogenic lineages[17-21], in this work, we used the recombinant limb (RL) model to evaluate the capacity of human MSCs to form complex skeletal structures[22]. The RL model recapitulates the differentiation, morphogenesis, and patterning programs that occur during normal limb development[23-25]. RLs consist of an ectodermal cover obtained from an early chicken LB (CK-LB) filled with dissociated-reaggregated cells grafted into the back of a donor chick embryo. Because of the high capacity of human MSCs from umbilical cord blood (UCB-MSCs) or placenta (PL-MSCs) to differentiate into osteogenic and chondrogenic lineages, we evaluated their ability to generate skeletal structures *in vivo*. Our results demonstrate that although MSCs receive and respond to the ectoderm's embryonic spatiotemporal signals, they do not generate complex skeletal structures, possibly due to the intrinsic characteristics of MSCs.

MATERIALS AND METHODS

Isolation and culture of MSCs

MSCs were collected from Villa Coapa Hospital, Mexican Social Security Institute (IMSS; Mexico City, Mexico) according to their ethical guidelines, including informed consent. MSCs derived from bone marrow (BM; n = 3) were used to validate the specificity of all primers used in this study. BM cells were obtained from hematologically normal BM transplantation child donors at the Bernardo Sepulveda Hospital (National Medical Center, IMSS). A cell population enriched for MSCs was isolated according to Montesinos *et al*[25] using a negative selection procedure [RosetteSep™ system; STEMCELL Technologies Inc. (STI), Vancouver, Canada] and a Ficoll gradient. The cells were resuspended in low-glucose Dulbecco's modified Eagle medium (Lg-DMEM; Gibco BRL, Rockville, MD, United States) supplemented with 10% fetal bovine serum (FBS) and seeded at a density of 0.2 × 10^6 cells/cm^2 into T25 cell culture flasks (Corning Inc., Costar, New York, NY, United States). After 4 d, the nonadherent cells were removed by pipetting, and fresh medium was added. Every 5 d, a medium change was performed. When the cultures reached 80% confluence, they were trypsinized (0.05% trypsin, 0.53 mmol/L EDTA; Gibco BRL, New York, NY, United States) and subcultured at a density of 0.01 × 10^6 cells/cm^2 into T75 flasks (Corning). In the second passage, cells were harvested and analyzed.

UCB-MSC and PL-MSC samples were obtained from two volunteer donors from normal full-term deliveries according to the institutional guidelines of Troncoso Hospital, IMSS, as previously described by Montesinos *et al*[25]. UCB-derived MSCs were obtained using a negative selection procedure (RosetteSep™ system; STI), as described for BM. Cells were resuspended in Lg-DMEM (Gibco) supplemented with 10% FBS (STI) and seeded at a density of 0.2 × 10^6 cells/cm^2 in T25 culture flasks (corning), and subsequent cultures were manipulated as described for BM. PL-derived MSCs were obtained using an enzymatic digestion procedure. The internal area (about 2 cm^3) of the central PL lobules was washed with phosphate-buffered saline (PBS) and dissected into small pieces with sterilized scissors and forceps. The chopped tissues were digested with trypsin-EDTA (Gibco) at 37 °C for 10 min. A single-cell suspension was collected by flushing the tissue parts through a 100-μm nylon filter (Falcon; Becton, Dickinson and Company, San Jose, CA, United States) with Lg-DMEM containing 10% FBS. The cell suspension was centrifuged for 10 min at 400 g to collect the cell pellet. Then, the cells were resu-spended in Lg-DMEM supplemented with 10% FBS. The total number of nucleated and viable cells was determined, seeded, and manipulated as described for BM. After the third passage, the cells were analyzed and cryopreserved. For all experiments, MSCs were used in passages 4-5.

RLs

RLs were established according to the protocol by Marín-Llera *et al*[24]. PL-MSCs, UCB-MSCs, or 22 Hamburger-Hamilton (HH) CK-LBMCs were collected to stuff 22 HH CK limb ectoderms, according to Hamburger and Hamilton [26]. After obtaining PL-MSCs, UCB-MSCs, or CK-LBMCs, they were centrifuged at 3000 rpm and incubated at 37 °C between 1.5 h and 2 h to form a compact pellet. Separately, to obtain ectoderms, LBs from about 10 of the 22 HH embryos were dissected in PBS, transferred to a tube, and digested in 0.5% trypsin in PBS for 30 min at 37 °C. Then, the LBs were transferred to PBS supplemented with 10% FBS, and the ectoderm was peeled off. Next, the pellet of PL-MSCs, UCB-MSCs, or CK-LBMCs was detached from the bottom of the tube and transferred to a small petri dish containing the ectoderms. Later, a pellet fragment was stuffed into each ectoderm. Ectoderms were individually transferred into a previously windowed 22 HH chick embryo, positioned between somites 15-20, and fixed with palladium wires over a previously scratched wound. Manipulated embryos were incubated for 24 h, 48 h, or 72 h at 37.5 °C until their collection and processing. The leftover pellet from three sources was independently frozen to evaluate its basal expression compared to RLs by quantitative polymerase chain reaction (qPCR). All RL experiments were performed in triplicate.

qPCR

RNA from RLs was extracted with NucleoSpin RNA (Cat. No. 740955; Macherey-Nagel, Düren, Ger-many) according to the manufacturer's instructions. Retrotranscription of total RNA was achieved using the RevertAid RT Kit (Cat. K1691; Thermo Fisher Scientific, Waltham, MA, United States). Gene expression levels were quantified using SYBR green (Cat. No. 4309155; Thermo Fisher Scientific), normalizing to the transcript level of ribosomal protein L13. The expression level was evaluated relative to a calibrator according to the $2^{-\Delta\Delta Ct}$ equation. Each plotted value represents the mean ± SD of at least three independent experiments. For each independent qPCR replicate, RNA was obtained from 25 to 30 RL pools for each condition. In addition, leftover pellets of MSCs were collected and processed for RNA extraction. The student's t-test

was performed to compare the expression levels between pellets and RLs and to determine the statistical significance among RL sources. Statistical significance was set at $P < 0.05$. To analyze the specificity of the amplification, a melting curve was achieved for each primer. The specificity of all primers was validated with human MSCs-BM before amplification in the RL. The primer sequences used in this study are included in Supplementary Table 1.

Alcian blue and hematoxylin staining

For Alcian blue staining of RLs, samples were fixed in 5% trichloroacetic acid (Cat. No. A-5268; Sigma-Aldrich, St. Louis, MO, United States) for 24 h and stained with 1% Alcian blue in ethanol-hydrogen chloride for 24 h. Then, the RLs were transferred to 100% ethanol for 24 h and cleared with methyl salicylate (Cat. No. M-2047; Sigma-Aldrich) until the skeleton was observed. RL images were acquired with the AxioZoom v16 microscope (Carl Zeiss, Oberkochen, Germany) using ZEN lite software (Carl Zeiss). After image acquisition, Alcian blue-stained RLs were dehydrated in ethanol and xylol before embedding in paraffin. Ten-micrometer sections were obtained with a microtome (RM2125 RTS; Leica, Wetzlar, Germany). For hematoxylin and eosin (H&E) staining, samples were rehydrated with an ascending gradient of xylol-ethanol, followed by incubation with H&E dyes. Next, slides were dehydrated with ethanol-xylol and mounted with DPX medium (Cat. 44581; Sigma-Aldrich). Images were acquired with the Olympus BX51-WI microscope equipped with a fluorescence and gyratory disc unit (Tokyo, Japan) using Stereo Investigator 9 software (MicroBrightField Inc., Colchester, VT, United States).

Detection of cell death with LysoTracker staining

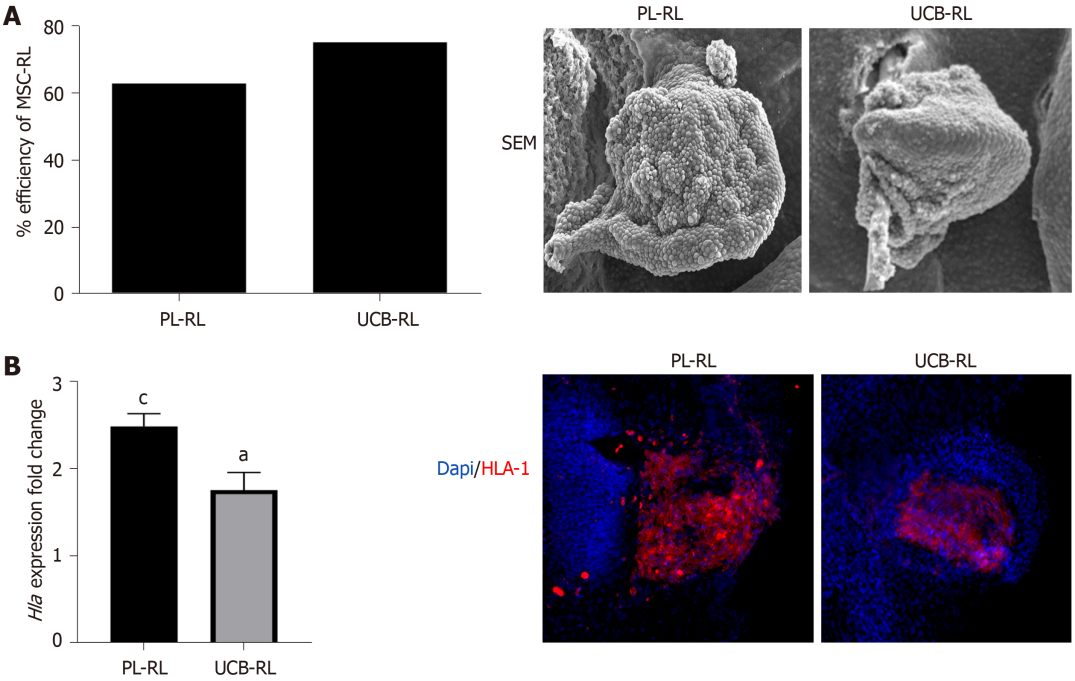
RLs were incubated in 1 μM LysoTracker Red DND-99 (Cat. L7528; Molecular Probes, Eugene, OR, United States) at 37 °C for 15 min. Then, the samples were rinsed with PBS and fixed in 4% paraformaldehyde overnight at 4 °C. Next, the RLs were dehydrated in an increasing methanol-PBS-Tween series and cleared with 2:1 benzylic alcohol-benzyl benzoate solution for 1 h (following the 1999 recommendations by Parish). Images were acquired with an Olympus BX51-WI microscope equipped with a fluorescence and gyratory disc unit using Stereo Investigator 9 software (MicroBrightField).

Scanning electron microscopy

RLs were washed twice with PBS and fixed in 2.5% glutaraldehyde in 0.1 M sodium cacodylate buffer (pH = 7.2) for 2 h. The fixation solution was washed three times with 0.1 M sodium cacodylate at 4 °C. For postfixation, samples were immersed in 1% osmium tetroxide in cacodylate solution for 2 h before dehydration in graded concentrations of ethanol. The samples were placed in microporous capsules submerged in pure ethanol and placed in the Critical Point drying equipment (SPI) for desiccation. Ethanol was replaced with liquid carbon dioxide until its critical constants (31.3 °C and 1072 PSI) were met. After drying, the sample was mounted on an aluminum specimen holder with a silver-based adhesive. The coating was performed by ionizing the sample with a layer of gold in a low vacuum ionizer. Images were acquired using the DSM-950 Carl Zeiss microscope.

In situ hybridization

RNA antisense probes were labeled with UTP-digoxigenin (Cat. No. 11209256910; Roche Applied Science, Indianapolis, IN, United States) and used for whole-mount *in situ* hybridization as previously described[6]. Samples were treated with 15 μg/mL proteinase K for 20 min at 21 °C, and the hybridization temperature was 68 °C. The *Fgf8* signal was visualized with BM Purple substrate for alkaline phosphatase (Roche). Images were acquired with the AxioZoom v16 microscope (Carl Zeiss).



RESULTS

RLs serve as a model to evaluate the morphogenesis and differentiation processes of human MSCs

We used RLs as an experimental model to evaluate the capacity of PL-MSCs and UCB-MSCs to differentiate into limb tissues and to determine their capacity to generate well-organized tissues in an *in vivo* context. In the first instance, we evaluated the competence of human MSCs to respond to embryonic signals present in the limb ectoderm (Figure 1). The results showed that 24 h postimplantation (hpi), the PL-MSCs and UCB-MSCs were successfully integrated and formed RLs, with an efficiency of 62.95% and 76.87%, respectively (Figure 1A). Next, we measured the expression and distribution of major histocompatibility complex 1 (HLA1) to determine whether the RLs were exclusively formed by MSCs. We observed that both MSCs-RLs expressed significantly higher levels of HLA1 compared with their own pellet before transplantation. In addition, the cells in the center of the RLs were HLA1$^+$ (Figure 1B). These results demonstrated the successful establishment of RLs composed of human MSCs for the evaluation of MSC behavior *in vivo*.

Morphology of MSCs changes as RL develops

To assess the capacity of human MSCs to form well-organized tissues, the phenotype of MSC-RLs and their cell organization were evaluated at 24 hpi, 48 hpi, and 72 hpi and compared with RLs formed with CK-LBMCs as a reference of the morphogenetic behavior under RL conditions. In contrast to CK-RL, no evidence of central skeletal elements was observed in RLs from either MSC source (Figure 2). Histolo-gical analyses revealed that the ectodermal cover in all RL conditions was maintained as a monostrati-fied epithelium, while cellular condensation in the center of the MSCs-RL was observed at all time points (Figure 2). Interestingly, the morphology of cell condensations in MSCs-RLs from both sources changed as the development of the RLs progressed, but UCB-RLs showed more evident progressive elongation of a

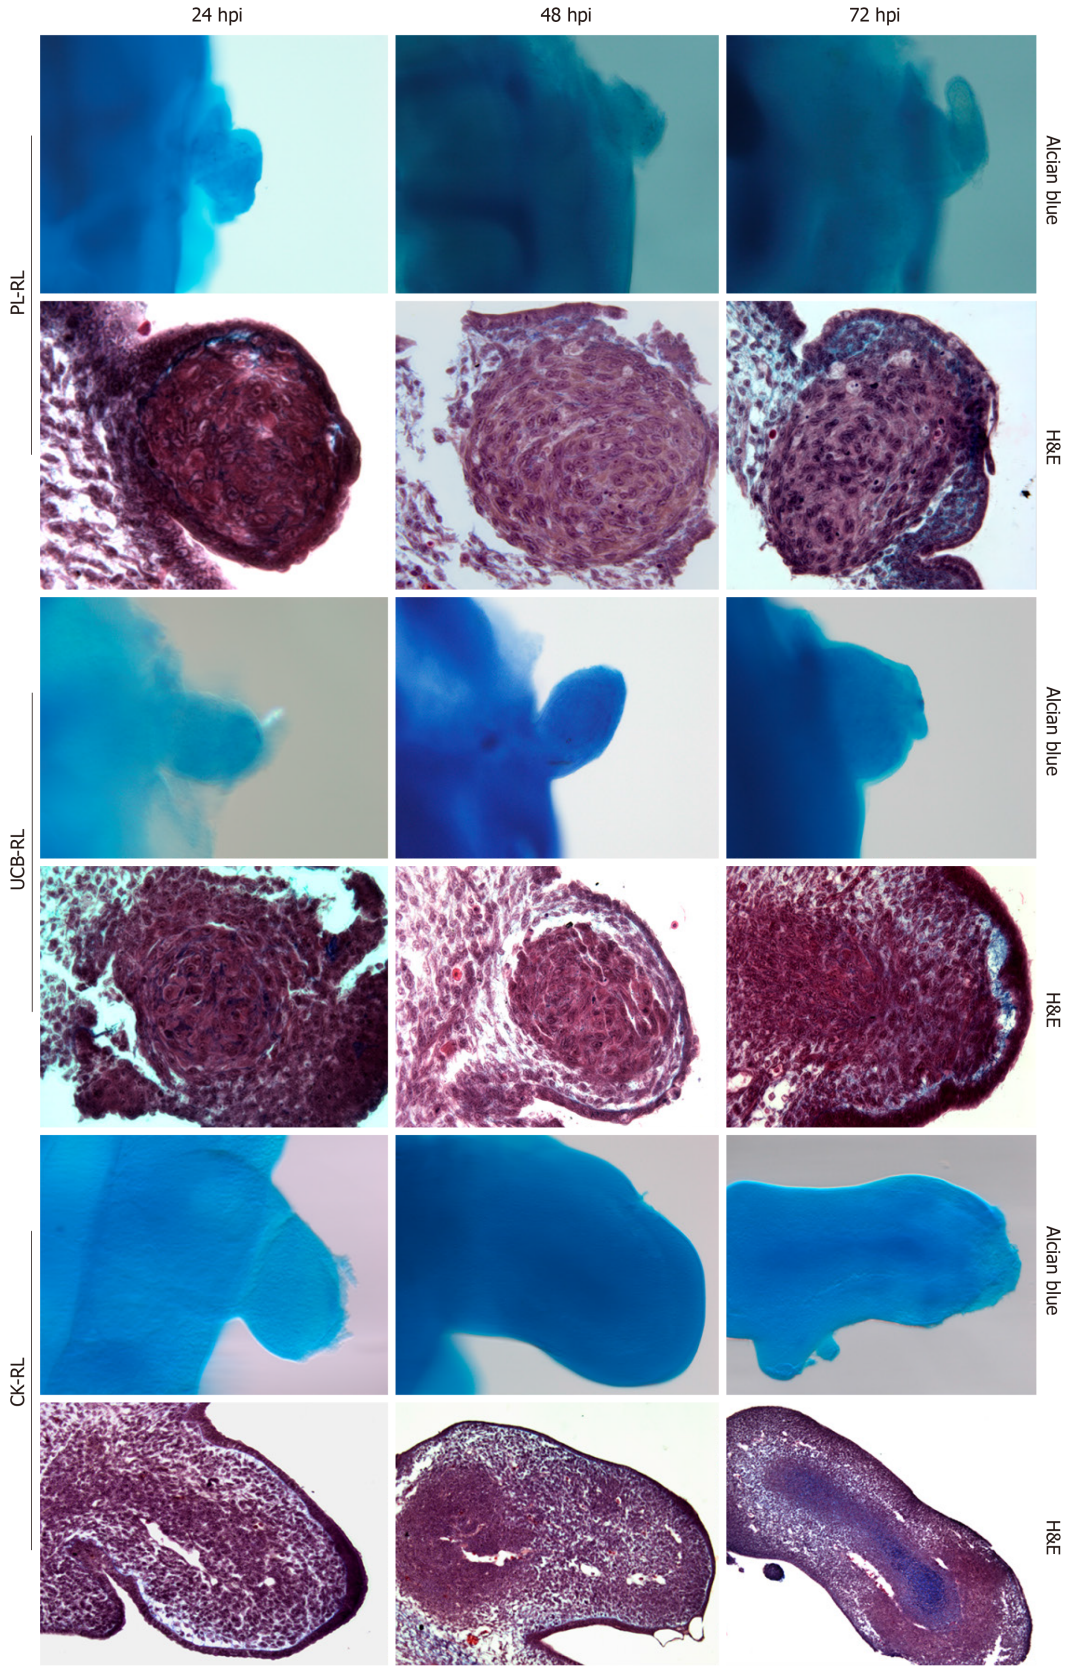

Figure 1 Validation of the recombinant limb system using human mesenchymal stromal cells. A: Implantation efficiency of umbilical cord blood (UCB)-recombinant limb (RLs) and placenta (PL)-RLs in chicken embryos after 24 h. Scanning electron microscopy of PL-RLs (n = 3) and UCB-RLs (n = 2) at 24 h postimplantation (hpi). The embryonic ectoderm and apical ectodermal ridge were conserved in RLs from both sources; B: Levels of human leukocyte antigen (*Hla*) detected by quantitative polymerase chain reaction at 24 hpi RLs from PL and UCB relative to its own pellet. Data represent three independent experiments. The major histocompatibility complex (HLA) expression pattern is shown in RLs from PL (n = 3) and UCB (n = 2). HLA expression was observed in the center of the RLs, indicating that mesenchymal stromal cells constituted the RLs. Statistical significance was set as follows: $^{a}P < 0.05$; $^{c}P < 0.0005$. UCB: Umbilical cord blood; PL: Placenta; RL: Recombinant limb; HLA: Human leukocyte antigen.

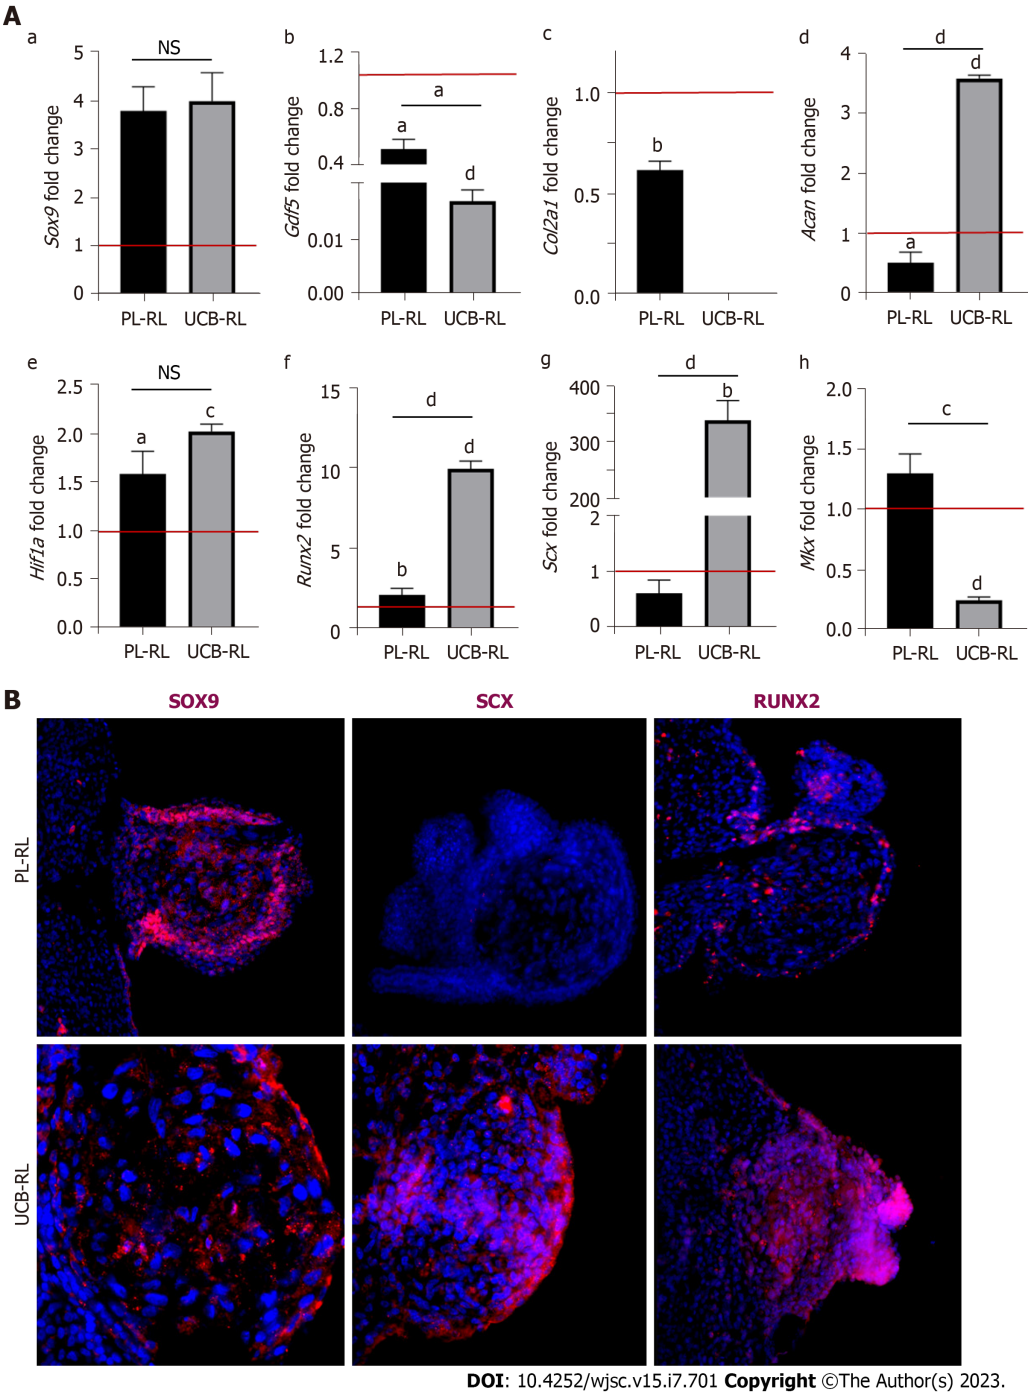
central structure than PL-RLs. Although Alcian blue staining around the condensed cells was observed in MSCs-RLs from both sources, cell morphology analyses showed no cartilage anlage formation after 72 hpi as observed in CK-RLs (Figure 2). The lack of well-formed skeletal elements and cartilage morphology in MSCs-RLs suggests that MSCs cannot form complex skeletal structures because they can remain undifferentiated or in an early committed state. These results also suggest that PL-MSCs and UCB-MSCs respond differently to embryonic ectoderm signals.

Molecular and in situ characterization of cell differentiation in MSC-RLs



In contrast to CK-RL, histological analyses of MSCs-RLs did not indicate specific tissue formation at any evaluated time. Thus, to determine if the PL-MSCs and UCB-MSCs committed to limb cellular lineages during MSCs-RL formation, we evaluated the expression profile of chondrogenic (*Sox9, Gdf5*, *Col2a1*, *Acan,* and *Hif1a*), osteogenic (*Runx2*), and tenogenic (*Scx* and *Mkx*) differentiation genes at 24 hpi in MSCs-RLs from both sources (Figure 3A). The results confirmed that MSCs commit to limb lineages but respond differentially to embryonic ectodermal signals as the expression of molecular markers of chondrogenic, osteogenic, and tenogenic lineages was induced at different levels in MSCs-RLs from both sources compared with its initial pellet (Table 1).

Comparative analyses of *Sox9* expression levels between MSCs-RLs showed no significant differences ($P < 0.8421$), but remarkably, it was highly induced in both MSCs after receiving ectodermal signals (Figure 3A, Table 1). By contrast, low *Gdf5* expression was observed in both sources compared with its initial levels. In addition, it was significatively reduced in UCB-RLs compared with PL-RLs ($P < 0.0205$; Figure 3A, Table 1). Regarding later chondrogenic-associated genes, expression of *Col2a1* was not detected in UCB-RLs, whereas its expression was significatively reduced in PL-RLs (Figure 3A, Table 1). On the other hand, *Acan* was overexpressed only in UCB-RLs and was significatively reduced in PL-RLs ($P < 0.0001$; Figure 3A, Table 1). Interestingly, the levels of *Hif1a* observed in both MSCs-RLs suggest that a hypoxic environment is favored under these conditions (Figure 3A, Table 1). Regarding osteo-genic commitment, *Runx2* was positively regulated in both PL-RLs and UCB-RLs; however, the expression levels of this gene in UCB-RLs were significatively higher than those observed in PL-RLs ($P < 0.0001$; Figure 3A, Table 1). The tenogenic marker *Scx* was markedly induced in UCB-RLs compared with PL-RLs ($P < 0.0004$), in which expression was inhibited (Figure 3A, Table 1). By contrast, *Mkx* expression was significantly downregulated in UCB-RLs compared with PL-RLs ($P < 0.0002$; Figure 3A, Table 1). To evaluate the spatial organization of committed cells, the protein distribution of SOX9, SCX, and RUNX2 was evaluated in MSC-RLs (Figure 3B). Importantly, the high protein expression was correlated with gene expression in all RLs, as assessed by qPCR (Figure 3B, Table 1). However, these results demonstrated that the localization of SOX9, SCX, and RUNX2 was not restricted to the center of the MSCs-RLs (Figure 3B). Together, these results suggest that at 24 hpi, cells in MSCs-RLs are committed early to the chondrogenic lineage. UCB-RLs can also commit to osteogenic lineage,

although preferentially to a tenogenic cell fate, but this cell fate is not promoted in PL-RLs.

Evaluation of Fgf-8 expression and cell death in MSCs-RLs

Signals from the ectoderm and AER are indispensable for maintaining cell survival and proliferation during limb development and RL formation[23]. During limb development, the undifferentiated cellular state and cell commitment balance depend on signals from the AER[2]. To determine whether the lack of ectodermal signals or massive cell death was the mechanism underlying the inability of MSC to form skeletal structures, ectoderm integrity by *Fgf8* expression and lysotracker staining were evaluated in RLs (Figure 4). The results showed that the cell death process was present in

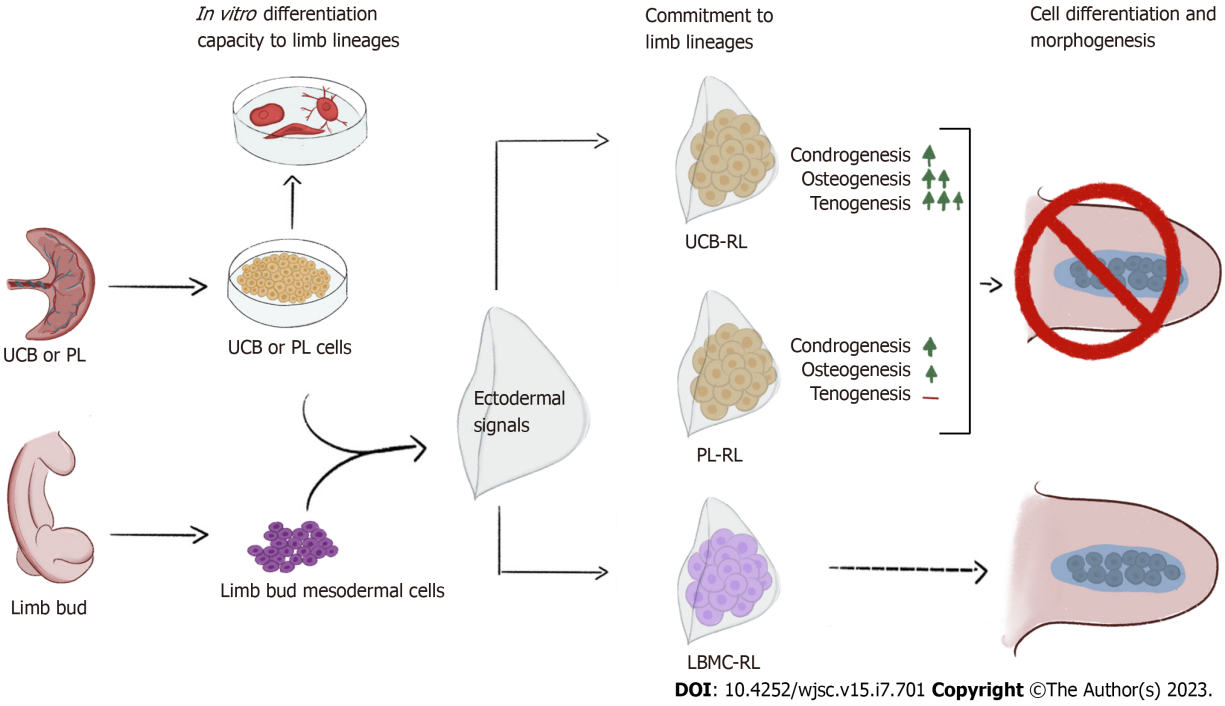
Figure 4 Cell death and fibroblast growth factor 8 expression pattern in mesenchymal stromal cells and chicken recombinant limbs at 24 h postimplantation. Lysotracker staining (Ltk) to evaluate cell death in recombinant limbs (RLs) from the placenta (PL-RLs; *n* = 6), umbilical cord blood (UCB-RLs; *n* = 6), and chicken (CK-RLs; *n* = 4) is shown. *In situ* hybridization of fibroblast growth factor 8 (*Fgf8*) in PL-RLs showed disrupted pattern of this gene in 2/4 RLs; *Fgf8* expression in UCB-RLs was detected in 3/6 evaluated samples, while 5/5 CK-RLs continued to express *Fgf-8* at 24 h postimplantation. UCB: Umbilical cord blood; PL: Placenta; RL: Recombinant limb; CK: Chicken; Ltk: Lysotracker staining; Fgf8: Fibroblast growth factor 8.

the ectoderm of all evaluated RLs; UCB-RLs showed a higher number of dead cells than PL-RLs and CK-RLs. Interestingly, in PL-RLs and CK-RLs, dead cells were concentrated in the apical area of the ectoderm, whereas in UCB-RLs, dead cells were distributed homogeneously on the ectoderm of all samples evaluated (Figure 4). Despite the death of ectodermal cells, *Fgf8* expression was maintained in some MSCs-RLs (see details in the figure legend) or its expression in PL-RLs was disrupted in the center of the ectoderm (Figure 4). These results suggest that at 24 hpi, signals continue to emanate from the AER, which are received by the MSCs or CK-LBMCs beneath the AER.

DISCUSSION



Cells commit to specific lineages once the expression of master genes occurs in response to inducing factors. However, the ability to interpret signals and acquire a particular fate and behavior depend on the developmental history of the cells. The capacity to organize complex structures depends on cell differentiation, cell recruitment, cell movement, differential cell proliferation, and cell death, which occur during the morphogenetic process of tissues and organs.

In this study, we used the RL model to evaluate the morphogenetic abilities of MSCs other than those observed in cell culture. Because RLs provide limb spatial-temporal signals, we evaluated the ability of MSCs to generate complex skeletal structures[23-25]. We found that human MSCs can integrate into an RL implanted in the CK embryo. PL- or UCB-MSCs from RLs respond differently to ectodermal signals, suggesting that the source of MSCs might be important to delineate a particular lineage *in vivo* (Figure 5). Although MSCs from both sources start the chondrogenic program with high levels of SOX9 expression, they do not necessarily equally follow and complete the cell differentiation process (Figure 5). *In vitro* studies have shown that UCB-MSCs preferentially differentiate into osteogenic lineages[17] and present a higher *in vivo* osteogenic and chondrogenic differentiation potential than BM-MSCs when grafted subcutaneously with a scaffold of hydroxyapatite/tricalcium phosphate[19]. By contrast, PL-MSCs preferentially differentiate into an osteogenic lineage when seeded into microcarriers or nanofiber scaffolds[20,21]. These findings suggest that depending on the tissue source, MSCs can represent a cell population with a different number of osteogenic or chondrogenic progenitors or both. Similarly, the molecular markers from chondrogenic and osteogenic lineages were induced at higher levels in UCB-RLs than in PL-RLs. However, the high expression levels of *Runx2* and *Scx* genes did not lead to the formation of well-defined bone tissue or tendons. In addition, the gene expression pattern of *Sox9, Scx,* and *Rux2* did not associate with a specific tissue pattern or arrangement inside the RLs. The expression of molecular markers was not sufficient to promote the formation of well-defined structures, likely because the morphogenetic program was not triggered. Interestingly, PL-RLs expressed high levels of *Mkx* while UCB-RL expressed high levels of *Scx*. It is unknown if in this system both genes are needed to form well-structured tendons. Nevertheless, the expression of *Mkx* or *Scx* can drive the *in vitro* differentiation of BM-MSCs to a tenocyte fate[13,27].

Table 1 Analysis of gene expression fold-changes of differentiation genes between pellets and their corresponding recombinant limbs of different mesenchymal stromal cell sources at 24 h postimplantation

Source	*Sox9*	*Col2a1*	*Acan*	*Gdf5*	*Hif1α*	*Runx2*	*Scx*	*Mkx*
UCB-RL *vs* UCB-pellet	3.99 ± 0.4, $P <$ 0.0004	ND	3.58 ± 0.10, $P <$ 0.0001	0.01 ± 00.003, $P <$ 0.0001	1.58 ± 0.79, $P <$ 0.0002	9.96 ± 0.65 $P <$ 0.0001	377.61 ± 78.24, $P <$ 0.002	0.24 ± 0.03, $P <$ 0.0001
PL-RL *vs* PL-pellet	3.79 ± 0.4, $P <$ 0.0007	0.61 ± 0.12, $P <$ 0.002	0.55 ± 0.21, $P <$ 0.052	0.56 ± 0.12, $P <$ 0.01	1.61 ± 0.28, $P <$ 0.03	2.18 ± 0.59, $P <$ 0.03	0.61 ± 0.33, $P <$ 0.14	1.29 ± 0.22, $P <$ 0.21

Gene expression fold-change was evaluated comparing the pellet of mesenchymal stromal cells (MSCs) after forming the recombinant limb (RL) with MSCs-RLs from both sources. Data from the pellet were set to 1.0. Statistical significance comparing placenta-RL *vs* umbilical cord blood-RL is shown in Figure 3A. All data are presented as mean ± SD. Statistical significance was set at $P < 0.05$. Figure 5 Mesenchymal stromal cells commit to limb mesodermal lineages but are not capable of forming skeletal structures. Mesenchymal stromal cells (MSCs) from umbilical cord blood (UCB) and placenta (PL) differentiated into chondrogenic, osteogenic, and tenogenic lineages *in vitro*. However, under the influence of differentiation and morphogenetic signals from limb ectoderm in the recombinant limb (RL) system, MSCs committed to limb lineages but failed to organize into tridimensional structures and form skeletal elements as observed with limb bud mesodermal cells under the same conditions. Similarly, the response to ectodermal signals depended on the source of MSCs: UCB-RLs had higher expression of osteogenic and tenogenic markers than PL-RLs, whereas in PL-RLs, tenogenic markers were downregulated after receiving ectodermal signals. UCB: Umbilical cord blood; PL: Placenta; LBMC: Limb bud mesodermal cell; RL: Recombinant limb.

The inability of MSCs to generate complex structures suggests that MSC populations, in addition to being composed of a wide variety of cell types, are unable to initiate or follow a morphogenetic program *in vivo*. Although MSCs can differentiate into skeletal lineages, it does not guarantee that they will organize into skeletal elements. It is possible that the RL model lacks signals to support the formation of skeletal elements. However, CK-LBMCs respond to differentiation signals, resulting in the generation of skeletal elements. Thus, the RL system provides signals that instruct cells to form skeletal elements.

We did not observe exacerbated cell death in the MSCs-RLs, but in some MSCs-RLs the loss of *Fgf8* expression in the AER was evident. Additional studies are needed to determine if this cell death results from the loss of FGF8 loop signaling between the AER and MSCs, or if MSCs cannot recover and maintain the loop to maintain FGF8 expression. Our data suggest that the differentiation process in MSCs is detached from the process of morphogenesis and patterning, although it is possible that addi-tional signals may be needed to promote the integration of morphogenetics with differentiation signals in MSCs. Accordingly, other studies have shown that after implantation in the kidney subcapsular region or nude mice[28-31], MSCs organize better than *in vitro* but never originate complex structures such as skeletal elements or other limb musculoskeletal tissues.

Although MSCs are considered relevant in regenerative medicine, their intrinsic cellular properties may explain why the reported therapeutic effects of MSCs are mostly indirect through immunomodulation or paracrine mechanisms rather than reliable integration into adult tissues or *de novo* tissue forma-tion[32-39].

CONCLUSION

This study demonstrates that the expression of differentiation markers of skeletal lineages in MSCs is not sufficient to generate skeletal structures *in vivo*, possibly due to the intrinsic characteristics of MSCs. In regenerative medicine, cells must be incorporated into well-defined tissues or generate new complex structures with a well-defined patterning. Thus, further application of MSCs in regenerative medicine needs to focus on understanding their biological characteristics to gain insights into how MSCs can integrate into adult tissues or properly rebuild tissues and organs.

ARTICLE HIGHLIGHTS

Research background

Mesenchymal stem cells (MSCs) differentiate *in vitro* to different skeletal lineages; however, it is un-known if they have the ability to form complex skeletal structures.

Research motivation

Although MSCs are considered relevant in regenerative medicine, reliable integration into adult tissues or *de novo* tissue formation has not been demonstrated. The application of MSCs in regenerative medicine needs to focus on understanding their biological characteristics to gain insights into how MSCs can integrate into adult tissues or properly rebuild tissues and organs.

Research objectives

To evaluate the ability of MSCs to organize and form complex skeletal structures *in vivo* under the influ-ence of embryonic signals.

Research methods

The recombinant limb (RL) is an experimental system that recapitulates the embryonic environment and its influence on cells to generate skeletal structures. Here, umbilical cord blood (UCB)-MSCs or placenta (PL)-MSCs were placed in an RL to assess their ability to form skeletal structures. The evaluation was conducted by Alcian blue staining, immunofluor-escence, and quantitative polymerase chain reaction of molecular markers of skeletal lineages.

Research results

MSCs expressed molecular markers of skeletal lineages but were unable to generate complex skeletal structures. PL-MSCs or UCB-MSCs integrated into an RL implanted in a chicken embryo. They res-ponded differently to ectodermal signals starting the chondrogenic, osteogenic, or tenogenic program with high *SRY-box transcription factor 9*, *Runt-related transcription factor 2*, and *scleraxis* gene expression levels. However, PL-MSCs or UCB-MSCs did not complete the cell differentiation and morphogenetic processes, likely due to the intrinsic characteristics of MSCs.

Research conclusions

PL-MSCs or UCB-MSCs express molecular markers of skeletal lineages but do not organize into com-plex skeletal structures. The use of RLs is an excellent model for determining the ability of cells from other origins than limb bud mesodermal cells to generate skeletal structures. The inability of MSCs to form skeletal structures might be due to their intrinsic characteristics. Additional studies are needed to understand the properties of MSCs and whether they can integrate into adult tissues or properly rebuild tissues and organs.

Research perspectives

The application of MSCs to regenerative medicine needs to focus on understanding their biological characteristics to gain insights into how MSCs can integrate into adult tissues or properly rebuild tissues and organs.

Abstract

BACKGROUND

Current evidence shows that human induced pluripotent stem cells (hiPSCs) can effectively differentiate into keratinocytes (KCs), but its effect on skin burn healing has not been reported.

AIM

To observe the effects of hiPSCs-derived KCs transplantation on skin burn healing in mice and to preliminarily reveal the underlying mechanisms.

METHODS

An analysis of differentially expressed genes in burn wounds based on GEO datasets GSE140926, and GSE27186 was established. A differentiation medium containing retinoic acid and bone morphogenetic protein 4 was applied to induce hiPSCs to differentiate into KCs. The expression of KCs marker proteins was detected using immunofluorescence staining. A model of a C57BL/6 mouse with deep cutaneous second-degree burn was created, and then phosphate buffered saline (PBS), hiPSCs-KCs, or hiPSCs-KCs with knockdown of *COL7A1* were injected around the wound surface. The wound healing, re-epithelialization, engraftment of hiPSCs-KCs into wounds, proinflammatory factor level, and the NF-κB pathway proteins were assessed by hematoxylin-eosin staining, carboxi-fluorescein diacetate succinimidyl ester (CFSE) fluorescence staining, enzyme linked immunosorbent assay, and Western blotting on days 3, 7, and 14 after the injection, respectively. Moreover, the effects of *COL7A1* knockdown on the proliferation and migration of hiPSCs-KCs were confirmed by immunohistochemistry, EdU, Transwell, and damage repair assays.

RESULTS
HiPSCs-KCs could express the hallmark proteins of KCs. *COL7A1* was down-regulated in burn wound tissues and highly expressed in hiPSCs-KCs. Transplantation of hiPSCs-KCs into mice with burn wounds resulted in a significant decrease in wound area, an increase in wound re-epithelialization, a decrease in proinflammatory factors content, and an inhibition of NF-κB pathway activation compared to the PBS group. The in vitro assay showed that *COL7A1* knockdown could rescue the inhibition of hiPSCs-KCs proliferation and migration, providing further evidence that *COL7A1* speeds up burn wound healing by limiting cell proliferation and migration.

CONCLUSION
In deep, second-degree burn wounds, *COL7A1* can promote KC proliferation and migration while also suppressing the inflammatory response.

INTRODUCTION

The skin acts as an environmentally protective barrier and has vital physiological functions such as sensation, absorption, secretion, excretion, and protection, as well as being involved in a variety of metabolic processes in the body and maintaining the stability of the internal environment[1]. Therefore, skin integrity is crucial to maintain its function. However, due to extensive skin integrity defects caused by different pathological conditions (including burns, scalds, vasculopathy-triggered skin ulcers, pressure ulcers, diabetic ulcerated feet, and others), which are caused by the action of internal and external factors, the underlying wounds develop pathological inflammatory reactions, which cannot adequately heal through normal repair procedures. Subsequently, such poorly-healing wounds will cause severe disability or patient death, together with adversely impacting the economic status of the patient's family and healthcare system[2-5]. Thus, developing novel therapeutics for chronic wounds is crucial to enhance the management practices and subsequent outcomes.

In August 2006, Takahashi and Yamanaka[6] at Kyoto University, Japan, first transfected four pluripotency related genes, *Oct4, Sox, c-myc,* and *KLF4*, into mouse fibroblasts using retroviruses as gene introduction vectors, which led to the creation of pluripotent stem cells with similar characteristics to ESCs and named them induced pluripotent stem cells (iPSCs)[6]. Today, iPSC technology has revolutionized basic research and clinical disease treatment in biology[7,8]. For instance, valproic acid strongly promotes the differentiation of human pluripotent stem cells into spermatogonial stem cell-like cells and provides a reliable tool and model for studying human germ cell development and male infertility[9]. Another study discovered that transplanting retinal pigment epithelial cells derived from human iPSCs (hiPSCs) is promising as a new treatment modality for age-related macular degeneration and Stargardt disease[10]. Moreover, the transplantation of hiPSC-derived neural stem/progenitor cells (hiPSC-NS/PCs) is a promising therapeutic approach for various neuropathological conditions[11,12].

For burn trauma, inducing re-epithelialization has received much attention as a therapeutic focus and a key indicator to evaluate the efficacy of clinical interventions[13]. To complete re-epithelialization, keratinocytes (KCs) migrate, proliferate, and differentiate, with migration being the most important[14]. In this context, KC initiation and migration are the initiating events and rate-limiting steps in the re-epithelialization process because impaired migration causes non-healing wounds and chronic wound formation, while the inhibition of their proliferation and differentiation functions does not[15,16]. A study showed that KC abnormalities were the main drivers that triggered psoriasis pathology, and the ability of iPSCs to efficiently differentiate into mature KCs played a crucial role in psoriasis treatment[17]. Replacement cells derived from hiPSCs have the potential for sufficient scalability, and selecting hiPSCs as the human pluripotent stem cells (hPSC) of choice ensures immunocompatibility. Ibrahim *et al*[18] showed that hiPSC-derived KCs would lose CD200 expression and express keratin 14 (*K14*), indicating the emergence of more mature terminally differentiated cells that

could be transplanted to treat large burns or ulcers. Accordingly, while the ability to obtain sufficient KCs from hiPSCs for transplantation repair is promising, further research is needed before this technology can be applied to skin wound repair. Moreover, the specific mechanism of hiPSCs involvement in burn repair has not been fully revealed.

In this study, we used the cell induced differentiation technique of hiPSCs to successfully differentiate hiPSCs into KCs. Subsequently, to study the effects of transplanting differentiated KCs on murine skin wound healing, a skin-deep second-degree burn model was created and successfully differentiated KCs were injected around the wound. In addition, a bioinformatics approach was taken to further explore the possible mechanism of hiPSCs-KCs transplantation role in wound healing.

MATERIALS AND METHODS

Bioinformatics analysis

GSE140926 and GSE27186 were found in the GEO database (https://www.ncbi.nlm.nih.gov/gds) for burn trauma-related mRNA expression profile datasets. The GSE140926 dataset was derived from the GPL15433 platform and included 3 burned eschars and 3 normal skin tissue samples. On the other hand, the GSE27186 dataset was derived from the GPL570 (Affymetrix Human Genome U133 Plus 2.0 Array) platform and included two iPSC and two KC samples. The raw data of the chip, including data matrix files in txt document format and corresponding platform annotation files, were subsequently downloaded. The difference analysis was performed *via* the limma package on R software, which employed the classical bayson's *t*-test analysis method with $|\log \text{Fold Change}| \geq 0.5$, and $P < 0.05$ as the filtering criteria. Visualization Differentially expressed genes (DEGs) were used to generate a volcano plot. There were three types of annotations present in gene ontology (GO) functional annotations: Molecular function, biological pathway (BP), and cellular component (CC). To perform GO functional annotation of DEGs, we used the online tool David (https://david.ncifcrf.gov/). GO pathway enrichment analysis was performed with the cluster profiler package on R software with the following filtering criteria: False discovery rate < 0.05, and adjusted $P < 0.05$. The enrichment results were visualized using R, as well.

Induced differentiation of hiPSCs into KCs

HiPSCs used in this study were purchased from Beijing Saibe Biotechnology Co., Ltd (Beijing, China). HiPSCs in the logarithmic growth period were digested and inoculated into the culture plate. The cells were grown in a cell incubator with 5% CO_2 at 37 °C for two days in DMEM culture medium containing 10% fetal bovine serum. Cells were cultured in a cell culture chamber with 5% CO_2 saturated humidity at 37 °C, and 0.1 mol/L retinoic acid (RA) and 10 mol/L bone morphogenetic protein 4 (BMP-4) (Thermofisher, United States) were added to the differentiated medium on days 3, 5, and 7. On the 14th day of differentiation induction, 0.1 mol/L Ca^{2+} was added to the differentiation medium, and the morphological changes of cells were observed.

Immunofluorescence staining

A total of 300 μL of each of primary antibody *K14* (1:200), *involucrin* (1:200), *loricrin* (1:200), and *COL7A1* (1:200) (Abcam, United States) dilutions diluted in phosphate buffered saline (PBS) were added to hiPSCs-KCs and incubated overnight according to the manufacturer's instructions. On the following day, after washing the cells using PBS, the corresponding fluorescent secondary antibodies Goat anti-mouse (1:200), and Goat anti-rabbit (1:200) were added and incubated in the dark at 37 °C for 1 h. After 15 min in the dark at room temperature, 300 μL of DAPI (1:1000 dilution) was added, and the images were acquired using an inverted fluorescence microscope.

Cell transfection

The shRNA sequences against *COL7A1* were purchased from Shanghai SANGON company (SANGON, Shanghai, China). *COL7A1* shRNA and its negative control NC shRNA were transfected into hiPSCs-KCs using Lipofectamine®3000 transfection reagent according to the manufacturer's protocol. hiPSCs-KCs were employed for the following experiments two days after transfection.

Clinical specimens

Skin samples were obtained from the remaining burned and normal skin tissue samples of 26 male patients, aged around 30 years old, who underwent autologous skin grafting in the Burn Department of the Second Affiliated Hospital of Soochow University from June 2019 to October 2021. All data extraction processes were reviewed and approved by the medical ethics committee of the First Affiliated Hospital of Soochow University while also obtaining informed patient consent.

Mouse burn model

Forty C57BL/6 male mice were purchased from Soochow University. The feeding formula was corn 35%, soy cake 15%, raw yellow beans 5%, wheat bran 15%, flour 15%, yeast meal 2%, bone meal 2%, sesame cake 5%, maltodextrin 2%, fish meal 2%, salt 0.5%, canola 1%, trace elements 0.2%, vitamins 0.1%, and choline chloride 0.2%. The experimental manipulation process strictly adhered to the relevant regulations and requirements of medical ethics. The mice were intraperitoneally injected with 40 mg/kg pentobarbital sodium. After shaving the dorsal hair of mice using a small animal shaver and smearing on the dorsal shaved area with 10% sodium sulfide, the back was wiped with water after 30 s to remove

any residuals. The mice were returned to the animal housing room for a further 24 h. Subsequently, after anesthetizing the mice by isoflurane inhalation, a 1.5 cm diameter circular mold was covered on the area that had been depilated on the back of the mice, and 92 °C hot steam was used to scald each back of the mice for 6 s. Deep second-degree burns were diagnosed when hematoxylin-eosin (HE) staining revealed scald tissue that was the full thickness of the epidermis and below the papillary layer of the dermis, the full thickness of unwounded skin, and still had hair follicles, sebaceous glands, and other skin appendages. After modeling, mice were randomly divided into four groups, including PBS, hiPSCs-KCs, hiPSCs-KCs + NC shRNA, and hiPSCs-KCs + *COL7A1* shRNA groups, which depicted the injection of 25 mL of 0.1 M PBS, 25 mL (2.0×10^7 cells) of hiPSCs-KCs, 25 mL of hiPSCs-KCs transfected with NC shRNA, and 25 mL of hiPSCs-KCs transfected with *COL7A1* shRNA around the postoperative wounds, respectively. On days 0, 3, 7, and 14 after injection, the wound healing area of each group was measured by a ruler, and photographed and recorded with a digital camera. To prevent the development of immune rejection, mice were injected with FTY720 (3 mg/kg/d), an immunosuppressive agent, to reduce any adverse reactions against hiPSCs. All animal experiments followed the Institutional Animal Care and Use Committee protocols.

HE staining

The skin 1 cm around the wound was cut and fixed using 4% paraformaldehyde at 4 °C for one week. After tissue paraffin embedding, and wax block sectioning, HE staining (Thermofisher, United States) was used according to the manufacturer's requirements. Finally, the slides were blocked after dehydration using ethanol, and observed under a microscope.

Immunohistochemical staining

Deparaffinization, hydration, antigen retrieval, serum blocking, primary antibody (*COL7A1* and *Ki67*, Abcam, United States) and secondary antibody incubation, washing, DAB color development, hematoxylin counterstaining, and mounting of burn wound tissue sections were performed sequentially. The number of cells positive for *COL7A1* and *Ki67* expression was counted in three randomly selected high-power fields per section under the microscope.

Cell proliferation assay

hiPSCs-KCs, hiPSCs-KCs + NC shRNA, and hiPSCs-KCs + *COL7A1* shRNA cells were harvested from three different treatments. The hiPSCs-KCs (20×10^5/well) were seeded in culture dishes. The EdU solution was diluted using DMEM medium at a 5000:1 ratio to make an appropriate amount of 50 μmol/L EdU medium. Subsequently, 200 μl of EdU medium was added to the culture dish and incubated for 2 h. After discarding the medium, cells were sequentially incubated with fixative solution (PBS containing 4% paraformaldehyde), glycine, and Permeabilizer. After 30 min incubation in the dark at room temperature with DAPI reaction solution, an anti-fluorescent quencher blocking reagent was added, and images were observed and acquired under a fluorescence microscope for analysis.

Carboxifluorescein diacetate succinimidyl ester fluorescent labelling

After dilution in PBS with xylene sulfoxide solution containing 10 mmol/L carboxifluorescein diacetate succinimidyl ester (CFSE) (Millipore, United States), a 5 μmol/L working solution was obtained. CFSE working solution at a final concentration of 5 μmol/L was added to the hiPSCs-KCs and incubated at 37 °C for 30 min. hiPSCs-KCs suspension was injected around the mouse skin burn wounds. The fluorescence intensity was observed under an inverted fluorescence microscope on the 14th postoperative day.

Cell migration assay

HiPSC-KCs from all three treatment groups were gathered. In the upper chamber of the Transwell, 1×10^5 diluted hiPSCs-KCs were added per well, and in the lower chamber, the DMEM medium was placed. Following a 24-h incubation in 4% paraformaldehyde, the cells were fixed in blotting fixative, washed three times with PBS, and incubated with 0.01% crystal violet before being randomly selected for observation and counting in five different fields. For damage repair experiments, cells were streaked in the central area of cell growth with a sterile pipette tip and then rinsed with PBS to remove dead cells. The scratch width was observed under a microscope at 24 h after scratching and was photographed and recorded.

Western blotting

Total cell and tissue protein was extracted with RIPA lysate, and the protein concentration was determined by a BCA protein assay kit (Thermofisher, United States) in a microplate reader. After denaturation for 10 min with the addition of loading buffer, 50 μg of protein samples were subjected to SDS-PAGE and transferred onto polyvinylidene fluoride membranes. The membrane was blocked with a blocking solution (5% nonfat dry milk) for 2 h and subsequently washed three times using TBST. Then, primary and secondary antibodies were added separately and shaken. Image J was used to analyze membrane protein band gray values.

RT-qPCR

The RNA concentration of 26 pairs of burned and normal skin tissue samples was determined, and the RNA was reverse transcribed into cDNA according to the instructions included in a reverse transcription kit. This cDNA was then used as a template for *COL7A1* amplification on Bio-Rad CFX90 RT-PCR. RT-PCR reaction conditions included pre-denaturation at 95 °C for 30 s, 39 cycles of denaturation at 95 °C for 5 s, annealing at 60 °C for 5 s, and extension at 65 °C for 5 s. *GAPDH* was used as an internal reference and the relative expression levels were calculated by the $2^{-\Delta\Delta CT}$ method.

Statistical analysis

Data was processed *via* SPSS 22.0 statistical software and presented as the mean ± SEM of the results from at least three independent experiments. Kruskal-Walli's test was used for the non-parametric statistical analysis. Differences among more than two groups in the above assays were estimated using one-way ANOVA, with $P < 0.05$ considered significant.

RESULTS

GEO datasets screening identified high COL7A1 expression in hiPSCs-KCs and low expression in burn wounds

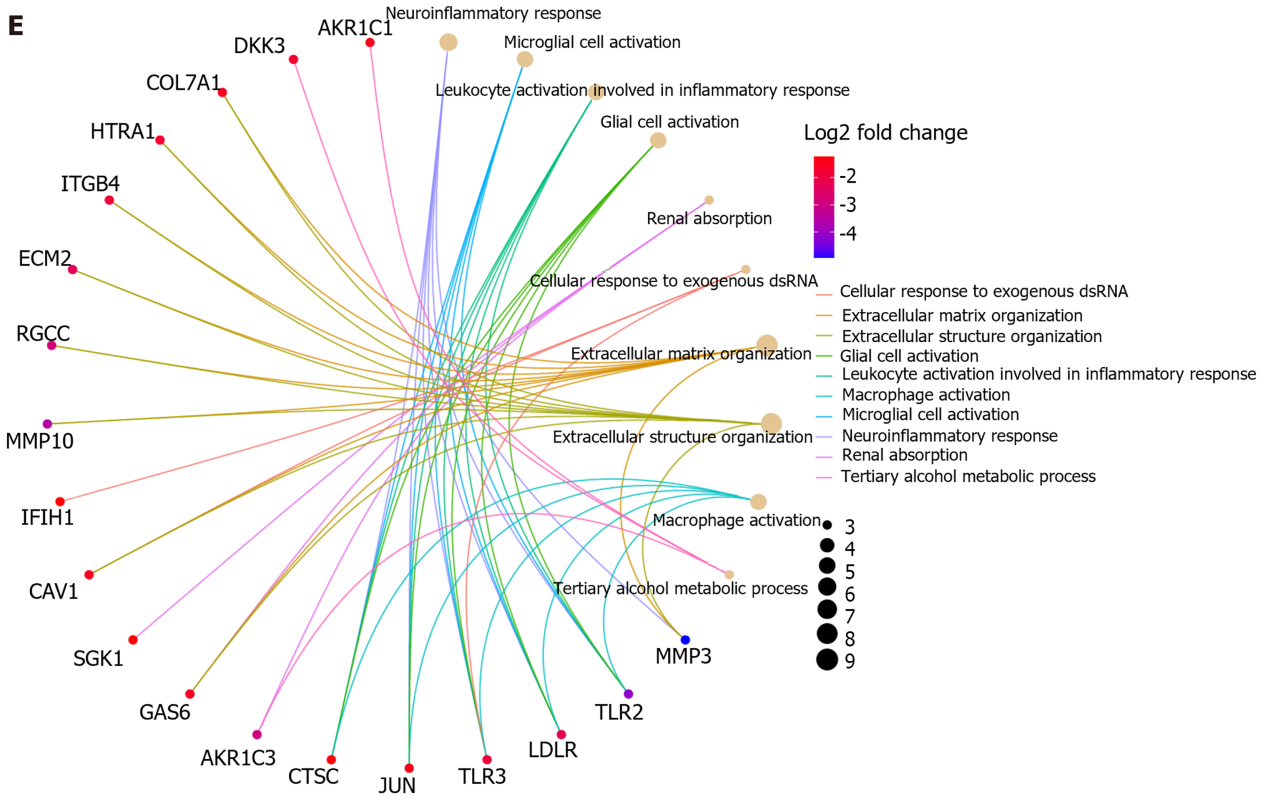
Data from the GSE140926 (containing 3 normal skin and 3 burn eschar tissue samples) and GSE27186 (2 hiPSCs and 2 hiPSCs-KCs samples) datasets were first screened for DEGs. A total of 3575 DEGs were found in hiPSCs-KCs samples compared to the hiPSCs ones, which included 1732 and 1843 downregulated and upregulated DEGs (Figure 1A). Furthermore, a total of 1634 DEGs were found in the burn eschar tissue samples compared to the human normal skin ones, which included 867 and 767 downregulated and upregulated DEGs (Figure 1B). Since KCs were damaged at the wound site, we selected DEGs downregulated at the wound site and upregulated in hiPSCs-KCs and intersected them to get 98 DEGs (Figure 1C). Using R software's cluster profiler package, 98 DEGs' GO pathway enrichment was analyzed (Figure 1D). Neuroinflammatory response, microglial activation, and leukocyte activation induced in inflammatory response were significantly enriched GO-BP pathways, and the main enriched genes were *AKR1C1*, *DKK3*, *COL7A1*, *HTRA1*, *ITGB4*, and others (Figure 1E). The most enriched GO-CC pathways were endocytic vesicle membrane and collagen-containing extracellular matrix, and the most enriched genes were *TLR3*, *RAB29*, *CTSC*, *COL7A1*, *LTBP2*, and others (Figure 1F). Furthermore, the significantly enriched GO-MF pathways included growth factor and steroid binding, while the main enriched genes included *PTPN3*, *FOXL2*, *CTSC*, *COL7A1*, *ITGB4* and others (Figure 1G). We additionally intersected the three groups of the significantly enriched DEGs and obtained four DEGs, including *COL7A1*, *HTRA1*, *CAV1* and *CTSC* (Figure 1H and I). Since *COL7A1* showed the greatest degree of differential expression in the burned tissue samples, we decided to investigate it further.

hiPSCs successfully differentiated into keratinocyte

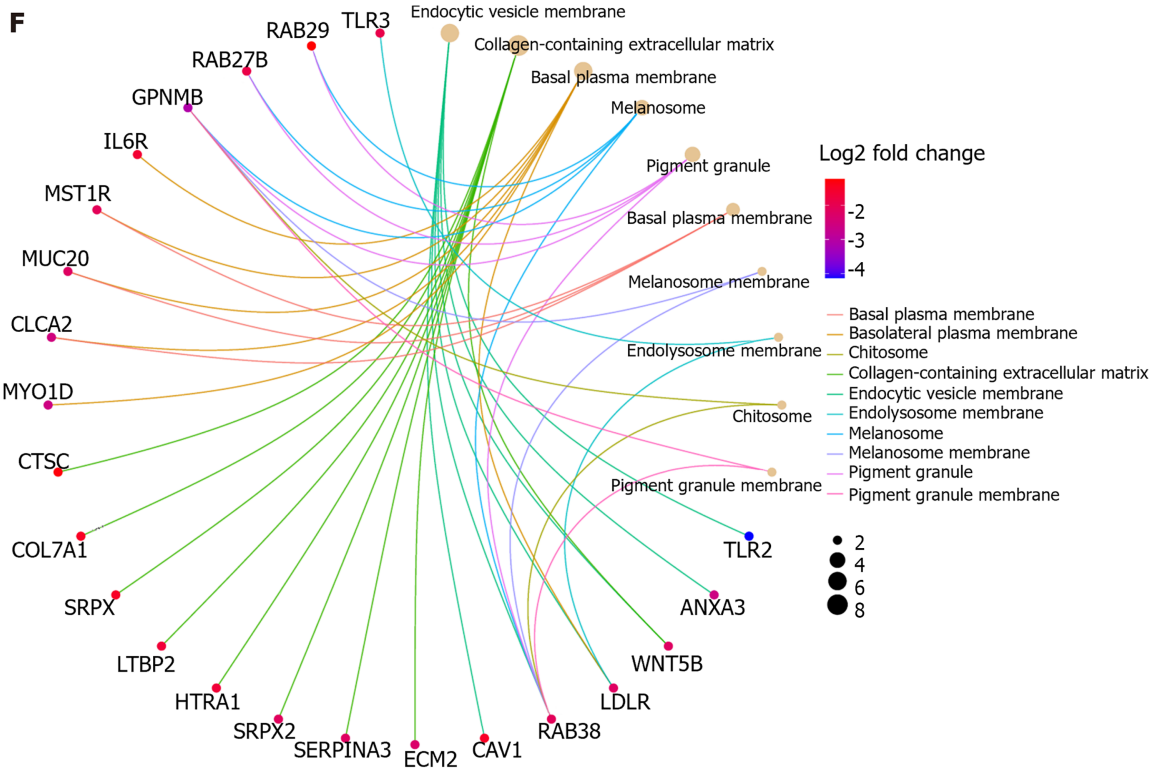
We used RA and BMP-4 to induce differentiation in hiPSCs before plating them to differentiate. The ability of hiPSCs to differentiate into KCs was then evaluated by analyzing the expression and cellular distribution of several KC-expressed proteins using immunofluorescence. Results showed that after 14 d of differentiation induction, the hiPSCs significantly expressed KCs marker proteins (*K14*, *involucrin*, and *loricrin*), as evidenced by increased fluorescence intensity (Figure 2). Afterward, at day 14, hiPSCs-KCs were implanted into mice.

COL7A1 was significantly under-expressed in second-degree burn tissues

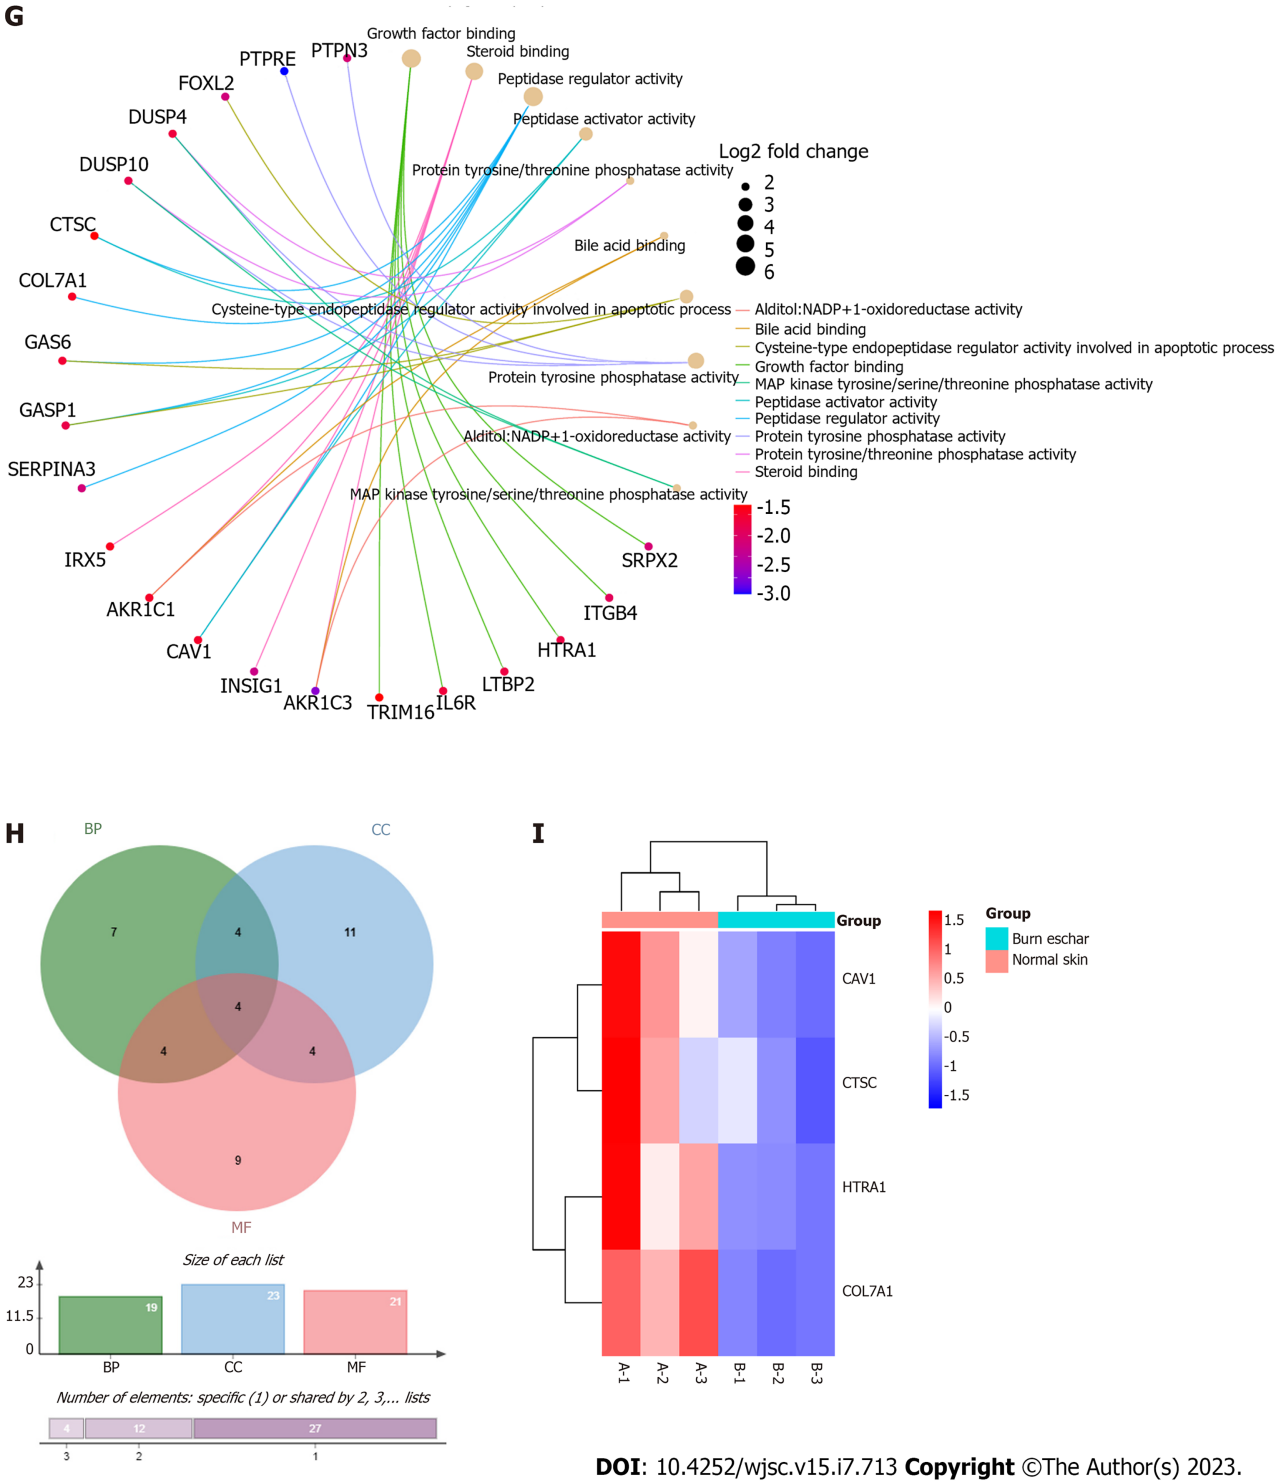
To validate *COL7A1* mRNA expression in human deep second-degree burn wound and normal skin tissues, RT-qPCR and Western blotting were applied and the results showed that *COL7A1* expression was downregulated in burn wound tissue (Figure 3A and B). Representative photomicrographs of HE stained mouse burned skin 24 h after the injury showed a damaged structure throughout the epidermis and deep dermis (Figure 3C). This might suggest that the mouse deep second-degree burn model was successfully constructed. Immunohistochemical detection of *COL7A1* expression levels in mouse burn wounds and the surrounding normal skin showed that *COL7A1* expression remarkably diminished in burn wounds (Figure 3D). We also compared fibroblast, fibroblast-like, and hiPSC-KC *COL7A1* expression levels. Immunofluorescence analysis revealed that *COL7A1* was only strongly expressed in hiPSCs-KCs cells, as indicated by increased green fluorescence (Figure 3E), while it was hardly expressed in hiPSCs and fibroblasts. Our findings further confirmed the results obtained by bioinformatics analysis.



