ABOUT COVER

Editorial Board Member of *World Journal of Stem Cells*, Irfan Khan, PhD, Assistant Professor, Stem Cells Lab. P-132, Dr. Panjwani Center for Molecular Medicine and Drug Research, University of Karachi, Karachi 75270, Pakistan. khan@iccs.edu

AIMS AND SCOPE

The primary aim of *World Journal of Stem Cells* (*WJSC*, *World J Stem Cells*) is to provide scholars and readers from various fields of stem cells with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJSC* publishes articles reporting research results obtained in the field of stem cell biology and regenerative medicine, related to the wide range of stem cells including embryonic stem cells, germline stem cells, tissue-specific stem cells, adult stem cells, mesenchymal stromal cells, induced pluripotent stem cells, embryonal carcinoma stem cells, hemangioblasts, lymphoid progenitor cells, *etc*.

INDEXING/ABSTRACTING

The *WJSC* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Journal Citation Reports/Science Edition, PubMed, PubMed Central, Scopus, Biological Abstracts, BIOSIS Previews, Reference Citation Analysis, China National Knowledge Infrastructure, China Science and Technology Journal Database, and Superstar Journals Database. The 2022 Edition of Journal Citation Reports cites the 2021 impact factor (IF) for *WJSC* as 5.247; IF without journal self cites: 5.028; 5-year IF: 4.964; Journal Citation Indicator: 0.56; Ranking: 12 among 29 journals in cell and tissue engineering; Quartile category: Q2; Ranking: 86 among 194 journals in cell biology; and Quartile category: Q2. The *WJSC*'s CiteScore for 2021 is 5.1 and Scopus CiteScore rank 2021: Histology is 17/61; Genetics is 145/335; Genetics (clinical) is 42/86; Molecular Biology is 221/386; Cell Biology is 164/274.

Abstract

BACKGROUND

The therapeutic effects of various stem cells in acute liver failure (ALF) have been demonstrated in preclinical studies. However, the specific type of stem cells with the highest therapeutic potential has not been determined.

AIM

To validate the efficacy of stem cells in ALF model and to identify the most promising stem cells.

METHODS

A search was conducted on the PubMed, Web of Science, Embase, Scopus, and Cochrane databases from inception to May 3, 2022, and updated on November 16, 2022 to identify relevant studies. Two independent reviewers performed the literature search, identification, screening, quality assessment, and data extraction.

RESULTS

A total of 89 animal studies were included in the analysis. The results of traditional meta-analysis showed that stem cell therapy could significantly reduce the serum levels of alanine aminotransferase [weighted mean difference (WMD) = -181.05 (-191.71, -170.39)], aspartate aminotransferase [WMD = -309.04 (-328.45, -289.63)], tumor necrosis factor-alpha [WMD = -8.75 (-9.93, -7.56)], and interleukin-6 [WMD = -10.43 (-12.11, -8.76)] in animal models of ALF. Further subgroup analysis and network meta-analysis showed that although mesenchymal stem cells are the current research hotspot, the effect of liver stem cells (LSCs) on improving liver function is significantly better than that of the other five types of stem cells. In addition, the ranking results showed that the possibility of LSCs improving liver function ranked first. This fully proves the great therapeutic potential of LSCs, which needs to be paid more attention in the future.

CONCLUSION

LSCs may have a higher therapeutic potential. Further high-quality animal

experiments are needed to explore the most effective stem cells for ALF.

Key Words: Acute liver failure; Stem cells; Animal model; Systematic review; Network meta-analysis

Core Tip: Determination of stem cells with the highest therapeutic potential in acute liver failure is crucial for future animal and clinical research. In this pioneer study, we conducted traditional meta-analysis and network meta-analysis to explore the efficacy of stem cells from four aspects: Alanine aminotransferase, aspartate aminotransferase, tumor necrosis factor-alpha and interleukin-6. We found that although mesenchymal stem cells are the current research hotspot, liver stem cells may have higher therapeutic potential and should be the focus of future research. In addition, we point out the problems existing and the direction of improvement in the future through the quality evaluation.

INTRODUCTION

Acute liver failure (ALF) is a clinical syndrome in which a large number of hepatocytes undergo necrosis resulting in severe liver function damage within a short period time. This condition occurs in the absence of chronic liver disease and is associated with severe complications, such as hepatic encephalopathy and even death, with a mortality rate of about 40%-62.2%[1-3]. The etiologies of ALF include heat pain poisoning, liver ischemia, viral hepatitis and autoimmune hepatitis, as well as prescription drugs, herbs and dietary supplements[1]. Currently, patients with ALF mainly receive medical supportive treatment due to the lack of specific therapy. Although liver transplantation is the only proven treatment, it is limited by the unavailability of donor organs, high medical costs, and the need for lifelong immunosuppressive drugs. Therefore, there is a need to develop newer and more effective therapeutic strategies.

Advances in clinical application of stem cells have provided a new perspective for ALF treatment[4]. Stem cells have many advantages, including self-renewal capacities, high proliferative activities, multi-directional differentiation, anti-inflammation, anti-apoptosis, and immunomodulatory activities. They can be obtained from various sources, such as the bone marrow, umbilical cord, adipose tissue, amniotic fluid and embryos among others[5,6]. After transplantation, naive stem cells or differentiated hepatocyte-like cells rapidly restore essential liver functions by replenishing functional hepatocytes and/or by stimulating endogenous liver regeneration processes through paracrine actions. Stem cell transplantation has been shown to increase the cumulative survival rate of ALF patients from 55.6% to 73.2%[7]. Stem cells improve damaged liver functions by increasing the activities of serum albumin, cholinesterase and prothrombin and reducing the levels of serum total bilirubin and alanine aminotransferase (ALT)[8].

Although the significance of stem cells in the treatment of ALF has been demonstrated in preclinical and clinical trials, there are still some controversies and obstacles that need to be resolved. For example, bone marrow mesenchymal stem cells (BMSCs) can be easily obtained without ethical problems and are considered the first-choice for autologous transplantation. However, their therapeutic effects are limited by easy aging and lack of vitality[9]. On the contrary, umbilical cord MSCs (UCMSCs) have become a new research hotspot because of their non-aging, low immunogenicity, and high proliferative activities [10]. Adipose MSCs (ADMSCs) can be prepared by minimally invasive methods, grow faster *in vitro*, and secrete abundant cytokines as well as growth factors related to immune regulation. Dysregulation of ADMSCs in clinical applications is significantly lower than that of embryonic stem cells (ESCs) or induced pluripotent stem cells (IPSCs)[11,12]. Therefore, ADMSCs are good candidates for ALF treatment. The non-invasive stem cell population, menstrual blood-derived stem cells (MenSCs), has been recently studied[13-15]. It has been postulated that MenSCs can express markers for both MSCs and ESCs, and can differentiate into the three germ layers. Fathi-Kazerooni *et al*[16] found that compared with BMSCs, MenSCs significantly reduced serum ALT and aspartate aminotransferase (AST) levels in ALF mice models. Therefore, the therapeutic potential of MenSCs cannot be ignored.

In conclusion, stem cells can improve liver failure. However, it is not clear which kind of stem cells has the best therapeutic effect. Solving this problem will improve the therapeutic effect and accelerate the clinical translation of stem cells. To date, few studies have directly compared the therapeutic effects

of different types of stem cells. In the absence of direct comparisons, systematic reviews and network meta-analyses can be used to perform direct and indirect comparisons between different interventions and estimate the ranking probabilities[17]. Therefore, we intend to compare the therapeutic potential of different types of stem cells through subgroup analysis of traditional meta-analysis and network meta-analysis. Our findings inform on optimal types of stem cells and provide a reference for animal experiments and clinical research.

MATERIALS AND METHODS

Inclusion and Exclusion Criteria

Patients and diseases (P): Animal models of ALF. Interventions (I): Stem cells. Control (C): (1) Positive control: Comparisons between different stem cells; and (2) Negative control: Blank, DMEM, PBS, saline. Outcomes (O): (1) Primary outcomes: ALT and AST levels; and (2) Secondary outcomes: Expression levels of genes or proteins of tumor necrosis factor-α (TNF-α) and interleukin-6 (IL-6). Type of studies (S): Controlled studies.

Data sources and searches

Candidate studies were identified *via* searching PubMed, Web of Science, Embase, Scopus, *Reference Citation Analysis*, and Cochrane databases from their inceptions until February 3, 2022, and updated on November 16, 2022. Search terms were: "stem cell" OR "stem cells" OR "stromal cells" OR "stromal cell" OR "mesenchymal cell" OR "mesenchymal cells" OR "cell therapy" OR "cellular therapy" OR "progenitor cell" OR "progenitor cells" OR "cytotherapy" AND "liver failure" OR "hepatic failure". The retrieval processes for each database are shown in Supplementary Table 1.

Literature screening, data extraction, and quality assessment

Two independent reviewers performed the literature search, identification, screening, quality assessment and data extraction. Literature screening was based on the inclusion and exclusion criteria, and data extraction was based the pre-established information (including basic information, outcome indicators, and key elements of quality evaluation) shown in Supplementary Table 2. Based on SYRCLE's risk of bias tool for animal studies[18], 10 items in 6 aspects including selection bias, performance bias, detection bias, attrition bias, reporting bias, and other biases were used to evaluate the quality of included studies.

Statistical analysis

Traditional meta-analysis was performed using the Stata16.0 software. Odds ratios were used for count data, while weighted mean differences (WMD) rather than standardized mean differences (SMD) were used as effect indicators for measured data. In fact, when performing meta-analysis, WMD eliminates the influence of the absolute value on the results, so that the original weight and measure can truly reflect the experimental effect, and it is easy to understand when applied. However, SMD not only eliminates the influence of the absolute value, but also eliminates the influence of weights and measures on the results, which makes the results difficult to interpret and requires caution when interpreting the results. Therefore, it is a better practice to choose WMD in our study. Confidence intervals were also reported. Heterogeneity was analyzed by the χ^2 test while I^2 was used to determine the degree of heterogeneity. If the findings were not statistically different, the fixed effects model was used for meta-analysis. Conversely, the source of heterogeneity was further analyzed, and the random-effects model used for meta-analysis. Reliability of the traditional meta-analysis results were determined *via* sensitivity analyses.

Network meta-analysis was performed using the Winbugs1.4.3 software. The evidence network diagram of the comparisons for each treatment was drawn to show the current research status in the field. Then, a comparison-correction funnel chart was established to evaluate the possibility of publication bias and small sample effects in the included studies. The Bayesian network meta-analysis was performed using the Markov Chain Monte Carlo method, and ranking probability for each intervention calculated[19]. In addition, potential false positive factor (PSRF) was used to evaluate the convergence of the results. A PSRF value is between 1-1.05 indicated complete convergence, good model stability, and reliable analysis[20].

Traditional meta-analysis was performed by subgroups to explore the therapeutic effects of different types of stem cells. Only ADMSCs, amniotic fluid MSCs (AFMSCs), BMSCs, liver stem cells (LSCs), MenSCs, and UCMSCs were subjected to the network meta-analysis because studies using these six stem cells reported all the primary and secondary outcomes. In this case, the results of network meta-analysis based on different outcome indicators are comparable.

RESULTS

Literature search results

A total of 5436 articles were obtained from the preliminary search. After excluding repetitive articles and those that did not meet the inclusion criteria, 89 articles were finally included (Figure 1).

Basic information of the included studies

Among the 89 studies, there were 74 randomized controlled trials and 15 controlled studies. The animal species involved in the studies included Sprague-Dawley rats (22 studies), Wistar rats (6 studies), Albino rats (2 study), BALB/c mice (16 studies), C57BL/6 mice (29 studies), ICR mice (3 studies), NOD-SCID mice (2 studies), Swiss albino mice (1 study), dogs (1 study), pigs (6 studies), and F344-Fischer rats (1 study). In terms of gender, 66 studies included male animals, 10 studies included female animals while 13 studies did not report the gender of the animals. The animals weighed between 18 g-18 kg, were aged between 4 wk and 1.5 years, and the sample sizes were between 6-94. Modeling methods for ALF included partial hepatectomy (7 studies), carbon tetrachloride (25 studies), Concanavalin A (6 studies), D-galactosamine (D-GalN, 10 studies), D-GalN/lipopolysaccharide (27 studies), acetaminophen (9 studies), thioacetamide (4 studies), and ischemia-reperfusion injury (1 study). The types of stem cells that were assessed included ADMSCs (21 studies), UCMSCs (21 studies), AFMSCs (2 studies), BMSCs (39 studies), ESCs (1 study), IPSCs (2 studies), LSCs (2 studies), MenSCs (4 studies), and placental stem cells (PMSCs, 1 study). The transplantation routes for the stem cells included intraperitoneal injection (4 studies), liver parenchyma (3 studies), portal vein (6 studies), splenic vein (2 studies), tail vein (71 studies) and stent loading (3 studies). The transplantation timing for the stem cells was within 4 d after modeling, while the transplantation dose was between (1×10^5)-(1×10^8). The negative control groups were treated with normal saline (32 studies), PBS (35 studies), Blank (16 studies) and DMEM (6 studies). The basic information of the included studies is shown in Supplementary Table 2.

Risk of bias assessment results

Although there were 74 randomized controlled trials among the included studies, there were no reports on specific randomized grouping methods or whether covert grouping was implemented. Eighty-one studies reported that the baseline characteristics of experimental animals, such as age, sex and weight were balanced. Stem cell transplantation before modeling was performed in 4 studies. Seventy-eight studies reported randomized placement of animals during the experiments. Due to limited information provided by the included studies, it was difficult to determine whether animal breeders and/or researchers had been blinded. Only eight studies reported randomly selecting animals in measurement of the results. Thirty-one studies had blinded outcome evaluators. There was no study that reported on the loss or follow-up of animals. Although protocols were not available for all studies, all expected results were clearly reported. Findings from the risk of bias assessment are shown in Figure 2.

Meta-analysis results

Serum ALT levels: A total of 78 studies reported on serum ALT levels. Meta-analysis of the random effects model showed that ALT levels in the stem cell group were significantly suppressed, relative to those of the negative control group [WMD = -181.05 (-191.71, -170.39)]. Subgroup analysis revealed that the trend of improving liver functions was: IPSCs, LSCs, UCMSCs, ADMSCs, PMSCs, MenSCs, BMSCs. Notably, the treatment effects of AFMSCs and ESCs were not markedly different from those of the control group (Supplementary Figure 1). The evidence network diagram showed that BMSCs and ADMSCs are the current research hotspots (Figure 3A). Network meta-analysis revealed that the effects of LSCs in reducing ALT levels were significantly better than those of the other five stem cells (Table 1). The asymmetrical comparative correction funnel chart suggested that there was publication bias and small sample effects (Figure 4A). The ranking results showed that LSCs had the best effects in reducing ALT levels (Figure 5A).

Serum AST levels: Seventy-one studies reported serum AST levels. The meta-analysis of the random effects model showed that serum AST levels in the stem cell group were significantly lower than those of the negative control group [WMD = -309.04 (-328.45, -289.63)]. Subgroup analysis showed that the trend for effects of improving liver functions was: LSCs, IPSCs, UCMSCs, AFMSCs, ADMSCs, MenSCs, BMSCs (Supplementary Figure 2). The evidence network diagram showed that BMSCs and ADMSCs are the current research hotspots (Figure 3B). Network meta-analysis showed that the effects of LSCs in reducing AST levels were significantly better than those of the other five stem cells (Table 1). The asymmetrical comparative correction funnel chart revealed the possibility of publication bias and small sample effects (Figure 4B). The rank ranking results showed that LSCs have the best effects in reducing AST levels (Figure 5B).

Serum TNF-α levels: Twenty-six studies reported the expression of TNF-α at gene or protein levels. The meta-analysis of random effects model showed that TNF-α levels in the stem cell group were significantly suppressed, relative to those of the negative control group [WMD = -8.75 (-9.93, -7.56)]. Subgroup analysis showed that the reduction trend in TNF-α levels was UCMSCs, LSCs, ADMSCs,

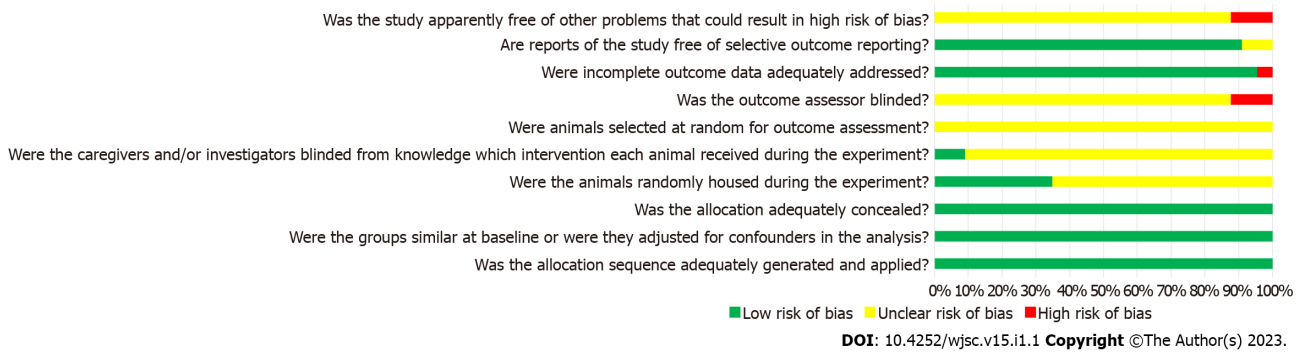
[1]Indicated statistical difference.

BMSCs: Bone marrow mesenchymal stem cells; LSCs: Liver stem cells; MenSCs: Menstrual blood-derived stem cells; AFMSCs: Amniotic fluid mesenchymal stem cells; ADMSCs: Adipose mesenchymal stem cells; UCMSCs: Umbilical cord mesenchymal stem cells; ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; TNF-α: Tumor necrosis factor-α; IL-6: Interleukin-6.

MenSCs, BMSCs. The treatment effects of AFMSCs were not significantly different from those of the negative control group (Supplementary Figure 3). The evidence network diagram showed that BMSCs and ADMSCs are the current research hotspots (Figure 3C). Network meta-analysis showed that differences in the effects of all stem cells on reducing TNF-α levels were insignificant (Table 1). The asymmetrical comparative correction funnel chart suggested the existence of publication bias and small sample effects (Figure 4C). The rank ranking results showed that LSCs was most effective in reducing TNF-α levels (Figure 5C).



Serum IL-6 levels: A total of 20 studies reported the expression of IL-6 at gene or proteins levels. A meta-analysis of the random effects model showed that that IL-6 levels in the stem cell group were significantly lower than those of the negative control group [WMD = -10.43 (-12.11, -8.76)]. Subgroup analysis showed that the trend in reduction of IL-6 was LSCs, ADMSCs, UCMSCs, BMSCs, MenSCs. The treatment effects of AFMSCs were not markedly different from those of the negative control group (Supplementary Figure 4). The evidence network diagram showed that BMSCs and ADMSCs are the current research hotspots (Figure 3D). Network meta-analysis did not reveal significant differences in the effects of all stem cells in reducing IL-6 levels (Table 1). The asymmetrical comparative correction funnel chart showed the possibility of publication bias and small sample effects (Figure 4D). The rank ranking results revealed that LSCs have the best effects in reducing IL-6 levels (Figure 5D).

Reliability test of meta-analysis results: Sensitivity analysis was performed to test the reliability of the results from the traditional meta-analysis. The four outcome indicators showed that after one by one exclusion of certain studies, directions of the confidence intervals of the combined results of the

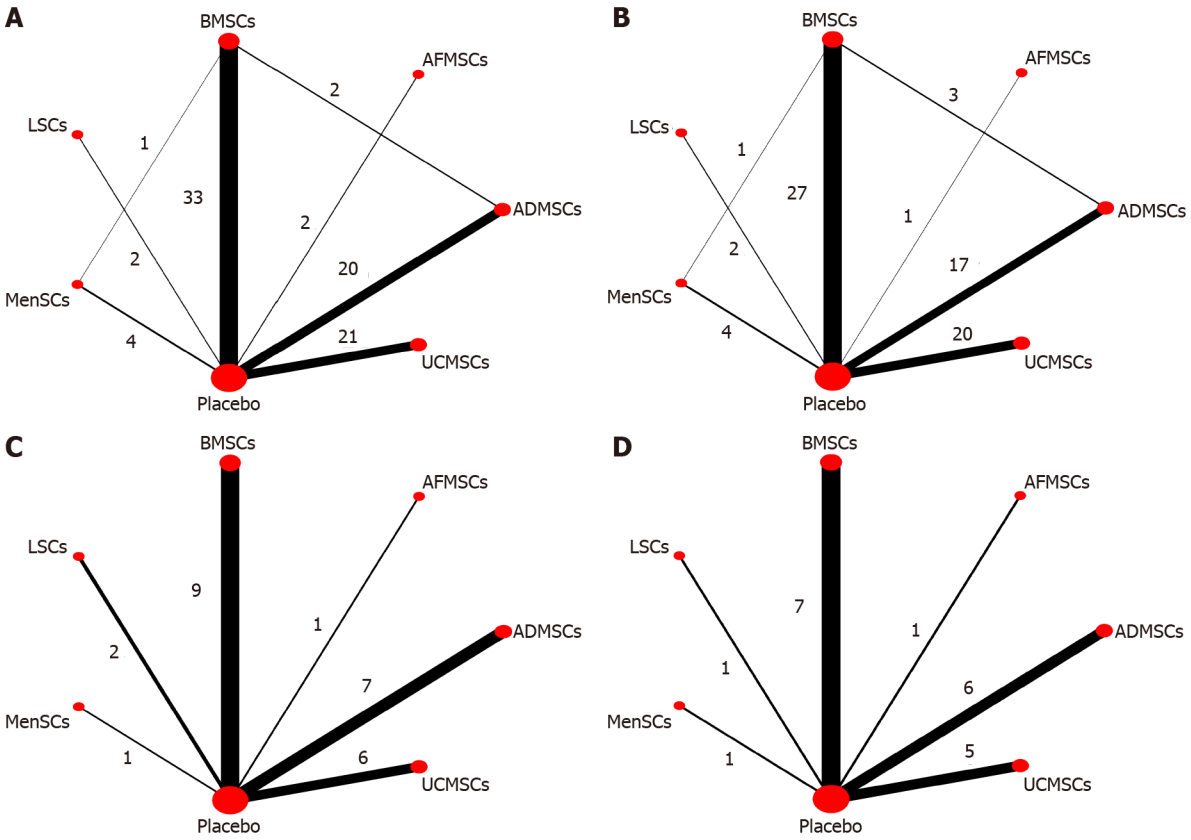

Figure 2 Risk of bias assessment results. 10 items in 6 aspects including selection bias, performance bias, detection bias, attrition bias, reporting bias, and other biases were used to evaluate the quality of included studies. The risk of bias of all studies about a certain item is expressed as a percentage.

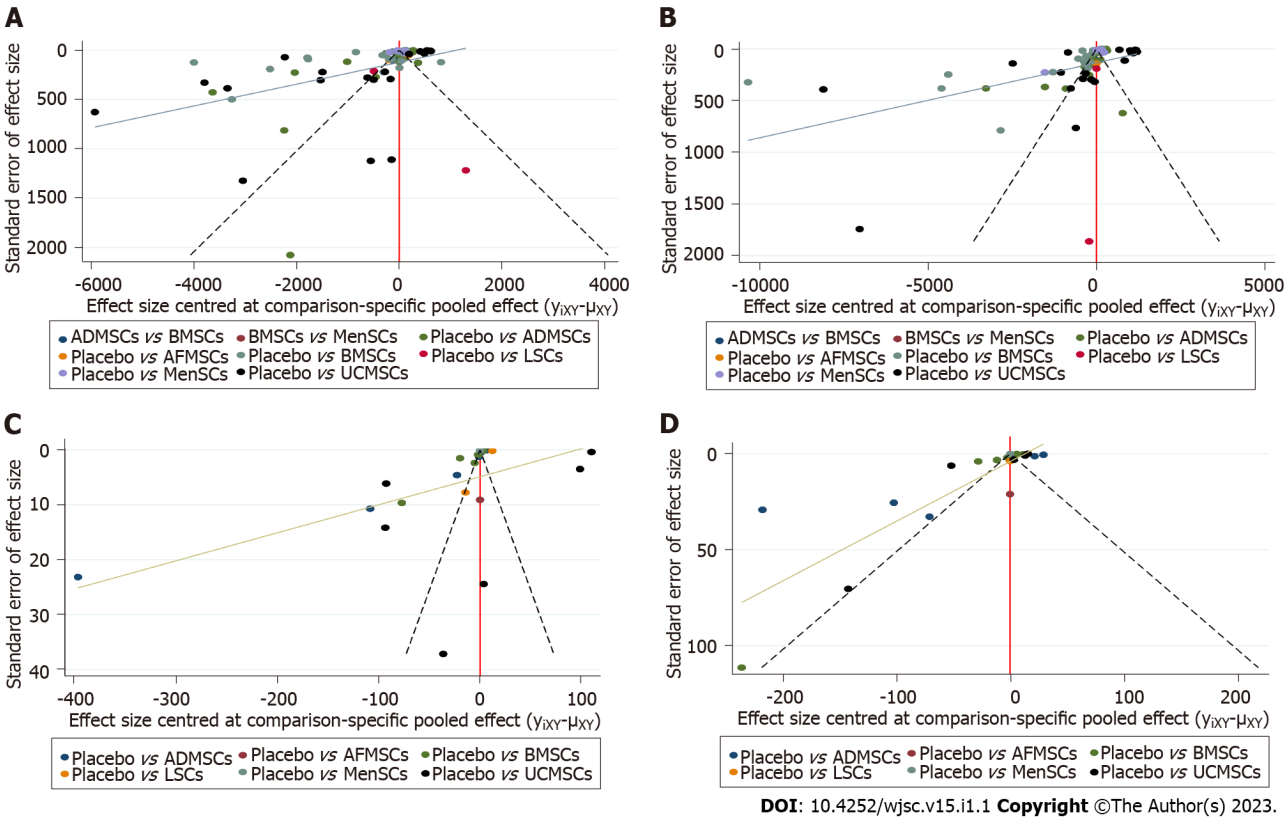
remaining studies did not change, indicating that findings from the meta-analysis were robust and reliable (Figure 6).

Then, PSRF was used to evaluate the fitting effects of the model, after which the reliability of the network meta-analysis results was determined. The four outcome indicators showed that PSRF converged to 1 after a certain number of iterations, indicating that robustness and reliability of the network meta-analysis results were good (Figure 7).

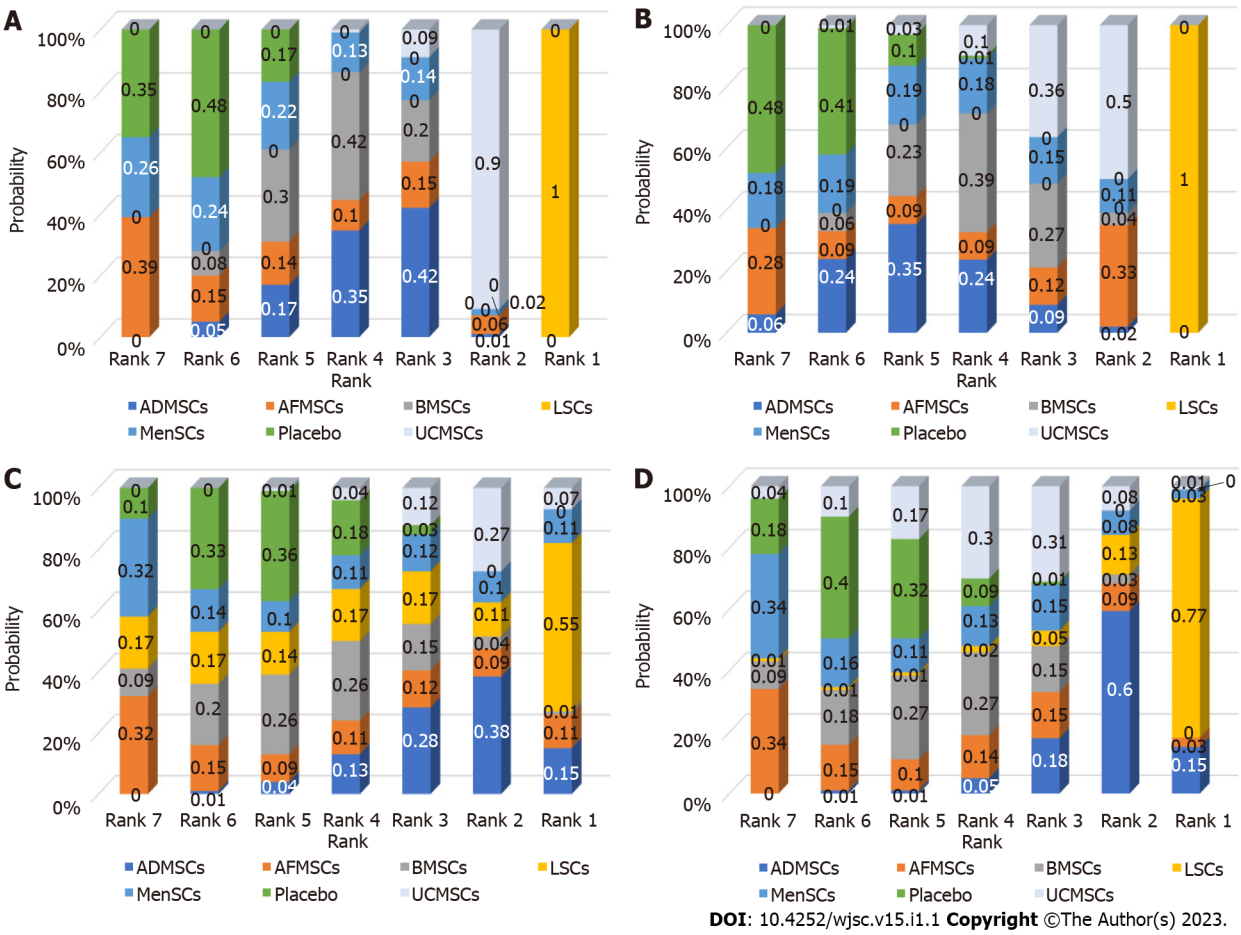
DISCUSSION



The mechanism for occurrence of ALF begins with hepatocyte necrosis[21], followed by damage to the membrane structure of hepatocytes and the release of AST and glutamic pyruvic transaminase (ALT)

DOI: 10.4252/wjsc.v15.i1.1 **Copyright** ©The Author(s) 2023.

Figure 3 Evidence network diagram. Circle size represents sample size involved, thickness of the line segment represents the number of studies involving both interventions. A: Alanine aminotransferase; B: Aspartate aminotransferase; C: Tumor necrosis factor-α; D: Interleukin-6. BMSCs: Bone marrow mesenchymal stem cells; LSCs: Liver stem cells; MenSCs: Menstrual blood-derived stem cells; AFMSCs: Amniotic fluid mesenchymal stem cells; ADMSCs: Adipose mesenchymal stem cells; UCMSCs: Umbilical cord mesenchymal stem cells.



from hepatocytes into the bloodstream. Therefore, the serum levels of AST and ALT are the most reliable markers of liver injury[22]. Stem cells can protect the damaged liver by promoting hepatocyte regeneration and inhibiting hepatocyte apoptosis[23]. Consistent with findings from current animal studies, our meta-analysis showed that different types of stem cell transplantation can significantly suppress serum ALT and AST levels. This indicates the great therapeutic potential of stem cells in ALF. By confirming that stem cells can improve liver functions, there is a need to elucidate on their therapeutic potential to accelerate their clinical translation. About 10 different types of stem cells have been studied in ALF, however, a limited number of studies have compared the therapeutic effects of different types of stem cells. We found that only four studies compared the therapeutic potentials of different types of stem cells in ALF. Among them, three studies compared ADMSCs with BMSCs. They showed that the effects of the two kinds of stem cells on improving liver functions were comparable[24-26]. In another study, MenSCs were found to be significantly better than BMSCs in reducing ALT and AST levels[16]. Studies have reported that MSCs have the advantages of easy access, multipotential, anti-apoptosis, immunosuppression, and paracrine characteristics[27]. Therefore, MSCs are the most studied stem cells in the field of ALF. This is consistent with results shown in the evidence map of our network meta-analysis, that is, MSCs derived from the bone marrow, fat and umbilical cord are the current research focus. However, further subgroup analysis and network meta-analysis showed that they are not the best in improving liver functions. Besides, LSCs are more effective in reducing serum ALT and AST levels. LSCs are MSC-like cells in the liver. In addition to having the same surface markers as MSCs, such as CD29, CD73, CD44, CD105 and CD146, they also express specific hepatocyte markers (albumin, cytokeratin8, and cytokeratin-18) and embryonic markers (Nanog, Oct3/4, Sox2, Musashi, SSEA4, and Pax2)[28,29]. Studies have shown that LSCs improve liver functions by directly differentiating into hepatocytes and secreting cytokines that inhibit injury progression[29]. A possible reason why LSCs showed a better ability to repair liver functions is their greater ability to migrate to the damaged liver. For example, after intravenous transplantation, LSCs preferentially aggregate and play a role in the damaged liver, while MSCs are mainly trapped in the lungs and do not migrate to the damaged liver[29,30]. In addition, human LSCs do not express human leukocyte antigen II molecules and costimulatory molecules (CD40, CD80 and CD86), which reduces the severity of immune responses [31].

Figure 4 The comparison-correction funnel plot. The dotted lines on both sides of the funnel plot represent 95% confidence intervals, and each point represents a study. If each point falls within the dotted line and is symmetrically distributed on both sides of the vertical line, there is no publication bias. On the contrary, it indicates the possibility of publication bias. A: Alanine aminotransferase; B: Aspartate aminotransferase; C: Tumor necrosis factor-α; D: Interleukin-6. BMSCs: Bone marrow mesenchymal stem cells; LSCs: Liver stem cells; MenSCs: Menstrual blood-derived stem cells; AFMSCs: Amniotic fluid mesenchymal stem cells; ADMSCs: Adipose mesenchymal stem cells; UCMSCs: Umbilical cord mesenchymal stem cells.

The most common causes of death in ALF patients is systemic complications with release of proinflammatory cytokines and impairment of associated molecular patterns of the necrotic hepatocytes, endothelial cells, and leukocytes[32,33]. Regardless of the cause, uncontrolled inflammation is crucial in ALF occurrence and development[34]. Reduction of pro-inflammatory cytokines and hepatocyte dysfunction is key in ALF treatment. Hepatocyte apoptosis is associated with excess activations of immune responses, usually mediated by TNF-α and IL-6[35]. TNF-α is a pro-inflammatory factor that regulates the expressions of pro-inflammatory genes, tissue factors and leukocyte antigen class I[36,37]. The TNF-α interacts with its receptor (TNF receptor I) to activate signal transduction pathways[38]. IL-6 is produced by Th2 cells, monocytes, and vascular endothelial cells, and is one of the core cytokines involved in liver injury development[39]. Excess secretion of IL-6 delays cell cycle progression and inhibits hepatocyte regeneration[40]. Therefore, plasma levels of TNF-α and IL-6 in ALF patients were significantly increased. Although previous studies have confirmed that MSCs from human cord blood can differentiate into hepatocyte-like cells *in vivo* and partially repair D-galactose/lipopolysaccharide-induced liver injury in mice models[41]. Menstrual fluid-derived stem cells showed the potential to restore liver functions in mice that had been subjected to 2/3 partial hepatectomy, and menstrual stem cell-derived hepatocyte-like cells were detected in the recipient liver [42]. However, transplanted stem cells are less likely to differentiate into functional hepatocytes and regenerate liver tissues within a short period of time. In early stages, stem cells protect against ALF *via* exerting their immunomodulatory and anti-inflammatory properties[43]. Consistent with the results of animal experiments, our meta-analysis found that stem cell transplantation significantly reduces TNF-α and IL-6 levels. In addition, consistent with ALT and AST levels, LSCs are the most potential stem cells for reducing serum TNF-α and IL-6 levels. The consistent results from four different outcome indicators prove that LSCs have the greatest therapeutic potential in ALF treatment. Our results are also in line with current research evidence, which has confirmed that serum IL-6 levels are positively correlated with ALT and AST levels. However, studies on LSCs are few, and the mechanisms by which they exert their repair effects have yet to be conclusively determined. There is also a lack of evidence for direct comparisons of LSCs with other stem cell types. Therefore, studies should elucidate on the roles of LSCs. In addition, due to differences in outcome reporting, AFMSCs, ESCs, and IPSCs were not analyzed in our network meta-analysis. This does not mean that other types of stem cells have limited therapeutic potential. On the contrary, studies should also focus on therapeutic effects of different types

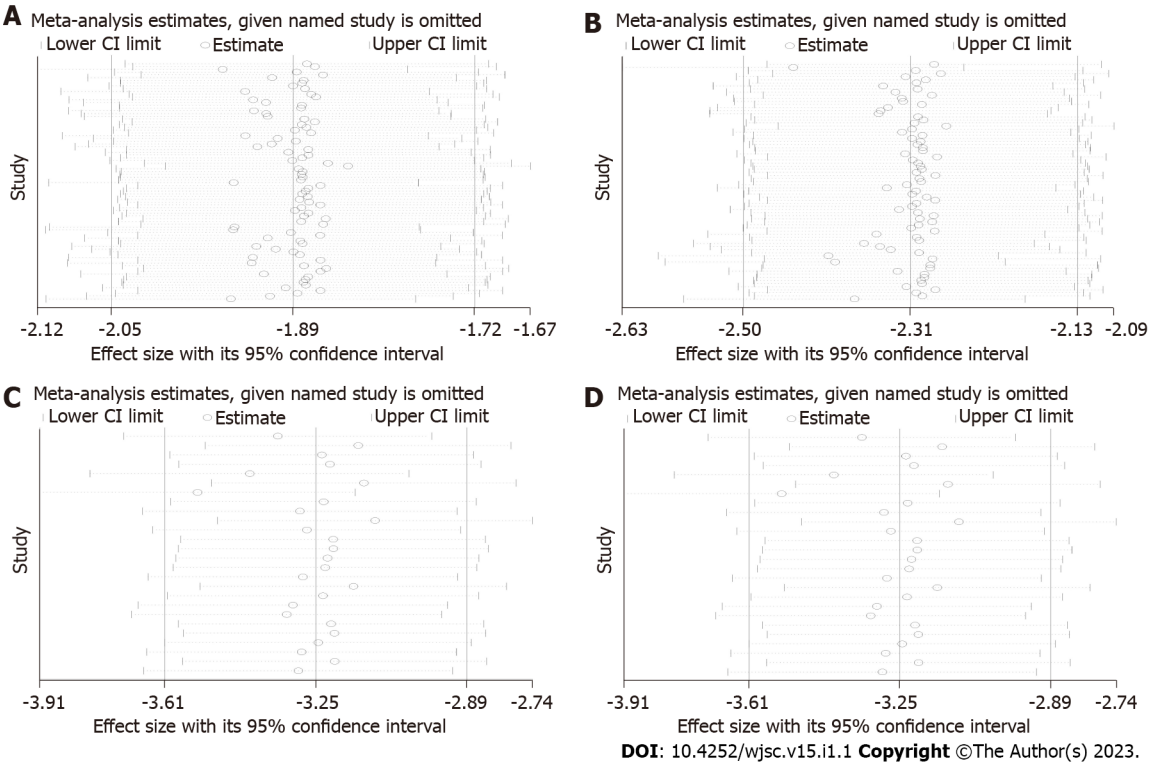

Figure 5 Ranking results. The higher the probability of being ranked first, the better the treatment effect of that intervention. A: Alanine aminotransferase; B: Aspartate aminotransferase; C: Tumor necrosis factor-α; D: Interleukin-6. BMSCs: Bone marrow mesenchymal stem cells; LSCs: Liver stem cells; MenSCs: Menstrual blood-derived stem cells; AFMSCs: Amniotic fluid mesenchymal stem cells; ADMSCs: Adipose mesenchymal stem cells; UCMSCs: Umbilical cord mesenchymal stem cells.

of stem cells, carefully compare their advantages and disadvantages, and construct stem cells with more potential through genetic modification and other means.

Evidence quality

Considerable heterogeneity among the included studies: The included studies involved 11 different animal species, 8 modeling methods, and there were wide variations in baseline characteristics of animals, such as body weight and age. In addition, there were differences in stem cell types, transplantation doses and routes, as well as in measurement and reporting of outcome indicators (such as protein levels, gene levels, *etc.*), resulting in greater heterogeneity among the included studies, which reduced the reliability of meta-analysis results. There is a need to standardize ALF animal models, experimental implementation and outcome measurements to improve the authenticity of experimental results and the reliability of systematic review results.

Insufficient internal authenticity of animal experiments: (1) Selection bias: Randomization and covert grouping of animals while ensuring the balance of their baseline characteristics is an important measure to avoid selection bias[18]. Although about 90% of the studies were randomized controlled trials and the baseline characteristics of the animals were balanced, no study reported the specific randomization method and whether they implemented concealed grouping, resulting in a certain selection bias; (2) Performance bias: Placement of animals, such as different light and temperature conditions, has an important impact on experimental results[18]. Although 87.64% of the studies randomized the placement of animals, no study had blinded animal breeders and researchers, resulting in a certain implementation bias; (3) Detection bias: Failure to blind the outcome assessors in animal experiments may lead to exaggeration of effects and produce false positive results[44,45]. Only 34.83% of the studies reported blinding the outcome assessors, and no study reported a specific blinding process. Therefore, studies should pay more attention to applications of blinding in experimental designs, and should provide more experimental details to improve the reporting quality; (4) Reporting bias: Selective reporting of results can lead to publication bias, which affects the reliability of experimental results[46].

DOI: 10.4252/wjsc.v15.i1.1 **Copyright** ©The Author(s) 2023.

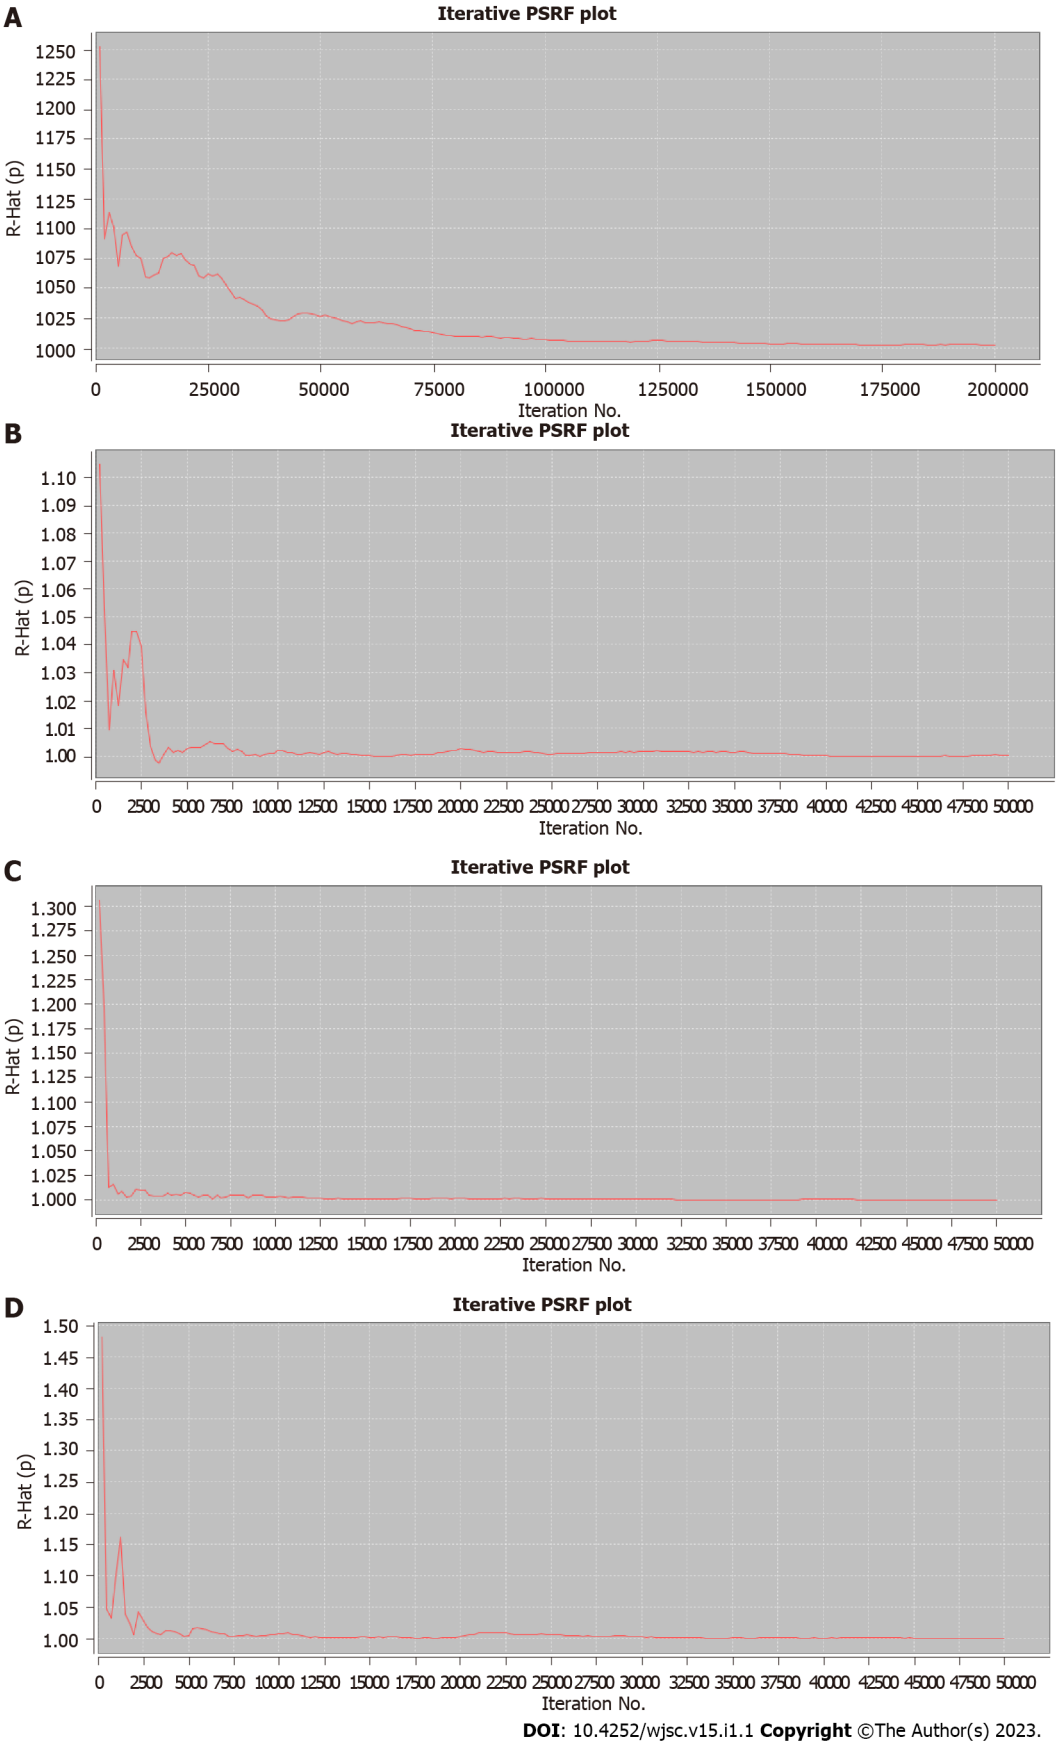

Figure 6 Results of sensitivity analysis. After excluding a certain study, the remaining studies were combined for analysis to see if there were any changes in the effect sizes. If the results of the remaining studies were basically the same as the previous total combined results (the range of the confidence interval did not change significantly), the results of the meta-analysis were considered to be reliable. Conversely, the results of the meta-analysis were considered unreliable. A: Alanine aminotransferase; B: Aspartate aminotransferase; C: Tumor necrosis factor-α; D: Interleukin-6. CI: Confidence interval.