COL7A1 inhibition abolished the promoting effects of hiPSCs-KCs on burn healing and re epithelialization in mice



We evaluated the transfection efficiency of *COL7A1* shRNA before and after hiPSCs-KCs transplantation. The mRNA expression level of *COL7A1* decreased nearly five folds after transfection of hiPSCs-KCs with *COL7A1* shRNA (Figure 4A). Interestingly, as a point of reference for our experimental manipulation, we also built the *COL7A1* overexpression vector to demonstrate the efficiency of *COL7A1* overexpression. The data indicated that *COL7A1* overexpression was just as effective. Furthermore, *COL7A1* expression was significantly upregulated after transplantation of hiPSCs-KCs around mouse wounds, while *COL7A1* knockdown was associated with a decrease in *COL7A1* expression after transplantation of hiPSCs-KCs. All of this suggests that knocking down *COL7A1* is effective and can be used in future experiments. At 3, 7, and 14 d after hiPSCs-KCs transplantation, the healing of burn wounds in mice was recorded by taking photographs with a digital camera. We found that burn wound edges significantly contracted at 7 d after hiPSCs-KCs transplantation with obvious epithelialization and newly regenerated epidermal tissue that partially covers the wound bed. On the other hand, the normal tissue at the wound periphery contracted mildly after *COL7A1* knockdown in hiPSCs-KCs with very little newly regenerated epidermis at the wound edge.



Moreover, by day 14, most of the hiPSCs-KCs transplanted group's wounds had been covered by newly formed epidermal tissue, and the wound margins had shrunk significantly. However, in the *COL7A1* knockdown group, wound size was reduced to a lesser extent and an exact re-epithelialization phenomenon was observed at the wound margin, but the majority of the wounds did not heal (Figure 4A and B).

Paraffin sections of the burned tissues were stained with HE at 7 and 14 d after hiPSCs-KCs transplantation to observe the pathological injury changes and regenerative epithelialization in each group. In the PBS group, the results showed

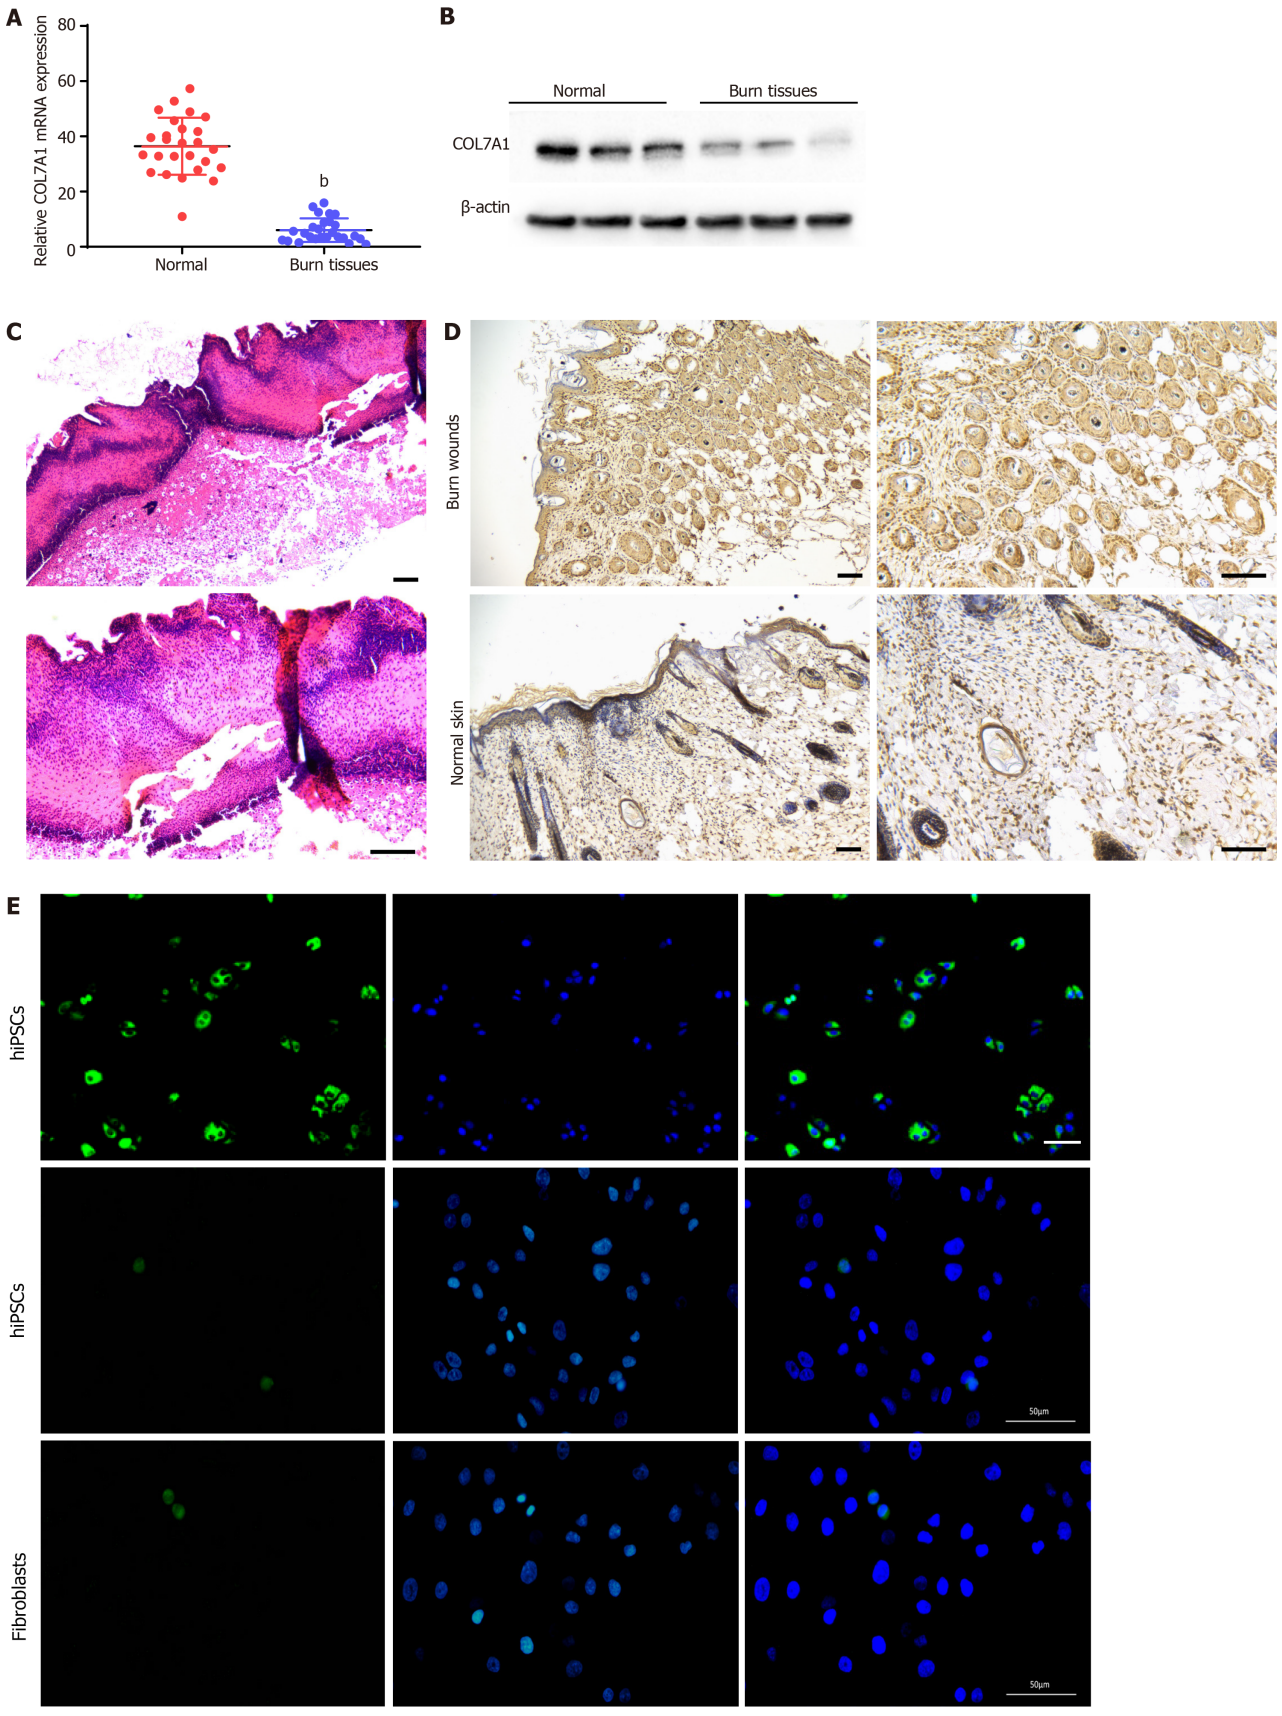
that inflammatory cells had clearly infiltrated the skin, the epidermal nuclei were deeply stained and pyknotic, the dermis was severely damaged, and the skin structure had been destroyed. In the hiPSCs-KCs group, the inflammatory cell infiltration reduced, the nucleus staining became pale, the skin structural damage improved, and the re-epithelialization of the wounds on the postoperative day 14 was complete. However, the improvement in skin injury was prevented after *COL7A1* knockdown in hiPSCs-KCs, and the re-epithelialization capacity of the wound was diminished (Figure 4C and

DOI: 10.4252/wjsc.v15.i7.713 **Copyright** ©The Author(s) 2023.

Figure 2 Human induced pluripotent stem cells successfully differentiated into keratinocyte. Retinoic acid (RA) and BMP-4 were used to induce differentiation of hiPSCs into keratinocyte. The images as immunofluorescence staining of keratinocyte marker proteins K14, involucrin and loricrin at 14 d of induced differentiation, scale bar: 25 μm.



D, Supplementary Figure 1). Accordingly, it can be suggested that hiPSCs-KCs transplantation promoted skin burn healing and wound re-epithelialization in mice, which was partially counteracted by *COL7A1* knockdown.

COL7A1 knockdown abolishes the facilitative effect of hiPSCs-KCs on keratinocyte proliferation in mouse burn wounds

We further explored whether the accelerating effect of hiPSCs-KCs on wound healing was associated with hiPSCs-KC proliferation. Immunohistochemical staining was used to evaluate *Ki67* positive cells around the wounds in each group at 14 d after hiPSCs-KCs transplantation. The results demonstrated that the rate of *Ki67* positive cells in burn wound tissues significantly increased after hiPSCs-KCs transplantation, whereas it decreased after *COL7A1* knockdown in hiPSCs-KCs (Figure 5A and B). Furthermore, the results were consistent with cell experiments, and *COL7A1* knockdown significantly inhibited the EdU fluorescence intensity in hiPSCs-KCs (Figure 5C and D). Figure 5E displays the results of double immunofluorescence staining with EdU and the human marker human leukocyte antigen (HLA) to identify the proliferating cell type. Transplantation of hiPSCs-KCs led to a dramatic increase in the number of proliferating cells, and analysis showed that most of the proliferating cells showed overlap with the human marker HLA, suggesting that most of the proliferating cells were hiPSCs-KCs. Additionally, a small number of active proliferating cells that did not coincide with HLA was noted, indicating that these cells were natural mouse cells involved in tissue repair. Therefore, it can be suggested that hiPSCs-KCs proliferates actively after human hiPSCs-KCs transplantation to the burn site in mice skin tissues and plays a major role in tissue repair, while a small number of mouse natural cells are activated and assist in tissue repair.

COL7A1 knockdown abolishes the positive impact of hiPSCs-KCs on keratinocyte migration in mouse burn wounds

We evaluated whether *COL7A1* accelerates wound healing by encouraging hiPSCs-KC migration. At day 14, frozen section results showed green fluorescence expression in the epithelium of skin wound healing in mice transplanted with CFSE-labeled hiPSCs-KCs, while the PBS group showed no fluorescence. This showed that hiPSCs-KCs could migrate into mouse skin wounds and participate in the epithelialization process. *COL7A1* knockdown also decreased green

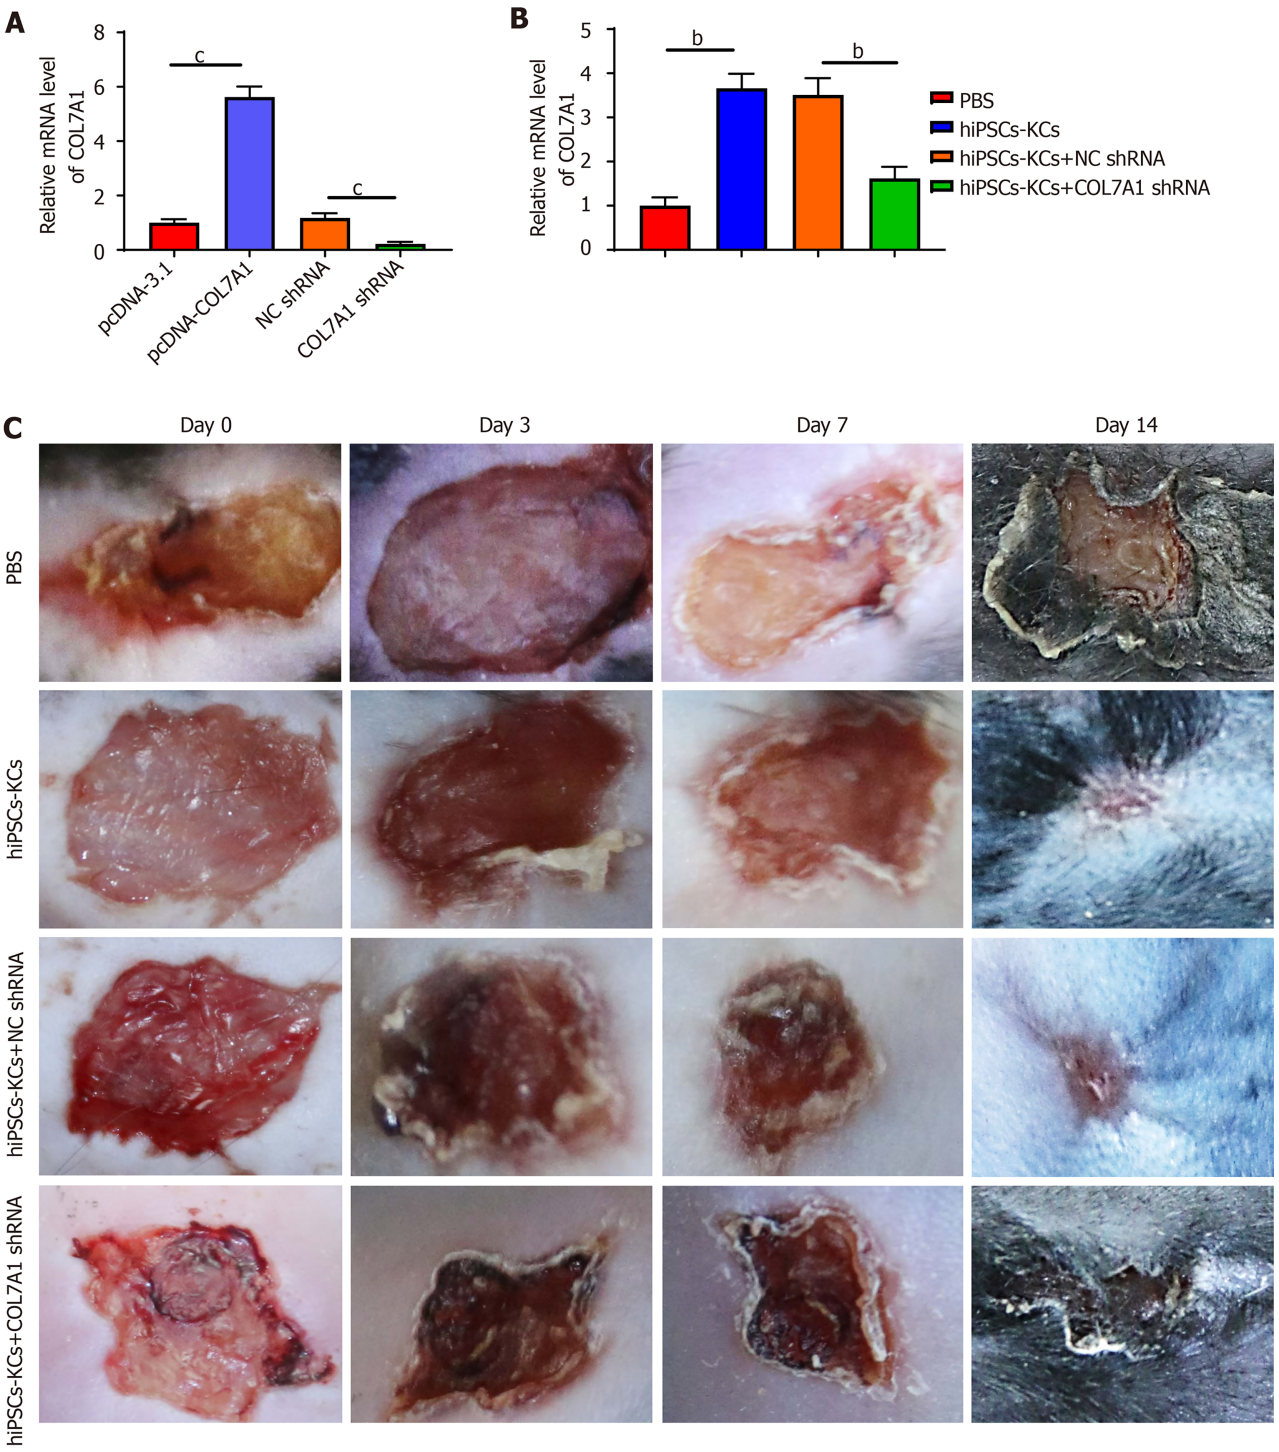
fluorescence expression at wound healing in hiPSCs-KCs, suggesting that it prevented migration toward wounds (Figure 6A). Besides, Transwell assay and injury repair results indicated that *COL7A1* inhibition reduced the migration ability of hiPSCs-KCs, as demonstrated by the decreased cell number in the lower chamber of Transwell and the decreased scratch healing rate (Figure 6B and C). Consequently, hiPSCs-KC transplantation promoted the proliferation and migration of KCs towards the wound site around the mic cutaneous wounds, which in turn accelerated the epithelialization process and wound healing.

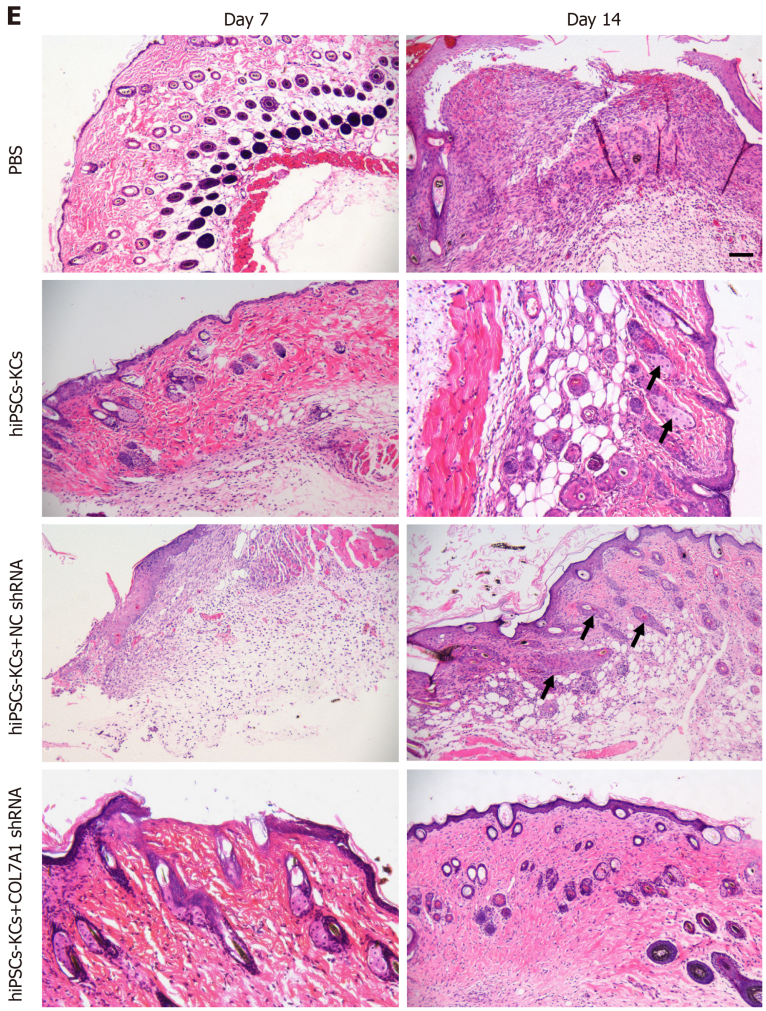
COL7A1 inhibition counteracted the inhibitory effects of hiPSCs-KCs on the inflammatory response to burn injury in mice

The effects of hiPSCs-KCs transplantation on the production of plasma inflammatory mediators in mice were investigated. Enzyme linked immunosorbent assay (ELISA) results showed that the levels of multiple inflammatory mediators, including tumor necrosis factor α (TNF-α), interleukin (IL)-1α, IL-1β, IL-6, IL-10, and IL-12, remarkably decreased in the plasma of mice after hiPSCs-KCs transplantation (Figure 7). Furthermore, the production of plasma inflammatory mediators significantly increased after *COL7A1* knockdown in hiPSCs-KCs.

COL7A1 inhibition reversed the inhibitory effect of hiPSCs-KCs on the NF-κB pathway in mouse burn wounds



The NF-κB inflammasome pathway is a major player in the wound inflammatory response. Upon damage by stimuli, IκB α is degraded by phosphorylation, which dissociates NF-κB to form a complex with IκBα and translocate to the nucleus, causing auto activation, therefore activated NF-κB has an important role in mediating inflammatory activity. We examined the effect of *COL7A1* inhibition on NF-κB pathway protein expression after hiPSCs-KCs transplantation. Western blotting results confirmed that the protein level of p-*p65* considerably increased (Figure 8A) and that of IκBα decreased (Figure 8B) in mice wound tissues. In addition, p-*p65* protein expression decreased while IκBα protein expression was upregulated in wound tissues after hiPSCs-KCs transplantation, which was partially counteracted by *COL7A1* knockdown.



DISCUSSION

Burn injury usually refers to heat-induced tissue damage with skin tissue damage as the first manifestation[19]. Skin and mucosal tissues are commonly involved at the site of burn injury, and deep tissues, such as muscle, bone, and internal organs, might also be affected in severe cases[20]. The skin is the largest organ and the first barrier of the human body, which has many important functions such as blocking pathogen invasion, preventing dehydration, regulating body temperature, and providing sensation[21]. Besides, the skin is also an active immune organ, maintaining the homeostasis of relevant intracellular environments for both specific and nonspecific immunity[22,23]. If severe and extensive skin burns occur, the regenerative capacity of the skin can be disrupted, leading various pathological problems. Therefore, timely repair and closure of wounds can effectively prevent these issues, including infections, delay and prevent progressive damage to the underlying organs, prevent scar and contracture, and others.

Wound repair involves many physiological processes, including inflammation, KC migration, proliferation, granulation tissue formation, and matrix remodeling[24]. KCs proliferation is relatively slow in the normal skin basal layer, but rapid in the damaged skin[25]. In addition, they can secrete specific keratins, and various cytokines and signaling molecules, which work together to promote the healing of skin wounds[26]. One of the current therapies for treating skin wounds is cell therapy, which entails the transplantation of KCs at the wound's periphery so that they can proliferate and migrate within the wound as it heals[27].

In theory, hiPSCs can differentiate to various skin cell types. Moreover, they have become the most ideal and abundant seed cell source for skin tissue engineering due to their characteristics, such as simple expansion in vitro and simple gene interference or overexpression. This is because hiPSCs have solved the problems limiting the research and development of other types of stem cells, such as material source, immune rejection, ethics, and others[28]. Recently, researchers have focused on finding effective means to induce the differentiation of pluripotent stem cells into a single KC population. Using the ability of KCs to rapidly attach to collagen IV, Bilousova *et al*[29] induced pluripotent stem cell differentiation in mice with RA and BMP4, and ultimately obtained 80%-90% *K14* + KCs[29]. Further evidence that RA alone can induce efficient differentiation of hiPSCs into *K14*+/*p63*+ KCs was published in 2013 by Selekman *et al*[30]. This not only widened the use of KCs in tissue engineering, but also demonstrated the promise of hiPSCs for use in skin regeneration and repair[30]. Moreover, researchers found that miR-762-mediated promotion of keratinocyte and endothelial cell migration by exosomes from hiPSCs-KCs aided in the healing of deep second-degree burn wounds in mice[31]. In the current investigation, we utilized RA and BMP-4 to induce hiPSCs differentiation into KCs, which has been demonstrated by immunofluorescence. Subsequent injection of hiPSCs-KCs around the mice skin wounds was associated with significant improvement in skin burn wound healing rate and re-epithelialization in mice, which may be attributed to the ability of hiPSCs-KCs to promote the proliferation and migration of KCs around the wounds.

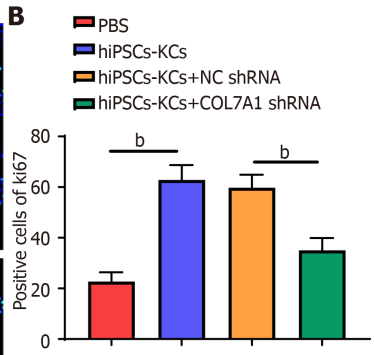

Figure 4 *COL7A1* inhibition abolished the promoting effects of human induced pluripotent stem cells derived keratinocytes on burn healing and re epithelialization in mice. A: RT-qPCR detection of the *COL7A1* mRNA levels in human induced pluripotent stem cells derived keratinocytes (hiPSCs-KCs) after transfection of pcDNA- *COL7A1* or *COL7A1* shRNA; B: RT-qPCR detection of the *COL7A1* mRNA levels in burned skin of mice after transplantation of hiPSCs-KCs or *COL7A1* knock-downed hiPSCs-KCs; C: At 3, 7, 14 d after hiPSCs-KCs transplantation, the healing of burn wounds in mice was recorded by taking photographs with a digital camera; D: Statistical analysis of relative size of burn wounds in each group of mice; E: Hematoxylin-eosin staining was performed after burn tissues were paraffin sectioned at 7 and 14 d after hiPSCs-KCs transplantation, and then wound healing as well as re-epithelialization were observed by histological sections in each group, scale bar: 200 μm; F: Re-epithelialization ratio of the burned window in mice of each group. Data: Mean ± SEM. $^{a}P < 0.05$, $^{b}P < 0.01$, $^{c}P < 0.001$. $n = 10$. NS: Not significant; PBS: Phosphate buffered saline; hiPSCs: Human induced pluripotent stem cells; KCs: Keratinocytes.

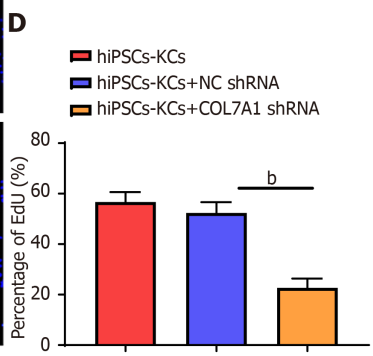
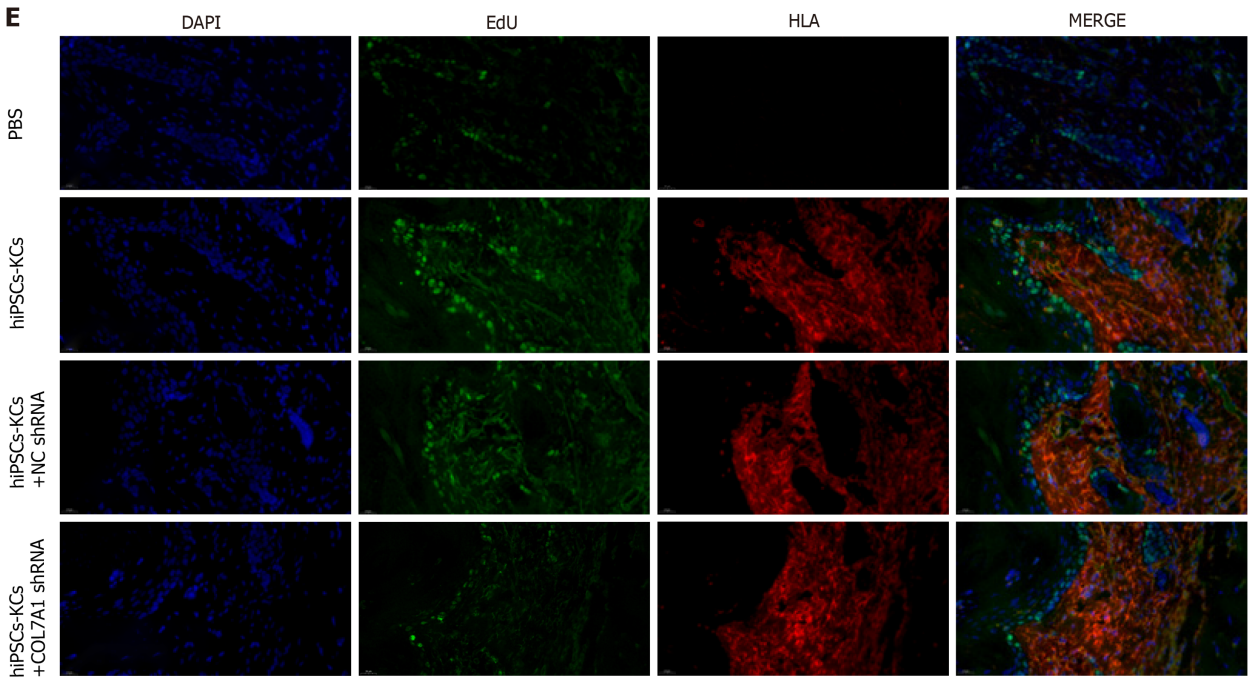


Through interactions with extracellular matrix (ECM) proteins like type IV collagen[32], the type VII collagen fibril (*COL7A1*), which is composed of three identical collagen chains, acts as an anchoring fibril between the outer epithelium and the underlying matrix to promote clustering and adhesion of the epithelial basement membrane. The skin, endometrium, and prostate are the most common normal human tissue types in which *COL7A1* is expressed[33]. KCs have been shown to have high levels of *COL7A1*[34]. By retroviral transduction, Pourreyron *et al*[35] increased KC adhesion, migration, and invasion in patients with recessive dystrophic epidermolysis bullosa (RDEB) by introducing type VII collagen into KCs. Mutations in the *COL7A1* gene lead to a lack of type VII collagen, which leads to RDEB. In addition, *COL7A1* was found to be an important factor in the physiological healing of wounds in humans and mice, which could aid in the development of therapeutic strategies for RDEB and other chronic wounds[36]. However, the function of *COL7A1* in the recovery from burns is not known currently. In the current investigtion, screening the GEO database revealed that *COL7A1* was highly expressed in hiPSCs-KCs, whereas it was poorly expressed in burn wounds. Besides, hiPSCs-KCs transplantation promoted cutaneous burn healing and wound re-epithelialization in mice, which was partially counteracted by *COL7A1* knockdown. Moreover, *COL7A1* positively contributes to the migratory ability of KCs. Subsequently, we also found that *COL7A1* knockdown partially abolished the promotion of KC migration towards the epithelium in wound healing by hiPSCs-KCs transplantation. According to the above findings, *COL7A1* is found mostly in KCs and promotes burn wound healing by enhancing KC migration.



Studies have shown that direct burn injury to the skin mucosa disrupts the important barrier against the outside environment and tissue organ system function, breaks the relative balance between the body and the outside environment, and causes various degrees of systemic inflammatory responses[37]. A variety of cellular immune (macrophages, neutrophils, endothelial cells, *etc*.) and immune molecules mediate tissue cellular immune defense

functions to collectively clear the source of infection, promoting wound repair and healing[38]. After burn injury, the levels of TNF-α, IL-1α, IL-1β, IL-6, IL-10, and IL-12 change significantly[39]. This has been indicated in this investigation as the ELISA results on wound tissues showed that the levels of multiple inflammatory mediators, including TNF-α, IL-1α, IL-1β, IL-6, IL-10 and IL-12 significantly decreased in the plasma of mice after hiPSCs-KCs transplantation, which were furtherly reversed by *COL7A1* knockdown in hiPSCs-KCs. Accordingly, it can be suggested that *COL7A1* might accelerate wound epithelialization by inhibiting wound inflammatory response and promoting KC migration and proliferation. However, the molecular mechanism is still unknown.

NF-κB is one of the major regulatory factors in the pathways related to inflammatory mediators regulation[40,41]. Recently, more and more attention has been paid to the role of NF-κB in infections, autoimmune diseases, tumors, and other conditions. For instance, Wang *et al*[42] discovered that foamy macrophages may inhibit fibroblasts functions and accelerate wound healing by inhibiting the activation of NF-κB signaling pathway in tuberculous wounds. Moreover, in a study on mouse back burn skin tissues, Jiang *et al*[43] found that MDL-800, a highly efficient and selective *SIRT6* activator, significantly reduced the expression levels of proinflammatory factors TNF-α and IL-6 by inhibiting the NF-κB pathway, thereby demonstrating anti-inflammatory and pro-healing effects. It has also been shown by Chen *et al*[44] that CFTR promotes skin wound healing by inhibiting the NF-κB inflammatory response, decreasing KC proliferation, and encouraging its differentiation. Normally, NF-κB exists in a "silent" state from which it can be triggered by proinflammatory factors. When activated, it promotes the production of additional factors—including proinflammatory factors, adhesion factors, chemokines, and others—that can either prolong the acute phase of an inflammatory response or cause it to transition into chronic inflammation[45]. These findings indicate the importance of NF-κB in wound healing. Additionally, it has been demonstrated that when the NF-κB pathway is activated leading to the phosphorylation and degradation of IκBα proteins, *p65* is translocated from the cytosol to the nucleus to further regulate downstream inflammatory cytokine signals[46]. This is consistent with the findings of our investigation. NF-κB expression in burn wounds of mice was detected by Western blotting, and the results indicated that the protein level of p-*p65* strikingly increased and that of IκBα decreased in the wound tissues of the included mice. In addition, after hiPSCs-KCs transplantation, p-*p65* protein expression remarkably decreased in the wound tissues, while IκBα protein expression was upregulated, which was partially counteracted by *COL7A1* knockdown.

The above results indicate that *COL7A1* plays a role in accelerating wound healing by inhibiting the inflammatory response and promoting keratinocyte proliferation and migration in deep second-degree burn wounds. Therefore, it can be suggested that *COL7A1* is vital for encouraging wound healing and providing a new target for deep second-degree

DOI: 10.4252/wjsc.v15.i7.713 **Copyright** ©The Author(s) 2023.

Figure 8 *COL7A1* inhibition reversed the inhibitory effect of human induced pluripotent stem cells derived keratinocytes on the NF-κB pathway in mouse burn wounds. A: The protein level of p-p65 in mouse wound tissues treated with hiPSCs-KCs, with or without *COL7A1* shRNA transfection, was employed by Western blotting; B: The protein level of IκBα in mouse wound tissues treated with hiPSCs-KCs, with or without *COL7A1* shRNA transfection, was employed by Western blotting. $^{b}P < 0.01$. $n = 10$. PBS: Phosphate buffered saline; hiPSCs: Human induced pluripotent stem cells; KCs: Keratinocytes.

burn wound treatment. However, there are a few limitations to our findings. For instance, we used FTY720 injection alone to suppress immune rejection in mice, based on previous experiments in the literature. FTY720 is a newly developed immunosuppressant that selectively reduces peripheral circulating lymphocytes and significantly prolongs the survival of transplanted organs in experimental animals. Ryu *et al*[47] reported an increase in the number of T lymphocytes in mesenteric lymph nodes and a reduction within the spleen among FTY720-treated mice. Besides, FTY720 has been shown to promote local wound healing *via* an immunomodulatory mechanism after being delivered using a biomaterial[48]. We hypothesized that local delivery of FTY720 can promote local wound healing through immunomodulatory mechanisms, which may also prevent delayed tissue repair after injury. Unfortunately, a control group without FTY720 injection was not considered in this investigation, so it was not possible to determine whether FTY720 could have an impact over tissue repair. Nevertheless, according to our findings, no immune rejection events were observed in our included mice, and the wound healing rate was within the normal range. Besides, future studies from our team will concentrate on modifying the experiment to account for FTY720's impact on tissue repair delay.

CONCLUSION

The above results indicate that *COL7A1* can play a role in accelerating wound healing by inhibiting the inflammatory response and promoting KC proliferation and migration in deep second degree burn wounds, revealing the mechanism of *COL7A1* for encouraging wound healing and providing a new target for deep second degree burn wound treatment.

ARTICLE HIGHLIGHTS

Research background

Based on the extensive skin integrity defects caused by burns, scalds, vasculopathy triggered skin ulcers, pressure ulcers, diabetic ulcerated feet, and so on, which are caused by the action of internal and external factors, the wounds develop pathological inflammatory reactions, which cannot achieve the healing through normal repair procedures, and then lead to slow or non-healing, causing severe disability or death to the patient, and at the same time, bringing a heavy economic burden to the patient's family. Studies have shown that impaired keratinocyte (KC) migration causes non healing wounds and is an important cause of chronic wound formation, whereas inhibition of their proliferation and differentiation functions does not result in the formation of non-healing wounds. Deriving the replacement cells from human-induced pluripotent stem cells (hiPSCs) allows for sufficient scale up and by using hiPSCs as the choice of human pluripotent stem cells (hPSC) will ensure immunocompatibility.

Research motivation

The specific mechanism of hiPSCs involvement in burn repair has not been fully revealed.

Research objectives

The current study showed that hiPSCs can effectively differentiate into KCs under the effect of inducers, but its effect on skin burn healing has not been reported. Therefore, this study was intended to observe the effects of hiPSCs-derived KCs transplantation on skin burn healing in mice, and to preliminarily reveal the related mechanisms by which it exerts its effects.

Research methods

In this study, we used the cell induced differentiation technique of hiPSCs to successfully differentiate hiPSCs cells into KCs (hiPSCs-KCs) using inducing factors. Subsequently, a murine skin-deep degree II burn model was constructed, and KCs induced to differentiate successfully were injected around the mouse skin wound, to deeply investigate the effect of transplantation of KCs induced to differentiate formed on the healing of murine skin wounds. In addition, a bioinformatics approach was taken to further explore the possible mechanism of hiPSCs-KCs transplantation involvement in wound healing.

Research results

The above results indicate that COL7A1 plays a role in accelerating wound healing by inhibiting the inflammatory response and promoting KC proliferation and migration in deep second-degree burn wounds. Therefore, it can be suggested that COL7A1 is vital for encouraging wound healing and providing a new target for deep second-degree burn wound treatment. However, there are a few limitations to our findings. For instance, we used FTY720 injection alone to suppress immune rejection in mice, based on previous experiments in the literature. FTY720 is a newly developed immunosuppressant that selectively reduces peripheral circulating lymphocytes and significantly prolongs the survival of transplanted organs in experimental animals. A study reported an increase in the number of T lymphocytes in mesenteric lymph nodes and a reduction within the spleen among FTY720-treated mice. Besides, FTY720 has been shown to promote local wound healing *via* an immunomodulatory mechanism after being delivered using a biomaterial. We hypothesized that local delivery of FTY720 can promote local wound healing through immunomodulatory mechanisms, which may also prevent delayed tissue repair after injury. Unfortunately, a control group without FTY720 injection was not considered in this investigation, so it was not possible to determine whether FTY720 could have an impact over tissue repair. Nevertheless, according to our findings, no immune rejection events were observed in our included mice, and the wound healing rate was within the normal range. Besides, future studies from our team will concentrate on modifying the experiment to account for FTY720's impact on tissue repair delay.

Research conclusions

The above results indicate that COL7A1 can play a role in accelerating wound healing by inhibiting the inflammatory response and promoting KC proliferation and migration in deep second degree burn wounds, revealing the mechanism of COL7A1 for encouraging wound healing and providing a new target for deep second degree burn wound treatment.

Research perspectives

This study will focus on the aspects of autologous transplantation of human iPSCs in the future.

Abstract

BACKGROUND

Haploid embryonic stem cells (haESCs) have been established in many species. Differentiated haploid cell line types in mammals are lacking due to spontaneous diploidization during differentiation that compromises lineage-specific screens.

AIM

To derive human haploid neural stem cells (haNSCs) to carry out lineage-specific screens.

METHODS

Human haNSCs were differentiated from human extended haESCs with the help of Y27632 (ROCK signaling pathway inhibitor) and a series of cytokines to reduce diploidization. Neuronal differentiation of haNSCs was performed to examine their neural differentiation potency. Global gene expression analysis was conducted to compare haNSCs with diploid NSCs and haESCs. Fluorescence activated cell sorting was performed to assess the diploidization rate of extended haESCs and haNSCs. Genetic manipulation and screening were utilized to evaluate the significance of human haNSCs as genetic screening tools.

RESULTS

Human haESCs in extended pluripotent culture medium showed more compact and smaller colonies, a higher efficiency in neural differentiation, a higher cell survival ratio and higher stability in haploidy maintenance. These characteristics effectively facilitated the derivation of human haNSCs. These human haNSCs can

be generated by differentiation and maintain haploidy and multipotency to neurons and glia in the long term *in vitro*. After PiggyBac transfection, there were multiple insertion sites in the human haNSCs' genome, and the insertion sites were evenly spread across all chromosomes. In addition, after the cells were treated with manganese, we were able to generate a list of manganese-induced toxicity genes, demonstrating their utility as genetic screening tools.

CONCLUSION

This is the first report of a generated human haploid somatic cell line with a complete genome, proliferative ability and neural differentiation potential that provides cell resources for recessive inheritance and drug targeted screening.

Key Words: Haploid; Neural stem cells; Extended pluripotency; Genetic screening; Cell therapy

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Human embryonic stem cells are widely used in preclinical and genetic screening studies. Haploid cells are ideal tools to perform genetic screening. To date, no human haploid somatic cell lines have been successfully created. We converted human haploid embryonic stem cells to an extended pluripotency state by optimizing the culture medium. The derived haploid neural stem cells can proliferate as a haploid genome and maintain multipotency to generate functional neurons and glia. The haploid neural stem cells can also be easily used for gene editing to generate numerous homozygous mutations for lineage-specific screens.

INTRODUCTION

Haploid cells have one set of chromosomes that can be genetically analyzed. Compared to diploid cells, haploid cells are more prone to homozygous mutation. This characteristic is important for gene screening[1-5], especially for recessive gene screening, and the study of cellular and chromosomal fusion[6-8]. Although haploid genetics has been mostly restricted to unicellular organisms, recent reports of haploid embryonic stem cells (ESCs) have extended the research into animal species, including mice[9-13], rats[14] and monkeys[15]. More excitingly, haploid ESCs (haESCs) have been successfully derived from human[16-18] blastocysts. The success in producing human haESCs raises a particularly challenging question of whether these cells can be further differentiated while maintaining haploidy. Medaka (fish) haESCs can maintain haploidy without the need for cell sorting[19], whereas mammalian haESCs tend to diploidize in cell culture, which limits their potential for use in genetic screening. Almost all differentiated cells derived from mammalian haESCs are diploid cells.

Neural stem cells (NSCs) are somatic stem cells that can differentiate into both neuronal and glial progeny. Although we can obtain haploid neural precursors and neurons by differentiating mouse and monkey haESCs[20,21], the pathogenesis of many diseases differs between humans and animals. For instance, the α7-nicotinic acetylcholine receptor is widely studied as a target for treating the cognitive symptoms of Alzheimer's disease, attention deficit–hyperactivity disorder and schizophrenia[22]. However, the distribution of this receptor differs across species[23]. In general, there are many differences in gene expression among species[24].

This issue raises the question of how long human haESCs can maintain pluripotency in the stable haploid state. It also remains undetermined whether neural differentiation can be stably induced in haploid human cells, which would be useful to help clarify the specific pathogenesis of human neurological diseases. Previous studies have shown that haploid cells have poor differentiation potency. Yang *et al*[25] and Liu *et al*[26] indicated that by introducing a variety of small molecule compounds into the stem cell culture medium, traditional stem cells can be transformed into extended pluripotent stem (EPS) cells with higher pluripotency. Since their establishment, EPS cells have been widely used in different fields of research[27-32]. Recently, Zhang *et al*[33] demonstrated that inhibition of apoptosis reduced the diploidization of mouse haESCs during differentiation.

In this study, we introduced a small-molecule inhibitor during haESC culture and differentiation to restrain diploidization and enhance differential multipotency. Protocols were established for the derivation of human haploid neural stem cells (haNSCs) from human haESCs. These cells displayed neural differentiation potential *in vitro*. In addition, haNSCs can be maintained as predominantly haploid cells for more than 90 d without fluorescence activated cell sorting (FACS) enrichment. More importantly, we provided evidence that human haNSCs can be easily manipulated. These haNSCs are functional haploid adult stem cells and can be used for high-throughput genetic screening, providing a valuable resource for neural recessive gene studies.

MATERIALS AND METHODS

Reagents and media

The reagents and media used in the experiments were purchased from Life Technologies (Carlsbad, CA, United States) or Stem Cell Technologies, Inc. (Vancouver, Canada), unless otherwise indicated. Mouse embryonic fibroblasts were purchased from the Institute of Biochemistry and Cell Biology Shanghai Institutes for Biological Sciences Chinese Academy of Sciences.

Cell culture

Human haESCs were a kind gift from Dr. Jinsong Li of the State Key Laboratory of Cell Biology, Shanghai Key Laboratory of Molecular Andrology, Center for Excellence in Molecular Cell Science, Shanghai Institute of Biochemistry and Cell Biology, Chinese Academy of Sciences, University of Chinese Academy of Sciences. The haESCs were cultured as previously reported[15,25,34]. Mouse embryonic fibroblasts were treated with 10 μg/mL mitomycin C for 3 h to generate a feeder layer and cultured in 10% fetal bovine serum (FBS) (BI) plus 1% penicillin-streptomycin Dulbecco's modified Eagle medium (DMEM). The ESC medium before optimization contained DMEM/F12 + 20% KnockOut Serum Replacement (Gibco, Billings, MT, United States) + 0.1 mmol/L non-essential amino acids, 100 U/mL penicillin-0.1 mg/mL streptomycin, 0.1 mmol/L 2-mercaptoethanol, 2 mmol/L L-glutamine and 10 ng/mL basic fibroblast growth factor (bFGF). Human EPS cells were cultured in N2B27-LCDM (consisting of hLIF, CHIR99021, (S)-(+)-dimethindene maleate, minocycline hydrochloride) medium under 20% O_2 and 5% CO_2 at 37 °C. Then, 50 mL of N2B27 medium was prepared and included the following: 24 mL of DMEM/F12 (Gibco); 24 mL of Neurobasal (Gibco); 0.25 mL of N2 supplement (Gibco); 0.50 mL of B27 supplement (Gibco); 1% GlutaMAX (Sigma-Aldrich, St Louis, MO, United States); 1% non-essential amino acids (Gibco); 0.1 mmol/L β-mercaptoethanol (Sigma-Aldrich), penicillin-streptomycin (Gibco); and 5% KnockOut Serum Replacement (Gibco). The optimized medium was named N2B27-LCDM. Y-27632 (2 mmol/L; Peprotech, Rocky Hill, NJ, United States) was included in some cases. ESCs were passaged routinely using 1 mg/mL type IV collagenase (Sigma-Aldrich) (traditional culture ESCs) and 0.05 trypsin (optimized culture ESCs) every 3-4 d. The haNSCs were passaged every 4 d with 0.05% trypsin. The haNSC medium contained D/F12 + 1% N2 supplement + 20 ng/mL bFGF (Peprotech) + 20 ng/mL epidermal growth factor (EGF) (Peprotech). All cells were cultured in a 5% CO_2 incubator at 37 °C.

Neural differentiation of EhPGES1

Well-conditioned EhPGES1 were selected for differentiation, as the state of haESCs plays a decisive role in neural differentiation. EhPGES1 were digested to single cells with 1 mg/mL 0.05% trypsin. Then, these single cells were placed into gelatin-coated dishes for 30 min to allow the feeder cells to attach to the bottom of the dish. Single cells were suspended in embryoid body (EB) medium in a suspension petri dish for 4 d to form EBs. During the 1st d of differentiation, we added 10 μM ROCKi (Peprotech) to the EB medium. On day 4, the EB medium was replaced by neural induction medium (NIM) for another 2 d. On day 6, we transferred the EB from the suspension petri dishes to laminin-coated dishes and incubated overnight. The next day, EB paste was added to the bottom of the dish. We changed the NIM every other day.

The growth of flat cells and an increasing number of slender small cells were observed in the center of the implanted EB. After approximately 10 d in NIM, the central, small, lanky cells generated rosettes. Clusters were picked and expanded as described by Zhang *et al*[37] with slight optimizations[35-37]. In short, rosette clusters were attached to laminin-coated petri dishes in N2 medium containing human bFGF and EGF. Then, haNSCs were derived from haploid rosette clusters with continuous culture on polyornithine and laminin-coated dishes in N2 medium with 20 ng/mL bFGF and 20 ng/mL EGF for 3 mo. The differentiation efficiency from haploid rosette clusters to haNSCs under this condition was nearly 100% according to cell morphology evaluation.

Neuronal differentiation of haNSCs

haNSCs were examined for their neural differentiation potency. For differentiation into neurons, D/F12 medium was added as basal medium and supplemented with N2, B27 (Gibco), BDNF (20 ng/mL), glial-derived neurotrophic factor (20 ng/mL), dibutyryl-cAMP (1 mmol/L) and ascorbic acid (200 nM). Then, the haNSCs were replated on laminin-coated petri dishes at a density of 1 × 10^4 cells/cm^2. The addition of 1% FBS (BI) to the primary medium was used to differentiate haNSCs into astrocytes and oligodendrocytes[36].

DNA content analysis of cells

Human ESCs and NSCs were dissociated into single cells by treatment with 0.05% trypsin/EDTA at 37 °C for approximately 3 min. Cells were fixed in 75% ethyl alcohol at 4 °C for at least 12 h and stained with propidium iodide plus RNase A. Flow cytometry data were recorded by a BD Aria II system (BD Biosciences, Franklin Lakes, NJ, United States).

FACS

For sorting of haploid cells, haESCs and haNSCs were disaggregated by 0.05% trypsin/EDTA, washed with Dulbecco's phosphate-buffered saline (PBS) and incubated with 4 μg/mL Hoechst 33342 in a 37 °C water bath for approximately 15 min. Subsequently, the haploid cells were collected using a BD FACSAria III (BD Biosciences) for further culture. ROCKi (10 μM Y27632) was added before and after sorting.

RNA isolation and real-time PCR

Total RNA from all cells was extracted with TRIzol reagent (Invitrogen, Waltham, MA, United States) and treated with DNase I (Promega, Madison, WI, United States). cDNA was obtained by first-strand synthesis using 2 μg of RNA and the ReverTra Ace system for reverse transcriptase-PCR (Toyobo, Osaka, Japan). Real-time PCR was performed as described in our previous report[21]. All reactions were repeated three times. Data are presented as the mean ± SD.

Immunocytochemistry

Immunostaining and alkaline phosphatase staining of ESCs and NSCs were performed as described previously[38]. In short, cells were fixed in formaldehyde, rinsed with PBS and permeabilized with Triton X-100 (Sigma-Aldrich). Then, the cells were incubated with blocking buffer, rinsed with PBS and incubated with primary and secondary antibodies (Abcam, Cambridge, and United Kingdom). After being rinsed with PBS, the cells were examined under a fluorescence microscope. The data represent three independent experiments.

Karyotype (G-banding) analysis

Cells were incubated with 0.2 μg/mL colchicine for 1 h (ESCs) or 2 h (NSCs). Then, the cells were disaggregated with 0.05% trypsin/EDTA and resuspended in 5 mL of culture medium. The cells were then harvested from the 5 mL suspension in an automatic cell harvesting apparatus (Chromprep II; Sinochrome/Cytogenetics, Shanghai, China) according to the set procedure. Briefly, 4.5 mL of preheated potassium chloride (0.075 mmol/L) was added at 37 °C for 30 min. Hypotonic solution-treated cells were fixed in methanol:acetic acid (3:1 volume:volume) for 20 min at 37 °C, and the fixation step was repeated three times. Then, they were dropped onto precleaned charged slides by an automatic production machine (Chromprep AS; Sinochrome/Cytogenetics). After air drying, the cells were stained with Metaphase Auto-Stainer (Chromprep G; Sinochrome/Cytogenetics). More than 20 metaphase spread G-bands were analyzed by Ikaros karyotyping software with the MetaClient dashboard (MetaSystems, Altlussheim, Germany).

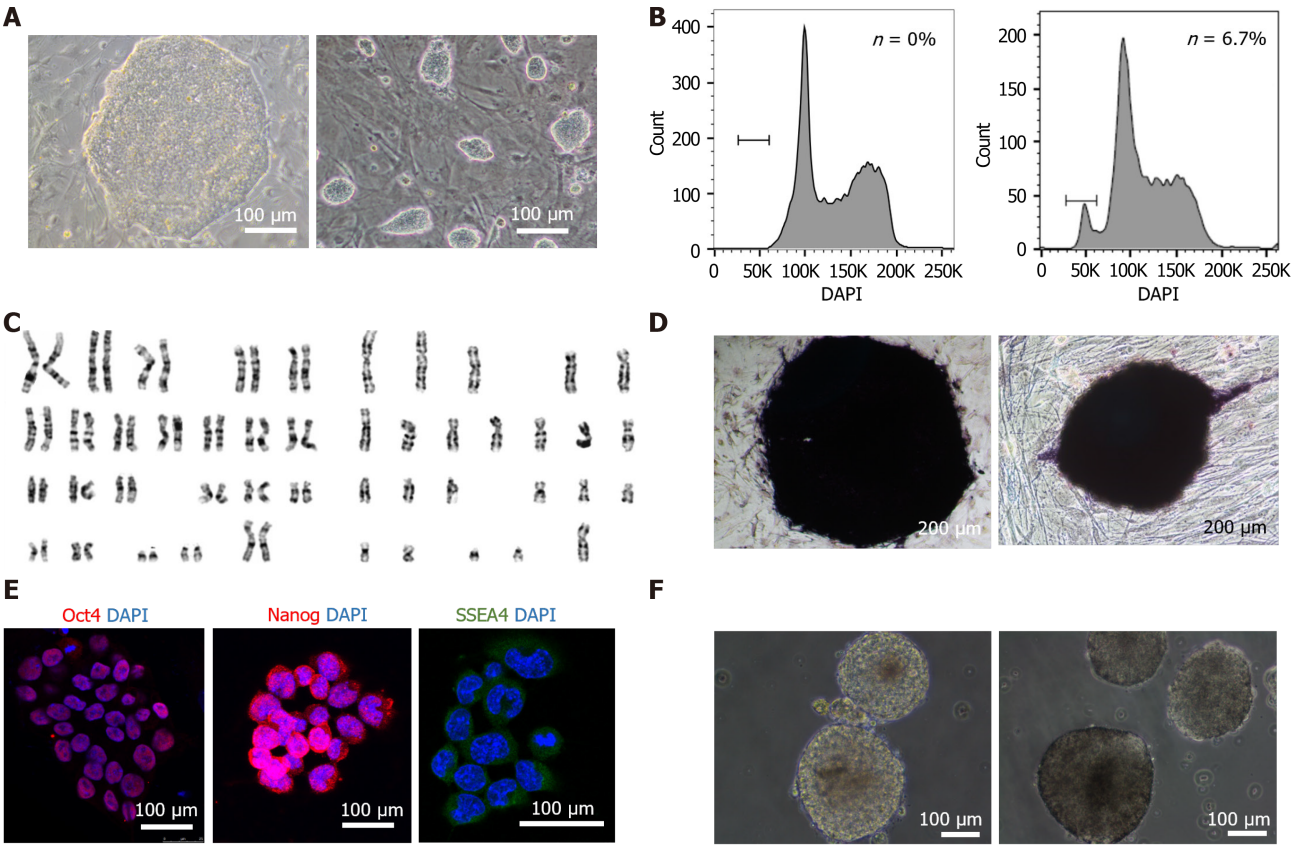
Growth curve detection

The Cell Counting Kit (CCK)-8 assays (Beyotime, Jiangsu Province, China) were performed as previously reported[15]. In short, cells were plated onto 96-well plates at a density of 1000 cells per well. Ten microliters of CCK-8 medium were added to each well on days 1, 2, 3, 4, and 5. The cells were incubated in a 37 °C 5% CO_2 incubator for 1-4 h. Optical density values of each well at 450 nm wavelength were detected by an enzyme labeling instrument.

Global gene expression analysis

The RNA-seq data were sequenced by Novogene (Beijing, China). Total RNA was extracted using TRIzol Reagent (Invitrogen). Following the manufacturer's instructions, raw data were processed with the FASTX toolkit (http://hannonlab.cshl.edu/fastx_toolkit/commandline.html) to remove noise and adaptors. The R heatmap function was used to perform hierarchical clustering.

PiggyBac transfection and splinkerette PCR



PiggyBac [PB Dual promoter PB513B-1; Applied Biosystems Inc (ABI), Waltham, MA, United States] and PBase (Super PiggyBac Transposase PB200PA-1; ABI) were cotransfected into cells with Lipofectamine 3000 (Invitrogen). Puromycin (250 μg/mL) was used to culture and screen the transfected cells. To characterize the sites of the PB element insertion, genomic DNA was digested with *BstYI* (Thermo Fisher Scientific, Waltham, MA, United States) at 37 °C for 16 h, and the products were self-ligated. Then, with the linked DNA as a template, PCR was performed with the primers PB-RF and PB-RR to detect the previously reported insertion sites. PCR was performed as previously reported[39]. The first round was performed as follows: 98 °C for 75 s; 2 cycles of 98 °C for 20 s and 64 °C for 20 s; 30 cycles of 98 °C for 20 s, 58 °C for 15 s and 72 °C for 2 min; 72 °C for 7 min; and a final hold at 4 °C. The second round was conducted as follows: 98 °C for 75 s; 30 cycles of 98 °C for 20 s, 58 °C for 15 s and 72 °C for 90 s; 72 °C for 7 min; and a final hold at 4 °C. Splinkerette PCR and deep sequencing were also performed to identify the integration sites. All primers used are listed in Supplementary Table 1.

High-throughput sequencing analysis

After sequencing of the PB mutation library, adapters and PB tags were removed from the read data before mapping to the genome using the FASTX toolkit (http://hannonlab.cshl.edu/fastx_toolkit/commandline.html). HaSAPPy (https://github.com/gdiminin/HaSAPPy) was utilized to align the trimmed reads to the genome assembly from UCSC (mm10) (http://genome.ucsc.edu/cgi-bin/hgGateway? db = mm10)[40]. We analyzed the insertions for each gene with GENCODE[41] using the default parameters.

Statistical analysis

Student's *t*-test was used to evaluate the differences in gene expression levels among groups. All statistical analyses were performed using SPSS software 13.0 (SPSS Inc., Chicago, IL, United States) and Image-Pro Plus (Media Cybernetics, Rockville, MD, United States).

RESULTS

Characterization of the pluripotency and haploidy of extended pluripotent human haESCs

To determine whether traditional and extended pluripotent human haESCs exhibited pluripotency and intact haploid genomes, we compared them (cell line: hPGES1) with diploid human ESCs from zygotes (H9) in different respects. Traditional hPGES1 cells appeared as flat, compact colonies, a standard morphology for primed pluripotent cells (Supplementary Figure 1A) resembling that of diploid ESC H9 (Figure 1A), whereas extended pluripotent hPGES1 cells appeared as domed compact and small colonies, a standard morphology for naïve pluripotent cells resembling that of mouse ESCs (Figure 1A). After FACS of haploid cells, traditional and extended pluripotent hPGES1 cells maintained an acceptable percentage of haploidy for more than 6 wk without further sorting according to DNA content analysis (Figure 1B, Supplementary Figure 1B). We further assessed the chromosome numbers and morphology in traditional and extended pluripotent hPGES1 cells by G-band analysis and found that most cells were haploid (23 chromosomes) cells. A few cells were found to be haploid and aneuploid (Figure 1C, Supplementary Figure 1C and D). Next, we assessed the pluripotency of traditional and extended pluripotent hPGES1 cells from different aspects *in vitro*. We observed (by immunostaining) strong alkaline phosphatase activity (Figure 1D, Supplementary Figure 1D) and strong expression of pluripotent markers, including Oct4, Nanog, Sox2 and SSEA-4 (Figure 1E, Supplementary Figure 1E). After withdrawal of bFGF and feeder cells, traditional and extended pluripotent hPGES1 cells formed typical EBs, guaranteeing their utility for subsequent differentiation experiments (Figure 1F, Supplementary Figure 1F).

Human haNSCs were derived from extended pluripotent haESCs

Suspension aggregation and posterior adherent culture are the most common methods for neural differentiation of human ESCs[37,42]. We thus developed a scheme to derive haNSCs based on a previously reported protocol with slight modifications (Figure 2A). During the first 5 d, well-formed human haESCs (Supplementary Figure 2A) were suspended and aggregated in EBs. EBs with better morphology (Supplementary Figure 2B) were cultured in suspension in NIM for 2

d. Neuroectodermal structures were observed in the middle part of the EB on day 7 (Figure 2B). All aggregates were seeded in laminin-coated dishes for adherence-induced culture. Aggregates adhering to laminin began to form primitive neuroepithelium after 4-5 d (Figure 2C). After approximately 15 d of differentiation, a large number of neuroepithelial cells had accumulated, and rosette structures were formed in the centers of the adherent cells (Figure 2D). The rosettes were manually selected and expanded in NSC medium for 14 d (Supplementary Figure 2C) before FACS. Haploid haNSCs in G0/G1 phase were predominant at the first round of sorting (Figure 2E). Interestingly, purified haNSCs could be amplified in NSC medium for more than 10 generations without sorting, and the proportion of haploid cells was still very high. haNSCs retained the standard NSC morphology (microscopic and bipolar) before and after sorting (Supplementary Figure 2D, Figure 2F) and were able to aggregate into typical neurosphere structures in suspension in petri dishes (Figure 2G). We also examined the chromosomes of haNSCs by G-banding analysis and found that haNSCs maintained intact haploid genomes without any aneuploid mutations (Figure 2H, Supplementary Figure 2E). We compared the cell growth rates of haNSCs and diploid NSCs using the CCK-8 method. The results showed no significant difference between the two cell types (Supplementary Figure 2F).

Derived haNSCs showed multipotency for neural subtypes in vitro

NSCs are proliferative adult stem cells that have the potential to differentiate into functional neurons or neuroglial cells, making them useful resources for cell replacement therapy and screening research[43]. To determine whether the haNSCs that we had generated possessed neural lineage properties, we assessed NSC-specific markers by immunostaining. The

results showed that haNSCs expressed NSC markers (including Nestin, Sox1, and Pax6) in both monolayer cells (Figure 3A) and neural spheres (Figure 3B), similar to that of the diploid NSCs used as a control (Supplementary Figure 3A). Additionally, the gene expression level of the haNSCs was very similar to that of the diploid NSCs (Supplementary Figure 3B). Furthermore, there was a significant difference in gene expression between haESCs and human fibroblasts (Figure 3C). According to real-time PCR analysis, haNSCs expressed only NSC marker genes (Nestin, *PAX6* and *SOX1*) and resembled diploid NSCs (Figure 3D).

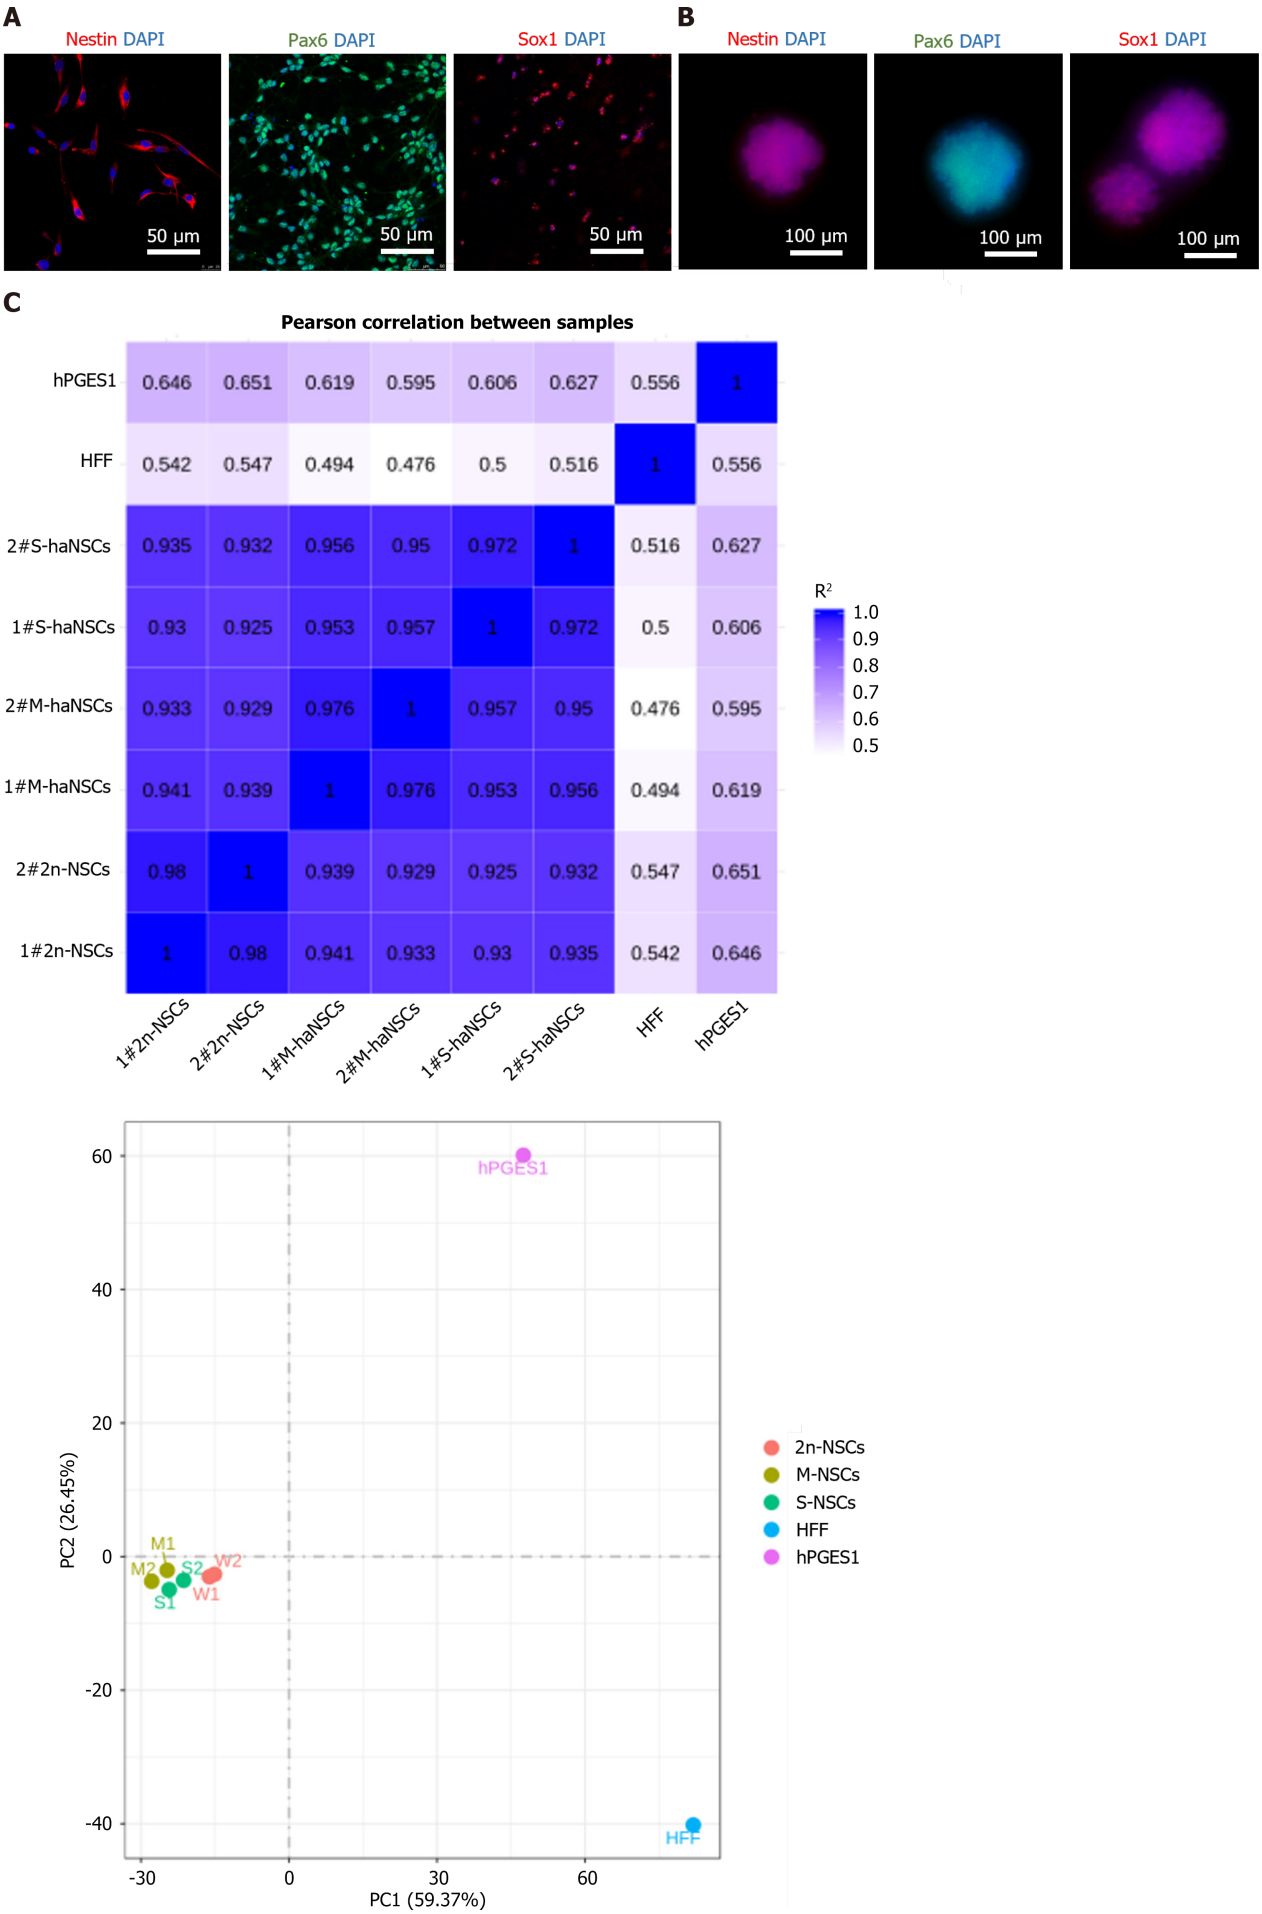
Next, to evaluate the differentiation potential of haNSCs, we induced them to differentiate into astrocytes, oligodendrocytes and neurons by applying specific growth factors for approximately 3 wk and then sorted out the haploid cells by FACS (Figure 3E). Immunostaining results demonstrated that astrocytes (GFAP) and oligodendrocytes (O4) could be obtained from haNSCs and maintained as haploid cells (Figure 3F). In a parallel experiment, diverse neurons (Tuj1- and Map2-positive) were also generated from haNSCs (Figure 3G). To evaluate the purity of the haNSCs, we randomly selected haNSC spheres for differentiation induction (Supplementary Table 2). The results showed that each haNSC sphere could differentiate into neurons, astrocytes and oligodendrocytes. Therefore, the haNSCs were deemed to have good homogeneity.

Better pluripotency yielded a higher efficiency of neural differentiation in human haESCs

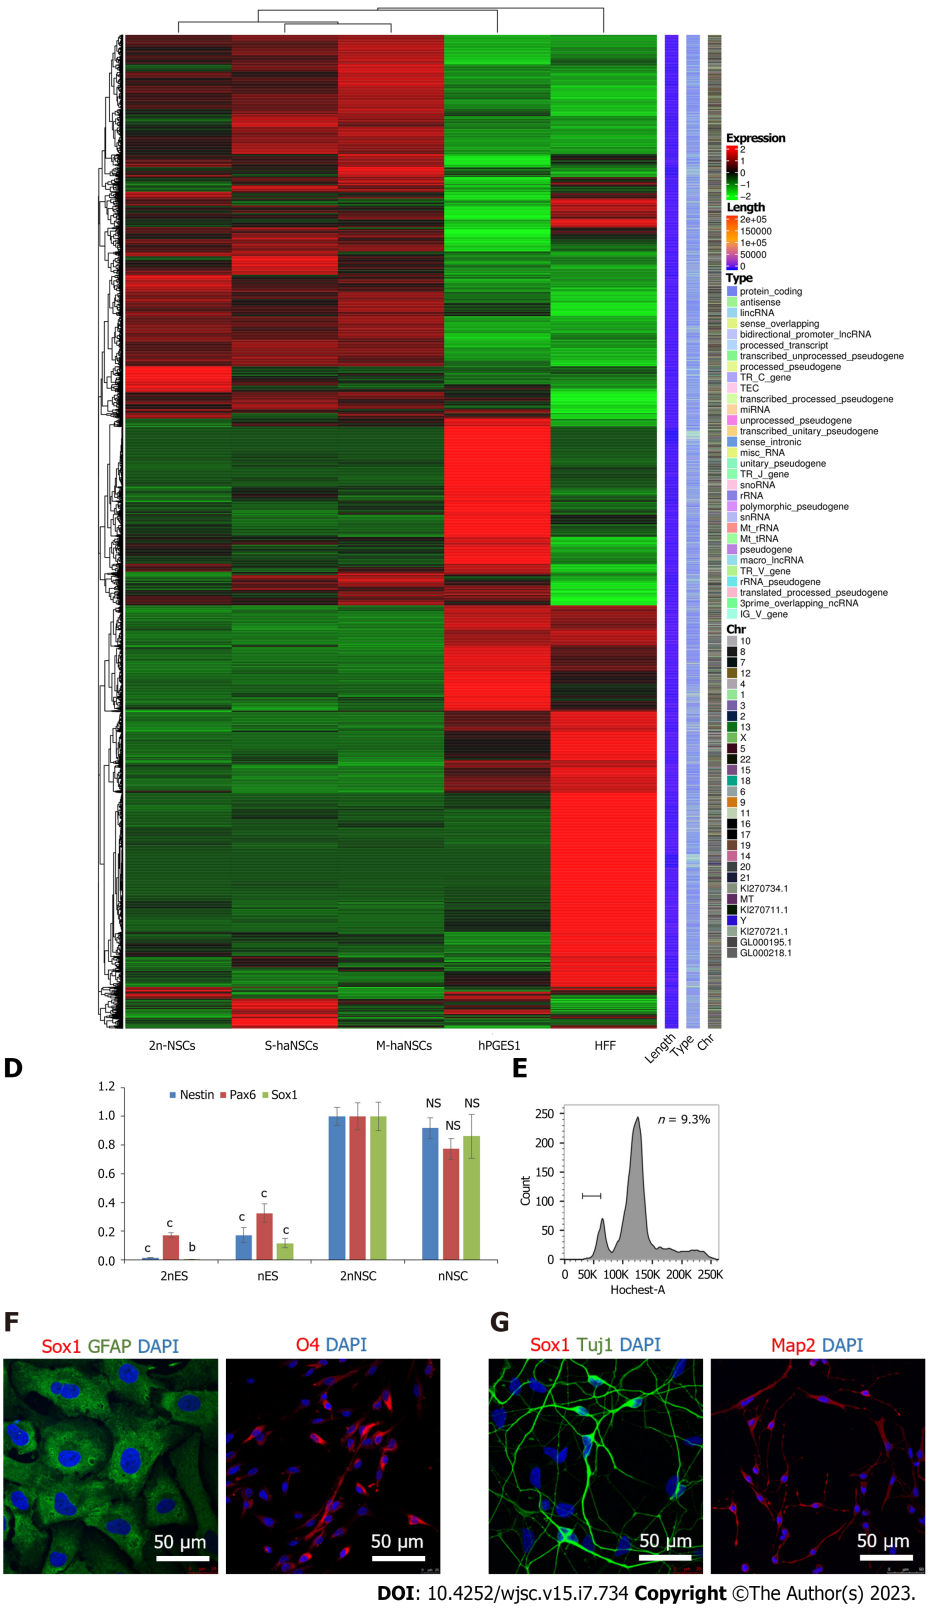
Recently, primate ESCs, including human ESCs, were converted to a better state by introducing small molecule compounds[25,44] or regulating transcription[45], with morphology and molecular levels similar to those of mouse ESCs. Whether extended haESCs in primate species show better pluripotency than traditional primed state ESCs has not been clarified. Herein, we optimized the culture system of human haESCs on the basis of previous research[25] with slight improvements (Supplementary Figure 4A). After culture in the optimized extended medium for approximately three passages, dome-shaped human pluripotent stem cell colonies formed, which is a morphological feature characteristic of mouse ESCs (Figure 4A). Optimized hPGES1 could be digested into single cells by 0.05% trypsin-EDTA in the absence of Y27632 (Figure 4B). The purified haESCs were divided into two populations and cultured in traditional and optimized media. FACS analysis showed that the proportion of haploid cells was higher in the optimized medium, indicating that the optimized medium could inhibit diploidy to some extent (Figure 4C, Supplementary Table 3).

To compare the EB formation ability between the optimized extended haESCs and traditional primed haESCs, we suspended approximately 10^6 cells from each group and allowed them to aggregate in untreated dishes. The number of EBs generated from optimized haESCs was more than two-fold that generated from the traditional group (Figure 4D). Moreover, the aggregate-generating neural rosettes from the optimized group were larger and more abundant than those from the traditional group (Figure 4E). When first sorting the haNSCs from optimized and traditional haESCs separately, the number of surviving cells from the optimized group was greater than that from the traditional group, according to the analysis of the side scatter and forward scatter plots (Figure 4F), indicating that haESCs in optimized medium could produce more NSCs with higher survival rates. A similar trend was found in harvested cells; we found that sorted cells from the traditional group had lower survival rates (Supplementary Figure 4B). Therefore, sorted haNSCs from the traditional group were limited in number and survival rate and readily became diploid NSCs. Overall, we generated two haNSC lines from four parallel differentiation lines established from the optimized groups. No haNSC lines were obtained from six parallel differentiation lines established from the traditional groups (Supplementary Figure 4C).

Genetic manipulation and screening in human haNSCs



Next, we studied the feasibility of gene manipulation in human haNSCs. We initially applied transposable element-based strategies to establish transgenic haNSCs (Figure 5A). First, we employed the transposon and splinkerette PCR system, which has been applied for a variety of genetic manipulations in cells from mice[46,47], nonhuman primates[21] and humans[48]. We performed gene trapping in haNSCs to generate mutation libraries, which might be useful for neural lineage genetic screening.



Specifically, haNSCs were transfected with PB transposon-based gene-trap vectors[46] carrying the enhanced green fluorescent protein (eGFP) gene. After transfection, haNSCs exhibited a PB insertion and expressed eGFP (Figure 5B). We then added the nerve agent manganese chloride to haNSCs carrying the mutant library. Five days later, all cells in the control group had died. We harvested the surviving haNSCs and amplified the integration sites by performing splinkerette PCR (Figure 5C). The PCR products were analyzed by agarose gel electrophoresis, and the 5′ inverted terminal repeat PCR results showed that the bands were relatively diffuse, indicating that there were multiple insertion sites in the haNSC genome (Figure 5D).

Deep sequencing analysis identified approximately 4 million independent insertions across more than 20000 genes, of which 51.8% were in the sense orientation (Figure 5E). We analyzed the hits across the whole genome, and the results showed that the insertion sites were evenly spread across all chromosomes, indicating genome-wide coverage of mutations (Supplementary Figure 5A). In addition, 93.00% of the insertions were located in intragenic regions (exon + intron + promoter + 5′/3′ untranslated region), whereas 6.24% of insertions occurred in intergenic regions (Figure 5F).

Gene Ontology enrichment analysis showed that insertions occurred preferentially in genes with specific functions in neural activity-related pathways, such as neuron projection guidance, neuron projection guidance and regulation of transmembrane ion transporters (Figure 5G). Ten genes with especially frequent insertions were identified by PB screening (Figure 5H). To comprehensively assess the inserted genes, we analyzed them for roles in previously reported neurotoxicity-related pathways (MAPK, Notch, Wnt and other pathways) (Supplementary Figure 5B). In summary, the derived haNSCs were found to be beneficial for genome-wide genetic screening.

Collectively, these results indicated that the optimized conditions supported the generation of human haNSCs, which can act as an ideal tool for screening key genes during neurogenesis.

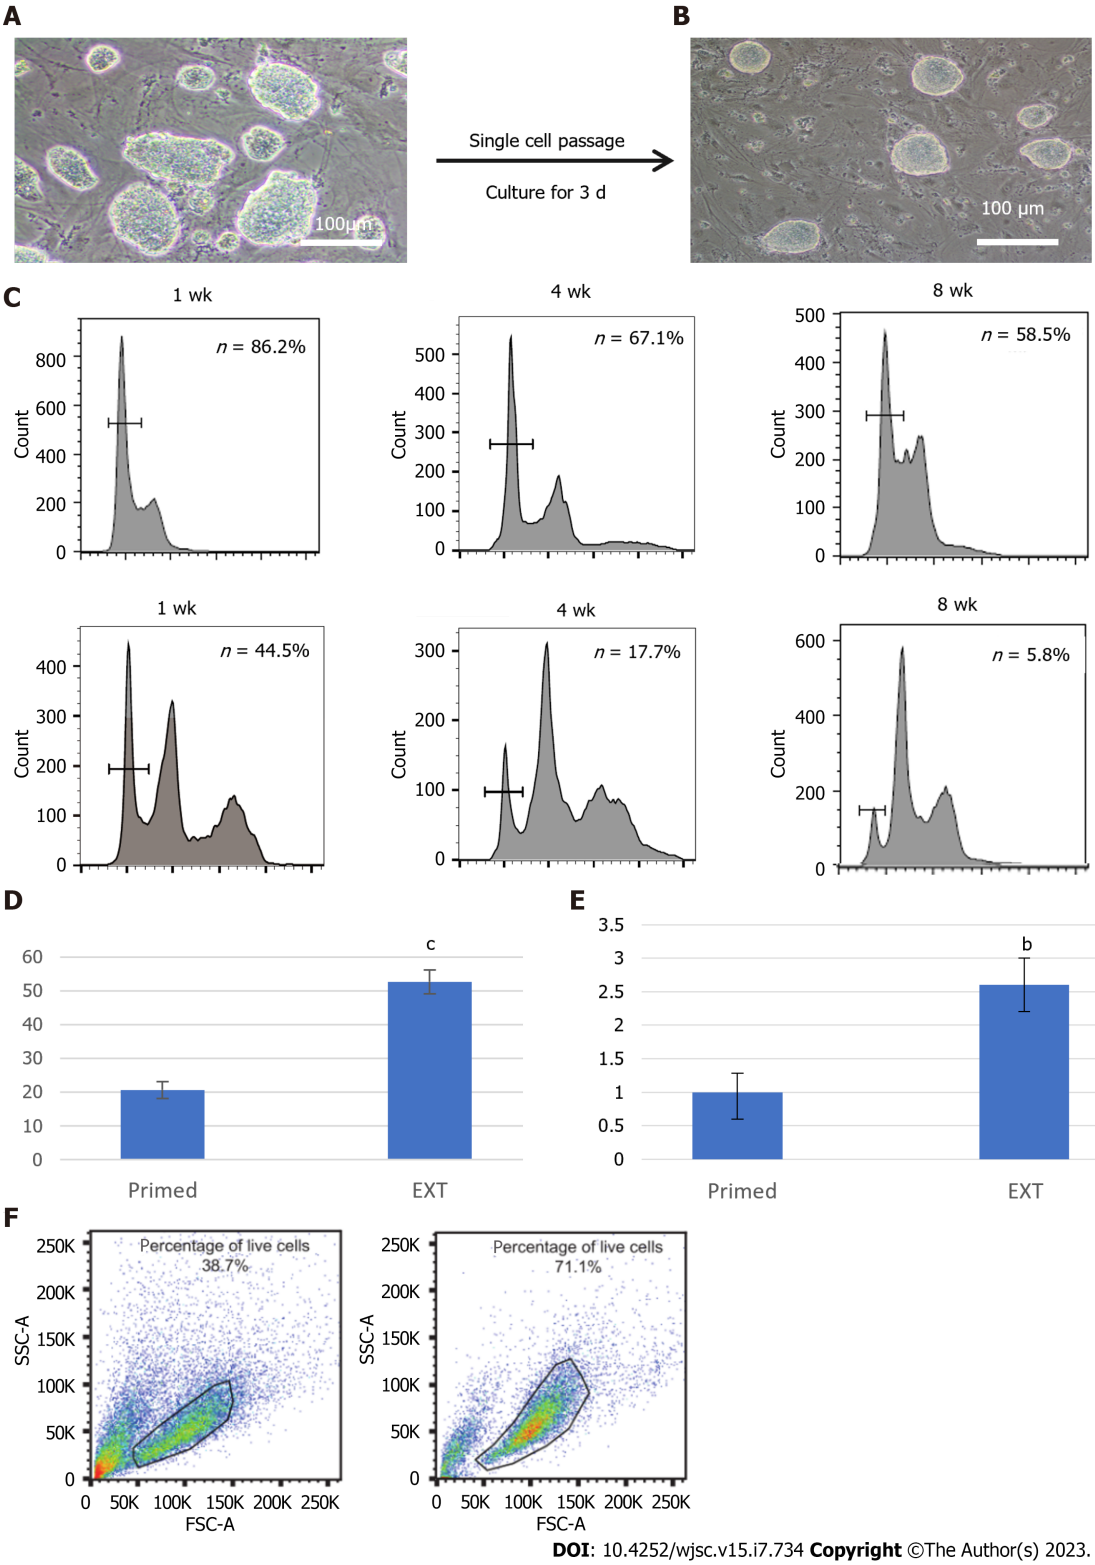
DISCUSSION

Researchers have obtained haESCs from a variety of species, including mammals[9-13], rhesus monkeys[15] and even humans[21]. Because there are obvious differences in the pathogenesis of many diseases between humans and other species[23,24], we urgently need to increase the number of available human cell models to more directly and efficiently explain the pathogenesis of human diseases. In this study, we demonstrated that tissue-specific adult cells (haNSCs) can be generated *in vitro* by the conversion of haESCs without chromosome doubling. Although severe diploidization was observed during ESC-NSC conversion, it was possible to optimize the differentiation system without gene modification through the addition of a number of small molecule inhibitors to the culture medium. With these modifications, we were able to establish haNSC lines relatively easily.

As the derived haNSCs were generated from haESCs *in vitro*, their purity and NSC properties needed to be confirmed. Nestin, SOX1 and PAX6 are NSC-specific markers that have been widely used in research related to neural cell fate[37]. Our results showed that these haNSCs express NSC markers and are similar to brain-derived NSCs in morphology. After functional verification, we found that these cells can differentiate into neurons and glial cells *in vitro*. In this regard, haNSCs have differentiation potential resembling that of brain-derived NSCs.

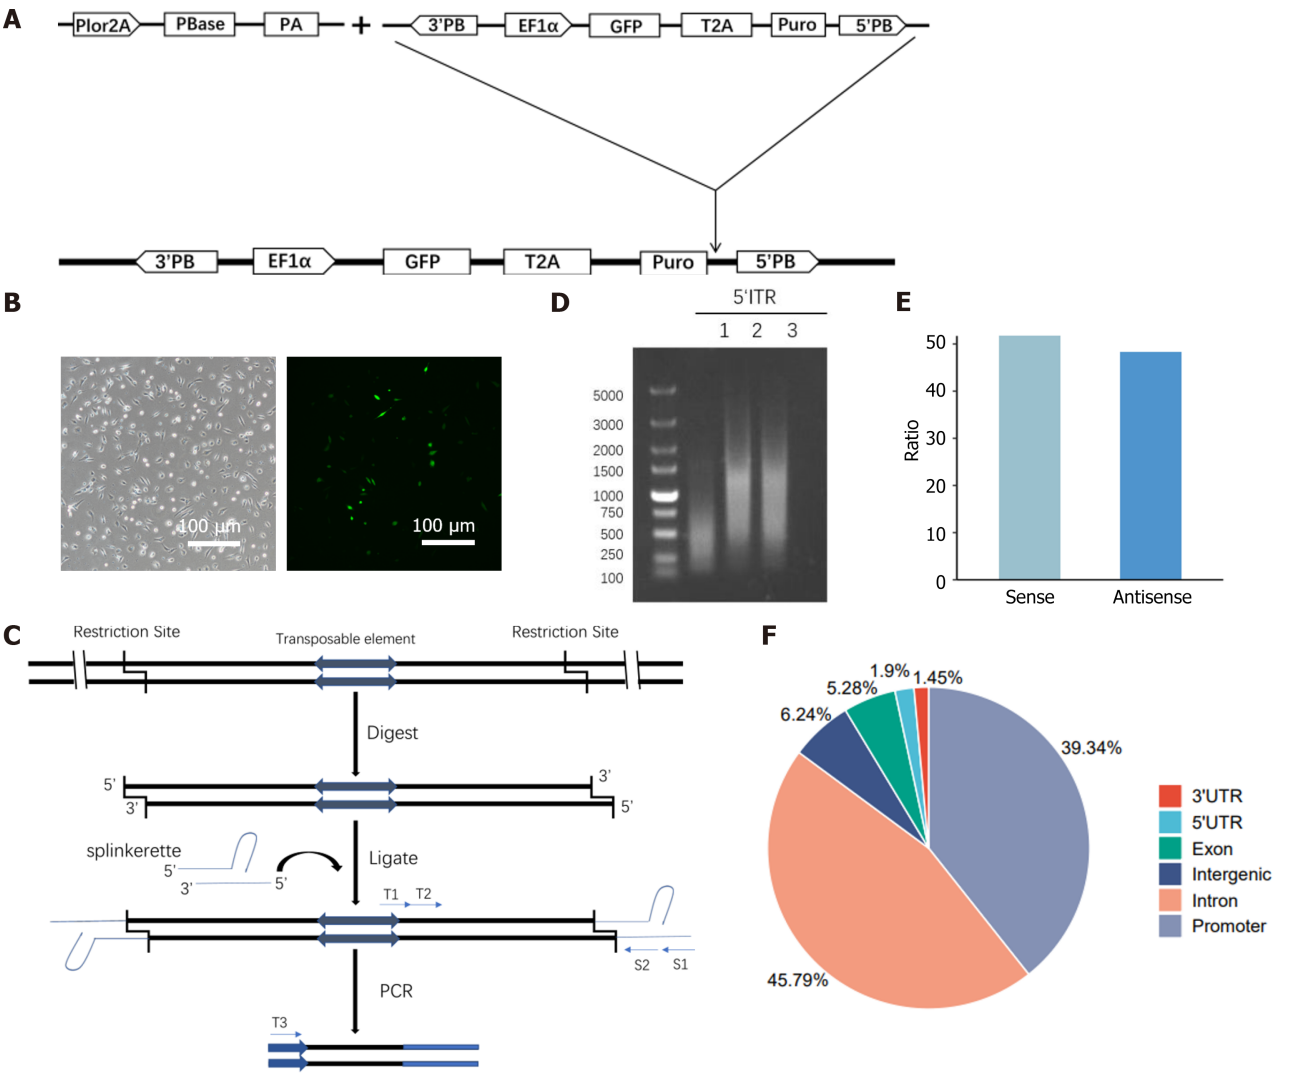
HaESCs are an important tool for mammalian genetic research. Human haESCs can differentiate into haploid somatic cells of the ectoderm, mesoderm and endoderm[16]. This result suggests that primate species may have a potential superiority for a haploidy maintenance mechanism. Our experiments with human haNSCs confirmed this finding, as this cell group maintained a stable haploid state during the culture process. These advantages guaranteed their utility in a subsequent gene trapping procedure.



The PB transposon can insert a large number of random mutations in the genome[21,48]. Therefore, we combined the PB transposon and haNSCs to conduct genetic screening. Previous work demonstrated that neural cells are more susceptible to manganese-induced toxicity[49]. We performed genetic screening to uncover the target genes of manganese in haNSCs. The results of the gene trapping using the PB transposon system showed that random insertions could be generated efficiently in these haploid somatic cells. This method could be used in combination with high-throughput sequencing analysis to easily identify the gene insertion sites and insertion frequencies in all of the 23 chromosomes.

As described previously, human haESCs could differentiate into Tuj1-positive cells with a haploid genome. However, the cells lacked stability and proliferation capacity to act as an ideal tool for screening key genes.

There were limitations of this study. The diploidization of the haploid cells was not completely terminated; it was only slowed down. The underlying mechanism remains to be further studied and explored.



CONCLUSION

In conclusion, we optimized a culture system for human haESCs and achieved the derivation of human haNSCs (Figure 6). This is the first human haploid somatic stem cell line reported with good proliferative ability and pluripotency toward neural subtypes. Moreover, through chromosome G-band karyotype analysis, we confirmed for the first time that the differentiated haNSCs maintained 23 chromosomes while not exhibiting fragmentation, deletion, duplication, translocation, inversion or other balanced variations. Meanwhile, we identified manganese-induced toxicity genes with the help of this haploid cell line. This cell line will be valuable for genetic screening relevant to human nervous system function and drug targeting research.

Figure 6 Summary graph for this research. Results show that human haploid embryonic stem cells cultured in optimized medium can stably maintain haploidy state and easily generate functional haploid neural stem cells with the help of Y27632 (ROCKi), thus contributing to human lineage-specific genetic screening. At last, we get a gene list relate to $Mn2^{+}$-induced toxicity with the help of this haploid cell line. FACS: Fluorescence activated cell sorting.

ARTICLE HIGHLIGHTS

Research background

Recently, haploid embryonic stem cells (haESCs) have been established in many species and are widely used in forward and reverse genetic screening. Differentiated haploid cell line types in mammals are lacking due to spontaneous diploidization during differentiation that compromises lineage-specific screens.

Research motivation

No human haploid somatic cell line has been generated, although there is an urgent need for lineage-specific screens.

Research objectives

This study aimed to derive haploid neural stem cells (haNSCs) from human extended haESCs by optimizing differentiation methods and verifying human haNSCs to easily carry out lineage-specific screens.

Research methods

Human haploid NSCs were differentiated from human extended haESCs with the help of Y27632 to reduce the diploidization. Neuronal differentiation of haNSCs was performed to examine their neural differentiation potential. Global gene expression analysis was performed to compare haNSCs with diploid NSCs and haESCs. Fluorescence activated cell sorting was conducted to assess the diploidization rate of extended haESCs and haNSCs. Genetic manipulation and screening were utilized to evaluate the significance of human haNSCs as genetic screening tools.

Research results

haNSCs can be generated by differentiation *in vitro*, and they maintain long-term haploidy with a complete genome and multipotency towards neurons and glia. Human haESCs cultured in extended pluripotency medium formed more compact colonies and exhibited more efficient neural differentiation and more stable maintenance of haploidy, which effectively facilitated the derivation of haNSCs. After PiggyBac transfection, there were multiple insertion sites in the haNSC genome and the insertion sites were evenly spread across all chromosomes.

Research conclusions

In this work, we demonstrated that human haNSCs can be generated by differentiation from extended haESCs. This is the first human haploid somatic cell line with a complete genome, acceptable proliferative ability and neural differentiation potential, which provides a cell resource for studies of recessive inheritance and drug targeted screening.

Research perspectives

This cell line will be valuable for genetic screening relevant to the function of the human nervous system and drug targeting research. Future research will be related to identifying key neurogenesis genes with the help of this cell line. Another research focus is to identify the underlying mechanisms of diploidization.

ACKNOWLEDGEMENTS

We thank Dr. Ling Shuai (State Key Laboratory of Medicinal Chemical Biology, Nankai University, Tianjin, China) for the PiggyBac-GFP vector. Dr. Jinsong Li (GTP Center and Stem Cell Bank, Shanghai Institute of Biochemistry and Cell Biology, Chinese Academy of Sciences) is acknowledged for assistance with human parthenogenetic ESCs.

Abstract

BACKGROUND

Zinc (Zn) is the second most abundant trace element after Fe, present in the human body. It is frequently reported in association with cell growth and proliferation, and its deficiency is considered to be a major disease contributing factor.

AIM

To determine the effect of Zn on *in vitro* growth and proliferation of human umbilical cord (hUC)-derived mesenchymal stem cells (MSCs).

METHODS

hUC-MSCs were isolated from human umbilical cord tissue and characterized based on immunocytochemistry, immunophenotyping, and tri-lineage differentiation. The impact of Zn on cytotoxicity and proliferation was determined by MTT and Alamar blue assay. To determine the effect of Zn on population doubling time (PDT), hUC-MSCs were cultured in media with and without Zn for several passages. An i*n vitro* scratch assay was performed to analyze the effect of Zn on the wound healing and migration capability of hUC-MSCs. A cell adhesion assay was used to test the surface adhesiveness of hUC-MSCs. Transcriptional analysis of genes involved in the cell cycle, proliferation, migration, and self-renewal of hUC-MSCs was performed by quantitative real-time polymerase chain reaction. The protein expression of Lin28, a pluripotency marker, was analyzed by immunocytochemistry.

RESULTS
Zn at lower concentrations enhanced the rate of proliferation but at higher concentrations (> 100 μM), showed concentration dependent cytotoxicity in hUC-MSCs. hUC-MSCs treated with Zn exhibited a significantly greater healing and migration rate compared to untreated cells. Zn also increased the cell adhesion rate, and colony forming efficiency (CFE). In addition, Zn upregulated the expression of genes involved in the cell cycle (*CDC20, CDK1, CCNA2, CDCA2*), proliferation (*transforming growth factor β1, GDF5, hypoxia-inducible factor 1α*), migration (*CXCR4, VCAM1, VEGF-A*), and self-renewal (*OCT4, SOX2, NANOG*) of hUC-MSCs. Expression of Lin28 protein was significantly increased in cells treated with Zn.

CONCLUSION
Our findings suggest that zinc enhances the proliferation rate of hUC-MSCs decreasing the PDT, and maintaining the CFE. Zn also enhances the cell adhesion, migration, and self-renewal of hUC-MSCs. These results highlight the essential role of Zn in cell growth and development.

Key Words: Human umbilical cord; Mesenchymal stem cells; Zinc; Cell proliferation; In vitro expansion

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Zinc (Zn) efficiently increased the proliferation of mesenchymal stem cells (MSCs) with a significant increase in the rate of population doublings, and at higher concentrations, it was cytotoxic. MSCs of the test group maintained a higher frequency of mesenchymal progenitors. Upregulation of genes involved in cell cycle, proliferation, pluripotency, and migration, was also observed in test groups. Zn increased the migration capability of MSCs and cell adhesion ability of MSCs. Overall, the results showed that Zn at lower concentrations supported cell growth, division, and proliferation of MSCs while maintaining the MSC-specific characteristics, including pluripotency, migration, and cell adhesion.

INTRODUCTION

Preclinical and clinical research supports regenerative medicine as a promising therapeutic approach to address degenerative disorders, including cardiovascular diseases, dermal wounds, rheumatic diseases, traumas, immune system diseases, neuronal diseases, and cancers[1,2]. Cell-based therapy approach in regenerative medicine utilizes undifferentiated stem cells and possesses the potential to proliferate clonally and differentiate into other types of cells[3-5]. Among these stem cells, mesenchymal stem cells (MSCs) are the multipotent stem cells that act as immune modulators, lack HLA-DR, and down-regulate the antigen-presenting and co-stimulatory molecules[6]. These immune privilege properties make MSCs a potential candidate in regenerative medicine[7-9]. Currently, more than 1000 registered clinical studies involve MSCs for the regeneration of tissues and organs[10].

MSCs from perinatal sources, such as umbilical cord tissue, umbilical cord blood, and amniotic fluid, are highly proliferative with a sustained tendency of differentiation[11-13]. Though MSCs can be isolated from various body tissues, their low number has created a need for *in vitro* expansion. Clinically, 20 to 100 × 10^6 MSCs are required for a single therapeutic dose, which minimally takes 4 to 8 wk for *in vitro* expansion[13]. The expansion period and the quality of MSCs depend on the isolation and cell culture protocols. In addition, the biological properties of MSCs are influenced by the patient's clinical history, including age and genetic makeup[14]. Non-physiological conditions, including cell density, oxygen level, passage number, culture medium ingredients, and senescence are also being reported to alter biological characteristics of MSC like stemness, morphological features, migration, and proliferative potential[13].

Zinc (Zn) is a trace element that is widely reported for its role in growth and proliferation of cells, namely osteoblasts (MC3T3-E1 cells)[15], endothelial cells[16], smooth muscle cells[17], CD8+T cells[18,19]. Its deficiency is directly proportional to stem cell proliferation[20]. Plasma contains more than 1% of the total Zn[21]. Biologically, Zn is involved in cell catalytic, structural, and regulatory functions[22]. It acts as a cofactor of more than 300 enzymes[23].

Based on the role of Zn in cell growth and proliferation, we hypothesized that the addition of Zn in the growth medium would significantly increase the growth and proliferation rate of MSCs, which will be helpful in their *in vitro* expansion for therapeutic purposes. To the best of our knowledge, no study has addressed the effects of Zn on human umbilical cord (hUC)-MSCs. Thus, for the first time, we anticipate the potential role of Zn in the proliferation, migration, morphology, doubling time, and gene expression profile of hUC-MSCs.

MATERIALS AND METHODS

Collection, Processing, and Culturing of Human Umbilical Cord Tissue Samples

Human umbilical cord tissue samples were collected during elective C-sections of healthy donors under formal consent from Zainab Panjwani Memorial Hospital, Karachi. The independent ethical committee of PCMD, ICCBS, University of Karachi, for human subjects has approved the protocol (IEC-009-UCB-2015). The samples were collected in phosphate buffer saline (PBS) containing 0.5% EDTA as an anticoagulant, and processed as reported previously[24,25]. The cord tissue was washed with PBS to remove blood clots and debris. After washing, the tissue was chopped into 3 mm^3 pieces or explants and transferred into T75 culture flask containing 10-12 mL Dulbecco's Modified Eagle's Medium (DMEM) supplemented with 10% fetal bovine serum, 1% penicillin-streptomycin, and 1 mmol/L sodium pyruvate. The flask was incubated at 37 °C in a humidified incubator set at 5% CO_2. The culture medium was changed at the interval of three days. After 10-15 days, an outgrowth of cells was noted from the explants, that was allowed to grow and proliferate. hUC-MSCs up to passage 5 were used in the experiments.

Characterization of MSCs

MSCs were characterized based on tri-lineage differentiation, immunophenotyping, and immunocytochemistry.

Tri-lineage differentiation: For differentiation towards adipogenic, chondrogenic, and osteogenic lineages, the cells at passage P3 were cultured in a 6-well plate and grown in DMEM until they achieved 60%-70% confluency. Subsequently, DMEM was replaced with an adipogenic induction medium (200 µM indomethacin, 1 µM dexamethasone, and 10 µM insulin), osteogenic induction medium (10 µM beta glycerophosphate, 50 µM ascorbic phosphate, and 0.1 µM dexamethasone), and chondrogenic induction medium [20 ng transforming growth factor β1 (TGFβ1), 10 ng insulin, 100 µM ascorbic acid, and 1 µM dexamethasone]. Cells in induction media were incubated for three weeks. After incubation, cells were fixed with 4% Paraformaldehyde (PFA) and stained with Oil red O, Alcian blue, and Alizarin red S stain to detect oil droplets, glycosaminoglycan content, and calcium deposited in induced adipocytes, chondrocytes, and osteocytes, respectively. Images were captured under a bright field microscope with a CCD camera (Ti2, Nikon, Japan).

Immunophenotyping: Immunophenotyping was performed for cell surface markers CD73, Vimentin, CD105, and CD45 (Cat No. 562245, BD Bioscience). MSCs were incubated in blocking solution with primary antibodies at recommended dilutions for 2 h at 37 °C, and finally with secondary antibody Alexa Flour 546 of 1:200 dilution for 1 h. Cells were analyzed on a flow cytometer (BD FACS Celesta, Becton Dickson, United States).

Immunocytochemistry: MSCs were cultured in a chamber slide with a density of 5000 cells per well. Cells were fixed with 4% PFA for 10 min at room temperature (RT) and then permeabilized with 0.1% Triton X-100. Blocking was performed with 2% bovine serum albumin for 20 min at RT. Primary antibodies for MSC antigens CD73 (550256, BD Pharmingen, United States), CD117 (32-9000, Zymed Laboratories, Inc., United States), CD29 (MAB-1981, Chemicon International, United States), CD105 (560839, BD Pharmingen, United States), Stro1 (14-6688-82, Molecular Probes, Invitrogen, United States), Vimentin (V6389, Sigma-Aldrich, Inc., United States), Lin28 (PA1-096, Molecular Probes, Invitrogen, United States), and CD45 (CBL415, BD Pharmingen, United States) were added at recommended dilutions and kept at 4 °C overnight. Following PBS washing, cells were incubated with Alexa fluor-546 secondary antibody having 1:200 dilutions for 1 h at 37 °C. Nuclei were stained with DAPI for 15 min. Finally, cells were mounted and visualized under a fluorescent microscope (NiE, Nikon, Japan).

MTT Assay

MTT assay was performed, taking different concentrations of $ZnCl_2$ in complete DMEM to determine minimal toxic concentration. MSCs (2000 cells) per well were seeded in a 96-well plate with 200 µL complete DMEM. The medium was aspired, and cells were incubated with 5 µM, 10 µM, 20 µM, 30 µM, 50 µM, 100 µM, 250 µM, and 500 µM concentrations of $ZnCl_2$ for overnight. The next day, the medium was removed, and cells were incubated with 200 µL of MTT dye (0.5 gm/mL stock) for 4 h and incubated at 37 °C with 5% CO_2. Then, the MTT solution was discarded, and 200 µL of DMSO was added to dissolve formazan crystals formed by metabolically active cells. The plate was kept on an orbital shaker for 5 min at RT, and absorbance was measured at 570 nm by spectrophotometer (SpectraMax, United States).

Alamar blue assay for hUC-MSC proliferation kinetics

To analyze MSC proliferation, 2000 cells per well were seeded in a 96-well plate and incubated with different concentrations of $ZnCl_2$ for 24 h, 48 h, and 72 h. After each time point, the medium was removed, and 0.02% Alamar blue solution was added to each well. Fluorescence intensity was measured using a fluorescence spectrophotometer with excitation at 560nm and emission at 600nm (Varioskan LUX, Thermo Scientific). The relative fluorescence unit (RFU) was calculated by the given formula given below:

Difference between treated and untreated (%) = (RFU of treated groups/RFU of untreated group) × 100

Proliferation rate of hUC-MSCs

To analyze the proliferation rate of hUC-MSCs, 10000 cells per well were seeded in a 24-well plate and incubated with 20 µM $ZnCl_2$. When cells attained 70%-80% confluency, they were detached and counted by hemocytometer for the number of population doubling (NPD), and population doubling time (PDT) by the formulae given below:

$NPD = 3.33 \times \log (N_t/N_i)$
$PDT = t \times \log (2)/[\log (N_t) - \log (Ni)]$
Where, N_i = no. of cells plated; N_t = no. of cells harvested; t_i = initial day (0 d) and t (harvesting day).

Colony forming unit assay

MSCs were seeded at 500 cells per cm^2 in a T25 culture flask. After two weeks of incubation, cells were fixed with 4% PFA, followed by incubation with 0.5% crystal violet prepared in 10% methanol. Cells were washed with distilled water, and colonies were visualized at 40 × magnification under bright field microscope. A cluster of 100 cells was considered a colony. Results were analyzed by SPSS software.

Transcriptional profile of genes involved in cell cycle, proliferation, pluripotency, and migration

Cells were harvested for RNA isolation, 1 mL Trizol reagent (15596026, Invitrogen) was added, followed by the addition of 500 µL chloroform for phase separation and centrifugation at 12000 rpm. The aqueous layer was collected and incubated with 1 mL absolute ethanol for 2 h at -80 ˚C. The suspension was centrifuged, and the pellet was rinsed with 70% ethanol. Finally, the pellet was reconstituted in 15 µL nuclease-free water, quantified by nanodrop spectrophotometer, and stored at -20 ˚C. cDNA was synthesized using 1 µg RNA by RevertAid first-strand cDNA synthesis kit (K1622, Thermo Scientific, United States). All the primers were designed by http://www.ncbi.nlm.nih.gov/tool/primerblast and synthesized commercially. quantitative real-time polymerase chain reaction (qPCR) amplification was performed in a triplicate manner using qPCR master mix (A600A, Promega, Madison, WI, United States) for the genes mentioned in Table 1.

Scratch assay

For cell migration, 4000 cells per well were seeded in a 24-well plate containing DMEM and incubated for 24 h. After monolayer formation, the scratch was developed using a 100 µL pipette tip, and cells were incubated with 20 µM $ZnCl_2$. Migration of cells was observed at 2 h, 4 h, 6 h, 8 h, and 24 h of scratch development. Images were captured at different time points under a phase-contrast microscope (Eclipse Ts2, Nikon, Japan) and migration was measured in percentage with the help of the following formula:

% of MSCs migration = [(hi − Δh) ÷ hi] × 100%

Where, hi = the area of scratch measured immediately after scratching, and Δh = is the area of scratch measured at 2, 4, 6, 8, and 24 h.

Cell adhesion assay

To analyze cell adherence in control and test groups, MSCs were harvested, seeded in a culture flask, and cell adhesion was determined by observing MSCs at different time points, *i.e.*, at 0 min (immediately after seeding), after 15 min, 30 min, 1 h, and 2 h. Cell adhesion was evaluated by the given formula:

%Percentage = no. of cells adhered on the flask surface/no. of floating cells in media.

Pluripotency retention of hUC-MSCs

To analyze the pluripotency marker after 20 µM $ZnCl_2$ treatment, MSCs were incubated with the primary antibody of Lin28 at 1:100 dilution and kept at 4 °C overnight. After PBS washing, cells were incubated with Alexa fluor-546 secondary antibody of 1:200 dilutions for 1 h at 37 °C. Nuclei were stained with DAPI for 15 min and then visualized under a fluorescent microscope (NiE, Nikon, Japan).

RESULTS

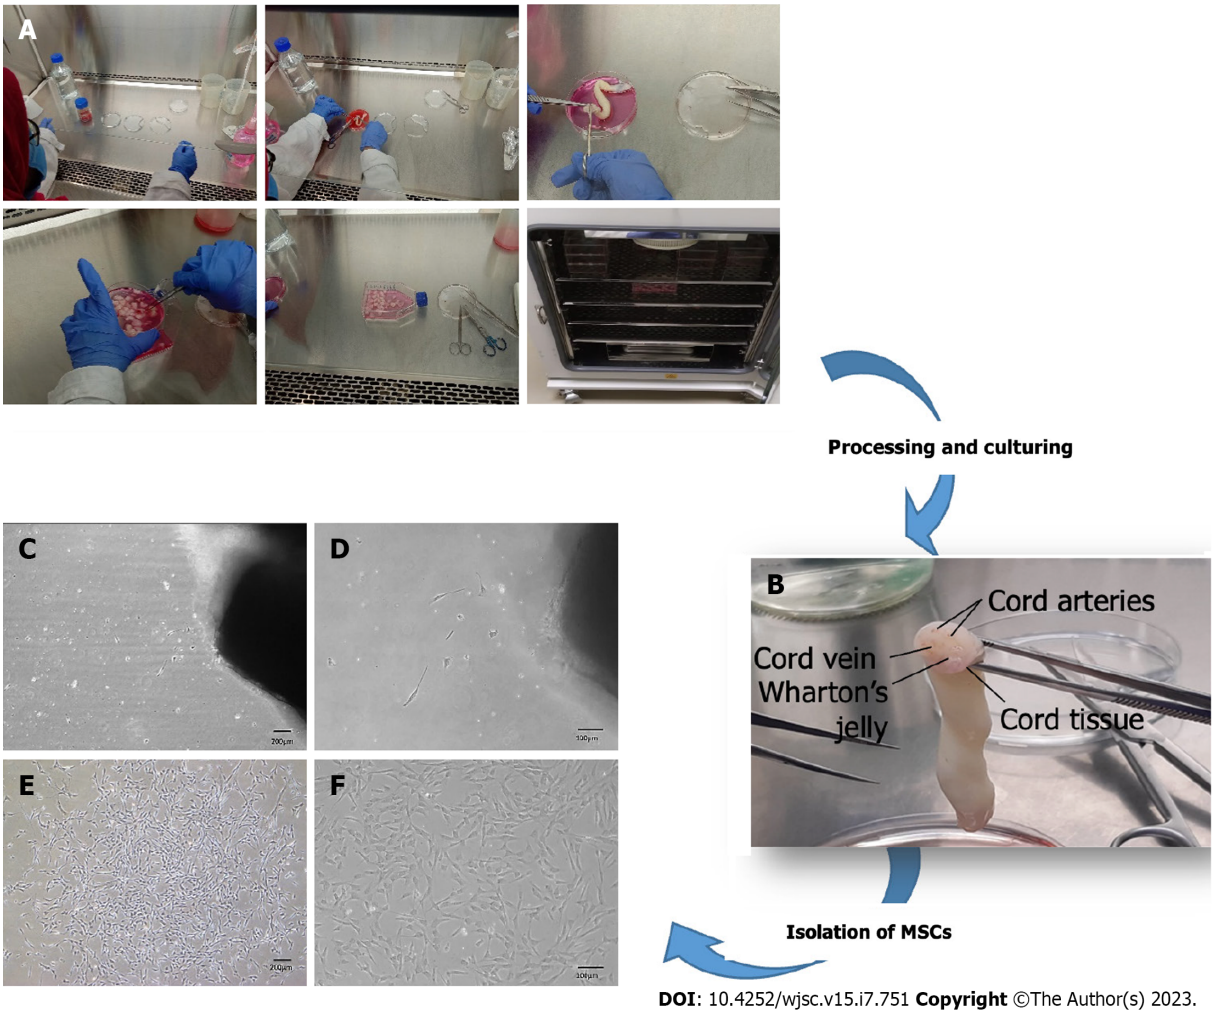
Human Umbilical Cord Processing and Culturing

MSCs were isolated from human umbilical cord tissue by the explant method (Figure 1A). Human umbilical cord tissue comprises one vein, two arteries, and Wharton's jelly (Figure 1B). MSCs started to outgrow the cord tissue after 10-15 d of cord processing. At this stage, cells adhered to the flask surface and appeared as trigonal shape (Figure 1C and D). After approximately 25 d, cells were observed to be interconnected with each other by their extensions, formed colonies, and exhibited elongated fibroblast-like morphology, which was termed P_0 (passage zero) MSCs (Figure 1E and F).

Characterization of hUC-MSCs

Cells isolated from the umbilical cord possessed adhesive properties and exhibited fibroblast-like morphology (Figure 2A). The isolated population of cells showed positive expression for MSCs specific markers, including CD73, CD117, CD29, CD105, Stro1, Vimentin, and Lin28, while negative for CD45, which is a hematopoietic marker (Figure 2B). Immunophenotypic analysis showed positive expression for CD73 (90%), vimentin (98%), and CD105 (80%), and less than 4% population was positive for CD45 (Figure 2C). The isolated cells successfully differentiated into adipogenic, osteogenic, and chondrogenic lineages as confirmed by Oil red O, Alizarine red S, and Alcine blue staining (Figure 2D).

Cytotoxicity analysis and proliferation kinetics of hUC-MSCs



$ZnCl_2$ concentrations ranging from 5 µM-100 µM did not show any cytotoxic effect on cells (Figure 3A and B). $ZnCl_2$ was found to be significantly cytotoxic above 100 µM concentration, and its cytotoxicity was found to be higher in a concen-

Housekeeping gene: *GAPDH* (Glyceraldehyde-3 Phosphate Dehydrogenase); cell cycle genes: *CDC20* (Cell-Division Cycle Protein 20), *CDK1* (Cyclin-Dependent Kinase 1), *CCNA2* (Cyclin-A2), *CDCA2* (Cell Division Cycle Associated 2); proliferation genes: *TGFβ* (Transforming Growth Factor β1), *1, GDF5* (Growth Differentiation Factor 5), *HIF1α* (Hypoxia-Inducible Factor 1α); pluripotency genes: *OCT-4* (Octamer-Binding Transcription Factor-4), *SOX2* (SRY-box 2), *NANOG*; migration genes: *CXCR 4* (Chemokine Receptor Type 4), *VCAM1* (Vascular Cell Adhesion Molecule1), *VEGF-A* (Vascular Endothelial Growth Factor-A), *MMP2* (Matrix Metallopeptidase 2).

tration-dependent manner. The IC_{50} of $ZnCl_2$ was found at 250 μM concentration (Figure 3A). For proliferation analysis, MSCs were treated with 5-50 μM $ZnCl_2$ for 24, 48, and 72 h. Fluorescence intensity was measured for each group at the respective time after incubating with Alamar blue for 4 h. Results of each temporal group were analyzed by one-way ANOVA between control and test groups. All test groups observed significantly increased proliferation after 48 and 72 h (Figure 4A and B). MSCs in passage 5 were analyzed for NPD and PDT. After 10 d, MSCs of the control and treated group (20 μM $ZnCl_2$), were counted, and significantly higher NPD was observed in 20 μM $ZnCl_2$ treated group (Figure 3C), while PDT reduced significantly in the treated group in contrast to the control group (Figure 3D).

MSCs: Mesenchymal stem cells.

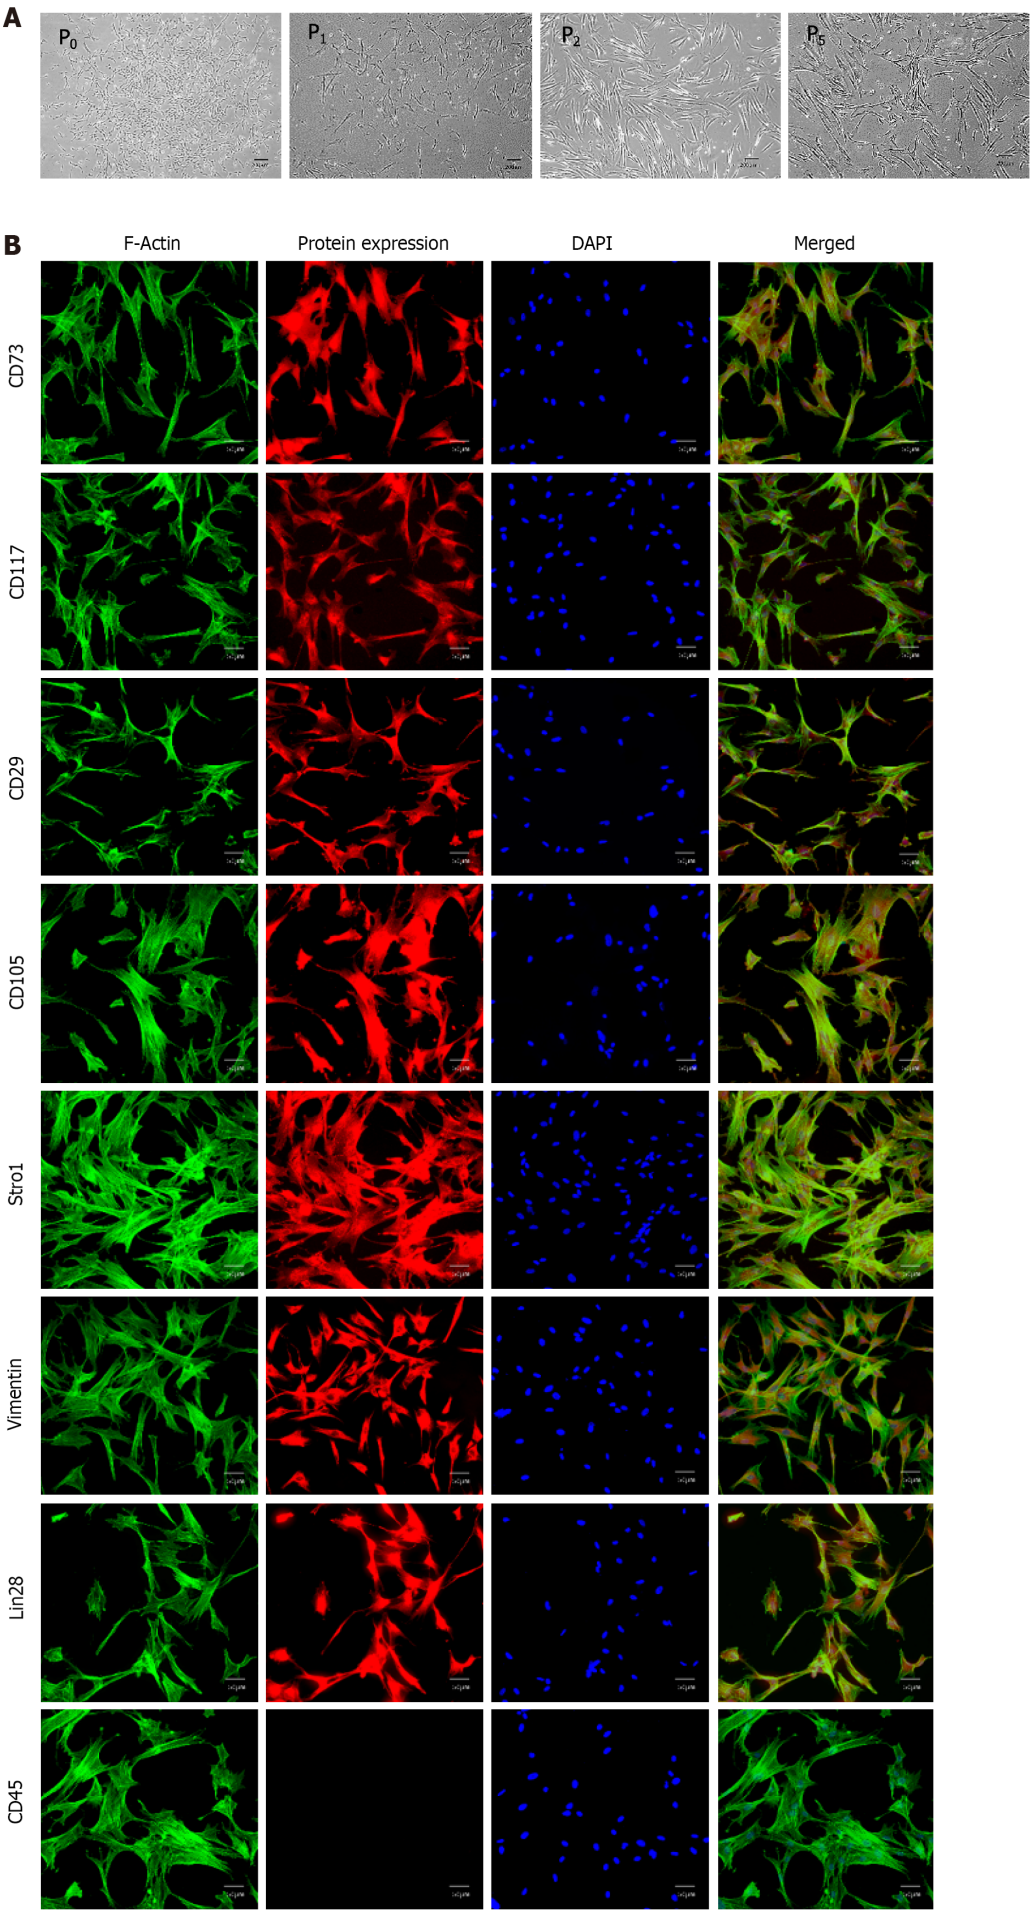
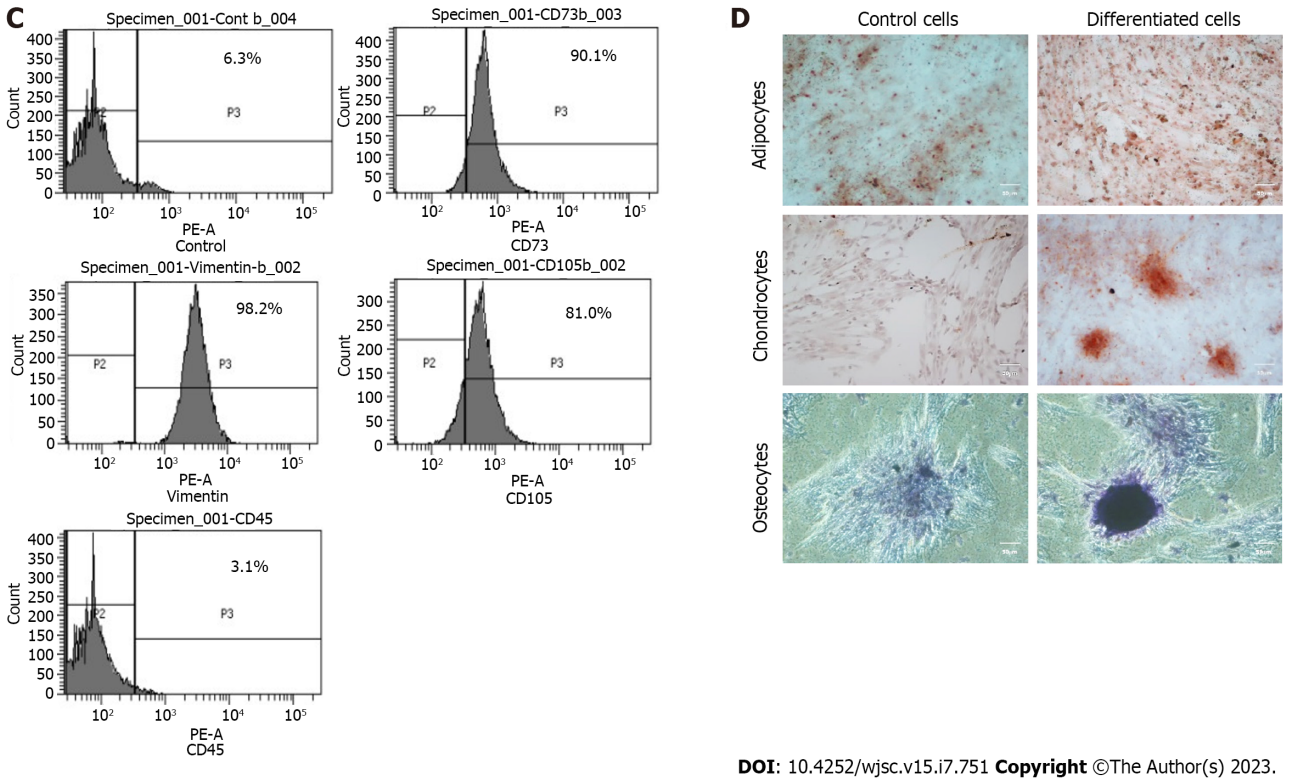
Colony forming unit assay and transcriptional analysis of cell cycle and proliferation genes



To analyze the presence of mesenchymal progenitors, colony forming unit (CFU) assay was performed. Colonies of hUC-MSCs were observed after 2 wk of cell seeding. The test group supplemented with 20 μM $ZnCl_2$, exhibited a significantly higher number of colonies than the control group (Figure 4A and B). To analyze the transcriptional changes of 20 μM $ZnCl_2$ treated MSCs to the untreated MSCs, fold change regulation ($2^{-\Delta\Delta Ct}$) of cell cycle and proliferation genes was analyzed at 12, 24, 48, and 72 h. Expression of cell cycle genes, *i.e.*, *CDC20, CCNA2,* and *CDCA2,* was comparatively increased in all temporal groups of 20μM $ZnCl_2$, while *CDK1* was upregulated after 24, 48, and 72 h (Figure 4C). Among proliferation genes, expression of *TGFβ1* and *GDF5* was significantly increased in all temporal groups of 20 μM $ZnCl_2$, whereas *hypoxia-inducible factor 1α (HIF-1α)* exhibited a significant upregulation after 24, 48, and 72 h (Figure 4D).



Cell migration assay and transcriptional analysis of genes involved in cell migration

$ZnCl_2$ was also found to facilitate the migration of hUC-MSCs (Figure 5A) and significantly increased ($^bP \leq 0.01$) migration was observed in 20 μM $ZnCl_2$ treated groups for 2-8 h, while scratch was completely healed after 24 h in both groups, *i.e.*, control and $ZnCl_2$ treated groups. The percentage of area healed is plotted against time (Figure 5B). Gene expression analysis of migration factors showed upregulation of *CXCR-4* at all the time points, *i.e.*, 24, 48, and 72 h, while *V-CAM1, VEGF-A* was significantly upregulated after 48 and 72 h. *MMP-2* was found to be upregulated after 24 and 72 h (Figure 5C).

Cell adhesion assay

To analyze the effect of $ZnCl_2$ on the adhesiveness of hUC-MSCs, *in vitro* cell adhesion assay, was performed. A significant increase in the cell adhesion rate of hUC-MSCs in the 20 μM $ZnCl_2$ treated group was noted at 15 min, 30 min,1 h, and 2 h, compared to the control group (Figure 6A). Cell adhesion rate (%) is plotted against time (Figure 6B).

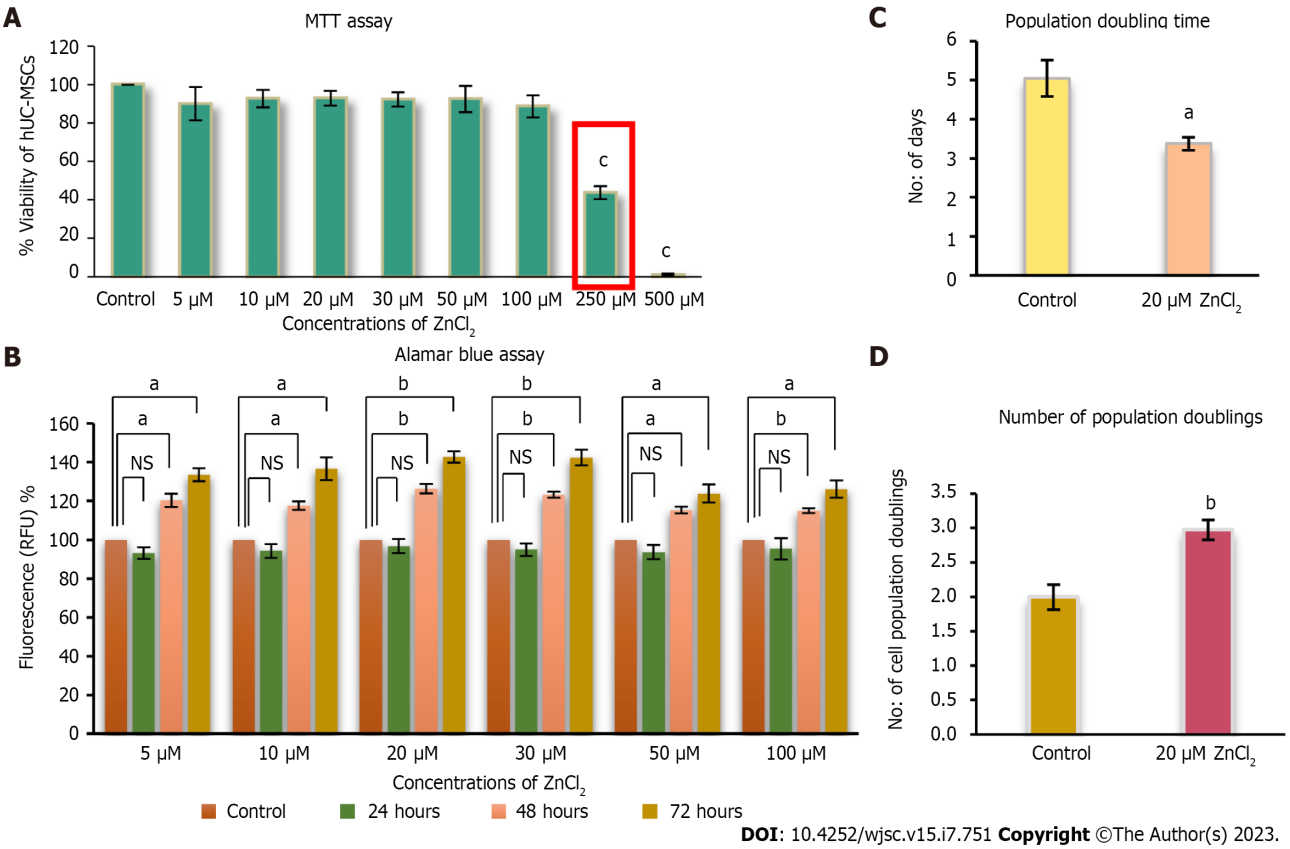
Figure 2 Characterization of human umbilical cord-derived mesenchymal stem cells. A: Isolated human umbilical cord-derived mesenchymal stem cells appeared as elongated, fibroblast-like cells which were slightly trigonal at P_0 and then gradually became elongated in latter passages (P_1, P_2, P_5); B: These cells positively expressed CD73, CD117, CD29, CD105, Stro1, Vimentin, and Lin28 while exhibiting negative expression of CD45; C: Cell surface analysis by flowcytometry showed that more than 80% of the cell population was positive for CD73, vimentin, and CD105 while less than 4% were positive for hematopoietic marker *i.e.* CD45; D: The cells were successfully differentiated into adipocytes, osteocytes, and chondrocytes. Oil red O stain, alizarin red S stain, and Alcian blue stain confirmed the presence of lipids vacuoles, calcium deposits, and glycosaminoglycan in adipocytes, osteocytes, and chondrocytes, respectively.

Retention of pluripotency markers



Immunostaining: Immunostaining of 20 μM $ZnCl_2$ treated MSCs showed positive expression of pluripotency marker Lin28 at all the time points (Figure 7A). The quantified mean fluorescence intensity showed a significant increase in expression at 24 h (Figure 7B).

Gene expression analysis: Genes expression analysis showed that *OCT4* was significantly upregulated in all temporal groups (12, 24, 48, and 72 h), of 20 μM $ZnCl_2$. In contrast, the expression of *SOX2* and *NANOG* was significantly higher in temporal groups of 24 and 48 h and then fell to the level of control in 72 h (Figure 7C).

DISCUSSION

Zn is among the essential trace elements that is ubiquitously found in the human body. According to prior investigations, it is one of the trace elements that is majorly involved in cell growth and proliferation[16,17,26]. It stimulates cell division and proliferation by regulating enzymes such as deoxythymidine kinase and/or by regulating hormones including insulin-like growth factor-I (IGF-I) and nerve growth factors[23,27]. Zn acts as a signal molecule for both extracellular and intracellular pathways. It upregulates PI3 kinase pathway which activates AKT in fibroblast cells and transactivates EGF receptor by Src pathway in epithelial cells of the airway. It also regulates the ERK1/2 pathway with the induction of p21 (CiP/WAF1), and cyclin D1 in colonocytes[21]. Studies reported the role of Zn on the proliferation of adipose derived MSCs[23,26]. A recent study reported the effect of Zn on human umbilical cord derived MSCs and showed its importance in MSC survival and differentiation properties. The study suggested that Zn could enhance antioxidative properties of MSCs by regulating Nrf2/Sirt3 signaling pathway[28]. In the present study, we analyzed the effect of $ZnCl_2$ on hUC-MSCs in the context of its proliferation and growth, pluripotency, migration, and cell adhesion properties.

$ZnCl_2$ is reported to have a biphasic effect on the viability and proliferation of the cells and exhibited dose-dependent response, which varies for different cell lines[29]. Most of the studies found $ZnCl_2$ cytotoxic above 100 μM in different dividing cells, including coronary artery endothelial cells, vascular smooth muscle cells, and even MSCs[16,17,23]. Our findings showed cytotoxicity of $ZnCl_2$ above 100 μM, which is in line with the previous study[23]. The proliferation profile of MSCs reported by previous studies gave a bell shape biphasic curve whose peaks vary for $ZnCl_2$ concentrations for different cells. We also obtained a bell shape biphasic curve representing an increase in MSC proliferation with increase of $ZnCl_2$ concentration up to 30 μM, and then gradually decreasing upon further increase. However, up to 100

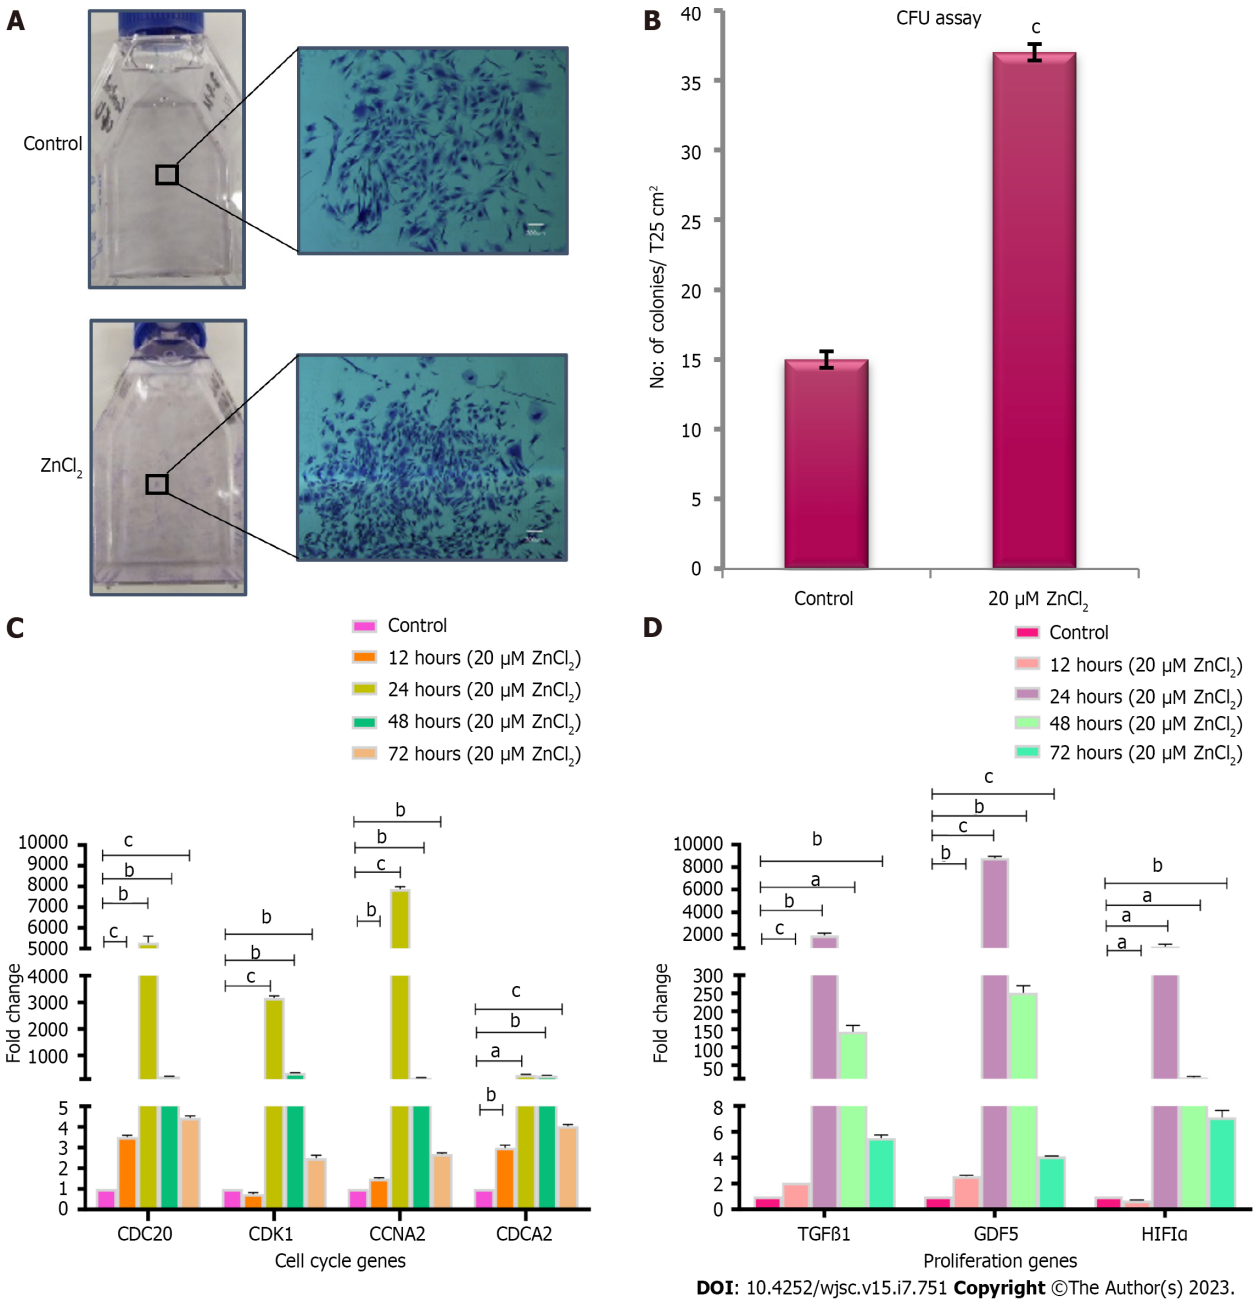

Figure 3 Cytotoxic analysis of $ZnCl_2$ for human umbilical cord-derived mesenchymal stem cells. A: Concentrations of $ZnCl_2$ 5 μM, 10 μM, 20 μM, 30 μM, 50 μM, 100 μM, 250 μM, and 500 μM were analyzed for their cytotoxicity by MTT assay. Concentrations from 5 μM to 100 μM did not show any significant decrease in viability (Percent) of human umbilical cord (hUC)-derived mesenchymal stem cells (MSCs) compared to control. 250 μM reflected IC_{50} value of $ZnCl_2$, and both 250 μM and 500 μM concentrations were found to be significantly ($^cP \leq 0.001$) cytotoxic. Results were analyzed by performing one-way ANOVA and Post-Hoc Bonferroni test; B: Alamar blue assay analysis of hUC-MSCs after 24 h after $ZnCl_2$ did not exhibit any significant difference between control and test groups. But after 48 and 72 h, the proliferation of MSCs was significantly increased ($^aP \leq 0.05$, $^bP \leq 0.01$) in all test groups. For further experiments, 20 μM of $ZnCl_2$ was selected as the test group concentration. C: Test group 20 μM $ZnCl_2$ exhibited significantly higher ($^bP \leq 0.01$) NPD *i.e.*, 2.9 ± 0.14, as compared to the control group, which showed 1.9 ± 0.18. Significantly reduced ($^aP \leq 0.05$) D: PDT was observed in the test group *i.e.*, approximately 3 d ± 0.16 in contrast to the control group having population doubling time of 5 ± 0.46 d. Results were analyzed by independent sample *t*-Test. Data is presented as mean ± SD ($n = 3$) where the significance level is $^aP \leq 0.05$. NS: Not significant.