Moreover, protocols were not available for all studies. Therefore, we suggest that animal experimental researchers prospectively register protocols to improve transparency; and (5) Publication bias: Negative results from animal experiments are difficult to publish[47]. If negative results are not included in systematic reviews, the effects of intervention will be overestimated. The corrected funnel chart revealed a certain publication bias in this field.

Limited external authenticity of included studies: External authenticity in animal experiments refers to reproducibility of results and feasibility of their translation to clinical research[48]. The lack of external authenticity in this study is reflected in the following aspects: (1) Although this study has preliminarily determined the best type of stem cells, the routes, dose, and timing of stem cell transplantation are also key factors for achieving desirable outcomes[49,50]. Until these experimental conditions are clearly explored, clinical translation of stem cells will remain immature; (2) In animal experiments, stem cells are often transplanted in early stages. However, clinical practice must be to recruit patients a few days or weeks after ALF; (3) Clinically, factors such as medical histories and physical conditions of patients may affect the efficacies of stem cells. For example, aging and diabetes can lead to impaired stem cell proliferation, decreased angiogenesis, and reduced wound healing. Animal experiments are difficult to simulate[51]; (4) The clinically used stem cells are all human stem cells, but in animal experiments, stem cells are obtained from various sources, which may lead to strong immune responses, affecting the authenticity of animal experimental results[50]; and (5) Stem cells have a potential risk of developing tumors because of their multi-directional differentiation ability, but no research has focused on the potential side effects of stem cells[49]. Therefore, studies should pay attention to effectiveness and safety of stem cell therapy.

Strengths and limitations

Strengths of this study: (1) As the first study in the ALF field, we systematically evaluated and analyzed the effects of different types of stem cells by subgroups, and pointed out the challenges and directions for improvement; (2) After testing the robustness and reliability of the results of traditional meta-analysis and network meta-analysis, we found that our results are very reliable; (3) In the absence of evidence for direct comparisons, the therapeutic potential of different stem cells was comprehensively compared through subgroup analyses of traditional meta-analyses and network meta-analyses; and (4) Based on the SYRCLE bias risk assessment tool, the internal authenticity of animal experiments was evaluated. At the same time, external authenticity was also evaluated.

DOI: 10.4252/wjsc.v15.i1.1 **Copyright** ©The Author(s) 2023.

Figure 7 Results of potential false positive factor. After a certain number of iterations, the curve finally approaches 1, which indicates that the results of the network meta-analysis have good robustness and reliability. A: Alanine aminotransferase; B: Aspartate aminotransferase; C: Tumor necrosis factor-α; D: Interleukin-6. PSRF: Potential false positive factor.

Limitations of this study: (1) Due to the small number of studies and the large differences in treatment strategies of stem cells in different studies, subgroup analysis of transplantation doses and route of stem cell administration were not performed; (2) Searches were only performed in English databases, which may have led to a certain linguistic bias; and (3) Failure to search grey literature and conference abstracts may have led to a publication bias.

CONCLUSION

This analysis showed that stem cell therapy can significantly reduce ALT, AST, TNF-α and IL-6 levels in ALF animal models through a comprehensive analysis of 89 studies. Importantly, although MSCs are the current research hotspot, we found that LSCs have superior therapeutic effects in ALF. However, because of the low quality of evidence from internal and external authenticity of animal studies, future high-quality animal studies should aim at identifying the best stem cells for therapeutic purposes.

ARTICLE HIGHLIGHTS

Research background

The therapeutic effects of various stem cells in acute liver failure (ALF) have been demonstrated in preclinical studies, however, it has not been determined which stem cells have the best therapeutic implications.

Research motivation

The efficacy of stem cells in ALF has been demonstrated in preclinical and clinical trials. However, it remains unclear which stem cells have the most therapeutic potential. Addressing this issue is critical to improve the efficacy of stem cells and to accelerate the progress of basic and clinical research of stem cells.

Research objectives

To explore the best type of stem cells for ALF treatment and to promote the clinical translation of stem cell therapy.

Research methods

A systematic review and meta-analysis of stem cell therapy for ALF. A search was conducted on the PubMed, Web of Science, Embase, Scopus, and Cochrane databases. Two independent reviewers performed the literature search, identification, screening, quality assessment, and data extraction. The data was analyzed by STATA 16 and Winbugs1.4.3 software.

Research results

Stem cell therapy can significantly reduce serum levels of alanine aminotransferase, aspartate aminotransferase, tumor necrosis factor-alpha, and interleukin-6 in animals with ALF. Although mesenchymal stem cells are the current research focus, among the six types of stem cells included in the analysis, liver stem cells (LSCs) have the greatest therapeutic potential.

Research conclusions

LSCs have the best effects in treating ALF.

Research perspectives

In ALF treatment, stem cell therapy, especially LSCs should be paid more attention to. In addition, to improve on the quality of research, future animal studies should be carefully designed and reported.

ABOUT COVER

Editorial Board Member of *World Journal of Stem Cells*, Li-Sheng Zhang, PhD, Professor, College of Biomedicine and Health/College of Veterinary Medicine, Huazhong Agricultural University, Wuhan 430070, Hubei Province, China. lishengzhang@mail.hzau.edu.cn

AIMS AND SCOPE

The primary aim of *World Journal of Stem Cells* (*WJSC*, *World J Stem Cells*) is to provide scholars and readers from various fields of stem cells with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJSC* publishes articles reporting research results obtained in the field of stem cell biology and regenerative medicine, related to the wide range of stem cells including embryonic stem cells, germline stem cells, tissue-specific stem cells, adult stem cells, mesenchymal stromal cells, induced pluripotent stem cells, embryonal carcinoma stem cells, hemangioblasts, lymphoid progenitor cells, *etc*.

INDEXING/ABSTRACTING

The *WJSC* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Journal Citation Reports/Science Edition, PubMed, PubMed Central, Scopus, Biological Abstracts, BIOSIS Previews, Reference Citation Analysis, China National Knowledge Infrastructure, China Science and Technology Journal Database, and Superstar Journals Database. The 2022 Edition of Journal Citation Reports cites the 2021 impact factor (IF) for *WJSC* as 5.247; IF without journal self cites: 5.028; 5-year IF: 4.964; Journal Citation Indicator: 0.56; Ranking: 12 among 29 journals in cell and tissue engineering; Quartile category: Q2; Ranking: 86 among 194 journals in cell biology; and Quartile category: Q2. The *WJSC*'s CiteScore for 2021 is 5.1 and Scopus CiteScore rank 2021: Histology is 17/61; Genetics is 145/335; Genetics (clinical) is 42/86; Molecular Biology is 221/386; Cell Biology is 164/274.

Abstract

Diseases caused by ischemia are one of the leading causes of death in the world. Current therapies for treating acute myocardial infarction, ischemic stroke, and critical limb ischemia do not complete recovery. Regenerative therapies opens new therapeutic strategy in the treatment of ischemic disorders. Mesenchymal stem cells (MSCs) are the most promising option in the field of cell-based therapies, due to their secretory and immunomodulatory abilities, that contribute to ease inflammation and promote the regeneration of damaged tissues. This review presents the current knowledge of the mechanisms of action of MSCs and their therapeutic effects in the treatment of ischemic diseases, described on the basis of data from *in vitro* experiments and preclinical animal studies, and also summarize the effects of using these cells in clinical trial settings. Since the obtained therapeutic benefits are not always satisfactory, approaches aimed at enhancing the effect of MSCs in regenerative therapies are presented at the end.

Key Words: Ischemia; Mesenchymal stem cells; Regenerative medicine; Stem cell therapy; Clinical applications

Core Tip: Mesenchymal stem cell (MSC) transplantation is an innovative therapy with positive therapeutic effects for many ischemic diseases. Ischemia of an area is defined as insufficient blood supply to specific tissues and various organs or individual parts of the body. The leading cause of tissue ischemia is the narrowing or blockage of the lumen of an artery, most often due to the formation of atherosclerotic plaques, thrombus, or spasms of a specific artery. Here, the potential therapeutic mechanisms of MSCs in ischemic diseases were discussed, along with examples of preclinical and clinical studies.

INTRODUCTION

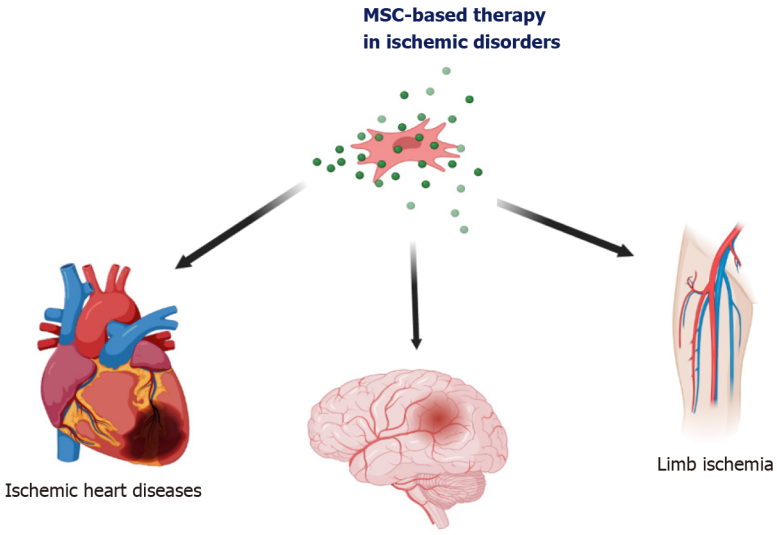
Ischemia of an area is defined as insufficient blood supply to specific tissues and various organs or individual parts of the body (*e.g.*, limbs). Reduced blood perfusion causes inadequate transport of oxygen and nutrients to tissue-resident cells, leading to ischemia and ultimately damaging tissues and organs. The leading cause of tissue ischemia is the narrowing or blockage of the lumen of an artery, most often due to the formation of atherosclerotic plaques, thrombus, or spasms of a specific artery[1]. Disruption of blood flow to particular organs or parts of the body may be chronic developing over several months or years or acute occurring suddenly (*e.g.*, during exercise) and usually takes a more rapid course often with a worse prognosis. Ischemia resulting from atherosclerotic lesions is most commonly found in the heart muscle, lower extremities, kidney, and brain[1-4]. Examples of ischemic diseases caused by the narrowing of the coronary and cerebral arteries that cause high morbidity and mortality in patients are myocardial infarction and ischemic stroke (Figure 1)[5]. Ischemia may entail several functional changes at the level of individual cells that build tissues, causing their dysfunction and death due to necrosis or apoptosis[6].

Standard treatments for ischemia include invasive and pharmacological control and treatments for the effects of ischemia in the damaged tissues. These methods emphasize improving the quality of and extending the patient's life, but they cannot fully reverse the effects of tissue ischemia in case of people suffering from congenital heart disease[7], ischemic heart failure[8], acute limb ischemia[9], critical limb ischemia[10], and ischemic stroke[11]. Even with the substantial progress of therapeutic strategies, these approaches do not provide the expected clinical benefits for all patients. Therefore, novel treatment pathways while replacing or supporting classic therapeutic approaches should continue to be investigated[12-14].

Currently, great hopes are placed on regenerative treatment, *i.e.*, therapies based on cellular preparations, including using various progenitor and stem cells (SCs) and their products[8,12,15]. Over the past decade, growing effort has been directed to the regenerative properties of SCs in relation to the biological treatment strategy of substitution of damaged cells in the tissue with new ones[16]. It is also believed that SCs may be involved in the neovascularization of ischemic tissues[17,18].

In 1970, Friedenstein *et al*[19] discovered an exceptional type of cell that has been extensively researched over the years for its potential use in regenerative medicine to treat ischemic damage[20]. These cells, called mesenchymal SCs (MSCs), reside in both young and adult donors [*e.g.*, umbilical cord (UC), Wharton's jelly (WJ) amniotic fluid, UC blood (UCB), placenta, adipose tissue (AT), bone marrow (BM), dental pulp (DP), and others], which has been a particular and exciting source of SCs for many years, mainly for autotransplantation and allotransplantation. Regardless of the tissue source, a cell that meets the criteria set out by the International Society for Cell Therapy (Table 1) may be qualified as MSCs[21].

They now account for the most popular SC population used in clinical trials worldwide (clinicaltrials.gov). MSCs derived from birth-related tissues have more promise due to better proliferative capacity compared with MSCs obtained from adult tissues. They are safe in terms of both sourcing and ethical aspects[22,23]. Due to several specific characteristics, these cells are essential candidates for regenerative therapies for ischemic tissues. Moreover, it is possible to use these cells to manufacture ready-to-use SC-based medicinal products. This review described the potential therapeutic mechanisms of MSCs in the context of ischemic disorder treatment. Exemplary clinical trials and procedures enhancing the therapeutic effect of MSCs were also discussed.



PATHOGENESIS OF ISCHEMIC DISEASES AND MSC-BASED THERAPY

The leading cause of ischemic disorders is the chronic inflammatory disease of the arteries, called "atherosclerosis". It can be caused by many risk factors, including aging, high blood pressure, diabetes, hypercholesterolemia, and smoking[24,25]. In the course of atherosclerosis, pathological damage and dysregulation of the endothelium lining the blood vessel wall, accumulation of lipids, smooth muscle cells, leukocytes, and foam cells are observed. Also, there is an aggregation of platelets in the lumen of the blood vessels, which leads to the formation of plaques narrowing the lumen of the vessels[26,27]. Moreover, in atherosclerotic lesions, increased expression of matrix metalloproteinases (MMP) and their participation in weakening the vascular wall through the degradation of the extracellular matrix (ECM) have been demonstrated[28].

Table 1 Minimal criteria for defining mesenchymal stem cells

Morphology, growth conditions	Spindle-shaped (fibroblast-like), adherent
Specific surface markers	CD73+, CD90+, CD105+, CD11b-, CD14-, CD19-, CD45-, CD79α-, MHC-II, HLA-DR-
Differentiation potential	Adipogenic, chondrogenic, osteogenic

HLA: Human leukocyte antigen; MHC: Major histocompatibility complex.

Figure 1 Mesenchymal stem cell therapy in ischemic diseases. The mesenchymal stem cells can be use as biological drugs in the treatment of ischemic disorders of various organs, including brain ischemia in ischemic stroke, heart ischemia in acute myocardial infraction, Chronic ischemic cardiomyopathy, ischemic heart failure, and chronic lower extremity ischemia. MSC: Mesenchymal stem cell.

To compensate for the degradation of the ECM, smooth muscle cells migrate from the outer layers of the artery wall to the inner lining of the sheath to increase the collagen secretion rate[25]. It often causes undesirable remodeling as macrophages secrete cytokines such as tumor necrosis factor (TNF)-α, interleukin (IL)-1β, and IL-6 to induce smooth muscle cell apoptosis[25]. The unbalanced degradation rate of the ECM caused by increased collagen production results in the formation of atherosclerotic plaques with a thin fibrous collagen cap[29]. Injecting MSCs at this stage can modulate immune cell function, MMP activity, and the secretion of proinflammatory cytokines and restore collagen homeostasis[30]. In addition, due to hemodynamic changes and high shearing stresses in atherosclerotic plaques, ruptures and bleeding may occur, increasing platelet recruitment, coagulation processes, and thrombus formation[31]. Due to the secretion of proangiogenic factors and the ability to differentiate in the endothelium, MSCs can promote angiogenesis to restore blood flow to ischemic tissues for tissue regeneration and organ function restoration[32].

KEY PLAYERS IN ISCHEMIC TISSUE REGENERATION

Over the past decade, scientists and clinicians often discuss the regenerative properties of SCs in the context of biological treatment approaches. These strategies involve the replacement of damaged tissue cells with new SCs, including ischemic myocardium[16,33]. SCs are also considered cells that can participate in the neovascularization of ischemic tissues, which may also be associated with the improvement of the function of this organ[18,34,35].

One type of cell studied for years for their potential future use in regenerative medicine to treat myocardial damage or improve perfusion in limb muscle tissue is the mesenchymal/stromal SC (MSC) isolated from the BM, AT, birth-associated tissues, and other sites. These cells were found in both young and adult donors and have been an essential and exciting source of SCs, primarily for autotransplantation. They now account for the most often used SC population in clinical trials worldwide (clinicaltrial.gov)[18,36,37].

The history of studies on MSCs began in the 1970s when Friedenstein *et al*[19] observed colony-forming unit-fibroblasts (today known as MSCs). These cells constituted a fraction of adherent cells in the BM[19]. Moreover, their previous studies showed that subpopulations of BM cells could differentiate to other cell types, *i.e.*, osteoblasts[38]. These discoveries initiated an increase in interest in MSCs and the search for these cells in other tissues as well.

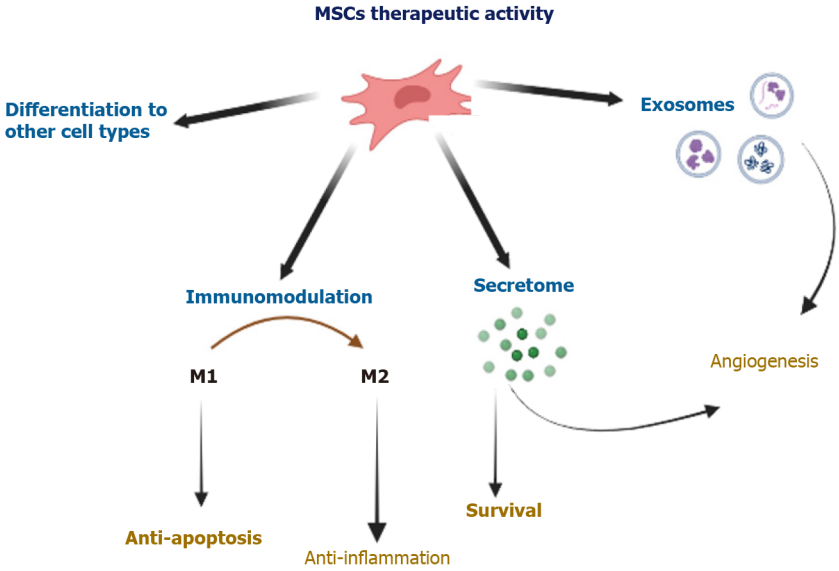
One of the primary and best-known sources of MSCs is BM[39,40]. Cells with similar morphology and biological characteristics can also be found in other tissues collected from adult donors, such as peripheral blood, AT, DP, and fetal tissues such as UCB and WJ[41].

BM-MSCs show morphological and phenotypic similarities to AT-MSCs and WJ-MSCs. These markers include CD29 +, CD44 +, CD73 +, CD90 +, CD105 +, CD166 +, human leukocyte antigen (HLA)-ABC +, CD11b-, CD14-, CD19a-, CD34-, CD45-, CD79-, and HLA-DR[42,43]. However, the source tissues from which MSCs are isolated differ in the content of these SCs. For example, the number of MSCs in the BM is lower than in AT[43,44]. The BM contains from 0.0017% to 0.02% of MSCs among all mononuclear cells, while in AT, these cells constitute 5.0% to 25.6% of all cells, which is the so-called stromal-vascular fraction obtained from this tissue[44-46]. The number of colony-forming unit-fibroblast colonies isolated from the same number of plated BM or AT cells is several times higher from AT than BM[42]. Also, WJ-MSCs cells have a higher frequency of colony-forming unit-fibroblasts than BM-MSCs cells[47]. Considering the differentiation potential of BM-MSCs, AT-MSCs, and UC-MSCs, these cells show a comparable capacity to differentiate into osteoblasts, chondrocytes, and adipocytes[42,48], confirming their mesodermal origin.

MSCs derived from various tissues can also be differentiated *in vitro* into phenotypically similar cells, including cardiomyocytes[49-53], vascular endothelial cells (ECs)[54,55], and nerve cells[56]. However, it has been shown that the effectiveness of such differentiation is variable and depends on the tissue origin[49,51,53,56]. Within one culture of MSCs, cells may be more or less predisposed to differentiate to a specific phenotype of the mature cell[57]. Despite the morphological and antigenic similarity between MSCs from different source tissues, the results of world studies showed that BM-MSCs may offer a different expression profile of many genes compared to placenta-derived MSCs[57], which suggests that MSCs obtained from BM, WJ, and AT may differ in terms of their molecular composition and their ability to differentiate.

The International Society for Cellular Therapy, to clarify the nomenclature and define the requirements of human MSCs and facilitate the comparison of test results between laboratories around the world, proposed three minimum criteria for characterizing human MSCs[21].

Due to numerous world studies showing the relatively wide potential of MSCs to differentiate into various types of tissues, these cells constituting a population obtained from mature tissues have for years interested scientists in the context of their potential use in tissue regeneration[58-60].



MSC MECHANISMS OF ISCHEMIC TISSUE REGENERATION

Multipotent MSCs show many features desirable from the point of view of their potential use in the regeneration of damaged tissues, not only in autologous but also in allogeneic transplants. Therefore, over the last decade, many studies have been undertaken to explain the mechanisms of action of these cells replaced by tissue damage. Figure 2 presents several essential mechanisms of action contributing to ischemic tissue regeneration.

Differentiation of MSCs

It was initially suggested that MSCs administrated into the area of tissue damage are able to differentiate into desired cell types, including muscle-building cardiac mesenchymal cells (CMCs), vascular smooth muscle cells, and ECs[59,61,62]. It was shown *in vivo* that MSCs injected to the heart muscle had a phenotype similar to differentiating cells, including CMCs and ECs[63-65]. Pochon *et al*[66] confirmed that WJ-MSCs differentiated into CMCs *in vitro*, expressing CMC markers and spontaneous throbbing, which might be evidence of their terminal maturation into specialized cells capable of playing their proper functions. Although MSCs show the potential to differentiate to CMCs *in vitro*, the fundamental issue is to restore damaged tissue *in vivo*. Effective delivery and retention must be emphasized here because if cells do not reach the target tissue, they cannot exert any therapeutic effect[60]. Even if studies have shown that MSCs can differentiate into various types of myocardial cells, an increasing number of studies show that this is not a main mechanism for their regenerative activity in the cardiovascular system.

Several articles now contain information on the neural differentiation of MSCs from various sources *in vitro*[67-69]. In the described studies, the prevailing view suggests that MSCs, derived from immature tissues due to their plastic properties, can differentiate more effectively into cells with neural phenotypes, showing the presence of typical linear markers[70]. Positive results of *in vitro* neural differentiation of MSCs were obtained in experiments using specific chemical compounds, growth factors, co-culturing with mature neurons, or the culture of three-dimensional aggregates[71,72]. Another study showed that neural differentiation of MSCs can be induced by a conditioned medium derived from

DOI: 10.4252/wjsc.v15.i2.16 **Copyright** ©The Author(s) 2023.

Figure 2 Proposed therapeutic mechanisms of mesenchymal stem cells, including differentiation, immunomodulation, secretion of paracrine factors, and secretion of microvesicles. Mesenchymal stem cells (MSCs) can repair and/or rescue injured cells *via* differentiation into replacement cell types including endothelial cells, and cardiomyocytes. The immunomodulatory activity of MSCs includes the suppression of macrophage polarization to M1, though favors M2 polarization. MSCs can secrete a number of factors that stimulate the regeneration of damaged cells and tissues [*e.g.*, vascular endothelial growth factor (VEGF), insulin-like growth factor 1 (IGF-1), hepatocyte growth factor (HGF), stromal cell-derived factor-1] and having a beneficial effect for neovascularization processes (*e.g.*, VEGF, IGF-1, HGF, fibroblast growth factor-2, platelet-derived growth factor-BB, placental growth factor), inhibiting the pathological remodeling of ischemic tissues [*e.g.*, matrix metalloproteinase 2 (MMP-2), MMP-9]. The exosomes secreted by MSCs contain cytokines and growth factors, signaling lipids, mRNAs, and regulatory microRNAs which can be responsible for the therapeutic effects. MSC: Mesenchymal stem cell.

cultures of olfactory ensheathing cells or Schwann cells[73]. Sotthibundhu *et al*[74] discovered that stimulation of autophagy MSCs could improve the efficiency of SC differentiation and the formation of neural-like cells.

Interaction of MSCs with other cells

MSCs can communicate with neighboring cells through direct cell-cell interactions, including gap junctions and tunneling nanotubes[75]. Moreover, MSCs are able to transport mitochondria through nanotubes and thus obtain cardiological protection by regaining the respiratory chain in myocytes[76]. To allow damaged tissue to regenerate, MSCs communicate with other cells in the damaged areas to recruit other types of SCs. For example, studies have demonstrated that CMCs can re-enter the cell cycle after supplementation with specific cytokines secreted by MSCs (*e.g.*, transforming growth factor-β)[77]. MSCs can also keep other cells to active migration to the area of tissue damage, as demonstrated by the trafficking of hematopoietic SCs to the damaged myocardium[78].

Immunomodulatory properties of MSCs

Despite the reported low rate of retention of MSCs in ischemic heart muscle after their injection, the results of many experiments showed improvement in the functional heart parameters, like inhibition of adverse tissue remodeling myocardium and left ventricle ejection fraction (LVEF)[33]. So, this begs the questions: Is the improvement in injured organ function following the administration of MSCs results only from the implantation and ability of MSCs to differentiate into specific cell types or is another mechanism also involved in this process?

No doubt, that in order to answer this question, other studies, which have focused on the immunomodulatory properties of MSCs, should be mentioned here[79-81]. The remarkable ability of MSCs to produce an enormous number of soluble factors, such as anti-inflammatory cytokines, enables them to modulate the immune system response[82,83]. For example, MSCs secrete the cytokines, IL-4 and IL-10, which inhibit the proliferation of T cells, the growth factor, hepatocyte growth factor, which inhibits the proliferation of CD4+ T cells, and transforming growth factor-β1, which with prostaglandin E2 inhibits the inflammation process[84-86]. Moreover, they encourage the maturation of monocytes towards anti-inflammatory macrophages type M2[79,87].

In addition, the most extraordinary attribute of MSCs is an immunological privilege. MSCs are known to be capable of avoiding and suppressing immune responses[88,89]. Most MSCs show the low expression of HLA class I and a lack of HLA class II markers. Due to this feature, they do not cause an immune conflict between the transplant recipient and the injected cells. Additionally, MSCs possess HLA-G, which is a key factor in the elimination of the fetus rejection by the maternal immune system

[90,91]. Because of the high expression of HLA-G, MSCs can modulate the tolerance of the immune system and it has a very beneficial effect on acceptance of the transplant.

Paracrine effects of MSCs

Another reported mechanism of therapeutic activity of MSCs can be attributed to the secretion of paracrine factors, including several cytokines, growth factors, and chemokines, that may regulate many regenerative processes at the MSCs implantation site[92]. Proangiogenic molecules produced by MSCs involve, among others, the protein fibroblast growth factor-2[92-94], platelet-derived growth factor[95], and an extremely proangiogenic vascular endothelial growth factor, supporting the proliferation of vascular smooth muscle cells and ECs as well as the migration and the new blood vessel structure formation[96].

On the other hand, molecules that promote ECM remodeling involve MMP1, MMP2, MMP9, a family of enzymes that degrade ECM structure, and TNF-α and the activator plasminogen that leads to ECM protein impairment[78,97]. A distinct category of molecules produced by MSCs are the factors responsible for MSCs survival, proliferation, and migration to the area of tissue injury, which involve fibroblast growth factor-2 supporting the proliferation of vascular smooth muscle cells and ECs, stromal cell-derived factor-1 reducing apoptosis and regulating cell migration, insulin-like growth factor-1 controlling cell differentiation and growth and inhibiting apoptosis, and a secreted frizzled-related protein-2 supporting CMC survival at the conditions of low oxygen availability *in vivo*[77,98].

Exosomes secretion

Extracellular vesicles are biological nanoparticle structures containing bioactive molecules, including protein, and nucleic acids. They can influence other cells and participate in intercellular communication over long distances[99]. Many studies on tissue regeneration mechanisms demonstrated that extracellular vesicles released by SCs can deliver bioactive molecules to target cells, which may influence the function of those cells, including the process of damaged tissue regeneration[100].

PRECLINICAL STUDIES: ANIMAL MODELS OF TISSUE ISCHEMIA

Most of the molecular and cellular mechanisms that affect the therapeutic potential of MSCs in the therapy of ischemic tissues were initially identified in animal models. The capacity of MSCs to survive in the recipient after administration and the ability to differentiate into Ecs and CMCs has been proven in acute myocardial infarction in a mini-swine model[65]. In this paper, Zhang *et al*[65] also confirmed the migratory activity of MSCs towards inflammation, inhibition of CMC apoptosis, stimulation of cardiac SCs, reduction of fibrosis, myocardium reverse remodeling, and enhancement of LVEF. It has been demonstrated that MSCs derived from UCB (UCB-MSCs) can reduce the acute myocardial infarction size by ≥ 50% and enhance LVEF[101]. The observed therapeutic effect may be due to the ability of MSCs to secrete bioactive factors. In turn, thanks to their immunosuppressive properties and the paracrine effect, MSCs can alleviate inflammation and ischemic heart disorders, contributing to the reduction of infarct size and improving LVEF through a paracrine effect[102].

The therapeutic efficacy of UC-MSCs and heart function improvement has been demonstrated[103]. Intravenous administration of MSCs has improved LVEF contractility, function, perfusion, and reverse remodeling[18]. The transplantation of MSCs in a rat model of acute myocarditis can reduce inflammation by decreasing the infiltration of an inflammatory cell, reducing CMC death, and remodeling adverse myocardium[104,105]. Based on the results of animal studies, hopes are high regarding enhancing many heart functions, such as reduction of scar tissue, myocardium reverse remodeling, increase in cardiac contractility, improvement of ejection fraction, and increase in heart perfusion. However, there is still a need for long-term observation of the effects of injecting MSCs to ensure the safety and efficacy of therapy.

In preclinical studies on transgenic animals of models of neurological diseases, significant functional improvement was observed after MSC cell transplantation[106]. The use of these cells may be related to their direct action, *i.e.*, replacement of damaged cells as a result of neural differentiation or to an indirect influence positively influencing the endogenous regenerative processes of the organism. In addition, preclinical studies on animals have confirmed the neuroprotective properties of MSC transplants, which may be linked to their production of numerous growth, anti-inflammatory, and anti-apoptotic factors important for neurons[107].

CLINICAL TRIALS: MSC AS MODERN THERAPEUTIC AGENTS IN ISCHEMIA

Clinical trials testing MSCs in regenerative therapy are growing (ClinicalTrials.gov). Regenerative therapies based on MSCs for several ischemic disorders are now carefully examined. The remedial effects obtained are promising and prove that the transplantation of MSCs may be beneficial in the

treatment of many diseases[108,109]. The concept of clinical application of MSCs may improve the health of patients suffering from many cardiovascular diseases[110]. So far, a few dozen studies have been registered in the international database of clinical trials to assess the safety and effectiveness of MSCs administration in the treatment of ischemic diseases.

The most popular source of therapeutic MSCs used in clinical practice is BM. The first MSC-based biological drug, AMI HeartiCellgram®, used in myocardial infarction therapy was also based on BM-MSCs. Lee *et al*[111] described the manufacturing procedure for this drug, and Kim *et al*[112] proved its effectiveness in a clinical experiment. The therapeutic benefits included the restoration of normal systolic heart function and the reduction of post-infarction scar tissue[113,114].

The pioneer pilot clinical study applying WJ-MSCs in treating ischemic disorders was performed by Musialek *et al*[115] in 2015. This group has shown the safety of injected MSCs as an off-the-shelf product, percutaneous allogeneic SC therapy in human acute myocardial infarction. Later observation proved no clinical adverse events in the treated tissue, except for a local rise in body temperature of 1 patient[115]. Currently, Musialek *et al*[115] are examining the safety and effectiveness of the "CardioCell" drug (WJ-MSC-based biological therapeutic) in a phase II/III randomized, placebo-controlled, double-blind clinical trial in several ischemic disorders [*i.e.*, acute myocardial infarction (EudraCT Number: 2016-004662-25), chronic ischemic heart failure (EudraCT Number: 2016-004683-19), and non-option critical limb ischemia (EudraCT Number: 2016-004684-40)][116,117].

A clinical trial with MSCs has shown the enhancement in heart muscle function in cases of heart failure. For example, Bartolucci *et al*[118] have shown that intravenous administration of UC-MSCs improved LVEF, functional status, and standard of living. Also, exosomes released by UC-MSCs can alleviate the effect of acute myocardial ischemic injury[119]. Scientists confirmed that the injection of UC-MSCs exosomes can greatly improve contractile heart function and minimize myocardial fibrosis. These bioactive bubbles protected heart cells from death and supported EC migration and angiogenesis. UC-MSCs have also been applied in a clinical study for the treatment of chronic coronary occlusion[17]. Also in this trial, the improvement the heart function and better left ventricular ejection fraction were reported[17].

So far, several clinical trials of ischemic stroke have shown that transplanting MSCs into patients with successful reperfusion therapy reduces the volume of lesions after stroke and promotes the regeneration of neurological function. This success is shown by improvements in human functional, behavioral, and sensorimotor assessments, such as the Barthel Index, Modified Rankin Scale, European Stroke Scale, Fugl-Meyer Scale, and National Institutes of Health Stroke Scale[120,121]. MSCs participate in the regeneration of ischemic tissues and organs with beneficial effects, as outlined above (Table 2). The therapeutic activity is presumed to include immunomodulation, cardioprotective effects, activation of endogenous repair processes, and tissue remodeling.

IMPROVING THE EFFECTIVENESS OF MSC-BASED THERAPY

MSCs can supply alternative therapy in the treatment of many disorders, but many studies have demonstrated that depending on the method of isolation, expansion, and delivery we can obtain cells with distinct functional features. The therapeutic benefits of MSC-based therapy involve paracrine activity, immunomodulation, and enhanced function of the damaged organ. However, not all patient responses to treatment are satisfactory; therefore this approach requires a deep understanding of the therapeutic actions of MSCs after injection into the recipient. The therapeutic efficacy of MSCs is affected by many factors, including the method of MSCs cultivation *in vitro*, the metabolic activity of the MSCs, the number of injected cells, the patient's genetic sensitivity, and the stage of the disease[136,137].

The selection of the appropriate source of therapeutic MSCs depending on the disease is crucial as more and more data show source-dependent variations in therapeutic activity such as levels of released trophic proteins or different differentiation capacities. There is much disagreement as to the therapeutic efficiency of MSCs derived from different tissues (fetal and adult sources). Therefore, extensive studies are desirable to obtain consistent data about remedial effects.

Another problem that is much debated is the type of transplant, *i.e.*, allogeneic or autologous. The results obtained from clinical trials showed no difference between the therapeutic effects of allogeneic and autologous MSCs in the treatment of ischemic cardiomyopathy[138]. The undoubted advantage of autologous transplants is the lack of burdening the cells with other diseases because in such cases the donors are healthy volunteers. Autologous SCs obtained from the patient do not have this privilege, which may limit the therapeutic effectiveness. In addition, it is an important issue to obtain the right dose of autologous cells. The autologous transplant requires the collection of appropriate tissue from the patient, isolation of SCs, and obtaining the necessary dose of therapeutic cells, which is a challenge as the disease and the patient's age may contribute to the reduction of the proliferative activity of MSCs [139,140].

To resolve these issues, scientists introduced allogeneic sources of SCs that can be used to produce ready-to-use biological products. The use of allogeneic SCs shortens the waiting time for a transplant. Allogeneic cells from young and healthy donors are used to produce biological drugs of quality that can

Table 2 Selected clinical trials of mesenchymal stem cell-based therapy in ischemic diseases

Disorder	Ref.	Trial number (acronym)	Type of transplant and stem cell source	Results
Myocardial infarction	Hare *et al*[36], 2009	NCT00114452	Allogenic BM-MSCs	No tumorogenicity, no arrythomogenicity
Myocardial infarction	Houtgraaf *et al* [37], 2012	NCT00442806 (APOLLO)	Autologous AT-MSCs	No adverse effects, decreased: Scar tissue; increased: Perfusion
Myocardial infarction	Gao *et al*[122], 2015	NCT01291329	Allogenic WJ-MSCs	Increased: Ejection fraction; decreased: Heart perfusion
Chronic ischemic cardiomyopathy	Hare *et al*[123], 2012	NCT01087996 (POSEIDON)	Allogenic *vs* autologous BM-MSCs	Increased: Ejection fraction; decreased: Scar tissue
Chronic ischemic cardiomyopathy	Karantalis *et al* [124], 2014	NCT00587990 (PROMETHEUS)	Autologous BM-MSCs	Local; increased: Contraction; decreased: Scar tissue
Chronic ischemic cardiomyopathy	Perin *et al*[125], 2014	NCT00426868 (PRECISE)	Autologous AT-MSCs	Increased: Left ventricular mass; increased: Contractility; increased: Perfusion
Chronic ischemic cardiomyopathy	Bartunek *et al* [126], 2013	NCT00810238 (C-CURE)	Preconditioned autologous BM-MSCs	Increased: Ejection fraction
Chronic ischemic cardiomyopathy	Bartolucci *et al* [118], 2017	NCT01739777 (RIMECARD)	Allogenic UC-MSCs	Increased: Ejection fraction
Ischemic heart failure	Teerlink *et al* [127], 2017	NCT01768702 (CHART-1)	Autologous BM-MSCs	Left ventricular reverse remodelling, increased: Left ventricular volume
Critical limb ischemia	Wijnand *et al* [128], 2018	NCT03042572 (SAIL)	Allogenic BM-MSCs	Safety, decreased: Pain rest
Critical limb ischemia	Norgren *et al* [129], 2018	NCT01732822 (EUCLID)	Allogeneic placental-derived MSCs	Increased: Amputation-free survival; decreased: Pain rest; increased: Tissue perfusion
Critical limb ischemia	Gupta *et al*[130], 2013	NCT00883870	Allogenic BM-MSCs	Decreased: Pain rest; increased: Ankle systolic pressure; increased: Ulcer healing
Ischemic stroke	Steinberg *et al* [131], 2016	NCT01287936	Modified BM-MSCs	Increased: Motor functions (ESS, NIHSS, Fugle-Meyer scales)
Ischemic stroke	Levy *et al*[132], 2019	NCT01297413	Allogenic BM-MSCs	Increased: Barthel index
Ischemic stroke	Savitz *et al*[133], 2019	NCT01273337 (RECOVER-Stroke)	Autologous BM-MSCs	Safety
Ischemic stroke	Laskowitz *et al* [134], 2018	NCT03004976	Allogenic UCB-MSCs	Safety and feasibility
Ischemic stroke	Jaillard *et al* [135], 2020	NCT00875654	Autologous BM-MSCs	Increased: Motor functions (NIHSS, Fugle-Meyer scales)

BM: Bone marrow; AT: Adipose tissue; WJ: Wharton's jelly; UC: Umbilical cord; MSCs: Mesenchymal stem cells; ESS: European Stroke Scale; NIHSS: National Institutes of Health Stroke Scale.

be stored frozen. The medicinal product prepared in this way, if necessary for clinical intervention, can be thawed at any time and administrated to the patient.

MSCs applied in the clinic as therapeutic agents must be carefully prepared, according to the good manufacturing practice and good clinical practice standards, with the established quality control system. The manufacturing process should be properly optimized in terms of therapy requirements to reach a sufficient remedial effect. MSCs applied in the clinic as therapeutic agents must be carefully prepared, according to the good manufacturing practice and good clinical practice standards, with the established quality control system. The manufacturing process should be properly optimized in terms of therapy requirements to reach a sufficient remedial effect. Here it should be emphasized that we can prepare therapeutic cells to treat different disorders, such as graft *vs* host disease, myocardial infarction, Crohn's disease, and others, however, the therapeutic benefits obtained may not be satisfactory. Therefore, there is still a need for a more sophisticated approach to obtaining highly effective biological medicines. The use of an appropriate approach to the production of therapeutic MSCs for the treatment of a particular disease should contribute to the achievement of satisfactory results.

Additionally, to adopt therapeutic MSCs for demanding conditions in the host body, preconditioning methods can be applied. This approach requires the presence of additional adverse factors (such as low oxygen availability or proinflammatory cytokines) during *in vitro* culture. Bernardo and Fibbe[141],

during the production of therapeutic MSCs, added proinflammatory cytokines to the culture medium, the concentration of which increased after acute myocardial infarction. In this study, an anti-inflammatory response of MSCs was observed within 24-48 h based on the analysis of the composition of the culture medium. The use of selected cytokines in MSCs cultures for the treatment of acute myocardial infarction enhanced anti-inflammatory secretory activity and therapeutic efficacy.

CONCLUSION

The remarkable ability of MSCs to regenerate damaged body parts to regain lost function is promising in many disorders, including ischemic diseases. Three properties of MSCs render them optimal for ischemic tissue repair and regeneration: (1) Immunomodulatory and immunoregulatory capacity beneficial to ameliorate abnormal immune responses; (2) Soluble and insoluble paracrine factor-generating potential; and (3) Endothelial differentiation.

While MSCs have several advantages, there are still many challenges to overcome. The unique immunomodulatory properties of MSCs are essential to their function, but the mechanisms of the immune regulation of MSCs have not been elucidated. Many factors can influence the therapeutic potential of MSCs, such as donor age, isolation and culture method, induction factors, oxygen concentrations, mechanical stimuli, and others. Hence, optimizing the culture conditions of MSCs may be an effective way to improve the therapeutic potential of MSCs for successful tissue repair.

ABOUT COVER

Editorial Board Member of *World Journal of Stem Cells*, Ratan K Choudhary, PhD, Assistant Professor, College of Animal Biotechnology, Guru Angad Dev Veterinary and Animal Sciences University, Ludhiana 141004, Punjab, India. ratanchoudhary@gadvasu.in

AIMS AND SCOPE

The primary aim of *World Journal of Stem Cells* (*WJSC*, *World J Stem Cells*) is to provide scholars and readers from various fields of stem cells with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJSC* publishes articles reporting research results obtained in the field of stem cell biology and regenerative medicine, related to the wide range of stem cells including embryonic stem cells, germline stem cells, tissue-specific stem cells, adult stem cells, mesenchymal stromal cells, induced pluripotent stem cells, embryonal carcinoma stem cells, hemangioblasts, lymphoid progenitor cells, *etc*.

INDEXING/ABSTRACTING

The *WJSC* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Journal Citation Reports/Science Edition, PubMed, PubMed Central, Scopus, Biological Abstracts, BIOSIS Previews, Reference Citation Analysis, China National Knowledge Infrastructure, China Science and Technology Journal Database, and Superstar Journals Database. The 2022 Edition of Journal Citation Reports cites the 2021 impact factor (IF) for *WJSC* as 5.247; IF without journal self cites: 5.028; 5-year IF: 4.964; Journal Citation Indicator: 0.56; Ranking: 12 among 29 journals in cell and tissue engineering; Quartile category: Q2; Ranking: 86 among 194 journals in cell biology; and Quartile category: Q2. The *WJSC*'s CiteScore for 2021 is 5.1 and Scopus CiteScore rank 2021: Histology is 17/61; Genetics is 145/335; Genetics (clinical) is 42/86; Molecular Biology is 221/386; Cell Biology is 164/274.

Abstract

For nearly 20 years, dental stem cells (DSCs) have been successfully isolated from mature/immature teeth and surrounding tissue, including dental pulp of permanent teeth and exfoliated deciduous teeth, periodontal ligaments, dental follicles, and gingival and apical papilla. They have several properties (such as self-renewal, multidirectional differentiation, and immunomodulation) and exhibit enormous potential for clinical applications. To date, many clinical articles and clinical trials using DSCs have reported the treatment of pulpitis, periapical lesions, periodontitis, cleft lip and palate, acute ischemic stroke, and so on, and DSC-based therapies obtained satisfactory effects in most clinical trials. In these studies, no adverse events were reported, which suggested the safety of DSC-based therapy. In this review, we outline the characteristics of DSCs and summarize clinical trials and their safety as DSC-based therapies. Meanwhile, we also present the current limitations and perspectives of DSC-based therapy (such as harvesting DSCs from inflamed tissue, applying DSC-conditioned medium/DSC-derived extracellular vesicles, and expanding-free strategies) to provide a theoretical basis for their clinical applications.

Key Words: Dental stem cells; Adult stem cells; Dental pulp; Tissue regeneration

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Since dental pulp stem cells were first isolated and identified in 2000, a variety of dental stem cells (DSCs) have been reported. DSCs have shown satisfactory clinical effects in the treatment of a variety of diseases and have great potential for clinical application. This paper will summarize DSC-based clinical trials and put forward the current limitations and perspectives to accelerate and extend the clinical application of DSCs.

INTRODUCTION

Mesenchymal stem cells (MSCs) are a population of unspecialized cells characterized by the properties of self-renewal and multidirectional differentiation[1,2]. Currently, MSCs are currently being explored for the treatment of many diseases, such as cardiovascular disease, neurodegenerative diseases, dental diseases, and metabolic diseases[1].

Dental SCs (DSCs) were reported to have similar features to MSCs[3]. Since dental pulp SCs (DPSCs) were first successfully isolated from the extracted third molar in 2000[4], multiple DSC types have been harvested from mature and immature teeth and their surrounding tissues, including periodontal ligament stem cells (PDLSCs), stem cells from apical papilla (SCAP), stem cells from exfoliated deciduous teeth (SHED), gingiva-derived mesenchymal SCs (GMSCs), and dental follicle progenitor cells (DFPCs)[5-7] (Figure 1). DSCs develop from the neural crest and express both stem cell markers and neural markers[8,9]. It was reported that DSCs have the potential for multipotent differentiation into osteogenic, chondrogenic, adipogenic, neurogenic, odontogenic, dentinogenic cells, and so on[10]. In addition to their self-renewal and differentiation properties, DSCs have also been reported to be involved in secretion, immunomodulation, and tumor processes[3,11]. Based on the characteristics of DSCs, many clinical articles and clinical trials have used DSCs in tissue regeneration and the treatment of various diseases, such as pulpitis, periapical lesions, and periodontitis[12].

In this study, the current status of clinical articles and clinical trials using DSCs in the treatment of various diseases and conditions are reviewed. In addition, current limitations and perspectives, including harvesting DSCs from inflamed tissue, applying DSC-conditioned medium (CM) and DSC-derived extracellular vesicles (EVs), and expanding-free strategies, are also discussed.

CHARACTERISTICS OF DSCS

Based on their various sources, DSCs are divided into DPSCs, SHED, PDLSCs, SCAP, GMSCs, and DFPSCs (Figure 1). DSCs are known to express not only mesenchymal and embryonic stem cell markers (such as CD44, STRO-1, and Nanog) but also neuronal markers because they originate from embryonic neural crests[8,9] (Table 1). However, they do not express CD34, CD45, or CD11b, which are defined as hematopoietic markers[7].

Similar to mesenchymal stem cells, DSCs showed the ability of self-renewal and multidirectional differentiation, such as osteogenic, chondrogenic, adipogenic, neurogenic, odontogenic, dentinogenic, cementogenic, and myogenic differentiation[13-16] (Table 1). In addition, even in the undifferentiated state, DSCs were able to secrete several angiogenic and neurotrophic factors, including vascular endothelial growth factor (VEGF), ciliary neurotrophic factor (CNTF), brain-derived neurotrophic factor (BDNF), glia-derived neurotrophic factor (GDNF), and β-nerve growth factor (β-NGF), to promote angiogenesis and tissue regeneration[17,18].

In addition, the immunomodulatory features of DSCs have also been the focus of a number of studies. First, it was reported that DSCs, like mesenchymal stem cells, faintly express the MHC class II antigen HLA-DR and maintain low immunogenicity[19-21]. Second, local tissue regeneration and inflammation could be influenced by the secretome of DSCs (including the production of inflammatory and anti-inflammatory cytokines and the regulation of immune cells), which is also regulated by the local inflammatory microenvironment[21-24]. Finally, the inflammatory microenvironment could impact the behaviors of DSCs, such as proliferation potential, migration, homing, and differentiation[22].

Based on the characteristics of DSCs, they have been widely studied in regenerative medicine and tissue engineering and have shown an amazing therapeutic effect on oral-facial, neurologic, corneal, cardiovascular, hepatic, diabetic, renal, muscular, tenogenic, dystrophic and autoimmune conditions in both animal and human models[21,25-27]. For example, the proliferation, paracrine effect, and multidirectional differentiation potential of DSCs support the application of DSCs in regenerative

Table 1 Characteristics of different types of dental stem cells

Cell types	Markers			Multidirectional differentiations
	Cell surface markers	Embryonic stem cell markers	Nerual markers	
DPSCs	CD13, CD29, CD44, CD59, CD73, CD90, CD105, CD146, STRO-1[7], CD81, CD49f[140], CD40, CD120a, CD261, CD262, CD264, CD266, CD121a, CD130, CD213a1, CD217, CDw210b[141]	OCT-4, Nanog[142], SSEA-1, SEEA-4[140], SOX-2[143]	βIII-tubulin, NFM, Nestin, CNPase[144], S100, CD271 [17]	Osteogenic, Odontogenic[145], Dentinogeni, Chondrogenic, Neurogenic, Myogenic, Adipogenic[13], Hepatogenic [146]
PDLSCs	CD13, CD29, CD44, CD49, CD73, CD90, CD105, CD146, CD166, CD271 [147], CD10[7], STRO-1[148]	SSEA-1, SSEA-3, SSEA-4, TRA-1-60, TRA-1-81, OCT-4, Nanog, SOX-2, REX1, and ALP[149]	Nestin, OCT-4, SSEA-4[9] CD271, SOX-10[147], SOX-2 [149]	Osteogenic, Cementogenic, Adipogenic, Chondrogenic, Neurogenic[13], Hepatogenic[149], Cardiac myogenic, Endothelial-like, Islet-like, Retinal ganglion-like[147]
SCAP	CD13, CD24, CD29, CD44, CD49, CD51, CD56, CD61, CD73, CD90, CD105, CD106, CD146, CD166, STRO-1, NOTCH-3[150], CD81, CD49f[151]	OCT-4, Nanog, SOX2 [143], CD49f[151]	βIII-tubulin, NFM, Nestin, CNPase[144], SOX-2[143], Vimentin, Survivin[150]	Osteogenic, Dentinogenic, Adipogenic [15], Neurogenic[13], Chondrogenic, Hepatogenic[150]
SHED	CD29, CD73, CD90, CD166[13], STRO-1, CD44[145], CD105[152], NOTCH-1, CD10, CD13, CD34, CD106, CD146, CD166, CD271[102]	OCT-4, Nanog, SSEA-3 [153], SSEA-4[152], NOTCH-1, OCT-4, SOX-2 [102]	βIII-tubulin, NFM, Nestin, CNPase, GAD, NeuN, GFAP [154], CD271, Vimentin, OCT-4, PAX-6, NSE, MAP-2, PSA-NCAM, TH[102]	Osteogenic, Odontogenic[145], Dentinogenic, Chondrogenic, Neurogenic, Myogenic, Adipogenic[13], Hepatogenic[155]
DFPCs	CD13, CD29, CD59, CD90[7], CD105, CD146[142], CD44, CD73, NOTCH-1, STRO-1[156]	OCT-4, Nanog[142], NOTCH-1, SOX-2[156]	OCT-4, SOX2[9], Nestin, SOX-2[156]	Osteogenic, Cementogenic, Odontogenic, Adipogenic, Chondrogenic[13], Hepatogenic[146]
GMSCs	CD13, CD29, CD44, CD73, CD90, CD105, CD146, STRO-1[16]	SSEA-4[16], OCT-4, Nanog[157]	Nestin, SOX10[16], βIII-tubulin, NFM, CNPase[144]	Osteogenic, Adipogenic, Chondrogenic, Neurogenic, Endothelial-like, Odontogenic[16], Myogenic[158]

ALP: Alkaline phosphatase; CD: Cluster of differentiation; CNPase: 2′,3′-cyclic nucleotide 3′-phosphodiesterase; GAD: Glutamic acid decarboxylase; GFAP: Glial fibrillary acidic protein; MAP-2: Microtubule associated protein 2; NeuN: Neuronal nuclei; NFM: Neurofilament medium chain; NGFR: Nerve growth factor receptor; NSE: Neuron-specific enolase; OCT: Octamer-binding transcription factor; PAX-6: Paired Box 6; PSA-NCAM: Polysialylated neural cell adhesion molecule; REX-1: RNA exonuclease 1 homolog; SOX: Sex determining region Y-box; SSEA: Stage-specific embryonic antigen; TH: Tyrosine hydroxylase; SHED: Stem cells from exfoliated deciduous teeth.

medicine (*e.g.*, dental pulp and bone tissue regeneration)[28,29]. The anti-inflammatory, immunomodulatory, and immunoevasive properties of DSCs also help in the treatment of plaque psoriasis[30] (Figure 1). DSC-based therapies have broad prospects for clinical application.

It is worth noting that the naming of mesenchymal stem cells and mesenchymal stromal cells remains controversial. Based on the position paper issued by The International Society for Cell & Gene Therapy (ISCT) Mesenchymal Stromal Cell (ISCT MSC) in 2005, mesenchymal stem cells are not equivalent or interchangeable with mesenchymal stromal cells[31]. Mesenchymal stem cells refer to progenitor cell populations with obvious self-renewal and differentiation functions, while mesenchymal stromal cells refer to large populations with significant secretion, immune regulation, and homing properties[32-34]. As we have just summarized, dental stem cells share some of the characteristics of both mesenchymal stem cells and mesenchymal stromal cells, and more consensus articles may be needed to further define the naming of dental stem cells.

DSC-BASED CLINICAL TRIALS FROM PUBLISHED ARTICLES

Pulpitis and pulp necrosis

Four studies were reported to treat pulp necrosis or irreversible pulpitis using autologous DPSCs or SHED, including a randomized controlled trial (RCT), two case series, and a case report[28,35-37] (Table 2). Xuan *et al*[28] applied SHED in the treatment of pulp necrosis caused by trauma and observed dental pulp tissue regeneration at 12 mo and 24 mo after transplantation. Meanwhile, the results also showed increased dental root length and decreased apical foramen width compared with traditional apexification treatment. Two case series reported by Nakashima *et al*[35,37] indicated that DPSCs transplanted with granulocyte colony-stimulating factor and gelatin sponges could increase pulp sensitivity and mineralization and recover the signal intensity (SI) of regenerated pulp tissue on MRI examination. Meza *et al*[36] transplanted DPSCs and leukocyte platelet-rich fibrin (L-PRF) harvested

from autologous inflamed dental pulp and blood, respectively, to the root canal of irreversible pulpitis teeth and observed dentin bridge formation and a response to the cold test and electric pulp test.

Periapical lesions

In a case report and two case series, SCAP/SHED combined with a polyethylene glycol polylactic-polyglycolic acid (PEG-PLGA) scaffold and SHED combined with bioglass were used for the treatment of periapical lesions[38-40] (Table 2). Periapical tissue healing was found in the follow-up examinations

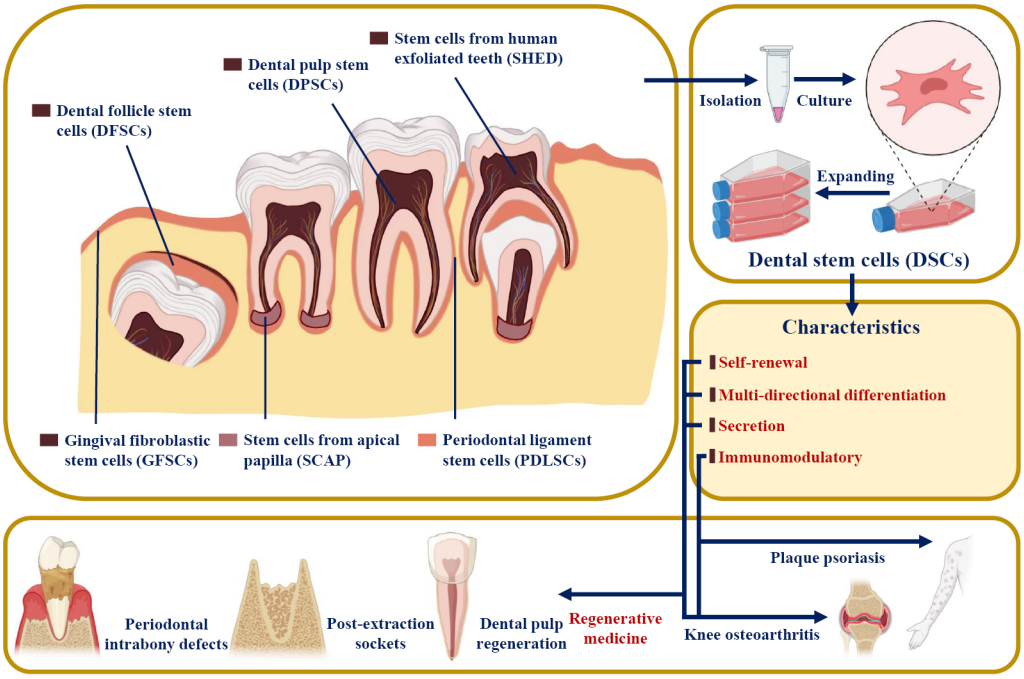

Figure 1 Tissue origin, harvest, characteristics, and clinical application potential of the various populations of dental stem cells. Dental pulp stem cells and stem cells from exfoliated deciduous teeth can be isolated from the inner dental pulp of permanent teeth and deciduous exfoliated teeth, respectively. Stem cells from apical papilla can be extracted from the apical papilla; periodontal ligament stem cells can be harvested from the periodontal ligament; and dietary fiber supplementation combinations can be derived from the dental follicle. Gingiva-derived mesenchymal stem cells can be extracted from gingiva. Citation: Sharpe PT. Dental mesenchymal stem cells. *Development* 2016; 143: 2273-2280[139]. Copyright ©The Authors 2016. Published by The Company of Biologists Ltd. The authors have obtained the permission for figure using from the Company of Biologists Ltd (Supplementary material).

of all three studies. It was reported a positive response in the test of dental pulp activity after SHED transplantation, suggesting the regeneration of pulp or pulp-like tissue, which does not occur in traditional root canal therapy[39,40].

Periodontal intrabony defects

There are two RCTs, a controlled clinical trial (CCT), three case series, and two case reports of DSC-based treatment for periodontal intrabony defects[29,41-46] (Table 2). The RCT of Ferrarotti *et al*[41] indicated that pulp micrografts applied with collagen sponges could significantly reduce PD and CAL and promote the regeneration of bone defects when compared with collagen sponges alone. Three case series and a case report using pulp micrografts/DPSCs and collagen sponges also reported similar results of periodontal benefits[46-49]. It was reported a novel approach using periodontal ligament soft tissue, gelatin sponges, and cementum scrapings, which reduced the CAL and PD of periodontitis teeth in their case report[45].

Although two case series demonstrated the periodontal benefits of PDLPs and PDL-derived cell sheets[43,44], significant differences in periodontal indices (including PD and CAL) were not observed between the test groups and control groups in the other two CCTs that applied PDLSC and PDLSC sheets[29,42]. Several factors might have contributed to the lack of significant differences in the outcomes, such as satisfactory scaffold material properties and small sample sizes. In these four studies, β-TCP, HA/TCP, and deproteinized bovine bone mineral (Bio-oss®) were applied as scaffold materials. Although some studies reported abilities to provide support for PDLSCs on osteogenic differentiation of these scaffolds*in vitro* and *in vivo*[50-53], only using these scaffolds also achieved great clinical benefits in the treatment of periodontitis[54-56]. The excellent performance of the scaffold may have overshadowed the contribution by PDLSCs. More clinical studies at multiple centers with different amounts and types of DSCs, more follow-up time points, and larger sample sizes are necessary, and the results of such studies would be meaningful.

Bone defects caused by other conditions

In addition to periodontal intrabony defects, DSCs were also used for the treatment of post-extraction sockets, mandibular osteoradionecrosis, bone defects after ameloblastoma resection, and sinus lifting [57-61] (Table 2). Two split-mouth RCTs reported by Barbier *et al*[57] and Cubuk *et al*[62] did not find significant differences in BD or interdental septum height between the pulp micrograft + scaffold (collagen matrix/L-PRF) group and the scaffold (collagen matrix/L-PRF) group after implantation into post-extraction sockets. However, in another split-mouth CCT designed for regenerating post-extraction

sockets, DPSCs combined with collagen sponges promoted the rate of mineralization, the levels of cortical bone, and the expression of bone morphogenetic protein-2 (BMP-2) and VEGF when compared with collagen sponge treatment alone[58]. Tanikawa *et al*[63] reported a historical control study comparing the effects of SHED, rhBMP, and iliac crest bone grafts in treating cleft lip and palate. The SHED group showed similar satisfactory performance in bone healing compared with iliac crest bone grafts and a higher bone filling percentage compared with the rhBMP group at the 6-mo follow-up[63].

Two case reports indicated that DPSCs combined with TCP could increase the bone regeneration of bone defects caused by osteoradionecrosis and ameloblastoma[59,60]. A case report by Brunelli *et al*[61] demonstrated that pulp micrografts + collagen sponges increased the BD in newly formed bone when applied for sinus lifting.

Other conditions

Koga *et al*[64] reported a case series that applied SHED conditioned medium (SHED-CM) to treat erectile dysfunction. In this study, the international index of erectile function (IIEF-5), which is clinically used to screen for erectile function and to assess treatment efficacy, was increased after SHED-CM injection into the corpus cavernosum of erectile dysfunction patients[64]. A case report indicated that SHED intravenous administrations could decrease the scale of unified Huntington's disease rating, which is designed to assess clinical performance and capacity in patients with Huntington's disease[65, 66]. Meanwhile, the patient with Huntington's disease also suffered from preexisting pulmonary nodules, and SHED injection did not result in long-term tropism or homing for the patient's lung adenocarcinoma[65]. In a case report by Wang *et al*[30], GMSCs were used to treat plaque psoriasis *via* bolus injection, and they observed fully cleared psoriatic lesions without recurrence.

Three clinical study protocols using DSCs have been published in recent years, including the treatment of acute ischemic stroke, chronic disability after stroke, and COVID-19[67-69].

DSC-BASED CLINICAL TRIALS FROM CLINICAL DATABASES

ClinicalTrials.gov (https://clinicaltrials.gov/) and the International Clinical Trials Registry Platform (ICTRP, https://trialsearch.who.int/) were screened for DSC-based clinical trials.

To date, there have been 21 clinical trials registered on ClinicalTrials.gov evaluating the use of DSCs in treating periodontitis (33.3%, 7/21), post-extraction sockets (4.8%, 1/21), edentulous alveolar ridge (4.8%, 1/21), cleft lip and palate (9.5%, 2/21), knee osteoarthritis (4.8%, 1/21), dental pulp necrosis (4.8%, 1/21), liver cirrhosis (4.8%, 1/21), type 1 diabetes (4.8%, 1/21), acute ischemic stroke (4.8%, 1/21), Huntington's disease (14.3%, 3/21), and COVID-19 (9.5%, 2/21) (Table 3). In addition to the 6 studies reported in ClinicalTrials.gov, 7 clinical trials were registered on the ICTRP using DSCs in the treatment of periodontitis (57.1%, 4/7), wrinkles (28.6%, 2/7), and hair loss (14.3%, 1/7) (Table 4). In all, 28 clinical trials were registered on these two platforms.

Several registered clinical trials applied two stages in one work. The most frequently appearing trial phases were phase 1 (42.9%, 12/28), followed by phase 2 (25%, 7/28), Phase 3 (7.1%, 2/28), and Phase 0 (3.6%, 1/28). There were 10 trials (35.7%) in which the phase design was not applied or not selected. One clinical trial reported the outcomes both on the registry platform and in a published article[63] (NCT01932164), and the published articles of seven trials stated the registered ID[29,42,62,63,67,69-71], while other trials did not publish any data.

Consistent with the literature, the proportion of clinical trials using DSCs to treat periodontitis was the highest. Eleven registered clinical trials researched the effect of DSCs on periodontitis (39.3%, 11/28). In these trials, various amounts, types, and injection times of DSCs and different application modes (such as DSCs, micrografts, cell sheet pellets, and cell sheet fragments) were applied. In addition, several scaffolds were used in combination with DSCs, including collagen sponges, deproteinized bovine bone minerals, β-TCP scaffolds, and hydroxyapatite-collagen scaffolds.

SAFETY ISSUES REGARDING DSC-BASED THERAPY

Although encouraging treatment effects on diseases have been achieved, the safety issues of stem cell-based therapy remain controversial, especially in long-term follow-up[72]. At present, the limitations of stem cell-based therapy are mainly focused on non-directional differentiation, accelerating tumor progression.

In addition, uncontrolled non-directional differentiation may have a great impact on the safety of stem cell transplantation. Breitbach *et al*[73] found that the encapsulated structures in the infarcted areas contained calcifications and/or ossifications in myocardial infarction mice after MSC injection. In another study, unselected bone marrow cells injected directly induced significant intramyocardial calcification in acutely infarcted myocardium[74].

DBBM: Deproteinized bovine bone mineral; GFs: Gingival fibroblast; PRF: Platelet-rich fibrin; TCP: Tricalcium phosphate; DPSCs: Dental pulp stem cells; SHED: Stem cells from exfoliated deciduous teeth.

Similar to the regeneration of damaged tissue, tumors exert chemotactic effects on MSCs, affecting their recruitment to tumor sites[75-77]. Current studies have shown that MSCs have bidirectional, anti-cancer and pro-cancer, regulatory effects, which raises safety concerns for clinical application. On the one hand, MSCs are the major component of the tumor microenvironment and can be reprogrammed to the pro-tumorigenic phenotype by the tumor[78]. MSCs have been revealed to participate in the initiation, development, progression, and metastasis of multiple cancers[79]. The pro-cancer effect of stem cells may be achieved by secreting molecules that affect the phenotype of tumor cells, promoting tumor angiogenesis, cancer-associated fibroblast differentiation, cell-to-cell contact, or cell engulfment [76]. In recent studies, DPSCs and their conditioned medium were reported to promote the proliferation and carcinogenic properties of prostate cancer, oral cancer, breast cancer, and melanoma cells*in vitro*[80-82].

On the other hand, there is also evidence that MSCs can inhibit the growth of a variety of tumors, including breast cancer, Kaposi's sarcoma, hepatoma, glioma, and melanoma[76,83-85]. DPSCs and their conditioned medium also showed a suppressive effect on the development and migration of colorectal cancer cells through mitogen-activated protein kinase pathways[86]. In fact, there are few reports of primary pulp malignancies[87]. In a genome-wide RNA-seq study, phosphatase and tensin homolog (PTEN) expression in DPSCs was higher than that in BMSCs[88]. PTEN, a phosphatase, can metabolize phosphatidylinositol 3,4,5-triphosphate and directly oppose the activation of the oncogenic PI3K/AKT/mTOR signaling network[89]. At present, the regulatory effects of stem cells on cancer are still controversial, and the difference in results may be related to cell lines, cell doses, animal models, cancer types, treatment duration time, and other factors.

In conclusion, no adverse events were reported in the published clinical articles or clinical trials using DSCs, which suggested the safety of DSC-based therapy. However, based on current concerns about the safety of stem cell therapy, more *in vivo* studies on the safety of DSC-based therapies are of great significance.

CURRENT LIMITATIONS AND PERSPECTIVES

Harvesting DSCs from inflamed tissue

Most studies applied stem cells extracted from healthy dental tissue for treatment, but additional surgery (such as third molar extraction) might increase patient suffering. Harvesting stem cells from inflamed dental tissue could be an alternative method, although stem cell abilities might be affected[36,90,91].

Several studies have researched the different biological properties of DPSCs derived from normal and inflamed pulps (iDPSCs), and the results are still in dispute[92-98]. In some studies, DPSCs showed better self-renewal ability[92,93] and multidirectional differentiation capacities than iDPSCs[92], while in other studies, no significant difference was observed[94,95,98]. A study by Nie *et al*[97] indicated that DPSCs showed higher colony-forming, proliferative, and osteo/dentinogenesis abilities, while iDPSCs

Table 4 Dental stem cell-based clinical trials registered on the International Clinical Trials Registry Platform

Ref.	Registration ID	Status	Diseases	Study design	Cell source	Administration route	Number of patients	Interventions		Follow-up period	Phase	Outcomes

-	JPRN-UMIN000042791	Complete: Follow-up complete	Periodontitis	Randomized; parallel assignment; single-blind (participants)	Deciduous pulp	Gargle	30	Mouthwash containing SHED culture supernatant	Mouthwash without SHED culture supernatant	1 mo	Not applicable	
-	ChiCTR2100051466	Recruiting	Periodontitis	Randomized; parallel assignment; open label	Dental pulp	Bilateral multipoint injection on a single tooth	96	DPSCs (1×10^7 cells) for once; DPSCs (1×10^7 cells) for twice	Saline	90, 180, 360 d	Phage 0	
-	ChiCTR2100049178	Pending	Periodontitis	Randomized; parallel assignment; double-blind	Dental pulp	Local injection	36	DPSCs (1×10^6 cells) for single injection; DPSCs (5×10^6 cells) for single injection; DPSCs (1×10^7 cells) for single injection; DPSCs (1×10^7 cells) for single injection in 2 locations; DPSCs (1×10^7 cells) for single injection in 3-4 locations	None		Phage 1	
Sánchez *et al* [42], 2020	ISRCTN13093912	Completed	Periodontitis	Randomized; parallel assignment; single-blind (patients and examiners)	Dental pulp	Implanted into bone defect sites *via* surgical approach	20	DPSCs (1×10^7 cells) + hydroxyapatite-collagen scaffold	Hydroxyapatite-collagen scaffold	1, 2, 4, 12, 24, 36 wk; 12, 24, 36, 48, 60 mo	Not applicable	
-	JPRN-UMIN000045926	Complete: Follow-up complete	Wrinkles	Randomized; parallel assignment; single-blind (outcomes assessor)	Dental pulp		12	All-in-one gel containing immortalized DPSCs-CM solution and various beauty ingredients	No treatment	4 wk	Not applicable	
-	JPRN-UMIN000043528	Complete: Follow-up complete	Wrinkles	Randomized; parallel assignment; single-blind (outcomes assessor)	Dental pulp		12	All-in-one gel containing immortalized DPSC-CM solution and the latest peptide raw materials	No treatment	4 wk	Not applicable	
-	JPRN-UMIN000045897	Complete: Follow-up continuing	Hair loss	Nonrandomized; parallel assignment; open label	Deciduous pulp	Injection	22	SHED-CM; after SHED-CM injection, one dose of micrografts (Rigenera) followed by another SHED-CM injection; SHED-CM injection after one dose of micrografts (Rigenera)	None	6 mo	Not applicable	

DPSCs: Dental pulp stem cells; SHED-CM: Stem cells from exfoliated deciduous teeth conditioned medium.

demonstrated enhanced chondrogenesis, neurogenesis, angiogenesis, and adipogenesis capacities. Park *et al*[96] reported that iDPSCs appear to have higher osteogenic differentiation potential and lower neurogenic differentiation potential than DPSCs.

Differences in inflammation levels may explain the discrepancy in the biological properties of DPSCs and iDPSCs in various studies. Intense and rapid inflammatory stimulation irreversibly initiates pulp necrosis, while low insult levels of inflammation are able to cause reversible pulpitis and promote dentine regeneration[99]. DPSCs are a suitable source of stem cells for pulp nerve regeneration because of their neuronal differentiation potential. It was reported that acute inflammation with a high level of proinflammatory cytokines could reduce neural precursor cell (NPC) survival and inhibit the neuronal differentiation of NPCs, while chronic inflammation expressed a potentially neuroprotective phenotype and supported neuronal differentiation[100]. Meanwhile, age, sex, tooth position, and sample size are also confounding factors affecting the function of DPSCs, which should be considered in subsequent studies and clinical practice.

DSC-CM and DSC-EVs

The culture medium collected from cells in culture is known as CM. CM is applied as an alternative therapy for tissue regeneration, which is a less ethical issue because it uses cells indirectly. Koga *et al*[64] applied SHED-CM in the treatment of erectile dysfunction, which is the only record of its clinical use to the best of our knowledge.

DSC-CM contains a variety of cytokines associated with vascular and nerve tissue regeneration, such as VEGF, BDNF, β-NGF, GDNF and neurotrophin-3 (NT-3)[101,102]. To date, DSC-CM has been reported to have the potential to promote bone regeneration[103], periodontal regeneration[104], angiogenesis[105], pulp regeneration[106], and nerve protection/regeneration[105,107-109] with great possibilities for clinical application.

In addition, DSC-CM showed satisfactory anti-inflammatory and immunoregulatory effects. Several *in vivo* studies based on various animal models reported that intravenous injection or intranasal administration of SHED-CM improved liver fibrosis[110], acute liver failure[111], acute lung injury [112], Alzheimer's disease, temporomandibular joint osteoarthritis[113], Sjögren's syndrome[114], and rheumatoid arthritis[115] by exerting anti-inflammatory effects. Meanwhile, studies have also reported the effect of SHED-CM on promoting Treg cell differentiation[114] and M2-like macrophage induction [111,112], as well as inhibiting Th17 cell differentiation[114] and inflammatory macrophage activation [116].

In addition to DSC-CM, DSC-EVs harvested from cell-culture medium have also been deeply studied in recent years. Multiple studies have indicated the promotion effect of DSC-EVs on jawbone and calvarial bone regeneration[117,118], angiogenesis and cutaneous wound healing *in vivo*[119,120]. Li *et al* [121] also reported that DSC-EVs could alleviate cerebral ischemia-reperfusion by suppressing the inflammatory response, which is related to the inhibition of the HMGB1/TLR4/MyD88/NF-κB pathway.

The poor survival rate of implanted DSCs and host immunogenic reactions are the main drawbacks of applying DSCs directly. In some comparative studies, stem cell-derived CM showed similar and even better treatment effects on acute lung injury, Parkinsonism, and type 1 diabetes than the direct use of stem cells[112,122,123]. DSC-CM and its components (such as EVs) provide several key advantages over cell-based applications, including avoiding the risk of host immunogenic reactions, cost-effectiveness, long-term storage capacity, and simpler evaluation of safety and efficacy[104,124]. Accumulating evidence indicates the great potential of DSC-CM/DSC-EV-based treatment in clinical applications.

Expanding-free strategy

Despite encouraging results of differentiation and tissue regeneration, DSCs still require rigorous cell-expanding procedures to obtain a sufficient number of cells for treatment, which is costly with great technique sensitivity, often taking tens of days. The *ex vivo* expansion of stem cells often reduces their self-renewal and proliferation abilities[125]. Direct mechanical digestion or tissue transplantation are promising solutions to these limitations.

In recent years, using mechanical disaggregation of dental tissues instead of cell-expending procedures was successful for harvesting autologous pulp micrografts rich in progenitor cells[41,126]. In 2016, Monti *et al*[126] indicated that DSCs harvested by mechanical digestion (Rigenera® system, HBW, Turin, Italy) were fully comparable to stem cells obtained after enzymatic digestion. In this study, mechanical digestion-obtained DPSCs showed osteogenic, adipogenic, and chondrogenic differentiation abilities*in vitro* and were able to increase the regeneration of post-extraction sockets *in vivo* when applied with the collagen sponge[126].

Pulp micrografts harvested by mechanical digestion were also applied in the treatment of sinus lifting, post-extraction sockets, and periodontal intrabony defects[46,47,49,57,61,62]. One clinical trial using pulp micrografts was also designed for periodontitis management (NCT03386877), but the outcome was not reported. Different systems of mechanical disaggregation were applied in these studies, including BD Medimachine (BD Biosciences San Jose, CA, United States)[62], the Rigenera® system (HBW, Turin, Italy)[46,57,61], and the Medimachine System (Consul TS, Orbassano, Italy)[47, 49]. In brief, dental pulp is first collected from extracted teeth and then sent to the mechanical disaggregation system to obtain pulp micrografts. After filtration or without filtration, pulp micrografts are combined with the scaffold for transplantation.

In addition, Vandana *et al*[125] described a novel approach using stem cell assistance in the periodontal regeneration technique (SAI-PRT), which contained periodontal ligament soft tissue gelatin sponge scaffolds and cementum scrapings. In their research, SAI-PRT successfully bypassed*in vitro* culture and expanded PDLSCs, resulting in satisfactory defect filling of periodontal intrabony defects [125].

Embryonic stem cells, PSCs, and DSCs

Embryonic stem cells (ESCs) are pluripotent cells of great significance to developmental biology. They give rise to all types of germ layer cells in the embryo. The self-renewal ability and plasticity of ESCs make it possible to generate unlimited numbers of different types of cells *in vitro*[127]. Similar to embryonic cells, PSCs derived from different somatic cells also have the ability to immortalize and differentiate into the three germ layers[128]. The properties of these two cell types make them promising sources for stem cell-based therapy for various diseases and injuries. However, due to the limitations of ESCs and PSCs, adult stem cells (such as DSCs) still possess high application value.

First, ethical issues regarding the use of ESCs make their clinical application challenging[128]. Second, the preparation of autologous PSCs takes a long time (more than 3 mo) and has high medical cost, and the immune rejection issue of allotransplantation should be considered[129]. In addition, teratomas are germ cell tumors containing cells of two or three germ lines that always occur *via* uncontrollable stem cell proliferation and differentiation[130,131]. In experimental studies, stem cell transplants (especially ESC and PSC transplants) have been found to increase the risk of teratomas, raising safety concerns[131-133]. Previously, viral vector integration and contamination of animal-derived components also posed obstacles to the use of PSCs, but these problems have been addressed by innovative techniques, such as integration-free methods and xeno-free culture[134-136].

DSCs did not show unlimited proliferation potential and demonstrated poorer differentiation ability than PSCs and ESCs[137]. However, the advantages of DSCs over ESCs and PSCs, such as fewer ethical issues and lower teratoma risk[87,88,138], lower cost and shorter preparation period, harvesting from medical waste, and implementing therapeutic effects without gene editing, grant them greater potential for clinical applications in the future.

CONCLUSION

Many clinical articles and clinical trials of autologous and allogeneic DSCs have aimed to evaluate their therapeutic effects on various diseases, such as pulpitis, periapical lesions, periodontitis, cleft lip and palate and Huntington's disease. In most studies, satisfactory clinical treatment results were obtained, while clinical benefits of using DSCs were not found in some research. Although safety risks exist for stem cell-based therapies, safety issues have not been reported in the clinical applications of DSCs. In the future, in addition to continuing to study the efficacy and safety of DSC-based treatment, harvesting DSCs from inflammatory tissues, expanding-free strategies, and applying DSC-CM or DSC-EVs should be studied, as they have strong research value and application potential. Taken together, DSC-based therapy is a promising tool for the treatment of various diseases and can be further promoted.

Abstract

Ischemic stroke (IS) is the most prevalent form of brain disease, characterized by high morbidity, disability, and mortality. However, there is still a lack of ideal prevention and treatment measures in clinical practice. Notably, the transplantation therapy of mesenchymal stem cells (MSCs) has been a hot research topic in stroke. Nevertheless, there are risks associated with this cell therapy, including tumor formation, coagulation dysfunction, and vascular occlusion. Also, a growing number of studies suggest that the therapeutic effect after transplantation of MSCs is mainly attributed to MSC-derived exosomes (MSC-Exos). And this cell-free mediated therapy appears to circumvent many risks and difficulties when compared to cell therapy, and it may be the most promising new strategy for treating stroke as stem cell replacement therapy. Studies suggest that suppressing inflammation *via* modulation of the immune response is an additional treatment option for IS. Intriguingly, MSC-Exos mediates the inflammatory immune response following IS by modulating the central nervous system, the peripheral immune system, and immunomodulatory molecules, thereby promoting neurofunctional recovery after stroke. Thus, this paper reviews the role, potential mechanisms, and therapeutic potential of MSC-Exos in post-IS inflammation in order to identify new research targets.

Key Words: Mesenchymal stem cells; Exosomes; Ischemic stroke; Immunomodulation; Inflammation; Exosome therapy

Core Tip: Mesenchymal stem cell-derived exosomes (MSC-Exos) are an emerging strategy for treating ischemic stroke (IS) and have demonstrated certain achievements in animal studies. Here, we review and discuss the mechanisms of MSC-Exos in treating IS through immunomodulation, the current responses to the clinical limitations of MSC-Exos therapy, and the issues that need to be addressed in future MSC-Exos research.

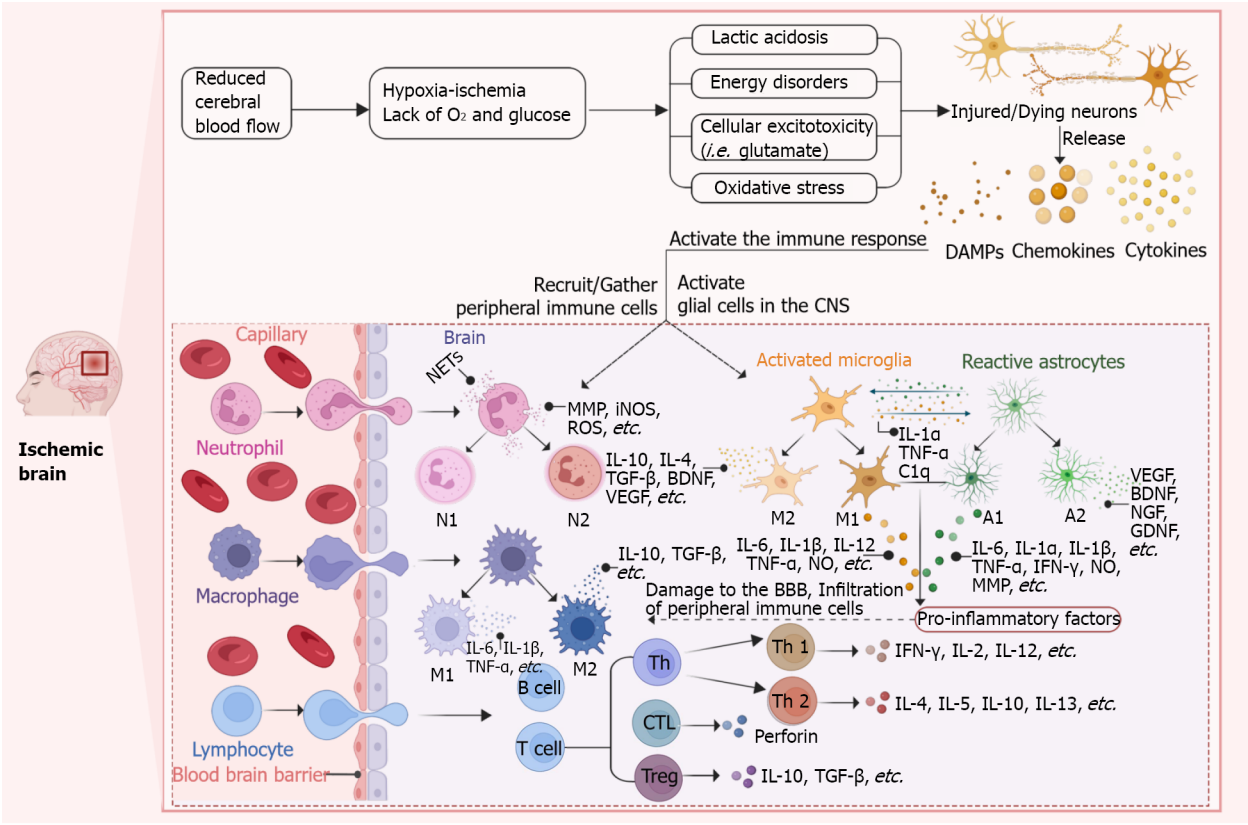
INTRODUCTION

Stroke is one of the leading causes of death and permanent disability on a global scale; ischemic stroke (IS) accounts for approximately 80% of stroke cases[1]. Currently, the mainstay of acute treatment for IS is limited to reperfusion by intravenous recombinant tissue fibrinolytic activator (tPA, thrombolysis) and rapid recanalization utilizing devices (thrombectomy)[2]. In clinical practice, however, the thrombolytic treatment conditions are strictly limited to presentation within 4.5 h of symptom onset[3]. Although the therapeutic window for thrombectomy has been extended to 24 h, there may be a risk of cerebral hemorrhage, occlusion after revascularization, and over-perfusion brain injury[4,5]. In recent years, other treatments that researchers have actively explored have also been prevented from being implemented on a large scale in clinical practice due to a variety of disadvantages. For instance, hypothermia treatment may reduce body metabolism while affecting neuronal death mechanisms, resulting in increased immunosuppression and susceptibility to infectious complications[6]. Prophylactic antibiotic treatment can decrease the incidence of infectious complications. However, antibiotic therapy is targeted, and broad-spectrum antibiotics can affect the body's normal flora if they are misused, which may increase organismal resistance[7]. By 2050, there will be more than 200 million stroke survivors and almost 300 million disability-adjusted life-years, 25 million new strokes, and 13 million deaths from stroke annually[1]. Therefore, there is a pressing need to discover effective treatments for IS that can be administered on a large clinical scale.

In acute stroke management, time is brain. The focus of stroke research should be on extending the time window for treatment. Examples include early measurement of immune biomarkers[8], improved efficiency of pre-hospital emergency transport[9], improved levels of care[10], and stem cell transplantation therapy[11]. Among these, stem cell transplantation therapy, which can extend the treatment window for IS to seven days, has become a hot research topic[11]. This also offers promising treatment options for patients outside the golden treatment period. MSCs are among the most hopeful candidates for stem cell therapy compared to other types due to their comprehensive source, ease of culture, pluripotent differentiation, immune tolerance, high survival rate, and strong paracrine effects [11-13]. It has previously been proved that nutrient factors and extracellular vesicles (EVs) secreted in situ by stem cells after transplantation enter the damaged brain and exert immunomodulatory, neuroprotective, angiogenic, and neural restructuring effects[13,14]. This phenomenon is known as the paracrine response (also called the "bystander" effect) and is the main mechanism by which stem cell's function. In comparison, exosomes are key effectors in the paracrine response of stem cells[14]. Mesenchymal stem cell-derived exosomes (MSC-Exos) therapy applied to stroke is superior to cell therapy in biodistribution, stability, safety, and development potential while ensuring therapeutic efficacy as an alternative therapy to stem cells.

In addition to the problem of a narrowing treatment window, the poor prognosis of IS is another pressing issue. Immunosuppression is the important cause of IS patients' poor prognosis and increased susceptibility. The inflammatory response underlies ischemic tissue damage. MSC-Exos, a highly promising treatment modality for brain injury, can effectively reduce neuroinflammatory reactions by modulating the immune system to promote recovery[15,16]. This paper reviews and discusses the immunomodulatory effects of MSC-Exos at the cellular and molecular levels following IS, as well as its application in therapy, in order to serve as a reference for future research and treatment.

IMMUNE RESPONSE AFTER IS



IS is caused by thrombosis or embolism, which could interrupt blood flow to the brain. After acute ischemic events, blood stagnation and altered hemodynamics restrict the availability of oxygen and glucose [oxygen-glucose deprivation (OGD). Then brain cell metabolism shifts from the oxidative phosphorylation to high levels of glycolysis, producing excess lactic acid[17,18]. Excessive accumulation

of lactic acid is able to trigger tissue acidosis, edema, blood-brain barrier (BBB) dysfunction, and extensive necrosis[18]. Firstly, once the Na^+/K^+ ATPase pump is affected, there will be an inward flow of Na^+ and an outward flow of K^+, which depolarizes the neuronal plasma membrane and promotes the release of excitatory neurotransmitters (including glutamate)[18-20]. Excess glutamate activates the N-methyl-D-aspartate receptor and the α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid receptor, thereby leading to cytotoxicity and cell death[19,21,22]. Next, an extracellular Ca^{2+} inward flow occurs after affecting the Ca^{2+} pump, which causes a dramatic rise in intracellular Ca^{2+}. Ca^{2+} overload activates calcium-dependent proteases, lipases, DNAases, kinase phosphatases, endonucleases, and other death signals, inducing ischemic core cell death[20,23]. Additionally, the Ca^{2+} influx activates nitric oxide synthase (iNOS), which subsequently generates oxygen radicals and peroxynitrite (ONOO-), causing oxidative stress in neural tissue[24]. Meanwhile, the depletion of ATP production and overproduction of reactive oxygen species (ROS) leads to mitochondrial dysfunction, further exacerbating oxidative stress [22,25]. In summary, OGD results in subsequent energy disturbances, lactic acidosis, cellular excitotoxicity, and oxidative stress, ultimately leading to brain cell damage or death. This is the initial step of ischemia-induced damage, which triggers the subsequent cascade responses. Injured/dying cells emit "danger signals" and thus activate the immune system (Figure 1).

Once the immune system is activated, immune cells enter the brain parenchyma sequentially. Microglia (MG), as the resident macrophages of the central nervous system (CNS), are the first to detect ischemia and rapidly activate in response[26,27]. MG recognizes "danger signals" [danger-associated molecular patterns (DAMPs)] released by dying and dead cells, primarily *via* the expressions of Toll-like receptors (TLR) and scavenger receptors. Then, the TLRs and scavenger receptors are activated, triggering a series of inflammatory events[28-30]. MG has been classified into two polarized phenotypes, including classical activation (pro-inflammatory, M1) and alternative activation (anti-inflammatory, M2). Anti-inflammatory cytokines [such as interleukin (IL)-4, IL-13, IL-10, and transforming growth factor (TGF)-β] activate the M2 phenotype. The M2 cells promote translocation of the transcription factor nuclear factor erythroid 2-related factor 2 (Nrf2) and proliferation-activated receptor gamma, and promote the secretion of anti-inflammatory IL-10, IL-4, TGF-β cytokines and growth factors (such as brain-derived neurotrophic factor and vascular endothelial growth factor) to suppress inflammation and enhance tissue repair[31,32]. In contrast, lipopolysaccharide (LPS) and interferon gamma (IFN-γ) activate the M1 phenotype. The M1 cells promote the transcriptional activation of nuclear factor-κB (NF-κB), a member of the signal transducer and activator of the transcription family (STAT), and promote the production of pro-inflammatory mediators like IL-12, tumor necrosis factor (TNF)-α, IL-6, IL-1β and NO, leading to the secondary brain damage[31,33,34]. Meanwhile, the chemokines and cytokines released by M1-MG and adhesion molecules highly expressed on endothelial cells can recruit peripheral blood leukocytes (including neutrophils, monocytes, and lymphocytes) to infiltrate the brain parenchyma, thereby mediating the adaptive immune response[28,30,31]. In the acute phase of brain injury, the M1 phenotype appears to predominate, whereas MG favors the M2 phenotype in the later stages. In addition, neurons can control MG activation by releasing "on" and "off" signals. MG is able to quickly recognize the "eat me" (CX3CL1) or "don't eat me" (*e.g.*, CD47-SIRPα and CD200-CD200R) signal on a neuron and engulf the live ischemic neurons[35]. In the same way like MG, macrophages can be polarized into two phenotypes, M1 and M2. The two are often described as MG/macrophages, because their roles in stroke are mostly similar[36]. However, in contrast, the main inflammatory factors produced by both are skewed. MGs secrete relatively high levels of ROS and TNF-α, while macrophages produce relatively high levels of IL-1β[37].