μM concentration of $ZnCl_2$ gave significantly increased proliferation of MSCs in test groups as compared to control. Increased population doublings (NPD) and reduced PDT were observed in the treatment group in contrast to control MSCs.

MSCs are the progenitor cells that proliferate rapidly[30,31]. MSCs retain their multipotent ability, but the expanded cultured population of MSCs shows heterogeneous morphology of cells with variations in the frequency of early progenitor cells[30]. It is reported that human umbilical cord-derived MSCs exhibit the highest percentage of colony-forming units in contrast to the MSCs derived from bone marrow, adipose tissue, and dental pulp[32]. By CFU assay, we analyzed the impact of Zn on the colony-forming potential of MSCs derived from the human umbilical cord. Our results revealed that $ZnCl_2$ maintains a high pool of early progenitor cells in the MSC population, as many colonies were found in the treated group. $ZnCl_2$ treated group also exhibited denser colonies with spindle-shaped morphology which represented the rapidly self-replicating cells[30]. MSCs of the control group showed broad morphology with less dense colonies, which reflected slow self-replicating cells[30].

Gene expression analysis of treated MSCs exhibited a significant increase in cell cycle genes, including *CDK1, CDC20, CCNA2,* and *CACD2*. The level of CDK1 remains constant in entire cell division, but its activity depends on cyclins that are synthesized at different cell cycle stages[33]. CCNA2 or cyclin A2 is important for G1/S and G2/M transition, thus responsible for cell cycle progression[34]. CDK1 and CDC20 are the key mitotic regulators[35,36]. CDC20 is a cofactor of CPC/C (anaphase-promoting complex/Cyclosome), by activating CPC/C, CDC20 regulates the activity of CDK1 and promotes chromosome segregation by degrading securin, thus responsible for anaphase transition[36]. Whereas CDCA2 is essential for retaining chromatin structure in post-mitotic nuclei and regulates DNA damage responses for mitotic to interphase transition[37]. Upregulation of these genes required at different stages of the cell cycle showed progression of the cell cycle in the test group.

Few growth factors are pleiotropic and are found to be involved in multiple biological functions. For instance, TGFβ is one of them, and previous studies have reported the role of TGFβ in MSCs proliferation[38,39], and differentiation towards chondrogenic lineage; however, it inhibits terminal differentiation[39]. TGFβ1 is found to promote hUC-MSCs

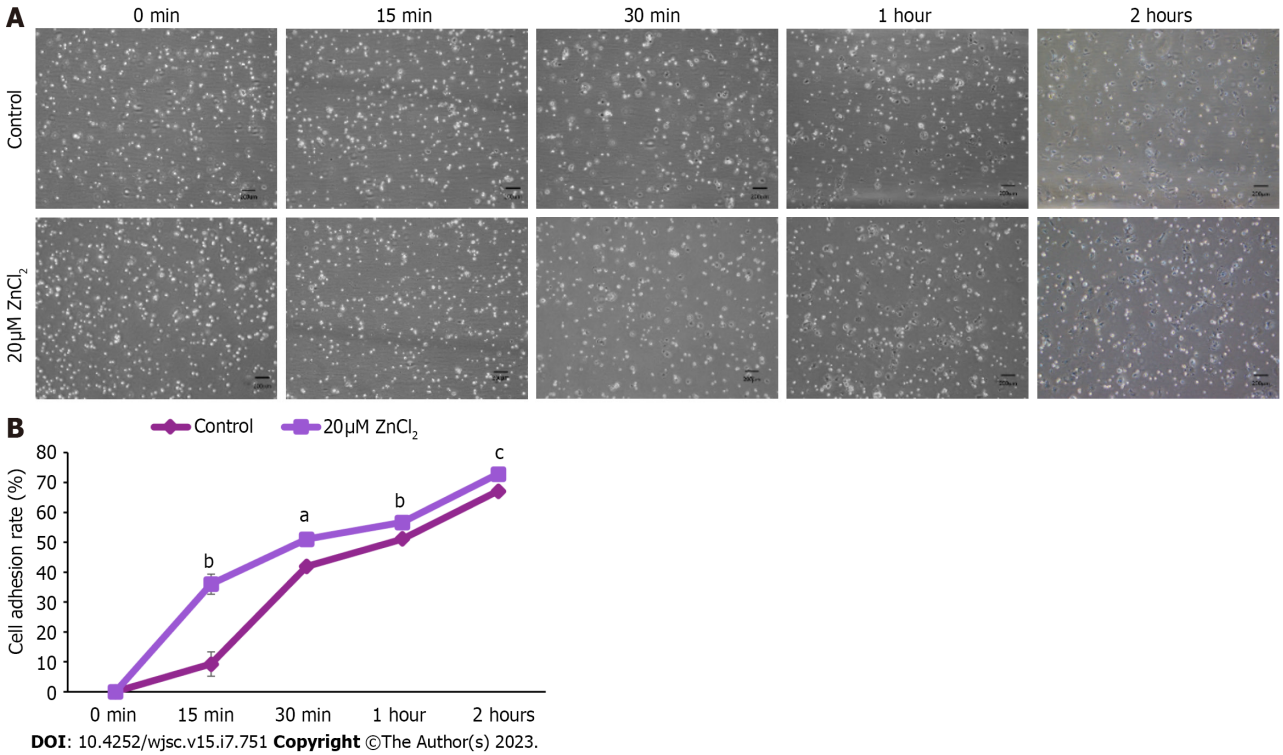
Figure 4 Colony forming unit assay and transcriptional analysis of cell cycle and proliferation genes. A: Colonies after crystal violet staining in control and test groups. Denser colonies were observed in $ZnCl_2$ treated group. Images were captured at 4 × magnification; B: A significantly higher number ($^cP \leq 0.001$) of colonies was observed in $ZnCl_2$ treated group with a mean number of 37 ± 0.57 colonies per T25 flask as compared to control *i.e.*, 15 ± 0.57 colonies per T25 flask. Results were analyzed by SPSS, performing an independent sample *t*-Test. C: Gene expression of cell cycle genes CDC20, CCNA2, CDCA2 was significantly increased in the test group after 12, 24, 48, and 72 h of treatment with 20 μM $ZnCl_2$. No significant difference was found in CDK1 gene expression after 12, but it was significantly enhanced after 24, 48, and 72 h. This fold change ($2^{-\Delta\Delta Ct}$) increase in genes expression was highest in the 24-h group. D: Gene expression of proliferation genes transforming growth factor β1 and GDF5 were significantly increased in all temporal groups *i.e.* 12, 24, 48, and 72 h, of 20 μM $ZnCl_2$. HIF1α significantly decreased after 12 h but then significantly increased after 24, 48, and 72 h. Results were analyzed by SPSS, performing an independent sample *t*-Test. Data was represented as mean ± SD ($n = 3$) where significance level $^aP \leq 0.05$ ($^aP \leq 0.05$, $^bP \leq 0.01$, $^cP \leq 0.001$).

proliferation without affecting the phenotype of MSCs[38]. Hence, our results are in the context of these findings as the $ZnCl_2$ treated group showed a significant increase in TGFβ1 expression and stemness markers like *OCT4, SOX2*, and *NANOG*.

Few studies have reported the effect of Zinc on the expression of HIF1-α, but there is inconsistency, as some studies on cancer cells proved down-regulation of HIF1-α caused by Zinc[40,41], while in keratinocytes and prostate cells, Zinc is found to stabilize HIF1-α expression[41,42]. Our findings showed enhanced expression of HIF1-α in $ZnCl_2$ treatment group which is in agreement with later studies[41,42]. Overall, the significantly increased expression of *TGFβ1, GDF5,* and *HIF1-α* suggested the increased proliferation and multipotency of MSCs in the test group.



Migration is an important factor that should be considered for better therapeutic effects of MSCs in regeneration and cell therapy. Studies reported that Zn enhances the migratory capability of cells[16,17,23,43]. For example, endothelial

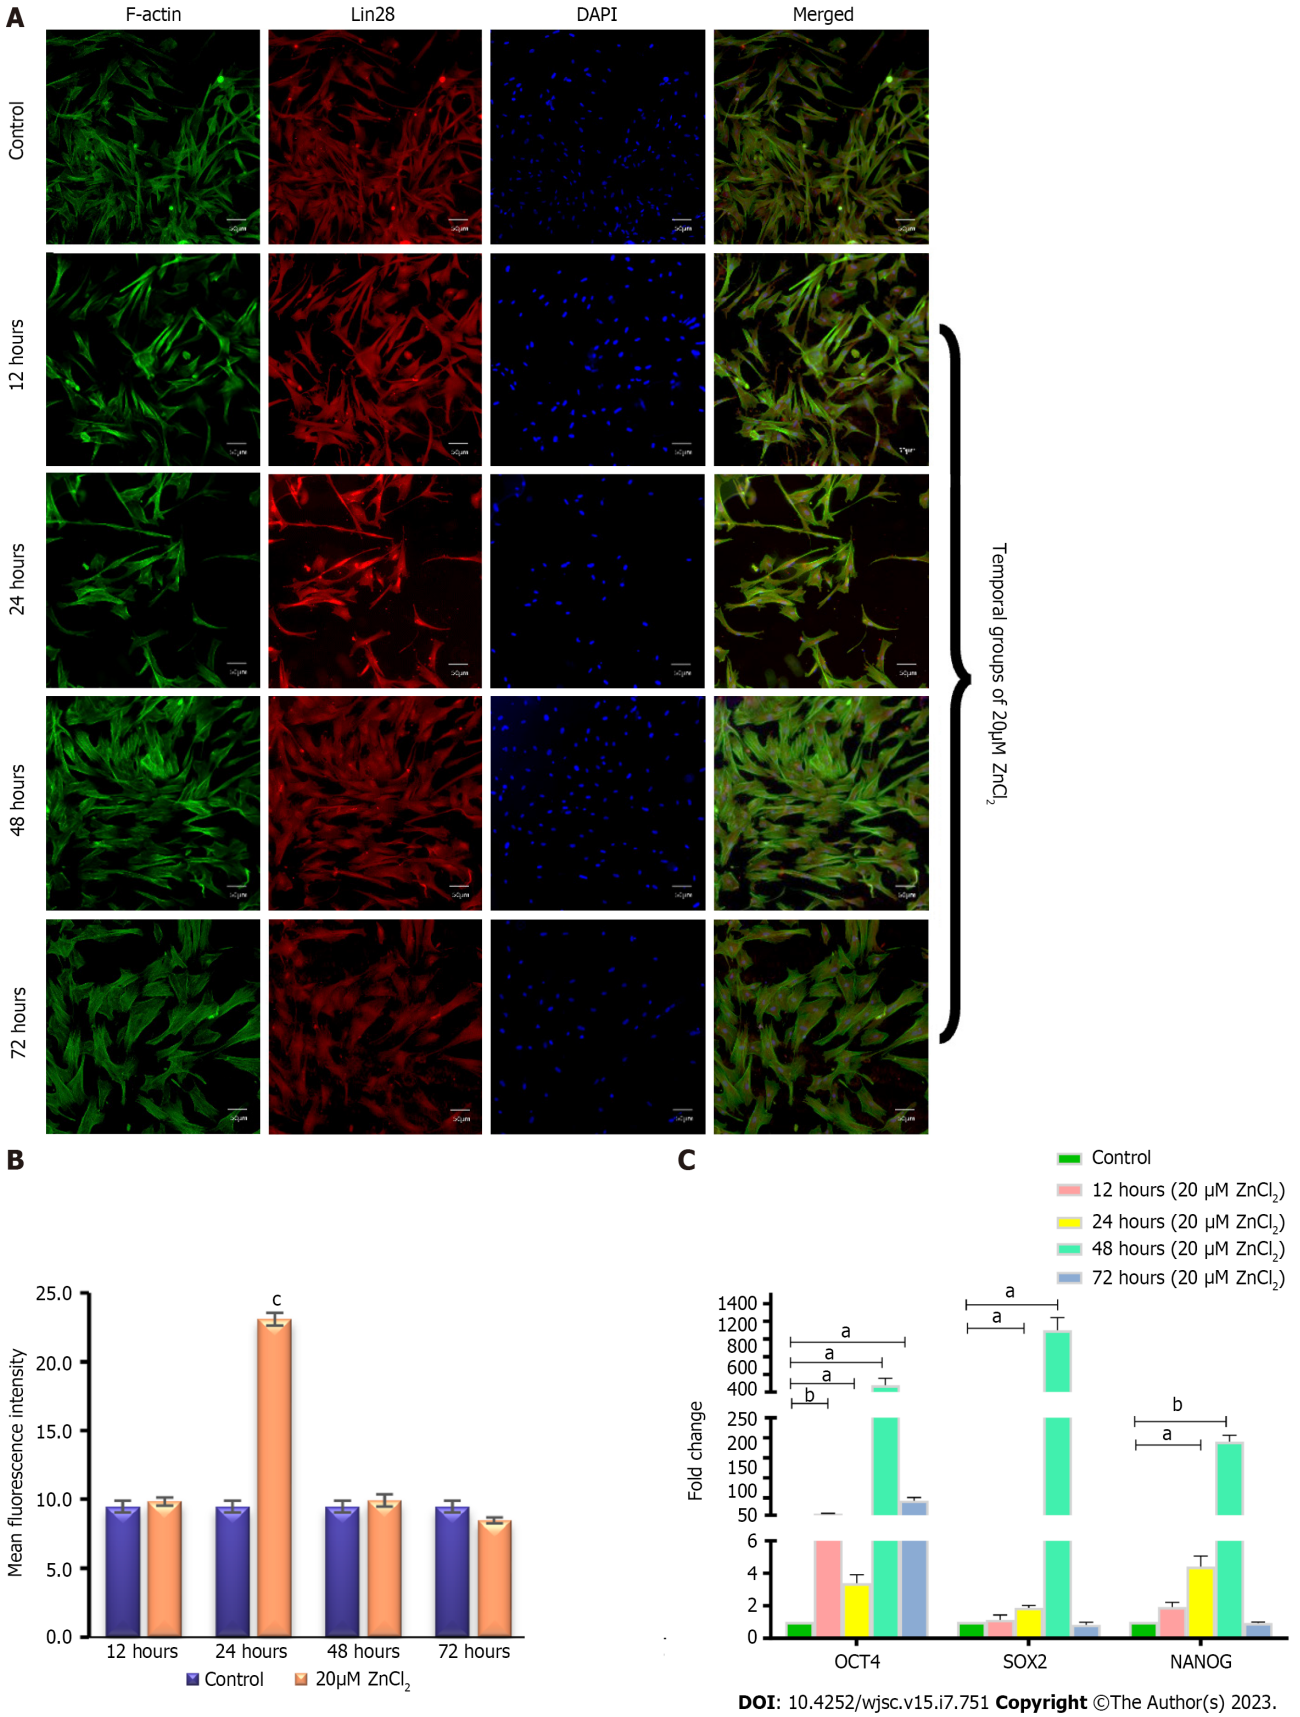
Figure 5 Effect of $ZnCl_2$ on the migration potential of human umbilical cord-derived mesenchymal stem cells. A: Microscopic examination of human umbilical cord (hUC)-derived mesenchymal stem cells (MSCs) immediately after the scratch was given, *i.e.*, 0 h, and after 2 h, 4 h, 6 h, 8 h, and 24 h. MSCs of the test group (20 μM $ZnCl_2$) exhibited faster migration as compared to control at all time points up to 8 h, and the scratch was completely healed after 24 h in both groups; B: Percentage of the area of scratch healed at time points, *i.e.*, 0 min, 2 h, 4 h, 6 h, 8 h, and 24 h, analyzed by independent sample *t*-test. MSCs exhibited a significantly ($^bP \leq 0.01$) increased migration (Percent) in the test group (20 μM $ZnCl_2$). C: Gene expression analysis of migration factors *CXCR-4, V-CAM 1, VEGF-A,* and *MMP2*, after 12, 24, 48, and 72 h of 20 μM $ZnCl_2$ treatment. *CRCR-4* exhibited significantly increased expression after 24 h, 48 h, and 72 h of treatment. *V-CAM1*, and *VEGF-A* showed significantly higher expression after 48 and 72 h of treatment. *MMP2* showed enhanced expression after 24 and 72 h. Results were analyzed by independent sample *t*-Test. Data was analyzed as mean ± SD ($n = 3$) where significance level $^aP \leq 0.05$ ($^aP \leq 0.05$, $^bP \leq 0.01$, $^cP \leq 0.001$).

cells and smooth muscle exhibited enhanced migration and cell adhesion when treated with $ZnCl_2$. These cells showed upregulation of focal adhesion molecules, including integrin, vinculin, actin, ICAM1, and VEGFA[16,17]. We analyzed the effect of Zn on the migration ability of MSCs by *in vitro* scratch assay, which showed a significant increase in MSC migration after $ZnCl_2$ treatment. These results were further confirmed by gene expression analysis of migration factors, including *CXCR-4, V-CAM1, VEGF-A,* and *MMP2*. These are involved in chemotaxis, cell rolling, and cell invasion and play their role in different phases of cell migration[44]. CXCR-4 and VEGF-A are the early migration markers, where CXCR-4 is a chemokine receptor, and VEGF is a growth factor, and both are involved in chemotaxis and trafficking of cells. V-CAM1 is a cell adhesion molecule, whereas MMP2 is required for cell invasion[44]. Here we analyzed these genes to estimate the migration ability of MSCs after $ZnCl_2$ treatment, and we found that after 12 h, only *VEGF-A* showed high



DOI: 10.4252/wjsc.v15.i7.751 **Copyright** ©The Author(s) 2023.

Figure 6 Effect $ZnCl_2$ on adhesion ability of human umbilical cord-derived mesenchymal stem cells. A: Images of human umbilical cord (hUC)-derived mesenchymal stem cells (MSCs) of the control group and 20 μM $ZnCl_2$ treated groups at 0 min, 15 min, 30 min, 1 h, and 2 h of cell seeding. Bright, rounded, and freely floating cells represent unadhered cells while dark cells represent adhered cells; B: Significant increase was observed in the adhesion ability of hUC-MSCs of the treated group after 15 min ($^bP \leq 0.01$), 30 min ($^aP \leq 0.05$),1 h ($^bP \leq 0.01$), and 2 h ($^cP \leq 0.001$). An independent sample *t*-test was performed to analyze results, and data were represented as mean ± SD ($n = 3$).

expression as compared to control, and after 24 h, all four migration markers exhibited significantly increased expression. After 48 h, *CXCR-4, V-CAM1, and VEGF-A* showed significantly increased expression, and after 72 h all of these genes showed significantly high expression, whereas *MMP2* showed the highest expression. Overall, up-regulation of these genes suggested that Zn also enhanced the expression of migration markers and promoted MSC migration, where fluctuations in their regulation may relate to their role at different stages of cell migration[44]. Studies reported that Zn promotes cell adhesion at lower concentrations in different cell types. Endothelial cells of coronary artery and smooth muscle cells exhibited increased cell adhesion ability when cultured in a $ZnCl_2$ supplemented medium[16,17]. We also found a considerably enhanced cell adhesion rate of MSCs when treated with 20 μM $ZnCl_2$.

Lin28, a pluripotency marker, was analyzed for its protein expression. It is an RNA binding protein that was first characterized in *C.elegans* as a heterochronic gene and was found to control developmental timing. In mammals, two homologs, including Lin28a and Lin28b are present in the cytoplasm as well as in the nucleus[45]. Structurally, Lin28 comprises the N-terminal cold shock domain and two zinc-binding motifs (CCHCx2) located at C-terminal. Lin28 is highly expressed in ESCs, while upon differentiation, its expression is suppressed by miRNAs, namely Let-7 and Lin-4 [45]. It is involved in post-translational modifications of specific subsets of mRNAs. In skeletal muscles, it binds to IGF-2 mRNA[46], while in mouse ESCs it is reported to bind with mRNAs of cell cycle-specific genes[47,48]. OCT4 mRNA is also reported as one of the targets of Lin28 for post-translational modifications[49]. Our results showed positive expression of Lin28 in all temporal groups, however, its expression exhibited fluctuations, *i.e.*, after 24 h of treatment, it was significantly enhanced, and then at later time points, the expression decreased gradually and became approximately similar to control group. It might be because of its post-translational role. That is why it showed higher expression before, *i.e.*, after 24 h than other pluripotency genes that exhibited their higher expression mainly after 48 and 72 h. Altogether, these factors make regulatory circuitry which is regulated through feed-forward loop and autoregulatory mechanism [49], and the fluctuations in their expression at time points may reflect this regulatory circuitry.

OCT4, *SOX2,* and *NANOG*, are the transcription factors that are conserved across mammalian species[50]. All three are highly expressed in ESCs and are responsible for the pluripotency and self-renewal of ESCs[51]. These transcription factors regulate gene expression in a highly cooperative fashion[52]. OCT4 and SOX2 form heterodimers and bind to specific promoters on DNA[53]. NANOG is a homeobox family gene that also forms heterodimer and regulates other pluripotency genes in feedback mechanism[53]. These are also found to have similar role in adult stem cells, including MSCs[11,50,54]. A study carried out by Hu *et al*[55], 2016, saw a significant increase in the expression of *OCT4, SOX2,* and *NANOG* in mouse ESCs when treated with $ZnCl_2$ for 48 h. The study further reported that as ESCs in humans and mice share the same key regulators, *i.e.*, *OCT4, SOX2, NANOG*[55], Zn might exert similar effects regarding the acquaintance and maintenance of the pluripotency in human stem cells. Mnatsakanyan *et al*[56], 2019 also showed significantly increased expression of *SOX2* in mouse ESC after long-term treatment, *i.e.*, 30 days with $ZnCl_2$[56]. In our study, gene

Figure 7 Protein expression of Lin28 and transcriptional analysis of pluripotency genes. A: Positive expression of mesenchymal stem cells (MSCs) specific marker Lin28 was observed after 12 h, 24 h,48 h, and 72 h of 20 μM $ZnCl_2$ treatment, as visualized by immunocytochemical staining; B: Quantified fluorescent intensities showed that 20 μM $ZnCl_2$ treated MSCs expressed Lin28 protein ($^cP \leq 0.001$); C: Quantitative real-time polymerase chain reaction analysis of pluripotency genes *OCT4, SOX2,* and *NANOG,* exhibited significantly increased ($^aP \leq 0.05$) expression of *OCT4* at 12, 24, 48, and 72 h, while *SOX2,* and *NANOG* showed significantly increased expression at 24 and 48 h ($^aP \leq 0.05$, $^bp \leq 0.01$). Results were analyzed by SPSS, performing an independent sample *t*-test. Data

were analyzed as mean ± SD (n = 3) where significance level $^{a}P \leq 0.05$.

expression analysis of all three genes *OCT4, SOX2, NANOG* showed a significant increase in the test group after 24 and 48 h. After 12 and 72 h of treatment, *SOX2* and *NANOG* did not exhibit any significant difference compared to the control, while *OCT4* represented a significant increase in all temporal groups.

Limitations of this study is that growth kinetics is analyzed by treating cells up to three days with zinc. Further temporal study is required to evaluate the long term effects of zinc. Also the signaling pathways that zinc utilizes to produce its effects are needed to be explored *via* protein quantification. An *in vivo* experimental evaluation is also needed to further support the *in vitro* findings.

CONCLUSION

At lower concentrations, Zn efficiently increased the proliferation of MSCs with a significant increase in the rate of population doublings, and at higher concentrations, it was cytotoxic. MSCs of the test group maintained a higher frequency of mesenchymal progenitors. Upregulation of genes involved in cell cycle, proliferation, pluripotency, and migration, was also observed in test groups. Zn increased the migration capability of MSCs and cell adhesion ability of MSCs. Overall, the results showed that Zn at lower concentrations supported cell growth, division, and proliferation of MSCs while maintaining the MSC-specific characteristics, including pluripotency, migration, and cell adhesion. Hence, Zinc could be a suitable constituent for cell culture medium that would help to enhance the quantity, quality, and rate of *in vitro* proliferation of MSCs for clinical and industrial-scale production. Though fewer studies are reported on Zinc effects on MSCs, further investigations are required to understand the mechanism that Zn utilizes to induce its effects.

ARTICLE HIGHLIGHTS

Research background

Zinc (Zn) is the second most abundant trace element after Fe, present in the human body. It is frequently reported in association with cell growth and proliferation, and its deficiency is considered to be a major disease contributing factor.

Research motivation

Trace elements are required to be supplemented in culturing media that will help to promote proliferation, cell division, and cellular growth, which will result in *in vitro* expansion of mesenchymal stem cells (MSCs) to achieve a desired number of cells for therapeutic dose.

Research objectives

In the present study, we aimed to determine the effect of Zn on *in vitro* growth and proliferation of human umbilical cord (hUC)-derived MSCs.

Research methods

hUC-MSCs were isolated from human umbilical cord tissue and characterized based on immunocytochemistry, immunophenotyping, and tri-lineage differentiation. The impact of Zn on cytotoxicity and proliferation was determined by MTT and Alamar blue assay. To determine the effect of Zn on population doubling time (PDT), hUC-MSCs were cultured in media with and without Zn for several passages. An i*n vitro* scratch assay was performed to analyze the effect of Zn on the wound healing and migration capability of hUC-MSCs. A cell adhesion assay was used to test the surface adhesiveness of hUC-MSCs. Transcriptional analysis of genes involved in the cell cycle, proliferation, migration, and self-renewal of hUC-MSCs was performed by quantitative real-time polymerase chain reaction. The protein expression of Lin28, a pluripotency marker, was analyzed by immunocytochemistry.

Research results

Zn at lower concentrations enhanced the rate of proliferation but at higher concentrations (> 100 μM), showed concentration dependent cytotoxicity in hUC-MSCs. hUC-MSCs treated with Zn exhibited a significantly greater healing and migration rate compared to untreated cells. Zn also increased the cell adhesion rate, and colony forming efficiency (CFE). In addition, Zn upregulated the expression of genes involved in the cell cycle (*CDC20, CDK1, CCNA2, CDCA2*), proliferation (*TGFβ1, GDF5, hypoxia-inducible factor 1α*), migration (*CXCR4, VCAM1, VEGF-A*), and self-renewal (*OCT4, SOX2, NANOG*) of hUC-MSCs. Expression of Lin28 protein was significantly increased in cells treated with Zn.

Research conclusions

Our findings suggest that zinc enhances the proliferation rate of hUC-MSCs decreasing the PDT, and maintaining the CFE. Zn also enhances the cell adhesion, migration, and self-renewal of hUC-MSCs. These results highlight the essential role of Zn in cell growth and development.

Research perspectives

Zinc at lower concentrations supported cell growth, division, and proliferation of MSCs while maintaining the MSC-specific characteristics, including pluripotency, migration, and cell adhesion. This will lead to produce large number of MSCs required for *in vivo* implanation in shorter period of time.

Abstract

BACKGROUND

Scar formation and loss of cutaneous appendages are the greatest challenges in cutaneous wound healing. Previous studies have indicated that antler reserve mesenchyme (RM) cells and their conditioned medium improved regenerative wound healing with partial recovery of cutaneous appendages.

AIM

To develop hydrogels from the antler RM matrix (HARM) and evaluate the effect on wound healing.

METHODS

We prepared the hydrogels from the HARM *via* enzymatic solubilization with pepsin. Then we investigated the therapeutic effects of HARM on a full-thickness cutaneous wound healing rat model using both local injections surrounding the wound and topical wound application.

RESULTS

The results showed that HARM accelerated wound healing rate and reduced scar formation. Also, HARM stimulated the regeneration of cutaneous appendages and blood vessels, and reduced collagen fiber aggregation. Further study showed that these functions might be achieved *via* creating a fetal-like niche at the wound site. The levels of fetal wound healing-related genes, including Collagen III and TGFβ3 treated with HARM were all increased, while the expression levels of

Collagen I, TGFβ1, and Engrailed 1 were decreased in the healing. Moreover, the number of stem cells was increased in the fetal-like niche created by HARM, which may contribute to the regeneration of cutaneous appendages.

CONCLUSION

Overall, we successfully developed an injectable hydrogel made from antler RM matrix for the regenerative repair of full-thickness cutaneous wounds. We uncovered the molecular mechanism of the hydrogels in promoting regenerative wound healing, and thus pave the way for HARM to be developed for the clinic use.

Key Words: Hydrogel; Antler reserve mesenchyme; Regenerative wound healing; Fetal-like niche

INTRODUCTION

As the biggest organ, skin serves multiple critical protective functions, including preventing harmful microorganism invasion, minimizing body fluid evaporation, and blockage of UV damage[1,2]. Healing in adult skin wounds usually results in scar formation, and scar consists of thick bundles of collagen fibers in the dermis and lacks functional cutaneous appendages (such as hair follicles and sebaceous glands). Scarring can result in patients experiencing bodily discomfort, including heat intolerance, pruritus, thermoregulatory and sensory disabilities, and psychological distress[3,4]. Therefore, realization of regenerative wound healing is the dream in clinics.

Biomaterials, especially the extracellular matrix (ECM) hydrogels, have become a promising strategy for treating severe skin injury[5-7]. ECM provides specific physical and chemical cues that regulate cell behaviors such as cell survival, proliferation, differentiation, and migration[8,9]. Thus far, quite a few types of ECM hydrogels from different animal tissues have been developed, including pig skin, bladder, and human placenta[10,11], and applied for inducing appendage regeneration in adult rat/mouse skin injury models. These hydrogels, however, have limited potential to maintain proliferation, differentiation, and migration of the cells resident in them, resulting in insufficient regeneration of nerves, blood vessels and cutaneous appendages in the healing wounds[10,11]. Therefore, the development of more effective alternative ECM hydrogels is highly desirable.

Deer antlers are the only mammalian organ that can fully regenerate after being lost[12-14]. Antler regeneration begins with regenerative healing of the wounds left after the previous antler casting. Studies show that this regenerative wound healing depends entirely on the adjacent pedicle periosteum (PP) or the PP-derived reserve mesenchyme (RM)[15,16]. The RM cells are a type of adult mesenchymal stem cell but with some embryonic stem cell properties[12,13]. The RM-derived paracrine factors are potential candidates that stimulate cell proliferation, migration and regenerative wound healing[17]. Recently, we applied RM cells through injection to treat rat cutaneous wounds and found that the healed skin consisted of basket-wave-like collagen fibers and numerous cutaneous appendages[18], thus at least partially achieving regenerative wound healing. The ability of the RM cells to stimulate regenerative wound healing is believed to rely on paracrine factors, because the RM cells did not survive in rats for more than 14 d[18]. Subsequently, we topically applied RM-cell-conditioned medium to treat the full-thickness wounds in rats and found that outcome of the healed wounds was comparable to that of using RM cells in a regenerative manner[19]. Therefore, we speculated that the ECM hydrogels prepared from the RM tissue should have similar if not better effects, as the ECM is the secretion of RM cells. Importantly, as a novel injectable hydrogel, antler RM matrix (HARM) is simpler to apply compared to RM cells or RM cell conditioned medium, as it does not need other carrier materials. At the same time, it can also be used as a carrier material for other factors for skin injury treatment.

This study reported the effects of HARM on the healing of full-thickness cutaneous wounds in rats. HARM had a stronger potential to promote skin cell proliferation and migration compared with the hydrogels from porcine urinary bladder matrix (HPUB, as a control), resulting in better wound healing quality. We believe that the regenerative wound healing achieved using the HARM is highly likely through creating a fetal-like niche in the wound area. Thus, HARM has the potential to be developed as a treatment for regenerative wound healing in clinics.

MATERIALS AND METHODS

Preparation of HARM

The preparation of HARM is described in the previous study[5]. Briefly, three 2-branch-antlers were collected from three healthy sika deer (*Cervus nippon*) about 30 d after casting of the previous hard antler buttons in a commercial deer farm (Purchased from Dongao Deer Farm). RM tissue located in the antler growth center of each antler tip was sampled and cut into small pieces (1 mm^3) using two handheld scalpel blades and rinsed with normal saline (NS), ground in liquid nitrogen to obtain RM powder. The RM powder was further mixed with pepsin in 0.01 M HCl with the ratio of 10:1:1 (w:w:v) and the solution was kept shaking at a constant rate of 200 rpm for 48 h at 25 °C. The final pH of the resultant solution (3.0 to 4.0) was adjusted to 7.4 by adding 0.1 M NaOH to inactivate pepsin. HARM was formed when 10 × PBS was added into the solution and stored at 37 °C for 1 h (Supplementary Figure 1A). The predetermined concentration of the hydrogels was made by adding cool 1 × PBS (4 °C). HPUB, a previously reported ECM hydrogel[20], was prepared by the same procedure as HARM.

Surface morphology of the hydrogels was visualized using a scanning electron microscope (SEM, JEO JSM-5600LV, Japan) at a voltage of 10 kV. Lyophilized-HARM (Supplementary Figure 1B) were sputter-coated with a thin layer of gold before observation.

Two-dimensional cell culture

The cell lines of human umbilical vein endothelial cells (HUVEC) and NIH 3T3 fibroblasts were cryopreserved in our laboratory. The mouse adipose mesenchymal stem cells (ADSC) and bone marrow mesenchymal stem cells (BMSC) were obtained from Prof. Yimin Wang of China-Japan Union Hospital of Jilin University. The cells were expanded in DMEM media supplemented with 10% FBS and 1% penicillin-streptomycin in an incubator at 37°C, 5% CO_2.

3D cell culture and related assays

Hydrogels were sterilized with UV for 30 min; then cells (1 × 10^5/mL) were mixed into the hydrogels and seeded in 96-well plates incubated at 37 °C with 5% CO_2 for 30 min. The growth medium was then added to each hydrogel and changed every 2 d. The related cells (HUVEC, NIH 3T3, ADSC, BMSC, ADSC, and BMSC) and assays were listed in Table 1.

Creation and treatment of full-thickness wounds in a rat model

Thirty 8-wk-old female SD rats (200-220 g/rat) were purchased from Liaoning Changsheng Biotechnology Co., Ltd. (Liaoning, China) and were raised under standard laboratory animal feeding conditions. All the rats received humane care, and all study protocols and procedures were approved by the Animal Ethics Committee of Changchun Sci-Tech University (Approval No. CKARI2020012). For skin wounding, rats were anesthetized with 3% pentobarbital sodium (30 mg/kg), and then the hair was removed from the area to be operated (dorsal surface). A 12-mm diameter skin biopsy punch was used to cut the full-thickness skin and make wounds.

The model rats were randomly divided into three groups (HARM, HPUB, and PBS), with each group having 10 rats. HARM was diluted with cold 1 × PBS to the final concentration of 20 μg/mL before use. HARM was administered *via* injection around the wound margins (25 μL/injection × 4 injections) together with topical application over each wound (100 μL/wound) once every 5 d in the first 15 d, thereafter *via* local injection (100 μL) only in the remaining 15 d. The wound healing status was photographed every 5 d and the healing area was calculated using Image-Pro Plus software. PBS solution and HPUB were used as negative control (N-CTRL) and positive control (P-CTRL), respectively. The healed tissues were collected on 15 d post wounding (DPW) and 30 DPW respectively, and each tissue sample was divided into two halves: (1) For protein and RNA extraction; and (2) fixed in 4% paraformaldehyde for histological examination.

Histology

Healed skin tissue was embedded in paraffin and sliced into 5 μm sections. The sections were stained with hematoxylin and eosin (HE), Masson, or immunofluorescence (IF). All antibodies used in IF were listed in Supplementary Table 1. Sections stained with HE and Masson were photographed using the Digital Imaging Scanning System (Precipoint M8; Freising, Germany); and stained with IF and photographed using Fluorescence Microscopes (BX63, Olympus, Japan). The collagen fibers (blue area on micrograph) in Masson staining and the positive expression (fluorescence area on microphage) of the target genes in IF staining were analyzed statistically using Image-Pro Plus software; then the ratio of the target area to the whole area was calculated.

RNA isolation and quantitative real time PCR

Trizol reagent (Sigma-Aldrich, United States) was used for total RNA isolation from the healed skin tissue samples. cDNA was prepared *via* reverse transcription of RNA. cDNA, primers (Supplementary Table 2) and SYBR premix (Roche, Basel, Switzerland) were mixed on quantitative real time PCR (qRT-PCR) using the qTOWER ^{3}G (Analykit Jena AG, Jena, Germany). Results of mRNA quantification were normalized against GAPDH and calculated using the $^{\Delta\Delta}$Ct method. Every experiment was repeated three times.

Western blot

Total proteins were isolated from the healed tissues: 20 μg of total protein was separated *via* polyacrylamide SDS gel and then transferred to a polyvinylidene fluoride membrane (Millipore, MA). After blocking in 5 % (w/v) non-fat milk, the membrane was first incubated with primary antibodies (Engrailed 1, Bioss; GAPDH, ProteinTech) at 4 °C overnight and

then with HRP-conjugated secondary antibody at 25 °C for 2 h. The bands were visualized using an ECL system and quantified using Image J software.

Statistical analysis

Results were expressed as mean ± SEM. Multi-comparisons were made using ANOVA in the package of GraphPad Prism 9.0. Significant differences were evaluated using *t*-test and one-way ANOVA. The difference was considered statistically significant ($^{a}P < 0.05$), or highly significant ($^{b}P < 0.01$, or $^{c}P < 0.001$).

RESULTS

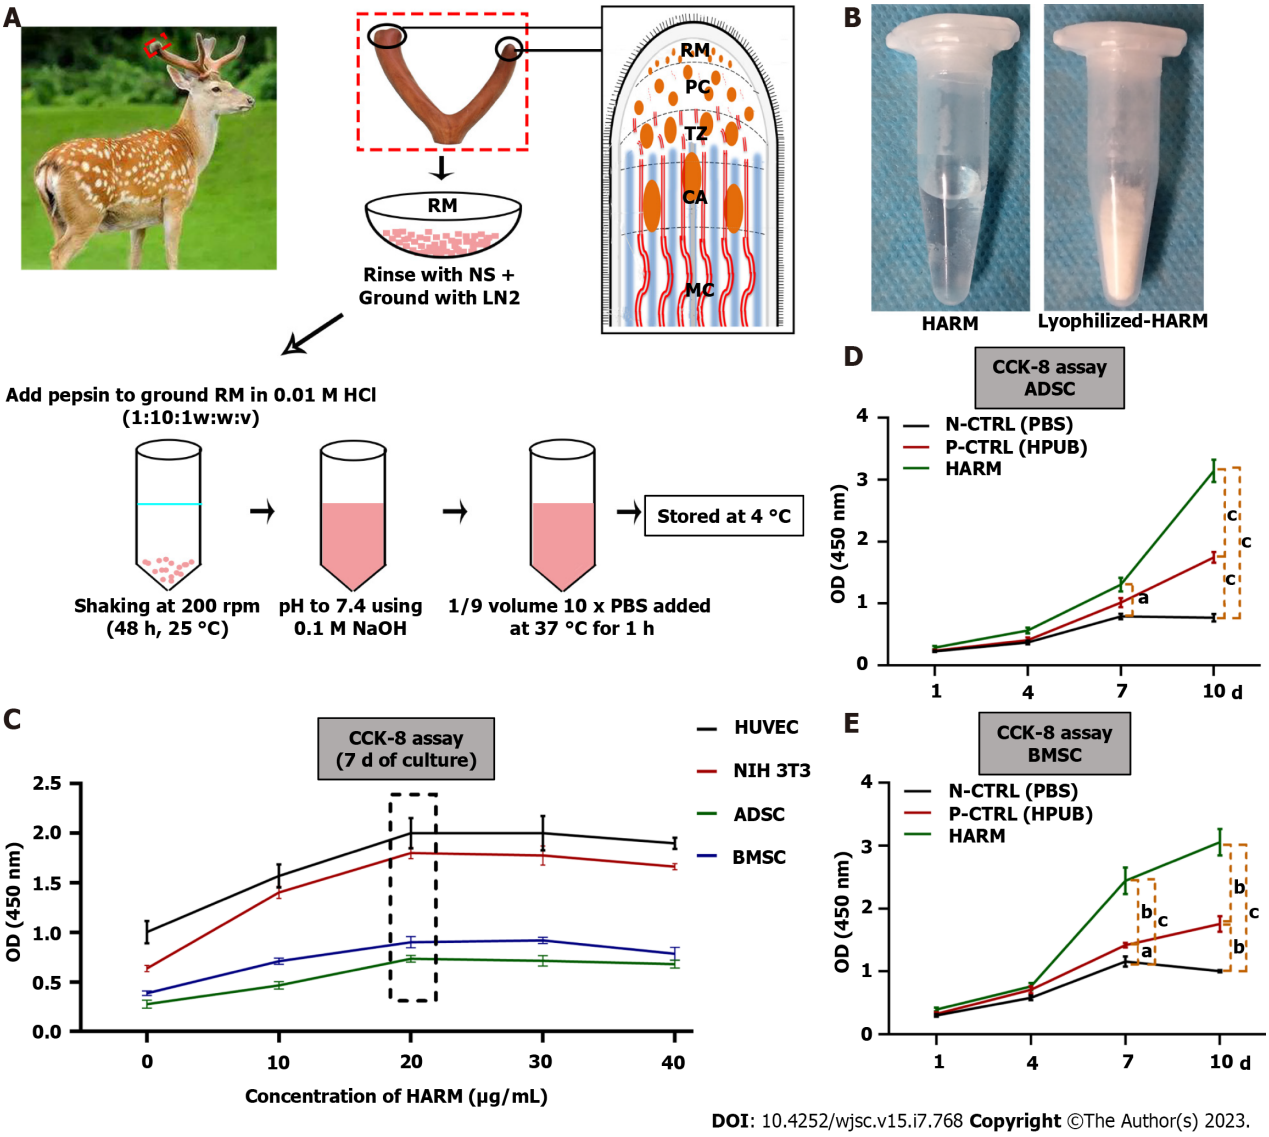
Characterization of HARM

We prepared HARMs (Figure 1A), which had typical gel properties (Figure 1B; Supplementary Figure 1). The effects of HARM on cell proliferation were evaluated *in vitro*. Firstly, the optimum concentration of HARM was determined based on cell proliferation rates. The results showed that proliferation rates of HUVEC, NIH 3T3, ADSC, and BMSC cultured in the medium containing 20 μg/mL HARM all reached their peaks across the concentration range from 0 to 40 μg/mL 7 d after culture (Figure 1C). Further, the proliferation rate of ADSC cultured in 20 μg/mL HARM was significantly higher than in N-CTRL ($P < 0.05$; Figure 1D), and that of BMSC cultured in 20 μg/mL HARM was significantly higher than N-CTRL and P-CTRL ($P < 0.001$; Figure 1E). The differences in cell proliferation rate between cells cultured in HARM and those cultured in N-CTRL or P-CTRL were increased at 10 d after further culture. These results suggest that HARM has great potential to stimulate cell proliferation *in vitro*.

HARM accelerates wound healing rate

To determine the effects of HARM on the rate and quality of cutaneous wound healing, HARM (20 μg/mL) was used to treat full-thickness skin wounds in rats (Figure 2A). The results showed that the areas of the wound in the HARM group were significantly smaller than those in the N-CTRL and P-CTRL groups ($P < 0.001$; Figure 2B and C) on 5 or 10 DPW; wound healing in the HARM group was completed on 20 DPW, but those in N-CTRL and P-CTRL groups were not completed until 30 DPW. These results suggest that HARM can effectively accelerate wound healing rate in the full-thickness skin wounds in rats.

HARM improves the quality of wound healing



Quality of wound healing was examined at histological level. The results showed significantly more appendages in the HARM group than in the N-CTRL or P-CTRL groups ($P < 0.001$; Figure 3A and B). The collagen fibers of healed skin in the HARM group were fewer and thinner than those in the N-CTRL group ($P < 0.001$; Figure 3A and C) on 15 DPW; moreover, the collagen fibers in the HARM group consisted of basket-wave-like collagens, which were drastically different from the thick-bundle-like collagens in the N-CTRL and P-CTRL groups. Likewise, healed skin in the HARM group on 30 DPW was similar to that in the N-CTRL and P-CTRL groups ($P < 0.01$; Figure 3A, D, and E). The expression levels of CD31 (the surface marker of neovascular endothelial cells[21]) and Ki67 (the marker of cell proliferation and division[22]) in the HARM group were significantly more than those in the N-CTRL or P-CTRL groups both on 15 DPW and 30 DPW (CD31: $P < 0.001$; Figure 3F-H); Ki67: ($P < 0.001$; Supplementary Figure 2). Overall, the results suggest that the HARM treatment can effectively improve the quality of wound healing in rats, and the effects are even better than the HPUB treatment.

HARM promotes the expression of fetal wound healing-related genes in rats

The expression levels of IL10 and TGFβ3, the fetal wound healing-related genes[23,24] were detected in the healed tissues. The results showed that expression levels of IL-10 and TGFβ3 in the healed skin of the HARM group were significantly higher than in those of the N-CTRL or P-CTRL groups on 15 DPW ($P < 0.001$; Figure 4A-C). Likewise, on 30 DPW, these gene expressions had a similar trend to those on 15 DPW ($P < 0.01$; Figure 4A-C). We further evaluated the status of expression of some other fetal wound healing-related genes using qRT-PCR. The results showed that the healed skin of the HARM group favored expression of fetal wound healing genes including collagen III (15 DPW: $P < 0.001$, $P < 0.001$; 30 DPW: $P < 0.01$, $P < 0.01$) and TGFβ3 (15 DPW: $P < 0.01$, $P < 0.01$; 30 DPW: $P < 0.001$, $P < 0.001$); but did not favor expression of scar healing genes including collagen I (15 DPW: $P < 0.01$, $P < 0.05$; 30 DPW: $P < 0.001$, $P < 0.01$) and TGFβ1 (15 DPW: $P < 0.01$, $P < 0.01$) when compared with those in the N-CTRL and P-CTRL groups to varying degrees (Figure 4D, E, G and H). The ratios of collagen III to collagen I and TGFβ3 to TGFβ1 in the healed tissue of the HARM group were all significantly higher than in those of N-CTRL or P-CTRL groups ($P < 0.05$; Figure 4F and I). Furthermore, the expression of Engrailed 1, activated in adult wound healing and prevented in fetal wound healing[25], was also down-regulated with the HARM treatment in the healed tissues (Figure 4J and K). These results suggest that HARM promotes regenerative wound healing which may be achieved *via* creating a fetal-like wound healing niche.

HARM promotes stem cell recruitment and/or plasticity maintenance

Next, the effects of the fetal-like wound healing niche created by HARM on recruitment of stem cells and maintenance of plasticity were detected. IF staining results showed that healed skin of the HARM group expressed significantly higher CD73 and CD90 than that of the N-CTRL or P-CTRL groups ($P < 0.01$, $P < 0.001$; Figure 5A-C) on 15 DPW. Likewise, on 30 DPW, a similar expression trend was observed as on 15 DPW ($P < 0.001$; Figure 5A, D and E). These results suggest that

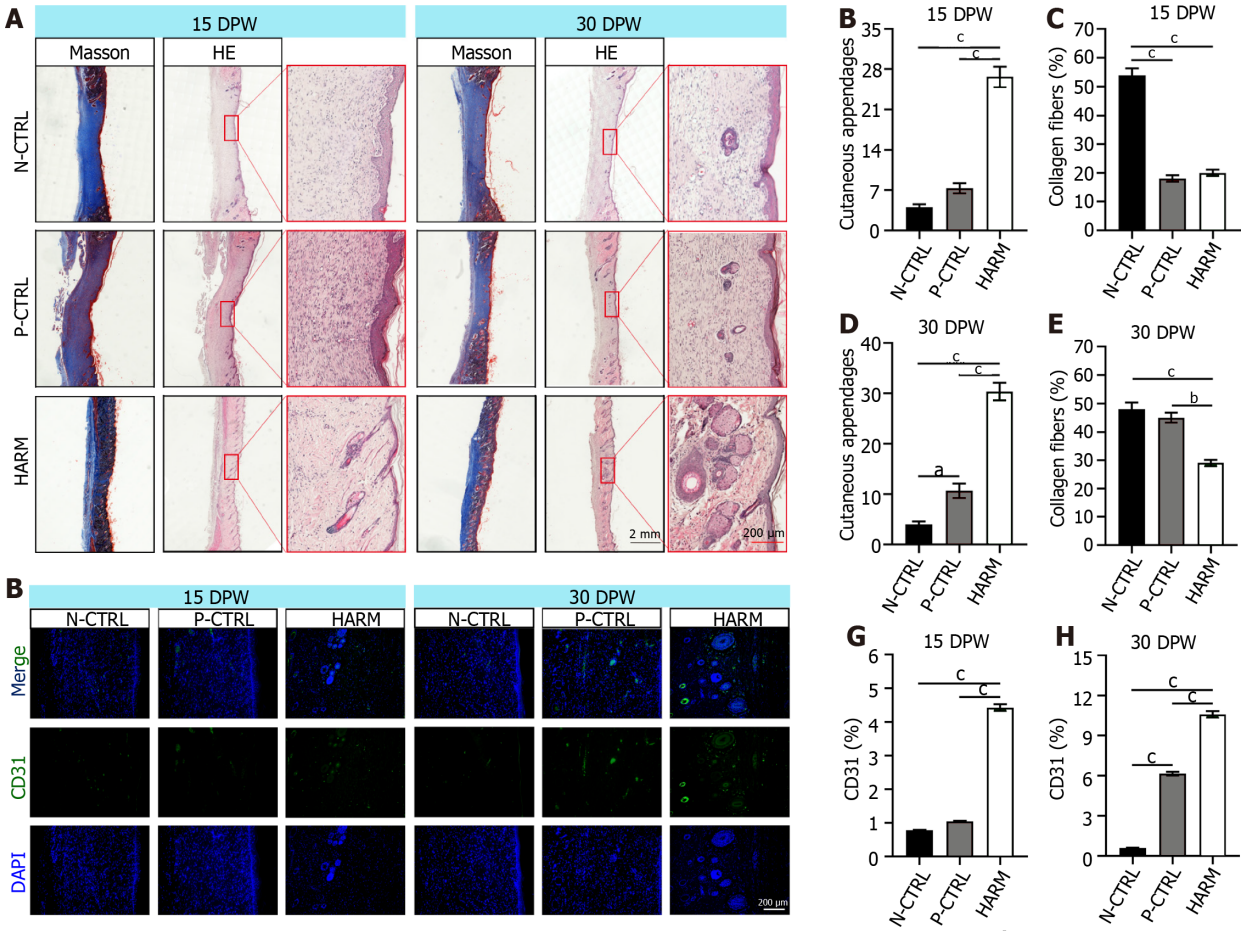
HARM may promote recruitment of stem cells or maintenance of plasticity which grows in the fetal-like wounding healing niche.

DISCUSSION

Scarring in wound healing is still a challenge in the clinic, where the goal is regeneration. The regeneration of functional cutaneous appendages and organized collagen is a complex process involving multiple factors and cells related to the microenvironment. Keeping the cells that regenerate the injured tissues in the optimum environment may be a practical approach to induce cutaneous regeneration and prevent abnormal scar formation. Although many approaches, such as synthetic hydrogels or ECM hydrogels, have been evaluated to improve the environment during wound healing, the outcomes have been unsatisfactory. This study is the first to report the role of an acellular ECM hydrogel prepared from stem cell tissue (antler RM) in cutaneous wound healing. Through a full-thickness rat model, we found that HARM improved the regeneration of cutaneous appendages and blood vessels and reduced the aggregation of disorganized

A: Experimental procedure; B: Macroscopically observation of the wound healing status; C: Quantification of the wound area using the Image J software according to macroscopical images. Note that the fastest wound healing rate and the smallest scar area were observed in the hydrogels from the antler reserve mesenchyme group. DPW: Days post-wounding; HARM: Hydrogels derived from antler reserve mesenchyme; N-CTRL: Negative control; P-CTRL: Positive control. Mean ± SEM; statistical significance set at $^{a}P < 0.05$, $^{c}P < 0.001$.



collagen fiber, which may be achieved *via* creating a fetal-like niche at the wound site.

Injectable hydrogels, as a promising strategy, are being used with increasing frequency for the treatment of wound healing. They have several desirable features, including targeted delivery by minimally invasive techniques, ability to fill an irregularly shaped space quickly, and polymerization to form a support structure suitable for host cell infiltration and remodeling[26]. The injectable hydrogels derived from naturally occurring biologic materials are claimed to possess superior biocompatibility and bioactivity compared to their synthetic counterparts, which are usually composed of the ECM of decellularized tissues, and can be partially digested with pepsin, solubilized, and polymerized in situ to form a hydrogel[20,27,28]. Intact ECM hydrogels retain numerous molecular constituents found in the native tissue, such as cell adhesion proteins and growth factors, and these hydrogels support a constructive, site appropriate, remodeling response when implanted in a variety of anatomical sites[29]. It is possible that a hydrogel formed from enzymatically degraded and solubilized ECM may maintain some of the biological activity found in the intact ECM. ECM hydrogels have been prepared from various tissues, including urinary bladder[20], dermis[27], cardiac tissues[28], adipose tissue[30], small intestine[31], and skeletal muscle[32]. The hydrogels derived from these tissue types differ in their composition and activity. However, a common problem is the lack of practical factors to stimulate tissue regeneration/repair, although they do induce a certain level of repair on tissue injury. Therefore, selecting suitable tissue for ECM hydrogel preparation is essential, especially if the tissue is rich in regeneration-stimulated factors; a tissue suitable for stem cell survival may be suitable and advantageous. In the annual regeneration of deer antlers, the RM tissue layer in the growth center is responsible for the growth of deer antlers with a growth rate of up to 2.75 cm/d[33]. RM-derived cells have the character-

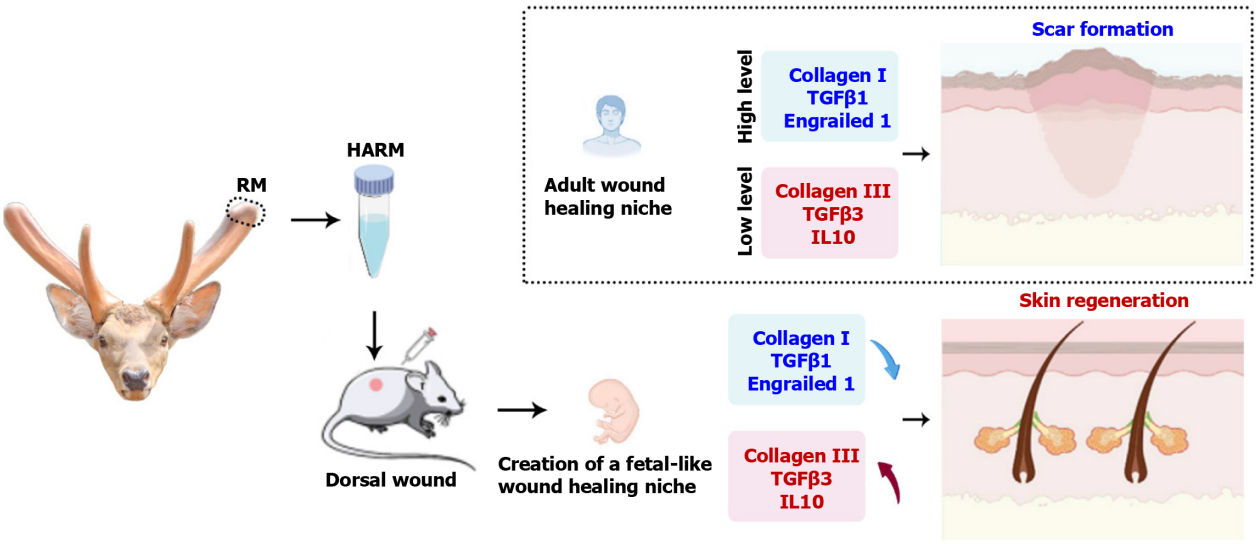
Figure 4 Effects of hydrogels from the antler reserve mesenchyme on the expression of typical genes related to fetal wound healing in healed skin of rat wounds. A: IL 10 and TGFβ3 immunofluorescence staining; B and C: Expression percentages of IL-10 and TGFβ3; D-I: mRNA expression levels of collagen III (D), collagen I (E), TGFβ3 (G), and TGFβ1 (H) *via* quantitative real time PCR assay; the ratios of collagen III/collagen I and TGFβ3/TGFβ1 (F and I); J and K: Protein expression of Engrailed 1 in the healed skin *via* Western blot assay. Note that hydrogels from the antler reserve mesenchyme up-regulated the expression levels of IL10, TGFβ3, and collagen III; but down-regulated the expression levels of collagen I, TGFβ1, and Engrailed 1. IL 10: Interleukin 10; TGFβ1: Transforming growth factor β1; TGFβ3: Transforming growth factor β3; DPW: Days post-wounding; HARM: Hydrogels derived from antler reserve mesenchyme; N-CTRL: Negative control; P-CTRL: Positive control. $n = 3$; mean ± SEM; statistical significance set at $^{a}P < 0.05$, $^{b}P < 0.01$, $^{c}P < 0.001$.



human body temperature; Supplementary Figure 1A). This is clinically important since the biomaterial as a solution can be used in the injection method and quickly reach a gel state that protects the integrity of the tissue and allows for native cells to adhere and grow. Importantly, HARM exhibits pores on the order of 100 μm (Supplementary Figure 1), providing an ideal space for cell division and proliferation. Further, we found that the concentration of 20 μg/mL HARM showed the strongest stimulation over the other concentrations on the proliferation rate of HUVEC, NIH 3T3, ADSC, and BMSC; moreover, proliferation rates of ADSC and BMSC cultured in HARM *in vitro* and cutaneous cells treated with HARM *in vivo* were both stronger than the previously reported hydrogel, HPUB. In general, our results demonstrated the advantage of HARM for cell proliferation, which is essential for reconstructing the lamellar stromal structure using acellular biomaterial.

A: CD73 and CD90 immunofluorescence staining; B and C: Expression percentages of CD73 and CD90 on 15 DPW; D and E: Expression percentages of CD73 and CD90 on 30 DPW. Note that the HARM group had the highest percent of CD73 and CD90 compared to the other two groups. DPW: Days post-wounding; HARM: Hydrogels derived from antler reserve mesenchyme; N-CTRL: Negative control; P-CTRL: Positive control. n = 3; mean ± SEM; statistically significant at $^{b}P < 0.01$, $^{c}P < 0.001$.

Based on the above characteristics of HARM, we used the full-thickness rat wound to evaluate the effects of HARM on wound healing. As expected, HARM effectively promoted the healing rate and improved the healing quality; these effects were better overall than the HPUB. To the best of our knowledge, this is the first report that a hydrogel derived from a tissue matrix can promote not only the healing rate but also healing quality. However, hydrogels from other tissue matrices can only promote wound healing[34,35]. The microenvironment of wound healing has been reported to be critical in influencing the type of healing. An ideal microenvironment, such as fetal wound healing, results in scarless regenerative healing; a normal microenvironment, such as adult wound healing, results in scarring[23,24]. There are many differences between fetal and adult wound healing, such as inflammatory reactions, growth factors and collagen synthesis[23,24]. It has been reported that IL10 expression is up-regulated in fetal wounds without scars, and wound healing occurs with scar formation in fetal mice with IL-10 deficiency. However, in clinical trials by intradermal injection of recombinant human IL-10 into the wound edge for 1 mo, IL-10 treatment reduced scar formation[36]. In the present study, we found that the expression of IL10 was increased in the healed tissues that had been treated with HARM. TGFβ, including TGFβ1, TGFβ2, and TGFβ3, signals are required for wound repair and regeneration. TGFβ1 causes scar formation after skin injury; on the contrary, TGFβ3 has an anti-fibrotic effect because the ratio of TGFβ3/TGFβ1 in fetal wounds was found to be higher than that in adults[36-38]. We also found that TGFβ3 was increased by HARM in the wound, while TGFβ1 was the opposite. Fetal wound healing differs from adult wound healing in collagen synthesis in terms of the speed of deposition, variation in collagen type ratios, and quantity of collagen. Most striking is the persistence of excess collagen III over collagen I, with healed wounds in the fetus; higher levels of collagen III yield smaller, reticular structures with more cross-linking than collagen I and contribute toward scarless wound healing. In the present study, we found that collagen III was increased by HARM in the wound, while TGFβ1 was the opposite. Engrailed 1 is another typical gene that is activated in adult wound healing, and preventing the activation would inhibit the scarring and achieve fetal-like wound healing[25]. This gene was also down-regulated with HARM treatment in the healed tissues. Above all, the HARM treatment favored expressions of fetal wound healing genes, including IL10, collagen III, and TGFβ3; but did not favor expression of scar healing genes, including collagen IS, TGFβ1, and Engrailed 1,

Figure 6 Hydrogels from the antler reserve mesenchyme promoted regenerative wound healing *via* creating a fetal-like niche. FMT inhibition. hydrogels from the antler reserve mesenchyme up-regulated the expression levels of fetal wound healing-related genes [interleukin 10, transforming growth factor β3 (TGFβ3), and collagen III]; but down-regulated the expression levels of adult wound healing-related genes (collagen I, TGFβ1, and Engrailed 1). HARM: Hydrogels derived from antler reserve mesenchyme; IL 10: Interleukin 10; TGF: Transforming growth factor.

in the healed tissues. Thus, we speculate that the effects of HARM on regenerative wound healing may be achieved *via* creating a fetal-like niche.

CONCLUSION

This study prepared a new injectable hydrogel using a stem cell tissue matrix, the antler reserve mesenchymal matrix. The therapeutic effects of the hydrogels were evaluated using full-thickness rats. The results revealed that the hydrogels effectively increased the healing rate and improved the healing quality of the wound, including regeneration of the cutaneous appendages and formation of the basketweave-like pattern of collagens. Further study showed that these effects of the hydrogels were likely achieved through creating a niche similar to the regeneration of fetal skin, thereby promoting skin regeneration without scars (Figure 6). Overall, we believe that our prepared hydrogels may have clinical benefits for stimulating regenerative wound healing, especially those large cutaneous wounds caused by burns, scalds, or machinery.

ARTICLE HIGHLIGHTS

Research perspectives

It believes that hydrogels from the antler reserve mesenchyme matrix (HARM) may have clinical benefits for stimulating regenerative wound healing, especially those large cutaneous wounds caused by burns, scalds, or machinery.

Research conclusions

This study prepared a new injectable hydrogel from antler reserve mesenchyme (RM) for regenerative wound healing *via* creating a fetal-like niche.

Research results

HARM was successfully prepared from antler RM. Through a full-thickness rat model, it was found that HARM improved the regeneration of cutaneous appendages and blood vessels and reduced the aggregation of disorganized collagen fiber, which may be achieved *via* creating a fetal-like niche at the wound site.

Research methods

The HARM was prepared *via* enzymatic solubilization with pepsin. Then the therapeutic effects of HARM on a full-thickness cutaneous wound healing rat mode were investigated.

Research objectives

To develop an injectable hydrogel made from antler RM matrix for the regenerative repair of full-thickness cutaneous wounds, which may have clinical benefits for stimulating regenerative wound healing, especially those large cutaneous wounds caused by burns, scalds, or machinery.

Research motivation

Deer antlers are the only mammalian organ that can fully regenerate after being lost. Antler regeneration begins with regenerative healing of the wounds left after the previous antler casting. Studies show that this regenerative wound healing depends entirely on the adjacent pedicle periosteum (PP) or the PP-derived RM.

Research background

Scarring in wound healing is still a challenge in the clinic, where the goal is regeneration. Keeping the cells that regenerate the injured tissues in the optimum environment may be a practical approach to induce cutaneous regeneration and prevent abnormal scar formation. Although many approaches, such as synthetic hydrogels or extracellular matrix hydrogels, have been evaluated to improve the environment during wound healing, the outcomes have been unsatisfactory.

ACKNOWLEDGEMENTS

We thank Dr. Peter Fennessy for his critical reading through the manuscript and valuable suggestions.

ABOUT COVER

Editor-in-Chief of *World Journal of Stem Cells*, Shengwen Calvin Li, BSc, MPhil, PhD, EIC, FRSM, FRSB, Children's Hospital of Orange County Children's Research Institute, Children's Hospital of Orange County, University of California-Irvine School of Medicine, Orange, CA 92868-3874, United States. shengwel@hs.uci.edu

AIMS AND SCOPE

The primary aim of *World Journal of Stem Cells* (*WJSC*, *World J Stem Cells*) is to provide scholars and readers from various fields of stem cells with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJSC* publishes articles reporting research results obtained in the field of stem cell biology and regenerative medicine, related to the wide range of stem cells including embryonic stem cells, germline stem cells, tissue-specific stem cells, adult stem cells, mesenchymal stromal cells, induced pluripotent stem cells, embryonal carcinoma stem cells, hemangioblasts, lymphoid progenitor cells, *etc*.

INDEXING/ABSTRACTING

The *WJSC* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Journal Citation Reports/Science Edition, PubMed, PubMed Central, Scopus, Biological Abstracts, BIOSIS Previews, Reference Citation Analysis, China National Knowledge Infrastructure, China Science and Technology Journal Database, and Superstar Journals Database. The 2023 Edition of Journal Citation Reports® cites the 2022 impact factor (IF) for *WJSC* as 4.1; IF without journal self cites: 3.9; 5-year IF: 4.5; Journal Citation Indicator: 0.53; Ranking: 15 among 29 journals in cell and tissue engineering; Quartile category: Q3; Ranking: 99 among 191 journals in cell biology; and Quartile category: Q3. The *WJSC*'s CiteScore for 2022 is 8.0 and Scopus CiteScore rank 2022: Histology is 9/57; Genetics is 68/325; Genetics (clinical) is 19/90; Molecular Biology is 119/380; Cell Biology is 95/274.

Abstract

The art of constructing an insightful literature review manuscript has witnessed an exemplar in the work of Oz *et al* (2023), wherein concept progression harmoniously merges with figures and tables. Reflecting on retrospective data science, it is evident that well-cited articles can wield a transformative influence on the Journal Citation Reports Impact Factor score, as exemplified by Robert Weinberg's landmark on cancer (Hanahan and Weinberg, 2011). Here, we aim to spotlight a commendable contribution by Tuba Oz, Ajeet Kaushik, and Małgorzata Kujawska in this issue while pivoting towards identifying the hallmarks of a subpar literature review-elements that hinder rather than promote advancement. The hurdles and roadblocks encountered within subpar literature reviews are multifold. Anticipation of emerging trends, identification of challenges, and exploration of solutions remain conspicuously absent. Original Contributions fail to surface amidst the vast sea of pre-existing literature, with noticeable gaps amplified by the lack of illustrative figures and tables. The manuscript, at times, assumes a skeletal form, reflecting an attempt to accommodate an excess of references, leading to convoluted sentences laden with citations. In contrast, a potent solution lies in adopting a comprehensive approach. A nuanced and critical evaluation of sources can culminate in a robust discussion, surpassing the mere summarization of conclusions drawn by others. This approach, often dismissed, holds the potential to elevate clarity, coherence, and logical flow, ultimately inviting engaged readership and coveted citations. The critical necessity of integrating visionary insights is underscored and achieved through a rigorous analysis of pivotal concepts and innovative ideas. Examples can be harnessed to elucidate the application of these solutions. We advocate a paradigm shift, urging literature review writers to embrace the readers' perspective. A literature review's purpose extends beyond providing a comprehensive panorama; it should illuminate avenues for concept development

within a specific field of interest. By achieving this balance, literature reviews stand to captivate a devoted readership, paving the way for manuscripts that are both widely read and frequently cited. The pathway forward requires a fusion of astute analysis and visionary insights, shaping the future of literature review composition.