Astrocytes (Ast) are among the first brain cells to be activated after an ischemic event. Ast undergoes a dramatic transformation called "reactive astrocytosis" after ischemic injury, forming glial scarring[38]. Similar to MG, the harmful or beneficial effects of reactive Ast depend on the different phenotypes of Ast (neuronal toxicity phenotype A1 and neuroprotective phenotype A2)[38,39]. In addition to the activation of Ast by DAMPs, there is growing evidence regarding the importance of MG-Ast crosstalk for activating Ast. MG activation, followed by the release of IL-1α, TNF-α and complement component subunit 1q, induces the activation of A1-type reactive Ast[38,40]. A1-Ast secrete pro-inflammatory mediators, like IL-6, TNF-α, IL-1α, IL-1β, IFN-γ, NO, matrix metalloproteinases (MMP), superoxide and ONOO-, inducing neuron and oligodendrocyte death[38,41]. MG also induces the A2 phenotype of Ast and attenuates the inflammatory response. Li *et al*[42] have reported that Zinc finger E-box binding homeobox 1 (ZEB1) was highly expressed in MG of the ischemic hemisphere after experimentally induced strokes[42]. ZEB1 overexpression mediates the MG response primarily through a TGF-β1-dependent pathway and subsequently reduces CXCL1 production in Ast, thereby reducing neutrophil infiltration in the brain parenchyma. Likewise, Ast also can regulate the phenotype and function of MG through crosstalk between Ast and MG[43]. Thus, when the brain is disturbed, MG and Ast seem to respond as a unit.

Different from other immune cells, the number of lymphocytes infiltrating into the stroke brain is relatively small[27]. T lymphocytes can enter the brain hours after a stroke and are preferentially accumulated at the edge of the lesion[44]. The T cells infiltrating into the ischemic tissue mainly comprise $CD8^+$ cytotoxic T lymphocytes (CTLs), $CD4^+$ T helper cells (Ths), and regulatory T cells (Tregs) [45]. Infiltrating MG/macrophages may stimulate the differentiation of activated $CD4^+$ T cells into Th1

Figure 1 Schematic representation of the immune response after ischemic stroke. After ischemic stroke (IS), the blood-brain barrier (BBB) is disrupted and the central nervous system (CNS) and the peripheral immune system are able to interact with each other. The cerebral blood flow is significantly reduced immediately after IS, which limits the availability of glucose and oxygen. The initial ischemic event leads to energy disturbances, acidosis, cellular excitotoxicity and oxidative stress ultimately resulting in neuronal damage or death and subsequent activation of the immune response. Dying/dead neurons release "danger signals" such as danger associated molecular patterns (DAMPs), cytokines and chemokines to recruit and activate peripheral immune cells (neutrophils, macrophages and lymphocytes) and activate glial cells (microglia and astrocytes) in the central CNS. Activated glial cells release a range of cytokines and chemokines that also recruit peripheral immune cells into the brain parenchyma and further destroy the BBB. Activated cells polarize into different cell phenotypes or subtypes to secrete pro-inflammatory or anti-inflammatory factors that act to damage or protect. (Figure created with BioRender.com). DAMP: Danger associated molecular patterns; CNS: Central nervous system; NET: Neutrophil extracellular trap; MMP: Matrix metalloproteinases; iNOS: Influx activates nitric oxide synthase; ROS: Reactive oxygen species; IL: Interleukin; TGF-β: Transforming growth factor-β; BDNF: Brain-derived neurotrophic factor; VEGF: Vascular endothelial growth factor; TNF-α: Tumor necrosis factor-α; NGF: Nerve growth factor; GDNF: Glial cell-derived neurotrophic factor; IFN-γ: Interferon-γ; BBB: Blood-brain barrier; CTL: Cytotoxic T lymphocyte; C1q: Component subunit 1q.

or Th2 cells[46]. Th1 cells are able to secrete pro-inflammatory factors like IFN-γ, IL-2, and IL-12 to exacerbate inflammation. In contrast, Th2 cells produce anti-inflammatory factors, such as IL-4, IL-5, IL-10, and IL-13, to suppress inflammation[47]. CTLs directly or indirectly kill neurons and aggravate brain damage through cell interactions and the release of perforin after antigen-dependent activation[48]. Tregs exert their protective effects mostly by inhibiting IL-1β and TNF-α through the expression of IL-10 [47,49]. The role of B lymphocytes in the immunology of stroke is not clear yet. Whereas, some studies have observed the local production of corresponding antibodies in the cerebrospinal fluid of stroke patients, indicating that B lymphocytes are indeed present in the ischemic brain and they may be involved in post-ischemic immunological events[50].

Neutrophils are the initial blood-derived immune cells to cross the BBB and invade ischemic tissues, and they can be detected as soon as 1 h after the event[51]. Neutrophils are activated and recruited to the injured brain parenchyma by inflammatory factors produced from some activated glial cells and dying neurons, and adhesion molecules expressed by endothelial cells (*e.g.*, intercellular adhesion molecule 1, P-selectin and E-selectin)[27,52,53]. Traditionally, the neutrophil aggregation has been considered detrimental to stroke. After infiltration into ischemic tissues, activated neutrophils produce inflammatory factors, such as MMP, iNOS, and ROS, and form neutrophil extracellular traps (NETs) to increase BBB permeability and exacerbate inflammation[54-56]. In addition, the accumulation of neutrophils can further block local blood flow, resulting in "no reflux" of the microcirculation[57]. Neutrophils also exhibit two kinds of phenotypes, comprising N1 (pro-inflammatory) and N2 (anti-inflammatory) phenotypes. Neutrophil's different phenotypes may shape other cellular effector functions and be cleared by phagocytosis of MG/macrophages[58,59].

In conclusion, the post-stroke ischemic environment induces immune cells to polarize into different phenotypes or type, acting either protectively or destructively. Hence, it is probably a promising mean to affect the immune cell heterogeneity and improve the post-stroke inflammatory environment.

EXOSOMES AS A REPLACEMENT THERAPY FOR MSCS ON IS

All above, it is clear that the immune responses following IS can influence the development of ischemic brain injury. Anti-inflammatory and immunomodulatory therapies have shown beneficial effects on several experimental stroke models[60]. Among them, MSCs transplantation is one of the most important therapeutic tools involved in regulating immunity and repairing ischemic tissues in clinical practice[61]. Initially, researchers have assumed that the primary mechanism of MSCs transplantation mainly involved in MSC's ability to differentiate into parenchymal cells to repair and replace injured tissues. However, many preclinical studies suggested that most MSCs were confined to the liver, spleen, and lungs, and only a few MSCs could reach the injury site, surviving and differentiating into neurons [62,63]. Interestingly, despite most transplanted MSCs stagnate in the organ, this does not prevent the therapeutic effect of MSCs transplantation. Thus, the distal therapeutic effect after transplantation of MSCs may be primarily attributable to the paracrine mechanism of MSCs[63]. MSC-Exos mainly mediate the paracrine secretion of MSCs. Exosomes are EVs with a single membrane structure of 30-150 nm in diameter, carrying proteins, lipids, nucleic acids (DNA, mRNA, miRNA, lncRNA, circRNA), and other substances[64]. When exosomes are circulating, the contents encapsulated within them can be delivered to target cells, mediating intercellular communication and regulating the function of the target cells[64,65]. This is essentially the role of the miRNAs contained by exosomes. MiRNAs are endogenous hairpin-loop structured non-coding RNAs, primarily binding to mRNA in specific ways to influence post-transcriptional events and regulate cellular behavior[66].

Furthermore, there are multiple advantages of transplanting exosomes rather than the entire "factory" (cell) into the body: (1) In terms of biodistribution, as nano-scale cellular secretions that could escape the phagocytosis of macrophages and readily cross the BBB to reach the brain parenchyma, they are considered to be natural therapeutic agents and innate drug delivery system for brain diseases[67]; (2) In terms of stability, exosomes have a stable bimolecular phospholipid structure that prevents the contents' biological activity from being broken down by extracellular hydrolytic enzymes[64]; (3) In terms of safety, compared to MSCs transplantation therapy, the cell-free therapy can avoid cell-mediated adverse effects, such as tumor formation, coagulation dysfunction, and infarction due to vascular occlusion[16]; and (4) In terms of development potential, exosomes can be enriched in large quantities within the culture medium (mass production) and easily retouched/retrofitted (controllable). Moreover, some studies comparing the therapeutic effects of MSC-Exos with MSCs in stroke rat models suggest that MSC-Exos treatment is indeed superior to treatment with MSCs themselves[68,69]. For above reasons, we believe that MSC-Exos is a crucial effector of MSCs to exert their immunomodulatory effects. Together with its unique advantages, MSC-Exos is expected to be a replacement therapy for MSCs in the treatment of stroke.

MSC-EXOS MODULATES IMMUNE RESPONSE AFTER IS

Recently, numerous studies have shown that MSC-Exos can promote recovery after stroke, *via* modulating the innate and adaptive immune responses activated after IS[70-72]. Firstly, MSC-Exos is able to regulate cell differentiation, activation, proliferation, and intercellular communication by delivering functional molecules to cells involved in immunity, for example, MG, Ast, macrophages, neutrophils, lymphocytes, dendritic cells (DCs), *etc.* (Table 1). There are three primary forms of action: (1) Through the signaling molecules on its surface as ligands binding to specific receptors on the target cell, the intracellular signaling pathways are regulated; (2) *via* fusing with the corresponding target cell membrane and releasing the contents into the recipient cell; and (3) by entering the target cell in the form of endocytosis and bringing the active factors into the cell[73]. Secondly, MSC-Exos can also mediate the immune response by down-regulating pro-inflammatory factors and/or up-regulating anti-inflammatory factors (Table 2).

MSC-Exos regulate the immune response through cells

MSC-Exos and CNS: MG is firstly activated after IS, as an immune sentinel of the CNS, exerting neuroprotective or neurotoxic effects[27,74]. A therapeutic strategy balancing the two polarization states of MG may become a future adjunctive stroke therapy. One study used protein blotting to analyze TLR-2, TLR-4 and TLR-6 levels in MG of ischemia/reperfusion (I/R) mice and found that the TLR/NF-κB pathway was activated in MG after an ischemic event, leading to the secretion of pro-inflammatory factors (IL-1β, TNF-α, IL-6, *etc.*) and that this signaling pathway was important in promoting M1 transformation and exacerbating the inflammatory response[75]. TLRs are pattern recognition receptors

Table 1 Mesenchymal stem cell-derived exosomes target cells to mediate immune responses on ischemic stroke

Origin	Targeted cells	Administration/cultivation routes	Pathways/factors involved	Function	Ref.
Human umbilical cord-derived mesenchymal stem cell exosome miR-26b-5p	Microglia	Tail vein injection and microglia co-culture	TLR signaling pathway	Balance microglia polarization	[75]
Bone marrow-derived mesenchymal stem cell exosome miR-182-5p	Microglia	Inject into the brain	TLR4/NF-κB		[81]
Mesenchymal stem cell exosome miR-223-3p	Microglia	Tail vein injection and BV-2 microglia co-culture	CysLT2R-mediated signaling pathway		[87,89]

widely expressed on the surface of immune cells and play a key role in the immune response. NF-κB is a key regulator of the immune response and is intricately involved in MG/macrophage M1 and M2 phenotypic signaling[31,76,77]. Various miRNAs encapsulated in exosomes can regulate the expression of TLRs on MG surface, which act on NF-κB to influence MG polarization[29,30,78]. It has been reported that Cholesterol 25-hydroxylase (CH25H) is significantly increased during inflammation and contributes to the immune response by recruiting Iba-1-positive MG and activating TLR-3[79]. Meanwhile, an experiment used microarray to analyze the expression differences of miRNAs in ischemic brain tissue after exosome treatment, and found that miR-26b-5p expression increased significantly after exosome treatment and could target CH25H in MG to inactivate the TLR pathway to inhibit M1 polarization[75]. Besides, miR-542-3p prevents the expression of pro-inflammatory factors and the production of ROS by post-ischemic activated glial cells through inhibiting TLR[71]. miR-202-3p [80], miR-182-5p[81], MiR-181c[82], and miR-1906[83] also play a role in inhibiting M1 polarization through downregulation of TLR expression. Also, in a further explanation of the potential mechanism of miRNA-mediated TLR/NF-κB pathway, Liu *et al*[84] have documented that miR-216a-5p activates the phosphatidylinositol 3-kinase/protein kinase B (PI3K/Akt) signaling cascade through inhibition of TLR4/NF-κB, enabling the M1 to M2 phenotypic shuttle[84]. Some data also suggest that miR-145-5p downregulates inflammatory responses by inhibiting the IL-1 receptor-associated kinase 1 (IRAK1)/TNF receptor-associated factor 6 (TRAF6) signaling pathway to reduce and increase the amount of M1-MG and M2-MG, respectively[85]. In contrast, overexpression of IRAK1 and TRAF6 is involved in the activation of TLR/NF-κB pathway and promotes the release of proinflammatory factors[78,85,86]. Hence, miR-145-5p may indirectly affect the TLR/NF-κB pathway by inhibiting the IRAK1/TRAF6 pathway. Exploring the crosstalk between TLR/NF-κB and other pathways may better interfere with MG polarization. As described above, exosome miRNAs acting on the TLR/NF-κB pathway and its upstream/downstream signaling pathways could influence MG phenotype as well as the expression of pro/anti-inflammatory factors to improve inflammation.

In the regulation of MG polarization, the TLR/NF-κB pathway has been studied the most. However, in stroke, MG polarization is complex and actually regulated by multiple factors. Thus, other pathways affecting the activation state of MG are discussed below. miR-223 is one of the most abundant miRNAs in MSCs and their exosomes. In vivo and *in vitro* experiments have revealed that miR-223-3p down-regulates the transcription and expression of Cysteinyl leukotriene receptor 2 (CysLT2R) to induce a conversion from deleterious M1 to beneficial M2 phenotype[87]. CysLTs secreted by dying/dead cells

are potent medium for inflammation. They are activated in various cell types during brain injury, further exacerbating the development of inflammation[88]. Zhao *et al*[89] conducted an in-depth study involving the miR-223-3p inhibiting CysLT2R expression *in vivo* and in vitro. They found that miR-223-3p reversed M1 polarization by apparently downregulating the expression of ERK1/2 downstream of CysLT2R, which led to a decrease in the secretion of pro-inflammatory factors and an increase in the secretion of anti-inflammatory and neurotrophic factors, thereby slowing down inflammatory damage [89]. In addition, miR-223-3p also effectively inhibits N-methyl-leukotriene C4/Leukotriene D4 to promote M1 to switch to M2[87,90]. Through targeting the autophagy-associated proteins Beclin-1 and Atg5, miR-30d-5p greatly inhibited autophagy-mediated polarization of MG towards M1 and reduced OGD-induced inflammatory responses[91]. Notably, autophagy may exert both beneficial and detrimental effects under IS conditions, depending on the degree of autophagy[92,93]. A moderate increase in MG autophagic activity can reduce MG activation and promote MG polarization towards the M2 phenotype, exerting a neuroprotective effect. Instead, excessive autophagy exacerbates cerebral ischemic injury. It has been demonstrated that regulation of autophagic flux and exosome biogenesis in MG plays a vital role in neuronal survival under conditions of cerebral ischemia[94]. Interestingly, the similar property was also reported in Ast[95,96]. As such, balancing the autophagic flux of immune cells after stroke may be a promising target for treating stroke. Cheng *et al*[97] have demonstrated that miR-26a-5p was downregulated and CDK6 was upregulated in MSCs-derived exosomes of middle cerebral artery occlusion (MCAO) and OGD model[97]. They then hypothesized that CDK6 might be a direct target of miR-26a-5p and further confirmed the correlation between exosome miR-26a-5p and CDK6 using a luciferase reporter gene assay. The data showed that miR-26a-5p inhibited MG apoptosis and attenuated I/R injury in mice by mediating CDK6 downregulation[97]. Besides, miR-424 can also reduce ischemic brain injury by targeting key activators of the G1/S transition in MG (including CDK6, CDC25A, and CCND1) to inhibit BV-2 MG activation[98]. CDK6 seems to be a good target of miRNAs in neuroprotection. As well as alleviating inflammation, MSC-Exos can also alleviate neuronal death by regulating MG polarization to downregulate inflammatory mediators relating to pyroptosis[99]. *In vitro* data suggest that the non-coding RNA H19 carried by MSC-Exos could attenuate M1 polarization and inflammatory responses by sponging miR-29b-3p and further inhibit neuronal apoptosis[100]. miR-29b-3p may prevent ischemic-hypoxic brain injury by activating the PI3K/Akt pathway *via* downregulating the protein phosphatase and tensin homolog (PTEN)[101]. Most studies have reported routes associated with miRNAs affecting M1 polarization, while studies acting on pathways associated with M2 polarization are still lacking and deserve further exploration.

Ast, the most abundant brain cells in the CNS, plays an essential role in neuroinflammation and neuroregeneration[40,41]. Following ischemic injury, Ast is activated by DAMPs and/or MGs and undergoes a transformation known as "reactive astrogliosis"[38]. Features include hypertrophy of the shape and overexpression of glial fibrillary acidic protein (GFAP)[102]. The activated Ast phenotype matches MG and is divided into pro-inflammatory A1 and anti-inflammatory A2. Notably, recent studies have shown that the inflammatory response mediated by Ast appears to last longer and induces more damage than MG[103]. This possibility further underlines the importance of targeted inhibition of Ast activation or induction of Ast phenotypic transformation in the treatment of IS. It has been demonstrated that Nrf2-related pathways are involved in the inflammatory response of Ast[104-106]. In one study, immunofluorescence experiments were performed after *in vivo* and *in vitro* administration of MSC-Exo, respectively, and protein blots showed that MSC-Exo reduced the expression of GFAP (Ast marker), C3 (A1 marker) and ki67 (cell proliferation marker) in LPS-stimulated cultured primary hippocampal Ast[104]. Meanwhile, the data show that MSC-Exo could reverse hippocampal Ast oxidation (*e.g.*, upregulation and nuclear translocation of Nrf2) and inflammation phenotypes (*e.g.*, NF-κB activation and translocation)[104]. These results suggest that MSC-Exo can inhibit inflammation-induced Ast activation by modulating the Nrf2-NF-κB signaling pathway. Nrf2 is a regulator of redox homeostasis and a target for the induction of inflammatory responses. In brain diseases with simultaneous inflammation and oxidative stress (*e.g.*, IS), the interaction between Nrf2 and NF-κB signaling pathway is the fundamental mechanism regulating these responses[107]. miR-146a-5p, one of the most abundant cargo miRNAs in human umbilical cord-derived MSC-Exos, dramatically decreased the expression of A1 markers [C3 and lipid chain lipoprotein-2 (LCN2)) by inhibiting the NF-κB signaling cascade, thereby reversing the neurotoxic phenotype of Ast[108]. Among them, LCN2 has been identified as a potent mediator of astrocyte neurotoxicity[109]. LCN2 secreted by reactive Ast can accelerate or propagate neuronal cell death and promote the activation of resting Ast and MG[109]. Moreover, a recent study identified high LCN2 expression in a mouse transient MCAO model and detected that IS patients with higher plasma LCN2 levels were more likely to develop a post-stroke infection[110]. Overexpression of miR-138-5p negatively regulates the LCN2 expression in Ast, thereby inhibiting inflammation and reducing ischemic nerve injury[111].

More importantly, the increase of reactive Ast results in further glial scarring. In the acute phase of IS, these physical barriers can limit the inflammation spread and infarct area to maintain CNS homeostasis. However, in the recovery phase of IS, their presence may impede the circulation and neurological tissue regeneration, affecting functional recovery in late stroke[41]. It has been demonstrated that in several previous cerebral ischemia and hypoxia models, transplantation of MSCs markedly reduced reactive Ast and further eliminated glial scarring around the lesion, promoting neuronal regeneration and

relieving inflammation[112,113]. Recently, the *in vitro* studies reported that MSCs improved brain function after transplantation mainly by reducing the number of hypertrophic Ast and GFAP overexpression through inhibition of p38 MAPK, JNK, and its downstream targets p53 and STAT1 activation by paracrine factors[114]. In addition, miR-124 attenuated Ast proliferation and migration by blocking the STAT3 pathway, thereby reducing the width of glial scarring and improving neurological function [115]. Meanwhile, miR-124 may also involve in the reprogramming neuronal progenitor cells by Ast through decreasing Notch1 expression and increasing Sox2 expression[115]. As Ast and neurons originate from the same precursor cells, Ast can be reprogrammed into neurons under some specific conditions, which can be achieved, for instance, by adjusting the expression of certain specific transcription factors (including Notch1, NeuroD1, Mash1, Ascl1, *etc.*) *in vivo*[115-117]. If Ast transdifferentiated neurons homed to the ischemic lesion and replaced lost neurons, this would help limit glial scar formation and neural connectivity after injury, contributing to neural remodeling. This may be used as an alternative therapy for neuronal replenishment after stroke in the future. Furthermore, exosomes can also mediate communication between MSCs and Ast to enhance neurological recovery after stroke. MSCs communicate with Ast and neurons by releasing miR-133b-containing exosomes and transferring miR-133b into neurons and Ast to promote neuroprotection regeneration[118]. Xin *et al*[119] further showed that miR-133b shared into Ast downregulated the expression of connective tissue growth factor, thereby reducing glial scar thickness in cerebral infarction[119]. All in all, Ast may be a potential target for the intervention in stroke. However, whether the responsiveness and function of Ast should be further reduced or enhanced may depend on the duration of the ischemic lesion, the location of the Ast, and the specific subtype of Ast.

MSC-Exos and peripheral immune system

Neutrophil: Neutrophils are the first peripheral immune cells to infiltrate into the brain parenchyma crossing the damaged BBB. Neutrophil infiltration after IS is now believed to be detrimental to stroke [27,54,56]. MSC-Exos can mitigate the harmful effects of neutrophils in several ways. Firstly, MSC-Exos can reduce neutrophil infiltration and inhibit neutrophil respiratory burst, thereby decreasing the expression of inflammatory mediators, including IL-1b, IL-6, and TNF-α, as well as suppressing the production of ROS in neutrophils[120]. Also, further studies have revealed that MSC-Exos may prevent the subsequent recruitment of monocytes/macrophages and lymphocytes after reducing neutrophil infiltration at the cerebral ischemia site[121]. Secondly, MSC-Exos inhibits neutrophil apoptosis and enhances neutrophil phagocytosis, then contributing to the clearance of cellular debris and eliminating inflammation and infection. This may result from the presence of IL-6 in MSC-Exos and its transfer into the neutrophil cytoplasm, which subsequently exerts an autocrine effect on neutrophils, thereby prolonging the survival of these cells and maintaining their effective function and viability to further improve the inflammatory response[122,123]. Thirdly, MSC-Exos inhibits the formation of terminal complement complexes on neutrophils *via* CD59, thus attenuating neutrophil activation and inhibiting the release of NETs and IL-17 from neutrophils[124]. Besides, human umbilical cord blood-derived MSC-derived EVs (exosomes) can also repair and enhance neutrophil mitochondrial function by transferring functional mitochondria, then reducing the formation of NETs[125]. Of greater importance, Soni *et al*[72] further investigated the differences in the regulation of neutrophil function by exosomes from different sources of MSCs. The results suggested that bone marrow-derived MSCs-derived exosomes (B-Exos) were more effective in prolonging the neutrophil lifespan. In contrast, adipose-derived MSCs (ADMSCs)-derived exosomes (A-Exos) were more prominent in increasing the phagocytic capacity of neutrophils and inhibiting the formation of NETs[72].

Macrophage: Activated macrophages are morphologically like MGs, which can be divided into neurotoxic M1 and neuroprotective M2 types[36]. Numerous experiments have demonstrated that MSC-Exos can effectively inhibit the effector function of M1 pro-inflammatory macrophages and/or promote the effector function of M2 anti-inflammatory macrophages, which contributes to alleviating the immune inflammatory response. It has been suggested that IFN regulatory factor (IRF) 5 could be reversibly induced by inflammatory stimuli in macrophages and IRF5 is associated with the plasticity of macrophage polarization (up- or down-regulation of M1 or M2 macrophage phenotypic marker expression)[126]. Overexpression of miR-22-3p promotes the polarization to macrophage M2, suppresses the inflammation, and attenuates I/R injury through downregulating IRF5, which is supported by increased expression of the M2 macrophage marker mannose receptor (CD206) and decreased expression of the M1 macrophage marker CD86[127]. B-Exos-derived miR-125a also exerts neuroprotective effects by targeting negative regulation of IRF5 to promote M2 phenotypic polarization [128]. Furthermore, A-Exos can promote M2 polarization by activating the M2 macrophage-specific transcription factors MafB and Stat6 to induce the expression of genes related to anti-inflammatory functions, supported by a mechanism that upregulates the expression of the M2 macrophage markers CD163, arginase-1 (Arg1) and CD206[129]. A-Exos also increased CD163, Arg1, CD206, TGF-β1, and IL-10 expression levels and decreased TNF-α, IL-6, and IL-8 expression levels by targeting the Rho associated coiled-coil containing protein kinase 1/PTEN pathway. The above results suggest that A-Exos may improve the inflammatory environment by promoting M2 polarization to increase the secretion of anti-inflammatory molecules and/or inhibiting M1 polarization from decreasing the

secretion of pro-inflammatory factors[130]. And similar to MG, miR-21, miR-146a, and miR-301a can also regulate macrophage polarization by inhibiting the TLR/NF-κB pathway[131-133].

Lymphocyte: First of all, T lymphocytes are at the heart of the adaptive immune system. Despite some subtypes of T lymphocytes exert a neuroprotective role in the early post-stroke phase, such as Tregs and Th2, on the whole, they have a negative impact on IS, as do neutrophils[45,134]. Accordingly, it appears to be a viable clinical treatment for stroke to modulate the differentiation, activation and function of various T lymphocyte subsets. In vitro studies indicated that A-Exos significantly inhibited the activation and proliferation of $CD4^+$ and $CD8^+$ T cells and reduced IFN-γ release, with directly immunosuppressive properties[135]. *In vivo* experiments showed that a dramatic reduction in the number of CTL was observed in a rat model of cerebral infarction injected intra-arterially with MSC-EV [136]. Another study has documented that MSC-Exos also promoted the Treg proliferation and induced the conversion of Th1 to Th2 by enhancing intracellular IL-10 and TGF-β secretion, thereby boosting its immunosuppressive capacity[137]. Soni *et al*[72] have further explored and found that MSC-Exos containing miR-146, miR-155, miR-21, and miR-29 may regulate the activation pathways of Th1 and Th2 [72]. And they showed that different sources of MSC-Exos all inhibited the proliferation of T lymphocytes. But in comparison, Wharton Jelly-derived exosomes and B-Exos had a better inhibitory capacity than A-Exos[72]. Additionally, DCs activate T cells through delivering co-stimulatory molecules, such as CD80 and CD86, to naive T cells[138]. However, MSC-Exos can reduce T-lymphocyte activity, increase IL-10 and TGF-β secretion, and reduce IL-6 secretion by inhibiting the maturation and differentiation of DCs[135]. Next, activation and isotype-transformed B-lymphocyte infiltration contribute to poor outcomes after IS. It has been previously reported that MSCs can reverse the unfavorable outcome by inhibiting B lymphocyte activation, proliferation, differentiation, and chemotactic response[139]. Recent studies have demonstrated that when co-cultured with lymphocytes derived from healthy human peripheral blood, B-Exos significantly inhibited lymphocyte proliferation and immunoglobulin M production, particularly exhibiting effects on B lymphocyte-specific mRNA expression[70].

MSC-Exos regulate the immune response through inflammatory mediators

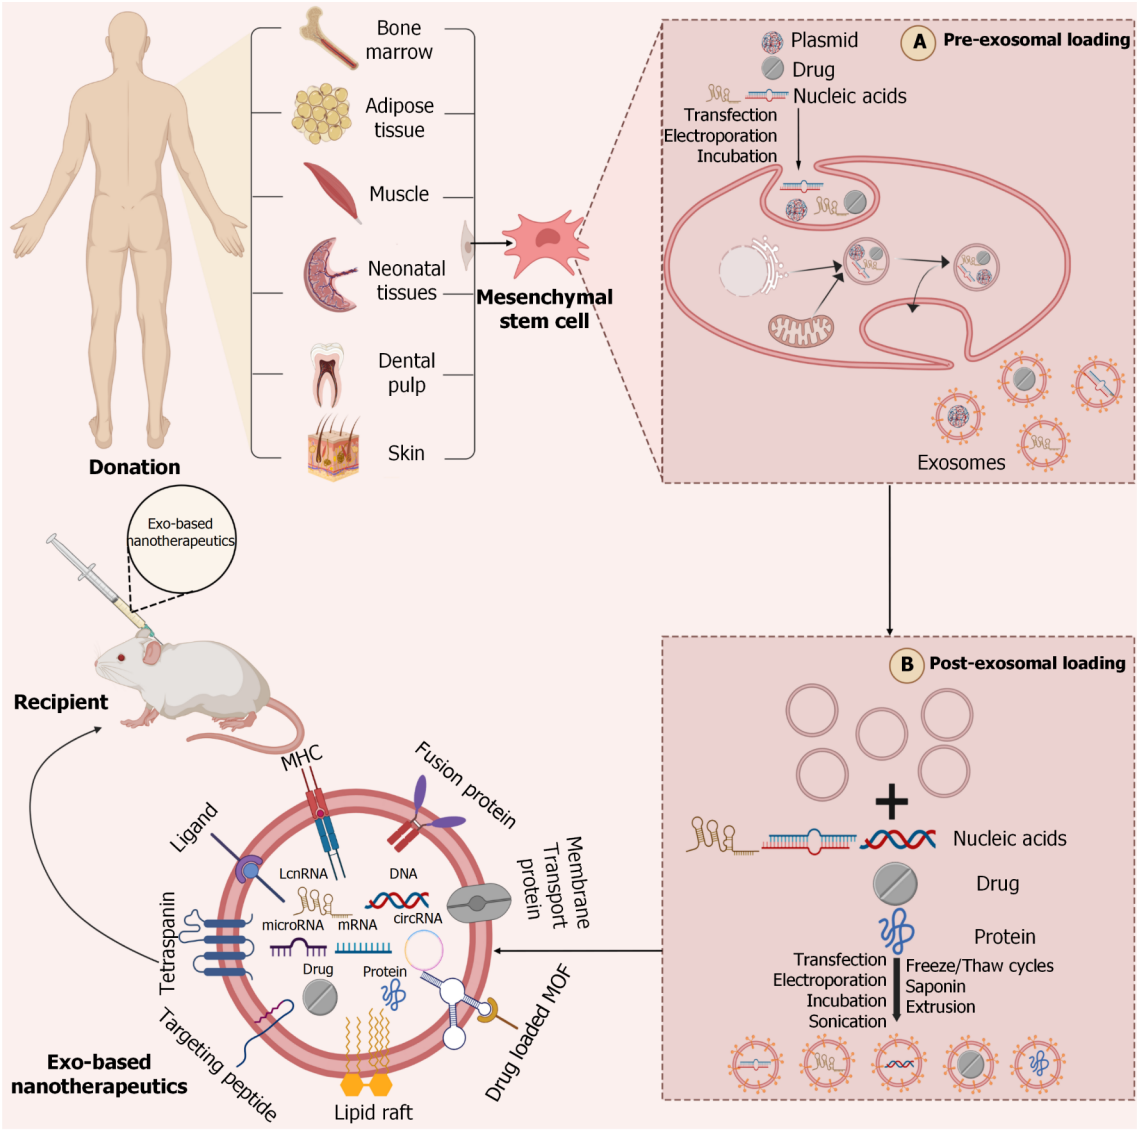
In addition to immune cells, changes in inflammatory mediators, such as cytokines and chemokines, are also observed in ischemic area. Among them, TNF-α, IL-1β, and IL-6 are the more typical pro-inflammatory factors, and their expression is significantly upregulated after ischemic events. MSC-Exos containing lncRNA ZFAS1[140], lncRNAH19[100], miR21-3p[141], miR-146a-5p[85], miR-138-5p[111], and miR182-5p[81] was able to reduce immunosuppression by downregulating the secretion of TNF-α, IL-1β, and IL-6. Of these, lncRNA ZFAS1 and lncRNAH19 may be associated with the competitive binding of miR-15a-5p and miR-29b-3p[100,140]. MSC-Exos also down-regulate other pro-inflammatory factors such as IFN-γ, iNOS, and IL-8[81,91,130,135]. Apart from down-regulating pro-inflammatory factors, some MSC-Exos can up-regulate the expression of anti-inflammatory factors such as IL-10, IL-4, and TGF-β1[91,100,130,142,143]. Furthermore, some studies have shown that MSC-Exos could reduce the secretion of chemokines (*e.g.*, C-C motif ligand 2) and cellular chemotactic proteins (*e.g.*, monocyte chemotactic protein), thereby inhibiting the migration and aggregation of peripheral immune cells and alleviating the inflammatory response[71,75,81]. Inflammasomes are equally important inflammatory mediators in regulating the onset and progression of IS. NLRP3 inflammasome contains a caspase-1 precursor that cleaves to caspase-1 (Cl) upon stroke stimulation. C1 not only is a critical executioner of pyroptosis (cleave full-length GSDMD to release GSDMD N-terminus) but also can convert precursors of IL-1β and IL-18 into mature pro-inflammatory cytokines exacerbating inflammation[144]. Liu *et al*[99] found that NLRP3 inflammasome was downregulated in MCAO mice after MSC-Exos treatment, thereby reducing inflammation and pyroptosis. They also observed that MSC-Exos contributed to MG polarization towards the M2 phenotype by inhibiting NLRP3[99]. On the one hand, it may be due to the high plasticity of the MG phenotype, which can dynamically switch according to brain environmental variables[74]. On the other hand, it may be related to the amount of autophagy[91,99,145].

Collectively, MSC-Exos could improve the immune inflammatory response after IS *via* affecting the activation of MG/macrophages and Ast, reducing reactive astrocyte hyperplasia, decreasing excessive infiltration of neutrophils, balancing the functional status of T cell subsets, suppressing the proliferation of B cells, inhibiting DC maturation, and regulating the secretion of inflammatory mediators. Therefore, MSC-Exos exhibits immunomodulatory effects and may help to reduce neurological damage and promote neurological repair after IS.

FROM BENCH TO BEDSIDE: RESPONSES TO THE LIMITATIONS OF MSC-EXOS THERAPY FOR IS

To date, a growing number of studies have demonstrated the great potential of MSC-Exos in treating IS. However, lacking target ability of natural exosomes produced by MSCs has greatly limited their clinical

application[146]. Regarding exosome producing, the cell membrane invaginates to form endosomes, which in turn form multivesicular bodies (MVBs), and the MVBs finally fuse with the plasma membrane to release luminal vesicles (called exosomes) into the extracellular matrix (ECM)[147]. At present, basing on the production process of exosome, two strategies are proposed to improve the targeting ability of exosomes, comprising "cell engineering" (pre-isolation) and "exosome engineering" (post-isolation) [147] (Figure 2). For example, the cyclin (Arg-Gly-Asp-DTyr-Lys) peptide [c(RGDyK)] and the rabies virus glycoprotein (RVG) peptide have been used explicitly to target the brain. B-Exos loaded with cholesterol-modified miR-210 coupled to c(RGDyK) could bind to integrin αvβ3 on the BBB and deliver miR-210 to the site of cerebral infarction, thereby ameliorating post-stroke symptoms[148]. Additionally, c(RGDyK)-modified MSC-Exos loaded with curcumin (cRGD-Exo-cur) was used in a study, followed by tail vein injection to target the area of cerebral ischemic injury and enter neurons, MG and Ast, effectively inhibiting the inflammatory response and cellular apoptosis[146]. RVG fused with exosomes protein lysosome-associated membrane glycoprotein 2b could bind to acetylcholine receptors on the BBB and effectively deliver miR-124 to the infarct site, therefore promoting post-IS neurogenesis and reducing ischemic injury[149]. In another study, high-mobility group box 1 (HMGB1)-siRNA was loaded into RVG-modified exosomes (RVG-Exos) by electroporation and injected into an MCAO model *via* tail vein. The results showed that RVG-Exos loaded with HMGB1-siRNA was effective in reducing the level of brain apoptosis and infarct size and had the potential to target IS[150].



Next, the "low yield bottleneck" of MSC-Exos is also one of the main causes limiting its clinical application. Some researchers have illustrated that the pretreatment of MSCs appears to increase the yield of MSC-Exos. For instance, the three-dimensional porous scaffold structure increases the surface area for cell-ECM interaction, compared to the traditional two-dimensional culture of BMSCs. In addition, the three-dimensional culture more closely resembled the natural ECM conditions, providing a better environment for cell attachment and growth, thus substantially increasing the yield of MSC-Exos[151]. Some studies have indicated that cultures using microcarriers and hollow fiber bioreactor can provide cells a larger attachment area and further enhance the secretion of MSC-Exos[152,153]. Moreover, a recent study found that pretreatment of MSCs with small molecule modulators (N-methyl-dopamine and norepinephrine) tripled the production of exosomes without altering the intrinsic regenerative effects of MSC-Exos and the level of total exosomes protein expression[154].

To sum up, enhancing the targeting of exosomes by modifying them and improving the yield of exosomes by pretreating MSCs can both improve the therapeutic ability of exosomes. And further exploration of exosome improvement methods offers the possibility of transitioning from bench to bedside.

CONCLUSION

IS is a severe cerebrovascular disease that adversely affects patient's health and quality of life. A growing body of evidence suggests that the immune inflammatory response plays a critical role in pathogenesis of IS. It has emerged as a promising target for intervention in stroke therapy. After IS, the boundary between the CNS and peripheral immune system disappears due to the disruption of the BBB. Subsequently, the CNS and peripheral immune system can interact with each other, providing a unique opportunity to regulate the pathological process of IS and the repair process. At the same time, immunomodulation is one of the main mechanisms by which MSC and MSC-Exos exert their therapeutic effects on IS. MSC-Exos is expected to be an alternative therapy to MSC in treating stroke due to its parental cell-like capabilities and specific advantages. MSC-Exos exerts immunomodulatory effects mainly by affecting the inflammatory phenotype of glial cells in the CNS, inhibiting peripheral immune cell activation, proliferation, differentiation, and hyperinfilation, and regulating the secretion of immune-related molecules. Meanwhile, to complement or enhance the therapeutic suitability of exosomes, researchers are actively exploring novel methods to expand, modify or enhance their therapeutic capacity, such as modifying exosomes (to improve targeting) and pretreating MSC (to increase exosome yield).

Although the results of numerous preclinical studies have shown MSC-Exos to be one of the key breakthroughs in treating IS. However, the study of MSC-Exos in the treatment of IS is still in its infancy in clinical practice. Currently, there is only one study in the Clinical Trials Registry database to determine the effect of MSC-Exos administration on improving functional impairment after IS. This trial used the administration of miR-124-enriched isoform MSC-Exos to treat IS and entered into a phase I/II clinical trial (NCT03384433)[155]. There are many challenges to overcome to transfer MSC-Exos therapy further into the clinic: (1) Optimal duration of treatment and effective dose. Numerous studies have shown that post-IS inflammatory cells play a dual role (beneficial and detrimental) and the inhibition of the same pathway at the wrong time may exacerbate ischemic damage[27,36,38,45]. Therefore, during developing new therapeutic strategies for IS, we need to pay more attention to the duration of treatment. Interestingly, there are also cases where the timing of transplantation based on previous cellular therapies may affect the therapeutic outcome[156]. Thus, we need to further investigate the optimal timing of treatment with exosomes that may be influenced by parental cells. Most preclinical

Figure 2 Strategies to enhance the targeting of mesenchymal stem cell-derived exosomes. Multiple strategies to be done before exosomes can be successfully translated into new technologies to improve the targeting ability of donor cells and therapeutic efficacy of chemical and biomolecular drugs. Current preclinical studies are focused on parental cells' modification (pre-isolation) (A); manipulation of exosome (post-isolation) (B). (Figure created with BioRender.com).

trials have currently chosen to administer a single dose of MSC-Exos in the acute phase of the stroke while showing beneficial effects. As such, the next step should investigate the effects of delayed-time dosing compared to acute phase dosing, in order to determine the optimal timing of treatment. However, determining the optimal timing of dosing may be difficult in practice, so we could further consider multiple repeat dosing; (2) A single research direction. Current experimental studies on the immunomodulatory aspects of MSC-Exos treatment with IS have focused on MG/macrophages, while other immune-related cells or factors remain poorly studied. Furthermore, the immune response following IS results from crosstalk within and between different cell types, which is complex and chronological. However, most experimental studies have usually explored a single mechanism of action mainly in a particular cell. There is no consensus on the exact molecular mechanism of MSC-Exos treatment of IS and further in-depth studies in multiple directions are urgently needed; (3) Lack of clinical trials; and (4) Stroke models combined with relevant clinical conditions. Current studies targeting MSC-Exos for treating IS have almost always been conducted in healthy animals. Therefore, when using stroke models, it should be as close as possible to achieve the clinical situation, like hypertension, diabetes, heart disease, atherosclerosis, secondary infections, *etc.*, as these diseases may affect the formation, treatment, and prognosis of stroke. To summarize, there are still many animal experiments and clinical trials to be finished before the fact that MSC-Exos can be applied as a routine treatment for stroke. However, based on the available evidence, we believe that MSC-Exos therapy is an emerging therapeutic strategy based on cellular therapy with great potential for future use in IS treatment, particularly in immunomodulation.

Abstract

Cardiomyopathy is a pathological condition characterized by cardiac pump failure due to myocardial dysfunction and the major cause of advanced heart failure requiring heart transplantation. Although optimized medical therapies have been developed for heart failure during the last few decades, some patients with cardiomyopathy exhibit advanced heart failure and are refractory to medical therapies. Desmosome, which is a dynamic cell-to-cell junctional component, maintains the structural integrity of heart tissues. Genetic mutations in desmosomal genes cause arrhythmogenic cardiomyopathy (AC), a rare inheritable disease, and predispose patients to sudden cardiac death and heart failure. Recent advances in sequencing technologies have elucidated the genetic basis of cardiomyopathies and revealed that desmosome-related cardiomyopathy is concealed in broad cardiomyopathies. Among desmosomal genes, mutations in *PKP2* (which encodes PKP2) are most frequently identified in patients with AC. *PKP2* deficiency causes various pathological cardiac phenotypes. Human cardiomyocytes differentiated from patient-derived induced pluripotent stem cells (iPSCs) in combination with genome editing, which allows the precise arrangement of the targeted genome, are powerful experimental tools for studying disease. This review summarizes the current issues associated with practical medicine for advanced heart failure and the recent advances in disease modeling using iPSC-derived cardiomyocytes targeting desmosome-related cardiomyopathy caused by *PKP2* deficiency.

Core Tip: Prevention of advanced heart failure caused by cardiomyopathy is an urgent unmet need in the field of cardiovascular medicine. Desmosome, a cell-to-cell junctional component, maintains the structural integrity of heart tissues. Genetic mutations in desmosomal genes cause desmosome-related cardiomyopathy, an intractable disease refractory to standard medical therapies. This review introduces the recent advances in disease modeling of desmosome-related cardiomyopathy caused by *PKP2* mutations using induced pluripotent stem cell-derived cardiomyocytes.

INTRODUCTION

Heart failure is a clinical syndrome characterized by dyspnea, malaise, swelling, and/or decreased exercise capacity owing to impaired cardiac pumping function[1]. The established optimal medical therapies for heart failure have increased the survival rates of patients in the last few decades[2-4]. However, some patients are refractory to medical therapies and develop symptoms that are diagnosed as advanced heart failure. Currently, the therapeutic strategies available for these patients are heart transplantation and implantation of the ventricular assisting device[1,5]. Cardiomyopathy is a disease of cardiac pump failure due to myocardial dysfunction and is the major cause of advanced heart failure requiring heart transplantation[6-11]. Cardiomyopathies are differentially diagnosed mainly by using imaging modalities, including echocardiography, scintigraphy, computed tomography, magnetic resonance imaging, and cardiac catheterization. Based on the findings of these modalities, cardiomyopathies are classified into dilated cardiomyopathy (DCM), hypertrophic cardiomyopathy (HCM), restrictive cardiomyopathy (RCM), or other rare cardiomyopathies, such as arrhythmogenic right ventricular cardiomyopathy (ARVC)[12]. Among 36,883 heart transplantation recipients registered in the International Society for Heart and Lung Transplantation Thoracic Organ Transplant Registry between 2010 and 2018, the major primary diagnoses were non-ischemic DCM (50.8%), ischemic cardiomyopathy (ICM) (32.4%) with coronary artery disease, RCM (3.5%), and HCM (3.4%)[13]. In Japan, cardiomyopathies [DCM (64%), end-stage HCM with left ventricular systolic dysfunction (12%), and ICM (9%)] account for more than three-quarters of underlying diseases among heart transplant recipients[14]. ARVC, a rare inherited disease, is characterized by the risk of life-threatening arrhythmias, myocardial dysfunction, and fibrofatty replacement of myocardial tissue, predisposing the patients to sudden cardiac death and heart failure[9,11]. The prevalence of ARVC among the registrants for heart transplantation is rare (0.3% and 1%-2% in the United Network for Organ Sharing registry[15] and Japan Organ Transplant Network[14], respectively).

DESMOSOME-RELATED CARDIOMYOPATHY IS CONCEALED IN ADVANCED HEART FAILURE

Recent clinical studies utilizing high-throughput sequencing technologies have elucidated the genetic basis of cardiomyopathies, identified various causative genetic variants, and revealed the correlation between genetic factors and clinical phenotypes or cardiac morphologies in patients with cardiomyopathies[16-20]. ARVC is an inherited disease caused by mutations in desmosomal genes (*PKP2*, *JUP*, *DSC2*, *DSG2*, and *DSP*) (Figure 1)[11,21,22]. These genes encode the structural components of the desmosome, a dynamic junction between cells that maintain the structural integrity of heart tissues[23,24]. The original disease phenotypes of ARVC are characterized by predominant right ventricular enlargement and contractile dysfunction. However, recent studies have reported left ventricular or biventricular involvement in patients with ARVC, resulting in the use of a broad phrase [arrhythmogenic cardiomyopathy (AC)][9,11]. Although the prevalence of AC in patients with advanced heart failure is rare, recent genetic analyses in large cohorts have demonstrated an increased incidence of desmosomal gene mutations in patients with DCM[18,25,26], which is the most frequent basal disease among heart transplantation registrants. Furthermore, homozygosity and compound or digenic heterozygosity of desmosomal genes are not rare, and patients with combined mutations exhibit a severe phenotype[27-30]. Recently, we identified *DSG2*-deficient cardiomyopathy caused by a rare homozygous stop-gain mutation in a patient initially diagnosed with idiopathic sporadic DCM[30]. *Dsg2* deficiency is associated with embryonic lethality in mice. Additionally, *Dsg2*-depleted embryonic stem cells do not proliferate[31]. However, a human male patient with a complete lack of *DSG2*

Figure 1 Modeling impaired desmosome assembly and reduced contractility using isogenic induced pluripotent stem cell-derived cardiomyocytes with the precisely adjusted dose of *PKP2*. Heterozygous frameshift mutation in patient-derived induced pluripotent stem cells (iPSCs) was repaired through homology-directed repair. Homozygous frameshift mutations were introduced in *PKP2* through non-homologous end joining in patient-derived iPSCs. The generated isogenic iPSC-derived cardiomyocytes with the precisely adjusted expression of *PKP2* recapitulated impaired desmosome assembly and reduced contractility caused by *PKP2* deficiency. Desmosomal cadherin proteins (DSG2 and DSC2) form homo-dimers and hetero-dimers. PKP2 is a scaffold protein for desmosomal cadherins, JUP, and DSP. Desmosomes are linked to sarcomere structure *via* the intermediate filament protein DES that targets both desmosome and Z disc structure. HDR: Homology-directed repair; NEHJ: Non-homologous end joining; Hetero: Heterozygous mutation.

expression did not exhibit pathological phenotypes at birth but developed advanced heart failure during the teenage years. Immunohistochemical and transmission electron microscopy analyses of left ventricular heart tissues revealed that the loss of *DSG2* leads to aberrant deposition of desmosomal proteins and disruption of intercalated discs in cardiomyocytes. These findings suggest that desmosome-related cardiomyopathy is concealed in patients with advanced heart failure who are diagnosed with idiopathic DCM. As desmosome impairment is the most upstream molecular change in these patients, experimental studies must focus on elucidating the molecular mechanisms underlying the instability of cell-to-cell junctions to overcome advanced heart failure caused by desmosome-related cardiomyopathy. For disease modeling, patient-derived induced pluripotent stem cells (iPSCs) in combination with genome editing, which allows precise genomic modification of the targeted mutations, are powerful experimental tools to recapitulate pathological phenotypes based on the molecular factors of inherited cardiomyopathies[30,32-35].

PHENOTYPIC RECAPITULATION OF CARDIOMYOPATHY CAUSED BY PKP2 DEFICIENCY USING PATIENT-DERIVED IPSC-CMS

PKP2, which is encoded by *PKP2*, is a desmosomal protein localized to the outer dense plaque and functions as a scaffold for the other desmosome proteins DSG2, DSC2, JUP, and DSP[23,36] (Figure 1). Among the desmosomal genes, mutations in *PKP2* are most frequently identified in patients with AC [11,37-39], and have been extensively studied using patient-derived iPSC-CMs compared to other desmosomal genes (*DSG2*[30,40,41], *DSP*[42,43], and *DSC2*[44,45]). Various clinical phenotypes and pathological characteristics observed in patients with AC harboring *PKP2* mutations, downregulated desmosomal protein expression, upregulated lipogenesis, and increased apoptosis in heart tissues have been recapitulated using genetically engineered mouse models[11] and human cardiomyocytes differentiated from iPSCs[46-54] (Table 1). Most known mutations of *PKP2* are heterozygous and are missense, nonsense, and frameshift mutations. Studies on patient-derived iPSCs have identified that *PKP2* variants are heterozygous missense[48], heterozygous frameshift[46,47,49,50,54], homozygous frameshift[47,51], compound heterozygous, and frameshift[52] mutations. Disease-specific iPSCs are generated from fibroblasts[46-48,51], keratinocytes[49], adipose tissue-derived stromal cells[52], and peripheral blood mononuclear cells[54], whereas control iPSCs are generated from healthy subjects[46-49,51,52], human embryonic stem cells[50], or isogenic cells engineered from patient-derived iPSCs using genome editing[54]. Genome editing allows disease modeling by introducing heterozygous and

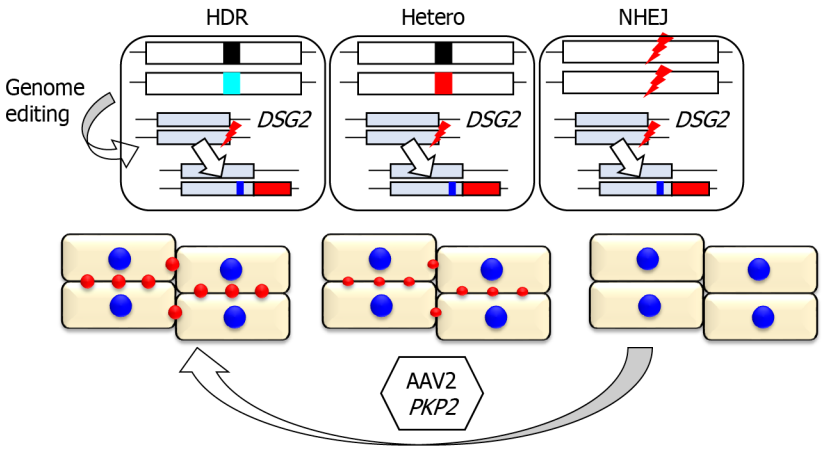
Gender of the patient or control donor is indicated if specified. Analytical methods along with time post-cardiomyocyte differentiation (if specified) are indicated. AAV: Adeno-associated virus; iPSC: Induced pluripotent stem cell; iPSC-CMs: Induced pluripotent stem cells-derived cardiomyocytes; PI: Propidium iodide; TEM: Transmission electron microscopy; NA: Not applicable; AC: Arrhythmogenic cardiomyopathy.

homozygous frameshift mutations in wild-type iPSC lines[53]. Decreased expression of desmosomal proteins, aberrant lipogenesis, and apoptosis of cardiomyocytes are observed in the heart tissues of patients with AC[9,55,56]. These pathological phenotypes are recapitulated in iPSC-CMs with *PKP2* mutations as determined using immunostaining[46-54], lipid staining[47-50], electron microscopy[46, 54], terminal transferase dUTP nick end labeling staining[46,47], and cleaved-CASP3 expression analysis [54]. Lethal arrhythmia is a hallmark of patients with AC. Arrhythmia phenotypes are recapitulated using iPSC-CMs with *PKP2* mutations as evidenced by the results of patch-clamp[48,52], multielectrode array[46], calcium imaging[47], and optical voltage recording[53]. In clinical settings, global or regional ventricular contractile dysfunction is defined as a major criterion for the diagnosis of ARVC in modified Task Force criteria[21] and Padua criteria[57]. However, the functional consequence in cardiomyocyte contractility caused by *PKP2* mutations has not been fully studied in human iPSC-CMs.

PKP2 DEFICIENCY AND CONTRACTILE DYSFUNCTION

We established iPSCs from a patient with AC harboring a heterozygous frameshift *PKP2* mutation



(c.1228dupG, p.D410fsX425) and generated an isogenic set of iPSC clones harboring three genotypes [heterozygous mutation (Hetero), homozygously corrected with homology-directed repair (HDR), and homozygously introduced frameshift mutations *via* non-homologous end joining (NHEJ)] using genome editing[54] (Figure 1). These isogenic sets of iPSCs comprise patient-derived Hetero-iPSCs, HDR-iPSCs with two-fold higher *PKP2* expression relative to Hetero-iPSCs, and NHEJ-iPSCs, which do not express *PKP2*, recapitulating both haploinsufficiency and complete loss of *PKP2*. After cardiomyocyte differentiation using the monolayer protocol with chemically defined medium[58], NHEJ-iPSC-CMs lacking *PKP2* expression exhibit lipid droplet accumulation, increased apoptosis, and decreased propagation rate (Table 1). However, patient-derived Hetero-iPSC-CMs with half-dose *PKP2* expression do not exhibit these pathological phenotypes, suggesting that the haploinsufficiency of *PKP2* is not sufficient to induce the above pathological phenotypes within 28 days after differentiation. In contrast, haploinsufficiency of *PKP2* decreased contractility, which was evaluated using motion vector analysis, within 14 days of differentiation. As the monolayer protocol confers strong contraction to iPSC-CMs on culture plates immediately after differentiation[58,59], continuous tensile overload may facilitate the contractile phenotype among isogenic iPSC-CMs. A recent study used isogenic iPSC-CMs in which heterozygous or homozygous frameshift mutation was introduced into wild-type iPSC-CMs[53]. The authors reported that *PKP2* deficiency decreased systolic force in three-dimensional cardiac microtissues. This further supported the functional relationship between *PKP2* deficiency and contractile dysfunction. An experimental study using cardiac tissue-specific *Pkp2* knockout mice demonstrated that the loss of *Pkp2* increased the distance between the cell periphery and DES, an intermediate filament protein in cardiomyocytes[60]. As DES connects Z-discs of sarcomeres to sarcolemmal costameres, desmosomes, and nuclear envelope[11,61], further experimental studies focusing on these cellular networks are required to elucidate the pathogenesis of desmosome-related cardiomyopathy.

DESMOSOME IMAGING USING THE ISOGENIC IPSC-CMS AND AAV-MEDIATED GENE REPLACEMENT

In the isogenic background, the haploinsufficiency of *PKP2* did not affect the localization or expression levels of desmosomal proteins in iPSC-CMs as evidenced by the results of immunostaining or western blotting analyses. However, the desmosome area represented by dot distribution on the cell periphery in Hetero-iPSC-CMs was significantly lower than that in HDR-iPSC-CMs[54], suggesting that desmosome assembly is impaired by *PKP2* haploinsufficiency. The impaired assembly of desmosomal proteins in human iPSC-CMs is supported by another study using isogenic iPSC-CMs. Fluorescence recovery after photobleaching experiments combined with lentivirus-mediated expression of fluorescent protein-tagged N-cadherin provided evidence that molecular stability of junctional N-cadherin is impaired by *PKP2* deficiency[53]. To trace the molecular behavior of endogenous proteins in cardiomyocytes, fluorescent tagging of the structural proteins through genome editing is a powerful tool[62,63]. However, fluorescent tagging of endogenous desmosomal genes might affect desmosome structures or cell-to-cell integrity in iPSCs or iPSC-CMs. We previously identified a patient with *DSG2*-deficient cardiomyopathy due to a rare homozygous stop-gain mutation and demonstrated that complete loss of *DSG2* in human iPSCs does not affect the differentiation or cellular morphology in iPSC-CMs[30]. These findings prompted us to use *DSG2* as the target of endogenous tagging by fluorescent protein to trace desmosome dynamics in live human iPSC-CMs. Genome editing targeting *DSG2* alleles was performed to establish the isogenic iPSC-CMs harboring identical two *DSG2* alleles comprising intact and knocked-in tdTomato alleles under the adjusted *PKP2* expression levels (Figure 2). The desmosome area (represented by desmoglein-2-tdTomato fusion protein) was significantly downregulated due to *PKP2* haploinsufficiency. Adeno-associated virus (AAV), a small, nonenveloped virus with a linear, single-stranded DNA, is widely used for gene therapy targeting human diseases, including heart failure[64,65]. AAV-mediated gene replacement of *PKP2* significantly restored the decreased contractility in Hetero-iPSC-CMs and NEHJ-iPSC-CMs, demonstrating the proof-of-concept for *PKP2* gene therapy in human cells. Furthermore, time-lapse imaging using NHEJ-iPSC-CMs captured the recovery of desmosomes, which gradually assembled at the cell periphery after AAV-mediated *PKP2* replacement (Figure 2). The established isogenic iPSCs harboring knocked-in tdTomato alleles allowed desmosome-imaging in living cells and provided distinct readouts for therapeutic development.

GENE REPLACEMENT THERAPY TARGETING HEART FAILURE

Several clinical trials using AAV-mediated gene replacement have been designed targeting cardiovascular disease[65,66]. A large-scale clinical trial was conducted as a randomized, multinational, double-blind, placebo-controlled phase 2 study targeting up to 250 patients with moderate-to-severe heart failure and reduced contractile function (CUPID2 trial)[67]. The study aimed to deliver

Figure 2 Allele-specific fluorescent labeling of *DSG2* captures desmosome dynamics in isogenic induced pluripotent stem cell-derived cardiomyocytes. To establish a model for desmosome imaging, the tdTomato fluorescent reporter was knocked-in at the 3'-terminus of *DSG2* in the three established isogenic induced pluripotent stem cells (iPSCs) using genome editing. These isogenic iPSCs carried identical *DSG2* alleles comprising intact and knocked-in alleles distinguished by a synonymous single nucleotide variant (indicated as blue line). These iPSC-derived cardiomyocytes enable desmosome imaging and capturing desmosome recovery after adeno-associated virus-mediated replacement of *PKP2*. HDR: Homology-directed repair; NEHJ: Non-homologous end joining; AAV: Adeno-associated virus; Hetero: Heterozygous mutation.

sarcoplasmic reticulum Ca^{2+}-ATPase (SERCA2a) into heart tissues *via* intracoronary injection. SERCA2a regulates cardiomyocyte contraction and relaxation by transporting Ca^{2+} from the cytosol into the sarcoplasmic reticulum during diastole[68]. The deficiency of SERCA2a is associated with heart failure progression[69,70]. Although promising results were achieved in preceding preclinical and clinical studies[71-73], gene replacement of SERCA2a did not improve the clinical course of patients with heart failure[74]. The two clinical trials of gene therapy targeting patients with heart failure conducted in the same period (AGENT-HF[75] and SERCA-LVAD[76]) were terminated due to the neutral result of the CUPID2 trial and the lack of functional benefit. The amount of vector DNA in heart tissues obtained from patients who received gene therapy and subsequently underwent heart transplantation or mechanical circulatory support device implantation was low, suggesting that only a small proportion of cardiomyocytes expressed AAV-delivered SERCA2a in the myocardium. Although these clinical trials demonstrate the difficulty of gene delivery targeting human heart tissues, they provide the evidence for the safety of cardiac gene therapy and a basis for the design of future gene therapy trials. Recent genetic analysis clarified a large number of genetic mutations that cause cardiomyopathies with advanced heart failure in a loss-of-function manner and can be targeted by specific gene replacement therapy[77,78]. In desmosome-related cardiomyopathy, most of the identified mutations in *PKP2* are heterozygous[22,37,79,80]. However, in extremely rare cases, homozygous mutations of *PKP2* cause lethal infantile heart failure with left ventricular non-compaction or hypoplastic left heart syndrome[81-83]. No effective therapies are available for these patients who require a novel therapeutic approach for desmosome-related cardiomyopathy. Proof-of-concept studies for structural and functional recovery using both human iPSC-CM models and *in vivo* models are required for future clinical application.

CONCLUSION

Although human iPSC-CMs are immature and do not fully recapitulate *in vivo* heart tissues[59], tissue engineering approaches[84,85] will promote the maturation of iPSC-CMs and provide a useful tool in combination with genome editing. The isogenic iPSC-CMs that we established represent a human disease model that recapitulates reduced contractility and impaired desmosome assembly and provides a convenient cellular platform for therapeutic screening to examine upstream molecular targets of desmosome-related cardiomyopathy.

ACKNOWLEDGEMENTS

The Department of Medical Therapeutics for Heart Failure was an endowment department supported by Actelion Pharmaceuticals Japan (2015–2020).

FOOTNOTES

Author contributions: Higo S wrote the manuscript; the author has read and approved the final manuscript.

Supported by JSPS KAKENHI, No. 20K21602, No. 21H02915, and No. 22K19526; the Japan Agency for Medical Research and Development, No. 21bm0804008h0005; the Cell Science Research Foundation; the Grant for Basic Research of the Japanese Circulation Society (2018); and SENSHIN Medical Research Foundation.

Conflict-of-interest statement: Department of Medical Therapeutics for Heart Failure is a Joint Research Department with TOA EIYO Pharmaceutical Company. Dr. Higo reports grants from TOA EIYO Pharmaceutical Company, during the conduct of the study.

Abstract

Osteoporosis is a systemic bone disease, which leads to decreased bone mass and an increased risk of fragility fractures. Currently, there are many anti-resorption drugs and osteosynthesis drugs, which are effective in the treatment of osteoporosis, but their usage is limited due to their contraindications and side effects. In regenerative medicine, the unique repair ability of mesenchymal stem cells (MSCs) has been favored by researchers. The exosomes secreted by MSCs have signal transduction and molecular delivery mechanisms, which may have therapeutic effects. In this review, we describe the regulatory effects of MSCs-derived exosomes on osteoclasts, osteoblasts, and bone immunity. We aim to summarize the preclinical studies of exosome therapy in osteoporosis. Furthermore, we speculate that exosome therapy can be a future direction to improve bone health.

Key Words: Mesenchymal stem cells; Exosome; Osteoporosis; Osteoblasts; Osteoclasts; Bone immunity

Core Tip: Osteoporosis is one of the major diseases endangering bone health in the elderly. The existing treatment drugs have problems such as long-term administration and side effects; thus, it is fundamentally difficult to cure osteoporosis. Exosomes derived from mesenchymal stem cells (MSCs) are vesicles that deliver signals and molecules between cells and have shown substantial positive effects in pre-clinical trials. In this review, we summarize the latest progress of MSCs-derived exosomes in the regulation of bone metabolism.

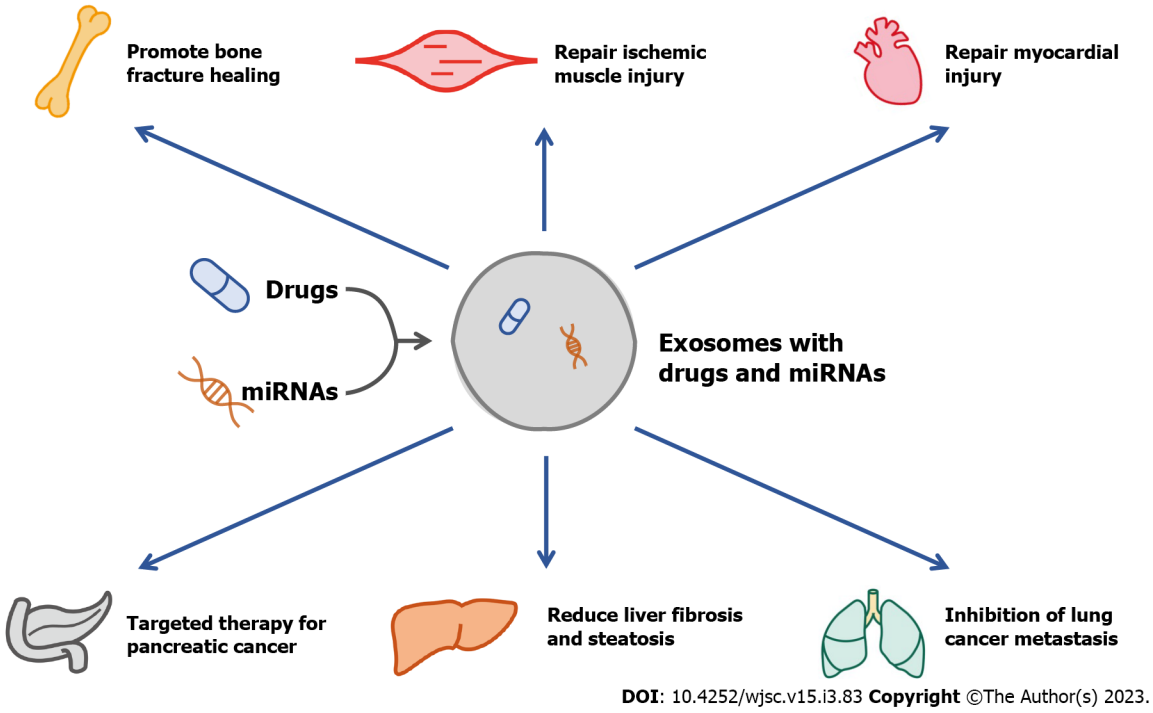
INTRODUCTION

Osteoporosis (OP) is a chronic systemic bone disease. It is characterized by decreased bone mass and destruction of bone microstructures, resulting in decreased bone mineral density (BMD) and ultimately an increased risk of fragility fractures[1]. The dynamic balance between bone formation and bone resorption is an important way to maintain normal bone metabolism. Osteoblasts promote bone formation by mineralizing the matrix, while osteoclasts degrade the bone matrix by secreting H+ and releasing cathepsin K, accelerating bone dissolution[2].

At present, the prevention and treatment of OP can be divided into adjuvant therapy and drug therapy. The therapeutic effects of drugs are mainly divided into two aspects: Inhibition of osteoclasts (inhibition of bone resorption) and stimulation of osteoblasts (promotion of bone formation). Among them, the drugs that inhibit bone resorption are denosumab, bisphosphonates and selective estrogen receptor modulators; and drugs that promote bone formation are teriparatide and abaloparatide. Romosozumab, a monoclonal antibody directed against sclerostin, has a dual regulatory effect, inhibiting bone resorption and promoting bone formation at the same time[3].

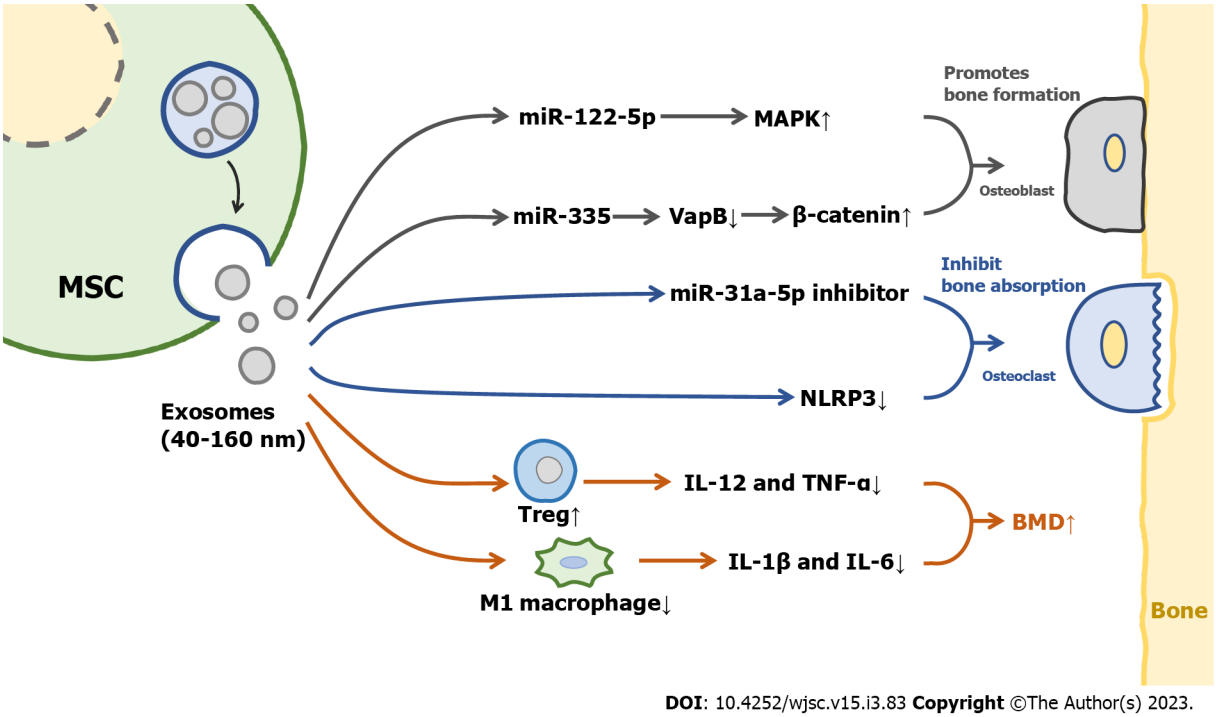
Although a variety of therapeutic drugs for OP have emerged, all the drugs mentioned above have side effects[4], and more novel and effective drugs and therapies are needed. There are new advances in the research on stem cells and their exosomes in tissue repair and treatment. Therefore, the new scheme of MSCs-derived exosomes for the treatment of OP has gradually become a therapeutic option[5].



EXOSOMES AND MESENCHYMAL STEM CELLS

Exosomes are small vesicles secreted by cells with a diameter of 40 to 160 nm, which carry signals and molecules among cells. In addition, the exosomes secreted by the cells in diseased states contain specific microRNAs (miRNAs), which is helpful for the diagnosis of diseases[6]. As a carrier of signal transduction and drug delivery, exosomes also have good potential in the treatment of diseases, and their effectiveness has been confirmed by numerous animal studies[7-13] (Figure 1). In 1974, Friedenstein *et al*[14] first discovered that mesenchymal stem cells (MSCs) in bone marrow have the potential for osteogenic differentiation. Later, researchers continued to explore the function of MSCs and found that MSCs are pluripotent stem cells, which have the ability to differentiate into osteoblasts, adipocytes, chondrocytes, cardiac muscle cells and skeletal muscle cells[15]. Previous studies have found that therapy with MSCs can accelerate bone tissue repair and regeneration and maintain bone mass in OP[16,17].

MSCs-derived exosomes are likely to play a major role in mediating the therapeutic effect of MSCs [18,19]. A schematic diagram illustrating the mechanisms of MSCs-derived exosomes in the treatment of OP is shown in Figure 2. Therefore, MSCs-derived exosomes are expected to be a new biological agent in the future.



MSCS-DERIVED EXOSOMES IN THE TREATMENT OF OP

Exosomes have the characteristics of good targeting ability, high permeability and low toxicity. Therefore, exosomes therapy has become one of the hot spots in the study of OP treatment. Bone regeneration is one of the main modalities in the treatment of OP and bone fracture. MSCs-derived exosomes can promote the formation of new bone with vasculature, biomechanics, and histology[20]. MSCs-derived exosomes regulate bone metabolism and treat OP through signaling pathways, such as stimulating osteoblast differentiation from bone marrow stem cells, promoting osteoblast proliferation,

inducing angiogenesis, and immunomodulation[21]. During treatment, MSCs-derived exosomes achieve the purpose of bone regeneration and treatment of OP by carrying and transporting proteins, miRNAs, and artificial synthetic drugs[22-24]. According to the pathogenesis of OP, exosomes are mainly involved in regulating the effects of osteoblasts, osteoclasts and bone immunity (Table 1).

Table 1 Summary of studies on mesenchymal stem cells-derived exosomes in osteoporosis treatment

Ref.	Exosome source	Cell type	Consequence
Zuo *et al*[24], 2019	BMSCs	BMSCs (after irradiation)	Alleviating radiation-induced bone loss by restoring Wnt/β-Catenin signaling pathway
Zhao *et al*[25], 2018	BMSCs	Osteoblasts (hFOB 1.19)	Promoting proliferation of osteoblasts *via* MAPK pathway
Liao *et al*[26], 2019	BMSCs	Osteoblasts	Promoting proliferation of osteoblasts by carrying miR-122-5p
Qi *et al*[27], 2016	hiPSC-MSCs	Osteoblasts	Promoting osteoblast proliferation, differentiation and bone formation
Hu *et al*[28], 2021	BMSCs	Osteoblasts	Promoting differentiation of osteoblasts by carrying miR-335
Zhang *et al*[31], 2021	AD-MSCs	Osteoclasts	Inhibiting NLRP3 inflammasome activation in osteoclasts
Nakao *et al*[32], 2021	GMSCs	Osteoclasts	Inhibiting RANKL and reducing osteoclast formation by carrying miR-1260b *via* Wnt5a/JNK signal pathway
Xu *et al*[33], 2018	BMSCs	Osteoclasts	Increasing the number of osteoclasts by carrying miR-31a-5p *via* RhoA pathway
Wei *et al*[40], 2019	BMSCs	Osteoblasts	Promoting osteoblast differentiation by inhibiting macrophage polarization and reducing the levels of inflammatory factors

BMSCs: Bone marrow mesenchymal stem cells; hiPSC-MSCs: Mesenchymal stem cells derived from human induced pluripotent stem cells; AD-MSCs: Adipose derived mesenchymal stem cells; GMSCs: Gingival tissue-derived mesenchymal stem cells; MAPK: Mitogen-activated protein kinase; NLRP3: NLR family pyrin domain containing 3; RANKL: Receptor activator of NF-κB ligand; Wnt5a: Wnt family member 5A; JNK: c-Jun N-terminal kinases.

EFFECTS OF MSCS-DERIVED EXOSOMES ON OSTEOBLASTS

Osteoblasts are derived from pluripotent MSCs, which are major functional cells in bone matrix synthesis, secretion, and mineralization. Exosomes can directly regulate the activity of osteoblasts and then affect OP. MSCs-derived exosomes promoted the cell cycle of hFOB 1.19 cells, a type of osteoblast, and activated their proliferative activity through the MAPK pathway[25]. It was also found that overexpression of miR-122-5p in MSCs-derived exosomes of bone marrow can increase the BMD of the femoral head through the MAPK pathway[26]. Co-culture of MSCs-derived exosomes with bone marrow MSCs from osteoporotic rats resulted in increased levels of osteogenesis-related proteins and mineral deposition; in addition, the use of MSCs-derived exosomes promoted bone regeneration in a rat model of calvarial defects[27]. One study showed that the infusion of bone marrow MSCs-derived exosomes carrying miR-335 into mice with fractures significantly accelerated fracture healing, as miR-335 in exosomes was able to inhibit VapB, activate the Wnt/β-catenin pathway, and promote osteoblast differentiation[28]. Notably, exosomal miRNAs derived from MSCs are critical in regulating the function of osteoblasts. These miRNAs participate in and regulate some key signaling pathways and alter protein expression in osteoblasts. The positive roles of exosomes in osteoblast proliferation and differentiation, and the excellent therapeutic performance of exosomes in bone repair and bone mass recovery, indicate the potential of MSCs-derived exosomes in the treatment of OP.

EFFECTS OF MSCS-DERIVED EXOSOMES ON OSTEOCLASTS

Osteoclasts originate from hematopoietic progenitor cells in the bone marrow, and play an osteolytic role by secreting H+ and cathepsin K[29,30]. Adipose MSCs-derived exosomes inhibited NLRP3 in the osteoclasts of diabetic OP rat models and increased BMD[31]. RANKL is a major factor in promoting the differentiation of preosteoclasts into osteoclasts, gingiva MSCs-derived exosomes can target Wnt5a in periodontal osteoclasts and inhibit the expression of RANKL, thus reducing the differentiation of osteoclasts[32]. Of course, as a carrier of miRNA, exosomes will also have an effect on osteoclasts by carrying miRNA. Bone marrow MSCs-derived exosomes delivered miR-31a-5p to osteoclasts, which increased osteoclast number and bone resorption. In addition, BMD significantly increased in a rat model treated with miR-31a-5p inhibitor[33]. These findings suggested that MSCs-derived exosomes can regulate osteoclast differentiation, increase bone density, and inhibit OP. Notably, bone marrow stromal cell-derived exosomes do not have any effect on osteoclasts at the surface of trabecular bone, and therefore do not play a role in preventing bone resorption[34]. There are few studies on the regulation of osteoclast differentiation by MSCs-derived exosomes. Therefore, we need to further explore the potential of MSCs-derived exosomes in the treatment of OP by regulating osteoclast differ-

entiation.

EFFECTS OF MSCS-DERIVED EXOSOMES ON BONE IMMUNITY

There is an intricate relationship between the immune system and the skeletal system. Activated immune cells release inflammatory mediators and cytokines that upset the balance of bone remodeling and activate osteoclasts, leading to bone loss and OP[35,36]. MSCs-derived exosomes can regulate the immune system[37]. After treatment with adipose MSCs-derived exosomes in mice with colitis, regulatory T cells returned to normal baseline level, and the levels of inflammatory factors such as interleukin (IL)-12 and tumor necrosis factor-α reduced[38]. Exosomes derived from adipose and bone marrow MSCs can significantly increase the level of type II collagen in articular cartilage, promote articular cartilage formation and accelerate the recovery of osteoarthritis in mice[39]. MSCs-derived exosomes promote the differentiation of bone marrow MSCs into osteoblasts by inhibiting the polarization of M1 macrophages and reducing the levels of inflammatory cytokines such as Il-1β and IL-6[40]. MSCs-derived exosomes can regulate immunity and inflammation in vivo. Unfortunately, little is known about their role in bone immunity. However, available findings suggest the potential of MSCs-derived exosomes in the treatment of OP by modulating bone immunity.

CONCLUSION

At present, drug treatment of OP still focuses on inhibiting bone resorption and promoting bone formation. Drug therapy has a good effect, but long-term use of drugs can cause serious side effects. In the field of bone regeneration, stem cell therapy has significant efficacy, and exosomes are one of the important carriers of cell information and factors. Therefore, MSCs-derived exosomes may be a promising biological agent in the treatment of OP. This review focuses on the mechanism of MSCs-derived exosomes in the treatment of OP, by delivering miRNA, regulating related targets, and regulating bone immunity. Therefore, the potential of MSCs-derived exosomes in the treatment of OP is anticipated, but further preclinical studies are needed to prove the safety and reliability of exosome therapy and provide strong evidence for the clinical conversion of exosome therapy.

Abstract

BACKGROUND

The low survival rate of mesenchymal stem cells (MSCs) caused by anoikis, a form of apoptosis, limits the therapeutic efficacy of MSCs. As a proapoptotic molecule, mammalian Ste20-like kinase 1 (Mst1) can increase the production of reactive oxygen species (ROS), thereby promoting anoikis. Recently, we found that Mst1 inhibition could protect mouse bone marrow MSCs (mBMSCs) from H_2O_2-induced cell apoptosis by inducing autophagy and reducing ROS production. However, the influence of Mst1 inhibition on anoikis in mBMSCs remains unclear.

AIM

To investigate the mechanisms by which Mst1 inhibition acts on anoikis in isolated mBMSCs.

METHODS

Poly-2-hydroxyethyl methacrylate-induced anoikis was used following the silencing of Mst1 expression by short hairpin RNA (shRNA) adenovirus transfection. Integrin (ITGs) were tested by flow cytometry. Autophagy and ITGα5β1 were inhibited using 3-methyladenine and small interfering RNA, respectively. The alterations in anoikis were measured by Terminal-deoxynucleoitidyl Transferase Mediated Nick End Labeling and anoikis assays. The levels of the anoikis-related proteins ITGα5, ITGβ1, and phospho-focal adhesion kinase and the activation of caspase 3 and the autophagy-related proteins microtubules associated protein 1 light chain 3 II/I, Beclin1 and p62 were detected by Western blotting.

RESULTS

In isolated mBMSCs, Mst1 expression was upregulated, and Mst1 inhibition significantly reduced cell apoptosis, induced autophagy and decreased ROS levels. Mechanistically, we found that Mst1 inhibition could upregulate ITGα5

and ITGβ1 expression but not ITGα4, ITGαv, or ITGβ3 expression. Moreover, autophagy induced by upregulated ITGα5β1 expression following Mst1 inhibition played an essential role in the protective efficacy of Mst1 inhibition in averting anoikis.

CONCLUSION

Mst1 inhibition ameliorated autophagy formation, increased ITGα5β1 expression, and decreased the excessive production of ROS, thereby reducing cell apoptosis in isolated mBMSCs. Based on these results, Mst1 inhibition may provide a promising strategy to overcome anoikis of implanted MSCs.

Key Words: Mouse bone marrow mesenchymal stem cell; Mammalian sterile 20-like kinase 1; Anoikis; Integrin; Autophagy; Reactive oxygen species

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: In isolated mouse bone marrow mesenchymal stem cell (mBMSCs), Mammalian sterile 20-like kinase 1 (Mst1) inhibition could ameliorate not only autophagy formation but also upregulate integrin (ITG) α5β1 expression (but not ITGα4, ITGαv, or ITGβ3). In addition, Mst1 inhibition-induced autophagy could scavenge the excessive production of ITGα5β1-triggered ROS. Therefore, Mst1 inhibition-based infusion may improve the survival of MSCs, thereby serving as an ideal candidate for clinical transplantation in pulmonary arterial hypertension.

INTRODUCTION

Mesenchymal stem cell (MSC) therapy is characterized by anti-inflammatory, immunomodulatory, and regenerative properties, providing an attractive therapeutic approach for pulmonary arterial hypertension (PAH)[1]. Despite the therapeutic potential of MSCs for improving the outcomes of PAH patients[2,3], no more than 5% of cells survive after transplant[4]. Thus, the low survival rate of the grafted cells is widely perceived as the major hindrance for an MSC-based therapy for PAH.

Anoikis occurs when cells detach from the extracellular matrix and subsequently undergo apoptosis, and potentially acts as a major enabling factor for the apoptosis of transplanted cells[5,6]. Indeed, after isolation from the extracellular matrix (ECM) and injection into the circulatory system for transplantation, MSCs will undergo anoikis, also referred to as cell isolation-induced apoptosis, leading to a series of alterations in anoikis signalling pathways[3,7,8]. Anoikis can be induced by destruction of integrin (ITGs) signalling or deletion of ITGs genes[9]. After isolation, focal adhesion kinase (FAK), a key downstream target of ITGs, is recruited to focal adhesion sites, consequently activating cell survival signals, such as blocking caspase 3 expression[10]. However, it remains unknown whether ITGs signalling is involved in the process of anoikis in MSCs.

Autophagy is a dynamic process that maintains homeostasis by preventing the accumulation of excessive biomolecules and impaired cells and organelles. There is accumulating evidence of a link between autophagy and anoikis[11]. Previously, we demonstrated that mammalian Ste20-like kinase 1 (Mst1) inhibition could reduce H_2O_2-induced apoptosis of mBMSCs by inducing autophagy formation [12]. Mst1 is a serine/threonine kinase, known as a key mediator in cellular processes, including mediating the apoptosis[13]. However, the molecular mechanism by which Mst1 inhibition mediates autophagy and anoikis in isolated mBMSCs remains to be clarified.

In this study, we investigated the potential regulatory effect of Mst1 inhibition on ITGs signalling, autophagy and anoikis in isolated mBMSCs.

MATERIALS AND METHODS

Cell culture

The mBMSCs were obtained as previously described[12]. Cultured mBMSCs between passages 3 and 5 were selected for subsequent experiments.

Adenovirus infection

Adenovirus harbouring Mst1 short hair RNA (Ad-sh-Mst1) and the control vector for Mst1 shRNA (Ad-NC-Mst1) were purchased from WZ Biosciences (China). Vector details have been previously described [12]. The shRNA sequence targeting Mst1 in mice was GCCCTCACGTA GTCAAGTATT.

siRNA transfection

The small interfering RNAs (siRNAs) were obtained from GenePharma (China). The sense and antisense strand sequences of siRNA are as follows: Mouse siRNA-ITGα5, 5'-GCAGGGAGA-UGAAGAUCUACC' (sense) and 5'-UAGAUCUUCAUCUCCCUGCAG' (antisense); mouse siRNA-ITGβ 1, 5'-GGAGAACCACAGAAGUUUACA-3' (sense) and 5'-UAAACUUCUGUGGUUCUCCUG-3' (antisense); and siRNA-negative control (NC), 5'-UUCUCCGAACGUGUCACGUTT' (sense) and 5'-ACGUGACACGUUCGGAGAATT-3' (antisense). Subsequently, 24 h after infection with Ad-sh-Mst1, mBMSCs at 75% confluence were transfected with ITGα5, ITGβ1 or NC siRNA (50 nM) using Lipofectamine RNAi MAX (13778500, Invitrogen) according to the manufacturer's instructions. The expression of ITGα5 or ITGβ1 was substantially blocked by the transfected siRNA.

Cell treatment

Petri dishes coated with polyhydroxyethyl methacrylate [Poly-HEMA, 529257, Sigma, United States of America (USA)] were used to prevent cells from adhering to the tissue culture plates. Briefly, poly-HEMA stock material was dissolved in 95% ethanol at a concentration of 12 mg/mL, and 1 mL of 12 mg/mL poly-HEMA was added to each well of a 6-well plate and then dried overnight on a clean bench. Cells were transfected as previously described. Cells (5×10^5) were coated with 12.5 mg/mL poly-HEMA in each well for a certain period of time.

To inhibit autophagy, cells were pretreated with 5 mmol/L 3-MA (189490, Selleck, USA) for 1 h and then cultured in poly-HEMA-precoated plates for a certain period of time.

Assay of intracellular ROS

As mentioned above, cellular ROS were assessed using the ROS probe 2,7-Dichlorodihydrofluorescein diacetate (DCFH-DA), S0033, Beyotime Biotechnology, China)[12]. The mean fluorescence intensity was detected *via* flow cytometry.

Isolation-induced anoikis assay

Anoikis was analysed using an in situ Direct DNA Fragmentation Terminal-deoxynucleoitidyl Transferase Mediated Nick End Labeling (TUNEL) Assay Kit [ab66108, Abcam, The United Kingdom of Great Britain and Northern Ireland (UK)]. After incubation in poly-HEMA-coated plates, the cells were collected and added to 70% ice ethanol for 30 min. Ethanol was then removed, and the cells were resuspended in washing buffer and then stained with a staining solution for 60 min. Prior to the addition of the PI/RNase A solution, the cells were washed twice with rinse buffer. Quantification analysis was performed by BectonDickinson Fluorescence Activating Cell Sorter (BD FACSDiva) software, [Ex/Em = 488/520 nm for fluoresceine isothiocyanate and 488/623 nm for propidium iodide)].

Anoikis was also detected by a CytoSelect™ 24-Well Anoikis Assay (XY-CBA-080, Cell Biolabs, USA) according to the manufacturer's instructions. Briefly, cells (1×10^6 cells/well) were cultured in each well of 24-well plate for 36 h before staining with ethidium homodimer (EthD-1) at 37°C for 1 h. The presence of red EthD-1 fluorescence in dead cells was observed by a fluorescence microscope, and cell viability was determined using a thiazolyl blue tetrazolium bromide (MTT) assay.

Flow cytometry

Cells were incubated in poly-HEMA-coated petri dishes for 36 h, centrifuged at 300 × *g* for 5 min and cultured in antibodies (ITGα4 [1/500 dilution, 553157, BD], ITGα5 [1/500 dilution, 557447, BD], ITGαv [1/300 dilution, 740946, BD], ITGβ1 [1/500 dilution, 561796, BD], ITGβ3 [1/100 dilution, 740677, BD]) for 1 h according to the operation manual.

Cell adhesion

After culture in poly-HEMA-coated petri dishes, the collected cells were resuspended in complete α-MEM and then plated in triplicate (5×10^4 cells/well) onto wells coated with fibronectin (10 g/mL), which was previously blocked with 1% BSA for 1 h. After 6 h, the cells were washed with phosphate belanced solution (PBS) and stained with crystal violet. Unbound dye was removed with PBS before adding a 10% acetic acid solution. The absorbance was read at 630 nm using a Multiskan MK3 microplate reader. The experiment was repeated three times. Cell adhesion was calculated according to the proportion of adhered cells in the control group.

Cytokine levels

The supernatants in each group were collected after culture in poly-HEMA-coated petri dishes for 36 h. The levels of anti-inflammatory cytokines were measured using a BD™ Cytometric Bead Array (CBA)

Mouse Th1/Th2/Th17 Cytokine Kit (561665, BD, USA) in accordance with the instruction manual. The levels of interleukin (IL)-4 (IL-4), IL-10, IL-17A and IL-6 in cell supernatants were measured using flow cytometry. Data analysis was performed as previously described[14].

Nude mouse tumorigenicity

All animal procedures were approved by the Animal Care and Use Committee of Shandong Provincial Hospital Affiliated to Shandong First Medical University (IACUC protocol, Approval No. 2020-333). A total of 10 female nude mice (4 wk old) were purchased from Beijing Vital River Laboratory Animal Technology Co., Ltd. and raised in a specific pathogen-free environment. Mice were placed at a standard room temperature at a normal day-night cycle with free access to standard diet and water. Afterwards, 5.0 × 10^6 mBMSCs (n = 3), mBMSC/NC-Mst1 (n = 3), and mBMSC/sh-Mst1 (n = 4) were injected into the right flank near the hind legs of each nude mouse. The tumours were measured with a Vernier calliper every 4 d. Sixty days after cell inoculation, all mice were anaesthetized with ether, and tissues were collected.

Quantitative real-time polymerase chain reaction (qPCR)

qPCR was performed as previously reported[12]. mBMSCs were differentiated *via* 21-d exposure to osteogenic or adipogenic conditions, and total mRNA from mBMSCs subjected to these conditions and siRNA-transfected cells was isolated using TRIzol Reagent (15596026, Thermo Fisher Scientific, USA). The RNA was subsequently reverse transcribed into cDNA and amplified using the SYBR® Premix Ex Taq™ II kit (RR420, Takara, JPN) and d ABI 7500 real-time PCR system (Applied Biosystems). Each experiment was repeated three times. Data were normalized through the $2^{-\Delta\Delta CT}$ method using the housekeeping gene glyceraldehyde-3-phosphate dehydrogenase. The primer sequences are shown in Supporting Information Supplementary Table 1.