Key Words: Literature review; Concept progression; Data science; Journal Citation Reports Impact Factor; Original contributions; Comprehensive approach; Clarity and coherence; Visionary insights; Reader engagement; Concept development

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: This manuscript highlights a remarkable literature review, demonstrating a seamless fusion of concept progression with figures and tables. Reflecting on data science, it reveals how influential articles can impact the Journal Citation Report Impact Factor. We focus on identifying elements hindering effective literature reviews. Key challenges include absent trend anticipation, gaps in original contributions, and skeletal content. To address this, we propose a comprehensive approach involving critical evaluation, fostering clarity, coherence, and reader engagement. Integration of visionary insights and examples further enhances the impact, emphasizing the importance of concept development and paving the way for influential literature reviews.

INTRODUCTION

As an editor-in-chief and academic editor, I have not read an insightful literature review until now[1], which came with concept progression well illustrated in figures and tables. Second, retrospective data science revealed a few well-cited articles elevated a Journal Citation Reports Impact Factor score tremendously, *e.g.*, the hallmarks of Cancer by Robert Weinberg, accumulating 69346 citations[2]. Thus, I would like to point out a good one in this issue by Tuba Oz, Ajeet Kaushik, and Małgorzata Kujawska, which might help extrapolate some elements from their writing. However, rather than talk about good elements, I wanted to illustrate the list of inferior elements: The elements that construct a sub-standard literature review, as my conviction was that spotting roadblocks and putting forth measures to tackle those help take success to a higher level.

HURDLES AND ROADBLOCKS

The manuscript text lacked anticipation of any trends, failed to identify or provide answers to particular challenges or problems, and did not identify any leading problems or exceptional opportunities in the sub-field. Given the abundance of existing literature in the field, no original contributions were apparent in the content. Additionally, there seemed to be general gaps in the material, particularly evident in the absence of figures and tables.

Certain sections of the text appeared to be very sketchy, giving the impression that the manuscript was significantly cut down to include over 100 references, and specific sentences crowded cited up to 10 references in one phrase without details on what was about each reference. Instead of merely describing conclusions drawn by other authors, *i.e.*, regurgitating the known facts and data, the authors did not propose their insightful themes based on updating the article by engaging in a more thorough analysis of key concepts and ideas to explore uncharted water, by asking new questions and offering innovative speculations.

The final obstacle in our pursuit was intricately related to the meticulous referencing of the primary data articles. It went beyond the straightforward act of merely acknowledging the sources; it encompassed the intricate task of accurately framing distinct data sets and explicitly attributing terminologies to their original sources. This presented a distinct challenge: The emergence of crowd-group-article citing, where up to seven citations were amalgamated within a single sentence or even a solitary phrase.

CIRCUMVENTING HURDLES IN THE ROAD LEADS TO WELL-READ AND FREQUENTLY-CITED MANUSCRIPTS IN A LITERATURE REVIEW

This flush-out thinking would involve drawing on a range of relevant sources to produce a detailed and insightful discussion. Such critical analysis would be preferable to the alternative of simply summarizing the conclusions drawn by

others. If addressed, all the above elements, particularly the visionary element, might lead to better clarity, coherence, and logical flow, which earns readership and citations. I could illustrate how to overcome these hurdles with examples. My conviction: Advancements in literature review manuscripts require vision, foresight, assiduity, tenacity, determination, and the unwavering courage to go where others fear and hesitate. Why not? Why not consider the unimaginable? It is often claimed that success comprises 99% hard work and 1% inspiration: Both are essential, and neither is a minus.

"Imagination is far more important than knowledge". These profound words, which sprang from the mind of a genius named Albert Einstein, reverberate through the halls of time, lighting a flame of inspiration that guides us beyond the limitations of what we know. Einstein tells us that the power of imagination is the lighthouse that lights up new horizons, which is a crucial point to remember in a society where facts and data often take center stage.

Consider the following: Every spectacular discovery, every extraordinary creation, and every creative leap began in the limitless world of the human imagination. Knowledge provides us with the instruments to comprehend, but imagination gives us the wings to transcend. Such a wing's power propels us sky-high to bird-view unexplored territory and invites us to dance on the edge of the known while welcoming us to embrace the mysteries that lie beyond.

Then there are inquiries, which are unassuming yet powerful forces that propel forward-growth. "Asking questions is more important than knowledge", remarked Albert Einstein. How accurately this is said! The very act of questioning, of attempting to understand the complexities of the cosmos, is a declaration of both our intrinsic curiosity and our unyielding willpower to learn more. Questions kindle the flame of discovery, taking us down roads we've never traveled before and opening the door to worlds we would never have imagined were possible.

Imagine a world in which people simply accepted what they already knew without any attempt to learn more or to satisfy their natural curiosity. In such a world, there would be no development or invention, and people would just sit about doing nothing productive. But we are not content to live in that reality because we are driven by an insatiable appetite to learn more, to understand better, and to elevate ourselves beyond the confines of the present. This hunger compels us to seek out new information and new perspectives.

The words of Albert Einstein are a tribute to the reality that knowledge is a basis but that imagination and inquiry are the wings that propel us to new heights. Knowledge is a foundation. Therefore, let us not be afraid to fantasize beyond the bounds of what is already known. Let us use the power of imagination to conceive of worlds that have not yet been seen and possibilities that have not yet been investigated. And let us never stop asking questions; for by doing so, we create the path for a future that is brighter, bolder, and bursting with the grandeur of human potential. Let us never stop asking questions.

Along the line of referencing, the challenge was not only ensuring accurate citations but also preserving the content's clarity and flow. The risk of overwhelming the reader with an excess of citations was ever-present, demanding a judicious selection process. Each citation had to be carefully evaluated for its relevance and its ability to enhance the understanding of the topic under discussion. Navigating this obstacle required a delicate balance between comprehensive acknowledgment and maintaining the coherence of the narrative. It necessitated the establishment of a coherent thread that seamlessly interwove the multitude of sources while upholding the integrity of the information presented. The complexity lay in recognizing that each citation represented a distinct facet of the overarching concept, contributing a unique perspective to the discourse. It necessitated precision in language, strategic distribution of citations, and a steadfast commitment to maintaining clarity. This intricate dance between referencing and readability was a testament to our dedication to scholarly rigor while delivering information in a manner that was accessible and engaging to our audience. Through this process, we not only conquered the hurdle of crowd-group citing but also upheld the standards of meticulous scholarship in our work.

THE EXAMPLES

The first classical example is the literature review "the hallmarks of Cancer" by Robert Weinberg and his collaborator Douglas Hanahan. They proposed six elements, including maintaining proliferative signaling, evading growth inhibitory signals, resisting programmed cell death, facilitating perpetual replication potential, inducing the formation of new blood vessels (angiogenesis), and triggering processes of cellular invasion and metastasis as the hallmarks of cancer in 2010[3], earning 41039 citations. Two underlying causes are fundamental to acquiring these hallmark traits: Genomic instability, which drives the rapid accumulation of genetic variants, and inflammation, which supports several hallmark activities. Beyond the boundaries of the cancer cells themselves, tumors add another level of complexity due to the presence of a group of cells that, on the surface, appear normal but are actually recruited to help the tumor develop its distinctive traits. This environment is known as the "tumor microenvironment". It is hoped that acknowledging these concepts' broad applicability would substantially impact the development of cutting-edge methods for battling human cancer.

Over the past ten years, there has been a remarkable surge of innovation in our understanding of fundamental concepts beyond the original six-element hallmarks. This period of intellectual evolution has unveiled a pair of promising new frontiers that hold the key to widespread applicability. These cutting-edge developments, akin to beacons illuminating uncharted territory, encompass the manipulation of energy metabolism and the art of outwitting the immune system's defenses, resulting in eight hallmarks of Cancer by Robert Weinberg, accumulating 69346 citations[2].

The canvas of knowledge has been enriched by an exciting brushstroke, as reprogramming the intricate dance of energy within cells emerges as a captivating endeavor. Imagine orchestrating a symphony within the microscopic realm, fine-tuning the metabolic pathways that govern life's essence as spatiotemporal regulation[4]. This spatial omics biology endeavor promises not only to enhance our ability to engineer solutions to a spectrum of challenges but also to unlock the potential for revitalizing weary cells, paving the way for novel therapies and rejuvenation.

In parallel, we witness a daring expedition into the realm of immune evasion-a pursuit that mirrors the cunning strategies of spies and adventurers. Just as an artful rogue slips through the clutches of pursuers, scientists are unraveling the enigmatic mechanisms that allow specific cells to evade the immune system's watchful eye, in particular, Carl June's invention of chimeric antigen receptor T cells immunotherapy (5702 citations)[5] in a designer fashion[6]. This tantalizing avenue opens avenues to fortifying our defenses against diseases, enabling medical interventions to bypass the barricades that often hinder treatment progress.

Together, these eight emergent pillars of insight symbolize a profound transformation in our comprehension of cancer's intricate dance. They beckon us to a landscape where creativity interlaces with knowledge, inviting us to craft innovative solutions, reinvigorate cellular vitality, and conquer challenges once deemed insurmountable. As we embark on this exhilarating voyage of discovery, the horizons of possibility stretch ever wider, promising a future enriched by the fusion of imagination and scientific achievement. All of the above visional elements earned 69346 citations, much higher than their previous 2000's article, which had 41039 citations on August 7, 2023, reflecting the conceptual development that attracts the increased readership.

The second example of a highly specialized and small domain is my own research to illustrate some visional elements by proposing new terminologies. We applied a new method that has been well used (1207 citations)[7]. We presented two new terminologies, the caveolin scaffolding domain (CSD) (969 citations)[8] and the CSD binding motif (CBM) (1129 citations)[9]. Both CSD and CBM have been well studied, which led to assistance to therapeutic development like albumin-bound (nab) paclitaxel (nab-paclitaxel; Abraxane), a $2.9 billion platform of cancer drug delivery by Patrick Soon-Shiong[10]. They further found that elevated levels of CAV1/2 expression are linked to poorer disease-free survival (DFS) and overall survival (OS) outcomes among individuals treated with paclitaxel. In contrast, among patients treated with nab-paclitaxel, heightened CAV1/2 expression appears to correlate with improved pathologic complete response rates while not imposing a significant negative impact on DFS or OS when compared to individuals with lower CAV1/2 expression levels[11]. This example manifested the conceptual development that prompted therapeutic development, followed by clinical validations.

The third approach is to propose a broad application of an envisioned technology. We hypothesized that "Hunting down the dominating subclone of cancer stem cells as a potential new therapeutic target in multiple myeloma: An artificial intelligence perspective" (16 citations)[12]. We also postulated "A biological global positioning system (bGPS): Considerations for tracking stem cell behaviors in the whole body", with eight elements to fulfill stem cell therapies (74 citations)[13]. Specifically, in response to monitoring the detrimental effects of stem cell therapies, we have outlined an all-encompassing bGPS designed to monitor the trajectory of transplanted stem cells. This system incorporates eight essential components, each meticulously tailored to ensure the efficacy of stem cell transplantation (SCT). These components encompass the following: (1) Sensitivity for single cell detection; (2) real-time positioning; (3) an inducible system; (4) retractable; (5) targeted and durable; (6) monitoring cell fate; (7) compliant with the FDA GMP guidelines for clinical applications; and (8) quantification capacity. By integrating these eight critical attributes, our proposed biological GPS not only addresses the aforementioned challenges but also provides a comprehensive framework for effectively tracking and assessing the transplanted stem cells during SCT. This holistic approach underscores our commitment to establishing a robust and clinically compliant solution that ensures the success of stem cell transplantation and holds the potential to enhance the field of regenerative medicine significantly. Future experimentation is needed to achieve the predictions.

The final approach could be to point out that some limitations exist in the current trend of studies. We pointed out that "Cancer genomic research at the crossroads: Realizing the changing genetic landscape as intratumoral spatial and temporal heterogeneity becomes a confounding factor" (44 citations)[14], thereby conjuring up hope for improvements through identifying potentials and challenges (76 citations)[15]. The manuscript led to sum up with specific solutions, such as "Control dominating subclones for managing cancer progression and posttreatment recurrence by subclonal switchboard signal: Implication for new therapies"-a key to two Nature articles and related column of "News & View" on the issue (28 citations)[16]. All of these thoughtful articles prompted the spatial and temporal intervention strategies of various diseases with the integration of machine learning models[17].

THE METRICS

We want to emphasize that while journal impact factors matter less, the impact of being cited does. An insightful remark during a prestigious award presentation caught attention: Physicists with 2000 citations or more fall within the top 1% globally. This figure corresponds to around 210 citations annually over a decade. Interestingly, citation thresholds vary by field, and approximately 44% of published manuscripts remain uncited. Strikingly, almost half of published manuscripts go uncited, and just a single citation places a manuscript near the upper half. Accumulating 10 citations elevates an article into the top quartile while surpassing 100 citations propels a paper to the top 1.8%. The crucial takeaway is that the average number of citations per manuscript tends to remain below 10 (Refer the details to Scott D. Weingart, MD: https://Lucbeaulieu.com/2015/11/19/how-many-citations-are-actually-a-lot-of-citations/) and (https://renaissance.stonybrookmedicine.edu/emergencymedicine/faculty/Weingart).

The database Thomson Reuters Web of Science's average number of citations per article published in scientific journals is as follows (URL: Web of Science Core Collection-Clarivate) using algorithms[18] and based on 4 million authors and 26 million scientific papers that span 15 years and 118 scientific disciplines[19] (Table 1).

Table 1 Average number of citations per article

Disciplines	Citations
Life sciences and medicine	6 to 30 citations
Physical sciences and engineering	5 to 20 citations
Social sciences	5 to 15 citations
Humanities, including literature, history, and philosophy	1 to 5 citations

CONCLUSION

In summary, authors should keep the readers' perspective in mind: Why did they come to read a literature review? A literature review should shed new light on concept development in a particular field. Not only does it offer a comprehensive snapshot of an area of interest, but it also provides promising directions for exploring questions. Both are essential; neither is minor to drum up an enthusiastic readership, leading to well-read and frequently-cited manuscripts in a literature review.

Abstract

BACKGROUND

The immunosuppressive capacity of mesenchymal stem cells (MSCs) is dependent on the "license" of several proinflammatory factors to express immunosuppressive factors such as programmed cell death 1 ligand 1 (PD-L1), which determines the clinical therapeutic efficacy of MSCs for inflammatory or immune diseases. In MSCs, interferon-gamma (IFN-γ) is a key inducer of PD-L1 expression, which is synergistically enhanced by tumor necrosis factor-alpha (TNF-α); however, the underlying mechanism is unclear.

AIM
To reveal the mechanism of pretreated MSCs express high PD-L1 and explore the application of pretreated MSCs in ulcerative colitis.

METHODS
We assessed PD-L1 expression in human umbilical-cord-derived MSCs (hUC-MSCs) induced by IFN-γ and TNF-α, alone or in combination. Additionally, we performed signal pathway inhibitor experiments as well as RNA interference experiments to elucidate the molecular mechanism by which IFN-γ alone or in combination with TNF-α induces PD-L1 expression. Moreover, we used luciferase reporter gene experiments to verify the binding sites of the transcription factors of each signal transduction pathway to the targeted gene promoters. Finally, we evaluated the immunosuppressive capacity of hUC-MSCs treated with IFN-γ and TNF-α in both an *in vitro* mixed lymphocyte culture assay, and *in vivo* in mice with dextran sulfate sodium-induced acute colitis.

RESULTS
Our results suggest that IFN-γ induction alone upregulates PD-L1 expression in hUC-MSCs while TNF-α alone does not, and that the co-induction of IFN-γ and TNF-α promotes higher expression of PD-L1. IFN-γ induces hUC-MSCs to express PD-L1, in which IFN-γ activates the JAK/STAT1 signaling pathway, up-regulates the expression of the interferon regulatory factor 1 (IRF1) transcription factor, promotes the binding of IRF1 and the PD-L1 gene promoter, and finally promotes PD-L1 mRNA. Although TNF-α alone did not induce PD-L1 expression in hUC-MSCs, the addition of TNF-α significantly enhanced IFN-γ-induced JAK/STAT1/IRF1 activation. TNF-α up-regulated IFN-γ receptor expression through activation of the nuclear factor kappa-B signaling pathway, which significantly enhanced IFN-γ signaling. Finally, co-induced hUC-MSCs have a stronger inhibitory effect on lymphocyte proliferation, and significantly ameliorate weight loss, mucosal damage, inflammatory cell infiltration, and up-regulation of inflammatory factors in colitis mice.

CONCLUSION
Overall, our results suggest that IFN-γ and TNF-α enhance both the immunosuppressive ability of hUC-MSCs and their efficacy in ulcerative colitis by synergistically inducing high expression of PD-L1.

Key Words: Human umbilical-cord-derived mesenchymal stem cells; Programmed cell death 1 ligand 1; Immunomodulation; Interferon-gamma; Tumor necrosis factor-alpha; Ulcerative colitis

Core Tip: Our study showed that interferon-gamma (IFN-γ) and tumor necrosis factor-alpha (TNF-α) significantly induced programmed cell death protein 1 ligand 1 (PD-L1) expression in human umbilical-cord-mesenchymal stem cells (hUC-MSCs), and pretreated hUC-MSCs exhibited stronger immunomodulatory capacity. Signaling pathway analysis showed that TNF-α up-regulated IFN-γ receptor expression in hUC-MSCs through nuclear factor kappa-B pathway, and then promoted IFN-γ -mediated activation of JAK/STAT1/interferon regulatory factor 1 pathway and PD-L1 expression. In ulcerative colitis mice, hUC-MSCs pretreated with IFN-γ and TNF-α exhibited stronger immunosuppressive ability through high expression of PD-L1, effectively inhibited the inflammation in the colon of mice.

INTRODUCTION

Mesenchymal stem cells (MSCs) are multipotent adult stem cells present in multiple tissues, including the umbilical cord, bone marrow, and fat tissue. MSCs can self-renew by dividing and differentiating into multiple tissues, including bone, cartilage, muscle, fat cells, and connective tissue[1]. In addition, MSCs have a strong immunomodulatory capacity, exerting both anti-inflammatory and pro-inflammatory effects[2]. Owing to their immunosuppressive function, MSCs are widely used to treat various inflammatory and autoimmune diseases, including inflammatory bowel disease, rheumatoid arthritis, pulmonary fibrosis, and systemic sclerosis[3-6]. However, the current clinical efficacy of MSCs transplantation (MSCT) is highly variable among individuals, even for the same autoimmune disease[7]. In general, the immunosuppressive function of MSCs depends on the licensing of the proinflammatory factor-mediated immunological microenvironment[8,9]. The individual differences in the clinical efficacy of MSCT might be explained by the substantial individual

variations in the pro-inflammatory factor-mediated immunological microenvironment at different stages of disease development in patients with inflammatory or autoimmune diseases. Therefore, to improve the therapeutic efficacy of MSCT in these diseases, there is an urgent need to explore the licensing mechanism of the immunosuppressive function of MSCs and to establish an optimal strategy for inducing and maintaining immunosuppressive MSCs.

It is currently believed that immunosuppressive MSCs induced by pro-inflammatory factors inhibit the activity of various immune cells by secreting many soluble immunosuppressive factors, such as indoleamine 2,3-dioxygenase (IDO). They also express many immunosuppressive receptors, such as programmed cell death 1 ligand 1 (PD-L1), which functions in a cell-to-cell contact manner[10,11]. Programmed cell death 1 (PD-1) is an immune-inhibitory receptor expressed in activated T cells, which binds to PD-L1 and can inhibit proliferation, induce apoptosis, and restore the subgroup balance of T cells[12]. PD-1/PD-L1 are important immune checkpoint molecules that play a pivotal role in tumor immune escape[13]. Emerging evidence suggests that PD-1/PD-L1 dysfunction is also involved in the immune hyperactivity observed in multiple autoimmune and inflammatory diseases[14,15]. Additionally, PD-L1 plays an important role in the immunosuppressive capacity of MSCs, inhibiting the activation of the immune response in a variety of ways. This includes reducing the release of inflammatory factors, the proliferation and activation of T cells, and the Th17-mediated autoimmune response, as well as augmenting the generation of regulatory T cells (Tregs)[15-17]. Therefore, to improve the therapeutic efficacy of MSCs for inflammatory or autoimmune related diseases, there is an urgent need to clarify the regulatory mechanism of PD-L1 expression in MSCs and to establish an optimal strategy for inducing and maintaining this expression.

Interferon-gamma (IFN-γ) alone has been suggested to upregulate PD-L1 expression in MSCs at low levels, although the specific mechanism remains unclear[18]. It is also unclear whether a combination of proinflammatory factors can synergistically enhance PD-L1 expression in MSCs and their immunosuppressive function. Notably, researchers have recently demonstrated that the immunosuppressive capacity of MSCs depends on stimulation by IFN-γ, and the effect can be amplified further by cytokines, such as tumor necrosis factor-α (TNF-α)[4,19]. In addition, Li *et al*[20] recently reported that TNF-α can enhance the IFN-γ-induced PD-L1 expression in hepatocellular carcinoma cells. Such findings suggest that TNF-α could also enhance IFN-γ-induced PD-L1 expression in MSCs. In the present study, we first confirmed that IFN-γ induced human-umbilical-cord-MSCs (hUC-MSCs) express PD-L1 through the JAK/STAT1/IRF1 pathway. Second, we observed that TNF-α synergistically enhanced PD-L1 expression induced by IFN-γ in hUC-MSCs. TNF-α also upregulated IFN-γ receptor 1 (IFNGR1) expression through the nuclear factor kappa-B (NF-κB) signaling pathway to promote IFN-γ/IFNGR/STAT1/ interferon regulatory factor 1 (IRF1)/PD-L1 signaling axis activation. Finally, based on an *in vitro* lymphocyte mixing experiment and an *in vivo* dextran sulfate sodium (DSS)-induced acute colitis mouse model, we found an optimal strategy of enhancing the immunosuppressive capacity of hUC-MSCs by licensing with IFN-γ and TNF-α. The results not only elucidate the specific molecular mechanism by which the IFN-γ and TNF-α combination enhances the immunosuppressive function of MSCs, but also provide a theoretical basis for improving the therapeutic efficacy of MSCT in future clinical applications.

MATERIALS AND METHODS

Culture and treatment of hUC-MSCs

All hUC-MSCs were provided by the FuMei Stem Cell Biotechnology Company (Chongqing, China). The hUC-MSCs used in the present study were identified by flow cytometry and three-lineage differentiation culture. The results showed that the hUC-MSCs had the correct molecular phenotype and three-lineage differentiation potential (Supplementary Figure 1). All hUC-MSCs used in the experiment were derived from passages 3 to 7. hUC-MSCs were cultured and stimulated in serum-free medium (LONZA). To measure the induction of PD-L1 expression, hUC-MSCs were incubated with human IFN-γ, TNF-α or both (Peprotech, United States). After 4 h of culture, the cells were harvested for mRNA expression analysis using quantitative real-time PCR (qRT-PCR). After 24 h of culture, they were harvested for protein expression analysis by western blot or flow cytometry.

Quantitative Real-time PCR

Total RNA was extracted from hUC-MSCs using Trizol (Sigma, T9424), and reverse transcribed into cDNA using HiScript® II Q RT SuperMix for qRT-PCR (+gDNA wiper) (Vazyme, China). The qRT-PCR assay was performed using ChamQ Universal SYBR qRT-PCR Master Mix (Vazyme, China). All qRT-PCR experiments were independently repeated three times. All primer sequences used for qRT-PCR are listed in Supplementary Table 1.

Flow cytometry

The hUC-MSCs were prepared as single-cell suspensions and stained for 30 min at room temperature. PD-L1-FITC antibody (BD Pharmingen, 558065), IFNGR1-PE antibody (BD Pharmingen, 558937), FITC isotype control antibody (BD Pharmingen, 555742), or PE isotype control antibody (BD Pharmingen, 555749) were used to quantify the expression of PD-L1 or IFNGR1 in hUC-MSCs. CD29-PE antibody (BD Pharmingen, 555443), CD34-PE antibody (BD Pharmingen, 555822), CD44-PE antibody (BD Pharmingen, 555479), CD45-PE antibody (BD Pharmingen, 555483), CD73-PE antibody (BD Pharmingen, 550257), CD90-PE antibody (BD Pharmingen, 555596), and CD105-PE antibody (BD Pharmingen, 560839) were used to identify hUC-MSCs. Our gating strategy was to select active hUC-MSCs groups. Flow cytometry was performed using a NovoCyte flow cytometer (ACEA Biosciences).

Western blot analysis

Western blot assay was performed to observe changes in relative protein content. Whole cell proteins were extracted from cells using radioimmunoprecipitation assay strong lysate (Beyotime Biotechnology, P0013). The cell lysates from each sample were separated by sodium dodecyl sulfate-polyacrylamide gel electrophoresis and transferred onto polyvinylidene fluoride (PVDF) membranes. The PVDF membranes were blocked with 5% skim milk in TBST for 60 min, incubated with primary antibodies and then with secondary antibodies conjugated with horseradish peroxidase (HRP), and developed using a chemiluminescence HRP substrate (Millipore, WBKLS0100). The primary antibodies used were PD-L1, IFNGR1, JAK1, p-JAK1, JAK2, p-JAK2, STAT1, p-STAT1, IRF1, IKKα, IKKβ, p-IKKα/β, IKBα, p-IKBα, p65, p-p65, and β-tubulin (1:1000, CST). The secondary antibodies were goat anti-rabbit IgG and goat anti-mouse IgG (1:10000, CST).

Signaling inhibition assay

To investigate the signaling pathways activated by IFN-γ or TNF-α in hUC-MSCs, we used the reagents: Ruxolitinib (10 μM) and BAY11-7082 (10 μM) (Selleckchem). After 30 min of pretreatment with the inhibitors, hUC-MSCs were co-cultured with IFN-γ, TNF-α, or IFN-γ plus TNF-α for 4 h or 24 h. The cells were collected for further investigation. The control cells were treated with these cytokines and DMSO.

Small interfering RNA assay

To identify the key pathway molecules involved in the inducible expression of PD-L1 or IFNGR1, a specific Small interfering RNA (siRNA) assay was performed. The siRNA synthesized by RiboBio Company (Guangzhou, China) have proven effective and were thus used in the siRNA assay (Supplementary Figure 2). The siRNAs were transfected into hUC-MSCs using Lipofectamine RNAiMAX transfection reagent (Life Technologies, United States) according to the manufacturer's protocol. After 24 h of transfection, the hUC-MSCs were treated with cytokines for 4 h or 24 h. They were then harvested and subjected to qRT-PCR analysis or western blot.

Gene promoter activity assay

Vector plasmids, IRF1 promoter plasmids, p65 promoter plasmids, PD-L1 promoter plasmids, IFNGR1 promoter plasmids, PD-L1 promoter point mutation plasmids, and IFNGR1 promoter point mutation plasmids were purchased from OBiO Technology (Shanghai). 293T cells were cultured in plates and transfected with the plasmids by DNA transfection reagent (NEOFECT, China) according to the manufacturers' instructions. Fluorescence intensity was determined using a Dual Luciferase Reporter Gene Assay Kit (Beyotime) according to the manufacturer's instructions.

Cell proliferation assay

Cell proliferation was analyzed using the Cell Counting Kit-8 (CCK-8) assay. The hUC-MSCs were plated in six-well plates (1×10^5 cells per well) and cultured for 24 h. Subsequently, the CCK-8 reagent (Beyotime Biotechnology, China) was added to each well, according to the manufacturer's instructions. The absorbance of each well at 450 nm was measured using an ELX808 microplate reader (Biotek, United States).

Cell apoptosis assay

Apoptotic hUC-MSCs were detected using the Annexin V-FITC/PI Apoptosis Detection Kit and Annexin V-APC/PI Apoptosis Detection Kit (KeyGEN BioTECH, China). The hUC-MSCs were plated in six-well plates (1×10^5 cells per well) and cultured for the indicated time. After TNF-α stimulation for 24 h, all hUC-MSCs were stained by Annexin V and PI, according to the manufacturer's instructions. Afterward, the cells were evaluated using the NovoCyte flow cytometer. The percentage of apoptotic hUC-MSCs was determined by the sum of Annexin V positive cells.

IFNGR1 overexpression assay

IFNGR1-overexpressing lentiviruses were purchased from Shanghai OBiO Technology. The lentivirus infection procedures were modified from a previously published protocol[21]. After IFNGR1-overexpressed hUC-MSCs were successfully constructed using IFNGR1-overexpressing lentivirus, we used small interfering RNA (siRNA) to interfere with the p65 expression in cells. PD-L1 mRNA expression was detected by qRT-PCR assays after induction by IFN-γ or TNF-α for 4 h.

PBMCs isolation and proliferation assays

Peripheral blood samples were obtained from healthy donors. Peripheral blood mononuclear cells (PBMCs) were isolated using a human peripheral blood lymphocyte separation tube (Dakewe, China), activated by monoclonal anti-human CD3 antibody (Acro, United States), and stained with 10 mmol/L 5-(and-6)-carboxyfluorescein diacetate succinimidyl ester (CFSE, Beyotime, China). CFSE-labeled PBMCs (1×10^6 cells/well) were co-incubated with hUC-MSCs at a ratio of 10:1 in the presence of 100 IU/mL IL2. After co-culturing for 3 d, the proliferation of PBMCs was analyzed using flow cytometry.

DSS-induced colitis and treatment

C57BL/6J mice were purchased from the Weitong Lihua Experimental Animal Technology Company (China). The animal protocol was designed to minimize pain or discomfort to the animals. The animals were acclimatized to laboratory conditions (23 °C, 12 h/12 h light/dark, 50% humidity, ad libitum access to food and water) for 2 wk prior to experimentation. Mice were randomly assigned to six experimental groups: WT, DSS, DSS + MSCs, DSS + IT-MSCs (IT-MSCs: hUC-MSCs treated with IFN-γ and TNF-α), DSS + IT-MSCs + iso antibody, and IT-MSCs + PD-L1 antibody (atezol-

izumab, Selleck). In the DSS, DSS + MSCs, DSS + IT-MSCs, DSS + IT-MSCs + iso antibody, and IT-MSCs + PD-L1 antibody groups, acute colitis was induced in mice by the addition of 4% (w/v) DSS (40 kDa, MP Biomedicals) to the drinking water for 7 d, until euthanasia. The WT group received drinking water only. All mice were weighed daily. On day 3, mice from the DSS + MSCs, DSS + IT-MSCs, DSS + IT-MSCs + iso antibody, and IT-MSCs + PD-L1 antibody groups were transfused with 1 × 10^6 hUC-MSCs *via* the tail vein, and the other mice were transfused with equal amounts of saline *via* the tail vein. Mice in the IT-MSCs group were transfused *via* the tail vein with 1 × 10^6 hUC-MSCs previously treated with IFN-γ and TNF-α for 24 h. The hUC-MSCs of the DSS + IT-MSCs + iso antibody group and the DSS + IT-MSCs+PD-L1 antibody group were treated with IFN-γ, TNF-α, isotype antibody or PD-L1 antibody for 24 h. After seven days of induction, the mice were sacrificed by cervical dislocation, and their colons were collected.

Colon histopathology analysis

For histological analysis, colon samples were fixed with 4% paraformaldehyde (Beyotime, P0099) for 24 h and embedded in paraffin for hematoxylin and eosin staining, as previously described[22]. We evaluated the histopathological scores of colon tissue using a combination of inflammatory cell infiltration and epithelial damage to the colon[22].

Colon immunohistochemistry analysis

Immunohistochemistry was performed on paraffin embedded sections of colon samples. The sections were incubated with anti-CD4 (Abcam, 1:1000) or anti-CD11b (Abcam, 1:4000) at 4 °C overnight and with anti-rabbit IgG and HRP-linked antibody (CST, 1:50) for 60 min. Immunoreactivity was analyzed with a microscope (Olympus CKX31). The total number of CD4 or CD11b positive cells in each of four nonadjacent fields of view was counted per colon sample.

Myeloperoxidase activity assay

We performed a myeloperoxidase (MPO) activity assay to determine the number of neutrophils in the colon tissue. The MPO activity kit was purchased from Jiancheng (Nanjing, China, A044-1-1). We determined the level of MPO activity in the colon tissue following the protocol recommended by the manufacturer. The absorbance of each well was evaluated using an ELX808 microplate reader.

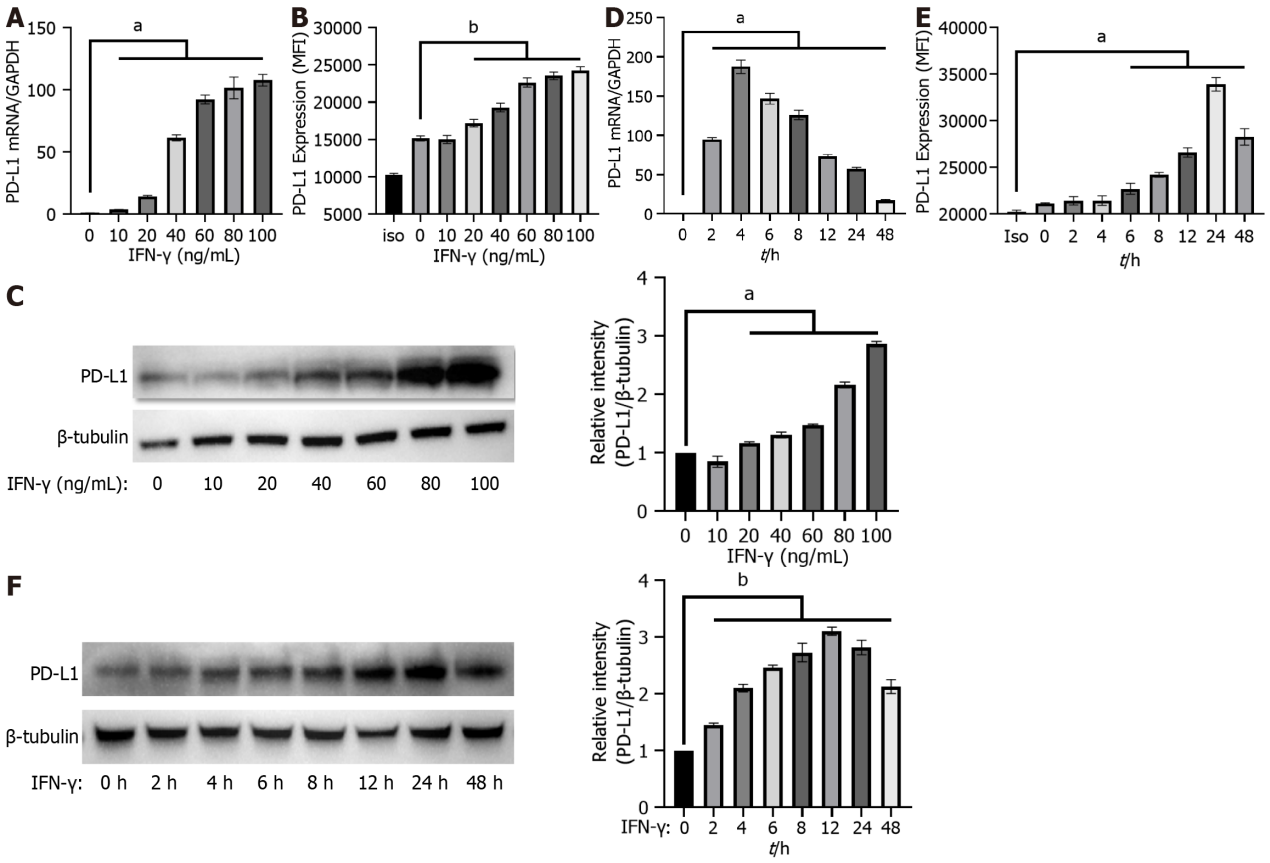
Enzyme linked immunosorbent assay

The concentrations of TNF-α, IFN-γ, and IL-6 secreted by mice with acute colitis were determined by enzyme linked immunosorbent assay (ELISA). The TNF-α, IFN-γ, and IL-6 ELISA kits were purchased from Boster (Wuhan, Hubei Province, China), and were used according to the manufacturer's instructions. The absorbance of each well was evaluated using an ELX808 microplate reader.

Statistical analysis

The results are shown as mean ± SD. Statistical analyses were performed using GraphPad Prism v8.4.2 (GraphPad Software Inc., San Diego, CA, United States). Student's unpaired t-test and one-way analysis of Variance were used to determine significant differences between groups. Statistical significance was set at $P < 0.05$.

RESULTS



IFN-γ induced the expression of PD-L1 in the hUC-MSCs

IFN-γ induces MSCs to express PD-L1, which exerts an immunosuppressive effect. In the present study, we further investigated the effect of IFN-γ on PD-L1 expression in hUC-MSCs. And hUC-MSCs were treated with either different concentrations of IFN-γ or fixed concentrations of IFN-γ for different time periods. PD-L1 expression in hUC-MSCs was detected using qRT-PCR, western blot, and flow cytometry. After treating hUC-MSCs with variable concentrations of IFN-γ for 24 h, the results showed that when the concentration of IFN-γ was 20 ng/mL, PD-L1 expression increased significantly; it was the highest under 100 ng/mL IFN-γ (Figure 1A-C). Moreover, PD-L1 mRNA expression induced by 20 ng/mL IFN-γ began to increase 2 h after stimulation, and was the highest at 4 h (Figure 1D). The total and membrane protein levels of PD-L1 in hUC-MSCs peaked at 24 h (Figure 1E and F). Based on the results above, we used 20 ng/mL IFN-γ stimulation for 4 h for follow-up qRT-PCR experiments, and 20 ng/mL IFN-γ stimulation for 24 h for western blot or flow cytometry experiments. The results confirmed that IFN-γ induced PD-L1 expression in hUC-MSCs.

IFN-γ upregulated PD-L1 expression through the JAK/STAT1/IRF1 pathway in hUC-MSCs

A previous study showed that IFN-γ increased PD-L1 expression in tumor cells by activating the JAK/STAT/IRF1 pathway[23]. To confirm this finding, we performed signaling inhibition and siRNA interference experiments. We found that ruxolitinib (10 μM), a JAK/STAT signaling pathway inhibitor, significantly reduced IFN-γ-induced PD-L1 mRNA expression (Figure 2A; Supplementary Figure 3A). The results of western blot and flow cytometry showed that ruxolitinib also significantly reduced the levels of IFN-γ-induced PD-L1 membrane protein and total protein (Figure 2B and C). The results suggest that IFN-γ could induce PD-L1 expression through the JAK/STAT pathway in hUC-MSCs.

To further confirm that the JAK/STAT pathway mediates the IFN-γ-induced effect on hUC-MSCs expressing PD-L1, we analyzed the total protein and the phosphorylation levels of key proteins in the JAK/STAT signaling pathway in hUC-MSCs. Western blot results showed that IFN-γ promoted JAK1/2 phosphorylation, STAT1 phosphorylation, IRF1 expression, and PD-L1 expression, while ruxolitinib reversed all these effects (Figure 2C). To confirm the findings, we

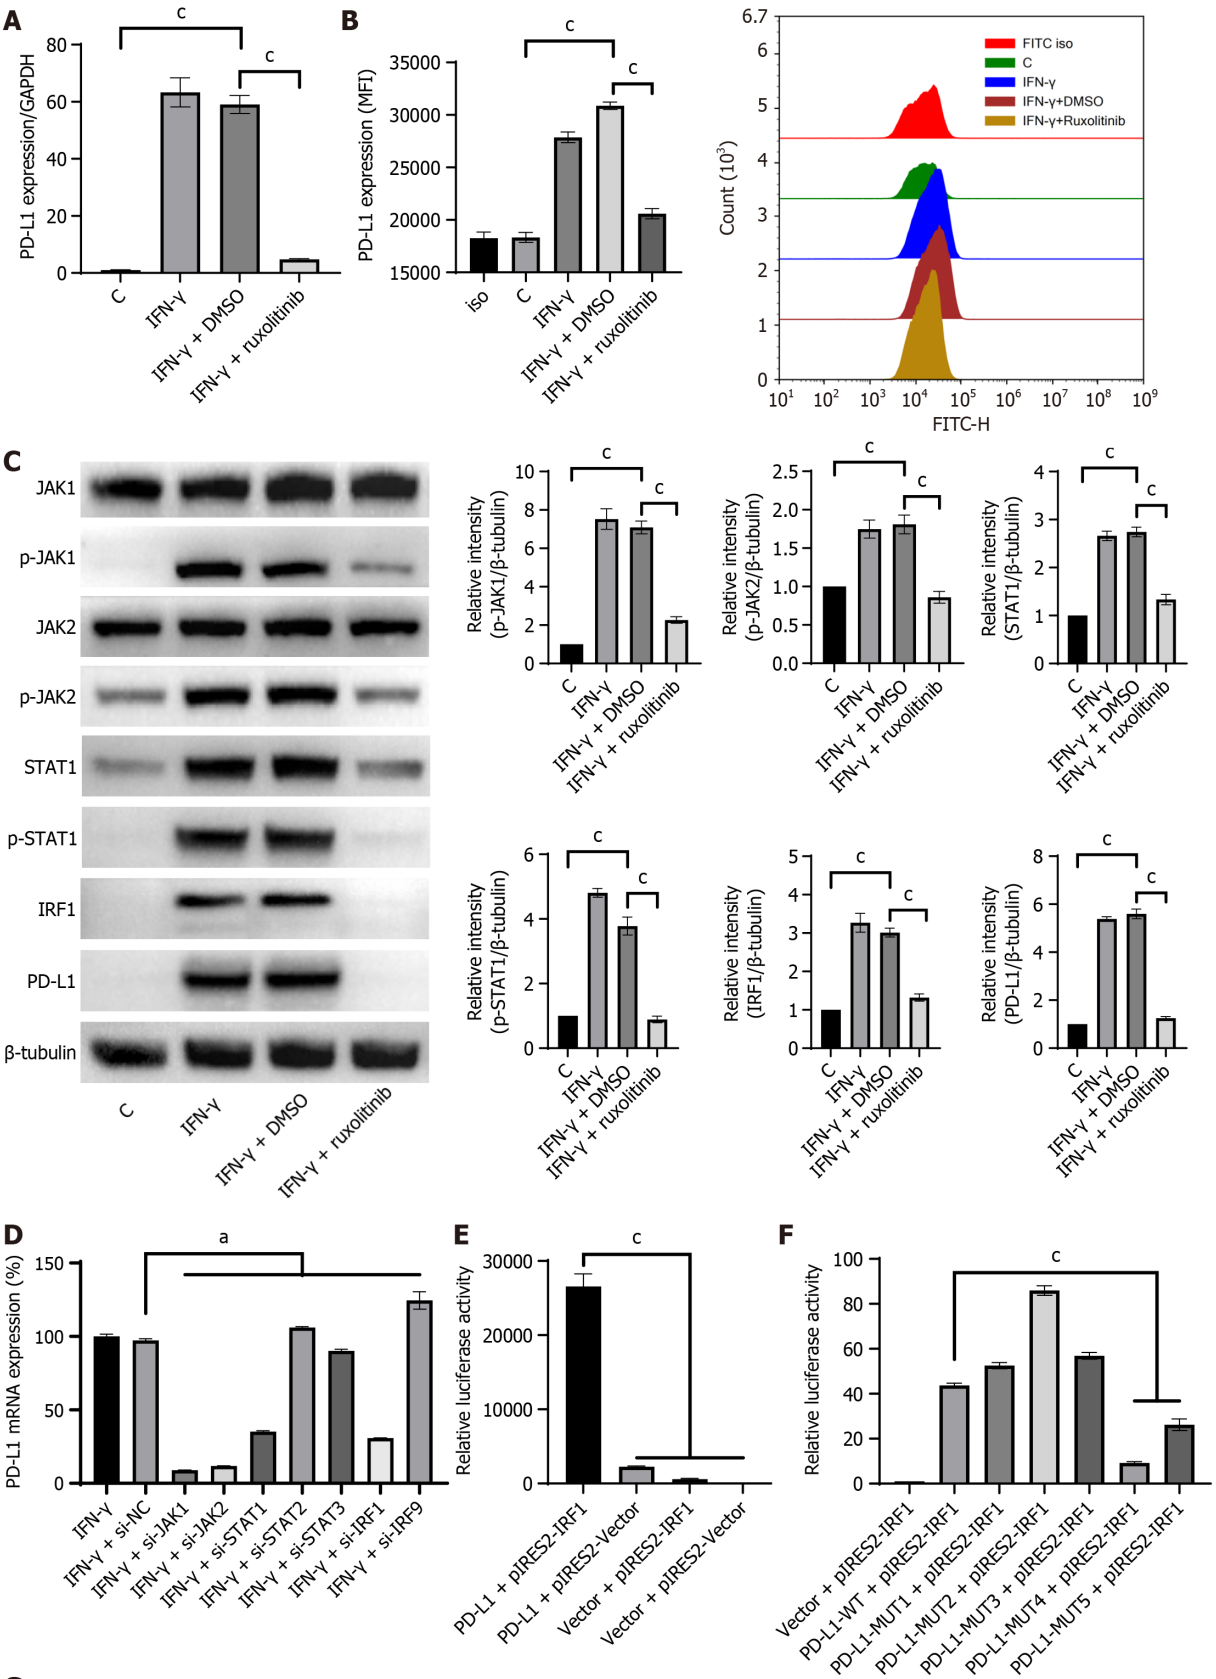
Figure 1 Interferon-gamma induced the expression of programmed cell death protein 1 ligand 1 in human umbilical-cord-mesenchymal stem cells. A-C: Programmed cell death protein 1 ligand 1 (PD-L1) expression was measured by quantitative real-time PCR (qRT-PCR), flow cytometry, and western blot in human umbilical-cord-mesenchymal stem cells (hUC-MSCs) treated with 0, 10, 20, 40, 60, 80 or 100 ng/mL interferon-gamma (IFN-γ) for 24 h; D-F: PD-L1 expression was measured by qRT-PCR, flow cytometry, and western blot in hUC-MSCs treated with 20 ng/mL IFN-γ for 0, 2, 4, 6, 8, 12, 24 or 48 h. Data were represented as mean ± SEM of $n = 3$. Iso: Isotype; C: Control; $^{a}P < 0.01$; $^{b}P < 0.001$. IFN-γ: Interferon-gamma; PD-L1: Programmed cell death protein 1 ligand 1.



performed an siRNA interference assay using the effective siRNAs for JAK1/2, STAT1/2/3, and IRF1/9, and observed that the siRNAs remarkably inhibited the PD-L1 expression induced by IFN-γ (Figure 2D). The results indicate that IFN-γ induced PD-L1 expression in hUC-MSCs *via* the JAK/STAT1/IRF1 pathway.

IRF1 is a key transcription factor in the JAK/STAT pathway. We constructed a dual-luciferase reporter system to confirm that IRF1 binds to the PD-L1 promoter to promote PD-L1 mRNA expression. In 293T cells, relative luciferase activity was weak when transfected with IRF1 or the PD-L1 promoter plasmid; it was the strongest when the two were co-transfected (Figure 2E). We then predicted the potential binding sites of the proximal part of the PD-L1 gene to IRF1 and identified the five most likely binding sites. Point mutant plasmids were constructed at the five binding sites to assess luciferase reporter activity. We co-transfected a WT-PD-L1 promoter plasmid and five IRF1 binding site mutant PD-L1 promoter plasmids into 293T cells with an IRF1 promoter plasmid and a Renilla luciferase plasmid. We measured the relative luciferase activity 24 h after transfection (Figure 2F). The locations of the binding sites in the PD-L1 promoter are shown in Figure 2G. According to the results, mutations at sites 4 or 5 reduced IFN-γ-induced PD-L1 promoter activity, with site 4 having the greatest effect (Figure 2F). These findings indicate that IFN-γ activated the JAK/STAT pathway in hUC-MSCs and induced IRF1 expression; IRF1, in turn, bound to the PD-L1 promoter, thereby promoting PD-L1 transcription.

TNF-α synergistically enhanced IFN-γ-induced PD-L1 expression in hUC-MSCs

As mentioned above, the mechanism by which TNF-α synergistically enhances IFN-γ-induced PD-L1 expression has not been elucidated. To study the effect of TNF-α alone or in combination with IFN-γ on PD-L1 expression in hUC-MSCs, we performed the following experiments. First, hUC-MSCs were stimulated with seven different concentrations of TNF-α (0 ng/mL, 10 ng/mL, 20 ng/mL, 40 ng/mL, 60 ng/mL, 80 ng/mL, and 100 ng/mL) for 24 h, or with the experimentally designed highest concentration (100 ng/mL) of TNF-α for different time periods (0 h, 2 h, 4 h, 6 h, 12 h, 24 h, and 48 h). Subsequently, the membrane expression of PD-L1 was detected by flow cytometry. Our results demonstrated that TNF-α stimulation alone did not affect PD-L1 expression in hUC-MSCs (Figure 3A and B).

Subsequently, to analyze the effect of TNF-α on hUC-MSCs viability, the proliferation and apoptosis of hUC-MSCs treated with TNF-α was tested using cell proliferation and apoptosis assays. We found that TNF-α had no effect on the proliferation or apoptosis of hUC-MSCs (Figure 3C and D). We then studied the effect of combined treatment with IFN-γ

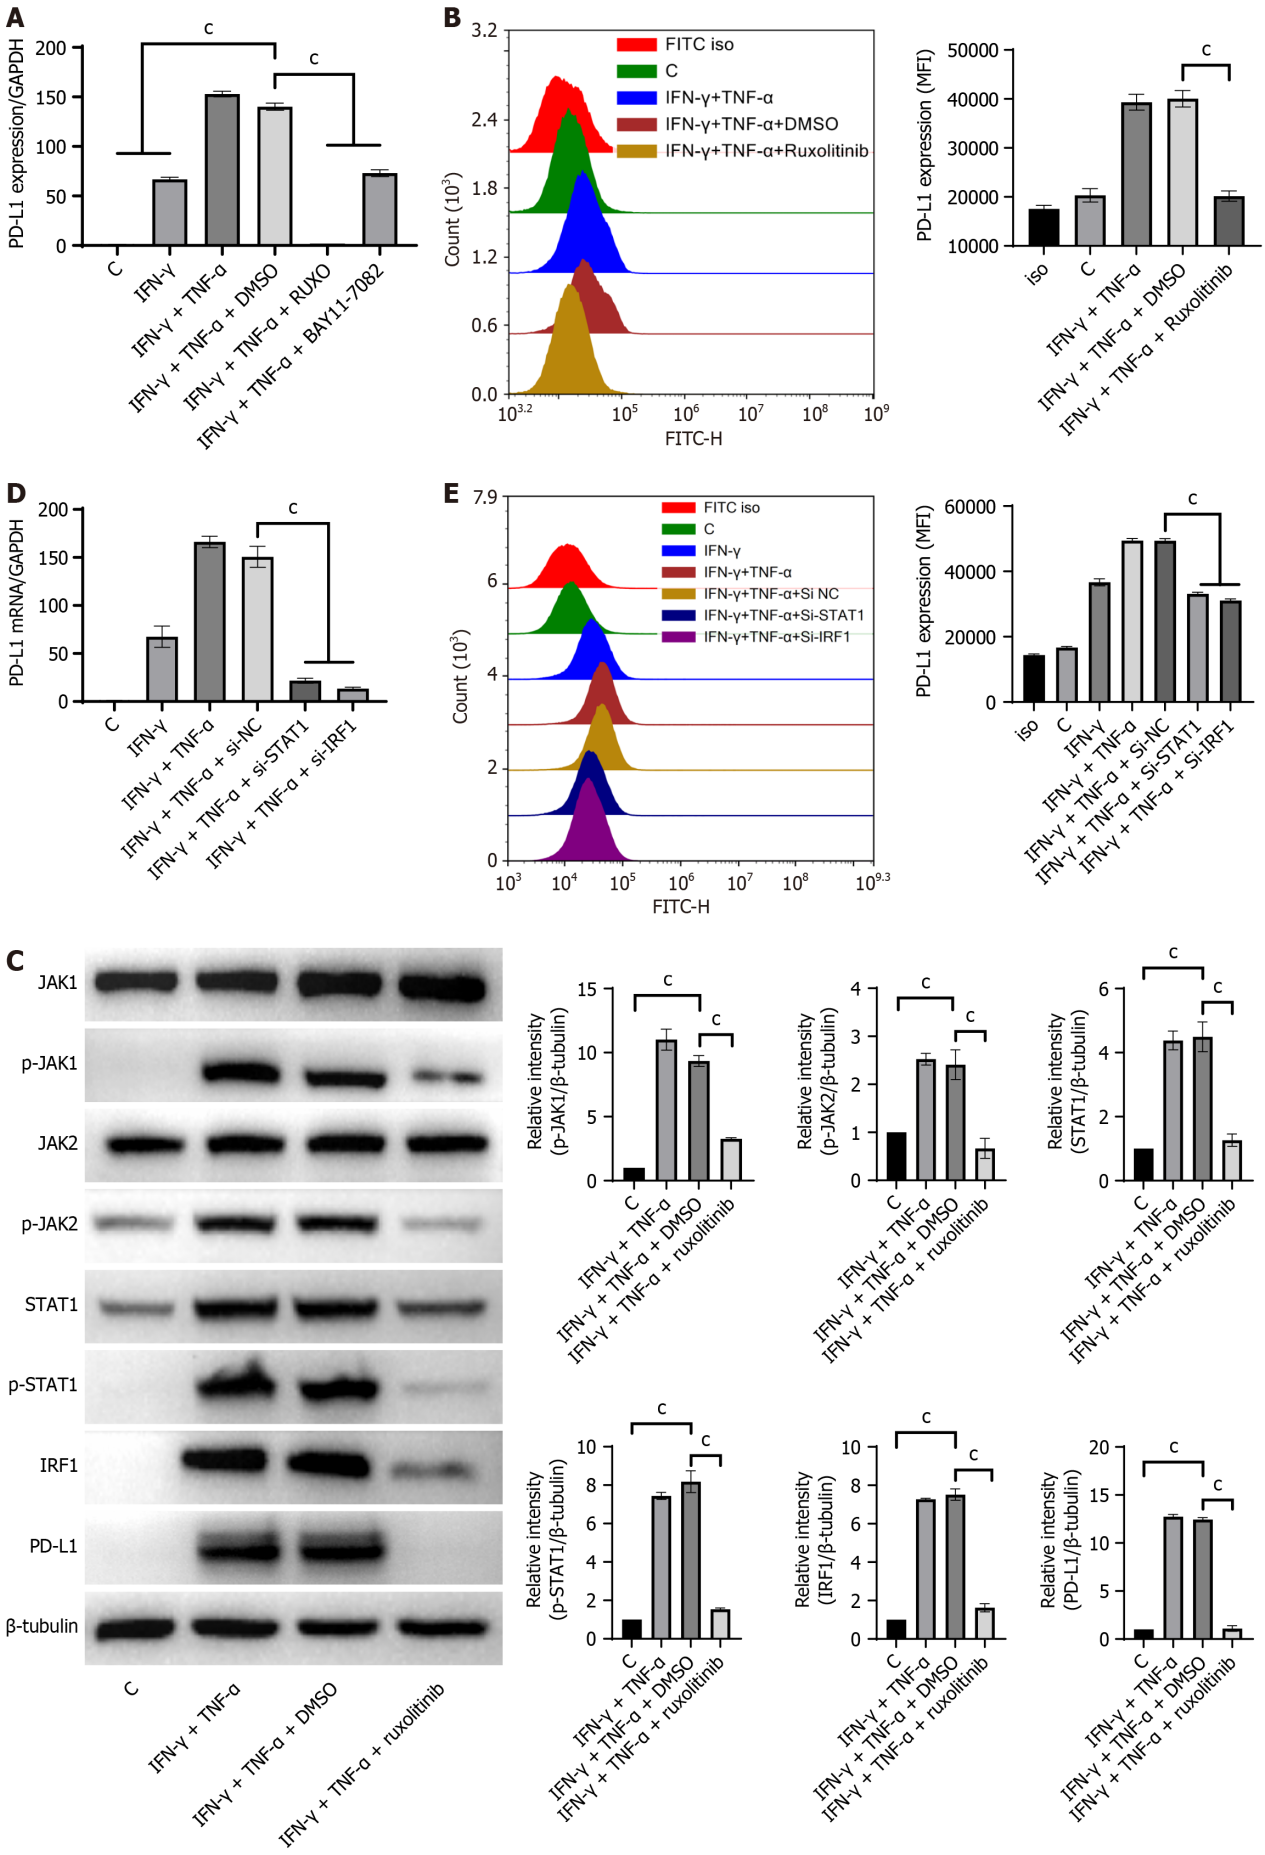
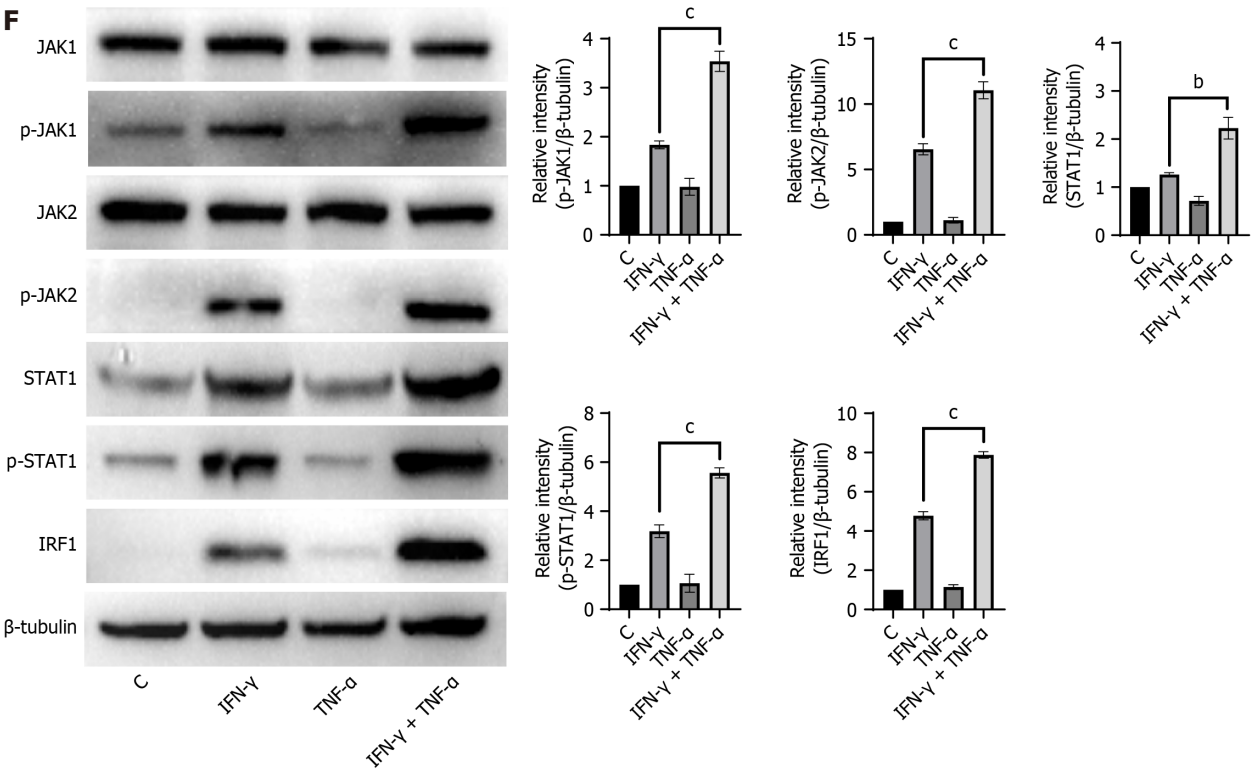
and TNF-α on PD-L1 expression in hUC-MSCs. We stimulated hUC-MSCs with 20 ng/mL IFN-γ and different concentrations of TNF-α (0 ng/mL, 10 ng/mL, 20 ng/mL, 40 ng/mL, 60 ng/mL, 80 ng/mL, and 100 ng/mL) and detected PD-L1 expression using flow cytometry. The results showed that 10 ng/mL TNF-α enhanced IFN-γ-induced PD-L1 expression significantly; however, the enhanced effect of TNF-α did not appear to be concentration-dependent (Figure 3E). Furthermore, qRT-PCR and western blot results showed that the mRNA and total protein levels of PD-L1 increased significantly when hUC-MSCs were simultaneously stimulated with 20 ng/mL IFN-γ and 10 ng/mL TNF-α when compared with IFN-γ or TNF-α alone (Figure 3F and G). Based on the results, 10 ng/mL TNF-α was used in follow-up experiments. In addition, we investigated the effects of IFN-γ (20 ng/mL) or TNF-α (10 ng/mL) stimulation individually or in combination on the proliferation or apoptosis of hUC-MSCs. Our results showed that the stimuli were unable to exert any effect on apoptosis or proliferation of hUC-MSCs at the current concentrations (Supplementary Figure 3B and C). The findings suggest that TNF-α alone had no effect on PD-L1 expression; however, TNF-α could synergistically increase IFN-γ-induced PD-L1 expression in hUC-MSCs.

TNF-α improved PD-L1 expression by promoting the activation of JAK/STAT1/IRF1 pathway induced by IFN-γ

As previous studies have demonstrated that IFN-γ induces hUC-MSCs to express PD-L1 through the JAK/STAT1/IRF1 pathway and TNF-α induces various downstream biological effects through activation of the NF-κB pathway[24], we explored the molecular mechanism by which TNF-α enhances IFN-γ-induced PD-L1 expression using signaling inhibition experiments. We treated hUC-MSCs with ruxolitinib and the NF-κB inhibitor BAY11-7082, and then detected PD-L1 mRNA levels after combined treatment with IFN-γ and TNF-α for 4 h. Our results showed that both BAY11-7082 and ruxolitinib inhibited PD-L1 expression induced by a combination of IFN-γ and TNF-α (Figure 4A). Ruxolitinib displayed a stronger inhibitory effect, almost completely inhibiting the induction of PD-L1 mRNA expression, while BAY11-7082 only partially inhibited the expression (Figure 4A). Flow cytometry and western blot assays also showed that ruxolitinib completely inhibited PD-L1 protein expression in hUC-MSCs treated with IFN-γ and TNF-α (Figure 4B and C). Furthermore, we performed an siRNA interference assay using STAT1 siRNA and IRF1 siRNA. The siRNA against STAT1 and IRF1 decreased PD-L1 expression induced by IFN-γ or TNF-α in hUC-MSCs (Figure 4D and E). The results indicated that PD-L1 gene transcription is also induced through the JAK/STAT1/IRF1 pathway when stimulated by IFN-γ and TNF-α.



To investigate whether TNF-α affects the activation of the JAK/STAT1/IRF1 pathway, we analyzed the activation of the JAK/STAT1/IRF1 pathway in hUC-MSCs treated with IFN-γ and TNF-α. The results showed that the activation level of the JAK/STAT1/IRF1 pathway was significantly higher following stimulation with IFN-γ and TNF-α (Figure 4F). Additionally, ruxolitinib significantly reduced the phosphorylation levels of JAK1/2 and STAT1, as well as the expression levels of IRF1 and PD-L1, in hUC-MSCs induced by IFN-γ and TNF-α (Figure 4C). The results revealed that the activation of the JAK/STAT1/IRF1 pathway was significantly stronger when co-stimulated with IFN-γ and TNF-α, thus leading to higher PD-L1 expression.



TNF-α synergistically amplified IFN-γ-induced JAK/STAT1/IRF1 signaling activation by upregulating NF-κB-mediated IFNGR1 expression

IFNGR1/2 acts as the membrane receptor of IFN-γ and transmits an activation initiation signal to the JAK/STAT1/IRF1 pathway, which is the key player in PD-L1 expression[23]. We speculated that the higher activation level of the JAK/STAT1/IRF1 pathway might be caused by TNF-α induced IFNGR1/2 expression. As predicted, TNF-α upregulated the expression of IFNGR1 mRNA and protein and the expression of IFNGR2 mRNA (Figure 5A-C). Notably, since no effective anti-IFNGR2 antibody is available, only IFNGR1 expression was detected in western blot experiments. Additionally, the siRNA for IFNGR1/2 decreased PD-L1 mRNA and protein expression in hUC-MSCs induced by IFN-γ and TNF-α (Figure 5D-F). Furthermore, western blot results showed that IFNGR1 siRNA reduced JAK1/2 and STAT1 phosphorylation, as well as IRF1 expression (Figure 5F). The results suggest that TNF-α amplifies the IFN-γ-induced activation of the JAK/STAT1/IRF1 pathway by upregulating IFNGR1/2 expression.

The NF-κB pathway inhibitor BAY11-7082 partially impaired the expression of PD-L1 induced by the combination of IFN-γ and TNF-α (Figure 4A; Supplementary 3D). This suggests that the NF-κB pathway is involved in the regulation of PD-L1 expression induced by IFN-γ and TNF-α. Therefore, we examined the expression of IFNGR1 and the activation of the NF-κB pathway in hUC-MSCs induced by TNF-α. As predicted, TNF-α upregulated IFNGR1 expression by activating the NF-κB pathway, while BAY11-7082 decreased the phosphorylation levels of IKK-α/β, IKB-α, and p65, as well as the expression of IFNGR1 (Figure 5G; Supplementary Figure 4A). To explore NF-κB pathway activation by TNF-α in hUC-MSCs, we assessed nuclear and cytoplasmic p65 and IκB expression after TNF-α treatment. The expression of IκB in the cytoplasm was reduced at 60 min and then restored, while the expression of p65 in the nucleus was significantly increased at 60 min (Figure 5H; Supplementary Figure 4B). These findings indicate that TNF-α can promote NF-κB pathway activation in hUC-MSCs, in addition to enhancing p65 translocation to the nuclei. Moreover, when the expression of p65 was downregulated by siRNA, the effect of TNF-α on the expression of IFNGR1 and PD-L1 induced by IFN-γ was significantly reduced (Figure 5I-K). Importantly, we found that IFNGR1-overexpressing lentivirus restored PD-L1 expression that was reduced by p65 siRNA (Figure 5L). Furthermore, TNF-α upregulated IFNGR1 expression through the NF-κB pathway, and synergistically amplified the activation of JAK/STAT1/IRF1 induced by IFN-γ, finally resulting in an increase in PD-L1 expression in hUC-MSCs.

To confirm that p65 binds to the IFNGR1 promoter to activate IFNGR1 expression, we constructed a luciferase reporter system with NF-κB-driven activity. In 293T cells, higher luciferase activity was observed when p65 and IFNGR1 promoter plasmids were co-transfected into the cells than when these were transfected separately (Figure 5M). As the proximal part of the IFNGR1 gene contained only one p65 binding site, we constructed an IFNGR1 promoter plasmid with a point

mutation at this binding site. We found that this p65 binding site mutant plasmid displayed weaker luciferase activity in response to TNF-α stimulation compared to the WT-type IFNGR1 promoter plasmid (Figure 5N). The results indicate that TNF-α induces NF-κB p65 activation of the IFNGR1 promoter.

Synergy of IFN-γ and TNF-α enhanced the immunosuppressive capacity of hUC-MSCs by inducing PD-L1 expression

To explore whether the high expression of PD-L1 in hUC-MSCs induced by a combination of IFN-γ and TNF-α could enhance their immunosuppressive function, we first conducted a T lymphocyte proliferation inhibition experiment *in vitro*. The results showed that PBMCs co-cultured with hUC-MSCs that were pre-treated with IFN-γ and TNF-α had higher CFSE fluorescence intensity than that in other groups, which indicated that IFN-γ- and TNF-α-pretreated hUC-MSCs showed a stronger inhibitory effect on PBMCs proliferation (Figure 6A). Meanwhile, the PD-L1 antibody eliminated the inhibitory effect of hUC-MSCs pre-treated with IFN-γ and TNF-α on PBMCs proliferation (Figure 6A). The results suggest that IFN-γ and TNF-α-pretreated hUC-MSCs, with high PD-L1 expression, exhibited a stronger inhibitory effect on T cell proliferation.