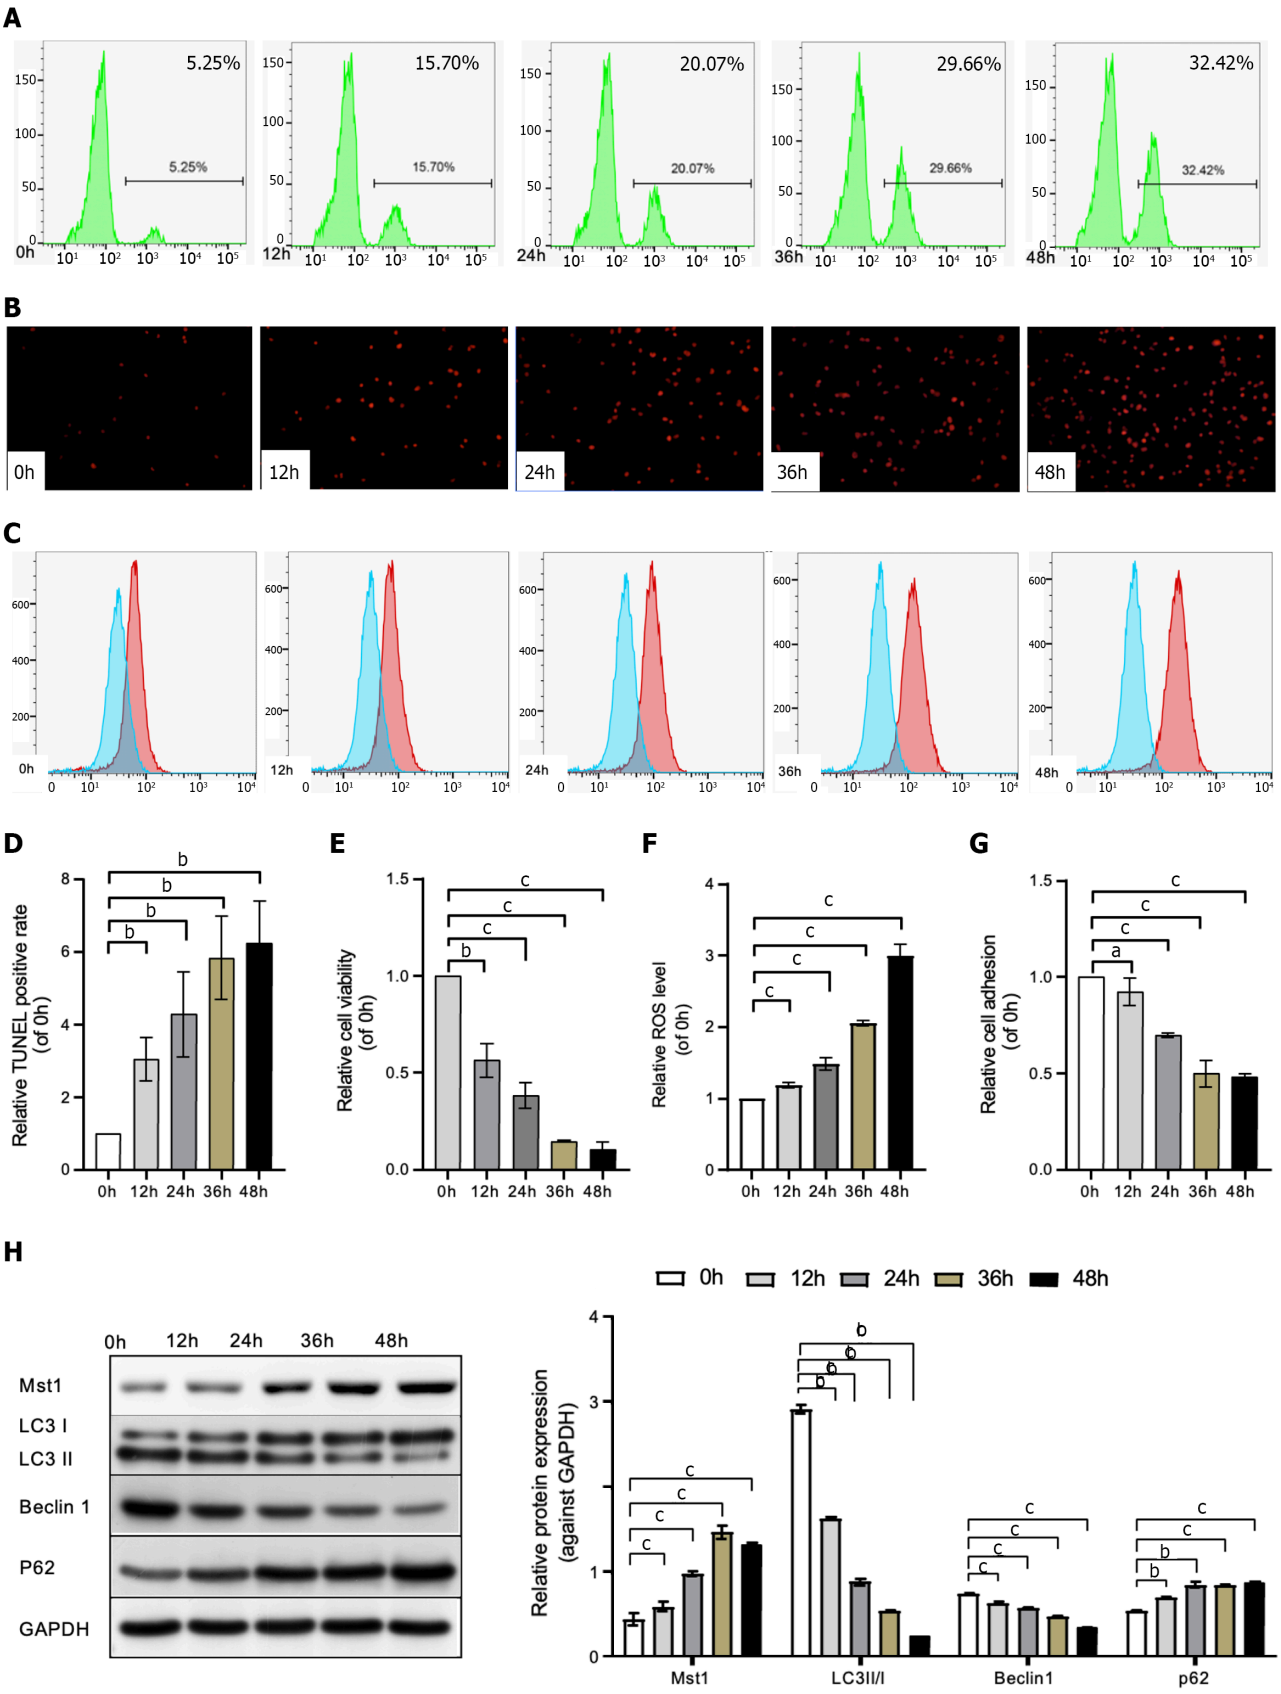
Western blot analysis

To determine protein expression, Western blot analysis was performed. After culture in poly-HEMA-coated plates, whole-cell protein extracts were prepared in radio-immunoprecipitation assay lysis buffer, subjected to sodium dodecyl sulfate-polyacrylamide gel electrophoresis, and transferred onto polyvinylidene fluoride membranes. The membranes were then blocked with 5% skimmed milk or Bovine serum albumin in Tris-Buffered Saline Tween-20 for 1 h and incubated overnight at 4 °C with the following primary antibodies (diluted by Western Primary Antibody Buffer, P0023A, Beyotime): Mst1 (1:1000, ab51134, Abcam), ITGα5 (1:1000, ab150361, Abcam), ITGβ1 (1:1000, ab179471, Abcam), phospho-FAK (Tyr397) [1:500, 3283S, Cell Signaling Technology (CST)], FAK (1:1,000, 3285S, CST), activated caspase 3 (1:1000, ab214430, Abcam), and caspase 3 (1:1000, ab18297, Abcam). GAPDH (1:1000, 5174S, CST) served as the loading control. Anti-rabbit IgG and HRP-linked antibodies (1:1000, 7074S, CST) were used. The relative protein expression levels were compared with GAPDH using ImageJ software.

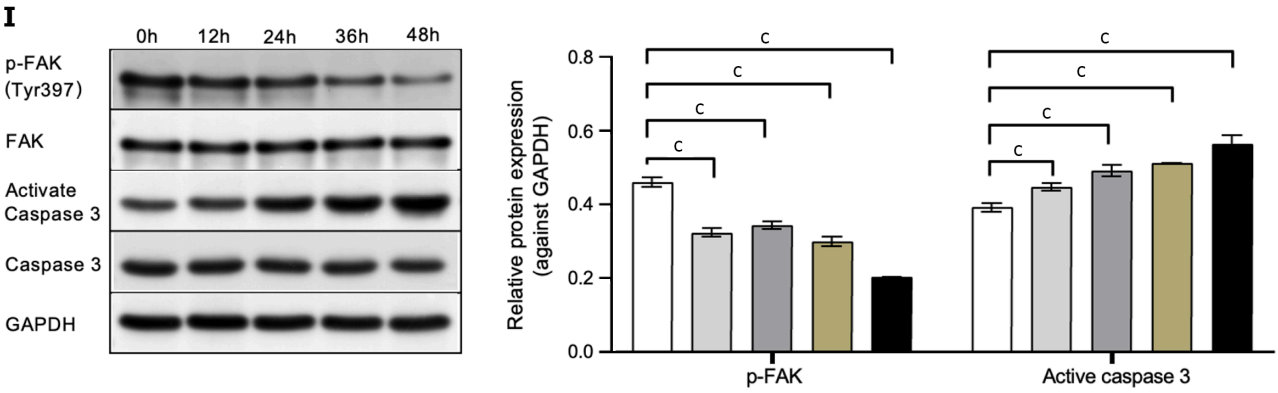
Statistical analysis

All results are expressed as the mean ± SD. One-way Analysis of Variance was used for data analysis. $P < 0.05$ was considered statistically significant.

RESULTS



The loss of attachment to ECM increased the rate of aberrant cell apoptosis, ROS levels, and Mst1 expression and inhibited autophagy in mBMSCs



As the ability to reduce cell adhesivity to culture plates, Poly-HEMA was used to simulate an anchorage-independent culture condition. In present study, the sensitivity of mBMSCs to anoikis in Poly-HEMA-pre-coated condition were tested.

Using the TUNEL and Anoikis Assay Kit, the results showed an increased rate of mBMSC apoptosis in a time-dependent manner under poly-HEMA-induced isolated conditions (Figures 1A, B, D and E), suggesting that anoikis of mBMSCs could be induced in precoated poly-HEMA plates. In addition, the cell adhesion decreased at 24 h, 36 h, and 48 h compared with that at 0 h (Figure 1G).

Moreover, staining of intracellular ROS with the ROS probe DCFH-DA showed increased ROS levels at 24, 36, and 48 h compared with 0 h (Figures 1C and F), demonstrating the production of ROS in poly-HEMA-induced isolated mBMSCs.

To determine the alterations in Mst1 expression, autophagy and the FAK/Caspase 3 pathway in mBMSCs under isolated conditions, the protein level of Mst1, autophagy-related proteins (LC3 II/I, Beclin1, p62), p-FAK, and activated caspase 3 was detected by Western blot analysis. The data suggested that Mst1 was upregulated in isolated mBMSCs (Figure 1H). Moreover, the expression of p-FAK decreased, and the activation of caspase 3 increased in a time-dependent manner (Figure 1I). Similarly, LC3 II/I and Beclin1 expression was downregulated, and p62 expression was upregulated in a time-dependent manner (Figure 1H).

Mst1 inhibition upregulated ITGα5 and ITGβ1 expression in isolated mBMSCs

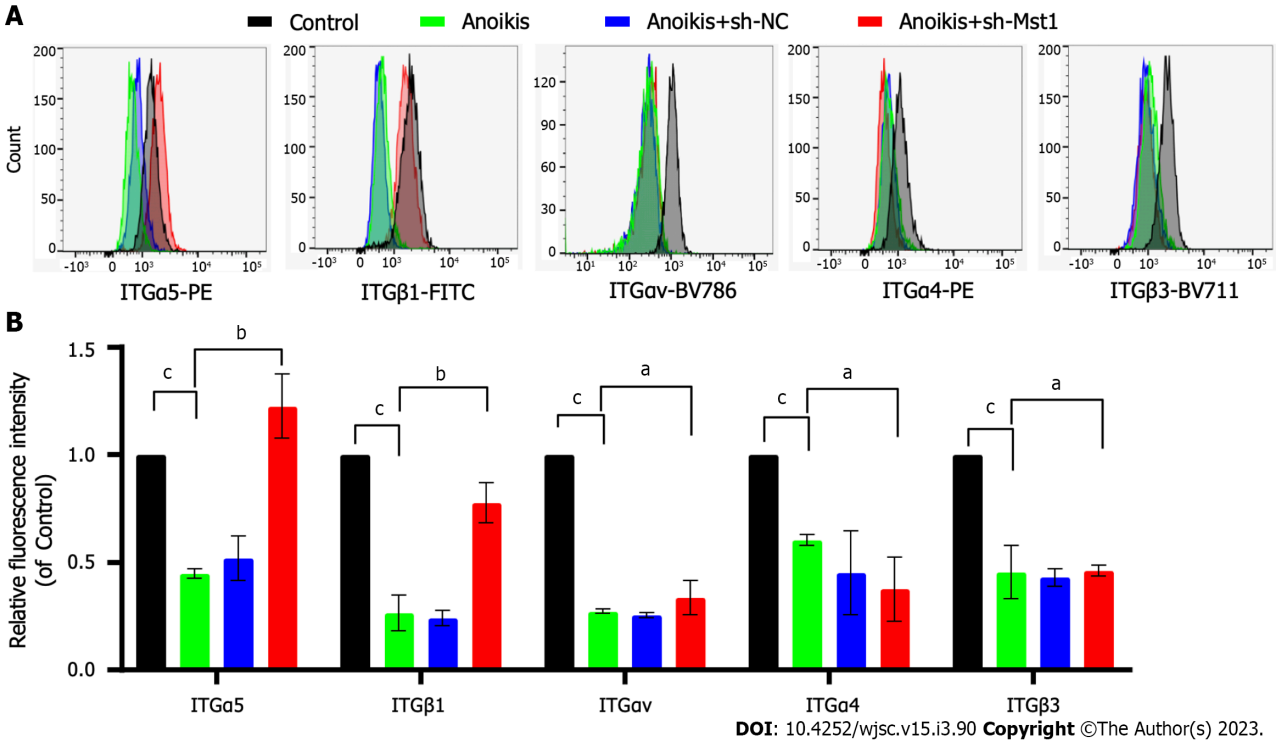
The mBMSCs were infected with adenovirus containing Mst1 shRNA. The effect of shRNA on inhibiting Mst1 expression were measured by qPCR and Western blot (Supplementary Figure 1).

Evidence has shown that ITGs, the heterodimeric cell surface adhesion receptors, mediates anoikis. In this study, the alterations of ITGs in isolated mBMSCs/sh-Mst1 were tested.

The expression profiles of ITGα5, ITGαv, ITGα4, ITGβ1, and ITGβ3 in poly-HEMA-treated mBMSCs were compared by flow cytometry. Compared with the control mBMSC levels, the poly-HEMA-treated isolated mBMSC levels of ITGα5, ITGαv, ITGα4, ITGβ1, and ITGβ3 were significantly decreased (Figure 2). Compared with isolated mBMSCs, isolated mBMSCs/sh-Mst1 show an upwards trend in ITGα5 and ITGβ1 expression. However, there was no difference of the expression profiles of ITGαv, ITG α4, and ITGβ3 between isolated mBMSCs and isolated mBMSCs/sh-Mst1 (Figure 2). This study suggested that the inhibition of Mst1 could reactivate the expression of ITGα5 and ITGβ1.

Suppression of Mst1 expression protected mBMSCs from anoikis by activating autophagy.

mBMSCs were cultured in precoated poly-HEMA plates for 36 h. A significant decrease in cell apoptosis was observed in mBMSCs/sh-Mst1 (Figures 3A, B, D and E). Similar to the above results, cell adhesion was ameliorated by silencing Mst1 expression (Figure 3G). These results indicated that Mst1 inhibition suppressed ECM-isolatedinduced anoikis in mBMSCs.



In addition, flow cytometric analysis confirmed decreased ROS levels in isolated mBMSCs/sh-Mst1 compared with those of isolated mBMSCs, whereas ROS levels were re-elevated by the autophagy inhibitor 3-MA (Figures 3C and F).

Western blot assay further suggested the above conception. FAK, has been recognised as the key mediator of cell–substrate adhesion. Western blot analysis results showed that mBMSC/sh-Mst1 exhibited robust FAK activation (Figure 3I). Similar to apoptosis, the activation of caspase can induce anoikis. Thus, we tested effect of Mst1 inhibition on the activation of caspase 3 by Western blotting. In Figure 3I, silencing Mst1 expression significantly inhibited caspase 3 activation in suspension-grown mBMSCs. This study indicated that silencing Mst1 expression could reactivate the FAK/Caspase3 pathway in anchorage-independent mBMSCs. However, 3-MA, an autophagy inhibitor, had no effect on the expression of ITGα5 and ITGβ1 or on cell adhesion (Figure 3I).

Consistent with the previous results, Mst1 inhibition reactivated autophagy in mBMSCs under isolated conditions, which can be demonstrated by the upregulated expression of LC3 II/I and Beclin1 and downregulated expression of p62 (Figure 3H). Furthermore, the number of mBMSCs/sh-Mst1 undergoing anoikis was increased after pretreatment with 3-MA (Figure 3H). In conclusion, the protective effect of Mst1 knockdown on anoikis in mBMSCs is associated with autophagy.

Inhibition of ITGα5β1 reversed the protective effects of Mst1 inhibition against anoikis in mBMSCs

To determine whether ITGα5 or ITGβ1 contributes to anoikis resistance in mBMSC/sh-Mst1 cells,

DOI: 10.4252/wjsc.v15.i3.90 **Copyright** ©The Author(s) 2023.

Figure 2 Changes in integrin protein expression in detached mouse bone marrow mesenchymal stem cells/sh-Mammalian Ste20-like kinase 1. Cells were cultured in detached conditions for 36 h. A: Flow cytometry analysis investigating the expression of integrinα5 (ITGα5), ITGαv, ITGα4, ITGβ1 and ITGβ3; B: Data are expressed as the fold change compared to the control groups. siRNA was used to knock down ITGα5 or ITGβ1 expression, respectively (Supplementary Figure 2).

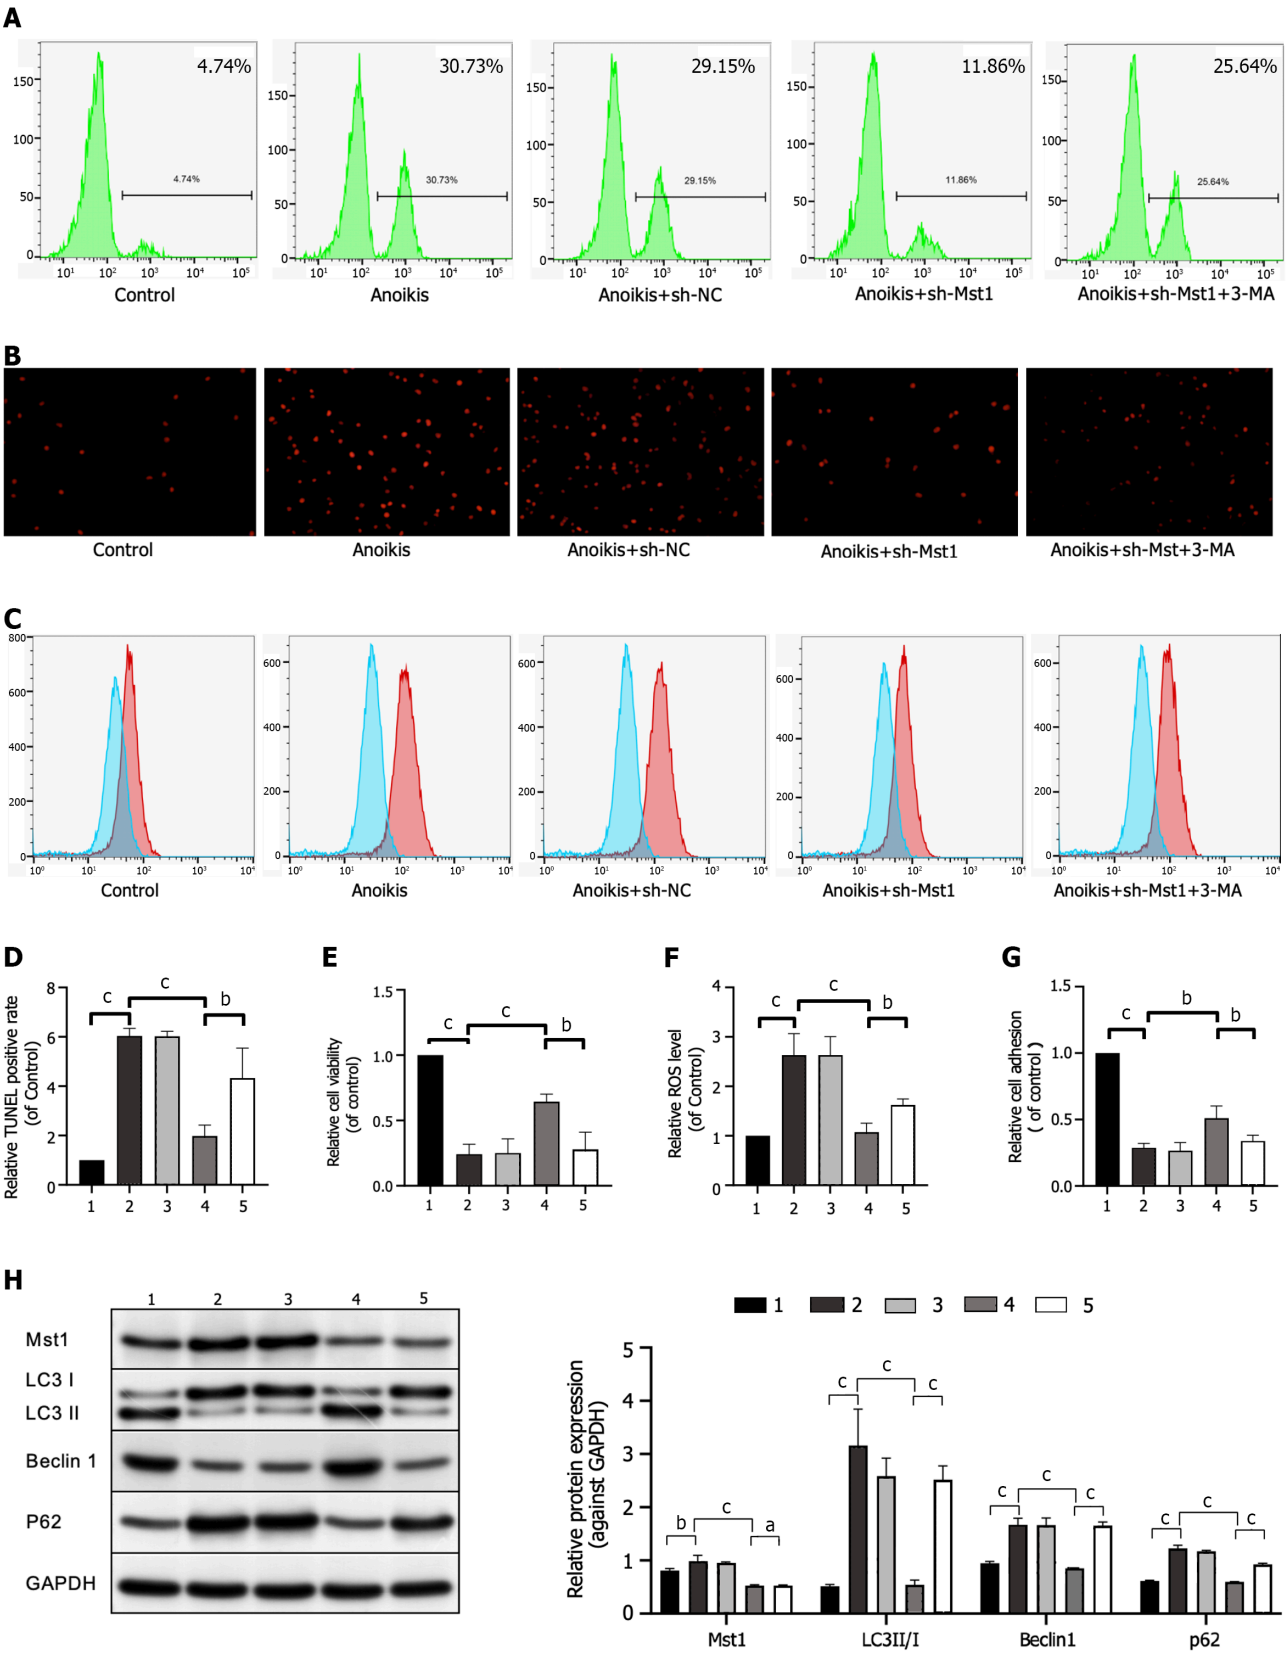
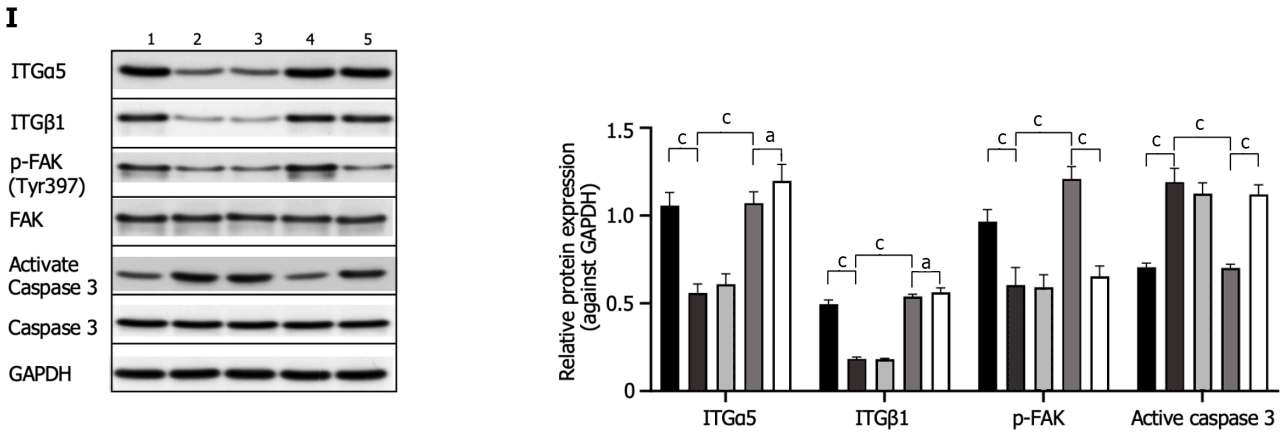
In isolated mBMSC/sh-Mst1, cell apoptosis was increased, and cell adhesion was blocked by siRNA-mediated ablation of ITGα5 or ITGβ1 (Figures 4A, B, D, E and G). Similarly, p-FAK expression was downregulated and caspase3 activation was upregulated using ITGα5 or ITGβ1 siRNA (Figure 4I). In addition, LC3 II/I, Beclin1 and p62 expression was also reversed by ITGα5 or ITGβ1 siRNA (Figure 4H). In addition, the results in Figures 4C and F suggested that the ROS level was reduced by ITGα5 or ITGβ1 siRNA.

The properties and biological safety of mBMSCs/sh-Mst1



In isolated conditions, the levels of anti-inflammatory cytokines IL-4, IL-10 and IL-17A increased, while the level of pro-inflammatory cytokine IL-6 decreased in mBMSCs/sh-Mst1 compared with those of other mBMSCs (Figure 5A).



We assessed the effect of silencing Mst1 expression on the osteogenic differentiation of mBMSCs. In Figure 5B, Mst1 inhibition was correlated with increased osteogenic differentiation of mBMSCs. Subsequently, qPCR was performed to accurately determine the role of Mst1 inhibition on osteogenic differentiation in mBMSCs. As known as the markers of osteoblast differentiation, we tested the mRNA levels of runt-related transcription factor 2 (Runx2) and alkaline phosphatase (ALP). We found that the expression of Runx2 and ALP were both increased in mBMSC/sh-Mst1 (Figure 5B)[15].

There was no tumour-like mass in animals injected with mBMSC/sh-Mst1 after 60 d post-injection. After 60 d post-injection, we collected the subcutaneous tissue and the lung, liver, kidney and heart. There were no difference of the weights of the lung, liver, kidney and heart among each group (Figures 5C and Supplementary Table 2). It also showed that no stromal structures appeared in subcutaneous tissue of mBMSCs/sh-Mst1 groups (Figure 5C).

DISCUSSION

Convincing suggestion has confirmed that anoikis limits the therapeutic efficacy of MSC transplantation for tissue repair[16]. Herein, this study has proven that mBMSC/sh-Mst1 could survive after isolation from the ECM, and this response was mediated by the effect of Mst1 inhibition-induced autophagy on ITGα5β1-modulated production of ROS.

Corresponding alterations in cell-ECM isolation and autophagy also exist[17]. As a special type of apoptotic cell death, anoikis contributes to the loss of cell attachment to the ECM[18,19]. In the present study, we observed increased cell apoptosis and inhibited autophagy, as well as upregulated Mst1 expression in isolated mBMSCs. One hypothesis derived from a combination of previous studies is that Mst1 inhibition can not only overcome anoikis but also induce autophagy in isolated mBMSCs. In this study, we confirmed that mBMSCs averted anoikis by Mst1 inhibition-induced autophagy. Autophagy promotes cell survival or apoptosis in a stimulus-dependent manner. A series of experiments have elucidated the role of autophagy in promoting cell survival during anoikis[20]. Accordingly, our results established Mst1 inhibition-induced autophagy as a survival mechanism in isolated mBMSCs.

ITGs are transmembrane αβ heterodimers, with at least 18 well-known α and 8 β subunits. An increasing amount of experimental data has demonstrated that cells can overcome anoikis by changing ITGs expression[21]. In addition, ITGs-mediated cell adhesion to ECM is critical for maintaining appropriate cellular function and survival[22]. Therefore, the upregulation of ITGs allows cells to survive during anoikis[9,22,23]. This study has proved that the expression of ITGα5 and ITGβ1 were increased in cultured mBMSCs/sh-Mst1 under cell isolation conditions. Furthermore, upregulated ITGα 5 and ITGβ1 expression may be the underlying mechanism of anoikis resistance in mBMSCs/sh-Mst1. These results suggested the role of ITGα5β1 downstream of Mst1, as well as a collaboration between ITG α5 and ITGβ1, in anoikis-resistant mBMSCs/sh-Mst1.

ITGs relay signals from the ECM to initiate intracellular signalling through intracellular ROS production[24], by which p-FAK expression is mediated[25]. Moreover, a recent study confirmed that excessive or persistent increases in ROS levels might promote the process of anoikis[26]. However, high ROS levels may also promote the formation of autophagy, which could contribute to reducing ROS accumulation[27]. Despite the essential role of increased ROS levels in anoikis resistance reported in several studies[28], we still hypothesized the necessity of appropriate cellular regulation of ROS levels for anoikis inhibition. As a result, we speculated that a negative-feedback loop was formed among Mst1 inhibition-induced autophagy, Mst1 inhibition-triggered ITGα5β1 and ROS levels. Mst1 inhibition increased ITGα5β1 expression, thereby facilitating cell adhesion. In addition, Mst1 inhibition-induced autophagy reduced the level of ITGα5β1-triggered ROS in isolated mBMSCs, which contributed to the evasion of anoikis, elucidating why 3-MA did not affect the expression of ITGα5 or ITGβ1.

Mst1 has been known to play a key role in the signalling pathway that controls manifold cellular processes[29]. In the present study, silencing Mst1 expression was found to ameliorate the anti-inflammatory cytokine production, osteogenic differentiation capability and cell proliferation of mBMSCs, thereby making mBMSCs/sh-Mst1 an attractive target for anti-inflammatory, immunomodulatory, and regenerative therapies and potentially improving the curative efficacy of mBMSCs in PAH[1-3].

Regardless of the extraordinary safety profile of MSC therapy verified in clinical trial data, several scholarly reviews have proposed that MSCs play a role in tumorigenesis and progression[18,30,31]. Therefore, the enhancement of the anti-anoikis ability of MSCs may promote tumorigenesis. However, in the present study, tumorigenic experiments in nude mice demonstrated the safety profile of mBMSC/sh-Mst1 administration.

CONCLUSION

In summary, the mechanism by which Mst1 inhibition acts on anoikis in mBMSCs was expounded in

this study. First, Mst1 inhibition was demonstrated to ameliorate not only autophagy formation but also ITGα5β1 expression. Second, Mst1 inhibition-induced autophagy could scavenge the excessive production of ITGα5β1-triggered ROS. Third, silencing Mst1 expression not only ameliorated the pluripotency of mBMSCs but also retained the safety profile of mBMSCs. Overall, Mst1 inhibition-based infusion may improve the therapeutic efficacy of MSCs, thereby serving as the ideal candidate for clinical transplant therapy in PAH.

ARTICLE HIGHLIGHTS

Research background

Anoikis plays a limiting role in the therapeutic efficacy of mesenchymal stem cells (MSCs). As a proapoptotic molecule, mammalian Ste20-like kinase 1 (Mst1) can increase the production of reactive oxygen species (ROS), thereby promoting anoikis. Recently, Mst1 inhibition was found to protect mouse bone marrow MSCs (mBMSCs) from H_2O_2-induced cell apoptosis by inducing autophagy and reducing ROS production. However, the influence of Mst1 inhibition on anoikis in mBMSCs remains unclear.

Research motivation

To investigate whether Mst1 inhibition could reduce anoikis in isolated mBMSCs.

Research objectives

To investigate the mechanisms by which Mst1 inhibition acts on anoikis in isolated mBMSCs.

Research methods

Poly-2-hydroxyethyl methacrylate-induced anoikis was used following Mst1 inhibition in mBMSCs. Integrin (ITGs) levels were tested by flow cytometry. Autophagy and ITGα5β1 were inhibited using 3-methyladenine and small interfering RNA, respectively. The alterations in anoikis were evaluated by Terminal-deoxynucleoitidyl Transferase Mediated Nick End Labeling and anoikis assays. The levels of the anoikis-related proteins ITGα5, ITGβ1, and phospho-focal adhesion kinase, which activate caspase 3, and the autophagy-related proteins microtubules associated protein 1 light chain 3 II/I, Beclin1 and p62 were detected by Western blotting.

Research results

In isolated mBMSCs, Mst1 expression was upregulated, and Mst1 inhibition significantly reduced cell apoptosis, induced autophagy and decreased ROS levels. Mechanistically, we found that Mst1 inhibition upregulated ITGα5 and ITGβ1 expression but not ITGα4, ITGαv, or ITGβ3 expression. Moreover, ITGα5β1 upregulation and autophagy induction by Mst1 inhibition played an essential role in terms of the protective efficacy of Mst1 inhibition on averting anoikis.

Research conclusions

Mst1 inhibition ameliorated autophagy formation, increased ITGα5β1 expression, and decreased the excessive production of ROS, thereby reducing cell apoptosis in isolated mBMSCs. On this basis, Mst1 inhibition may provide a promising strategy to overcome the anoikis of transplanted MSCs.

Research perspectives

In isolated mBMSCs, Mst1 inhibition ameliorated not only autophagy formation but also ITGα5β1 expression (not ITGα4, ITGαv, or ITGβ3). Mst1 inhibition-induced autophagy scavenged excessive ITGα5β1-triggered ROS. Consequently, Mst1 inhibition-based infusion may improve the therapeutic efficacy of MSCs, thereby serving as an ideal candidate for clinical transplantation in pulmonary arterial hypertension.

ABOUT COVER

Editorial Board Member of *World Journal of Stem Cells*, Mariarosaria Miloso, PhD, Associate Professor, Experimental Neurology Unit, School of Medicine and Surgery, University of Milano-Bicocca, Via Cadore 48, Monza 20900, MB, Italy. mariarosaria.miloso@unimib.it

AIMS AND SCOPE

The primary aim of *World Journal of Stem Cells* (*WJSC*, *World J Stem Cells*) is to provide scholars and readers from various fields of stem cells with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJSC* publishes articles reporting research results obtained in the field of stem cell biology and regenerative medicine, related to the wide range of stem cells including embryonic stem cells, germline stem cells, tissue-specific stem cells, adult stem cells, mesenchymal stromal cells, induced pluripotent stem cells, embryonal carcinoma stem cells, hemangioblasts, lymphoid progenitor cells, *etc*.

INDEXING/ABSTRACTING

The *WJSC* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Journal Citation Reports/Science Edition, PubMed, PubMed Central, Scopus, Biological Abstracts, BIOSIS Previews, Reference Citation Analysis, China National Knowledge Infrastructure, China Science and Technology Journal Database, and Superstar Journals Database. The 2022 Edition of Journal Citation Reports cites the 2021 impact factor (IF) for *WJSC* as 5.247; IF without journal self cites: 5.028; 5-year IF: 4.964; Journal Citation Indicator: 0.56; Ranking: 12 among 29 journals in cell and tissue engineering; Quartile category: Q2; Ranking: 86 among 194 journals in cell biology; and Quartile category: Q2. The *WJSC*'s CiteScore for 2021 is 5.1 and Scopus CiteScore rank 2021: Histology is 17/61; Genetics is 145/335; Genetics (clinical) is 42/86; Molecular Biology is 221/386; Cell Biology is 164/274.

Abstract

Mesenchymal stromal/stem cells (MSCs) are currently applied in regenerative medicine and tissue engineering. Numerous clinical studies have indicated that MSCs from different tissue sources can provide therapeutic benefits for patients. MSCs derived from either human adult or perinatal tissues have their own unique advantages in their medical practices. Usually, clinical studies are conducted by using of cultured MSCs after thawing or short-term cryopreserved-then-thawed MSCs prior to administration for the treatment of a wide range of diseases and medical disorders. Currently, cryogenically banking perinatal MSCs for potential personalized medicine for later use in lifetime has raised growing interest in China as well as in many other countries. Meanwhile, this has led to questions regarding the availability, stability, consistency, multipotency, and therapeutic efficiency of the potential perinatal MSC-derived therapeutic products after long-term cryostorage. This opinion review does not minimize any therapeutic benefit of perinatal MSCs in many diseases after short-term cryopreservation. This article mainly describes what is known about banking perinatal MSCs in China and, importantly, it is to recognize the limitation and uncertainty of the perinatal MSCs stored in cryobanks for stem cell medical treatments in whole life. This article also provides several recommendations for banking of perinatal MSCs for potentially future personalized medicine, albeit it is impossible to anticipate whether the donor will benefit from banked MSCs during her/his lifetime.

Key Words: Mesenchymal stromal/stem cells; Adult mesenchymal stromal/stem cells; Perinatal mesenchymal stromal/stem cells; Perinatal tissue; Stem cell bank; Personalized medicine

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: This article reviews the current research related to the potential use of banked perinatal mesenchymal stromal/stem cells (MSCs) for future personalized medicine. This article also discusses the matters needing attention for cryopreservation of perinatal MSCs that are possible to be banked and stored over many years. Acknowledging the limitations and uncertainties of long-term cryopreservation of perinatal MSCs, several key recommendations need to be addressed in this article for future stem cell-based medical treatments.

INTRODUCTION

Mesenchymal stromal/stem cells (MSCs) possess their unique properties that have attracted great attention in regenerative medicine and tissue engineering. Understanding of the biological properties of MSCs has been continued over a long period of time. Approximately 50 years ago, Fridenshteĭn *et al*[1] found a minor subpopulation of transplanted bone marrow (BM) cells cultured in the diffusion chambers that can act as osteogenic stem cells to show the differentiation of these cells towards osteogenesis. MSCs were initially identified in animal BM in a series of studies as fibroblast-like cells that were plastic-adherent and formed discrete fibroblast colonies[1-3]. Such fibroblast colony-forming cells were also shown to display high proliferative capacity and osteogenic potential[3]. Caplan first coined the name "mesenchymal stem cells" in 1991 on the basis of their *in vitro* capacity to give rise to bone, cartilage, *etc*.[4], but, to date, the stem cell properties of these cells remain controversial due to the multipotent uncertainty of MSCs *in vivo*. The essential features of MSC population have been identified as the minimal criteria by the International Society for Cell & Gene Therapy (ISCT) based on the specific phenotypic markers, adherence to plastic, and the potential of tri-lineage differentiation (adipogenesis, chondrogenesis, and osteogenesis)[5]. Given the unknown self-renewal and differentiation properties *in vivo*, later, Caplan[6] proposed to change the name of MSCs to more accurately reflect their main immunomodulatory and trophic potential not for multipotency of MSCs[7]. In 2019, to further consolidate and clarify the nomenclature of MSCs unless rigorous evidence for stemness exists, the ISCT MSC committee offers a position on the functional definition of mesenchymal stem *vs* stromal cells[8].

MSCs are well known to be isolated from various adult tissues including BM, adipose (AD) tissue, skeletal muscle, dental pulp, and blood[9,10], as well as vascularized tissues[11,12]. Given the immunomodulatory functions, paracrine capacity, and tropic aspects of MSCs, as well as the lacking of human leukocyte antigen (HLA)-DR, a major histocompatibility complex class II molecule, the potential therapeutic properties of MSCs in clinical trials are being explored for MSC-based regenerative medicine. Typically, MSCs are expanded *in vitro*, tested, cryopreserved, and banked for later use in preclinical and clinical studies[13-15]. Biobanking of MSCs from perinatal/neonatal tissues such as umbilical cord tissue, placental tissue, as well as placenta-associated amniotic fluid (AF) and amniotic membrane (AM) for potentially personalized medicine in the future has become more popular over the last few years in China. These newborn tissues would be routinely thrown away after birth. Importantly, these neonatal tissues are an abundant and easily available source of MSCs at birth. In this rapidly growing field, usually, stem cell banking companies involved in the stem cell industry in close collaboration with hospitals in China take over neonatal tissue collection, and preparation and cryobanking of the perinatal MSCs proposed for personal or family use for future stem cell therapies when a person develops a disease. Banking of perinatal MSCs has attracted renewed attention not only in China and probably in many other countries as well. However, serious concerns have been also raised pertaining to the maintenance of functionality and stability of stem cells along with therapeutic potential of MSCs at the time of release years. It is hard to predict the true likelihood of perinatal MSC transplantation later in whole lifetime and, noticeably, there is great uncertainty regarding whether or not these MSCs can be used to treat certain diseases after decades. As such, this opinion review article highlights several key observations in regard to the limitation of perinatal MSCs stored in stem cell cryobanks for later personal or family use in the future, which should be widely considered in the settings of cryostorage to minimize the possible side effects of these MSCs for future stem cell therapies.

Importantly, this review provides several practical recommendations for banking of perinatal MSCs to better serve patients who might be desperately in need for potential personalized medicine for future stem cell-based treatments.

PERINATAL MSCS *VS* ADULT MSCS IN THEIR BIOLOGICAL AND THERAPEUTIC PROPERTIES

MSCs from adult and perinatal sources exhibit differentiated biological and therapeutic properties. The preclinical and clinical data reported in the literature are varied to this end. With a focus on whether the perinatal MSCs are worth biobanking, the pros and cons of perinatal *vs* adult MSCs need to be addressed in this section.

Compared to adult MSCs, the newborn stem cells obtained from perinatal tissues rarely carry any infectious diseases and reduce risk of exposure to environmental toxins. Perinatal MSCs have their own advantages such as easy availability, lacking stem cell variability, and comparably low risk of donor environmental effects, as well as immune privileged property. The diversity of MSC differentiation potential is also observed among MSCs from different source tissues. For example, Hou *et al*[16] conducted an analysis of single-cell RNA-seq using MSCs derived from various tissues. By comparison, umbilical cord-derived MSCs (UC-MSCs), one of the most explored perinatal MSC types, and BM-derived MSCs (BM-MSCs) exhibited the highest osteogenic potential, while AD-derived MSCs (AD-MSCs) and BM-MSCs had the highest potential of adipogenesis and chondrogenesis, respectively[16]. Meanwhile, UC-MSCs showed the highest immunosuppression as well as the highest stemness among all MSC samples in this study by Hou *et al*[16]. Although human UC-MSCs and BM-MSCs exhibited similar immunosuppressive properties, the differences in immunomodulatory effects of UC-MSCs and BM-MSCs were also suggested in a previous study[17]. In contrast, BM-MSCs expressed more indolamine 2,3-dioxygenase (IDO) in *in vitro* inflammatory environment, while UC-MSCs expressed more prostaglandin E2, interleukine-6, and programmed death-ligands 1 and 2. In addition, there were more T helper 17 cells inhibited and more regulatory T cells induced by UC-MSCs compared with BM-MSCs in co-culture[17]. In an experimental model of sepsis, BM-MSCs but not UC-MSCs were proposed to improve survival rate in septic mice due to the enhanced immunoregulatory properties through a variety of mechanisms[18]. In an *in vitro* study, UC-MSCs showed a higher angiogenic capacity in comparison with BM-MSCs and AT-MSCs[19]. Park *et al*[20] conducted an *in vivo* study to test the angiogenic potential of perinatal chorion-derived MSCs (C-MSCs), which revealed that C-MSCs significantly increased the capillary formation in the C-MSCs injected myocardium compared to UC-MSCs and BM-MSCs. Transplantation of UC-MSCs and BM-MSCs also showed similar therapeutic effects for type I diabetes in a mouse model as well as in treated patients with type I diabetes, respectively[21]. Compared to the mice with BM-MSCs treatment, the UC-MSCs treated mice had seemingly higher β-cell mass post-transplantation, although no significant difference was observed between the two treatment groups[21]. There was no difference in the therapeutic efficacy of BM-MSCs and UC-MSCs at one-year follow-up, albeit both types of MSCs decreased the levels of haemoglobin A1c and fasting and postprandial C-peptide[21].

Overall, the relevant preclinical and clinical studies to date by the use of adult and perinatal MSCs have yielded comparable results, which may contribute to a fuller understanding of their therapeutic potential in laboratory and clinical settings. The biological and therapeutic properties of both perinatal and adult MSCs are summarized in Table 1.