We further explored the therapeutic efficacy of hUC-MSCs pre-treated with a combination of IFN-γ and TNF-α in mice with DSS-induced colitis. Colitis was induced in mice by feeding them DSS added to drinking water, and hUC-MSCs were transplanted according to the schematic diagram shown in Figure 6B. Compared with the wild-type hUC-MSCs treatment group, hUC-MSCs pretreated with a combination of IFN-γ and TNF-α displayed a better therapeutic efficacy in DSS-induced mice, including mitigated bodyweight loss (Figure 6C); improved colonic morphology (Figure 6D); relieved colonic ulcer, mucosal edema, epithelial cell injury, and inflammatory cell infiltration (Figure 6E); lower histopathological scoring of colon tissue (Figure 6F); inhibited infiltration of immune cells including $CD4^+$ T cells, $CD11b^+$ macrophages, and neutrophils (lower MPO activity) in colon tissue (Figure 6G and 6H); more Treg ($Foxp3^+$) cells in colon tissue (Figure 6I), and significantly decreased levels of inflammatory factors such as TNF-α, IFN-γ, and IL-6 in colon tissue (Figure 6J). However, PD-L1 antibody treatment significantly inhibited such effects. In addition, no adverse reactions related to hUC-MSCs transplantation were observed. The results suggest that the combination of IFN-γ and TNF-α synergistically enhanced the immunosuppressive capacity of hUC-MSCs by upregulating the expression of PD-L1,

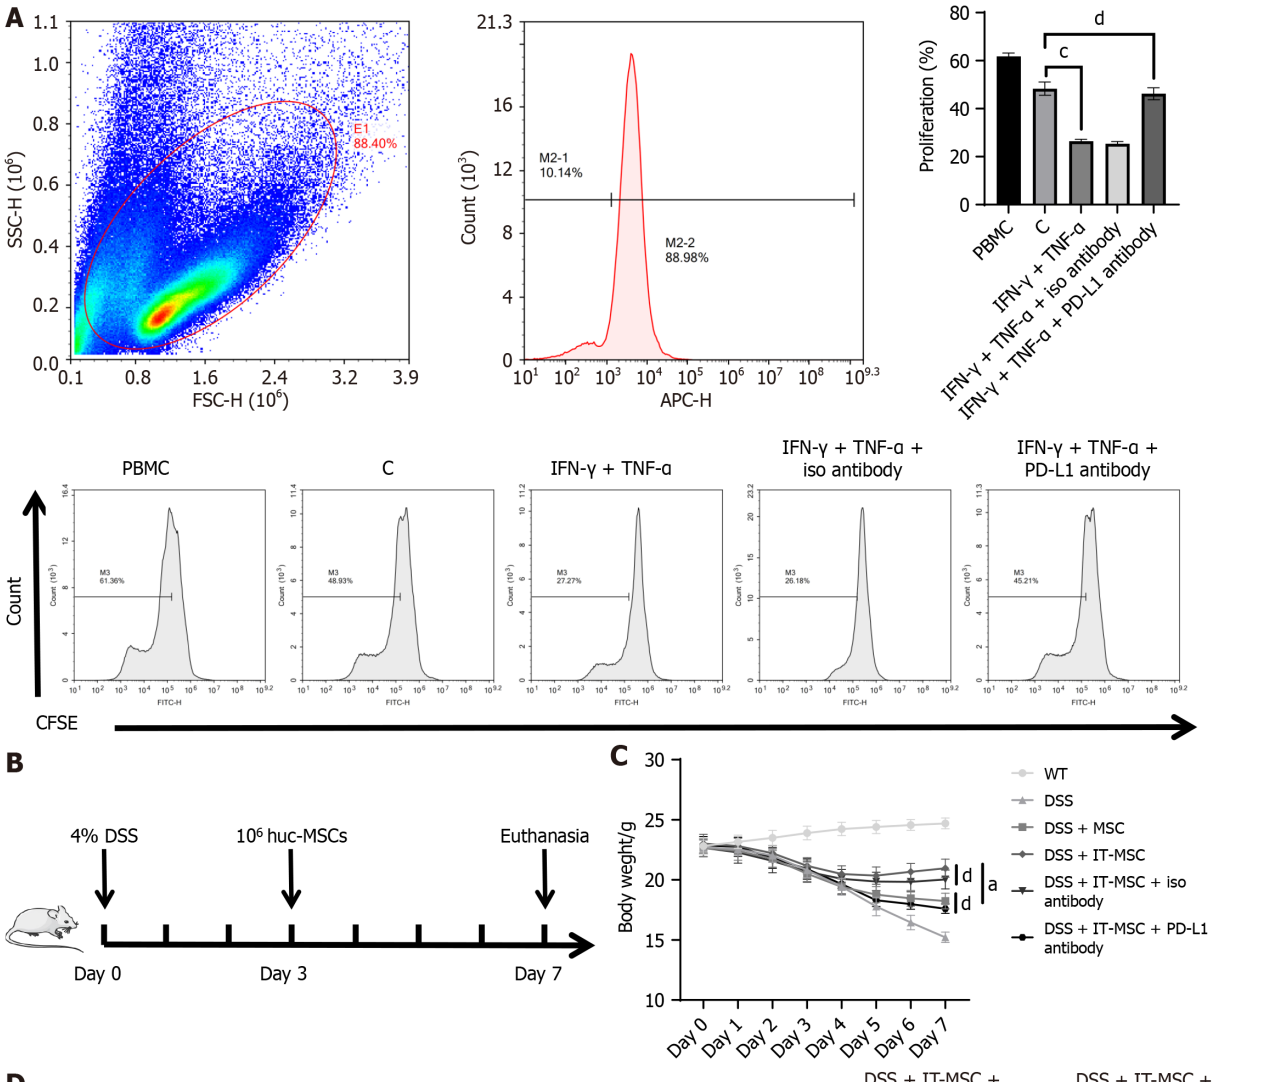
Figure 5 Tumor necrosis factor-alpha synergistically amplified interferon-gamma-induced JAK/STAT1/interferon regulatory factor 1 signaling activation by upregulating NF-κB-mediated interferon-gamma receptor 1/2 expression. A: The expression of NF-κB-mediated interferon-gamma receptor 1/2 (IFNGR1/2) were quantified by quantitative real-time PCR (qRT-PCR) in human umbilical-cord-mesenchymal stem cells (hUC-MSCs) treated with IFN-γ and tumor necrosis factor-alpha (TNF-α) alone or in combination for 4 h; B and C: IFNGR1 expression was quantified by flow cytometry or WB in hUC-MSCs treated with IFN-γ and TNF-α alone or in combination for 24 h; D and E: PD-L1 expression was quantified by qRT-PCR or flow cytometry in hUC-MSCs transfected with siRNA against NC, IFNGR1, or IFNGR2, and subsequently treated with IFN-γ and TNF-α for 4 h or 24 h; F: Activation of the JAK/STAT1/interferon regulatory factor 1 pathway and the expressions of PD-L1 and IFNGR1 were analyzed by western blot in hUC-MSCs after 24 h of incubation with IFN-γ and TNF-α in the presence or absence of IFNGR1 siRNA; G: Activation of the NF-κB pathway and expression of IFNGR1 were analyzed by western blot in hUC-MSCs after 24 h of incubation with TNF-α in the presence or absence of the NF-KB inhibitor BAY11-7082 (10 μM); H: IKKα, IKKβ, p65 and IκBα protein levels in the cytoplasm and nucleus of hUC-MSCs after TNF-α stimulation were measured through western blot; I: IFNGR1 expression was quantified by qRT-PCR in hUC-MSCs transfected

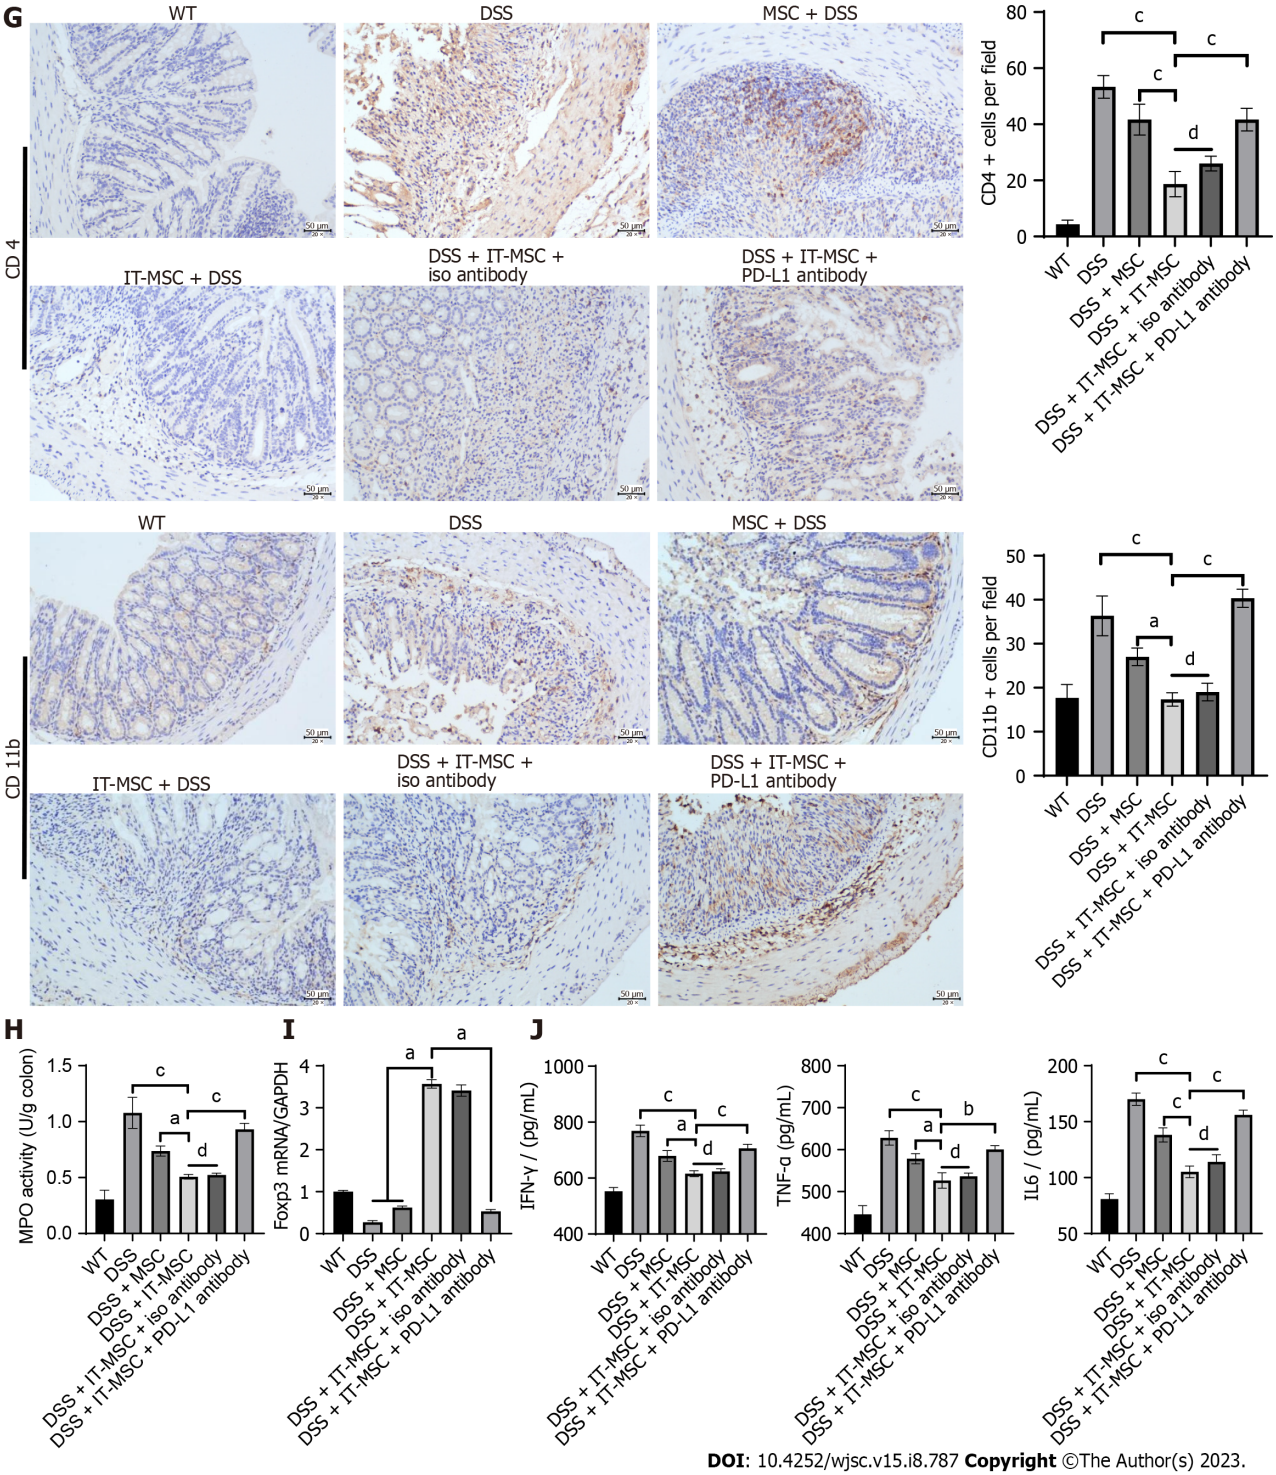
with p65 siRNA and subsequently treated with IFN-γ and TNF-α for 4 h; J and K: PD-L1 expression was quantified by qRT-PCR or flow cytometry in hUC-MSCs transfected with p65 siRNA and subsequently treated with IFN-γ and TNF-α for 4 h or 24 h; L: hUC-MSCs were infected with IFNGR1 overexpressed lentivirus and transfected with siRNA of p65, and induced with IFN-γ and TNF-α for 4 h, and then PD-L1 expression was quantified by qRT-PCR; M: PGL4.10-IFNGR1 promoter plasmid, pIRES2-p65 plasmid, and Renilla luciferase plasmid were transfected together or separately into 293T cells. Cells were lysed 24 h after transfection and luciferase activity was measured; N: pIRES2-p65 plasmid and Renilla luciferase plasmid were transfected into 293T cells with the PGL4.10-IFNGR1 promoter plasmid or the p65 binding site mutant PGL4.10-IFNGR1 promoter plasmid. Cells were lysed 24 h after transfection and luciferase activity was measured. The predicted binding sites of p65 to the IFNGR1 promoter are above the graph. Data were represented as mean ± SEM of $n = 3$. C: Control; Iso: Isotype; [b]$P < 0.001$; [c]$P < 0.0001$; [d]$P > 0.05$. IFN-γ: Interferon-gamma; PD-L1: Programmed cell death protein 1 ligand 1; TNF-α: Tumor necrosis factor-alpha.

yielding a better therapeutic efficacy in DSS-induced mice.

DISCUSSION



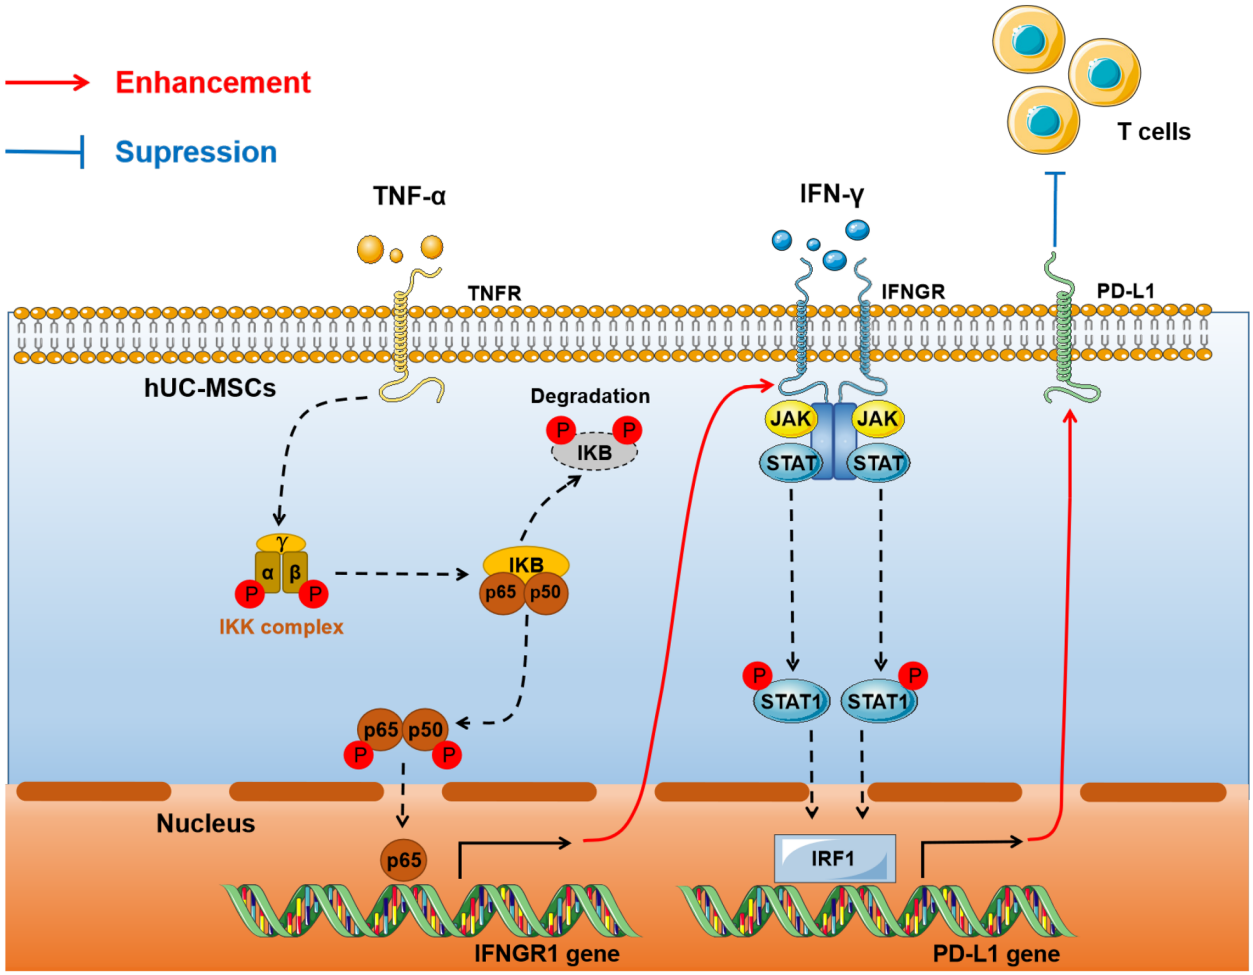
MSCs are usually derived from the umbilical cord, bone marrow, and adipose tissue. In the present study, hUC-MSCs were selected based on multiple considerations. First, as a type of medical waste, umbilical cord tissue is easier to obtain with less ethical controversy. A large number of MSCs are easily obtained from umbilical cord tissue by mature isolation methods. Second, hUC-MSCs have greater proliferative capacity and immunomodulatory ability than other types of MSCs[25,26]. Third, the major histocompatibility complex I (MHC-I) expression level and the immunogenicity of hUC-MSCs is lower. Hence, although the biosafety of MSCs has been a matter of great concern, hUC-MSCs have become the main source of cells for mesenchymal stem cell transplantation therapy[27]. Therefore, as hUC-MSCs have greater clinical application potential, they were selected for use in the study. In DSS-induced colitis mice, MSCs not only significantly improved the colonic lesions of mice but also ameliorated the tumorigenesis of colitis[28]. In a clinical trial, researchers followed up 34 patients with ulcerative colitis who received hUC-MSCs for up to two years, and no long-term complications such as malignant tumors and immune rejection were observed during follow-up[29]. Similarly, except for the therapeutic effect of hUC-MSCs on colitis mice, no MSC-related side effects or toxicities were observed in the present study. Overall, MSCs have a high safety profile in the treatment of ulcerative colitis.



PD-L1 plays an important role in the immunosuppressive capacity of hUC-MSCs. Although the mechanism of PD-L1 expression has been thoroughly elucidated in tumors[30], it remains to be explored in MSCs. The cytokines that induce MSCs to express PD-L1 include IFN-γ, IL25, and IL27, and the relevant pathways are STAT1, JNK/STAT3, and JAK/STAT1[31-33]. We performed this study to investigate the mechanism of PD-L1 expression in MSCs under IFN-γ and TNF-α stimulation and to find a way to enhance the immunosuppressive capacity of MSCs. In the present study, we confirmed that IFN-γ induces PD-L1 expression through the JAK/STAT1/IRF1 pathway in hUC-MSCs. TNF-α upregulates the expression of IFNGR1/2 *via* the NF-κB pathway, which promotes the activation of the JAK/STAT1/IRF1 pathway induced by IFN-γ, significantly increasing PD-L1 expression. Furthermore, synergistic IFN-γ and TNF-α induction of high PD-L1 expression in hUC-MSCs strongly inhibited T-cell proliferation[33]. In mice with DSS-induced colitis, tail vein infusion of pretreated hUC-MSCs reduced disease activity, colonic tissue damage, cytokine levels, and inflammatory cell infiltration. Thus, combined treatment with IFN-γ and TNF-α synergistically induces high PD-L1 expression in hUC-MSCs, which strengthens the immunosuppressive capacity of hUC-MSCs (Figure 7).

PD-L1 expression has been extensively studied in inflammatory diseases and tumors. In tumor cells, various pathways are involved in IFN-γ-induced PD-L1 expression[30]. For instance, IFN-γ induces PD-L1 expression *via* the JAK/STAT/IRF1 pathway in tumor cells[34,35]. Similarly, studies have shown that PD-L1 expression in MSCs can be induced by IFN-γ mediated by STAT1. Based on these studies, we speculated that these signals are similar, and that PD-L1 expression induced by IFN-γ in hUC-MSCs might have occurred through the JAK/STAT1/IRF1 pathway. To verify our hypothesis, we conducted signaling pathway inhibitor, RNA interference, and luciferase reporter gene experiments. Our results showed that IFN-γ activates the JAK/STAT1 pathway and promotes IRF1 binding to the PD-L1 promoter, increasing PD-L1 mRNA expression. The results reveal the molecular mechanism by which IFN-γ induces the expression of PD-L1 in hUC-MSCs in detail.

In tumor cells, TNF-α co-stimulation with IL4 or IFN-γ increased PD-L1 expression, and the effect was associated with the NF-κB pathway[20,36]. HCC cells induced by IFN-γ and TNF-α had higher PD-L1 expression than those induced by IFN-γ alone, and had stronger resistance to adaptive immunity[20]. Such findings suggest that TNF-α enhances PD-L1 expression induced by IFN-γ and NF-κB signaling might be involved. In our results, we found that TNF-α significantly increased IFN-γ-induced PD-L1 expression in hUC-MSCs. Importantly, we demonstrated that TNF-α upregulated IFNGR1 expression through the NF-κB pathway, which enhanced IFN-γ/IFNGR/JAK/STAT1/IRF1 signaling axis activation, significantly upregulating PD-L1 expression. In addition, we found that trends of PD-L1 expression in two others common MSCs pretreated with IFN-γ and TNF-α were similar to those of hUC-MSCs (Supplementary Figure 4C). The results suggest that IFN-γ and TNF-α synergistically induce high PD-L1 expression, which may be universally present in MSCs from different sources. Another issue to consider is that IFN-γ or TNF-α may affect cell survival. Therefore, the effect of such cytokines on the proliferation and apoptosis of hUC-MSCs was evaluated. Additionally, the results showed that IFN-γ and TNF-α stimulation alone or in combination had no effect on the proliferation and apoptosis of hUC-MSCs (Figure 3C and D; Supplementary Figure 3B and C).



Ulcerative colitis is an autoimmune disease with complex mechanisms[37]. PD-L1 is involved in the pathogenesis of colitis by targeting T cells[38]. The high PD-L1 expression in colitis regulates cytokine production in colonic dendritic

Figure 7 Molecular mechanism of interferon-gamma and tumor necrosis factor-alpha synergistically upregulated expression of programmed cell death protein 1 ligand in human umbilical-cord-mesenchymal stem cells to inhibit T cells. IFN-γ: Interferon-gamma; PD-L1: Programmed cell death protein 1 ligand 1; TNF-α: Tumor necrosis factor-alpha; hUC-MSCs: Human umbilical-cord-mesenchymal stem cells; IRF1: Interferon regulatory factor 1.

cells, inhibits Th1/Th17 cell activity, and promotes Treg cell proliferation[38-40]. Therefore, DSS-induced colitis models are often used to evaluate the efficacy of drugs and the immunomodulatory ability of MSCs[22,41,42]. We used T-cell proliferation inhibition experiments *in vitro* to confirm that hUC-MSCs treated with IFN-γ and TNF-α have a stronger immunosuppressive capacity than untreated hUC-MSCs. Furthermore, we evaluated the immunosuppressive capacity of hUC-MSCs treated with IFN-γ and TNF-α in a DSS-induced mouse colitis model and found that they exhibited fewer disease symptoms and less tissue damage, as well as lower inflammatory cell infiltration, lower inflammatory factors, and greater Treg cells recruitment than untreated hUC-MSCs. Moreover, we performed RNA-seq analysis on hUC-MSCs treated with IFN-γ and TNF-α. We found that with a combination of IFN-γ and TNF-α treatment, hUC-MSCs also expressed IDO, TSG-6, and other immunosuppressive molecules (data not shown). The results suggest that hUC-MSCs treated with IFN-γ and TNF-α have a stronger immunomodulatory capacity than untreated hUC-MSCs, perhaps because hUC-MSCs can express PD-L1 as well as other immunosuppressive molecules. This idea is worthy of further investigation.

In recent years, MSCT therapy has been rising in popularity for the treatment of various inflammatory diseases due to the immunosuppressive ability of MSCs. However, due to differences in both the sources of MSCs and the techniques of cell extraction and culture, the efficacy of MSCT in patients is not stable. Based on the present study, it is likely that the abundance of immunosuppressive molecules expressed by MSCs plays an important role. Therefore, this study provides two possible solutions to improve the efficacy of MSCT in diseases. On the one hand, MSCs can express more immunosuppressive molecules (PD-L1) after co-induction with lower concentrations of inflammatory factors (IFN-γ and TNF-α) without impairing cell viability. On the other hand, the efficacy of MSCT can be improved by detecting and screening for MSCs with high expression levels of immunosuppressive molecules before transplantation. In future studies, to compensate for some of the limitations of this study in a translational application, it is necessary to investigate the effect of more combinations of inflammatory factors on PD-L1 expression in MSCs, and also investigate the immunosuppressive molecules induced by other inflammatory factors. More research in this area will contribute to the translational application of MSCT in clinical practice.

CONCLUSION

In the present study, we found that IFN-γ and TNF-α synergistically induce a high level of PD-L1 expression in hUC-MSCs, and we elucidated the molecular mechanism involved. More importantly, both *in vitro* and *in vivo* experiments confirmed that INF-γ- and TNF-α-pretreated hUC-MSCs with these high PD-L1 expression levels have strong immunosuppressive capacity and, therefore, have great potential for clinical application in the treatment of autoimmune diseases.

ARTICLE HIGHLIGHTS

Research background

The immunosuppressive capacity of Mesenchymal stem cells (MSCs) is dependent on the "license" of several proinflammatory factors to express immunosuppressive factors such as programmed cell death 1 ligand 1 (PD-L1), which determines the clinical therapeutic efficacy of MSCs for inflammatory or immune diseases. In MSCs, interferon-gamma (IFN-γ) is a key inducer of PD-L1 expression, which is synergistically enhanced by tumor necrosis factor-alpha (TNF-α), but this; however, the mechanism is unclear.

Research motivation

The efficacy of MSCs transplantation (MSCT) is limited by the expression of immunosuppressive molecules of MSCs, including PD-L1. However, the mechanism of IFN-γ alone or in combination with TNF-α inducing MSCs high expression of PD-L1 remains unclear.

Research objectives

To reveal the mechanism of high PD-L1 expression in MSCs pretreated with IFN-γ and TNF-α and explore the application prospects of MSCs with high PD-L1 expression in ulcerative colitis.

Research methods

We assessed PD-L1 expression in human umbilical cord-MSCs (hUC-MSCs) induced by IFN-γ and TNF-α, alone or in combination. Additionally, we performed signaling inhibition and RNA interference experiments to elucidate the specific cross-talk signaling pathways between IFN-γ and TNF-α. Finally, we evaluated the immunosuppressive capacity of hUC-MSCs treated with IFN-γ and TNF-α in an *in vitro* mixed lymphocyte culture assay, and *in vivo* in mice with dextran sulfate sodium (DSS)-induced acute colitis.

Research results

Our results showed that IFN-γ upregulated PD-L1 expression in hUC-MSCs to enhance their immunosuppressive activities through the JAK/STAT1/interferon regulatory factor 1 (IRF1) pathway. TNF-α synergistically enhanced IFN-γ-induced PD-L1 expression in hUC-MSCs by upregulating nuclear factor kappa-B (NF-κB)-mediated expression of IFN-γ receptor 1 to activate JAK/STAT1/IRF1 signaling. Furthermore, high PD-L1 expression in hUC-MSCs induced by IFN-γ and TNF-α significantly attenuated DSS-induced acute colitis in mice.

Research conclusions

Our study revealed that IFN-γ and TNF-α synergistically induce the high PD-L1 expression of hUC-MSCs through the JAK/STAT1/IRF1 pathway and the NF-κB pathway, which effectively improves the immunosuppressive capacity of hUC-MSCs.

Research perspectives

The results of the present study could facilitate the optimization of clinical application strategies of MSCT.

Abstract

BACKGROUND

Bone marrow mesenchymal stromal cells (BMSCs) are the commonly used seed cells in tissue engineering. Aryl hydrocarbon receptor (AhR) is a transcription factor involved in various cellular processes. However, the function of constitutive AhR in BMSCs remains unclear.

AIM

To investigate the role of AhR in the osteogenic and macrophage-modulating potential of mouse BMSCs (mBMSCs) and the underlying mechanism.

METHODS

Immunochemistry and immunofluorescent staining were used to observe the expression of AhR in mouse bone marrow tissue and mBMSCs. The overexpression or knockdown of AhR was achieved by lentivirus-mediated plasmid. The osteogenic potential was observed by alkaline phosphatase and alizarin red staining. The mRNA and protein levels of osteogenic markers were detected by quantitative polymerase chain reaction (qPCR) and western blot. After coculture with different mBMSCs, the cluster of differentiation (CD) 86 and CD206 expressions levels in RAW 264.7 cells were analyzed by flow cytometry. To explore the underlying molecular mechanism, the interaction of AhR with signal transducer and activator of transcription 3 (STAT3) was observed by co-immunoprecipitation and phosphorylation of STAT3 was detected by western blot.

RESULTS

AhR expressions in mouse bone marrow tissue and isolated mBMSCs were detected. AhR overexpression enhanced the osteogenic potential of mBMSCs

while AhR knockdown suppressed it. The ratio of CD86+ RAW 264.7 cells cocultured with AhR-overexpressed mBMSCs was reduced and that of CD206+ cells was increased. AhR directly interacted with STAT3. AhR overexpression increased the phosphorylation of STAT3. After inhibition of STAT3 *via* stattic, the promotive effects of AhR overexpression on the osteogenic differentiation and macrophage-modulating were partially counteracted.

CONCLUSION
AhR plays a beneficial role in the regenerative potential of mBMSCs partially by increasing phosphorylation of STAT3.

Key Words: Aryl hydrocarbon receptor; Bone marrow mesenchymal stromal cells; Osteogenesis; Macrophage; Signal transducer and activator of transcription 3; Interaction

Core Tip: Aryl hydrocarbon receptor (AhR) was positively expressed in murine bone marrow tissue and bone marrow mesenchymal stromal cells (BMSCs). *In vitro*, overexpression of AhR enhanced the osteogenic potential of mouse BMSCs. Additionally, AhR-overexpressed BMSCs had an increased ability to polarize macrophages to an anti-inflammatory phenotype. While knockdown of AhR showed the opposite effects. Mechanistically, the beneficial effects of AhR were partially dependent on increased phosphorylation of signal transducer and activator of transcription 3. This study suggests that AhR might be a target for achieving optimal bone regeneration in mouse BMSCs-based tissue engineering.

INTRODUCTION

Cell-based tissue engineering is an important method for the treatment of bone defects. Bone marrow mesenchymal stromal cells (BMSCs) are one of the most commonly used seed cells. The osteogenic potential of BMSCs is the premise of their applications in bone regeneration[1]. Additionally, the crosstalk between BMSCs and immune cells like macrophages has been recognized as a critical element in achieving ideal bone tissue repair[2]. Plenty studies have demonstrated that BMSCs are able to trigger a functional switch in macrophages from pro-inflammatory classically activated macrophages (M1) to anti-inflammatory alternatively activated macrophages (M2)[3]. In turn, macrophage polarization is essential for the osteogenic potency of BMSCs. M2 macrophages promote the osteogenesis of BMSCs by secreting pro-regenerative cytokines[4], while M1 macrophages suppress the process[5]. Accordingly, approaches to enhance the osteogenic potential and macrophage-modulating capacity of BMSCs, such as genetic engineering to express specific genes, are continuously being explored.

Aryl hydrocarbon receptor (AhR) is a member of the helix-loop-helix transcription factor superfamily[6]. Historically, AhR has been recognized as a nuclear receptor that responds to environmental toxic stimuli. Recently, increasing number of studies have demonstrated that AhR is an essential modulator in bone turnover[7] and immune responses[8]. AhR can be activated by chemosynthetic agonists such 6-formyl (3,2-b) carbazole (FICZ)[9]. In our previous studies, AhR signaling was suppressed in periodontitis, and FICZ alleviated the inflammatory responses by activating AhR and promoting the phosphorylation of signal transducer and activator of transcription 3 (STAT3)[10]. In another study of our group, FICZ was found to play a beneficial role in the proliferation, osteogenic potential and macrophage-modulation of rat BMSCs and primed cartilage templates[11].

Except for ligand-activated AhR, the role of constitutive unligated AhR in the osteogenic and macrophage-modulating potential of BMSCs has not been investigated. Therefore, the aim of the present study was to: (1) Establish stable AhR-overexpressing or AhR-knockdown mouse BMSCs (mBMSCs); (2) explore the osteogenic differentiation of different mBMSCs; (3) observe the phenotype of macrophages cocultured with different mBMSCs; and (4) investigate the involved molecular mechanism.

MATERIALS AND METHODS

Animal

Six-week-old male C57BL/6 mice were obtained from the Hubei Research Centre of Laboratory Animals (Wuhan, China) and kept in specific pathogen free condition. All experimental protocols were approved by the Institutional Animal Care and Use Committee of School and Hospital of Stomatology, Wuhan University (No. 2020-A08).

Isolation of BMSCs

BMSCs was isolated from 6-week-old male C57BL/6 mice *via* whole femur bone marrow adherent culturing. The femora were excised aseptically, cleaned of soft tissues, and passed through 3 washes with phosphate buffered saline (PBS). The ends of the bones were removed, and the marrow flushed out. The released cells were collected in two 75 cm^2 flasks (Corning) containing 10 mL of 10% fetal bovine serum (Hyclone) in -minimum essential medium. Cultures were maintained in a humidified atmosphere of 95% air and 5% CO_2, at 37°C. After 72 h, all medium was aspirated and replaced to remove the non-adherent cells. The medium was replaced every 2–3 d.

Immunohistochemistry staining

The mice femurs were collected and fixed with 4% paraformaldehyde and then decalcified in 10% ethylene diamine tetraacetic acid for 6 wk. The tissue was subsequently processed for paraffin embedding and serial 4-mm-thick sections were prepared. Then the sections were dewaxed in xylene and rehydrated through graded ethanol to water. Antigen retrieval was conducted in stomach enzyme antigen repair solution for 30 min at 37 °C. Immunostaining was performed by incubating the sections with anti-AhR (NB300-515, 1:200, Novus) at 4 °C overnight. The slides were then washed with PBS and incubated with secondary antibody (Maxim Biotechnology) for 30 min at 37 °C. Staining was visualized with 3, 3-diaminobenzidine and counterstained with hematoxylin.

Immunofluorescent staining

BMSCs at third passage were seeded in cell dish (801002, NEST). After the cells reached 80% confluence, BMSCs were fixed with 4% paraformaldehyde for 15 min and permeabilized with 0.1% Triton X-100 for 20min. Then the cells were blocked with bovine serum albumin (BSA) for 1 h. Subsequently, the cells were incubated with primary antibody against AhR (NB300-515, 1:100, Novus) at 4 °C overnight. After washing, cells were incubated with dylight 594-conjugated secondary antibody (1:200, A23420, Abbkine) for 1 h at room temperature. Then, the cells were stained with 4',6-diamidino-2-phenylindole staining solution (C1005, Beyotime) for 5 min. Finally, the stained cells were observed and photographed under confocal microscope (Leica-LCS-SP8-STED).

Short hairpin RNA design and plasmid preparation

Based on the published sequence of mouse AhR (NM_013464), certain short hairpin RNA (shRNAs) specifically targeting AhR were designed to knockdown their expressions in mBMSCs. The shRNA sequences are as follows: 5′-CATCGA-CATAACGGACGAAAT-3′ (AhR sense) and 5′-ATTTCGTCCGTTATGTCGATG–3′ (antisense). These plasmid DNAs transcribed shRNAs with loop sequences of 5′-CTCGAG–3′. In parallel, a negative control (NC) sequences were projected (sense: 5′-TTCTCCGAACGTGTCACGT-3′, antisense: 5′-ACGTGACACGTTCGGAGAA-3′), which had no homology with human proteins. The generated oligo DNA was cloned into GV493 vector (hU6-MCS-CBh-gcGFP-IRES-puromycin) (GENECHEM, Shanghai).

AhR overexpression plasmid

The coding sequences of mouse AhR (NM_013464) was cloned into GV358 vector (Ubi-MCS-3FLAG-SV40-EGFP-IRES-puromycin) (GENECHEM, Shanghai). The empty Ubi-MCS-SV40-EGFP-IRES-puromycin vector was served as NC.

Lentiviral packaging and infection of mBMSCs

The 293T packaging cell line was co-transfected with plasmid and lentiviral helper vectors (GENECHEM, Shanghai). The medium was replaced with fresh dulbecco's modified eagle medium overnight. After another 48 h, the supernatants were collected and filtered. The viral supernatants were concentrated *via* ultracentrifuging at the speed of 25000 rpm for 2 h at 4°C. One day prior to infection, mBMSCs were seeded in 6-well plates at the density of 10^5 cells/well. Then the mBMSCs were infected with lentiviral particles containing plasmids of knockdown-NC (sh-NC), knockdown-AhR (sh-AhR), overexpression-NC (oe-NC) or overexpression-AhR (oe-AhR) *via* multiplicity of infection level of 20. After 12-16 h, the culture medium was refreshed. Then the cells were cultured in complete medium containing 2 mg/mL puromycin.

qPCR

Total RNA from different cell samples were isolated by Trizol reagent (Takara Bio). SYBR Green Reagent (Takara Bio) was used to perform qPCR in a 7500 Fast Real-Time PCR system (Applied Biosystem). The primer sequences used in the study was showed in Table 1. The relative expression levels were calculated using the 2-DDCt method. Three biological replicates were conducted.

Western blot

Total proteins were extracted from cells with radio immunoprecipitation assay buffer supplemented with 1:100 proteinase and phosphatase inhibitors. The proteins were separated by 10% sodium dodecyl sulphate (SDS)-polyvinylidene fluoride membranes (Roche). After blocked with 5% milk, the membranes were incubated with primary antibody at 4°C overnight. Then the membranes were then incubated with horseradish peroxidase-conjugated secondary antibody for 1 h at room temperature. Subsequently, the bands were visualized with electro-chemi-luminescence detection reagents (Thermo Scientific). Anti-AhR (NB300-515, 1:200, Novus), anti-biomineralization associated [tissue-nonspecific alkaline phosphatase (ALPL)] (11187-1-AP, 1:1000, Proteintech), anti-runt-related transcription factor 2 (RUNX2) (PB0171, 1:2000, Boster), anti-phosphorylated STAT3 (Tyr705) (9145, 1:1000, CST), anti-STAT3 (9139, 1:1000, CST) and anti-glyceraldehyde-3-phosphate dehydrogenase (GAPDH) (BM3876, 1:5000, Boster) primary antibodies were

used. Three biological replicates were conducted.

Osteogenic induction, alkaline phosphatase staining and alizarin red staining

For osteogenic induction, mBMSCs at passage 3 from different groups (sh-NC, sh-AhR, oe-NC or oe-AhR) were cultured in medium supplemented with 50 mg/mL ascorbic acid, 10 mmol/L b-glycerophosphate and 10^{-8} mol/L dexamethasone (Sigma). Then, cells were fixed in 4% paraformaldehyde for 10 min and stained using alkaline phosphatase (ALP) Color Development Kit (C3206, Beyotime) following the manufacturer's instructions. For alizarin red staining (ARS), cells were fixed and stained with alizarin red solution (Cyagen) for 10 min. Three biological replicates were conducted.

Co-culture of mBMSCs and RAW264.7 cells

For direct coculture, mBMSCs from all groups (sh-NC, sh-AhR, oe-NC or oe-AhR) were plated in monoculture at the density of 5 10^5 cells/well at 6-well plate. After the adherence of mBMSCs, the macrophage linage RAW264.7 cells (ScienceCell, Shanghai) (1 10^5 cells/well) were seeded into the wells. The cells were harvested after 24 h of coculture.

For indirect coculture, conditional medium from the culture of sh-NC, sh-AhR, oe-NC or oe-AhR mBMSCs were collected. The conditioned medium was harvested and centrifuged for 10 min at 1000 rpm and then frozen at -20 °C until used. The RAW 264.7 was treated with 1:2 fresh medium and conditioned medium for 24 h.

Flow cytometry

The macrophage surface markers of RAW264.7 cells in the coculture system was detected by flow cytometry. Three biological replicates were conducted.

For direct coculture, the mBMSCs and RAW264.7 cells were collected from 6-well plates after coculture for 24 h and washed three times with PBS. The cell suspensions were divided into 1.5 mL Eppendorf micro test tubes (EP tubes) and incubated with blocking 3% BSA. Then the cell suspensions were incubated with allophycocyanin anti-F4/80 (157305, BioLegend), combined with fluorescein isothiocyanate (FITC) anti-cluster of differentiation (CD) 86 (105005, BioLegend) or PerCP/Cy5.5 anti-CD206 (141715, BioLegend) at 4°C for 1 h.

For indirect coculture, the RAW264.7 cells were collected and washed three times with PBS. The cell suspensions were divided into 1.5 mL EP tubes and incubated with blocking 2% BSA. Then the cell suspensions were successively incubated with CD86 (13395-1-AP, Proteintech) or CD206 (18704-1-AP, Proteintech), and FITC conjugated immunoglobulin G (BA1105, Boster).

The above cells were washed three times after incubation and suspended in 500 mL containing 3% fetal bovine serum and then detected by Beckman Coulter CytoFLEX S and analyzed by CytoExpert.

Co-immunoprecipitation

The AhR and p65 protein-protein interaction was detected by co-immunoprecipitation (Co-IP) kit (P2179S, Beyotime) following manufacturer's instructions. The mBMSCs protein sample was extracted from cells with lysis buffer supplemented with protease inhibitor cocktail. The AhR antibody (NB300-515, 1:100, Novus) was incubated with protein A+G beads at room temperature for 2 h and then washed three times using Tris buffered saline. Then the beads-antibody complex was immunoprecipitated with mBMSCs protein sample at 4°C overnight. After washed three times using lysis buffer, the beads-antibody-antigen complex was eluted SDS-polyacrylamide gel electrophoresis sample loading buffer. After magnetic separation, the expression of STAT3 in the supernatant was detected using STAT3 primary antibody (9139, 1:1000, CST) *via* western blot. Three biological replicates were conducted.

STAT3 inhibitor stattic

To testify whether the effects of AhR in osteogenic differentiation and macrophage-modulating was partially STAT3-

dependent or not, a specific STAT3 inhibitor stattic (Selleck) was introduced. In osteogenic induction, oe-NC and oe-AhR mBMSCs were cultured in osteogenic medium supplemented with or without 2 mmol/L stattic. For indirect coculture system of mBMSCs and RAW 264.7 cells, the mixed fresh and conditioned medium from mBMSCs was supplemented with or without 2 mmol/L stattic. Three biological replicates were conducted for each treatment.

Statistical analysis

All data were expressed as the mean ± SD. For comparison between two groups, statistical differences were evaluated by a two-tailed Student's *t* test. For multiple comparisons, a one-way analysis of variance (ANOVA) followed by Tukey's test were conducted. *P*-value < 0.05 was considered statistically significant.

RESULTS

The expression of AhR in bone marrow of mouse femurs and isolated mBMSCs

The immunohistochemistry (IHC) staining showed that AhR was expressed in parts of mouse femur bone marrow (Figure 1A-C). In isolated mBMSCs derived from femurs, AhR expression was positively observed *via* immunofluorescence staining (Figure 1D-I), which was consistent with the IHC results.

AhR overexpression or knockdown in mBMSCs

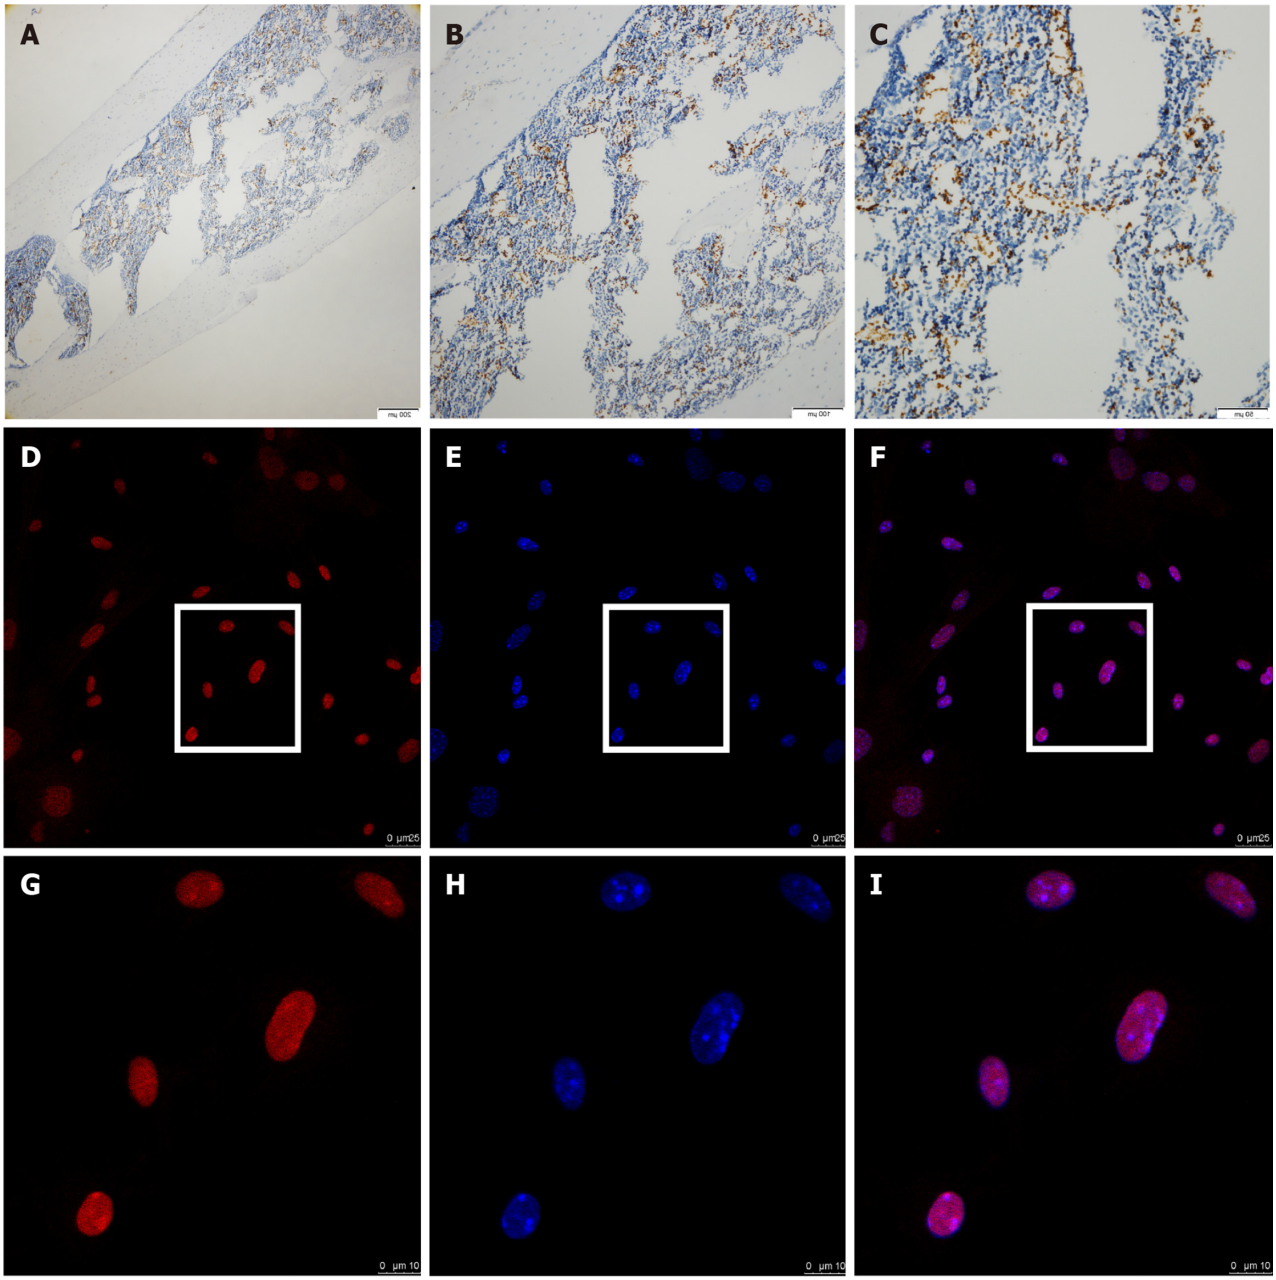
At 48 h after infection with oe-AhR or sh-AhR and their NC lentivirus (oe-NC and sh-NC), the efficiencies of AhR overexpression or knockdown were confirmed by qPCR and western blot. The qPCR data (Figure 2A) showed that the relative AhR mRNA expression level of the oe-NC and oe-AhR groups were 0.85 ± 0.08 and 4.39 ± 0.23 respectively, and those of the sh-NC and sh-AhR groups were 1.13 ± 0.14 and 0.16 ± 0.01, respectively. The western blot results (Figure 2B and C) demonstrated that the relative AhR/GAPDH protein levels of the oe-NC and oe-AhR groups were (0.29 ± 0.05) and (0.45 ± 0.07), and those of the sh-NC and sh-AhR groups were 0.31 ± 0.11 and 0.04 ± 0.01 respectively. The data indicated that AhR was significantly overexpressed or knocked down in oe-AhR or sh-AhR mBMSCs.

The effect of oe-AhR or sh-AhR on the osteogenic differentiation of mBMSCs

At the 7th day of osteogenic induction, ALP staining showed that AhR overexpression resulted in more positive nodules than the NC (Figure 3A). Consistently, after 14 d of osteogenic induction, the visualization of calcium deposits and mineralized nodules by ARS also demonstrated that AhR overexpression promoted the osteogenic potential of mBMSCs (Figure 3A). In contrast, AhR knockdown suppressed the nodules formation and calcium deposition, as showed by ALP staining and ARS, compared to the NC (Figure 3A).

At the 7th day of osteogenic induction, the mRNA levels of the osteogenic markers ALP, ALPL and RUNX2 in oe-AhR mBMSCs were significantly higher than those in oe-NC mBMSCs (Figure 3B), while those in sh-AhR cells were lower than those in sh-NC cells (Figure 3C). Then, the protein samples were harvested after 7 d of osteogenic induction and were subjected to western blotting. The bands showed increased protein expressions of ALPL and RUNX2 in oe-AhR mBMSCs compared to oe-NC mBMSCs, while sh-AhR inhibited their expressions compared to sh-NC (Figure 3D), which was basically consistent with the mRNA results.

The effect of oe-AhR or sh-AhR on the macrophage-modulating capacity of mBMSCs



Brightfield images of direct coculture were captured prior to analysis (Figure 4A), and the morphologies of the RAW 264.7 cells and different groups of mBMSCs were similar. In flow cytometry analysis of direct coculture samples, the ratio of M1-like macrophages among RAW 264.7 cells was calculated as CD86 + (Q1-UR)/F4/80 + (Q1-UR + Q1-LR) (Figure 4B). Similarly, the ratio of M2-like macrophages among RAW 264.7 cells was calculated as CD206 + (Q2-UR)/F4/80 + (Q2-UR + Q2-LR) (Figure 4C). Quantitative analysis (Figure 4D) demonstrated that the ratio of CD86+ cells and CD206+ cells was not significantly different between RAW 264.7 cells cocultured with oe-AhR and those cocultured with oe-NC mBMSCs. While the ratio of CD86+ cells among RAW 264.7 cocultured with sh-AhR mBMSCs was significantly higher than that among RAW 264.7 cocultured with sh-NC mBMSCs.

In the indirect coculture system, RAW 264.7 cells were cultured with conditioned medium from different mBMSCs. The CD86 and CD206 expressions were demonstrated using histograms (Figure 5A and B). Quantitative analysis (Figure 5C) showed that the ratio of CD86+ cells was significantly lower and the ratio of CD206+ cells was significantly higher in the oe-AhR group than oe-NC. The ratio of CD86+ cells in the sh-AhR group was significantly higher than that in sh-NC.

The above data suggested that knockdown of AhR in mBMSCs tends to drive macrophages toward the M1-like phenotype and inhibit M2-like polarization. Overexpression of AhR in mBMSCs showed the opposite macrophage-modulating effect.

The molecular mechanism underlying the role of AhR in the osteogenic differentiation and macrophage modulation of mBMSCs

First, the AhR and STAT3 protein-protein interaction was detected *via* Co-IP (Figure 6A). Then, the effect of AhR overexpression or knockdown on the phosphorylation of STAT3 was explored by western blotting (Figure 6B). The results showed that oe-AhR promoted the phosphorylation of STAT3 while sh-AhR suppressed it. To test whether the effects of AhR on osteogenic differentiation and macrophage-modulating were partially STAT3-dependent or not, a specific STAT3

Figure 1 The expression of aryl hydrocarbon receptor in bone marrow tissue of mouse femur and isolated bone marrow mesenchymal stromal cells. A-C: Immunochemistry staining showed positive aryl hydrocarbon receptor (AhR) expression in bone marrow tissue [bar: 200 mm (left), 100 mm (middle) and 50 mm (right)]. D-I: Immunofluorescence staining of AhR in mouse bone marrow mesenchymal stromal cells *via* confocal microscopy (red: AhR; blue: 4',6-diamidino-2-phenylindole; pink: Merge) [bar: 25mm (D-F) and 10mm (G-I)].

inhibitor, stattic, was introduced. The western blotting lanes testified that 2 mmol/L stattic partially alleviated the AhR overexpression-mediated increase in STAT3 phosphorylation (Figure 6C). ALP staining at the 7th day of osteogenic induction and ARS at the 15th day indicated that 2 mmol/L stattic partially reversed the elevated osteogenic potential mediated by AhR overexpression (Figure 6D). Regarding macrophage modulation, the flow cytometry and quantitative analysis manifested that 2 mmol/L stattic partially reversed the inhibition of CD86 expression and promotion of CD206 in RAW 264.7 cells cultured with conditioned medium from oe-AhR mBMSCs (Figure 6E and F). The above data suggested that AhR promoted the osteogenic and macrophage-modulating potentials of mBMSCs partially by interacting with STAT3 and increasing the phosphorylation of STAT3.

DISCUSSION

Based on the results, and within the limitations of the present study, it could be concluded that: (1) Endogenous unligated AhR promoted osteogenic potential of mBMSCs; (2) endogenous unligated AhR played a positive role in polarizing

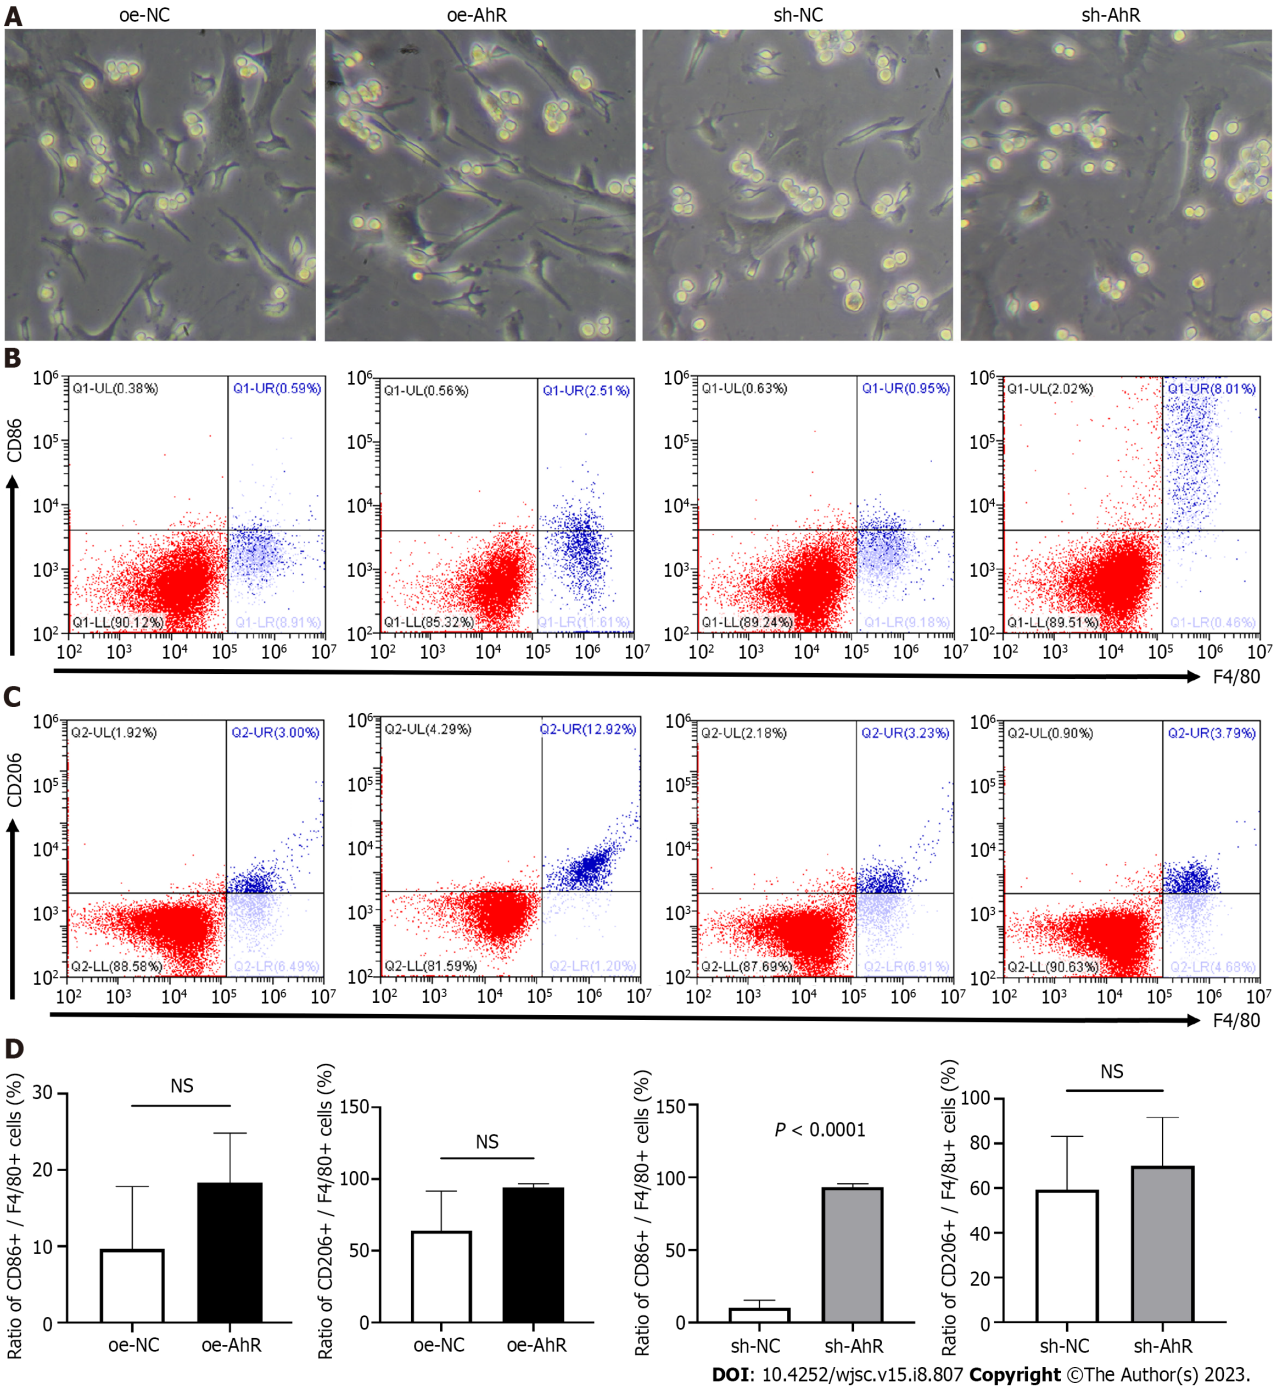
macrophages towards the M2-like phenotype of mBMSCs; and (3) the function of AhR was partially dependent on interacting with STAT3 and increasing the phosphorylation of STAT3. The present study offered new insights into the role of AhR and the involved molecular mechanism in the regenerative potential of mBMSCs, which might be a target for achieving optimal bone regeneration in mBMSCs-based tissue engineering.

The nuclear receptor AhR is positively expressed in bone tissue, including osteoblasts and osteoclasts, and the AhR signaling pathway plays a vital role in bone homeostasis[12]. AhR was previously considered as an environment xenobiotic sensor and mediates oxidative stress[13]. In recent decades, the roles of AhR as a transcription factor in regulating various biological processes have been revealed. Plenty studies have focused on the functions of ligand-activated AhR in biological processes. However, the effects of AhR might vary due to interactions with different ligands. The first identified AhR ligand was a dioxin-like compound (DLC), 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD), which mediates toxic effects after binding to AhR. Then, various kinds of non-dioxin-like endogenous ligands were identified, such as FICZ, 2-(1′-H–indole–3-carbonyl) thiazole–4-carboxylic acid methyl ester, and tryptophan metabolites such as kynurenine, which demonstrated functional diversity[9].



Regarding osteogenic potential, AhR activated by DLC ligands such as TCDD is basically harmful[14], but the effects of endogenous ligands such as FICZ are controversial. In a recent study, two different AhR ligands, benzo[a]pyrene (B[a]P) and FICZ, were analyzed in mice temporomandibular joint osteoarthritis[15]. The above study demonstrated that B[a]P induced mandibular subchondral bone resorption in an AhR-dependent manner. However, FICZ exerted a therapeutic effect and rescued the bone loss *in vivo* at both low (100mg/kg) and high (100mg/kg) concentrations. Moreover, 200ng/mL FICZ promoted the osteogenic differentiation on MC3T3 E1 cells *in vitro*, resulting in more obvious ALP staining and ARS, and increased mRNA expressions of osteogenic markers, including ALP, osteocalcin (OCN) and collagen type I alpha 1. Consistently, in a previous study by our group, 500 nM FICZ enhanced the ALP staining and ARS of rat BMSCs

after osteogenic induction[11]. In addition to ligand-activated AhR, its role in bone ossification was investigated in transgenic mice. In the semistable fracture healing model in mice, the expression of AhR in the healing callus tissue was more than 2-fold higher on the seventh day after fracture than in uninjured samples. On the 14th day after fracture, AhR expression had increased by 10-fold in callus tissue. To determine whether the loss of AhR affects bone healing, the researchers established a tibial fracture model in wild type (WT) mice and AhR knockout (KO) mice and performed micro-computed tomography (micro-CT) scan analysis two weeks later. Mineralized callus tissue in the fracture gap was

Figure 5 The cluster of differentiation (CD) 86 and CD206 expressions of RAW 264.7 cells that cocultured with conditioned medium from different mouse bone marrow mesenchymal stromal cells. A: The typical histograms of CD86 expressions of RAW 264.7 cells; B: The typical histograms of CD206 expressions of RAW 264.7 cells; C: Quantitative analysis of ratios of CD86+ and CD206+ cells. oe-NC: Overexpression-negative control; oe-AhR: Overexpression-aryl hydrocarbon receptor; sh-NC: Knockdown-negative control; sh-AhR: Knockdown-aryl hydrocarbon receptor; NS: Not significant.

observed in the former but not the latter mice. At the third week, micro-CT analysis also showed that AhR KO mice had less bone formation than WT mice[7]. In another study[16], the ALP and OCN mRNA expression levels of BMSCs obtained from AhR KO mice were lower than those of WT mice after 8-10 d of osteogenic induction. Interestingly, the ALP and OCN expression patterns in the BMSCs of AhR KO mice after osteogenic induction were rather parallel to the TCDD-suppressed responses in BMSCs from WT mice. The results of present study were consistent with above literatures.

Additionally, AhR has been proven to be involved in modulating immune/inflammatory disease by targeting specific gene expression and altering immune differentiation[8]. Similarly, complex ligand interactions that control AhR function might result in diverse immunologic effects including immunosuppressive or pro-inflammatory downstream functions [17]. In another study, peritoneal macrophages from WT and AhR-null mice were polarized toward the M1 or M2 phenotype by stimulation with lipopolysaccharide/interferon-g or interleukin (IL)-4[18]. The results indicated that AhR-null macrophages presented higher levels of M1 markers including IL-1b, IL-6, IL-12 and tumor necrosis factor-a, and lower levels of M2 markers, including chitinase-like 3 (or called Ym1) and IL-10. It was found that the binding of AhR to the promoters of IL-10 and arginase-1 was increased in macrophages after uptake of apoptotic cells to promote M2 polarization[19]. AhR not only affects the phenotype of macrophages themselves but also influences the results of other cells in regulating macrophage polarization. Treatment with the AhR ligand FICZ attenuated calcium oxalate nephrocalcinosis in a mouse model. Bone marrow-derived macrophages (BMDMs) and calcium oxalate monohydrate (100mg/mL)-treated renal tubular epithelial cells were cocultured in transwell system. FICZ supplement in the system promoted the expression of M2 markers and diminished the expression of M1 markers in BMDMs. The molecular mechanism was that AhR directly targeted downstream microRNA-142a-3p, which suppressed interferon regulatory factor 1 and hypoxia inducible factor 1 alpha by binding to their 3′ untranslated region[20]. In another study, another AhR ligand, TCDD, was added to a coculture system of mBMSCs and macrophages. Treatment of BMSCs with TCDD resulted in a significant increase in M2 markers and a decrease in M1 markers in macrophages. The AhR antagonist CH223191 alleviated the macrophage-modulating effect[21]. In the present study, AhR overexpression in mBMSCs promoted its ability of polarizing macrophages into M2-like phenotype.

Figure 6 The molecular mechanism of the role of aryl hydrocarbon receptor in osteogenic differentiation and macrophage-modulating in mouse bone marrow mesenchymal stromal cells. A: Co-immunoprecipitation assay showed that aryl hydrocarbon receptor (AhR) and signal transducer and activator of transcription 3 (STAT3) directly interacted in mouse bone marrow mesenchymal stromal cells (mBMSCs); B: Western blot lanes demonstrated that AhR overexpression promoted phosphorylation of STAT3 compared to negative control, while AhR knockdown suppressed it; C: The specific STAT3 inhibitor stattic (2

mmol/L) partially alleviated the promoted STAT3 phosphorylation by AhR overexpression; D: Alkaline phosphatase (upper) and alizarin red staining (lower) staining indicated that 2 mmol/L stattic partially inhibited the elevated osteogenic potential by AhR overexpression; E and F: The histograms of flow cytometry and quantitative analysis manifested that 2 mmol/L stattic partially reversed the CD86 inhibition and CD206 promotion in RAW 264.7 by conditioned medium from overexpression-AhR mBMSCs. AhR: Aryl hydrocarbon receptor; oe-NC: Overexpression-negative control; oe-AhR: Overexpression-AhR; sh-NC: Knockdown-negative control; sh-AhR: Knockdown-AhR; STAT3: Signal transducer and activator of transcription 3; p-STAT3: Phosphorylated STAT3; GAPDH: Glyceraldehyde-3-phosphate dehydrogenase.

It was reported that AhR signaling exhibits considerable crosstalk with other transcription factors, such as those in the nuclear factor-kB family and signal transducer and activator of transcription family[17,22]. AhR can bind to other molecules to undergo a conformational change exposing a nuclear localization signal[17]. STAT3 is critical in regulating immune responses[23] and osteogenic differentiation processes[24]. Our previous study showed that FICZ-stimulated AhR alleviated the inflammatory response in periodontal ligament cells by increasing the phosphorylation of STAT3[10]. The interplay between AhR and STAT3 was explored in various cell types. In A549 cells the interaction of AhR and STAT3 was detected *via* Co-IP. Increased AhR by reduning upregulated the expression of STAT3 and the downstream IL-10, which alleviate severe pneumonia[25]. *Lactobacillus johnsonii* N6.2-derived nano-sized vesicles led to the nuclear translocation of AhR in pancreatic b cells and enhanced the phosphorylation of STAT3 and expression of IL-10, which reduced the apoptosis and improved the expression of genes related to glucose transport[26]. In the present study, the direct AhR and STAT3 interaction was also observed in mBMSCs. Moreover, AhR overexpression upregulated the phosphorylation of STAT3. However, the further research is needed to fully understand the precise molecular mechanisms underlying the AhR-STAT3 interaction.

CONCLUSION

In conclusion, AhR plays a promotive role in the regenerative potential of mBMSCs, including osteogenic differentiation and polarizing macrophages to an anti-inflammatory phenotype. Mechanistically, AhR can interact with STAT3, thereby increasing the phosphorylation level of STAT3. Inhibition of STAT3 partially counteracted the beneficial effect of AhR. Hence, AhR might be a target for achieving optimal bone regeneration in mBMSCs-based tissue engineering.

ARTICLE HIGHLIGHTS

Research background

Bone marrow mesenchymal stromal cells (BMSCs) are one of the most commonly used seed cells in bone tissue engineering. Aryl hydrocarbon receptor (AhR) has been recognized as a nuclear receptor that modulates bone turnover. However, the function of constitutive AhR in BMSCs remains unclear.

Research motivation

To explore whether AhR is involved in the regenerative potential of mouse BMSCs (mBMSCs).

Research objectives

To investigate the role of AhR in the osteogenic and macrophage-modulating potential of mBMSCs and the underlying mechanism.

Research methods

Immunochemistry and immunofluorescent staining were used to observe the expression of AhR in mouse bone marrow tissue and mBMSCs. The overexpression or knockdown of AhR was achieved by lentivirus-mediated plasmid. The osteogenic potential was observed by alkaline phosphatase and alizarin red staining. The mRNA and protein levels of osteogenic markers were detected by quantitative polymerase chain reaction and western blot. After coculture with different mBMSCs, the cluster of differentiation (CD) 86 and CD206 expressions levels in RAW 264.7 cells were analyzed by flow cytometry. To explore the underlying molecular mechanism, the interaction of AhR with signal transducer and activator of transcription 3 (STAT3) was observed by co-immunoprecipitation and phosphorylation of STAT3 was detected by western blot.

Research results

AhR expressions in mouse bone marrow tissue and isolated mBMSCs were detected. AhR overexpression enhanced the osteogenic potential of mBMSCs while AhR knockdown suppressed it. The ratio of CD86+ RAW 264.7 cells cocultured with AhR-overexpressed mBMSCs was reduced and that of CD206+ cells was increased. AhR directly interacted with STAT3. AhR overexpression increased the phosphorylation of STAT3. After inhibition of STAT3 *via* stattic, the promotive effects of AhR overexpression on the osteogenic differentiation and macrophage-modulating were partially counteracted.

Research conclusions

AhR plays a beneficial role in the regenerative potential of mBMSCs partially by increasing phosphorylation of STAT3.

Research perspectives

This study suggested that AhR and its interaction with STAT3 might be a potential candidate target for achieving optimal bone regeneration in mBMSCs-based tissue engineering.

Abstract

BACKGROUND

Cardiovascular diseases particularly myocardial infarction (MI) are the leading cause of mortality and morbidity around the globe. As cardiac tissue possesses very limited regeneration potential, therefore use of a potent small molecule, inhibitor Wnt production-4 (IWP-4) for stem cell differentiation into cardiomyocytes could be a promising approach for cardiac regeneration. Wnt pathway inhibitors may help stem cells in their fate determination towards cardiomyogenic lineage and provide better homing and survival of cells *in vivo*. Mesenchymal stem cells (MSCs) derived from the human umbilical cord have the potential to regenerate cardiac tissue, as they are easy to isolate and possess multilineage differentiation capability. IWP-4 may promote the differentiation of MSCs into the cardiac lineage.

AIM

To evaluate the cardiac differentiation ability of IWP-4 and its subsequent *in vivo* effects.

METHODS

Umbilical cord tissue of human origin was utilized to isolate the MSCs which were characterized by their morphology, immunophenotyping of surface markers specific to MSCs, as well as by tri-lineage differentiation capability. Cytotoxicity analysis was performed to identify the optimal concentration of IWP-4. MSCs were treated with 5 μM IWP-4 at two different time intervals. Differentiation of MSCs into cardiomyocytes was evaluated at DNA and protein levels. The MI rat

model was developed. IWP-4 treated as well as untreated MSCs were implanted in the MI model, then the cardiac function was analyzed *via* echocardiography. MSCs were labeled with 1,1′-dioctadecyl-3,3,3′,3′-tetramethylindocarbocyanine perchlorate (DiI) dye for tracking, while the regeneration of infarcted myocardium was examined by histology and immunohistochemistry.