PERINATAL MSC BANKING FOR PERSONALIZED MEDICINE OVER LIFETIME: CONCERNS AND UNCERTAINTIES

Over the past 20 years of MSC translational research, clinical experiences have shown that MSCs are seemingly unmet medical needs[22-24]. Translation of stem cell potential into medical practices still confronts many challenges. Clearly, these challenges include the long- and short-term therapeutic safety and efficacy of transplanted MSCs, the sufficient capability of homing and engraftment, the long-term cultivation associated alteration of MSC therapeutic properties, loss of stem cell potency with culture time, heterogeneous functions, and consistency and stability of MSCs or MSC-based therapeutic products. While clinical studies have shown the therapeutic benefits of using MSCs in various human diseases, including cardiomyopathy, autoimmune diseases, diabetes and diabetic complications, bone and cartilage repair, and fibrosis[9], rigorous clinical evidence for MSC therapeutics is still actually lacking. The positive, negative, or mixed clinical results have also been frequently observed in MSC clinical studies. Currently, MSCs based medicine still remains unproven and experimental. Therefore, it is possible to consider the limitation and uncertainty of perinatal MSC biobanking for personalized medicine in the context of the future therapeutic potential. Several important issues illustrated by the use of adult MSCs but not well discussed in perinatal MSCs are exemplified in this section to extend the

Table 1 Perinatal *vs* adult mesenchymal stem/stromal cells in their biological and therapeutic properties

	Perinatal mesenchymal stem/stromal cells	Adult mesenchymal stem/stromal cells
Availability	Readily available	Readily available
Ethical concerns	Minimal crucial ethical concerns and possible religious barriers	Minimal ethical concerns and impossible religious barriers

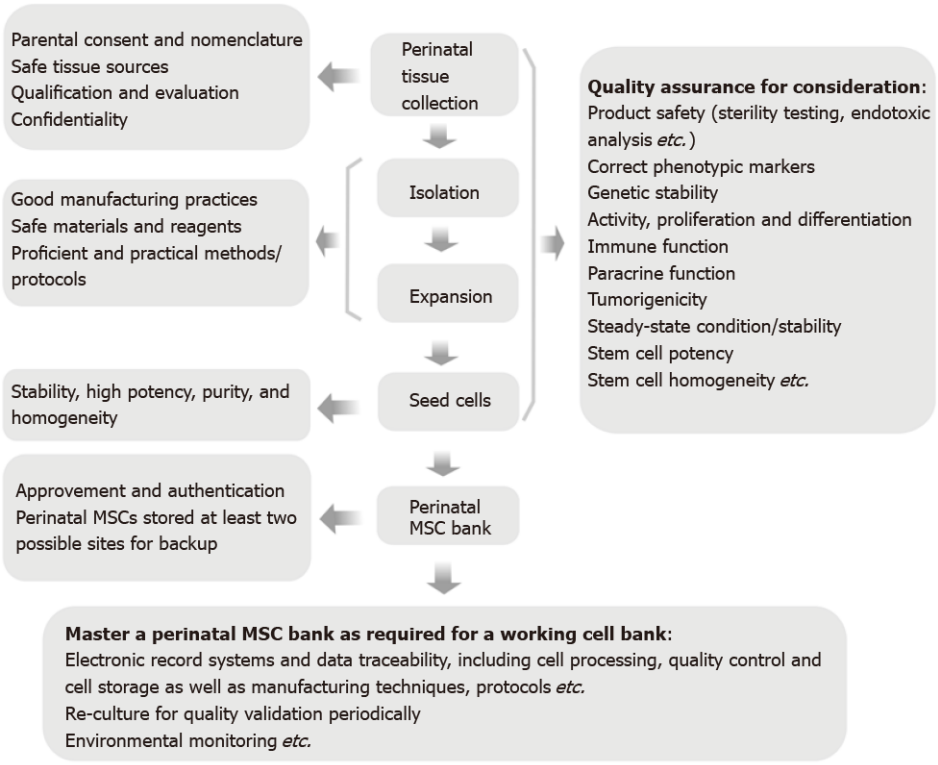
Therapeutic mechanisms	Lacking of precise therapeutic mechanisms	Lacking of precise therapeutic mechanisms
Cost for banking	Expensive for banking	Expensive for banking
Stem cell nomenclature	Controversial stem cell nomenclature	Controversial stem cell nomenclature



discussion regarding these relevant aspects of perinatal MSCs. The key issues have been identified to date, including the following.

Quality assurance before cryobanking for likely future personalized medicine

It is well known that functional properties and intrinsic multipotency of MSCs can be negatively affected by donor factors such as increased donor age, genetics, and health status. Banking of MSCs at their most potent state from perinatal tissues, the "best" cell source over one's lifetime, has been supposed for future use in need of regenerative therapies. Certainly, cryobanking of perinatal MSCs is a prerequisite in personalized medicine strategy; however, the great uncertainty remains concerning the final function of perinatal MSCs, the accessibility of MSCs (*e.g.*, a change in business circumstance), and therapeutic potential for the intractable diseases (*e.g.*, cancer) decades later. Due to no expiration date of the perinatal MSCs cryopreserved in biobanks, exploiting and developing new approaches to testing cellular variability and stability, functionality, and heterogeneity during the processing of preparation and banking of the end MSC products should be considered carefully for cell quality assessed over longer time periods. The quality assurance programs should be performed to ensure the quality of stem cell products during the whole banking process including the perinatal tissue collection, processing, testing, preparation, and storage, as well as additional analysis (Figure 1). It should be also considered that there should be minimal levels of differentiation of perinatal MSCs in the course of the overall culture period to preserve stem cells at their most multipotent state for future use. New quality control to meet the product standards is required to be developed during the process of banking of perinatal MSCs. Except for routine multiple experiments for cell quality assessment (*e.g.*, cell viability, proliferation, and differentiation potential), it is important to determine a panel of predicative *in vitro* tests for a system of quality assurance and these may be applied including but not limited to stem cell potency assay, spectral karyotyping, and genetic etiologies (Figure 1). Perinatal MSC potency assessment needs to be further validated for their therapeutic safety and effectiveness in the future. Specially, genetic etiologies associated with multi-factorial or monogenetic diseases may potentially influence stem cell safety. The wide analysis in identifying genetic/epigenetic etiologies is necessitated for therapeutic safety. For example, considering the importance of disease-associated individual single-nuleotide polymorphisms (SNPs), it is enabling to analyze and investigate whether stem cells carry disease-associated SNPs. Therefore, there is a critical need to further consider about whether it is worth biobanking of perinatal MSCs and whether it is to be stopped early if there is a family history of genetic conditions. Careful measuring and monitoring are extremely important before biobanking.

Reconsidering of pretreatment of perinatal MSCs before cryobanking

There are more and more *in vitro* and *in vivo* studies on pretreatment of MSCs, *e.g.*, pretreatment with cytokines or growth factors and hypoxia-priming, to improve their biological properties and therapeutic effectiveness. Acknowledging and understanding a beneficial role of pretreatment, the details given in this subsection describe the feature of pretreatment among MSCs from different source tissues including

Figure 1 Operating model of banking perinatal mesenchymal stromal/stem cells. Perinatal mesenchymal stromal/stem cells banking process includes the perinatal tissue collection, isolation, stem cell expansion, testing, preparation, and storage. The quality assurance programs are performed during the whole banking process. MSCs: Mesenchymal stromal/stem cells.

adult and perinatal sources, specifically, with the BM appearing the most common. This would be conducive to a better understanding of the stem cell therapeutic advantages and matters needing attention before banking of perinatal MSCs.

Biological properties could be altered by pre-conditioning of MSCs during *in vitro* expansion. Cell culture variables should be documented and, conventionally, growth medium containing fetal bovine serum and supplemented with basic fibroblast growth factor (bFGF) is considered to be the "gold standard" medium for primary human MSC expansion[25]. To remove animal components, serum-free medium throughout the process of cell preparation is being developed for clinical applications and MSC cryobanking. Usually, serum-free medium contains various cytokines/growth factors. Medium supplementation with bFGF is shown to increase the proliferation capacity of BM-MSCs over multiple passages[26]. Expansion is further improved in UC-MSCs by addition of bFGF in growth medium and the highest cell yield is detected in UC-MSCs among MSC lines pre-treated with bFGF including BM-MSCs and AD-MSCs during the whole culture period[27]. Additionally, despite the increased expression of HLA-DR induced by bFGF in AD-MSCs, the addition of bFGF in culture media seems not to affect the expression levels of HLA-DR in UC-MSCs and BM-MSCs in the course of passages[27]. Furthermore, the percentage of HLA-DR positive cells increases after inflammatory priming of all these three types of MSCs expanded in the bFGF-supplemented media[27]. As regards MSC differentiation, on the one hand, pretreatment with bFGF enhances BM-MSC chondrogenesis during chondrogenic pellet culture, resulting in upregulation of collagen type X and matrix metalloproteinase 13, the hypertrophic markers, in pellet cultures after 5 wk of endochondral ossification[26]. On the other hand, the supplementation with bFGF in medium has been also shown to have a negative effect on chondrogenesis of BM-MSCs[28,29] as well as their adipogenesis and osteogenesis[29,30]. Studies in laboratories demonstrate a time-dependent contribution of bFGF signaling to the reduced osteogenic/adipogenic differentiation of BM-MSCs throughout the culture[30,31]. For instance, the activity of alkaline phosphatase, a marker of osteogenesis, is significantly reduced during osteogenic differentiation in the case of addition of bFGF after passage 4 compared to the control at the same passage of MSCs and, similarly, adipogenesis potential is also significantly decreased by time during differentiation[30].

Pretreatment of MSCs has been observed to enhance the biological properties of the frozen and thawed MSCs. For example, one study reports that there are more apoptotic cells in the post-thawed cryopreserved BM-MSCs than the live BM-MSCs in active culture[32]. These frozen-thawed BM-MSCs are susceptible to complement-mediated lysis[33] and T-cell mediated apoptosis[34]. Interestingly, frozen-thawed MSCs primed by interferon-gamma (IFN-γ) in the culture medium for 48 h prior to

cryopreservation may partly avoid the lysis by activated T cells[34]. The mechanism of MSC-mediated immunosuppression has been previously proposed as IDO expression in BM-MSCs[35] as well as UC-MSCs[36] induced by IFN-γ. However, while pre-licensing MSCs with IFN-γ have been seen to enhance their IDO expression *in vitro*[37,38], the pre-licensed MSCs by IFN-γ, compared to the unstimulated MSCs, have let to the loss of their effectiveness in rescuing retinal ganglion cells in a retinal ischemia/reperfusion injury mouse model[37]. Together, the results of pretreatment with cytokines including but not limited to bFGF and IFN-γ indicate the different effects on the biological properties of MSCs depending on their existing microenvironment (*e.g.*, inflammation) or the specific pathological contexts.

Apart from pretreatment with cytokines, other approaches can also be proposed to boost the therapeutic potential of MSCs, for example, microenvironmental hypoxia-primed MSCs[39]. One previous study shows that, compared to standard 21% O_2 tension, 3% O_2 can increase clonogenic potential, *in vitro* migration, and stemness of MSCs from the Wharton's jelly (WJ) of human umbilical cord (WJ-MSCs)[40]. Another previous study indicates that umbilical cord blood (UCB)-derived MSCs (UCB-MSCs) primed with hypoxia and calcium ions exhibit improved self-renewal, migratory, anti-inflammatory and immunomodulatory capacities, resulting in further improving therapeutic potential for graft *vs* host disease in an animal model[41].

As mentioned above, in theory, pretreatment of MSCs from adult or perinatal sources with cytokines can improve their biological and functional properties. However, previous *in vitro* and *in vivo* studies could not prove the therapeutic efficacy of the freshly cultured or post-thawed MSCs with cytokine pre-treatment. Microenvironment conditions (*e.g.*, hypoxia) have become a promising strategy prior to cryopreservation, which is possible for the enhancement of MSC-based therapeutic potential. *In vitro* and *in vivo* studies indicate that pretreatment strategy may benefit patients in a disease specific context. However, without knowing the context of a specific pathology, it is not possible to assess and predict the function of perinatal MSCs pretreated with cytokines for stem cell medical treatments after many years. Therefore, whether pretreatment of perinatal MSCs should become the standardization for biobanking for their future applications as stem cell-based treatments remains to be further investigated.

Pre-selection for biobanking to decrease the heterogeneity of perinatal MSCs

As known, there are diverse heterogeneities of MSCs including inter-donor/individual, inter-tissue/source, inter-cellular, and inter-colony heterogeneities involved in the manufacturing and biobanking of MSCs. MSC heterogeneity reflects the diversity of MSC-associated environments or niches. The present paper extends the relevant discussion regarding the pre-selection required prior to banking with the aim to control product consistency for a stem cell bank for maximizing the "homogeneity" of perinatal MSCs. As well known, MSCs including adult and perinatal MSCs derived different tissues differ in their functional characteristics. Wegmeyer *et al*[42] conducted one previous study to evaluate the source- and donor-dependent differential stem cell properties and found UC-MSCs, AM-derived MSCs (AM-MSCs), and BM-MSCs exhibited comparable differences between each other. Interestingly, UC-MSCs and AM-MSCs exhibited different growth characteristics and morphologies as well as high inter-donor variability of AM-MSCs but not UC-MSCs. In contrast, another previous report indicated that, compared to UCB-MSCs, placental tissue MSCs, and WJ-MSCs, umbilical cord lining-derived MSCs showed the highest proliferation and migration rates and prolonged survival in immunodeficient mice [43]. Concerning immunosuppressive properties, in contrast to placenta MSCs, both UC- and BM-MSCs significantly reduced the proliferation of activated CD4+ and CD8+ T cells[44]. Additionally, the heterogeneous proangiogenic properties of perinatal and adult MSCs were observed in one previous study, which showed that both BM-MSCs and placental chorionic villi MSCs had significant proangiogenic activities on endothelial cells in matrigel *in vitro* compared to AD-MSCs and UC-MSCs[45]. Importantly, compared to dental pulp MSCs and AD-MSCs, WJ-MSCs showed the strongest therapeutic efficacy in reducing fasting glucose levels in type II diabetic mice in one previous *in vivo* study[46].

As mentioned above, due to inconsistency of MSCs, different perinatal MSCs populations may have heterogeneous functional properties, consequently leading to different therapeutic efficiency. Therefore, a pre-selection may be required before stem cell banking to identify relatively homogeneous perinatal MSCs for potential later use in life. As known, pretreatment with cytokines before banking may be a suitable approach to support therapeutic potential of perinatal MSCs in the future as exemplified by IFN-γ pre-licensing. Peltzer *et al*[47] conducted a previous study to create an *in vitro* "tolerogenic" niche priming mimicking placental environment, which showed that primed perinatal MSCs (UC-, UCB-, AM-, and chorionic-MSCs) with IFN-γ could enhance their immunomodulatory potential in a dose- and donor-dependant manner. This study by Peltzer *et al*[47] may suggest that an approach to screen the large number of perinatal MSCs with cytokine priming will be beneficial for the consistency of banking MSCs. Sorting of perinatal MSCs may be another effective approach for pre-selection, for example, pre-selection of MSC subpopulation using surface markers to increase the purity of the expanded MSCs. A series of markers need to be considered in sorting of perinatal MSCs, including cell surface markers related to MSC clonogenicity, potency, differentiation, and immunomodulatory properties[48]. Practically, a few conventional approaches to increasing the consistency of perinatal MSCs may be also considered, such as the use of the single colony of MSCs and specific biomaterials (see below), and the handing of MSCs by the standardized protocols for manufacturing consistency.

Biomaterial scaffold approach to maintain the maximal biological properties of perinatal MSCs

MSCs within the body have their own physical microenvironments or niches to maintain their unique biological properties. In order to mimic a specific stem cell niche, various biomaterials such as alginate, chitosan, collagen hyaluronic acid, silica gel, silk fibroin, poly(lactic acid), and graphene-base materials are being explored for use as scaffolds/surfaces supporting the growth and differentiation of MSCs *in vitro* and *in vivo*. By comparing the conventional techniques with monolayer culture of MSCs, biomaterial scaffold approach such as cell surface modification and encapsulation technology for tissue engineering exhibits improved MSC survival and proliferation, increased differentiation potential, and maintenance of stem cell stemness[49,50]. Further studies indicate that biomaterials can enhance the paracrine function of MSCs[51]. While technical challenges for development of biomaterials remain the degradability, viscoelasticity/elasticity, architecture property, and compatibility, the non-toxic 3D porous biomaterials are already widely used for delivery of encapsulated UC-MSCs or BM-MSCs in pre-clinical studies[52,53] as well as in clinical trials[54,55]. Interestingly, cryopreservation of microencapsulated stem cells in alginate hydrogel has been reported to suppress ice formation that contributes to the effect of cryoprotection[56]. Importantly, there are no significant differences in cell viability and multi-lineage differentiation potential between the MSCs post cryopreservation either encapsulated or without encapsulation[56]. Similar studies have been also conducted with MSCs cryopreserved in degradable hyaluronic-acid based hydrogel[57]. In addition, intravenous injection of freeze-thawed mouse MSC encapsulates with microgel into recipient mice shows similar levels of cell survival as fresh non-cryopreserved MSC encapsulates[58]. As mentioned above, previous and current studies are instructive to note that using special biomaterial scaffold may be considered as a suitable new strategy for banking of MSCs from different source tissues including but not limited to perinatal tissues.

Dimethyl sulfoxide and dimethyl sulfoxide-free cryoprotectants

Dimethyl sulfoxide (DMSO), as a key cryopreservation agent, is most often used in the cryostorage to protect cells from mechanical and osmotic stress due to the formation of ice crystals[59]. DMSO is also observed to have significant influence on the viability, phenotype, and proliferation of MSCs, as well as cellular epigenome, and to induce changes in cellular processes[60,61]. As such, low concentrations of DMSO and DMSO with combinations of non-cytotoxic biocompatible agents/substances are being explored for MSC culture and cryopreservation in preclinical and clinical studies. For example, one previous study demonstrated that human BM-MSCs modified to express tumor necrosis factor-related apoptosis inducing ligand were cryopreserved in a low concentration (5%) of DMSO (accepted as nontoxic concentrations of below 10%) with 95% human serum albumin without affecting their biological properties[62]. However, a question may be raised as to whether DMSO at a very low concentration may not be sufficient to prevent freezing damage to MSCs.

Currently, there are different types of effective and non-toxic cryoprotective agents/compounds used as suitable replacements for DMSO, such as glycerol, hydroxyethyl starch, trehalose, and dextran[59,61]. One study reports that DMSO-free cryopreservation solutions composed of sugars, sugar alcohols, and small-molecule additives have been showed to retain MSC post-thaw viability, cell surface markers, and proliferation and differentiation potential[60]. The osmolyte-based freeze solutions also exhibit a more normal alignment of the actin cytoskeleton of MSCs compared to DMSO frozen cells[60]. A non-toxic cryoprotective agent, a combination of trehalose and glycerol, has been tested in another study for cryopreservation of AD-derived stem cells, and the cells cryopreserved with this cryoprotective agent presented high cell viability and proliferation and migration capacity after thawing[63]. Overall, while various studies are being devoted to possible improvement of DMSO as a cryoprotectant, some alternatives to DMSO are being evaluated as cryopretectants for cryopreservation of MSCs from different tissue sources including perinatal tissues. DMSO together with alternatives to DMSO have not been tested enough to advocate their use for biobanking of MSCs stored over many years. Therefore, the use of DMSO alone as a cryopreservation agent may not insure the final functional properties of MSCs for stem cell-based treatments after many years and the new freezing solutions need to be intensively investigated for long-term therapeutic stem cell cryopreservation.

Ethical and regulatory concerns

Banking stem cells using neonatal birth-associated tissues or other related sources began with the establishment of banking cord blood for hematopoietic cell transplantation in the early 1990s[64]. Given that perinatal MSCs have the positive characteristics of both embryonic stem cells and adult stem cells, the ethical issue involvement may be related to the use of embryonic stem cells. In particular, there are further ethical and regulatory issues that will challenge banking of perinatal MSCs. In China, currently, there are so many exaggerate advertisements directly to consumers on banking of life-saving perinatal stem cells to insure infants or family members against serious illnesses in the future. Parents are encouraged to make decision for the preservation of their children' stem cells in a private stem cell bank for the future health of their children. Indeed, the current applications of MSCs as stem cell medical treatments are sometimes also exaggerated by the social media. Parents or requestors need to pay thousands of dollars for the commercial banks of perinatal MSCs as well as an annual fee for the maintenance of stem cells. Therefore, physicians and clinical investigators in hospitals who have

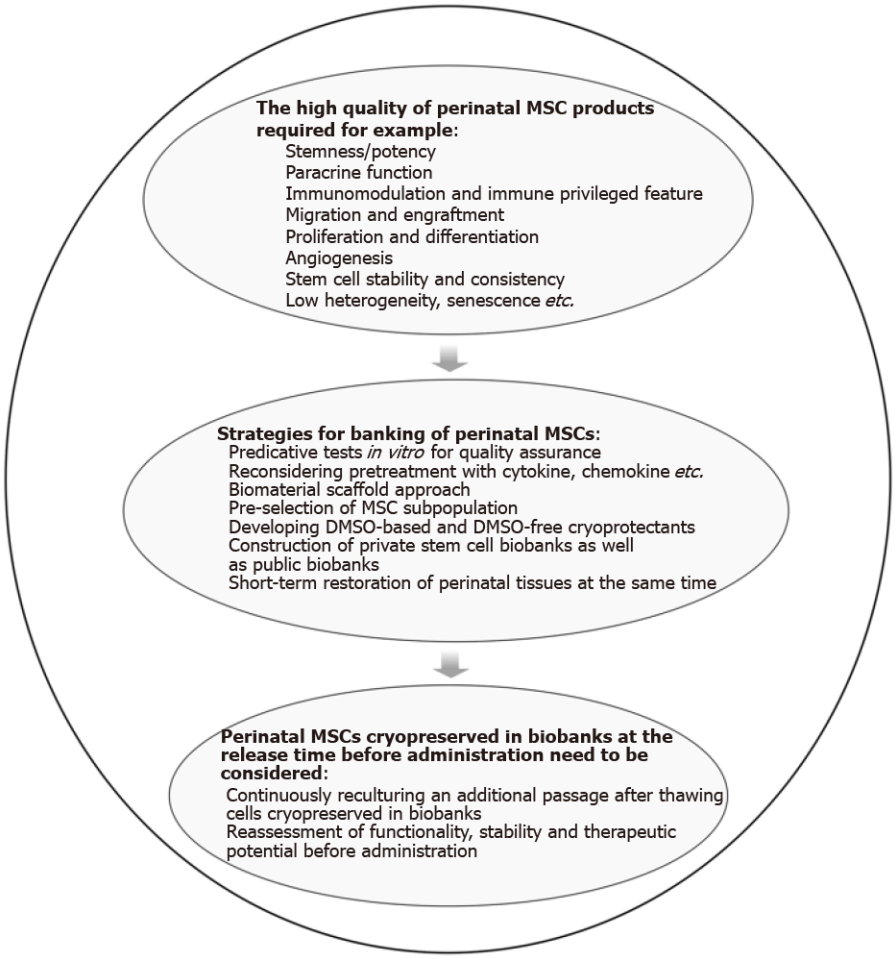
financial conflicts of interest associated with stem cell banking should disclose any financial relationship. Currently, there is a lack of clarity in country-level regulations in China for the management of stem cell banking and the guidance document for quality control on the banking of MSCs. Accordingly, technical and ethical guidelines are imperative for the appropriate governance and restriction of banking perinatal MSCs to insure standardization for MSCs with good quality for future stem cell therapies. Technical and ethical guidelines should also be in line with the international standardized regimens such as guidelines from the International Society for Stem Cell Research and the International Stem Cell Banking Initiative. Lastly, the most established private banks of perinatal MSCs in China, previously engaged in cord blood storage, are paid by the parents and these banks store the source of stem cells for future use by the donor and, probably, the donor's relatives.

Correspondingly, an additional challenge is whether the source of MSCs with potential applications in the future can be shared by the donor-unrelated recipients. In this regard, many public banks that store the perinatal MSCs derived from the donated newborn tissues should be established free charge of anything for banking. In accordance, these banks are open for research and they store stem cells for all recipients in future personalized medicine including the donors, the donor's families, and those unrelated with donors when they might be desperately in need due to life-threatening diseases. Due to no data available for the use of public banks of perinatal MSCs in China, clinical applications of cord blood stem cells from the banks are illustrated for the perspective in the future. One representative example is that the public cord blood banks have released at least 30 times for the usage rate of previously cryopreserved cord blood stem cells as compared to the private banks worldwide[65]. Almost over the past 30 years, cord blood banks have been successfully achieved for safe storage and rapid availability for cord blood stem cell-based treatments[66]. Another example is that, in a cord blood bank (MEDIPOST Co., Ltd., Seongnam-si, Gyeonggi-do, Korea), cell populations were evaluated and, among 557 UCB units, 128 units cryopreserved for more than 10 years were used for transplantation [67]. Therefore, the useful value of public or private stem cell banks to society or the donors is important for the stem cell medicine potential in the future.

Reculturing post-thawed cryopreserved perinatal MSCs from stem cell banks at the release time

Usually, the freshly cultured perinatal MSCs are seemingly to be more potent than freshly thawed cells in therapeutic properties of MSCs. Some studies suggest that perinatal MSCs may lose their functionality with cryopreservation, which could in turn affect the efficacy. Whether the characteristics of thawed perinatal MSCs *vs* cultured MSCs would be changed needs to be further discussed here. One previous study showed that freshly cultured UC-MSCs were superior to cryopreserved and thawed UC-MSCs in regard to cell viability[68]. Another previous study demonstrated that osteogenic and chondrogenic capacities were slightly reduced in cryopreserved human UC-MSCs for one year, compared to non-cryopreserved UC-MSCs from the same donor[69]. In contrast, one previous study showed that short-term cryopreservation and subsequent thawing of UC-MSCs could not alter the specific MSC surface markers and the proliferation capacity[70]. There was no obvious difference in fibroblast-like morphology and cellular viabilities between freshly frozen thawed and culture-rescued UC-MSCs[71,72]. Frozen thawed and culture-rescued UC-MSCs also displayed similar osteogenesis, chondrogenesis, and adipogenesis[71]. Similarly, one previous study by Narakornsak *et al*[73] to compare the post-thawed human AF MSCs (AF-MSCs) after one-month cryopreservation to the non-frozen AF-MSCs showed no statistical differences between these cells in MSC surface markers, cell proliferation, chondrogenic differentiation, and immune privileged properties. Still, one previous study to analyze immunomodulatory activity *in vitro* indicated no significant differences in the suppression of activated T cells in the freshly thawed UC-MSCs *vs* the freshly cultured UC-MSCs[70]. Comparatively, there were different observations reported by assessing the potential in immunosuppression between freshly thawed and cultured UC-MSCs[71], as showed the freshly culture-rescued UC-MSCs to be more potent in immunosuppression than the frozen-thawed UC-MSCs.

In animal experiments, immunomodulatory activity in an adjuvant-induced arthritis rat model and angiogenic potential using a mouse model for hindlimb ischemia were observed and *in vivo* studies showed no significant difference in immunomodulatory and angiogenic potential of freshly thawed and freshly cultured UC-MSCs[70]. Treatment with the freshly thawed UC-MSCs improved the regeneration of rotator cuff tendon in an animal model after injection at 2 and 4 wk, respectively, which was comparable to the therapeutic potential for tendon regeneration by the use of the culture-rescued UC-MSCs[72]. In a ventilator-induced lung injury animal model, the fresh UC-MSCs as well as the fresh BM-MSCs were found to enhance injury resolution and repair, while the cryopreserved UC-MSCs were comparably effective[74]. As mentioned above, these experimental and preclinical data were provided to support short-term cryopreserved perinatal MSCs (*e.g.*, UC-MSCs) for stem cell-based applications in translational medicine. However, long-term cryopreserved perinatal MSCs need to be further explored to achieve preclinical and clinical safety and efficiency after intervention. Accordingly, it is advisable to continuously culture post-thawed perinatal MSCs for at least an additional passage at the release time for restoration of stem cell biological properties and, meanwhile, it is also required to conduct extra assessment of safety and therapeutic effectiveness.



Short-term but not long-term cryopreservation of perinatal tissues for MSC preparation

Last but not least, a key issue has also been identified to date: Instead of banking perinatal MSCs, shot-term cryopreservation of perinatal tissues (*e.g.*, umbilical cord tissue) potentially for perinatal MSC storage for future stem cell-based treatments. Freezing of umbilical cords that yield post-thaw MSCs with high scalability is still controversial. One previous study reported that the frozen umbilical cord tissues for at least 2 wk were thawed and minced to generate a large number of MSCs by *in vitro* expansion[75]. UC-MSCs from cryopreserved and thawed umbilical cord tissues exhibited characteristics such as cellular phenotypes, immunosuppressive properties, and differentiation potentials similar to those of UC-MSCs from fresh tissues[75]. Another previous study reported that the fresh WJ cryopreserved for 30 d in liquid nitrogen can yield large numbers of post-thaw MSCs[76]. However, one previous study reported that although the cryopreserved umbilical cord tissue segments were thawed 5 years later to release MSCs after enzymatic digestion, those displayed poor recoveries and produced few viable UC-MSCs compared with fresh cord tissue samples[77]. Still, one previous study to assess the optimal isolation culture and cryopreservation methods to facilitate cord WJ-MSCs banking failed as no MSC cultures were obtained from the thawed cord WJ samples stored for 1 wk, 1 mo, or 6 mo in liquid nitrogen, respectively[78]. In addition, one study showed that cryopreservation of umbilical cord tissues for at least 1 mo in liquid nitrogen did not prevent the later collection of UC-MSCs by the explant method[79]. Currently, transplantation of UC-MSCs from fresh and short-term cryopreserved-then-thawed cord tissues is an issue of increasing interest. Similar to cord blood banks, perinatal umbilical cord tissue cryobanks are present in many other countries including United States, United Kingdom, Australia, and South Africa[80]. As a whole, given that cryopreservation cannot prevent the high cord quality, long-term restoration of perinatal umbilical cord tissue in banks may be unadvisable for potentially later use for post-thaw MSC preparation.

Collectively, when considering subsequent events, there are many limitations and uncertainties for stem cell medical treatments using perinatal MSCs banked over many years. Although most (if not all) aforementioned key issues, as summarized in Figure 2, are not specific to perinatal MSCs, such as cell quality insurance, heterogeneity, genetic etiologies, supplementation of scaffold, and use of cryoprotectants, these should be considered for the application of biobanking of perinatal MSCs. Research and development of different types of stem cell-based medication must be viewed with a forward-looking perspective. Importantly, when contemplating these issues including biological and technical concerns, this is a question as to whether any specific types of perinatal MSCs are worth biobanking. Without knowing the specific clinical applications, it is impossible to develop (*e.g.*, potency assay), and without a potency assay, it is not possible to assess the quality of perinatal MSCs stored by cryopreservation over many years. The question will always be raised as to what functions perinatal MSCs banked over many years can still actually play for the possible applications in their clinical practices. Realizing that short-term banking and restoration of perinatal MSCs is being routinely applied particularly in regenerative medicine and tissue engineering, long-term banking of perinatal MSCs as well as perinatal tissues for stem cell medical treatments within the lifetime should not be encouraged.

DISCUSSION

This opinion review focuses on several important points of view that are currently attracting people's attention. The review article does not diminish the clinical translational perspective of MSCs from either adult or neonatal tissues. Given the current situation of banking perinatal MSCs, the aim of this article is to contribute a balanced, comprehensive, and critical view in the settings of cryobanking of perinatal MSCs to probably maximize their potentially therapeutic activity in the future. As described above, there is no expiration date of cryostorage of the perinatal MSCs and it is not known about future timeline of stored perinatal MSCs for potential therapeutic applications. Therefore, the key issues have been identified in this article and, on the one hand, it is possible that the stored perinatal MSCs would be used for potential personalized medicine for a child when he/she develops a disease later on. On the other hand, it is too remote to assess the therapeutic benefit in the next decades. For example, by the time when a baby reaches the age of 50, no one knows whether these cells could be accessible and useful for personalized medicine at that time because there is a potential change for therapeutic benefit of perinatal MSCs. Although the short-term cryopreserved-then-thawed perinatal MSCs or the recultured MSCs are being widely used in pre-clinical and clinical studies, there are no data provided to support applications of long-term low-temperature storage of perinatal MSCs in banks, *e.g.*, cryopreservation of MSCs over a period of more than 10 years. Furthermore, it is not clear about how much the advanced techniques in science would be developed, for example, genome editing and precision medicine technologies to provide the best tools, probably, as opposed to MSC-based therapies looking forward 50 years. Science still drives the development of the advanced techniques and, eventually, the emerging advanced technologies are likely to influence the direction of therapeutic strategies in MSC-based translational medicine.

Figure 2 Strategies and administrative requirements for high-quality stem cell banks. MSCs: Mesenchymal stromal/stem cells; DMSO: Dimethyl sulfoxide.

To date, banking perinatal stem cells and stem cell-derived newborn tissues have raised growing interest potentially for future stem cell applications. Due to less information available in scientifically understanding stem cell biology *in vivo* from the transplanted patients, such as stem cell proliferation, differentiation, immunomodulation, homing, and fate of MSCs, the true function and the precise mechanisms of the therapeutic benefit remain largely unclear. More importantly, given the unknown context of a specific pathology in the future, it should be noted as to whether perinatal MSCs are worth biobanking for a long period of time to achieve clinical efficiency. People believe that banking of perinatal MSCs may serve patients well one day in the foreseeable future, ideally for several years, when they may really need for the personalized medicine. But instead, the great uncertainties remain for potential use of the cryopreserved perinatal MSCs for stem cell-based treatments in the unforeseeable future. Acknowledging the limitations and uncertainties of banking perinatal MSCs for future potential personalized medicine, the following key recommendations should be addressed and the most of the recommendations proposed do not apply to the perinatal MSCs only.

For the sake of therapeutic safety and effectiveness in the future, a series of predicative tests *in vitro* for quality assurance as well as the additional analysis of genetic/epigenetic etiologies should be considered before cryobanking of perinatal MSCs. The novel strategic approaches, for example, biomaterial scaffold techniques, should be encouraged to use for maintaining the maximal biological and functional properties of perinatal MSCs in the routine banking practices.

Emerging practicable technologies would also be applied to yield a number of the desired stem cell types, *i.e.*, homogeneous and consistent perinatal MSCs, and, consequently, it is essential to develop novel biological technologies with a high yield of stem cells for cryobanking. The appropriate governance is required and banking of the perinatal MSC-based therapeutic products should comply with accreditation standards and the international standardized guidelines.

The public banks are to be built as a priority to better serve all recipients who might be desperately in need in the future and, therefore, the roles played by the public banks should not be underestimated. Lastly, instead of banking perinatal MSCs, short-term but not for long-term restoration of perinatal tissues, for instance umbilical cord tissue, may be suggestive of a possible approach of cell preparation

for stem cell-based medicine.

CONCLUSION

MSCs can provide therapeutic benefit given their unique biological characteristics, but, to date, there is still much to learn about stem cell science and medicine. MSCs derived from diverse tissues have their different functional properties and perinatal MSCs have their own advantages. Therapeutic properties of perinatal MSCs have been shown by multiple preclinical and clinical studies; however, banking of perinatal MSCs for personalized medicine in whole life remains to be unforeseeable. Therefore, it is extremely important for parents, physicians, and clinical investigators to be aware that there are limitations and uncertainties of banking perinatal MSCs for the future personalized medicine. Based on the above consideration, this opinion review article is conducted to address the concerns raised and provides several practical recommendations for banking perinatal MSCs for future potential personalized medicine. Accordingly, different strategic approaches can be employed in this rapidly growing field to improve this process, making perinatal MSCs available for future stem cell based therapies when needed to avoid banking poor-quality MSCs discarded as novel medical waste products in the future.

Abstract

Obesity, the global pandemic since industrialization, is the number one lifestyle-related risk factor for premature death, which increases the incidence and mortality of various diseases and conditions, including cancer. In recent years, the theory of cancer stem cells (CSCs), which have the capacity for self-renewal, metastasis and treatment resistance, has been bolstered by increasing evidence. However, research on how obesity affects CSCs to facilitate cancer initiation, progression and therapy resistance is still in its infancy, although evidence has already begun to accumulate. Regarding the ever-increasing burden of obesity and obesity-related cancer, it is pertinent to summarize evidence about the effects of obesity on CSCs, as elucidating these effects will contribute to the improvement in the management of obesity-related cancers. In this review, we discuss the association between obesity and CSCs, with a particular focus on how obesity promotes cancer initiation, progression and therapy resistance through CSCs and the mechanisms underlying these effects. In addition, the prospect of preventing cancer and targeting the mechanisms linking obesity and CSCs to reduce cancer risk or to improve the survival of patients with cancer is considered.

INTRODUCTION

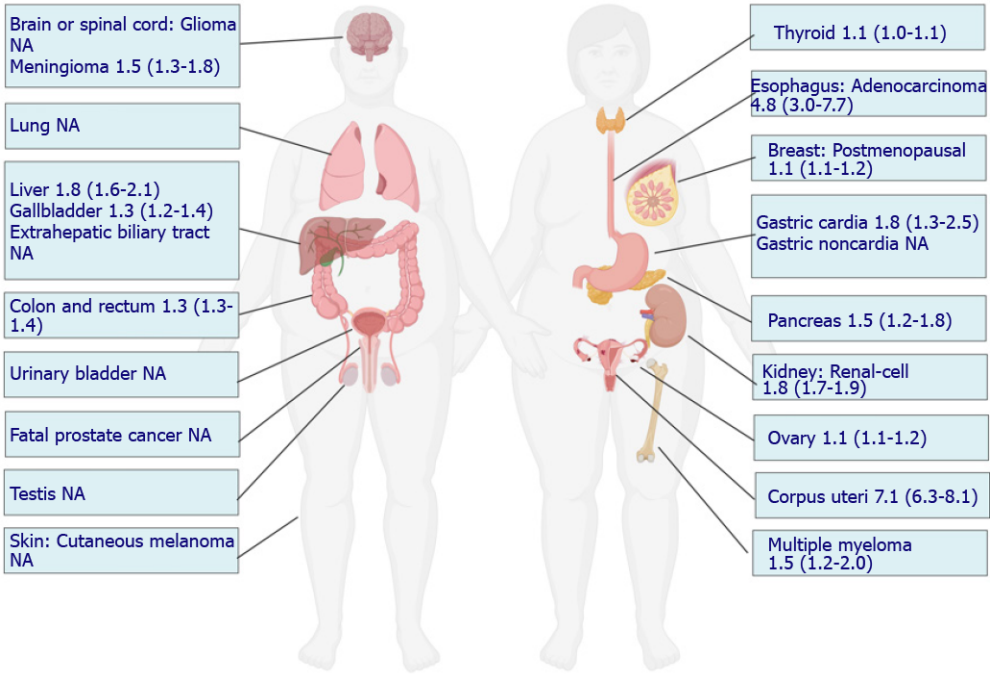
For millions of years, humans and their predecessors have evolved under the pressure of undernutrition, which selects a genotype that enables overeating, low energy expenditure, a high degree of calorie absorption and efficient energy storage in adipose tissue[1]. Therefore, with the development of the social economy in the past few decades, overnutrition and an increasingly sedentary lifestyle tip the balance from a few calories consumed but more expended to more calories consumed but little expended, leading to the pandemic of excess body weight, which is mainly measured by body mass index (BMI). Over the past four decades, the prevalence of overweight and obesity has nearly tripled globally. Between 1975 and 2016, the worldwide prevalence of obesity increased from less than 1% to 6%-8% among children, from 3% to more than 11% among men and from 6% to 15% among women[2]. Based on data from the Global Burden of Disease (GBD) 2015, overweight or obesity affects over 2.1 billion people, or nearly 30% of the global population[3]. Obesity was estimated to increase the economic burden by approximately 2 trillion United States dollars, or 2.8% of the global gross domestic product, and to lead to the loss of an estimated 5-20 years of life expectancy, representing one of the most serious unmet public health challenges of the 21st century[4-6].

Malignancy, a set of diseases caused by the interplay between genetic and environmental or behavioral factors, ranks as the third leading cause of premature death and disability attributable to excess body weight worldwide following cardiovascular disease and type 2 diabetes mellitus[7]. Recent studies have demonstrated that excess body weight is associated with higher risks of several types of cancer, including esophageal adenocarcinoma, multiple myeloma, and cancers of the gastric cardia, colon, rectum, biliary tract system, pancreas, breast, endometrium, ovary, and kidney[8]. In 2019, the estimated number of high BMI-related cancer cases accounted for 4.59% and 4.45% of all cancer-cause deaths and disability-adjusted life years, respectively[9]. Obesity can not only increase the risk of tumorigenesis but also promote the progression and metastasis of developed cancer and can affect the therapeutic efficacy and survival of patients with cancer[10].

Regarding the altered biological processes that occur in the context of obesity that contribute to cancer, the majority of studies have focused on common themes, including inflammation, hypoxia, angiogenesis and altered energy metabolism, which influence the proliferation and survival of cancer cells[10]. However, in recent years, emerging challenges in cancer management have promoted the proposal of many theories to explain the initiation and progression of cancer; one of them is the hypothesis of cancer stem cells (CSCs), which has been bolstered by an accumulating body of evidence [11]. CSCs, also referred to as treatment-refractory, tumor-initiating cells, constitute a small subpopulation of cancer cells within tumors capable of self-renewal, which can divide and differentiate into various tumor cell types (intratumoral heterogeneity). They can secrete antiapoptotic factors, undergo epithelial-to-mesenchymal transition (EMT), and display a higher performance of drug efflux pumps. Therefore, CSCs are preferentially aggressive and pose a high risk of therapy resistance and disease relapse[11]. With the rapidly increasing incidence of cancer attributable to obesity, a better understanding of the roles of obesity in CSC biology is of paramount significance. However, research in this area is in its infancy. In this review, we discuss the association between obesity and CSCs, with a particular focus on how obesity promotes cancer initiation, progression and therapy resistance through CSCs and the mechanisms underlying these effects. In addition, the prospect of prevention and targeting mechanisms linking obesity and CSCs to reduce cancer risk or to improve the survival of patients with cancer is considered.

OBESITY AND CSCS IN CANCER INITIATION

In the context of an increase in the global prevalence of obesity, large-scale epidemiological studies have demonstrated a compelling increased risk of tumorigenesis in individuals with obesity, and several landmark studies have summarized this evidence. To evaluate the strength and validity of the evidence for the association between adiposity and the risk of developing or dying from cancer, an umbrella review of the literature comprising 204 meta-analyses of large studies with limited heterogeneity or evidence of bias was published in 2017, which concluded that the associations for 11 cancers were supported by strong evidence, while others could be genuine, but substantial uncertainty remains[8]. In 2016, data from a meta-analysis reported by the International Agency for Research on Cancer supported relative risks of 1.5 to 1.8 in obesity for these tumor sites[12]. In GBD 2019, 13 cancer types were also found to be affected by a high BMI[9]. Although some inconsistencies in cancer types contributing to obesity were reported across these studies, a consistent and compelling association has been demonstrated in many cancer types, including esophageal adenocarcinoma, multiple myeloma, and cancers of the gastric cardia, colon, rectum, biliary tract system, pancreas, breast, endometrium, ovary, and kidney (Figure 1). In the majority of these cancers, the CSC theory has been established in tumorigenesis. For example, in the intestine, inactivation of the adenomatous polyposis coli (APC) gene can lead to the rapid and lethal generation of adenomas in intestinal stem cells (ISCs) but not in non-stem cells[13]. Breast cancer was found to originate from a rare population of mammary gland progenitor cells, the depletion of which significantly impaired tumor growth[14]. Therefore, to increase the risk of these cancers, obesity may disturb the normal biology of stem/progenitor cells residing in these tissues, which is conducive to their transformation.



Except for compelling epidemiological evidence, no attempts have been made to investigate the biology of cancer-related adult stem cells in populations with obesity. Multiple animal models have been developed to recapitulate the effects of obesity or a pro-obesity diet on the initiation of cancer and have suggested that a high-fat diet (HFD) can promote tumorigenesis in the colorectum, prostate and liver[15-17]. However, the cellular origin of cancer was not defined in these studies. In recent years, research revealing the links between obesity or HFD and adult stem cells has increased (Table 1)[18-28]. Although discrepancies exist, the majority of these studies reported one or more of the following findings: Obesity or a HFD increases the depth or number of crypts in the intestine; non-stem cell progenitors in a HFD setting acquire stem cell attributes; the number and the capacity to form organoids of stem cells or progenitor cells are increased by a HFD; stem cells undergo autonomous changes in response to a HFD that poise them for niche-independent growth. Although studies exploring the initiation of carcinogenesis from these stem cells are very limited, the alterations in stem cells reported in these studies can predispose them to transformation. First, obesity or a HFD expands the pool of cells - both stem cells and progenitor cells - that can serve as the cellular origin of nascent cancers. Second, stem cells from mice on a HFD become functionally uncoupled from their niche in the organoid assay and *in vivo*, consistent with the hallmarks of cancer cells. Third, several studies have shown the possible links between these perturbations and tumorigenesis. For instance, when injected with azoxymethane, aberrant crypt foci (ACF), an early-appearing lesion of colon carcinogenesis, were increased in male mice fed a HFD[21]. In another study, more spontaneous intestinal low-grade adenomas and carcinomas were observed in HFD-fed mice than in standard diet-fed mice[19].

At present, elucidating how obesity and a pro-obesity diet contribute to the cellular origin of cancer in the intestine is the central focus of research, and data on stem cells in other tissues are very limited. Several reasons can explain such a tissue preference for studying the impact of obesity and HFD physiology on the initiation of cancer. First, robust epidemiological evidence has been accumulated for the increased risk of colon cancer in obese populations, and a better understanding of the altered biology of ISCs that occurs in the context of obesity will provide immeasurable public health benefits [10]. Second, the stem cell theory advanced most rapidly in ISCs, from which the histological architecture of the intestine has been well established[29]. Third, ISCs reside in the base of the intestinal crypt and directly interact with luminal nutrients, bacteria, and other intraepithelial and subepithelial cells, making the intestine an ideal system for studying the pathophysiological changes on a HFD[29]. Finally, the natural orifice of the intestine makes in situ manipulations for tumor induction or diagnostic tests easier than other *in vivo* cancer models[30]. Despite all of this, as consistent and compelling associations have been demonstrated between obesity and more than 10 cancer types, elucidating how stem cells in tissues other than the intestine are perturbed by obesity or HFD holds the same importance. Currently, the majority of obesity models are induced by HFD; however, other dietary patterns, such as a high-sugar diet and Western-styled diet, have also been shown to be obesogenic, and the effects of these dietary patterns on the initiation of cancer warrant further studies. Furthermore, the alterations in stem cell biology in tissues with increased cancer incidence warrant further investigation in obese human beings, not just in animals.

Table 1 Murine models of high-fat diet-induced obesity and cancer stem cells

Tissue	Findings	Ref.
Intestine	Increased crypt depth and villus height; increased number of Olmf4-positive ISCs; increased size of the enterospheres that developed from ISCs	[18]
Intestine	Increase in crypt depth; non-stem progenitor intestinal cells gain more stemness features and self-renewal; 50% increase in the number of Olfm4+ ISCs; 23% decrease in the number of Paneth cells; more likely to initiate mini-intestines; organoids had higher frequencies of Lgr5+ ISCs; ISCs by themselves had an increased capacity to initiate organoids	[19]
Intestine	Combined with Pten inactivation, obesity is insufficient to drive Lgr5+ ISC-derived tumorigenesis	[20]
Intestine	Increased aberrant crypt and crypt foci; increased proliferation of colonocytes per mouse	[21]
Intestine	Higher number of Lgr5+ stem cells per crypt	[22]
Intestine	Increased number of ISCs and progenitor cells; crypts are further likely to form mini-intestine organoids in a 3D culture	[23]
Intestine	Increased intestinal epithelial cell proliferation	[24]
Intestine	Reprograms Bmi1+ cells to function and persist as stem-like cells in mucosal homeostasis and tumor development	[25]
Intestine	Increased number of crypts; increased total numbers of ISCs and percentage of ISCs in S-phase; reduced numbers of Paneth and goblet cells	[26]
Lung	Increased number of AT2 cells; higher stem cell colony forming efficiency	[27]
Esophagus	Increased numbers of epithelial progenitors in Barrett's esophagus	[28]

ISC: Intestinal stem cell; Lgr5: Leucine-rich repeat-containing G protein-coupled receptor 5; AT2: Alveolar type-2.