RESULTS

MSCs were isolated and characterized. Cytotoxicity analysis showed that IWP-4 was non-cytotoxic at 5 μM concentration. Cardiac specific gene and protein expression analyses exhibited more remarkable results in fourteen days treated group that was eventually selected for *in vivo* transplantation. Cardiac function was restored in the IWP-4 treated group in comparison to the MI group. Immunohistochemical analysis confirmed the homing of pre-differentiated MSCs that were labeled with DiI cell labeling dye. Histological analysis confirmed the significant reduction in fibrotic area, and improved left ventricular wall thickness in IWP-4 treated MSC group.

CONCLUSION

Treatment of MSCs with IWP-4 inhibits Wnt pathway and promotes cardiac differentiation. These pre-conditioned MSCs transplanted *in vivo* improved cardiac function by cell homing, survival, and differentiation at the infarcted region, increased left ventricular wall thickness, and reduced infarct size.

Key Words: Myocardial infarction; Inhibitor Wnt production-4; Differentiation; Mesenchymal stem cells; Wnt pathway; Cardiac function

Core Tip: This study highlights the role of Wnt signaling pathway in the differentiation of mesenchymal stem cells (MSCs) into cardiac progenitor cells and the therapeutic potential of MSCs conditioned with inhibitor Wnt production-4 (IWP-4) for the treatment of heart disease. Further studies are required to comprehend the mode of action of IWP-4 on MSCs and to assess its potency and safety in human clinical trials. Nevertheless, this research is an exciting step forward for new treatments for heart diseases and is more focused on the importance of continued investment in the development of innovative therapies for this devastating condition.

INTRODUCTION

Cardiovascular diseases (CVDs) remain the major mortality cause around the globe[1]. The associated morbidity and mortality may rise to 23.6 million by 2030, which emphasizes the urgent need of addressing the issue of regenerating the damaged heart[2]. CVDs account for a wide range of pathological changes in the blood vessels and heart. Current treatment strategies include inhibitors of beta and aldosterone, angiotensin altering enzyme inhibitors, and biventricular striding. However, heart failure related morbidity and mortality cause temporary success due to these therapeutic interventions and highlight the need for novel therapy that can inhibit and reverse heart dysfunction. Cell therapy emerged in the 1990s and was perceived as a promising strategy to repair an injured heart after myocardial infarction (MI)[3].

Mesenchymal stem cells (MSCs) are the epitome of tissue regeneration due to their easy isolation and existence in almost all types of tissues. They can be differentiated into multiple lineages. Their immunological properties such as immunosuppressive, anti-inflammatory, and immunoregulatory potential make them potent immunotolerant cells[4]. MSCs isolated from the umbilical cord are relatively advantageous over other adult sources owing to their ability to high passaging, expansion on a larger scale, higher anti-inflammatory effects, and more significant senescence retardation[5].

The Wnt signaling pathway comprises a complex network of signaling molecules that play a crucial role in stem cell growth, survival, and differentiation. Wnt antagonists (IWPs) inhibit Wnt ligand release by inhibiting a membrane bound O-acyltransferase, Porcn, responsible for catalyzing Wnt palmitoylation[6]. Several studies reported that the inhibition of Wnt pathway promotes the differentiation of stem cells toward cardiomyocytes. Inhibitor Wnt production-4 (IWP-4) was also reported to produce functional cardiomyocytes from induced pluripotent stem cells and embryonic stem cells[7,8].

In this study, we investigated the role of IWP-4, a potent inhibitor of the Wnt signaling pathway on human umbilical cord derived MSCs. Our results showed that treatment with IWP-4 promotes MSCs differentiation into cardiac progenitor cells *in vitro*, which is a promising step towards the development of stem cell treatment for heart disease. To assess the

therapeutic potential of IWP-4 treated MSCs, cells were transplanted in rat MI model. Our results demonstrated that treatment with IWP-4 improves the efficacy of the MSCs to recover cardiac function of the MI rats, as evidenced by an increase in the ejection fraction. These findings suggest that preconditioning of MSCs with IWP-4 may be a promising approach for the treatment of heart diseases and that targeting Wnt signaling pathway may represent a promising approach for this debilitating condition.

MATERIALS AND METHODS

In vitro studies

Ethical approval: This study was conducted according to the institutional ethical standards outlined in the protocol #ICCBS/IEC-067-HT/UCB-2021/Protocol/1.0, which was approved by the ethical review committee. Healthy donors' umbilical cords were obtained from Zainab Panjwani Memorial Hospital with informed consent after C-section delivery. The cord samples were collected aseptically and transferred into a sterile glass bottle filled with 0.5% EDTA in phosphate buffer saline (PBS) and kept at 4 °C. The samples were processed immediately after collection.

Human umbilical cord tissue processing: The biosafety cabinet class II, type A2 (ESCO, Singapore) was used for sample processing. The cord sample was washed with sterile PBS and then cut into 1-3 mm pieces. These pieces were placed in T-75 flasks containing 10-12 mL complete DMEM (10% fetal bovine serum, 100 U of streptomycin/penicillin, and 1 mmol/L sodium pyruvate). The flasks were kept at 37 °C in a humidified CO_2 incubator. The flask was monitored regularly for cell growth, and the medium was changed after every 3 d. After 10-14 d of initial culture, MSCs from the explant were migrated and adhered to the surface of the flask. When the cells were adequately attached, explants were removed and cells were supplied with fresh medium for further propagation. The cells were labeled as passage zero (Po). When the cells became 80% confluent, they were trypsinized for the next passage using 1× trypsin-EDTA. The experiments were carried out using passages (P_2 to P_3) MSCs.

Characterization of MSCs: The isolated MSCs were characterized based on phase contrast microscopy, immunocytochemistry, immunophenotyping, and trilineage differentiation.

Phase contrast microscopy: Phase contrast microscopy was performed for the morphological analysis of MSCs at different passages. The images were captured with phase contrast microscope (Ti-2, Nikon, Tokyo, Japan).

Immunocytochemistry: Coverslips were placed in a 24-well tissue culture plate and 5000 cells were seeded with 200 µL of complete DMEM in each well, then the plate was incubated in a CO_2 incubator at 37 °C for 24-48 h to allow for monolayer formation. The next day, DMEM was discarded and cells were washed with 1× PBS, and fixed with 200 µL of 4% Paraformaldehyde (PFA) for 10 min. Cells were again washed with PBS and then permeabilized with 300 µL of 0.1% Triton X-100 for 10 min followed by 3 washes with PBS. The cells were then blocked for 1 h at 37 °C using a blocking solution containing 2% BSA, 0.1% Tween-20, and 1× PBS to prevent non-specific binding. After blocking, the monoclonal primary antibodies CD117 (32-9000, Zymed, United States), CD29 (MAB-1981, Chemicon International, United States), Lin28 (PA1- 096, Invitrogen, United States), CD105 (560839, BD Pharmingen, United States), Vimentin (V6389, Sigma-Aldrich, United States), and CD45 (CBL415, BD Pharmingen, United States) were added to each well, and the plate was incubated at 4 °C overnight. The next day, primary antibodies were removed, and cells were washed with 1× PBS. Cells were then incubated with Alexa Fluor 546 conjugated goat anti-mouse secondary antibody (A-11010, Molecular Probes, Invitrogen, United States) at 37 °C for 1 h, followed by washing with 1× PBS. The cells were stained with a 0.5 µg/mL solution of DAPI-PBS (4', 6-diamidino-2-phenylindole) for 15 min at room temperature followed by washing with 1× PBS. Finally, coverslips were placed on a glass slide, and then slides were mounted with 5 µL of aqueous mounting medium. The fluorescence microscope (Nikon Ti2; Nikon, Japan) was used to observe the slides.

Flow cytometry: Immunophenotypic characterization was performed by flow cytometry. MSCs were trypsinized and washed with PBS then resuspended in FACS buffer (1 mmol/L EDTA, 1% BSA, and 0.1% sodium azide). Cells were incubated with primary antibody CD73 (550256, BD Pharmingen, United States), CD105, Vimentin, and CD45 incubated at 37 °C for 2 h. The primary antibody was removed and cells were washed with PBS. Then Alexa Fluor 488 goat anti-mouse secondary antibody was added for 1 h at 37 °C. Cells were washed and analyzed *via* FACS Calibur (Becton Dickinson, United States). For control, unlabeled and isotype labeled cells were used.

Tri-lineage differentiation: For the characterization of MSCs through tri-lineage differentiation, cells were allowed to grow in complete DMEM in a 6-well plate. For the differentiation of MSCs into adipocytes, MSCs were allowed to grow in adipogenic induction medium containing complete DMEM, 1 µM dexamethasone, 10 µg/mL insulin, 200 µM indomethacin, and 0.5 µM isobutyl methylxanthine for 21 d. MSCs were differentiated into osteocytes in osteogenic induction medium containing complete DMEM with 0.1 µM dexamethasone, 0.2 mmol/L L-ascorbic acid-2-phosphate, and 10 mmol/L glycerol-2- phosphate for 28 d. For chondrogenic differentiation, MSCs were allowed to grow in chondrogenic induction medium containing complete DMEM, 1 µM dexamethasone, 20 ng/mL transforming growth factor-β, 100 mmol/L ascorbic acid, and 10 ng/mL insulin for 21 d. Differentiated cells were stained with Oil Red O for the detection of lipid droplets inside the cells for adipocytes. Alizarin Red staining was performed to detect calcium deposits in osteocytes. Alcian Blue staining confirmed the presence of proteoglycans and glycosaminoglycans (GAG).

Cytotoxicity analysis of IWP-4 by JC-1 assay: JC-1 cytotoxicity analysis was performed to determine the cytotoxic effect of IWP-4 on MSCs. MSCs were grown in complete DMEM in T-75 flasks and then treated with the different concentrations (5, 10, 20, 30, 50, and 100 µM) of IWP-4 for 24 h. Cells were trypsinized, washed, and then stained with 500 µL of 10µg/mL JC-1 dye working dilution and incubated for 15 min at 37 °C. Afterwards, MSCs were washed and resuspended in PBS. Data were analyzed with BD CellQuest pro software.

Treatment with IWP-4: The concentration of 5 µM was selected for cardiac differentiation based on JC-1 cytotoxicity assay. Working solutions were prepared from 2 mmol/L IWP-4 stock solution. Complete DMEM was used for the preparation of conditioned medium. 20 µL stock compound was added in 50 mL of media and stored at 4 °C. When cells became 60% confluent, normal media was discarded, and conditioned media was added to the flask and then kept in a CO_2 incubator for seven, and fourteen days. The conditioned medium was replaced every 3 d.

Gene expression of cardiac markers: For cardiac gene expression analysis, RNA was isolated from untreated, seven and fourteen days IWP-4 treated MSCs *via* Trizol method according to the manufacturer's instructions. The concentration and purity of RNA were checked by using Nanodrop2000 (Thermo Fisher Scientific, United States) at 260 nm absorbance. A 260/280 absorbance ratio was used to determine the purity of isolated RNA. cDNA was synthesized from 1 µg of RNA by using RevertAid First Strand cDNA Synthesis Kit (K1621, Thermo Fisher Scientific, United States), according to the manufacturer's protocol. Cardiac specific genes were amplified using primer sequences enlisted in Table 1, by quantitative real-time polymerase chain reaction (qPCR) using a CFX96 Touch Real-Time PCR Detection System (Bio-Rad Laboratories, United States). Bright Green 2× qPCR master mix (Applied Biological Materials, Canada) was used for the amplification. For gene amplification, initial denaturation was performed at 95 °C for 10 min, 40 cycles of denaturation at 95 °C for 15 s, and extension at 60 °C for 1 min. The *GAPDH* gene (a housekeeping gene) was used as endogenous control. To analyze the relative gene expression level, the cycle threshold (Ct) value was acquired after the completion of the reaction, and the fold change was calculated using $2^{-\Delta\Delta Ct}$ method.

Gene expression of Wnt pathway genes: For Wnt pathway gene expression analysis, total RNA was isolated and cDNA was prepared and amplified as described above. For gene amplification, initial denaturation was performed at 95 °C for 10 min, and 40 cycles of denaturation at 95 °C for 15 s, and extension at 60 °C for 1 min. Wnt specific genes were amplified using primer sequences enlisted in Table 2. The *GAPDH* gene (a housekeeping gene) was used as endogenous control. To analyze relative gene expression level, the Ct value was acquired after completion of the reaction, and the fold change was calculated using $2^{-\Delta\Delta Ct}$ method.

Immunocytochemistry of cardiac protein: To examine protein expression, immunofluorescence staining was performed on both untreated and fourteen days IWP-4 treated MSCs by the same protocol as explained earlier for the characterization of MSCs. Untreated and IWP-4 treated MSCs were washed with PBS and fixed with 4% PFA, and then incubated in cardiac specific antibodies such as α-actinin (sc-17829, Santa Cruz Biotech, United States), Connexin-43 (C-43) (13-8300, Thermo scientific, United States), cardiac troponin I (cTnI) (Ab209809, Abcam, United Kingdom), Desmin (MAB3430 Chemicon International, United States), GATA-4 (sc-25310, Santa Cruz Biotech, United States), Nkx 2.5 (sc-376565, Santa Cruz Biotech, United States). Next, Alexa Fluor 488 conjugated goat anti-mouse secondary antibody (A-11001, Invitrogen, United States) was added followed by washing with 1× PBS. The cell nuclei were counterstained with DAPI in 1× PBS for 15 min at room temperature and washed again with 1× PBS. Protein expression was observed using a fluorescence microscope. Fluorescent images were processed and quantified by ImageJ software.

In vivo studies

Animal care and ethical approval: MI model was developed using Wistar rats weighing between 220-230 g. The study was conducted in compliance with the international guidelines for laboratory animal care and use under protocol number 2021-006, with ethical approval obtained from the Institutional Animal Care and Use Committee at the Dr. Panjwani Center for Molecular Medicine and Drug Research, International Center for Chemical and Biological Sciences, University of Karachi. The animals were housed in separate cages, in a room maintained at a temperature of 22 °C ± 2 °C, 55 ± 5% relative humidity, and a 12 h light: 12 h dark cycle, with unrestricted access to water and food.

Cardiac model development: To develop the MI model, a metal rod was cooled in liquid nitrogen for 15 min. Rats were anesthetized with xylazine and ketamine (7 mg/kg and 60 mg/kg, respectively), according to their body weights. To initiate artificial ventilation, a rodent ventilator was used and endotracheal intubation was performed. Left thoracotomy was performed through the anterolateral 4th and 5th intercostal space, and a retractor was used to expose the heart. Then the rod was removed from liquid nitrogen and placed on the left ventricle of the heart for 10 s. Successful MI model development was confirmed with the change in color of the infarcted region from red to pale color. The chest cavity was closed with 5-0 suture (Ethicon, United States), and the skin was closed with a 4-0 suture. Trachea was closed with the help of 6-0 suture. Animals were administered diclofenac sodium (25 mg/mL) and antibiotics (penicillin and streptomycin 10000 U/mL) subcutaneously. Animals were observed until they regained consciousness. In the sham control group, the chest cavity was opened and then closed without the exposure of an ultracold rod.

Transplantation of cells in MI model: After model development, one million cells resuspended in 1× PBS were transplanted in the left ventricular wall immediately after infarction. For *in vivo* cell tracking, untreated and IWP-4 treated MSCs were labeled with the red fluorescent dye, 1,1′-dioctadecyl-3,3,3′,3′-tetramethylindocarbocyanine perchlorate (DiI) according to the manufacturer's instructions and transplanted into the rats.

Echocardiography: Cardiac functional analysis was performed by echocardiography after 2 and 4 wk of MI with the help of an Echo machine (Aloka, Japan) provided with 7-MHz transducer. Motion-mode (M-mode) and 2D-bright mode (B-mode) were used to scan the parasternal long-axis view of papillary muscles. Left ventricular internal systolic and diastolic dimensions (LVIDs and LVIDd) were calculated using M-mode scans, and averaged three consecutive cardiac cycles were taken for measurements. Percent ejection fraction (%EF) and fractional shortening (%FS), and end diastolic and systolic volumes (EDV and ESV) were calculated by using the formula as given below:

$$FS\ (\%) = (LVIDd - LVIDs)/LVIDd \times 100$$

$$EF\ (\%) = SV/EDV \times 100$$

$$EDV = [7/(2.4) + LVIDd] \times LVIDd^3$$

$$ESV = [7/(2.4) + LVIDs] \times LVIDs^3$$

Heart harvesting and tissue processing for histology: After 4 wk from surgery and cell transplantation, rats were anesthetized, perfused with 1× PBS, and then fixed with 4% PFA. The hearts were removed and placed in 4% PFA overnight, then dehydrated in graded alcohol, and afterward immersed in xylene then xylene-paraffin mixture followed by embedding in paraffin. Microtome sectioning was performed to cut 5 μm thick sections of paraffin blocks. Sections were taken on gelatin coated slides. Hematoxylin-Eosin (H&E) and Masson's trichrome staining were performed according to the manufacturer's instructions. For histological analysis, the stained section images were observed under a bright-field microscope (NiE, Nikon, Japan).

Tracking of DiI labeled cells in MI model: For DiI labeled cell tracking in animals, hearts were perfused with 1× PBS, fixed with 4% PFA for 4 h, and then mold was prepared in optimal cutting temperature medium. Mold was cryosectioned and cells were tracked by observing them under a fluorescent microscope. To assess the long-term survival, distribution, and differentiation of the transplanted cells in the MI model, tissue was permeabilized with triton-X 100, and blocked with blocking solution. The sections were stained with cardiac specific primary antibodies against GATA-4, cTnI, and

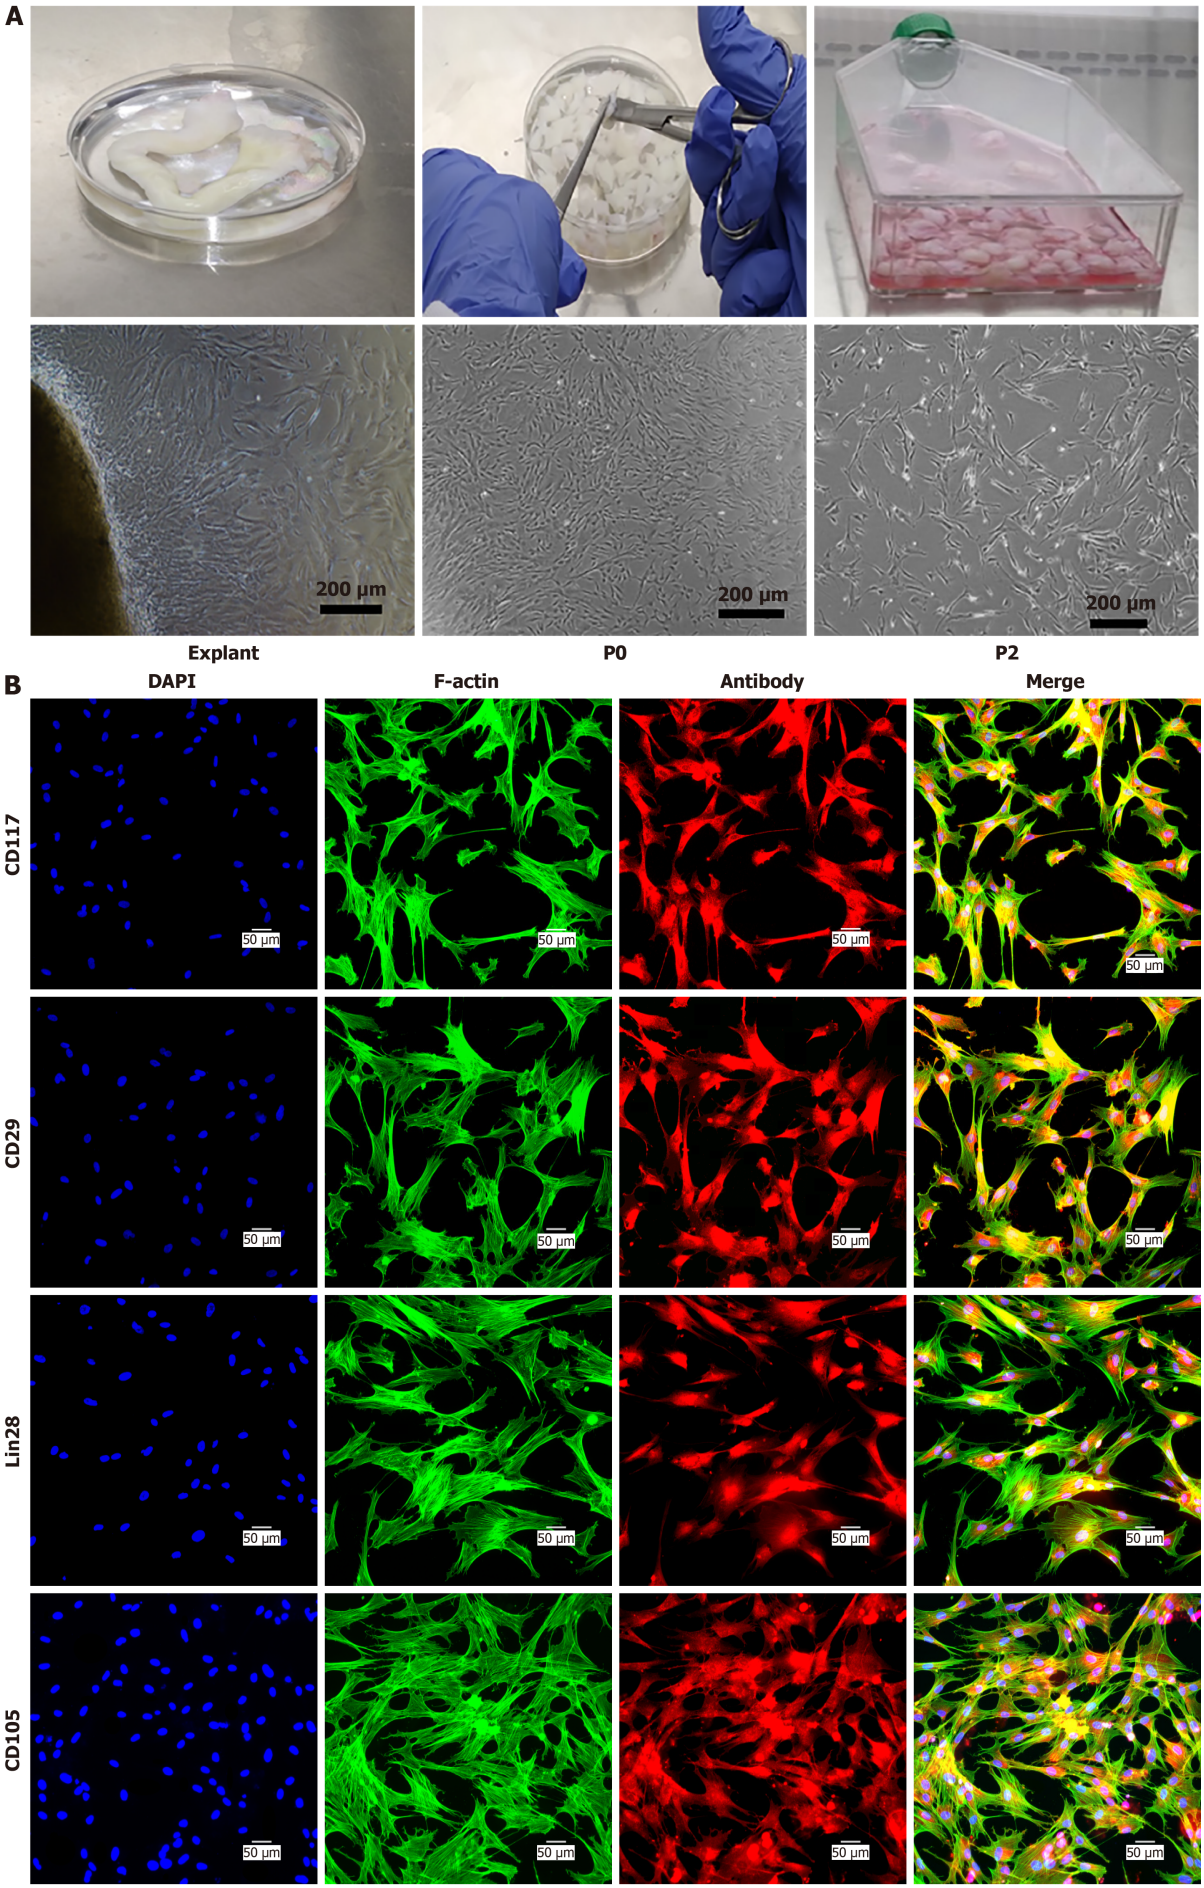
alpha actinin. Alexa fluor 488 secondary antibody was used to detect primary antibodies. Fluorescent microscope images were captured and quantified using Image J software and plotted using GraphPad Prism software.

Statistical analysis

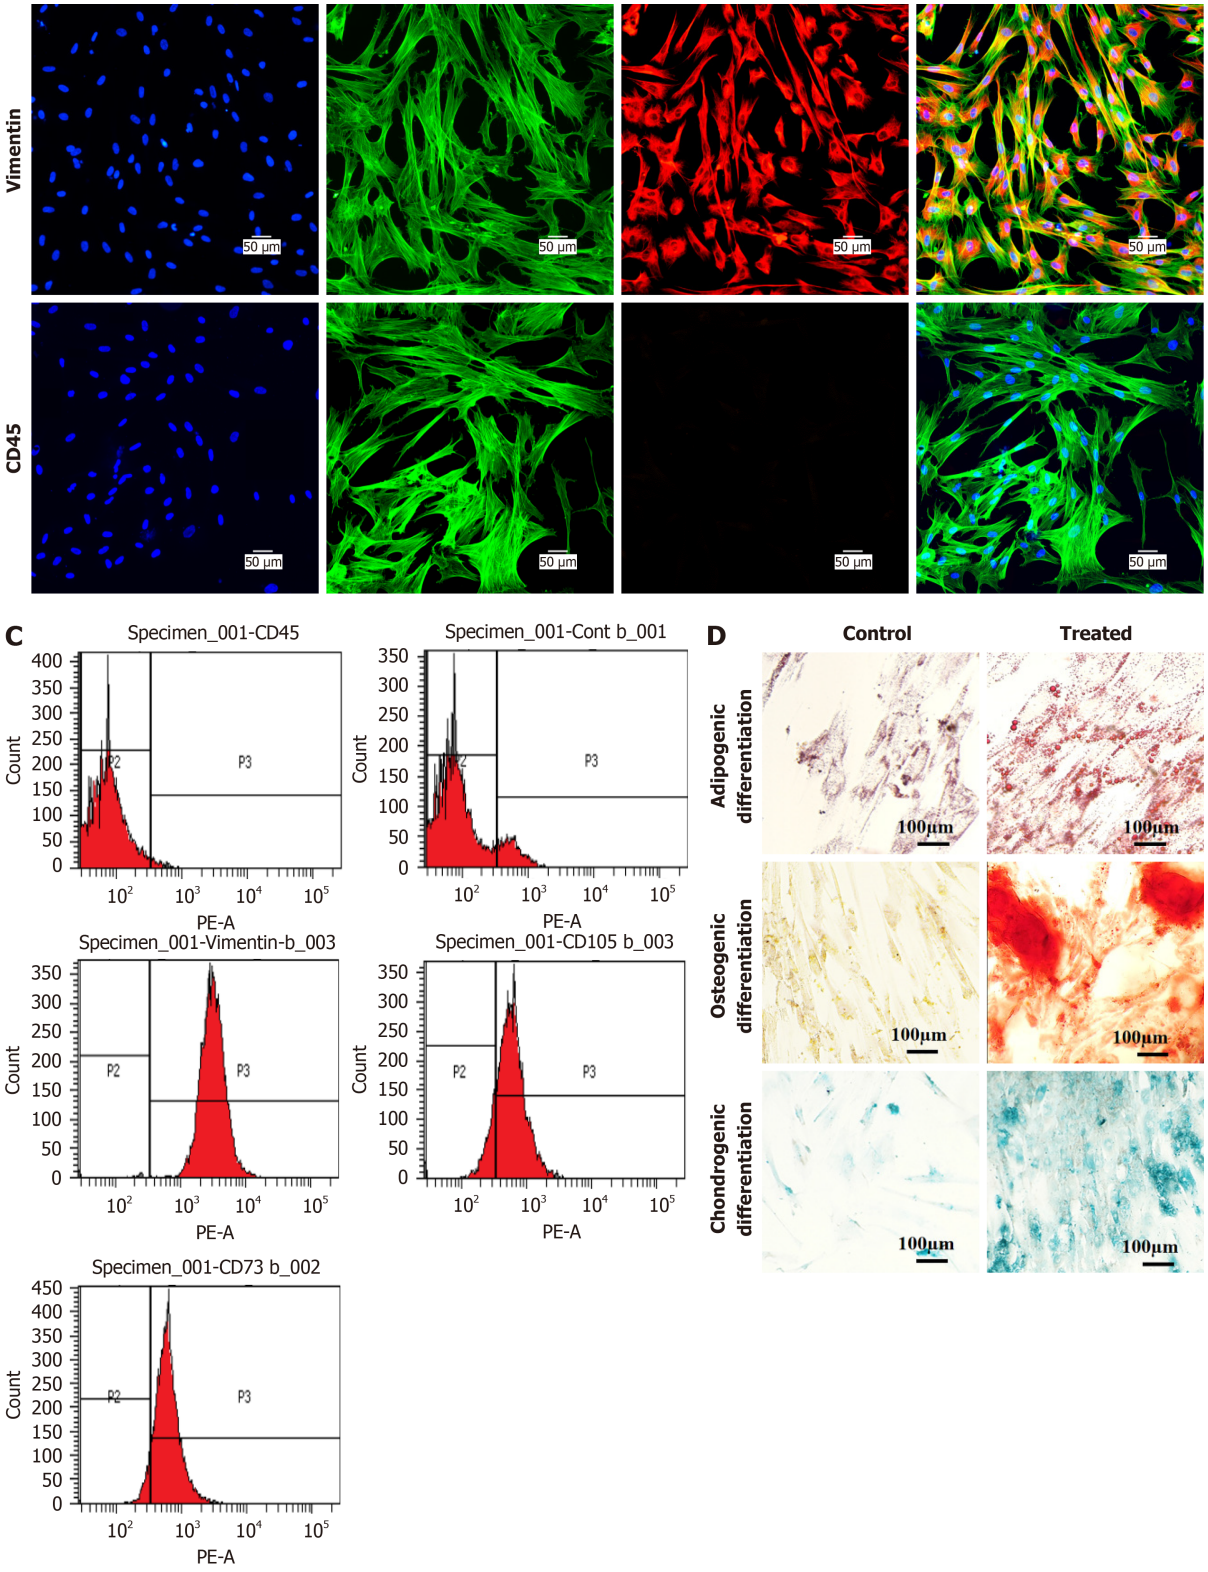
The statistical analysis was conducted using IBM SPSS Statistics software version 23. For comparison between the two groups, independent sample *t*-test analysis was performed. However, for the comparison between multiple groups, One-way analysis of variance with post-hoc Bonferroni corrections was used. The results were expressed as mean ± SEM, and statistical significance was determined at $^{a}P < 0.05$, $^{b}P < 0.01$, and $^{c}P < 0.001$.

RESULTS

In vitro studies



Morphology of human umbilical cord-derived MSCs: MSCs culture exhibited spindle shape morphology. Explant of cord tissue culture showed outgrowth of MSCs after 7-10 d of processing after adhering to the tissue culture flask which then showed gradual expansion and propagation. After 15 d, P_o cells were grown in colonies and possessed elongated, fibroblast like morphology. P_o cells were trypsinized and sub-cultured to get the homogeneous population of MSCs at P_1. Human umbilical cord processing and morphology of MSCs sub-culture at different passages are shown in Figure 1A.



Immunocytochemistry of MSCs: MSCs showed positive expression of specific cell surface markers CD117, CD29, Lin28, CD105, Vimentin, and negative expression of CD45 which is a hematopoietic marker, as shown in Figure 1B.

Flow cytometric analysis

Immunophenotyping was performed with flow cytometry that showed greater than 90% of the cell population expressed CD105, Vimentin, and CD73, while CD45 exhibited negative expression that confirms the presence of MSCs in culture, as shown in Figure 1C.

Tri-lineage differentiation: MSCs possess tri-lineage differentiation potential that was confirmed by differentiating them into adipogenic, osteogenic, and chondrogenic lineages. Mineral deposition confirmed the differentiation of MSCs into

Figure 1 Isolation, propagation, and characterization of human umbilical cord-derived mesenchymal stem cells. A: Explant processing and isolation of human umbilical cord-derived mesenchymal stem cells (MSCs). Phase contrast images showing homogenous fibroblast like morphology and growth; B: Characterization of MSCs by immunocytochemistry representing the positive expression of CD117, CD29, Lin28, CD105, Vimentin, and negative expression of CD45; C: Immunophenotyping of MSCs by flow cytometry showing positive expression of CD105, Vimentin, and CD73, and negative expression of CD45; D: Tri-lineages differentiation of MSCs into osteogenic, adipogenic, and chondrogenic lineages.

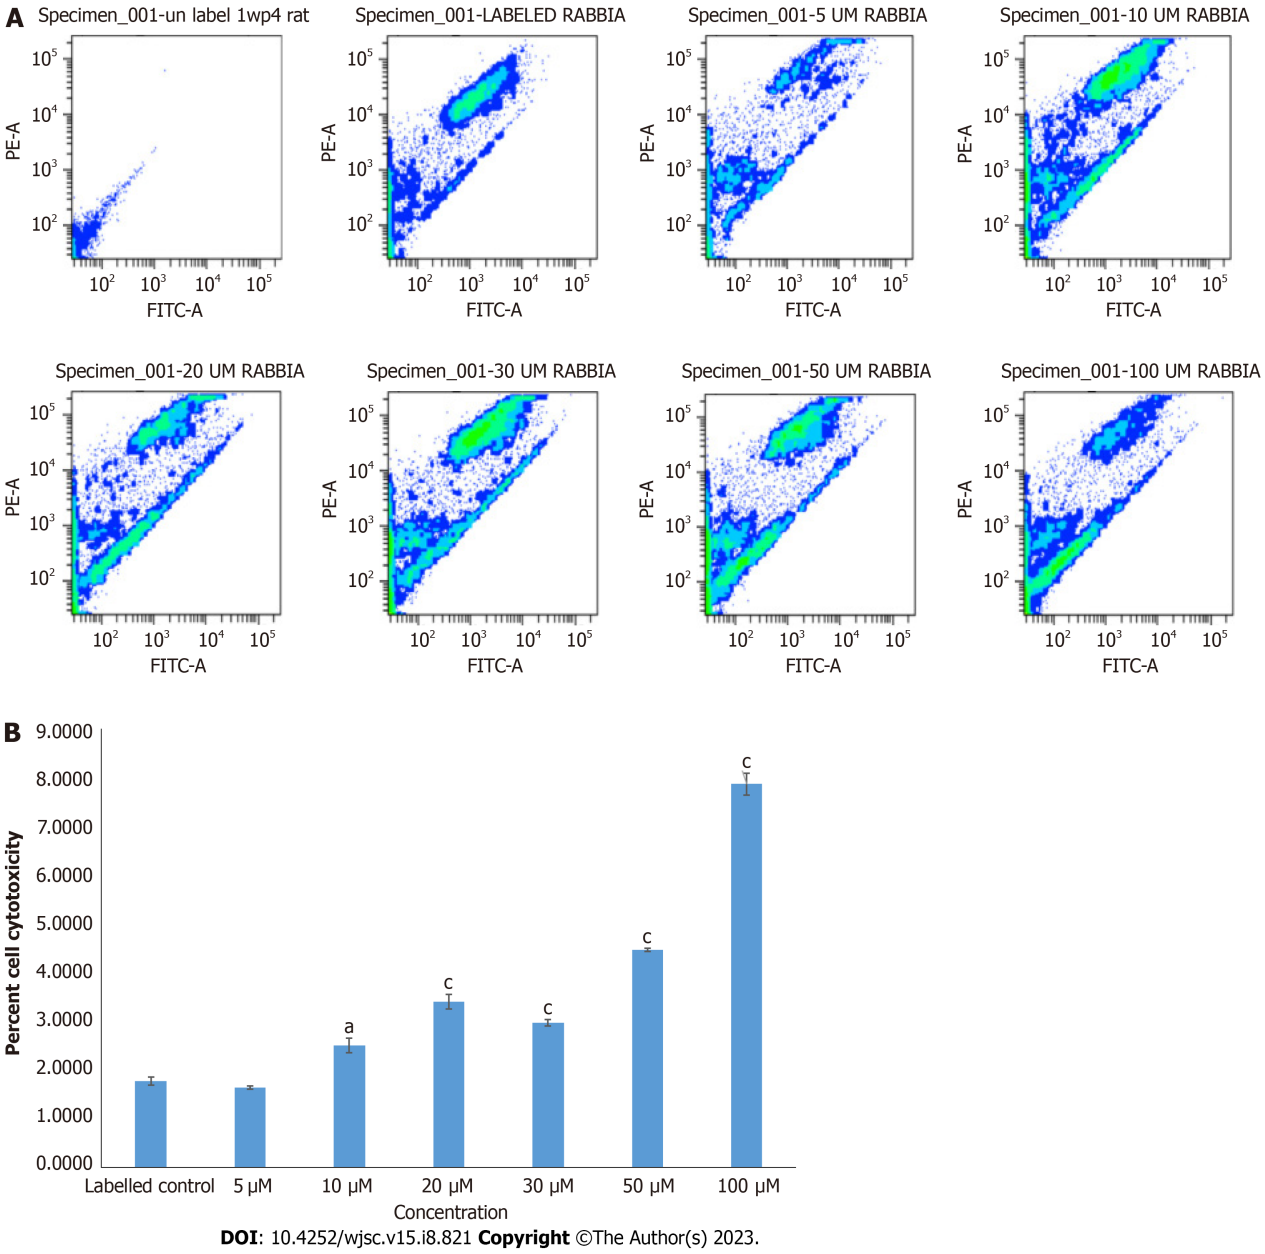
the osteogenic lineage. Adipogenic differentiation was confirmed by the accumulation of intracellular lipid droplets in treated MSCs, which turn out to be bright red with an Oil Red O stain. Alizarin Red stained differentiated MSCs into orange red color, while large mineral deposits appeared dark red. Chondrogenic differentiation was observed by the

accumulation of GAG that stained blue after Alcian Blue staining. The results are shown in Figure 1D.

Cytotoxicity analysis by JC-1 assay: MSCs treated with different concentrations of IWP-4 were stained with JC-1 dye. Percent cell cytotoxicity was calculated by the shift of cells in the lower right quadrant of density plot in flow cytometer software. JC-1 assay showed that IWP-4 at 5 μmol/L concentration was non cytotoxic for MSCs. The results are shown in Figure 2.

Cardiac gene expression analysis: After fourteen days of treatment of MSCs with IWP-4, cardiac gene expression analysis showed significant upregulation of early and late cardiac genes. After seven days of treatment with IWP-4, myosin light chain-2 (MLC-2v) ($P < 0.01$), and Ca-channel ($P < 0.05$) genes were significantly upregulated, while MHC-β and cardiac troponin C (cTnC) showed non-significant change. However, Na-channel ($P < 0.05$), cardiac troponin T (cTnT), GATA4 ($P < 0.01$), alpha-actinin, cTnI, Mef2D, and Nkx2.5 ($P < 0.001$) showed significant downregulation as shown in Figure 3A. After fourteen days treatment of MSCs with IWP-4, when compared to control, alpha-actinin ($P < 0.05$), MHC-β, MLC-2v, Mef2D, cTnT, cTnC, cTnI, Ca-channel, Na-channel, Nkx2.5, and GATA4 ($P < 0.001$) were significantly upregulated as shown in Figure 3B.

Gene expression analysis of Wnt pathway genes: Wnt pathway gene expression profile was analyzed after seven and fourteen days treatment of MSCs with IWP-4. Gene expression profile showed that seven days treatment of MSCs with IWP-4 inhibit Wnt pathway. When compared to control, Wnt pathway genes, *GSK, DVL, Wnt, TCF, β-catenin,* and downstream transcription factors *C-jun, C-myc, Cyc-D* ($P < 0.001$) were significantly downregulated, while *Axin* showed upregulation ($P < 0.01$) (Figure 4A). After fourteen days treatment of MSCs with IWP-4, Wnt pathway was further downregulated. When compared to control, Wnt pathway genes *DVL, Wnt, and β-catenin* ($P < 0.001$) showed significant downregulation, while negative regulators of pathway *GSK* ($P < 0.01$), and *Axin* ($P < 0.05$) were upregulated. However, downstream transcription factors *C-jun, Cyc-D, TCF* showed non-significant change, while *C-myc* ($P < 0.05$) was upregulated as shown in Figure 4B.



Analysis of differentiated cells: Differentiated MSCs showed cardiac like cell morphology as shown in Figure 5A. Seven days IWP-4 treated MSCs showed positive expression of C-43, cTnI, ($P < 0.001$), desmin, GATA-4, and Nkx2.5 ($P < 0.05$), while alpha-actinin protein expression showed non-significant change. As compared to untreated MSC control, fourteen days IWP-4 treated MSCs showed positive expression of alpha-actinin, C-43, cTnI, desmin, GATA-4, and Nkx2.5 ($P < 0.001$). As compared to seven days IWP-4 treated MSCs, fourteen days IWP-4 treated MSCs showed positive expression of alpha-actinin, C-43, cTnI, desmin, GATA-4, and Nkx2.5 ($P < 0.001$) as shown in Figure 5B and C.

In vivo studies

Cardiac function analysis by echocardiography: Echocardiographic analysis of cardiac function showed decreased left ventricular wall contraction in rats with an infarcted heart (MI group) as compared to the sham control. A significant difference ($P < 0.001$) in the left ventricular systolic and diastolic dimensions, %EF, %FS, and end-systolic and -diastolic volumes were measured after two and four weeks of MI as compared to sham control. The infarcted hearts that received untreated MSCs and IWP-4 treated MSCs showed significant improvement in heart function. As compared to the MI group, left ventricular systolic and diastolic dimensions were significantly decreased ($P < 0.001$) after two and four weeks of transplantation. The %EF and %FS showed significant improvement ($P < 0.001$) in untreated and IWP-4 treated MSCs. End-systolic and -diastolic volumes were also significantly improved ($P < 0.001$) in both the cell transplantation groups as compared to the MI group as shown in Figure 6.

Analysis of isolated rat hearts: Treated and untreated MSCs were transplanted immediately after the MI model development. Hearts were isolated after 4 wk of surgery for histological (Figure 7A and B) and macroscopic analysis (Figure 7C). Macroscopic analysis revealed a major difference in the appearance of hearts in all groups. Hearts from the sham control group appeared normal, containing healthy myocardium, while in the case of MI group, the left ventricular wall of the heart showed a white fibrous scar. In the untreated MSCs transplanted group, the area of white fibrous scar was lower as compared to that of MI group, while in IWP-4 treated MSCs transplanted group, the white fibrous scar was greatly reduced as shown in Figure 7C.

Histological analysis: Cross-sections of heart tissue were differentially stained with Masson's trichrome staining which showed the fibrotic green regions of the collagen deposition in the left ventricle of the MI heart as compared to sham control, while red stained regions showed the normal tissue and myocytes with blue/black stained nuclei. At high magnification, the infarcted region of the MI heart showed fibrous tissue and tightly packed collagen fibrils. The sham control heart section showed healthy myocytes with interconnected cytoplasmic junctions in the left ventricle. The untreated MSCs transplanted group showed reduced fibrosis, while the IWP-4 treated MSCs transplanted group showed complete restoration of the left ventricle and regeneration of the myocytes as shown in Figure 7A and B. Quantification of the total fibrotic area showed that the IWP-4 treated MSCs transplanted group has significantly reduced ($P < 0.001$) fibrosis as compared to the MI model and untreated MSCs transplanted group (Figure 7D). Measurements of left ventricular wall thickness revealed that in the untreated MSCs transplanted group, the restoration of left ventricular wall thickness was non-significant, while in the case of IWP-4 treated MSCs, the left ventricular wall thickness was significantly improved ($P < 0.001$) as compared to the MI group as shown in Figure 7E. H&E staining showed the accumulation of inflammatory cells in the left ventricular region of the infarcted heart in the MI group as compared to the sham control. However, it was improved in untreated MSCs and IWP-4 treated MSCs transplanted group as shown in Figure 8.

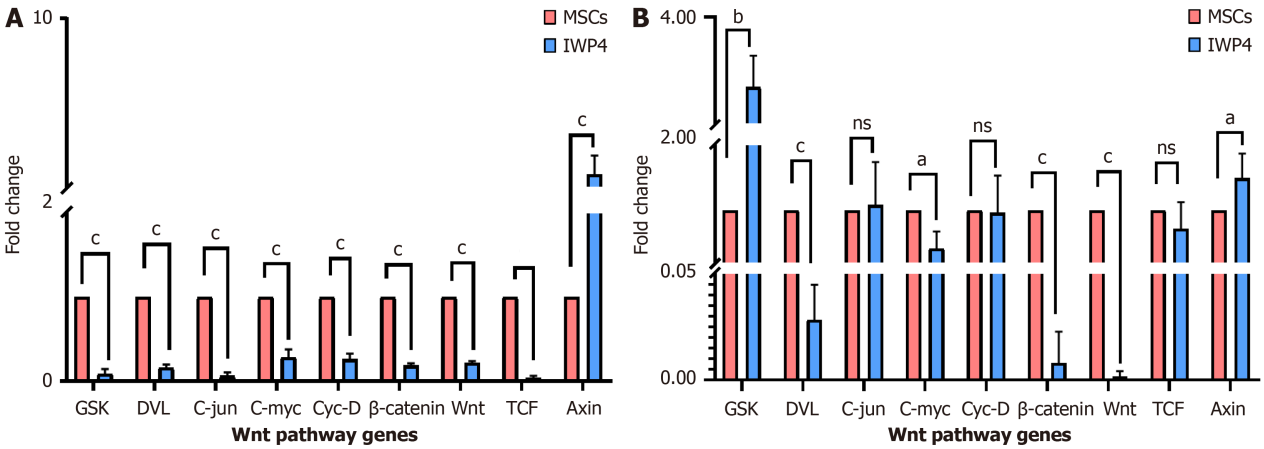
Figure 2 Cytotoxicity analysis of mesenchymal stem cells treated with different concentrations of inhibitor Wnt production-4 by JC-1 assay. A: Mesenchymal stem cells (MSCs) treated with 5 μM concentration of inhibitor Wnt production-4 showed non-significant number of apoptotic cells, while 10 μM concentration or above showed significant cytotoxic effect on MSCs; B: Quantification of apoptotic and non-apoptotic cells presented in bar graphs. For statistical analysis, One-way ANOVA was used followed by the Bonferroni post-hoc test. Values are expressed as means ± SEM; level of significance is $P < 0.05$ ($^{a}P < 0.05$, $^{c}P < 0.001$).

Tracking of DiI labeled cell: Fluorescence images of DiI labeled untreated MSCs, as well as IWP-4 treated MSCs showed cell distribution and homing in the infarcted myocardium, in both transplanted heart sections. The DiI labeled cells in the cardiac tissue were immunohistochemically stained for cardiac proteins including GATA-4, cTnI, and alpha actinin which showed that the transplanted cells differentiated into cardiac lineage. However, more pronounced cardiac differentiation and cell density were observed in the IWP-4 treated MSCs transplanted group, with GATA-4, cTnI ($P < 0.001$), and alpha actinin ($P < 0.01$) as compared to untreated MSCs group as shown in Figure 9.



DISCUSSION

In this study, we explored the role of IWP-4 on MSCs in cardiac differentiation *in vitro* and cardiac function restoration *in vivo*. Human umbilical cord derived MSCs are a potential candidate for cell therapy as they are easy to isolate and have a high proliferation rate, low immunogenicity, and immunomodulatory effects. MSCs have various therapeutic advantages that have been explained in several MI models[9]. Unfortunately, transplanted MSCs show poor survival and homing in

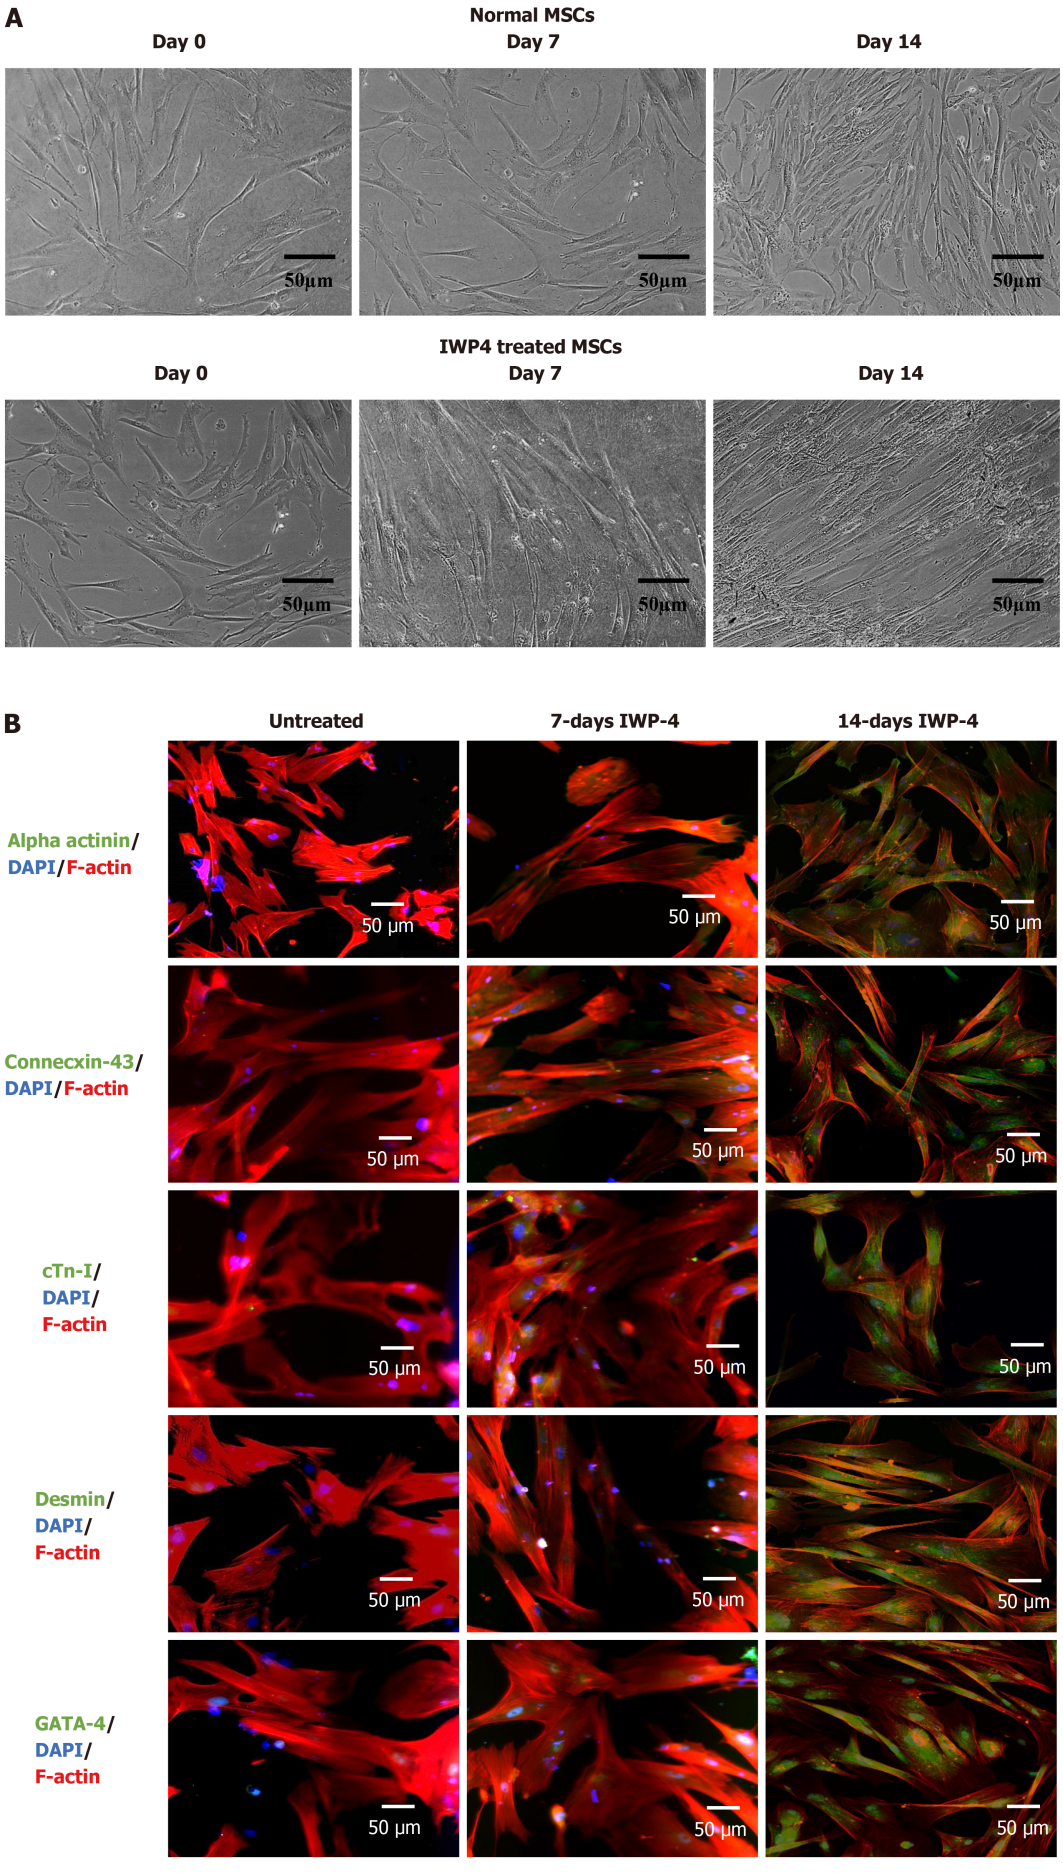

Figure 4 Wnt pathway gene expression analysis: Wnt pathway gene expression analysis by quantitative real-time polymerase chain reaction. Seven days, and fourteen days treatment of mesenchymal stem cells with inhibitor Wnt production-4, in comparison with untreated control showing significant decrease in the expression of Wnt pathway genes, *DVL*, *Wnt*, *TCF*, *Axin*, and *β-catenin*, and downstream transcription factors *C-jun*, *C-myc*, and *Cyc-D*. A: Seven days; B: Fourteen days. *GSK* increased in the fourteen days treatment. Quantitative two fold ($2^{-\Delta\Delta CT}$) difference of mean is represented by ΔΔCt method. Statistical analysis was performed using an Independent sample t-test. Values are presented as mean ± SEM from three independent biological triplicates; level of significance is $P < 0.05$ ($^{a}P < 0.05$, $^{b}P < 0.01$, and $^{c}P < 0.001$). IWP-4: Inhibitor Wnt production-4; MSC: Mesenchymal stem cell; NS: No significant.

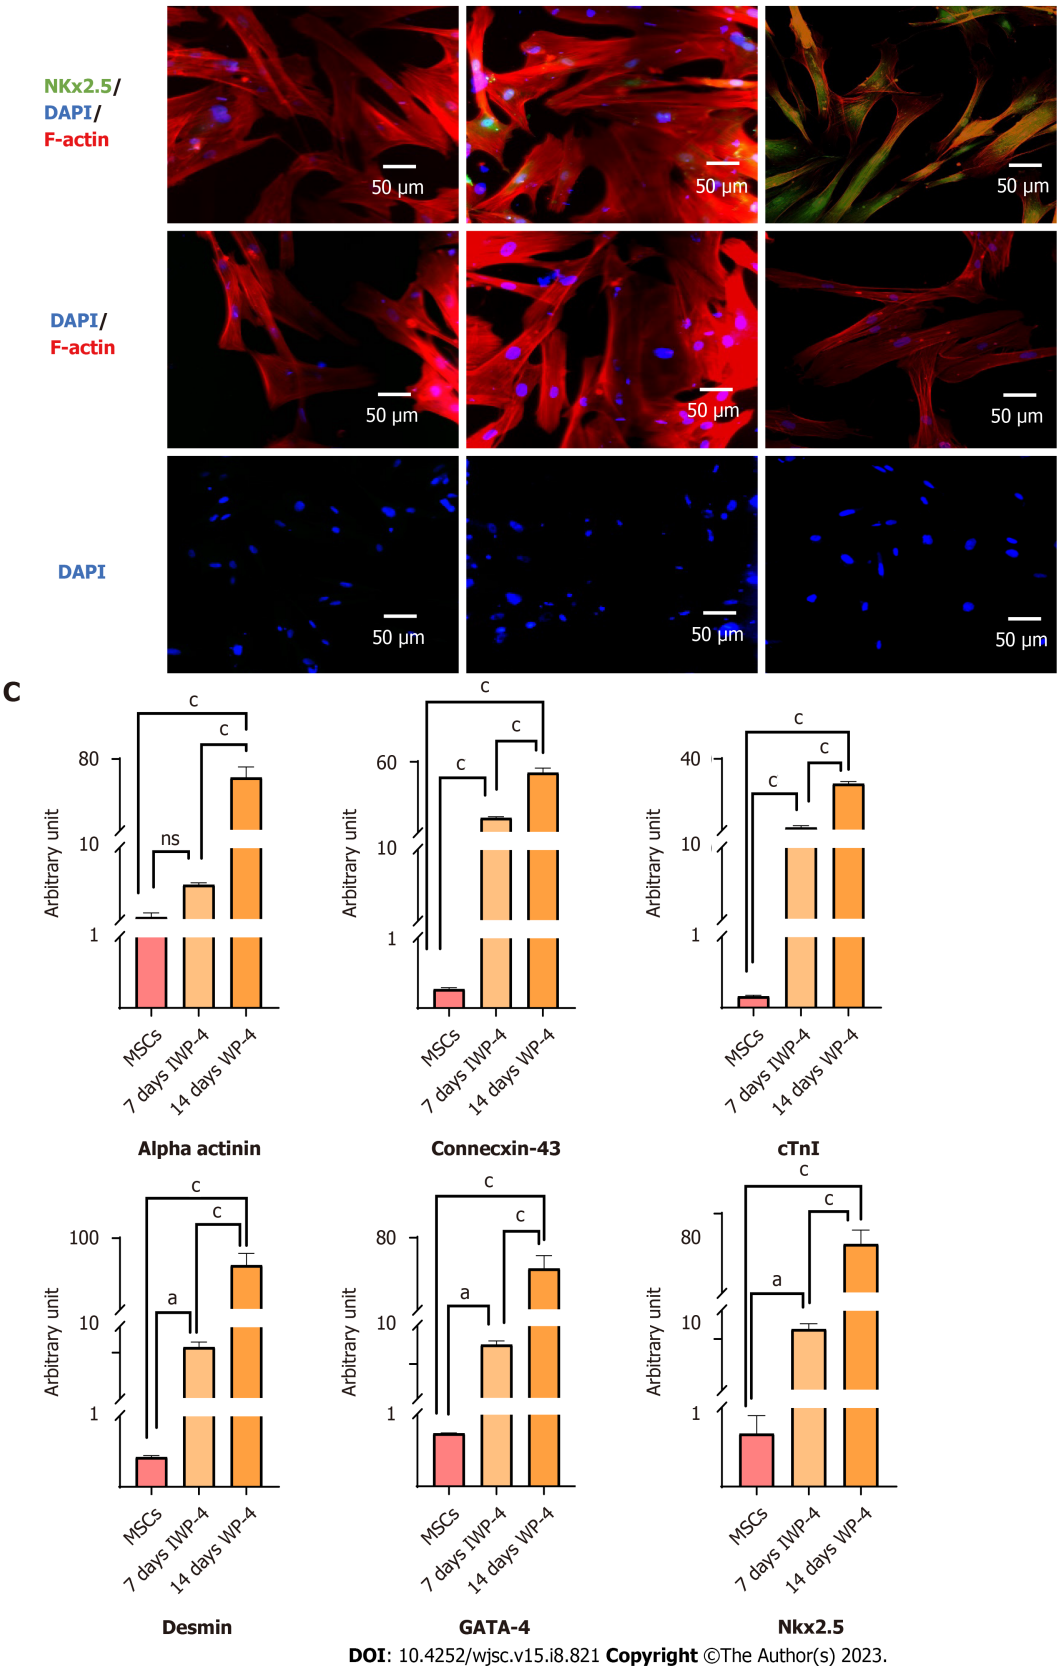
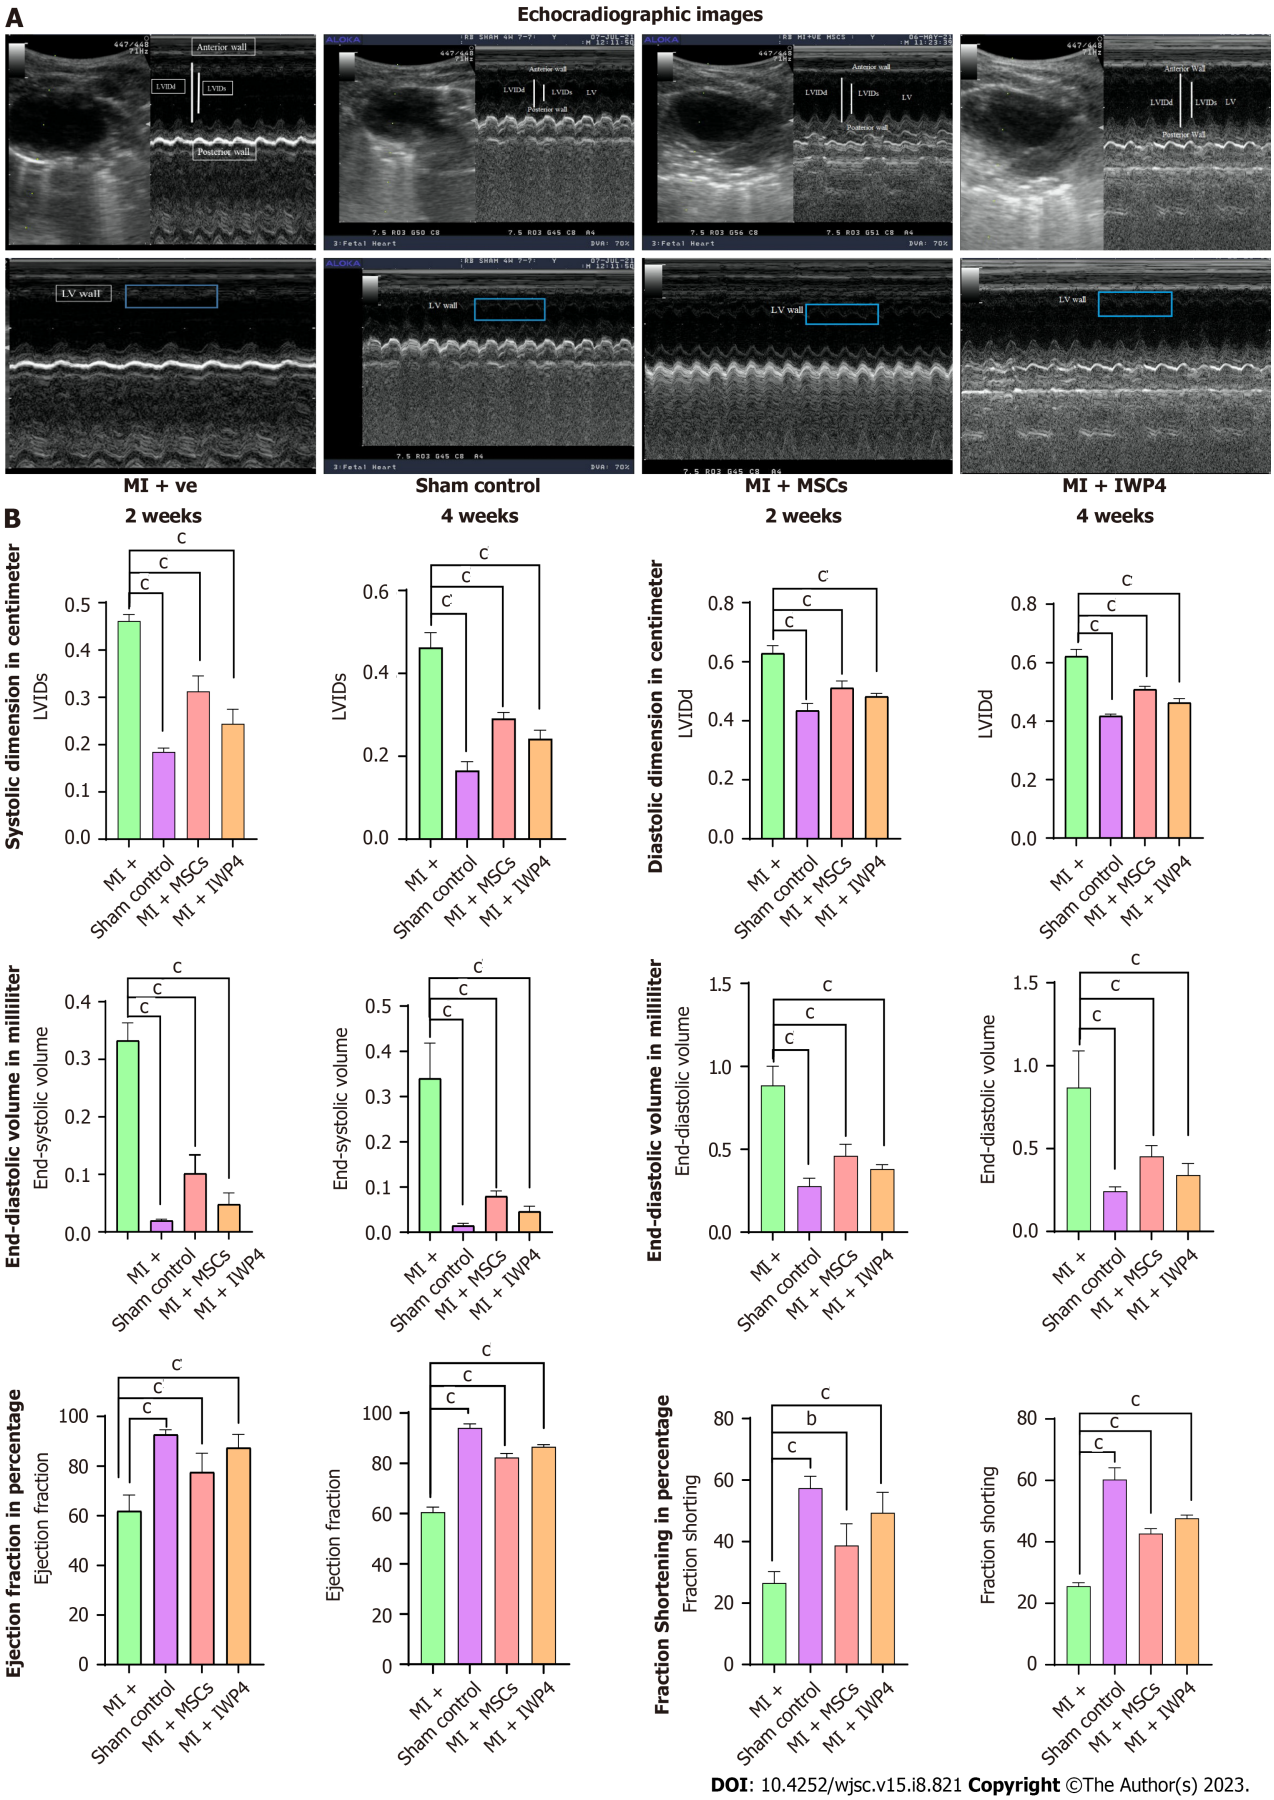


the infarcted myocardium[10], while pre-differentiated MSCs have several advantages over MSCs[11].

Wnt and Smad signaling pathways play an important role in the fate determination of stem cell and their potential for cardiovascular differentiation. Several studies reported that Wnt and Smad signaling pathways play an important role in the fate determination of stem cells and their potential for cardiovascular differentiation. Several studies reported that early application of Wnt/β-catenin signaling pathway inhibitor, IWR1 promotes cardiomyocyte differentiation[12]. Similarly, IWP-4 is a potent small molecule that has been reported to differentiate embryonic stem cells into cardiomyocyte like cells[7]. IWP-4 was also reported to differentiate human umbilical cord derived induced pluripotent stem cells into cardiomyocyte like cells[13].

In this study, IWP-4 was used to differentiate human umbilical cord derived MSCs into cardiomyocyte like cells. First, MSCs were isolated, propagated, and expanded from cord tissue according to the minimum criteria established by the International Society for Cellular Therapy.



To identify the optimal non-toxic concentration of IWP-4, MSCs were treated with different concentrations of IWP-4. 5 μM concentration was found to be non-cytotoxic after 24 h of treatment and analyzed *via* JC-1 assay.

To confirm the Wnt pathway inhibition, Wnt pathway gene expression profile was analyzed after seven and fourteen days treatment of MSCs with IWP-4. Gene expression profile revealed that seven days treatment of MSCs with IWP-4 inhibits Wnt pathway as compared to untreated MSCs; Wnt pathway genes, *GSK*, *DVL*, *Wnt*, *TCF*, *β-catenin*, and downstream transcription factors *C-jun*, *C-myc*, *Cyc-D* ($P < 0.001$) were significantly downregulated, while *Axin* showed upregulation ($P < 0.01$). However, fourteen days treatment of MSCs with IWP-4, further downregulated the Wnt pathway as compared to untreated control; Wnt pathway genes *DVL*, *Wnt*, *β-catenin* ($P < 0.001$) showed significant downregulation, while negative regulators of the pathway *GSK* ($P < 0.01$), and *Axin* ($P < 0.05$) were upregulated. Downstream transcription factors *C-jun*, *Cyc-D*, *TCF* were non-significant, while *C-myc* ($P < 0.05$) was upregulated.

The Wnt (β-catenin dependent) comprises several proteins that are crucial for embryonic development as well as adult tissue homeostasis. In the absence of Wnt ligands, cytoplasmic β-catenin is captured by the destruction complex including glycogen synthase kinase-3β (GSK3β), axin, adenomatous polyposis coli, and casein kinase 1 (CK1). This destruction complex induces the β-catenin phosphorylation at the amino terminus by CK1 and GSK3β, that results in the ubiquitination and degradation of β-catenin[14]. In the presence of ligands, Wnt binds to its receptor and activates the signaling pathway. This ligand receptor binding recruits the axin and DVL protein towards the cell membrane, thus resulting in the inactivation of the destruction complex. As a result, β-catenin translocate to the nucleus where it binds to the transcription

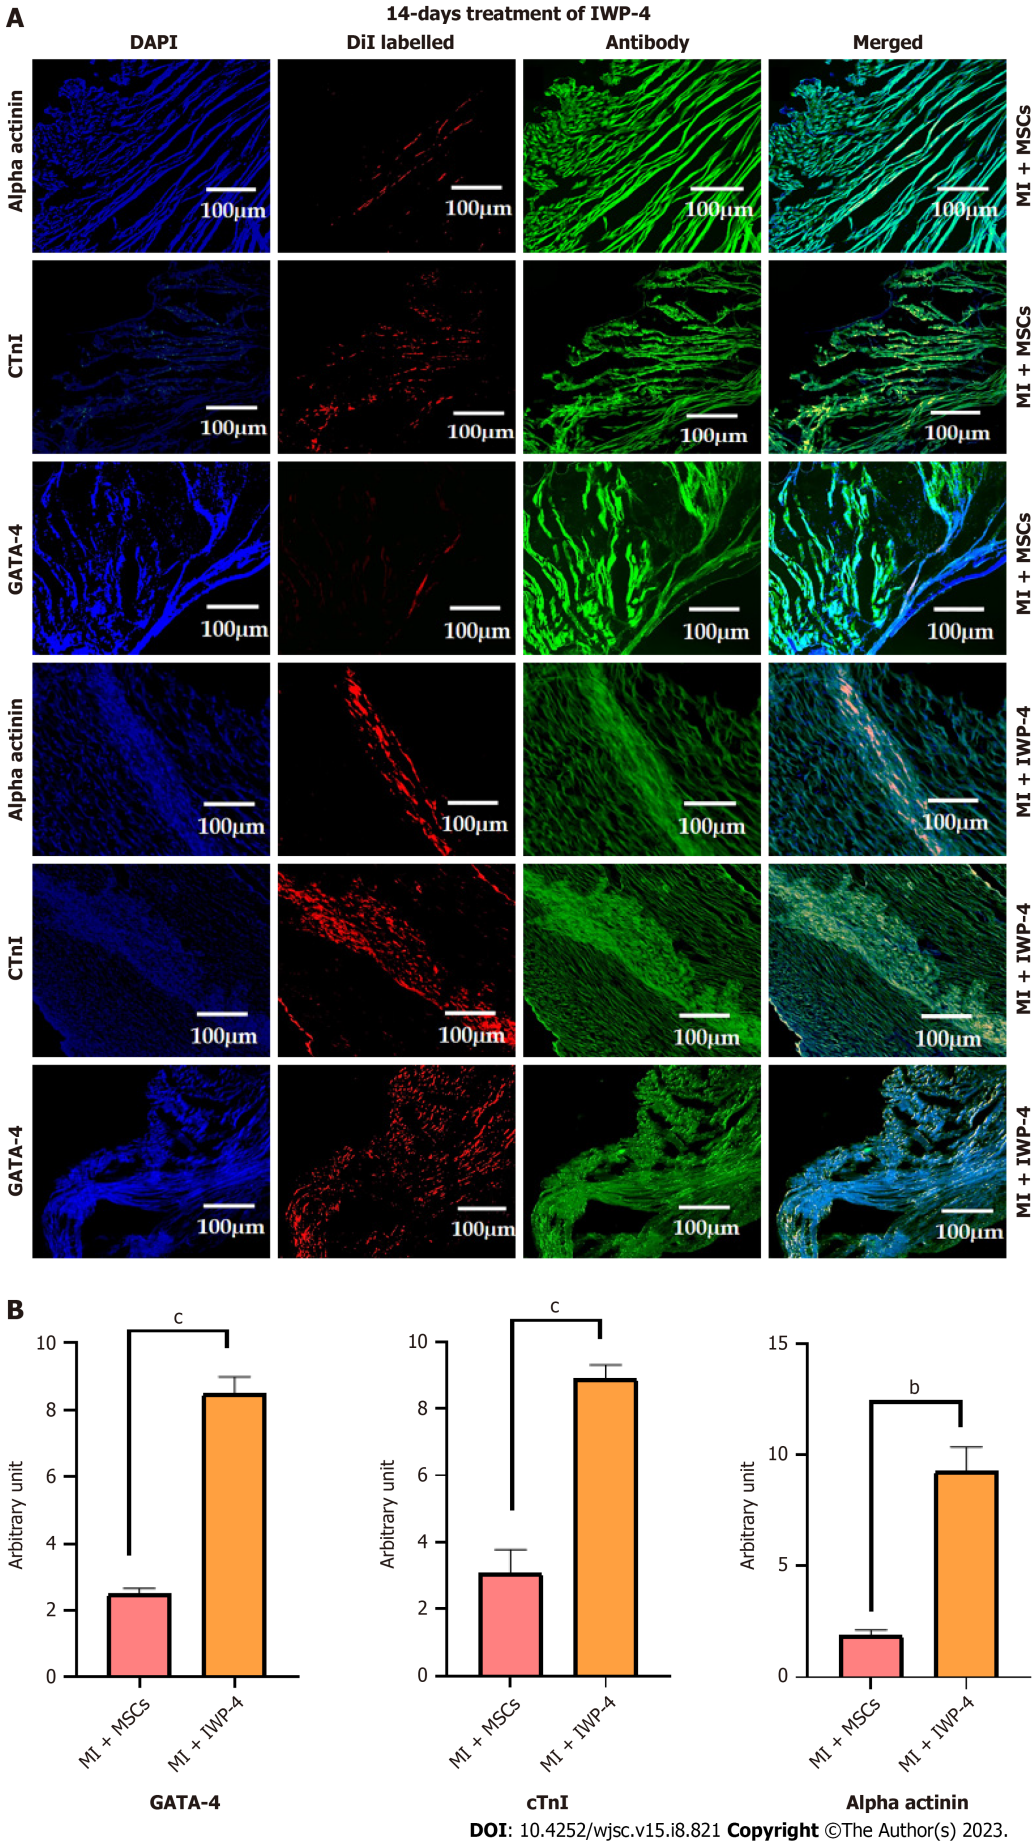

Figure 8 Hematoxylin-Eosin staining of heart section. Large scan images showing Hematoxylin-Eosin (H&E) stained transverse section of the whole heart. Magnified images showing H&E stained sections in sham control, myocardial infarction (MI) group, mesenchymal stem cells (MSCs) (MI+MSC) group, and inhibitor Wnt production-4 (IWP-4) treated MSCs (MI+IWP-4) group after 4 wk of MI. IWP-4: Inhibitor Wnt production-4; MSC: Mesenchymal stem cell; MI: Myocardial infarction.

factor TCF and increases the expression of Wnt target genes[13,15].

In our study, IWP-4 treatment was given for seven and fourteen days. Morphological features of fourteen days treated MSCs showed cardiomyogenic differentiation; the cells were flattened and appeared larger with myotube like structures. To confirm the differentiation of cells toward cardiac lineage, cardiac specific gene expression profile was analyzed through qPCR. In the seven days treated MSCs, only two cardiac genes *MLC-2v* ($P < 0.01$) and *Ca-channel* ($P < 0.05$) showed upregulation, while *Na-channel* ($P < 0.05$), *cTnT*, *GATA4* ($P < 0.01$), *alpha-actinin*, *cTnI*, *Mef2D* and *Nkx2.5* ($P < 0.001$) genes showed significant downregulation; *MHC-β* and *cTnC* were non-significant. However, fourteen days treated MSCs showed significant upregulation of all cardiac genes including *alpha-actinin* ($P < 0.05$), *MHC-β*, *MLC-2v*, *Mef2D*, *cTnT*, *cTnC*, *cTnI*, *Ca-channel*, *Na-channel*, *Nkx2.5* and *GATA4* ($P < 0.001$) as compared to untreated MSCs.

The cardiac markers GATA-4 and Nkx2.5 play important role in the cardiac development[16]. GATA-4 is an important early cardiac transcription factor that regulates several cardiac genes[17]. Nkx2.5 is another important transcription factor that showed high expression in the cardiac progenitor cells and promotes cardiomyocyte maturation[18]. Cardiac troponin exists in three different subunits, cTnT, cTnI, and cTnC. Troponin proteins are linked with tropomyosin which is present in all skeletal and cardiac muscle cells and plays an essential role in cardiac contractile movement. cTnT directly binds with the thin filaments, while cTnI and cTnC bind with cTnT. It is also reported to be circulated into the blood after cardiomyocyte injury[19]. cTnI and cTnT are the essential components of the cardiac troponin complex particularly involved in the formation of cardiomyocyte contractile network and regulate cardiac contraction and relaxation[20,21].

In the human heart, cardiac myosin heavy chain is expressed in two isoforms *i.e.* α-MHC and β-MHC. β-MHC is an important cardiac marker, predominant ventricular isoform, and principal mediator of cardiac contractile function[22]. Any change regarding the expression of MHC isoforms disturbs the cardiac contractile functions[23]. Ventricular MLC-2v is the ventricular cardiac muscle form of myosin light chain 2. MLC-2v is regarded as a ventricular-specific marker of the myocardium. MLC-2v is expressed during early cardiac development in humans[24]. Mef2 is a transcription factor that is important for right ventricle development[25]. Cardiac α-actinin-2, also known as alpha actinin, is a homodimer, Z-disk component of sarcomere responsible for three important functions: Anchoring of thin filaments actin, sarcomere formation, and interaction with titin[26]. The upregulation of cardiac ion channels (sodium and calcium) decides the cell fate to become mature functional cardiomyocytes[27]. Calcium acts as a second messenger in signal transduction pathways as well as necessary for muscular contraction. Calcium is controlled by calcium transport proteins, calcium channels, carriers and pumps[28]. Voltage-gated sodium channels are transmembrane proteins that generate action potentials in neurons and cardiac cells[29].

Figure 9 Immunohistochemistry of heart tissue section. A: Immunohistochemical images of heart sections showing the transplanted untreated

mesenchymal stem cells (MSCs) and fourteen days inhibitor Wnt production-4 (IWP-4) treated MSCs labeled with red fluorescent DiI dye. Cardiac specific proteins α-actinin, cTnI, and GATA-4 were immunostained for the expression of cardiac proteins. Alexa fluor 488 secondary antibody was used for detection; B: Quantification of the fluorescence intensities of the DiI labeled cells presented in bar graphs. As compared to normal MSCs, fluorescence intensity was significantly increased in case of alpha actinin, GATA-4, and cTnI in the fourteen days IWP-4 treated MSCs group in the infarcted myocardium. For statistical analysis, One-way ANOVA was used followed by the Bonferroni post-hoc test. Data are presented as mean ± SEM with significance level $P < 0.05$ where ($^{b}P < 0.01$, $^{c}P < 0.001$). IWP-4: Inhibitor Wnt production-4; MSC: Mesenchymal stem cell; MI: Myocardial infarction.

Cardiac specific protein expression analysis was also performed to further confirm myogenic differentiation. Cardiac protein expression was analyzed in untreated, and seven and fourteen days treated MSCs. Seven days treated MSCs showed less protein expression of C-43, cTnI, ($P < 0.001$), desmin, GATA-4, and Nkx2.5 ($P < 0.05$), while alpha-actinin protein expression was non-significant. Fourteen days treated MSCs showed significant positive expression of cardiac proteins including alpha-actinin, C-43, cTnI, desmin, GATA-4, and Nkx2.5 ($P < 0.001$). C-43 is a gap junction protein that connects the neighboring cardiac cells. C-43 is abundant and expressed in atrial as well as ventricular cardiomyocytes [30]. Desmin is an important intermediate filament that maintains the cytoskeletal structure and cellular integrity in skeletal, smooth, and cardiac muscles[31]. The presence of cardiac specific proteins further confirmed the differentiation of MSCs into cardiomyocytes, as these proteins are necessary for several developmental processes and functioning of the heart. Hence, a pronounced effect was observed in fourteen days treated MSCs, so it was selected for *in vivo* studies.

To examine the ability of pre-differentiated MSCs to regenerate the infarcted myocardium *in vivo*, a rat MI model was established and fourteen days treated pre-differentiated MSCs were transplanted. In previous studies, it was reported that the pre-differentiated MSCs homed and survived better than the untreated MSCs in the injured myocardium[11,32]. To confirm, untreated MSCs, as well as IWP-4 treated MSCs, were transplanted in the left ventricular wall of the infarcted hearts immediately after MI induction.

For cardiac functional analysis, echocardiography was performed after 2 and 4 wk of MI. Functional studies revealed a significant increase in LVIDd, LVIDs, EDV, and ESV in the MI model; however, FS and EF were significantly decreased as compared to the sham control. These results confirmed the successful MI model development. When compared with the MI group, LVIDd, LVIDs, EDV, and ESV were significantly reduced, while EF and FS were significantly improved after 2 and 4 wk in both untreated and IWP-4 treated MSCs transplanted groups. However, the IWP-4 treated group showed more pronounced results.

For histological analysis, heart tissue was harvested after 4 wk of infarction. The MI heart exhibited a whitish scar with no blood vessels in the infarcted area, while in the IWP-4 transplanted heart, the area of scar was reduced with blood vessels in the repaired myocardium. To observe the histology, and to calculate the fibrotic area and wall thickness, H&E and Masson's trichrome staining were performed. Histological analysis revealed that the fibrotic area was reduced and wall thickness was increased in the untreated MSCs transplanted heart sections, while the IWP-4 treated group showed significantly reduced fibrosis, and improved wall thickness as compared to the MI group. Untreated as well as IWP-4 treated MSCs were labeled with DiI dye to track the localization and homing of cells in the infarcted myocardium, and analyzed through immunohistochemistry. Cardiac functional proteins GATA-4, alpha actinin and cTnI were used for immunohistochemical analysis of the cryosectioned heart that showed cardiac proteins as well as DiI dye expression in the myocardium. Fluorescence intensity calculation revealed the transplanted cell density and significantly higher cardiac protein expression in the IWP-4 treated MSCs group as compared to the untreated group. This data further supports the histological results that revealed a markedly decreased fibrotic area and increased regeneration of the infarcted myocardium. Altogether, the results showed that IWP-4 treated MSCs regenerated myocardium, ventricular remodeling, and improved heart function.

CONCLUSION

This study focused on the treatment of hUC-MSCs with IWP-4 for differentiation of MSCs into cardiomyogenic lineage *via* inhibiting Wnt pathway and their consequent role in the cardiac function restoration in the rat MI model. Fourteen days IWP-4 treatment increases the expression of cardiac markers in MSCs, both at the gene and protein levels, as compared to the untreated control. Transplanted pre-differentiated cells in the rat MI model not only distributed, survived, and homed, but also differentiated into mature cardiomyocytes better than untreated MSCs. The results obtained from the current preclinical study suggests that treatment with the small molecule IWP-4 could be a good option for the differentiation of MSCs into functional cardiomyocytes in clinical trials of MI patients in future.

ARTICLE HIGHLIGHTS

Research background

Cardiovascular diseases particularly myocardial infarction (MI) is a global health complication with high mortality and morbidity rate. As cardiac tissue lacks regeneration potential, so cardiac tissue regeneration using a potent small molecule inhibitor Wnt production-4 (IWP-4) for stem cell fate transition towards cardiomyocytes could be an effective approach.

Research motivation
Inhibition of Wnt pathway is important in stem cell fate determination towards cardiomyocytes. Wnt pathway inhibitor, such as IWP-4, may promote the differentiation of mesenchymal stem cells (MSCs) into cardiac lineage. These pre-conditioned cells may provide better survival, homing and migration capability at the site of injury.

Research objectives
This study was designed to evaluate the IWP-4 cardiac differentiation capability and its subsequent *in vivo* effects.

Research methods
Human umbilical cord-derived MSCs were characterized on the basis of morphology, immunophenotyping of surface markers associated with MSCs and tri-lineage differentiation capability. Isolated MSCs were treated with 5 μM IWP-4 at two different time intervals. Cardiomyogenic differentiation of treated MSCs was evaluated at DNA and protein levels. MI rat model was developed. IWP-4 treated as well as untreated MSCs were implanted in the MI model, and cardiac function was analyzed *via* echocardiography. MSCs were labeled with 1,1′-dioctadecyl-3,3,3′,3′-tetramethylindocarbocyanine perchlorate (DiI) dye for tracking, and regeneration of the infarcted myocardium was examined by histology and immunohistochemistry.

Research results
Isolated MSCs were characterized and then pre-conditioned with 5 μM concentration of IWP-4. The cardiac specific gene and protein expression analysis exhibited more remarkable results in fourteen days treated group that was eventually selected for *in vivo* transplantation. Cardiac function was restored in the IWP-4 treated group in comparison to the MI group. Immunohistochemical analysis confirmed the homing of pre-differentiated MSCs that were labeled with DiI cell labeling dye. Histological analysis confirmed the significant reduction in the fibrotic area, and improved the left ventricular wall thickness in the IWP-4 treated MSC group.

Research conclusions
Our data suggest that treatment of MSCs with IWP-4 inhibits Wnt pathway and promotes cardiac differentiation. These pre-conditioned MSCs transplanted *in vivo* improved cardiac function by cell homing, survival, and differentiation at the infarcted region, increased left ventricular wall thickness, and reduced infarct size.

Research perspectives
The study demonstrated that treatment with IWP-4 improves the efficacy of the MSCs to ameliorate the cardiac function of the MI rats, as evidenced by an increase in the ejection fraction. Pre-conditioning of MSCs with IWP-4 may serve as a promising strategy to treat heart disease. Targeting the Wnt signaling pathway may represent a promising therapeutic approach for this debilitating condition.

Abstract

BACKGROUND

Intervertebral disc degeneration (IDD) is a main contributor to low back pain. Oxidative stress, which is highly associated with the progression of IDD, increases senescence of nucleus pulposus-derived mesenchymal stem cells (NPMSCs) and weakens the differentiation ability of NPMSCs in degenerated intervertebral discs (IVDs). Quercetin (Que) has been demonstrated to reduce oxidative stress in diverse degenerative diseases.

AIM

To investigate the role of Que in oxidative stress-induced NPMSC damage and to elucidate the underlying mechanism.

METHODS

In vitro, NPMSCs were isolated from rat tails. Senescence-associated β-galactosidase (SA-β-Gal) staining, cell cycle, reactive oxygen species (ROS), real-time quantitative polymerase chain reaction (RT-qPCR), immunofluorescence,

and western blot analyses were used to evaluated the protective effects of Que. Meanwhile the relationship between miR-34a-5p and Sirtuins 1 (SIRT1) was evaluated by dual-luciferase reporter assay. To explore whether Que modulates tert-butyl hydroperoxide (TBHP)-induced senescence of NPMSCs *via* the miR-34a-5p/SIRT1 pathway, we used adenovirus vectors to overexpress and downregulate the expression of miR-34a-5p and used SIRT1 siRNA to knockdown SIRT1 expression. *In vivo,* a puncture-induced rat IDD model was constructed, and X rays and histological analysis were used to assess whether Que could alleviate IDD *in vivo*.

RESULTS

We found that TBHP can cause NPMSCs senescence changes, such as reduced cell proliferation ability, increased SA-β-Gal activity, cell cycle arrest, the accumulation of ROS, and increased expression of senescence-related proteins. While abovementioned senescence indicators were significantly alleviated by Que treatment. Que decreased the expression levels of senescence-related proteins (p16, p21, and p53) and senescence-associated secreted phenotype (SASP), including IL-1β, IL-6, and MMP-13, and it increased the expression of SIRT1. In addition, the protective effects of Que on cell senescence were partially reversed by miR-34a-5p overexpression and SIRT1 knockdown. *In vivo*, X-ray, and histological analyses indicated that Que alleviated IDD in a puncture-induced rat model.

CONCLUSION

In summary, the present study provides evidence that Que reduces oxidative stress-induced senescence of NPMSCs *via* the miR-34a/SIRT1 signaling pathway, suggesting that Que may be a potential agent for the treatment of IDD.

Key Words: Quercetin; Nucleus pulposus-derived mesenchymal stem cells; Oxidative stress; Senescence; Intervertebral disc degeneration; miR-34a-5p/SIRT1 pathway

Core Tip: In our article, we provide the evidence that quercetin (Que) can prevent oxidative stress induced senescence of nucleus pulposus-derived mesenchymal stem cells *via* miR-34a/SIRT1 signaling pathway. Moreover, Que could ameliorate the progression of intervertebral disc degeneration (IDD) in rat model. Thus, Que can be considered as a potential agent for the treatment of IDD.

INTRODUCTION

As a widely known musculoskeletal disorder, low back pain (LBP) is the leading cause of disability and results in a huge economic burden on the family and society[1,2]. Intervertebral disc degeneration (IDD) is a main contributor to LBP, but the etiology of IDD is multifactorial[3]. Therefore, elucidating the underlying molecular mechanisms of IDD will help develop solutions for the prevention and treatment of IDD.

Several previous studies have indicated that oxidative stress and reactive oxygen species (ROS) are highly associated with the progression of IDD[4-7]. While ROS production is inevitable during the metabolic processes of disc cells, the progression of IDD is considered to be the result of disc cell senescence caused by ROS accumulation[7,8]. Recently, stem cell-based endogenous repair has been shown to play a significant role in the repair and regeneration of degenerative intervertebral discs (IVDs)[9,10]. Nucleus pulposus-derived mesenchymal stem cells (NPMSCs) were first reported by Risbud *et al*[11] in 2007, which rendered a basis for the endogenous repair of IDD[11]. We also previously found NPMSCs in normal and degenerated IVDs[12-15]. Wu *et al*[16] indicated that the regenerative potential of NPMSCs decreases with aging and degeneration of IVDs[16]. In addition, Ma *et al*[17] proposed that the decrease in endogenous NPMSCs caused by adverse microenvironments, such as oxidative stress, low nutrition, and inflammation, is one of the main reasons for the failure of endogenous repair of IDD[17]. Therefore, inhibition of oxidative stress-induced senescence of NPMSCs may be of great significance in alleviating IDD.

Quercetin (Que), a natural flavonoid widely present in various plants, has antioxidative stress, anti-inflammatory, and antiaging properties. Que has been used as a senolytic to prevent diverse degenerative diseases[18-20]. Zhu *et al*[21] found that Que reduces senescent cells by selectively killing senescent human epithelial cells and mouse bone marrow mesenchymal stem cells[21]. Feng *et al*[22] reported that Que attenuates oxidative stress-induced apoptosis in rat

chondrocytes and prevents the progression of osteoarthritis in a rat model[22]. Previous clinical studies have also demonstrated that Que reduces the expression levels of senescence-related markers[23].

MicroRNAs (miRNAs) are small double-stranded noncoding RNAs that are approximately 20 nucleotides in length and interfere with RNA translation by binding to the 3'UTR sequence of the target gene RNA. Abnormal expression of miRNAs has been observed in degenerative IVD, indicating that miRNAs play an important role in the pathophysiological process of IDD[24,25]. A previous study has also demonstrated that the expression of miR-34a-5p is significantly upregulated in degenerated IVDs and that miR-34a-5p increases extracellular matrix degradation and cell apoptosis. Sirtuins 1 (SIRT1), the target of miR-34a, is a member of the sirtuin family and plays a significant role in cancer, age-related diseases, and degenerative diseases[26-28]. Several studies have reported that SIRT1 delays the senescence of IVD cells by decreasing oxidative stress and inflammation as well as by improving mitochondrial function[29,30]. However, the protective effect of Que on NPMSCs is still unknown.

In the present study, tert-butyl hydroperoxide (TBHP) was used to trigger oxidative stress in NPMSCs, which is widely accepted as an apoptosis and senescence *in vitro* model. The effects of Que on senescence in NPMSCs under oxidative stress and the role of the miR-34a-5p/SIRT1 pathway were investigated. Finally, the therapeutic effects were also evaluated in a puncture-induced rat IDD model.

MATERIALS AND METHODS

Isolation and culture of NPMSCs

All the procedures performed in this study were approved by the Ethical Committee of the Clinical Medical College of Yangzhou University. Sprague-Dawley (SD) rats (2-4 mo old and weighing 200-300 g) were obtained from Yangzhou University, No. SYXK (Su) 2017-0044. The separation of nucleus pulposus (NP) tissues and the isolation of NPMSCs were performed as previously described[14]. Briefly, the NP tissues obtained from SD rats were carefully separated by a microscope under sterile conditions, and the NP tissue was mechanically fragmented into 1 mm^3 pieces and digested with 0.2% collagenase type II (Gibco, United States) at 37 °C in 5% CO_2 for 12 h. Cells were filtered through a 75-μm cellular filter, centrifuged at 1000 rpm for 3 min, washed with phosphate-buffered saline (PBS), resuspended in Mesenchymal Stem Cell Complete Medium (Cyagen, United States) with 10% fetal bovine serum (FBS; HyClone, United States) and 1% antibiotics (Gibco, United States), and cultured in an incubator at 37 °C with 5% CO_2. NPMSCs were subcultured at a ratio of 1:3 when they reached 80% confluence. The third passages of NPMSCs were used for the subsequent experiments.

Surface marker identification of NPMSCs

NPMSCs were cultured in a 12-well plate with a 25 mm diameter cell slide in complete medium. Cells were fixed in 4% paraformaldehyde for 15 min and permeabilized with 0.5% Triton X-100 for 15 min. Subsequently, cells were blocked with 10% bovine serum albumin for 1 h at room temperature and incubated with the following primary antibodies (1:100) overnight at 4 °C according to the International Society for Cellular Therapy (ISCT): CD34 (ABclonal, China), CD45 (ABclonal, China), CD73 (ABclonal, China), CD90 (ABclonal, China), CD105 (Proteintech, China), and tyrosine kinase with Ig and EGF homology domains 2 (Tie2, a disc NP progenitor marker) (Biodragon, China). Cells were then incubated with FITC- or Cy3-conjugated secondary antibodies (1:200) at room temperature for 1 h in the dark. After treatment with 4',6-diamidino-2-phenylindole (DAPI) for 5 min, the cell slides were observed under a fluorescence microscope (Leica, Wetzlar, Germany).

Cell treatment and cell viability assay

To establish an oxidative stress-induced model of NPMSCs, NPMSCs were cultured in complete medium with different concentrations (0, 25, 50, 100, 200, and 400 μM) of TBHP (Sigma-Aldrich, United States) for 12 h. Cells were pretreated with different concentrations (0, 10, 20, 40, 80, and 160 μM) of Que (MedChem Express, China) for 24 h before the addition of a suitable concentration of TBHP to investigate the suitable dose of Que. A cell counting kit-8 (CCK-8, Beyotime, China) was used to evaluate cell viability according to the manufacturer's instructions. Briefly, 2 × 10^3 cells/well were seeded in 96-well plates and cultured overnight at 37 °C in 5% CO_2. After the cells were treated as described above, a mixture of 10 μL of CCK-8 reagent and 100 μL of fresh medium was added to each well for 1 h at 37 °C. The optical density (OD) value of each well was measured at 450 nm by a microplate reader (Bio-Rad, United States). Cells were divided into the following groups: Control group (untreated), TBHP group (treated with 100 μM TBHP) and Que + TBHP group (treated with 20 μM Que and 100 μM TBHP).

Cell proliferation assay

Cell proliferation was evaluated by an 5-ethynyl-2'-deoxyuridine (EdU) assay (Beyotime, China). Cells (5 × 10^5 cells/well) were seeded in 12-well plates and cultured at 37 °C in 5% CO_2. According to the manufacturer's instructions, NPMSCs were incubated with EdU for 2 h, fixed with 4% paraformaldehyde for 10 min, permeabilized with 0.5% Triton X-100 for 15 min, and incubated with Click Reaction Mixture for 30 min. After washing with PBS, cells were counterstained with Hoechst 33342 in the dark for 10 min. Finally, cells were observed under a fluorescence microscope and analyzed by ImageJ software (NIH, United States).

Senescence-associated β-galactosidase (SA-β-Gal) staining

NPMSCs were seeded in a 6-well plate at a density of 4 × 10^5 cells/well at 37 °C in 5% CO_2. Cells were stained with SA-β-

Gal using a SA-β-Gal staining kit (Beyotime, China) according to the manufacturer's instructions. Cells were fixed with SA-β-gal fixing solution for 15 min at room temperature and then incubated overnight with an SA-β-Gal working solution at 37 °C without CO_2. Cells were observed under a microscope and analyzed by ImageJ software.

ROS assay

According to the manufacturer's instructions provided by a ROS detection fluorescent probe-DHE kit (Keygen, China), NPMSCs were incubated with 20 μM DHE for 30 min at 37 °C. Cells were then observed under a fluorescence microscope and analyzed by ImageJ software.

JC-1 assay for mitochondrial membrane potential

A JC-1 Detection Kit (Keygen, China) was used to measure mitochondrial membrane potential (MMP). Briefly, NPMSCs were cultured in medium containing 2 μM JC-1 dye, a cationic dye, for 20 min. After being washed twice with incubation buffer, cells were cultured in complete medium, observed by fluorescence microscopy, and analyzed by ImageJ software.

Cell cycle assay

The cell cycle phases of TBHP-induced senescent NPMSCs were determined by flow cytometric analyses using a Cell Cycle Detection Kit (Keygen, China). Briefly, NPMSCs were harvested from 6-well plates, washed twice with ice-cold PBS, fixed with 75% ethanol at 4 °C for 2 h, and incubated with a mixed solution of propidium iodide (PI) and RNase A for 30 min in the dark. Flow cytometry (BD Company, USA) was used to analyze the cell cycle phases.

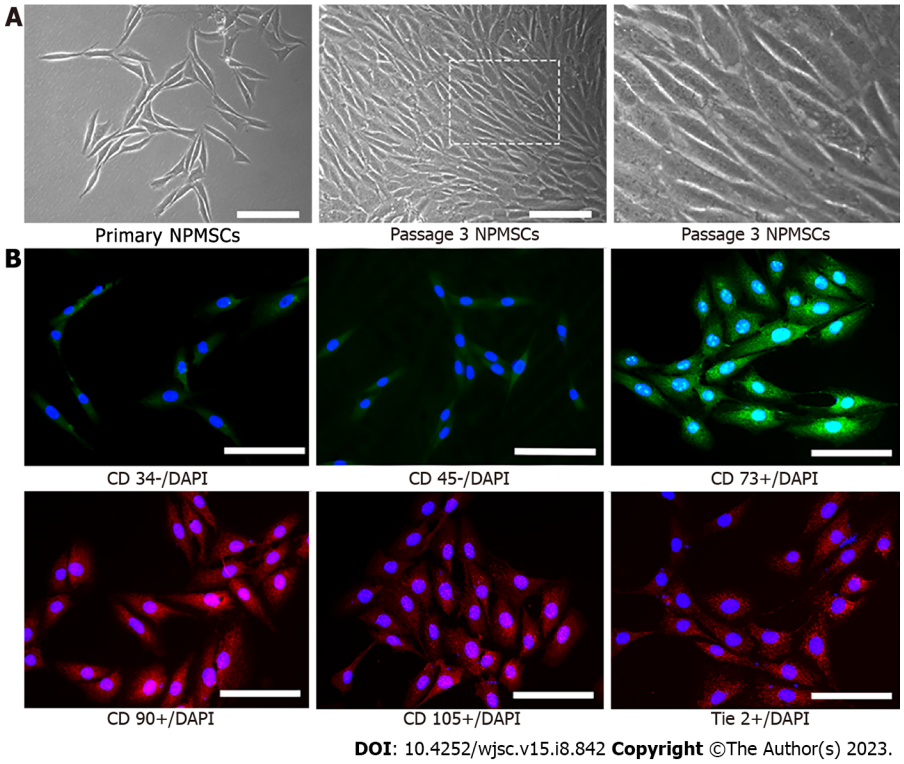
Cell transfection

Adenovirus vectors containing miR-34a-5p mimic, miR-34a-5p inhibitor, and their corresponding negative controls were obtained from GeneChem (Shanghai, China). SIRT1 siRNA and scrambled siRNA were obtained from Gene Pharma (Shanghai, China). NPMSCs (5×10^5/well) were seeded in 6-well plates and then transfected with miR-34a-5p mimic or miR-34a-5p inhibitor using Lipofectamine 2000 (Thermo Fisher, UT, USA) for 12 h at 37 °C according to the manufacturer's protocol. After replacing the medium with fresh complete medium, NPMSCs were cultured for an additional 24 h. Cells were then harvested for subsequent experiments.

Dual-luciferase reporter assay

The TargetScan Human database (https://www.targetscan.org/vert_80/) was used to predict the complementary binding site of miR-34a-5p in the 3'-UTR of SIRT1 mRNA. According to the Lipofectamine 2000 transfection protocol, SIRT1 3'-UTR wild-type plasmids or mutant plasmids were cotransfected with miR-34a-5p mimic and mimic control into cells. After 48 h, a dual-luciferase reporter assay kit was used to detect luciferase activity.

qRT-PCR



TRIzol reagent (Invitrogen, United States) was used to extract total RNA from NPMSCs. To measure the expression levels of mRNA, RNA was reverse-transcribed into complementary DNA (cDNA) by a Prime Script-RT reagent kit (Vazyme Biotech, China) according to the manufacturer's protocol. cDNA was amplified by SYBR Premix Ex Taq (Vazyme Biotech, China). To measure the expression levels of miR-34a, reverse transcription of RNA and amplification of cDNA were performed using the miRNA 1st Strand cDNA Synthesis Kit (by stem-loop) (Vazyme Biotech, China) and miRNA Universal SYBR qPCR Master Mix (Vazyme Biotech, China). The $2^{-\Delta\Delta CT}$ method was used to calculate the expression level of target genes. The expression levels of mRNA or miRNA were normalized to Gapdh or U6. The primers for the target genes used in this study are listed in Table 1.

Western blot analysis

The total protein of NPMSCs was extracted by a Whole Cell Lysis assay (Keygen Biotech, China), and the protein concentration was determined by a BCA protein assay kit (Beyotime, China). Each sample containing 30 μg of protein was separated by 10%-12% sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) and transferred to a polyvinylidene difluoride membrane (Millipore, United States). After being blocked in 5% skim milk for 2 h at room temperature, the membranes were incubated overnight with the following primary antibodies at 4 °C: P16 (1:1000; Proteintech, China), p21 (1:1000; Proteintech, China), p53 (1:5000; Proteintech, China), SIRT1 (1:1000; ABclonal, China), IL-1β (1:1000; ABclonal, China), IL-6 (1:1000; ABclonal, China), matrix metalloproteinase-13 (MMP-13, 1:1000; ABclonal, China) and Gapdh (1:1000; Servicebio, China). The membranes were then incubated with horseradish peroxidase (HRP)-labeled secondary antibodies (1:5000; Abcam). The protein bands were observed with an enhanced chemiluminescence system, and the expression of protein was analyzed by ImageJ software.

Puncture-induced rat IDD model

In total, 15 male SD rats (2-4 mo old and weighing 200-300 g) were randomly divided into the following three groups: Control group (n = 5), IDD group (n = 5), and Que group (n = 5). The IDD model of SD rats was established as previously described[13]. Briefly, the rats were anesthetized with pentobarbital, and the tail skin was sterilized by povidone iodine. A 21 G needle was used to puncture the coccygeal IVD (Co 6-7), and the needle was rotated 180° and kept in the disc for 5 s at a depth of 5 mm. After surgery, the Que group was treated with Que (100 mg/kg, 5 mg/mL of Que suspended in 0.5% sodium carboxymethyl cellulose solution) every other day by intragastric administration for 4 wk. The control group and IDD group were treated with 0.5% sodium carboxymethyl cellulose solution for 4 wk.

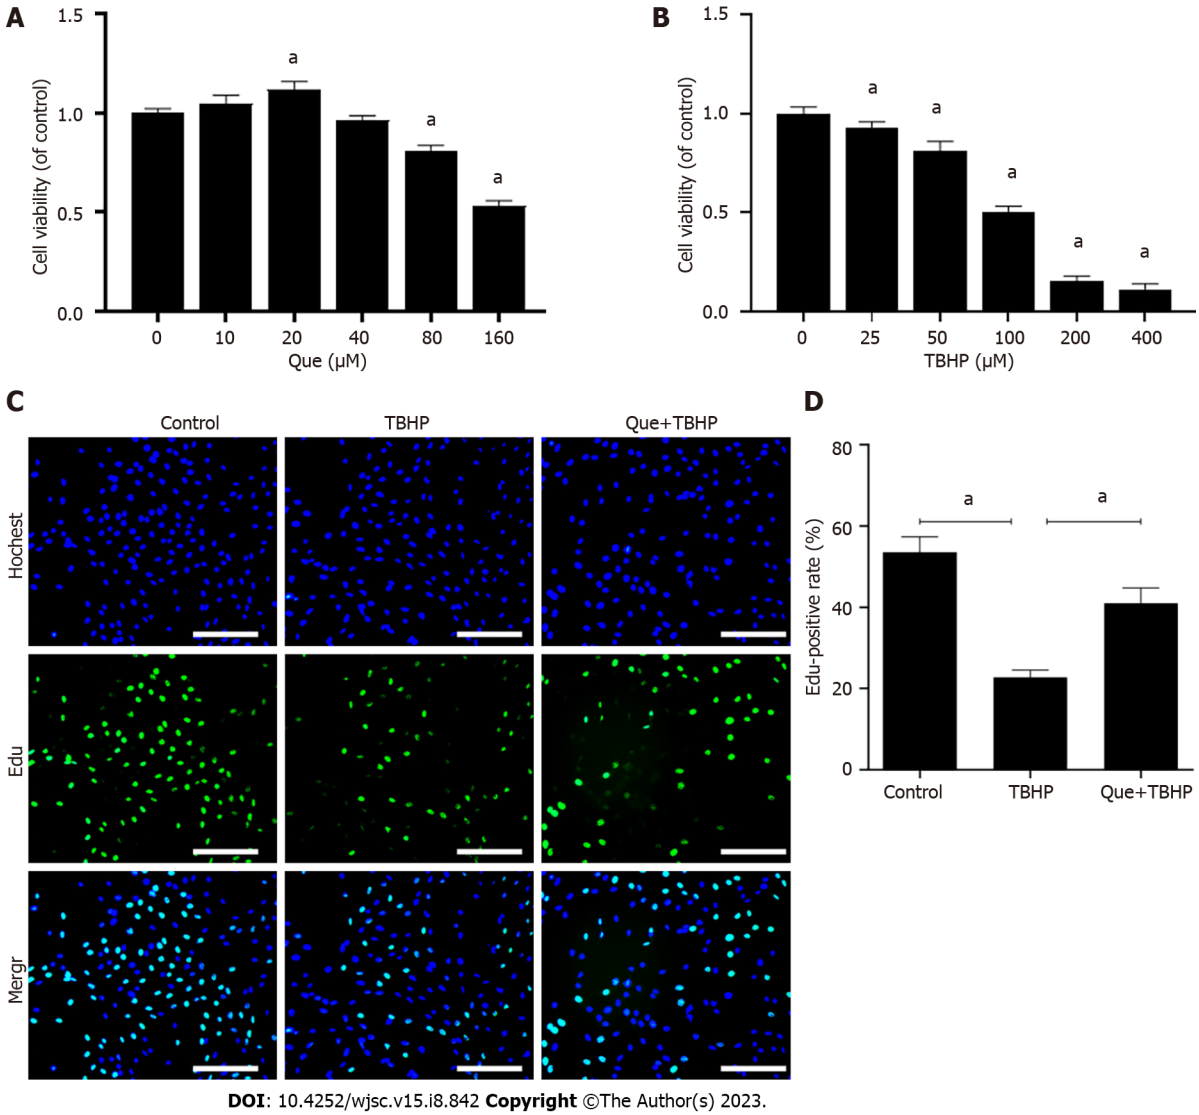
Figure 1 Identification of nucleus pulposus derived mesenchymal stem cells. A: Primary nucleus pulposus-derived mesenchymal stem cells (NPMSCs) presented with elongated spindle shape and grew in flower formation; B: NPMSCs exhibited low fluorescent expression of CD34 and CD45, but a high fluorescent expression of CD73, CD90, and CD105. Scar bar = 100 μm.

Radiographic evaluation and histological analysis

At 4 wk postinjury, all rats were placed in a prone position after anesthetization with pentobarbital, and X-ray images were acquired. ImageJ software was used to calculate the disc height index (DHI) as previously described[31]. The tails were harvested after the rats were euthanized with an overdose of sodium pentobarbital. The specimens were fixed in 4% paraformaldehyde for 48 h, decalcified in EDTA for 1 mo, dehydrated in gradient alcohol, and embedded in paraffin. The specimens were cut into 5 μm sections, and the sections were stained with hematoxylin-eosin (HE), Alcian blue, and Safranin O-fast Green. Histological scores were evaluated as previously described[31,32] based on the following scale: 5, normal discs; 6-11, moderately degenerated discs; and 12-14, severely degenerated discs.

Immunofluorescent staining

After the IVD specimens were prepared, a freezing microtome (Leica, Wetzlar, Germany) was used to cut the specimens into 5-μm sections. The sections were fixed in 4% paraformaldehyde for 15 min and permeabilized with 0.5% Triton X-100 for 15 min. Subsequently, the sections were blocked with 10% bovine serum albumin for 1 h at room temperature and incubated with the following primary antibodies (1:100) at 4 °C overnight: Collagen type II (ABclonal, China) and aggrecan (ABclonal, China). The sections were then incubated with FITC- or Cy3-conjugated secondary antibodies (1:200) at room temperature for 1 h in the dark. Fluorescence microscopy and ImageJ software were used to observe and analyze the sections.



Statistical analysis

All data were analyzed by GraphPad Prism 8 (GraphPad, La Jolla). Data are expressed as the mean ± SD. Student's t test and one-way analysis of variance (ANOVA) was used to analyze the data of two groups and multiple independent groups, respectively. The Kruskal-Wallis H test was used to analyze the histological score. A P value < 0.05 was considered significant.

RESULTS

Characterization of NPMSCs

Elongated spindle-shaped NPMSCs were successfully isolated and cultured from rat IVDs (Figure 1A). Based on the immunofluorescence staining analysis, the MSC-associated markers, namely, CD73, CD90, and CD105 were highly expressed, whereas the expression of CD34 and CD45 was low (Figure 1B). Moreover, the expression of Tie2, a disc NP progenitor marker, was also high in NPMSCs (Figure 1B). These results indicated that NPMSCs isolated from IVD

correspond to the standards of stem cells described by ISCT.

Effects of Que and TBHP on the viability and proliferation of NPMSCs

A CCK-8 assay was used to evaluate the effect of Que and TBHP on NPMSC viability. As shown in Figure 2A, Que showed no significant cytotoxic effect at concentrations up to 20 μM for 24 h. Therefore, a concentration of 20 μM Que was selected for the subsequent experiments. NPMSC viability was decreased after treatment with TBHP in a dose-dependent manner (Figure 2B), and 100 μM TBHP was selected for use in subsequent experiments. The effect of Que on NPMSC proliferation was detected by EdU staining. Compared to the control group, the positive rate of EdU in the TBHP group was significantly lower ($P < 0.05$), and the positive rate of EdU was partially increased in the Que + TBHP group ($P < 0.05$) (Figure 2C and D).

Effects of Que on SA-β-Gal staining and the cell cycle in NPMSCs

SA-β-Gal accumulation is an indicator of cellular senescence. Compared to the control group, the number of SA-β-Gal-positive senescent NPMSCs in the TBHP group was significantly higher ($P < 0.05$), while the number of SA-β-Gal-positive cells was decreased in Que + TBHP group (Figure 3A). Compared to the control group, the percentage of NPMSC in the G2/M phase in TBHP group was higher, which indicated cell cycle arrest, but treatment with Que decreased the percentage of NPMSCs arrested in G2/M phase (Figure 3B).

Significant differences between groups are indicated as $^{a}P < 0.05$, $n = 3$. TBHP: Tert-butyl hydroperoxide; Que: Quercetin.

Effects of Que on MMP and ROS generated in TBHP-treated NPMSCs

When the MMP is high, JC-1 exists in the mitochondria as J-aggregates of polymers, which produce red fluorescence. When the MMP is low, JC-1 is released from the mitochondria matrix and exists in the cytoplasm in the form of monomers, which produce green fluorescence. As shown in Figure 4A and B, the MMP was decreased after TBHP treatment, and this effect was partially reversed by pretreatment with Que. Figure 4C and D show that NPMSCs in the TBHP group had higher ROS levels compared to the control group, and pretreatment with Que partially reversed the effect of TBHP on ROS generation.

Que inhibits oxidative stress-induced senescence of NPMSCs

Cell senescence is broadly characterized by cell cycle arrest and the production of SASP. To explore the effect of Que in

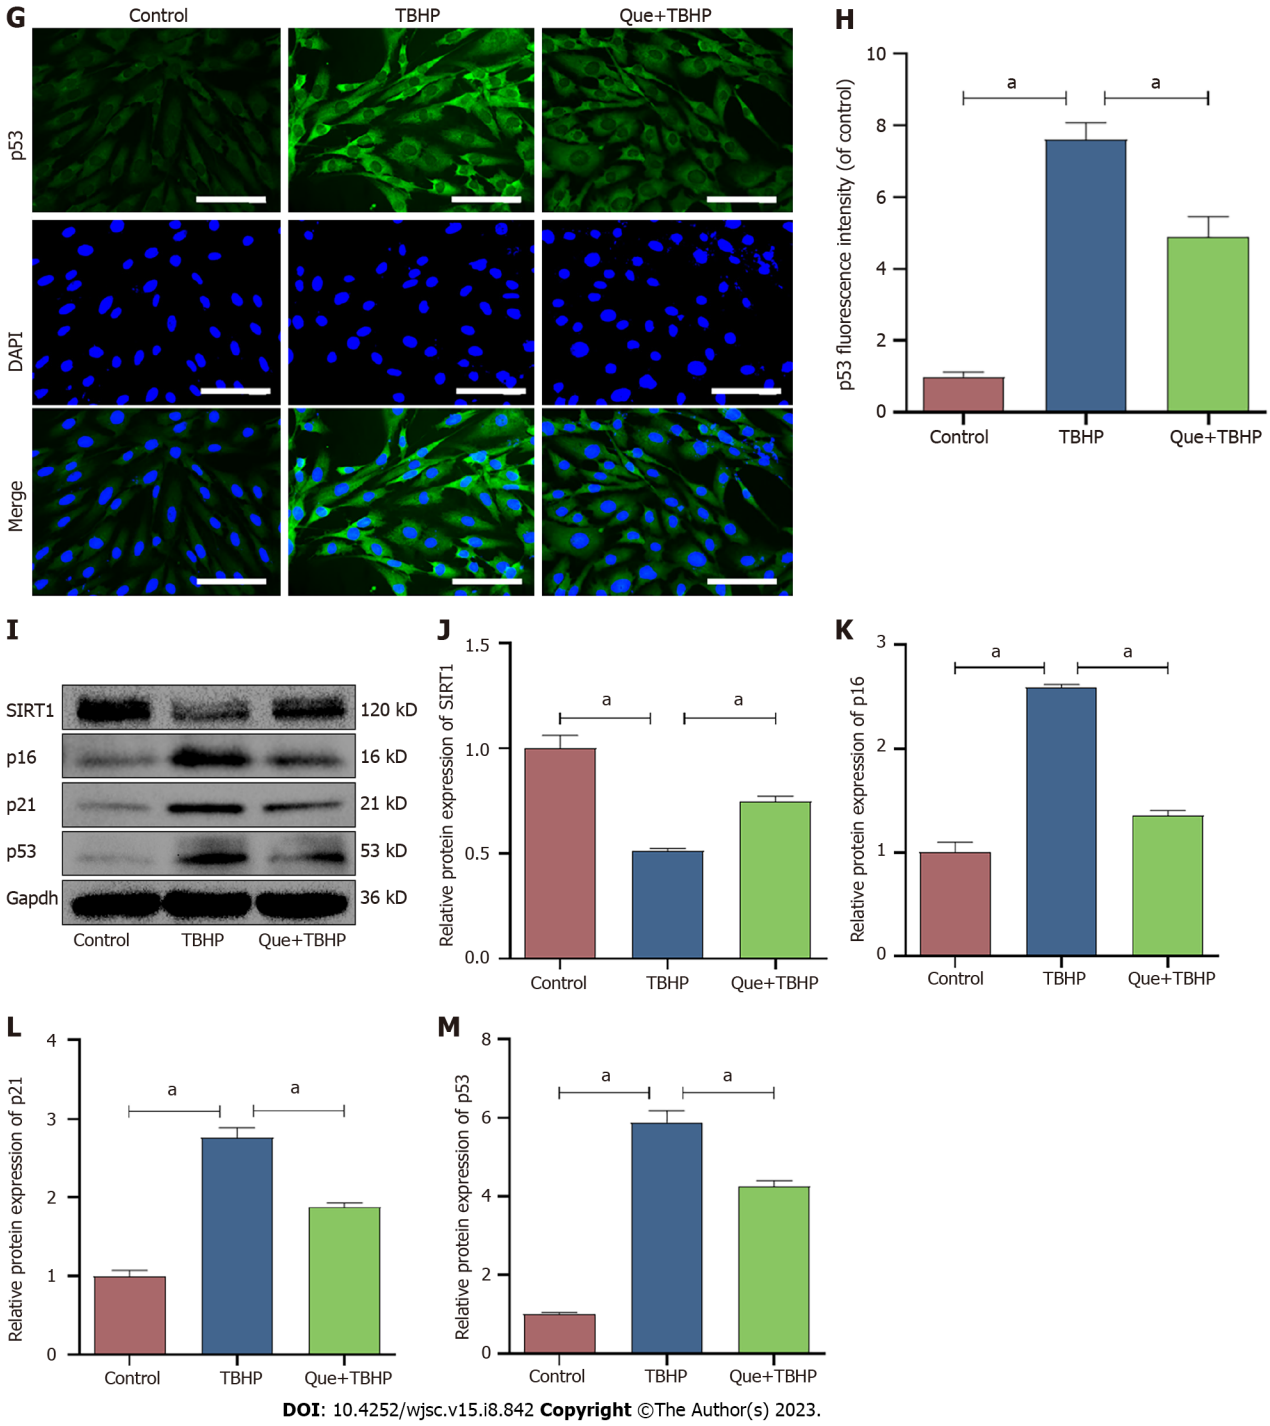
TBHP-induced NPMSCs, western blot analysis and immunofluorescence staining were used to evaluate the expression of SIRT1, cell senescence-related proteins (p16, p21, and p53), and SASP (IL-1β, IL-6, and MMP-13). The expression of SIRT1 was downregulated after TBHP treatment, and this effect was partially reversed by Que pretreatment ($P < 0.05$; Figure 5). Moreover, Que treatment significantly decreased the upregulation of p16, p21, p53, IL-1β, IL-6, and MMP-13 expression induced by TBHP ($P < 0.05$; Figures 5 and 6). Taken together, these results indicated that Que may have a protective role in TBHP-induced oxidative stress injury of NPMSCs.



MiR-34a-5p represses SIRT1 expression by targeting the 3'-UTR of SIRT1

According to the TargetScan online prediction database, SIRT1 is a potential target of miR-34a-5p (Figure 7A). A dual-luciferase reporter assay revealed that the miR-34a-5p mimic significantly inhibited the relative luciferase activity in the wild-type SIRT1 reporter vector (WT-SIRT1), whereas there was no significant change in the luciferase activity in the mutant SIRT1 reporter vector (MUT-SIRT1) (Figure 7B). These data indicated that miR-34a-5p inhibits SIRT1 expression by directly binding to the 3UTR of SIRT1. In addition, the mRNA and protein expression levels of SIRT1 were significantly inhibited by overexpression of miR-34a-5p (Figure 7C-E). Conversely, downregulation of miR-34a-5p increased the expression level of SIRT1 (Figure 7F-H). Moreover, the expression of SIRT1 was successfully downregulated by siRNA (Figure 7I-K).

MiR-34a-5p enhances oxidative stress-induced senescence of NPMSCs

According to the qRT-PCR analysis, the expression of miR-34a-5p was increased by TBHP treatment, and it was suppressed and promoted by the miR-34a-5p inhibitor and miR-34a-5p mimic, respectively (Figures 8A and 9A). In contrast, the expression of SIRT1 was suppressed after TBHP treatment, and it was promoted and suppressed and by miR-34a-5p inhibitor and miR-34a-5p mimic, respectively (Figures 8 and 9). The TBHP-enhanced senescence-related proteins (p16, p21, and p53) and SASP (IL-1β, IL-6, and MMP-13) were significantly suppressed after miR-34a-5p knockdown (Figure 8). In contrast, the expression levels of senescence-related proteins and SASP were increased when cells were treated with the miR-34a-5p mimic (Figure 9).

Que modulates TBHP-induced senescence of NPMSCs via the miR-34a-5p/SIRT1 pathway

To explore the relationship between miR-34a-5p/SIRT1 and oxidative stress-induced senescence in Que-treated NPMSCs, the miR-34a-5p mimic and siSIRT1 were used to investigate whether overexpression of miR-34a-5p and knockdown of SIRT1, respectively, counteracts the effects of Que on the expression of senescence-related proteins (p16, p21, and p53), SASP (IL-1β, IL-6, and MMP-13), and SIRT1. As shown in Figures 10 and 11, Que suppressed the expression of senescence-related proteins and SASP but promoted the expression of SIRT1, whereas overexpression of miR-34a-5p and knockdown of SIRT1 impaired this protective effect in TBHP-treated NPMSCs. These results suggested that Que may protect NPMSCs from TBHP-induced senescence *via* the miR-34a-5p/SIRT1 pathway.

Que ameliorates disc degeneration in a rat model

A puncture-induced rat model was established to investigate the effect of Que in IDD *in vivo*, and disc height was measured by X-ray images at Week 0 and Week 4 after puncture (Figure 12A). Compared to the control group, the DHI of the IDD group was significantly decreased (Figure 12B-E). Interestingly, the DHI of the Que group was significantly higher than that of the IDD group ($P < 0.05$) (Figure 12B-E). According to the Hematoxylin & eosin staining, NP tissues occupied most of the area in the discs, and NP cells were well dispersed in the matrix. The annulus fibrosus (AF) was well organized in the remaining area. In the IDD group, the NP tissues almost disappeared, and the border between NP and AF was severely disrupted (Figure 12F). However, Que treatment alleviated the degeneration and morphological changes in the NP and AF (Figure 12F). The histological score was higher in the IDD group compared to the control group ($P < 0.05$) (Figure 12G). Both Safranin-O Fast Green and Alcian blue staining showed that the proteoglycan matrix area was lower in the IDD group compared to the control group (Figure 12F). However, Que treatment alleviated the proteoglycan decrease compared to the IDD group (Figure 12H). Immunofluorescence was also used to assess the expression of collagen II and aggrecan in the disc tissue. Compared to the control group, the expression of collagen type II and aggrecan was significantly lower in the IDD group, and Que treatment significantly attenuated the decrease in collagen type II and aggrecan compared to the IDD group (Figure 12I and J). Taken together, these results suggested that Que alleviates the IDD process in a puncture-induced rat model.

DISCUSSION

In the present study, the results demonstrated that Que ameliorates oxidative stress-induced senescence in NPMSCs *via* the miR-34a-5p/SIRT1 axis. The *in vivo* results also demonstrated that Que inhibits the expression of senescence-related proteins (p16, p21, and p53) and SASP (IL-1β, IL-6, and MMP-13) as well as promotes the expression of SIRT1, suggesting that it has a therapeutic effect in the IDD rat model.

Several previous studies have found that oxidative stress is highly associated with the progression of IDD[4,7]. Oxidative stress is triggered in the microenvironment of degenerative IVD when the balance between generation and elimination of ROS is broken[33]. ROS not only trigger oxidative damage of the extracellular matrix of IVD but also induce oxidative damage to DNA, proteins, and mitochondria[33]. Moreover, ROS promote the production of ROS in IVD cells, forming a positive feedback loop[5-7,34]. The discovery of NPMSCs provides a theoretical basis for the endogenous repair of IDD[9,11]. The endogenous repair ability of NPMSCs in degenerative IVD is achieved by differentiation into NP

Figure 7 miR-34a-5p represses SIRT1 expression by targeting the 3'-UTR of SIRT1. A: Schematic of the predicted miR-34a-5p binding sites in the 3'-UTR of SIRT1 mRNA from TargetScan online database; B: Luciferase reporter activity of SIRT1 co-transfected with miR-34a-5p nc or miR-34a-5p mimic; C-E: The protein and mRNA expression level of SIRT1 in nucleus pulposus-derived mesenchymal stem cells (NPMSCs) transfected with miR-34a-5p mimic; F-H: The protein and mRNA expression level of SIRT1 in NPMSCs transfected with miR-34a-5p inhibitor; I-K: The protein and mRNA expression level of SIRT1 in NPMSCs transfected with Si-SIRT1. Data are represented as mean ± SD. Significant differences between groups are indicated as $^{a}P < 0.05$, $n = 3$. TBHP: Tert-butyl hydroperoxide.

cells and inhibiting cell apoptosis and/or senescence[10,35]. Oxidative stress in the microenvironment of IVD induces NPMSC senescence, and senescent NPMSCs decrease multipotency and self-renew ability, thus decreasing the regenerative potential and endogenous repair ability of NPMSCs[17,36-38]. In the present study, we found increased expression of senescence-related proteins (p16, p21, and p53), increased SASP (IL-1β, IL-6, and MMP-13), increased SA-β-Gal-positive senescent cells, decreased expression of SIRT1, decreased proliferation, and decreased viability after TBHP treatment in NPMSCs. Therefore, it is important to understand how to maintain the quantity and quality of NPMSCs under adverse microenvironments in degenerative IVD, such as oxidative stress, hypoxia, nutrient deficiency, and compression.

As a potent antioxidant, Que scavenges ROS, scavenges free radicals, inhibits lipid peroxidation, and inhibits xanthine oxidase activity[18-20,39]. Previous studies have reported that Que is an effective activator of SIRT1[40-42]. Feng *et al*[22] reported that Que attenuates oxidative stress-induced apoptosis of rat chondrocytes *via* the SIRT1/mitogen-activated protein kinase (AMPK) pathway and prevents the progression of osteoarthritis in a rat model[22]. Lou *et al*[43] confirmed that Que inhibits HepG2 cell apoptosis through the p53/miRNA-34a/SIRT1 pathway[43]. To evaluate the effect of Que in TBHP-induced NPMSCs, we pretreated cells with Que (20 μM) for 24 h before the addition of TBHP (100 μM) in the present study. Pretreatment with Que decreased ROS generation, decreased SA-β-Gal activity, and partially restored cell proliferation in oxidative stress induced-NPMSCs. Further, Que significantly reduced the expression of senescence-related proteins (p16, p21, and p53), reduced SASP (IL-1β, IL-6, and MMP-13), and increased the expression of SIRT1. Therefore, these results indicated that Que may have a protective effect against TBHP-induced oxidative stress in

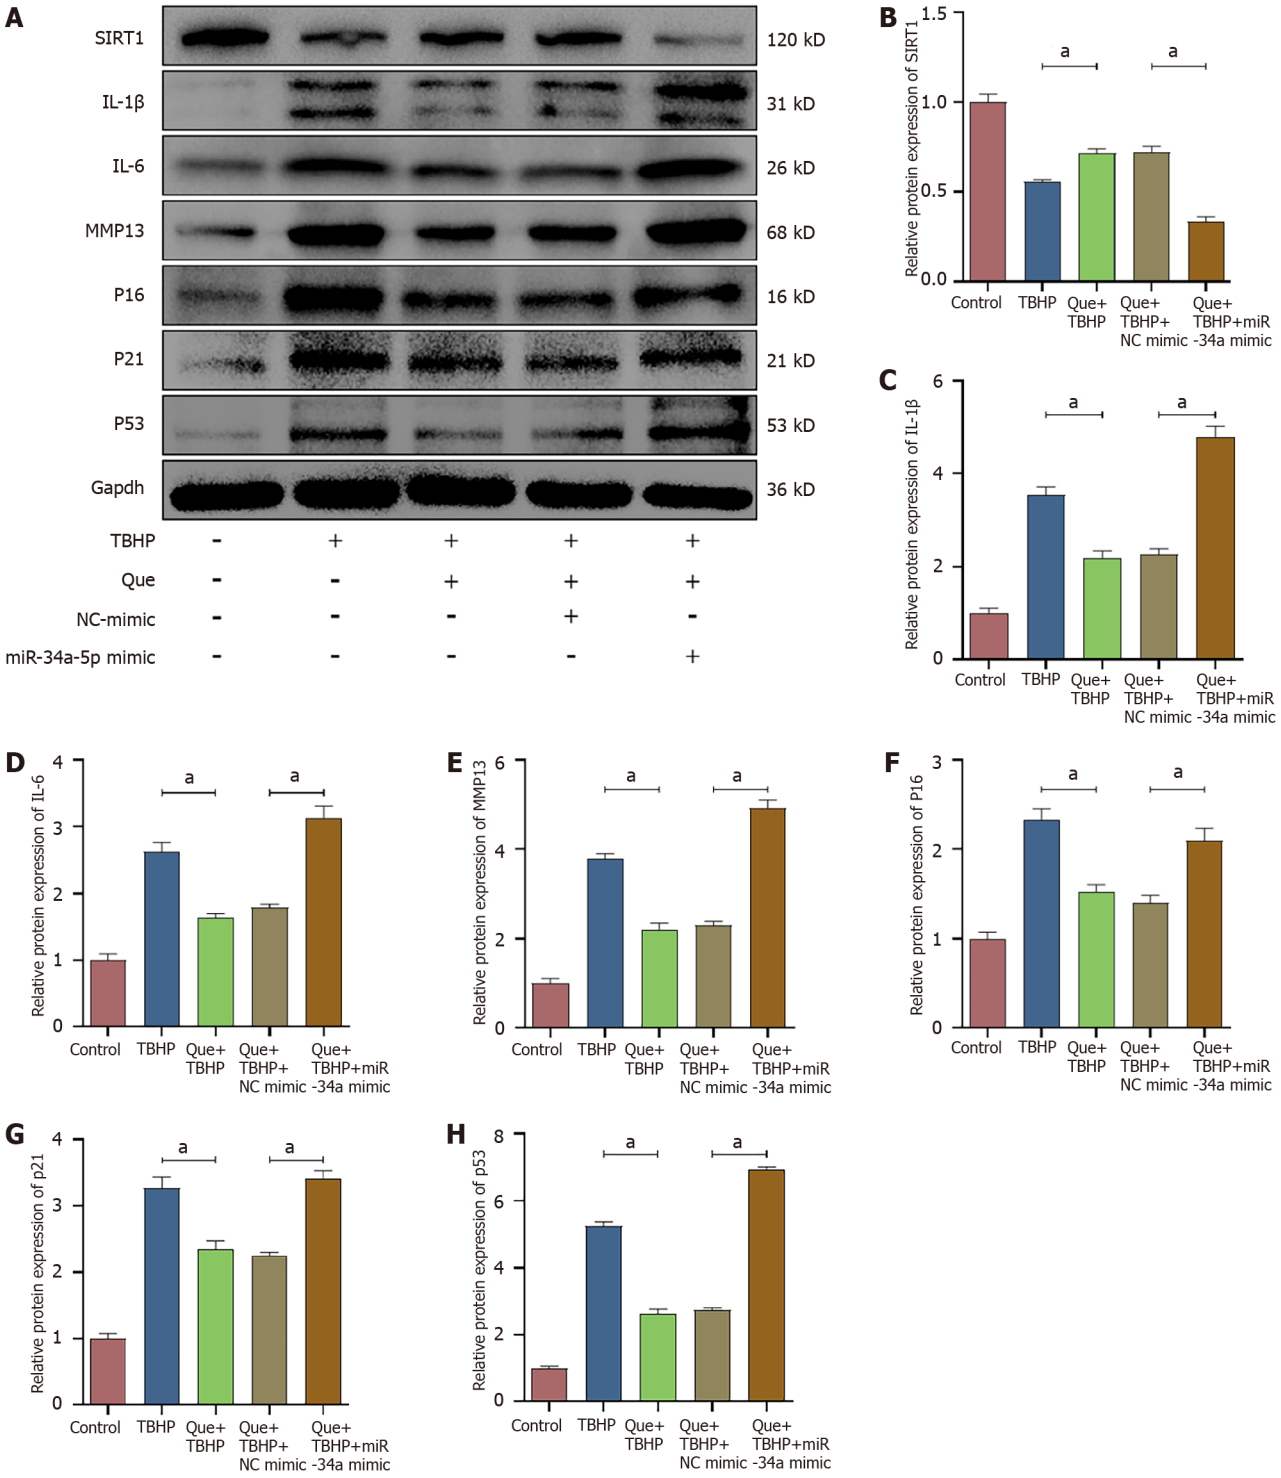
NPMSCs.



A previous study has also demonstrated that the expression of miR-34a-5p is significantly upregulated in degenerative IVD and that miR-34a-5p increases extracellular matrix degradation and cell apoptosis. Chen *et al*[44] reported that miR-34a increases apoptosis in degenerated cartilage endplate (CEP) chondrocytes. In addition, inhibition of miR-34a reduces cell apoptosis, while upregulation of miR-34a has an opposite effect in CEP cells[44]. In the present study, TBHP significantly upregulated miR-34a-5p expression. Overexpression miR-34a aggravated the oxidative stress damage

DOI: 10.4252/wjsc.v15.i8.842 **Copyright** ©The Author(s) 2023.

Figure 9 Overexpression of miR-34a-5p enhanced oxidative stress-induced nucleus pulposus-derived mesenchymal stem cells senescence. A: The RNA levels of miR-34a-5p in nucleus pulposus-derived mesenchymal stem cells (NPMSCs) were transfected with miR-34a-5p mimic and treated with TBHP; B: The protein levels of SIRT1, p16, p21, p53, IL-1β, IL-6 and MMP-13 in NPMSCs transfected with miR-34a-5p mimic; C-I: Quantitative analysis of protein expression in different groups. induced by TBHP in NPMSCs, including increased the expression of senescence-related proteins and SASP as well as and decreased the expression of SIRT1, whereas knockdown of miR-34a had an opposite effect in NPMSCs. Accumulating studies have demonstrated that SIRT1 exerts important function in the progression of IDD. The expression level of SIRT1 in IVD cells decreases with the progression of IDD[45], and SIRT1 expression is negatively correlated with Pfirrmann grade in IDD[46]. It has been reported that SIRT1 decreases the oxidative stress-induced senescence in CEP cells through the p53/p21 pathway[47]. H_2O_2-induced oxidative stress reduces the expression of SIRT1 as the expression of SIRT1 is downregulated with the increasing concentration of H_2O_2, and SIRT1 activation alleviates oxidative stress-induced

senescence in NP cells[29,48]. Xia *et al*[49] found that the expression of p16 is downregulated by activating SIRT1 in rat IDD model[49]. The present study found that SIRT1 expression was downregulated in TBHP induced-NPMSCs, which was rescued by Que and inhibiting miR-34a-5p. These results suggested that SIRT1 plays a protective role in TBHP induced-NPMSCs. miR-34a-5p overexpression and SIRT1 downregulation in NPMSCs were utilized to investigate whether Que reduces oxidative stress damage *via* the miR-34a/SIRT1 pathway to delay NPMSC senescence. The results demonstrated that the protective effect of Que is reversed by miR-34a-5p overexpression and SIRT1 knockdown.

In the present study, Que was also administered to IDD animal models to evaluate the protective effect of Que *in vivo*. X-ray analysis indicated the loss of DHI in the IDD model, but Que treatment ameliorated the decreased DHI. Moreover, histological analysis using HE, Alcian blue, and S-O staining as well as immunofluorescence analysis of collagen type II

and aggrecan confirmed that Que had a positive effect on delaying the degree of IDD.

The present study had several limitations. Previous studies have shown Que has pleiotropic properties. In addition to the activation of SIRT1, Que has anti-inflammatory and antioxidative effects *via* activating nuclear factor erythroid 2-related factor 2 (NRF2)[39], mitogen-activated protein kinase (MAPK)[39], and phosphatidylinositol 3-kinases/protein kinase B (PI3K/AKT)[50]. Hence, it remains unknown whether Que plays a role in NPMSC senescence induced by oxidative stress *via* other signaling pathways, suggesting that further study is needed to explore the other mechanisms underlying the protective effect of Que on NPMSCs. Moreover, future clinical studies are needed to evaluate the effect of Que on IDD progress.

CONCLUSION

In summary, the present study demonstrated that Que prevents oxidative stress-induced senescence of NPMSCs *via* the miR-34a/SIRT1 signaling pathway (Figure 13). Moreover, Que ameliorates the progression of IDD in a rat model. These findings suggested that Que may be a potential agent for the treatment of IDD.

ARTICLE HIGHLIGHTS

Research background

Intervertebral disc degeneration (IDD) is a main contributor to low back pain. Oxidative stress, which is highly associated with the progression of IDD, increases senescence of nucleus pulposus-derived mesenchymal stem cells (NPMSCs) and weakens the differentiation ability of NPMSCs in degenerated intervertebral discs (IVDs). Quercetin (Que) has been demonstrated to reduce oxidative stress in diverse degenerative diseases.

Research motivation

An adverse microenvironments of degenerative intervertebral disc such as oxidative stress, low nutrition, and inflammation leads to increased senescence NPMSCs, which severely affects endogenous repair. Therefore, inhibition senescence of NPMSCs may be of great significance in alleviating IDD.

Research objectives

The present study aimed to investigate the role of Que in oxidative stress-induced NPMSC damage and to elucidate the underlying mechanism.

Research methods

In vitro, NPMSCs were isolated from rat tails. Senescence-associated β-galactosidase (SA-β-Gal) staining, cell cycle, reactive oxygen species (ROS), real-time quantitative polymerase chain reaction (RT-qPCR), immunofluorescence, and western blot analyses were used to evaluate the protective effects of Que. Meanwhile the relationship between miR-34a-5p and Sirtuins 1(SIRT1) was evaluated by dual-luciferase reporter assay. To explore whether Que modulates tert-butyl hydroperoxide (TBHP)-induced senescence of NPMSCs *via* the miR-34a-5p/SIRT1 pathway, we used adenovirus vectors to overexpress and downregulate the expression of miR-34a-5p, and used SIRT1 siRNA to knockdown SIRT1 expression. *In vivo*, a puncture-induced rat IDD model was constructed, and X rays and histological analysis were used to assess

whether Que could alleviate IDD *in vivo*.

Research results

We found that TBHP can cause NPMSCs senescence changes, such as reduced cell proliferation ability, increased SA-β-Gal activity, cell cycle arrest, the accumulation of ROS, and increased expression of senescence-related proteins. While abovementioned senescence indicators were significantly alleviated by Que treatment. Que decreased the expression levels of senescence-related proteins (p16, p21, and p53) and senescence-associated secreted phenotype (SASP), including IL-1β, IL-6, and MMP-13, and it increased the expression of SIRT1. In addition, the protective effects of Que on cell senescence were partially reversed by miR-34a-5p overexpression and SIRT1 knockdown. *In vivo*, X-ray, and histological analyses indicated that Que alleviated IDD in a puncture-induced rat model.

Research conclusions

In summary, the present study provides evidence that Que reduces oxidative stress-induced senescence of NPMSCs *via* the miR-34a/SIRT1 signaling pathway, suggesting that Que may be a potential agent for the treatment of IDD.