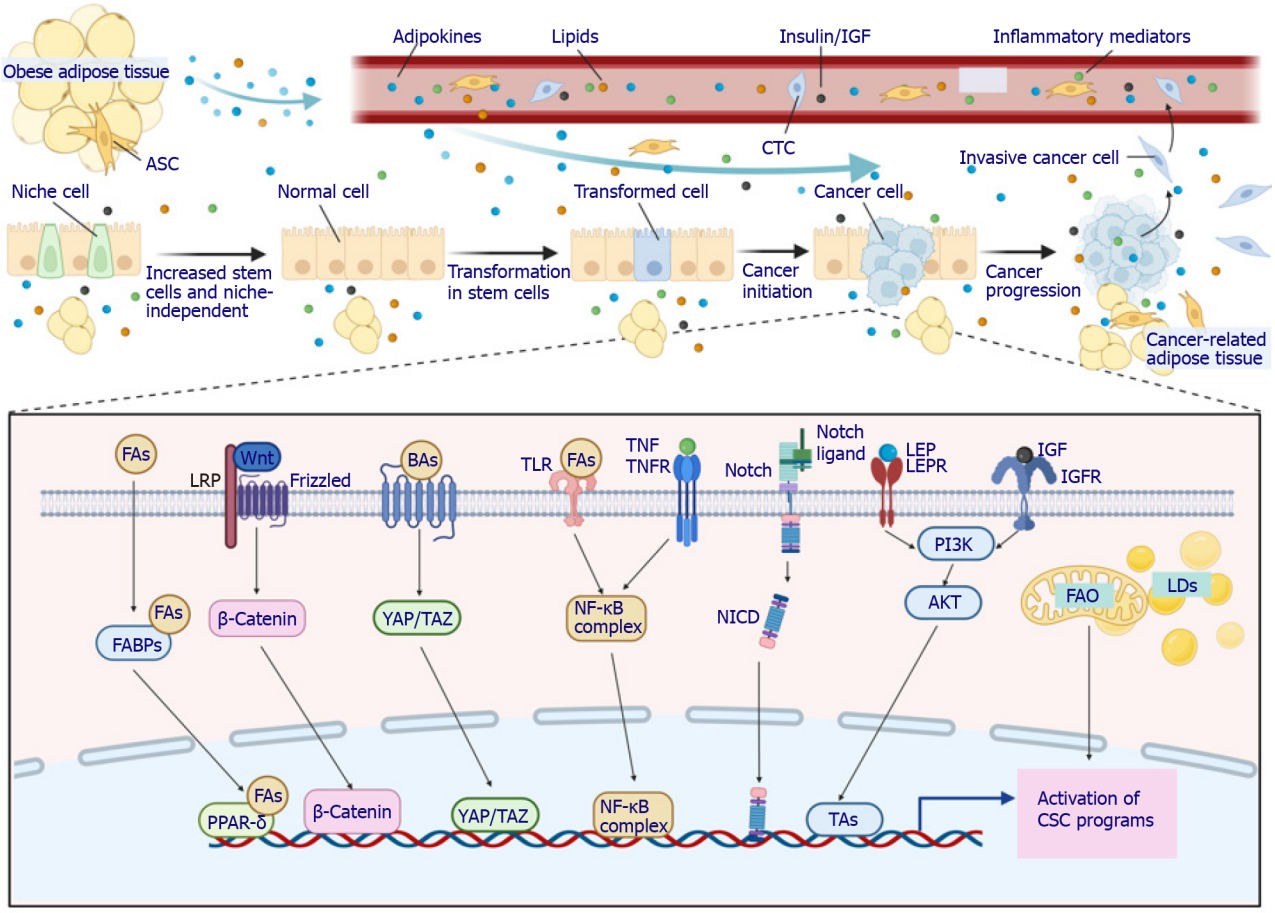
Figure 1 Relative risk of individual cancers at high body mass index. Data were obtained from a meta-analysis reported by the International Agency for Research on Cancer working group. The number represents the relative risk and its 95% confidence interval of the highest body mass index category *vs* normal body mass index. NA: Not available.

OBESITY AND CSCS IN CANCER PROGRESSION AND THERAPY RESISTANCE

In addition to promoting tumorigenesis, obesity might also promote the progression of established cancers, affect the efficacy of present forefront antitumor therapies and shorten the survival of patients with cancer. For instance, a meta-analysis including 86490 patients treated for clinically localized prostate cancer showed a moderate and consistent relationship between obesity and biochemical recurrence, and there was a 10% increase in biochemical recurrence per 5 kg/m^2 increase in BMI[31]. In the Carolina Breast Cancer Study phase 3, a high waist-to-hip ratio was found to be associated with a

high risk of metastasis[32]. Poor survival was also reported in overweight or obese patients with colorectal, endometrial and breast cancer[33-35]. In addition to the increased likelihood of recurrence, the poor prognosis of obese patients with cancer also results from the reduction in the efficacy of antitumor therapies[36]. Mechanistically, the link between obesity and increased recurrence, therapy resistance and poor survival is likely multifactorial, with some differences related to more advanced stages being attributed to reduced participation in routine screening or the systemic effects of obesity on drug pharmacokinetics and metabolism[37,38]. In addition to these explanations, emerging evidence has shown that the activation of stem cell programs in cancers can lead to progression, metastatic growth and therapy resistance[11].

The key roles of obesity in the activation of stem cell programs have attracted much attention in recent years; however, as in studies on the effects of obesity on cancer-initiating cells, the promotion effects of obesity on cancer through CSCs are also mainly limited to animal models, which are utilized to investigate how specific obesity-related factors induce the stemness of cancer cells. Knowledge about CSCs in obese patients with cancer is still not clear. For example, obesity increases inflammation in the tumor microenvironment (TME) through local and systemic adipokines, proinflammatory cytokines or hormones, which modulate the stemness of cancer cells[39]. In a mouse model of hepatocellular carcinoma, diet-induced obesity increased inflammatory signaling *via* STAT3, and this finding was associated with larger tumors with a cancer-stem-cell-like phenotype[40]. Prolonged culture of breast cancer cells, which developed from a fat-rich environment, with adipocytes increased the proportion of cells expressing stem-like markers *in vitro* and the abundance of cancer cells with metastatic potential *in vivo*[41]. Regarding the involvement of CSCs in therapy resistance, leptin was found to interfere with the efficacy of 5-fluorouracil (5-FU) in colon tumor stem cells by increasing cell viability and reducing 5-FU-induced DNA damage[42].



EMT is a reversible cellular process during which epithelial cells transiently acquire mesenchymal phenotypes, such as an elongated, fibroblast-like morphology as well as an increased capacity for migration and invasion[43]. It is now widely accepted that EMT has well-established roles in cancer metastasis[43]. In the majority of carcinomas, only CSCs exhibit aspects of EMT-program activation[44]. Various extracellular stimuli, including obesity-related factors, have been implicated in the induction of EMT programs. For instance, esophageal cancer cells cocultured with visceral adipose tissue taken from obese patients resulted in the induced expression of genes involved in EMT, which was also noted in tumor biopsies from obese patients[45]. Cytokines and growth factors released by adipose stem cells (ASCs) can induce EMT-like changes in various cancer cells[10]. The adipokine leptin has also been found to activate EMT programs to enhance the proliferation and metastasis of breast cancer cells[46]. Therefore, obesity can propel primary tumor cells toward EMT events, leading to malignant progression.

THE LINKS BETWEEN OBESITY AND CSCS

As discussed above, CSCs participate in every step of tumorigenesis promoted by obesity. Understanding the key links between obesity and CSCs, therefore, offers important potential to decrease the incidence and improve the outcomes of obese patients with cancer. Several main factors are considered to connect obesity and cancer: Components of pro-obesity diets, metabolic and hormonal alterations associated with obesity, dysfunctional adipose tissue in the TME, low-grade obesity-related inflammation, self-renewal and stemness pathways, and microbiome dysbiosis. Each of these factors is intimately linked to and cross-talks with each other. For example, fatty acids in pro-obesity diets accumulate in adipocytes, leading to expansion and dysfunction of adipose tissue, which is intimately linked to endocrine and paracrine dysregulation, such as increased circulating insulin, insulin-like growth factor-1 (IGF-1) and leptin. All of these alterations activate and maintain a prolonged low-grade inflammatory state, predisposing individuals with obesity to an increased cancer risk and poor outcomes[47-49]. Although these factors were mainly investigated in nonspecific conditions, their involvement in CSC biology is also beginning to accumulate evidence (Figure 2).

Components of pro-obesity diets

Although the mechanistic links are not completely understood, nutrient-sensing signaling activated by components of a pro-obesity diet has been shown to influence stem cell behavior and tumorigenesis. This was also indirectly suggested in a leptin-receptor-deficient (*db/db*) mouse model, which becomes obese on control diets and does not rely on a HFD. In *db/db* mice, the number of ISCs was reduced, while ISC function was not affected, highlighting that components of a pro-obesity diet can regulate stem cells independently of obesity[19]. As early as 1989, Blakeborough *et al*[50] reported that diets high in fat support a *Bacteroides*-dominated colonic microflora and increase the excretion of secondary bile acids to augment free radical production, which may overcome the antioxidant defense mechanisms of stem cells, causing DNA damage, tumorigenesis and proliferation of transformed stem cells. Since then, numerous studies have suggested for decades that a pro-obesity diet engages many diverse pathways in stem cells in various tissues that collectively contribute to tumorigenesis. For instance, a HFD increases

Figure 2 Mechanisms linking obesity and cancer stem cells. In the obese microenvironment, the stem cell pool is increased and loses niche dependence, predisposing these stem cells to transformation. Several main factors are considered to connect obesity and cancer stem cells (CSCs): Components of pro-obesity diets, metabolic and hormonal alterations associated with obesity, dysfunctional adipose tissue in the tumor microenvironment, low-grade obesity-related inflammation, self-renewal and stemness pathways, and microbiome dysbiosis. These factors are intimately linked to and cross-talk with each other, synergistically leading to the activation of CSC programs through various signaling pathways. ASC: Adipose stem cell; BAs: Bile acids; CSC: Cancer stem cell; CTC: Circulating tumor cell; FAs: Fatty acids; FABPs: Fatty acid binding proteins; FAO: Fatty acid oxidation; IGF: Insulin-like factor; IGFR: Insulin-like receptor; LDs: Lipid droplets; LEP: Leptin; LEPR: Leptin receptor; LRP: Low-density lipoprotein receptor-related protein; NCID: Notch intracellular cytoplasmic domain; PI3K: Phosphatidylinositol 3-kinase; PPAR-δ: Peroxisome proliferator-activated receptor δ; TAZ: Transcriptional coactivator with PDZ-binding motif; TFs: Transcription factors; TLR: Toll-like receptor; TNF: Tumor necrosis factor; TNFR: Tumor necrosis factor receptor; YAP: Yes-associated protein; NF-κB: Nuclear factor-kappaB.

leucine-rich repeat-containing G protein-coupled receptor 5 (Lgr5) expression and promotes tumor growth in a xenograft model independent of obesity. Mechanistically, dietary fats stimulate vitamin A-bound serum retinol-binding protein 4 and retinoic acid 6, which are implicated in colon stem cell self-renewal, to activate the JAK-STAT3 pathway and boost Lgr5 expression and the tumorigenicity of ISCs [51].

The representative components of a pro-obesity diet, that is, fatty acids such as palmitic acid or oleic acid, were found to enhance the number and self-renewal potential of ISCs and to permit organoid body formation without supporting signaling from their niche cells in a well-designed study[19]. The molecular mechanism by which fatty acids deregulate ISCs to promote tumorigenesis was also delineated in this study. It was proposed that fatty acids can be transported to the nucleus by fatty acid-binding proteins or can be produced directly by lipid metabolism in the nucleus, where they increase the number and self-renewal of ISCs *via* peroxisome proliferator-activated receptor δ (PPAR-δ), a nuclear receptor that senses fatty acid derivatives, the synthetic activation of which mimics both the *in vivo* and *in vitro* impact of a HFD and fatty acid treatment[19]. In contrast, loss of PPAR-δ completely abrogated the effects of fatty acids on Lgr5+ ISC function with respect to organoid-initiating capacity [19]. The downstream signaling mediating the effects of PPAR-δ activation was attributed to WNT/β-catenin, as demonstrated by increased β-catenin staining and upregulation of its target genes (Jag1, Jag 2 and Bmp4) in ISCs and progenitors from HFD- and PPAR-δ agonist-treated mice[19]. Free fatty acids produced by obese fat lipolysis also serve as ligands for Toll-like receptor 4 (TLR4) on cancer cells to activate nuclear factor-kappaB (NF-κB), leading to an increase in CSCs[52]. Another critical element in a pro-obesity diet that is significantly elevated in some obese individuals, cholesterol, was also demonstrated to affect stem cell function, thus promoting tumorigenesis. In *Drosophila*, dietary

cholesterol modulated the differentiation of ISCs by stabilizing the Delta ligand and Notch extracellular domain and altering their trafficking in endosomal vesicles, while a low-sterol diet slowed the proliferation of enteroendocrine tumors initiated by Notch pathway disruption[53]. In a rodent animal model, evidence also showed that dietary cholesterol acts as a mitogen for ISCs, while disruption of cholesterol homeostasis dramatically enhances tumor formation in APC_{min} mice[54].

Although bile acids are not elements in a pro-obesity diet, their excretion is essential for the digestion and absorption of dietary fat and is increased when a HFD is consumed. Bile acids are endogenous agonists of the G protein-coupled bile acid receptor, the activation of which augments Yes-associated protein 1 (YAP1) signaling, leading to increased stem cell number and proliferation and enhanced organoid-forming capability of ISCs[55]. In addition, bile acids, such as tauro-β-muricholic acid and deoxycholic acid, can antagonize intestinal farnesoid X receptor (FXR), a master regulator of bile acid homeostasis. Antagonizing FXR in the intestinal lumen enhances the proliferation and DNA damage of stem cells, initiating the transformation of ISCs to a malignant phenotype and promoting adenoma-to-adenocarcinoma progression[56]. Conversely, selective activation of intestinal FXR by its agonist can restrict abnormal ISC growth and skew differentiation toward goblet cells, thus curtailing HFD-induced intestinal cancer progression[56].

Metabolic alterations

Aerobic glycolysis has long been viewed as the main metabolic characteristic of cancer cells. However, in recent years, CSCs have been found to be intimately dependent on lipid metabolism to maintain their self-renewal capability. Therefore, in addition to the abovementioned studies that investigated the regulation of CSC function by lipids as elements of a pro-obesity diet, numerous studies have explored the effects of lipids on CSCs at the cellular metabolism level. Metabolism of fatty acids and cholesterol, including *de novo* biosynthesis, storage and fatty acid oxidation (FAO), supports the stemness, proliferation and chemotherapy resistance of CSCs[57]. Metabolic analysis demonstrated that lipid synthesis, including *de novo* lipid biosynthesis, lipid desaturation, and cholesterol synthesis, displays high activity in CSCs, indicating that lipid synthesis plays critical roles in stemness maintenance[58]. Human breast cancer-derived data suggest that FAO promotes cancer cell stemness and chemoresistance. Blocking FAO resensitizes them to chemotherapy and inhibits CSCs in mouse breast tumors *in vivo*[59]. Furthermore, cytarabine-resistant acute myeloid leukemia cells, which are enriched in leukemic stem cells, exhibited increased FAO[60]. FAO is also responsible for the stemness and chemotherapy resistance in gastric cancer induced by mesenchymal stem cells (MSCs)[61]. To meet the critical functions of lipids in CSCs, lipid droplets, organelles that store neutral lipids, accumulate and are more abundant in CSCs in numerous types of cancer[57]. Although evidence connecting lipid metabolism and CSCs is increasingly accumulating, whether obesity can augment the lipid metabolic alteration in CSCs is not clear because studies on the metabolic adaptations of CSCs in obese environments are limited. However, the incidence of hyperlipidemia is higher in obese populations, and in obese individuals, CSCs more readily reside in a fat-rich TME, which may provide more lipids to CSCs. Therefore, theoretically, lipid metabolic alterations in obesity support the stemness of cancer cells, although further studies are warranted to validate such effects.

Another common metabolic alteration of obese patients is insulin resistance, leading to increased levels of circulating insulin and IGF-1, which contribute to the increased risk and mortality of several cancers in obese individuals. Mice with diet-induced obesity exhibited increased concentrations of plasma glucose, insulin, and IGF-1, which were significantly correlated with increased proliferation and self-renewal of ISCs, as well as decreased Paneth cell numbers[26]. In addition, insulin significantly increased the capacity of organoid formation *in vitro*[26]. Reports have suggested that the PI3K/AKT pathway is the major contributor to the abnormal renewal of ISCs endowed by insulin/IGF-1[62]. Therefore, insulin/IGF-1 signaling was suggested to mediate the effects of obesity on the function of stem cells, which is conducive to their transformation. Even insulin/IGF-1 levels in newborns are associated with the risk of future breast cancer, possibly resulting from an increased total number of stem cells[63]. Parallel to their function in normal stem cells, evidence suggests the roles of insulin/IGF-1 in cancer progenitor/stem cells from solid and hematopoietic malignancies. Insulin/IGF-1 and their receptors are overexpressed or overactivated in human thyroid, hepatic and breast CSCs and participate in the self-renewal, EMT and chemoresistance of cancer cells[64]. These emerging discoveries will undoubtedly promote renewed efforts aimed at targeting the insulin/IGF-1 system that contribute to CSC biology.

Hormonal alterations

Adipose tissue has long been viewed as an energy reservoir; however, this perspective has changed in recent years, as numerous bioactive adipokines, including more than 50 different metabolic and hormonal factors, cytokines and chemokines, were reported to be released by adipose tissue[65]. Two of the major adipose tissue-derived hormones are leptin and adiponectin, which have opposite effects. In contrast to lean adipose tissue, which mainly secretes the antimitogenic adipokine adiponectin in obesity, increased preadipocytes yield high levels of leptin, which has proangiogenic and promitogenic effects[66,67].

Leptin acts as a growth factor for many tissues, such as the mammary gland, lung, liver, and colonic epithelium[68]. The links between leptin and CSCs have been comprehensively studied in breast cancer [69]. In a diet-induced obese mouse model, mammary epithelial polarity was disrupted, which can contribute to overactivation of the PI3K/AKT pathway downstream of the paracrine effect of leptin expressed by neighboring adipocytes. Leptin expands the pool of stem/progenitor cells in the breast epithelium and causes mitotic spindle misalignment, which is an early step in tumor initiation[70]. The leptin receptor was found to be expressed on breast CSCs, and in orthotopically transplanted breast cancer, leptin can promote CSC enrichment[71,72]. Inactivation of the leptin receptor attenuated the expression of CSC transcription factors and reduced the self-renewal of cancer cells in tumor sphere assays[71]. Leptin-mediated cancer initiation, progression and therapy resistance through CSCs in other cancers have also been extensively investigated[69]. For instance, leptin was found to initiate the early transformation of colon cancer. ACF multiplicity, as early-appearing lesions of tumorigenesis, was increased by a HFD in *ob/ob* mice or in a genetic mouse (*db/db*) model with leptin receptor deletion[73, 74]. However, in *db/db* mice fed a control diet, the function of ISCs and the activity of PPAR-δ and Wnt/β-catenin signaling were not changed, indicating that obesity and elements in a pro-obesity diet may cause different alterations in the function of stem cells[19]. In addition, no leptin receptor was found on colonic stem cells, and leptin did not increase the pool of Lgr5+ stem cells, suggesting that leptin may be dispensable in the early stages of colon carcinogenesis[22]. Collectively, these findings indicate that although the crucial role of leptin in CSCs may be affected by the cellular origin of cancer, the potential of leptin pathways in cancer initiation and progression will lead to future areas of therapeutic management.

Although data are scarce, other adipokines with altered secretion in obese adipose tissue were also shown to affect the function of CSCs. For example, DeClercq *et al*[22] specifically investigated the effect of a HFD on colonic stem cell maintenance during cancer initiation and found that the number of stem cells and their proliferation capacity were significantly increased, while the incidence of apoptosis was decreased. The authors proposed that these effects are the result of decreased adiponectin signaling based on the findings that the reduction in stem cell number and increase in apoptosis were diminished in organoid cultures from obese mice treated with an adiponectin receptor agonist[22]. In addition, following a decrease in adiponectin signaling, obesity can increase tumorigenesis in the intestine[22]. Resistin, another adipokine, was highly associated with the transcription of genes related to CSCs in low malignant breast cancer cells and noncarcinogenic breast epithelial cells[75]. These adipokines with different effects on CSCs and their therapeutic translational potential need further research.

Dysfunctional adipose tissue in the TME

Despite the systemic effects of adipose tissue on CSCs through the secretion of circulating metabolic and hormonal factors, adipose tissue also constitutes an important part of the microenvironment of several cancers, and its dysfunction resulting from obesity is considered a critical determinant of cancer progression[76]. For example, cancer-associated adipose tissue obtained from obese patients with breast cancer was found to increase inflammatory breast cancer aggressiveness *via* the regulation of CSC markers[77]. Coculture of breast cancer cells with human-derived adipocytes increased the abundance of mammosphere-forming cells and stem-like cancer cells *in vitro* and increased tumor-initiating cells and metastasis in mouse models[41]. Mechanistic investigations demonstrated that immature adipocyte contact activates Src, thus promoting embryonic stem cell transcription factor upregulation, including Sox2, c-Myc, and Nanog, to mediate CSC expansion[41]. Moreover, Sox2-dependent induction of miR-302b further stimulated c-Myc and Sox2 expression and potentiated cytokine-induced CSC-like properties[41]. However, adipose tissue from different anatomical sites may have different effects on CSCs. For example, serial transplantation of pluripotent stem cells cultured in conditioned medium of breast cancer cells into mammary fat pads evoked the same features of breast cancer, while this result was perturbed following subcutaneous transplantation, indicating that mammary adipose tissue can synergize with secretory factors produced by cancer cells to transform normal cells into CSCs, while subcutaneous adipose tissue cannot[78]. Such performance differences may be caused by the various metabolic characteristics of adipose tissue from different anatomical sites determined by sex steroid hormones[79].

Among various adipose tissue cell types, ASCs are key players in adipose tissue. Under obese conditions, the biology of ASCs is dramatically altered, and ASCs can be recruited to sites of inflammation, including tumors[80]. ASCs are able to produce a large variety of circulating growth factors, cytokines and adipokines, which play important roles in CSC function. In addition to their systemic effects, ASCs represent an important cellular component in the TME. Therefore, in a breast cancer patient-derived xenograft model, cancers grown in the presence of ASCs had increased numbers of CD44+CD24− CSCs in the peripheral blood and had a higher tendency to form metastases[81]. This effect may be mediated by leptin, as the stable knockdown of leptin in obese ASCs led to a significant reduction in circulating CSCs[81]. In addition, ASCs reshape the TME and support the generation of CSCs, which are associated with radioresistance and chemotherapy resistance[82].

Low-grade obesity-related inflammation

In recent decades, the contribution of inflammation to cancer initiation, progression and therapy resistance has regained enormous interest, and the association between inflammation and CSCs has also been explored extensively[83]. Obesity has long been considered a facilitator of mild, chronic, systemic inflammation. Along with the expansion of adipose tissue in obesity, hypoxia causes adipocyte stress and malfunction, recruiting different types of immune cells[84,85]. Both adipocytes and immune cells release numerous adipokines, cytokines, chemokines and hormones, which perpetuate the inflammatory state[84,85]. Therefore, it is reasonable to speculate that obesity can affect CSCs through low-grade inflammation. Although chronic inflammation is not induced consistently in obese mouse models, which may be related to the differences in feeding patterns and other combined interventions, current evidence indicates that inflammation might have a role in alterations in stem cells leading to tumorigenesis. Inflammatory mediators were found to be increased in the intestinal mucosa in mice with obesity or those fed a HFD, resulting from cytokine release by myofibroblasts and immune cells[86]. Local inflammation has been demonstrated to expand colon cell progenitors or stem cells and to induce their proliferation in the intestine. For example, HFD-induced obesity elevated both the colonic proliferative zone and stem cell zone in a pig model, and the proliferative zone was associated with an increase in the innate inflammatory markers TLR4, NF-κB, IL-6, and lipocalin-2[87]. In addition, activation of NF-κB, the central pathway downstream of the majority of proinflammatory cytokines, following local inflammation enhanced the reprogramming of non-stem enterocytes to acquire stem-cell-like properties, which expanded the pool of stem cells and generated tumor-initiating cells[88]. HFD-induced obesity promoted the phosphorylation of GSK3β and then increased the nuclear translocation of β-catenin, thereby activating the expression of WNT signaling target genes[89]. These effects were diminished by the deletion of tumor necrosis factor-alpha (TNF-α), indicating the role of inflammation induced by TNF-α in colon tumorigenesis associated with obesity[89]. Another inflammatory mediator, prostaglandin E2, was also found to be elevated by HFD in the circulation or in local tissues, leading to an increased number and division rate of stem cells[22].

Other proinflammatory mediators have also been demonstrated to facilitate CSC expansion. For example, IL-6 can induce malignant features in human ductal breast carcinoma stem/progenitor cells [90]. IL-8 treatment leads to breast cancer cells partially acquiring some stem-like cell attributes, thereby increasing their aggressiveness[91]. Chemokine (C-C motif) ligand 2, derived from cancer-associated fibroblasts, stimulates the stem cell-specific, sphere-forming phenotype in breast cancer cells and CSC self-renewal[92]. Although these studies were not carried out under obese conditions, these proinflammatory mediators are consistently elevated in obese individuals and are upregulated upon contact with cancer cells. The enrichment of CSCs may be partially attributed to these cytokines, as a few studies indeed found that proinflammatory cytokines, including IL-6, IL-8 and monocyte chemoattractant protein 1, are overexpressed in cancer-associated adipose tissue from obese patients and induce the stemness of cancer cells, while such effects were not found in nonobese patients[77]. Considering the importance of localized and systemic inflammation in the induction and maintenance of stemness in cancer cells and the definite association between inflammation and obesity, elucidating how these inflammatory pathways increase the risk of cancer incidence, progression and therapy resistance *via* CSCs holds great promise to decrease the burden of cancer in obesity.

Self-renewal and stemness pathways

Stem cells are proposed to reside in a distinctive microenvironment, that is, the stem cell niche, which induces and maintains the self-renewal and differentiation of stem cells. In the TME, niche signals also play critical roles in cancer cells acquiring more stemness. Although the pathways responsible for establishing a CSC phenotype are diverse and differ among cancer entities, developmental signaling pathways, including the Notch, WNT, Hedgehog and Hippo pathways, are commonly altered in CSCs and interact with each other and with other common oncogenic signaling pathways and have key regulatory functions that support the maintenance and survival of these cells, making them prime targets for anti-CSC therapy[82]. Obesity, HFD and abnormal adipocytes may engage in these self-renewal and stemness pathways directly or indirectly through increased local and systemic levels of many cytokines and adipokines. For example, in ISCs and progenitors from mice fed a HFD, the expression of Jag1 and Jag2, which are ligands for the Notch pathway and are normally expressed by neighboring niche cells, was increased by the activation of WNT/β-catenin, indicating that a HFD drives ISCs to niche independence[19]. Within the ISC niche, MSCs were expanded and secreted predominant levels of Wnt2b in the colon of HFD-fed mice, which promoted the growth of tumorigenic properties and accelerated the expression of CSC-related markers in colon organoids[93]. CSCs isolated from obese mice also exhibited enhanced Notch2 expression[94]. However, such direct evidence supporting the association between obesity and alterations in stemness pathways is scarce, and more studies are needed to test this model. Nonetheless, some emerging data demonstrate alterations in these stemness pathways in obesity-induced cancers. For instance, HFD consumption could upregulate the expression of β-catenin proteins in a mouse xenograft tumor model[95]. Notch signaling activity was increased in breast cancer cells following coculture with obesity-altered ASCs[96]. In addition, YAP, the major player in the Hippo pathway, dictates mitochondrial redox homeostasis to facilitate obesity-associated breast

cancer progression[97]. Although the contributions of CSCs were not examined in these studies, regarding the definitive effects of these signaling pathways on CSCs, it is reasonable to speculate that the upregulated activity of these pathways in obesity may promote the progression of cancer through CSCs and that targeting these pathways may be more promising in obesity-induced cancers.

Microbiome dysbiosis

The epithelial barrier surfaces of our body host a diverse microbial community, or microbiota, that is composed of a variety of microorganisms, such as bacteria, fungi, and viruses[98]. Substantial studies have reported that obesity or HFD markedly affects the composition of the commercial microbiota, especially in the intestine[48]. Obesity-induced perturbation of the gut microbiota has been demonstrated to influence stem cell phenotypes. For example, structural changes in the microbiota were associated with HFD-induced myeloid progenitor skewing of the differentiation capacity of hematopoietic stem cells[99]. The intestinal tract bacteria *Lactobacillus* induces the release of adiponectin by niche cells through NF-κB activation[100]. In pigs with HFD-induced obesity, the elevation of the proliferative zone and stem cell zone was associated with increased abundance of the gut bacterial phyla *Proteobacteria* and *Firmicutes*[87]. In addition to these initial data suggesting the association between obesity-related microbiome dysbiosis and the possible development of CSCs, evidence linking the microbiome in obesity to CSC function is lacking. Whether obesity-induced alterations in the composition of the host microbiota affect initiation, progression and therapy resistance and the underlying mechanisms need more investigation with the hope of providing more strategies for cancer prevention and treatment.

CLINICAL SIGNIFICANCE

If the above-discussed links between obesity and CSCs are founded on convincing evidence, an obvious question is whether targeting both can prevent or improve the outcomes of cancer. At present, targeting both obesity and CSCs has great challenges; however, progress is gradually being made. For example, bariatric surgery has been popularized globally, leading to more weight loss and longer maintenance than diet and lifestyle changes[101]. Intriguingly, in these patients with obesity who received bariatric surgery, a decrease in overall cancer diagnoses was observed[102,103]. However, surgical intervention does not guarantee the recovery of obese patients to a normal state and is typically a harmful method. Theoretically, obesity prevention represents the most promising and scientific solution, which requires joint efforts and cooperation from throughout the whole world[104]. However, under obesity pandemic conditions, exploring strategies to lower the incidence of obesity-related cancer represents the primary goal. Unfortunately, no experience has been gained. As low-grade inflammation plays a central role in linking obesity and cancer, anti-inflammatory therapy may be a promising direction, which has been validated in the prevention of colorectal cancer[105]. For obese patients with established malignancies, there is an urgent need to improve therapeutic efficacy and long-term survival. As mentioned above, various mechanisms have been proposed to link obesity and CSCs; thus, whether blocking these connections can prevent or delay the initiation and progression of cancer needs further study. Encouragingly, such strategies have been explored extensively, and some of them have already advanced into clinical use. For example, the clinical development of therapeutics targeting CSC-associated developmental signaling pathways has resulted in improved patient outcomes[82]. Some inflammatory factor-targeting therapies also show promising results in improving outcomes in patients with cancer[106]. Lifestyle interventions, such as reduced dietary intake and increased physical activity, were demonstrated to cause weight loss, leading to altered expression of inflammatory factors and maintenance of stem cell homeostasis[107,108]. Therefore, what awaits us next is to validate their efficacy in obese people with cancer.

CONCLUSION

As stated above, notwithstanding the clear and compelling link between obesity and CSCs, as well as an understanding of the mechanisms connecting them, this research area is still in its infancy. Most scientific research exploring the association of CSCs and obesity originates from mouse models or was inferred indirectly from the conclusions of different research fields. Therefore, there are still many major questions waiting for answers. For example, how can the profound differences in cancer incidence across different anatomical sites influenced by obesity be explained? Do the differences in the microenvironment across adult stem cell niches contribute to these variations? Regarding alterations in stem cell biology, how much overlap is there among animal models and obese patients? What role does the microbiome play in mediating the induction, maintenance and therapy response of CSCs? Does obesity differentially regulate normal and malignant stem cells, and how does it do so? How does obesity influence the crosstalk between CSCs and immunoediting? To what extent are stem cells conditioned in

obesity reversed when obesity is improved? Does obesity enhance the establishment of premetastatic niches? Can strategies aimed at targeting the mechanisms linking obesity and CSCs prevent the initiation and delay the progression of cancer?

Despite a wealth of unknowns, it is clear that obesity increases the stem cell pool and induces biological modulation in these cells, which predisposes these stem cells to transformation. Regarding the increased prevalence of obesity and its convincing association with cancer, programs are urgently needed to decrease the incidence of obesity. At this time, primary obesity prevention through public health policies, including dietary and lifestyle changes, represents a compelling approach toward a reduction in the incidence of obesity and its associated cancer. Identifying obese patients with increased cancer risk and developing appropriate management of obesity or applying cancer prevention methods such as anti-inflammatory agents in these populations represents another compelling approach toward a reduction in the burden of cancer in obesity. Several mechanisms have been proposed to explain the association between obesity and CSCs, and large amounts of agents targeting these pathways have been developed. Testing them in patients with obesity and comparing their efficacy with that in nonobese individuals are important components of future translational research and clinical trials.

ACKNOWLEDGEMENTS

Abstract

Since dental pulp stem cells (DPSCs) were first reported, six types of dental SCs (DSCs) have been isolated and identified. DSCs originating from the craniofacial neural crest exhibit dental-like tissue differentiation potential and neuro-ectodermal features. As a member of DSCs, dental follicle SCs (DFSCs) are the only cell type obtained at the early developing stage of the tooth prior to eruption. Dental follicle tissue has the distinct advantage of large tissue volume compared with other dental tissues, which is a prerequisite for obtaining a sufficient number of cells to meet the needs of clinical applications. Furthermore, DFSCs exhibit a significantly higher cell proliferation rate, higher colony-formation capacity, and more primitive and better anti-inflammatory effects than other DSCs. In this respect, DFSCs have the potential to be of great clinical significance and translational value in oral and neurological diseases, with natural advantages based on their origin. Lastly, cryopreservation preserves the biological properties of DFSCs and enables them to be used as off-shelf products for clinical applications. This review summarizes and comments on the properties, application potential, and clinical transformation value of DFSCs, thereby inspiring novel perspectives in the future treatment of oral and neurological diseases.

Key Words: Dental follicle stem cells; Oral disease; Neurological disease; Tissue engineering; Regeneration; Immunoregulation

Core Tip: This review is intended to summarize and comment on the properties, application potentials, and clinical transformation value of dental follicle stem cells (DFSCs). Stem cells derived from dental SCs (DSCs) originating from the craniofacial neural crest exhibit dental-like tissue differentiation potentials and neuro-ectodermal features, making them a promising alternative for the treatment of oral and neurological diseases. Moreover, in contrast to other DSCs, DFSCs from the early-developing tissues exhibit a number of superior properties, including larger tissue volume, higher cell proliferation rate, more similar biological profiles to progenitor cells of origin, and better anti-inflammatory effects, *etc.* These advantages are part of the critical mechanism by which DFSCs exert therapeutic effects and are relevant for large scale scaling and industrial generation for clinical applications. Moreover, cryopreservation preserves the biological properties of DFSCs and enables them to be used as off-shelf products for clinical applications. Therefore, DFSCs could have great clinical prospects and translational value in oral and neurological diseases with natural advantages.

INTRODUCTION

Stem cells are undifferentiated cells characterized by the ability of self-renewal, clonality, and differentiation into various types of cells[1]. With the development of cell biology and modern medicine, the application of stem cells has brought a new approach for restoring tissue defects and treatment of some refractory diseases[2,3]. To date, regenerative medicine has become an important branch of modern medical science and has played an increasingly important role in clinical treatment. Stem cells are a vital element of regenerative medicine, and different stem cell types have their own advantages and drawbacks[4]. With stem cell research deepening, it is crucial to explore the appropriate stem cells to solve clinical problems and obtain better clinical outcomes.

Stem cells for application in regenerative medicine are divided into the following two categories: Pluripotent and multipotent. Pluripotent stem cells include natural embryonic stem cells (ESCs) originating from the inner cell mass of the blastocyte and artificially induced pluripotent SCs (iPSCs)[5]. Multipotent stem cells refer to adult stem cells that exist in different tissues of the body, and their main function is general homeostasis and repair of injured tissues by differentiation[6]. Adult stem cells are also known as postnatal stem cells and mainly originate from either epithelial cells or mesenchymal cells [4].

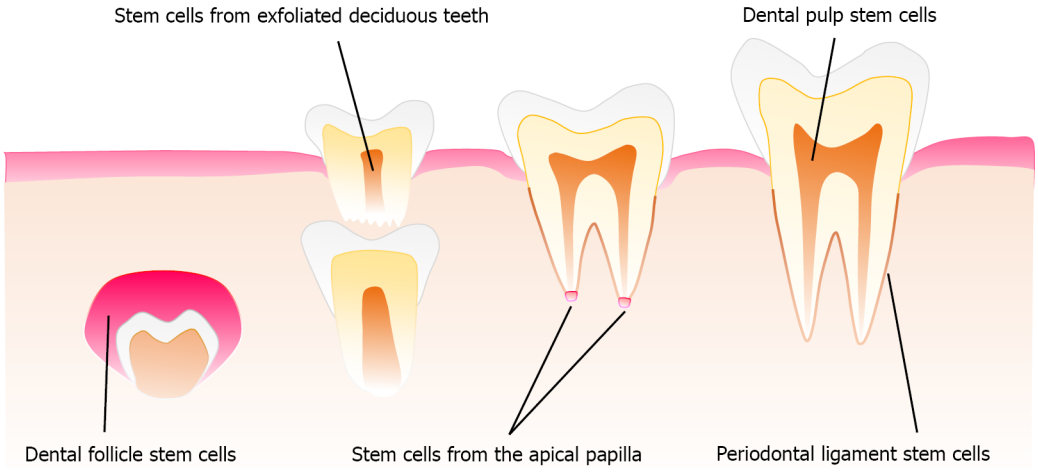
Mesenchymal SCs (MSCs) are typical adult stem cells derived from mesenchymal tissues. In addition to the ability of self-renewal, high proliferation, and multidirectional differentiation, MSCs also present high immunomodulation and antiapoptotic capacity, to achieve the purpose of promoting tissue regeneration and disease treatment. Compared with ESCs, MSCs are multipotent but limited in terms of differentiation ability. However, the acquisition and clinical application of ESCs are also dramatically restricted to ethical, legal, safety, and source constraints[7]. Moreover, since iPSCs were first generated in 2006 by Takahashi *et al*[8] with four factors, a growing number of researchers have focused on the clinical application prospects and transformation value of iPSCs and their specialized differentiation cells. Nevertheless, iPSCs also present some worrying aspects as follows: (1) iPSCs have pluripotency, similar to ESCs, as well as the ability to cause possible teratomas while the specialized differentiated final product contains undifferentiated cells[9]; (2) there is possibility of tumor formation by integrated oncogenes, insertional mutagenesis, and disrupting tumor suppressor genes[9]; (3) epigenetic memories and genomic aberrations have been detected in reprogrammed cells[10]; and (4) human skin fibroblast-derived iPSCs have a 72% ultraviolet light-related damage, and human blood-derived iPSCs have a high prevalence of acquired BCL6 corepressor mutations (26.9% of lines)[11].

The first human trial using retinal pigment epithelium derived from iPSCs for the treatment of age-related macular degeneration was started in Japan in 2014 but was later suspended[12]. Recently, another study has reported a distinctive case of immature teratoma after the patient underwent autologous iPSC-derived cell therapy for diabetes. Two months after the cells had been injected into the deltoid muscle, a teratoma formed in the injection area[13]. Safety remains the most important criterion of a cellular product for clinical applications[9]; thus, more safety-related quality detections with iPSC-derived cell therapy should be performed. In contrast to ESCs, iPSCs, and iPSCs specialized differentiation cells, several studies have demonstrated that MSCs exhibit good safety profiles, making MSCs

the most widely used cell type for clinical applications at present[14-16]. To date, various MSCs have been discovered in different tissues, including bone marrow, umbilical cord, umbilical cord blood, placenta, amniotic fluid, hair follicle, adipose tissue, and dental tissues[17-26].

Since dental pulp stem cells (DPSCs) were first reported by Gronthos *et al*[27] in 2000, a growing interest has been observed toward the potential of dental stem cells (DSCs) for the treatment of oral and neurological diseases[28,29]. Six types of human DSCs have been isolated and identified at different stages of tooth development[30]. For instance, DPSCs, stem cells from apical papilla (SCAPs)[31], stem cells from human exfoliated deciduous teeth (SHEDs)[32], periodontal ligament stem cells (PDLSCs)[33], and gingival mesenchymal stem cells (GMSCs)[34] can be gained after tooth eruption, while dental follicle stem cells (DFSCs) are a special kind of DSCs, which can be obtained at the early developing stage of the tooth prior to eruption[35] (Figure 1).

The dental follicle is an ectomesenchyme-derived and loose connective tissue originating from the cranial neural crest. During the bud stage of tooth development, the dental follicle is formed and surrounds the dental papilla and enamel organ, which plays a critical role in tooth eruption *via* regulating bone resorption and formation[36]. In the late bell stage, the dental follicle gives rise to the supporting tissues of the tooth-periodontium, including cementum, alveolar bone, and periodontal ligament[37]. Compared with other dental tissues, dental follicle tissue has the obvious advantage of large tissue volume, which is the premise of obtaining a sufficient number of cells to meet the needs of clinical application. Meanwhile, the number of DFSCs obtained in the same passage is far greater than that of DPSCs, accordingly being more suitable for large-scale expansion and industrial generation[38]. Due to the origin of dental follicle tissue in the early stage of tooth development, it has been demonstrated that DFSCs have the following advantages over DPSCs. First, DFSCs exhibit a significantly higher cell proliferation rate and colony-formation capacity than DPSCs[38], which further suggests that DFSCs may be better able to meet the needs of clinical transformation in terms of quantity and quality. Second, DSCs originate from neural crest cells. DFSCs have more similar protein profiles with cranial neural crest cells (CNCCs) than DPSCs, and possess high potency in odontogenic differentiation *in vitro*[39], which demonstrates that DFSCs may have better transformation advantages for the treatment of neurological and oral diseases. Third, DFSCs have better inhibitory effects on the proliferation of proinflammatory lymphocytes and better promote the proliferation of anti-inflammatory Treg cells than SHEDs and DPSCs[40], which indicates that DFSCs have better immunoregulation capacity. Of note, the advantages in terms of quantity, quality, differentiation, and immunoregulatory properties, as mentioned above, are part of the critical mechanism by which MSCs exert therapeutic effects. In this regard, DFSCs appear to be the candidate cells with natural advantages for regenerative medicine compared with stem cells from other dental tissues. Indeed, as a kind of dental tissue-derived stem cells originating from the neural crest, DFSCs may be more advantageous in promoting oral tissue regeneration, including periodontium, dental pulp, and tooth regeneration, as well as in treating neurological injury and neurodegenerative diseases, such as spinal cord and brain injury, as well as Parkinson's disease (PD) and Alzheimer's disease.



ORAL DISEASES AND FUNCTIONAL UNIT REGENERATION *VIA* DENTAL FOLLICLE STEM CELLS

Periodontitis and periodontal regeneration

The periodontium is a complex functional unit that plays a critical role in the oral cavity[41]. Periodontitis is a common and chronic inflammatory disease caused by plaque in the teeth[42]. As the disease progresses, gingival recession, loss of soft tissue attachment, and even intrabony defects can occur, ultimately resulting in premature tooth loss[43]. To date, while numerous conventional clinical treatments for periodontitis have been shown to control inflammation and aggressive progression, these strategies have not been able to achieve periodontal regeneration. Previous preclinical studies have demonstrated that the transplantation of stem cells presented the potential and provided new hope for periodontal regeneration[44,45].

The combination of DFSCs and hydroxyapatite scaffold forms a cementum-like matrix *in vivo* after transplantation into mice[35]. Scaffold plays a critical role in tissue engineering, providing support for transplanted stem cells and enhancing the therapeutic effects of tissue regeneration. The cell sheet technique prevents extracellular matrix degradation and provides a novel scaffold-free cell delivery strategy[46]. The extracellular matrix contains numerous growth factors and provides support to the cells without the need for additional scaffolds[47]. In addition, cell viability and function can be restored without the digestion operation step. A complex of dental follicle cell sheets forms periodontal tissue-like structures, including cementum-like structures and periodontal ligament with abundant blood vessels after transplantation into the subcutaneous areas of nude mice[48], demonstrating that DFSC sheets have the potential to achieve the goal of periodontal regeneration.

The tooth root development requires stimulation from Hertwig's epithelial root sheath (HERS), and DFSCs differentiate into cementoblasts during the epithelial-mesenchymal interaction process[49]. Accordingly, it has been demonstrated that the formation of cementum and periodontal ligament-like

Figure 1 Main dental stem cells derived from different dental tissues. This image shows the six types of human dental stem cells isolated and identified at different stages of tooth development. Dental follicle stem cells are obtained at the early developing stage of the tooth prior to eruption.

tissue was enhanced at 5 wk after implantation into rat submentum when DFSCs had been pre-exposed to HERSCs[50], suggesting that establishing a microenvironment similar to tooth root development is important for periodontal regeneration. Moreover, appropriate microinflammation preconditioning is important for improving the regeneration and immunoregulation capacity of DFSCs and their secreted exosomes. Lipopolysaccharides (LPS) upregulated the expression of osteogenic and adhesion-related proteins in DFSC sheets, which showed good performance in canine periodontal regeneration[51]. Furthermore, LPS enhanced the paracrine activity and immunomodulatory effect of DFSCs, and LPS-preconditioned DFSC-derived small extracellular vesicles (sEV) were beneficial for repairing lost alveolar bone in rats[52]. A later study further clarified that LPS-preconditioned DFC-sEV inhibited intracellular reactive oxygen species (ROS) as an antioxidant; it reduced the NF-κB receptor activator ligand/osteoprotegerin ratio of PDLSCs by inhibiting ROS/Jun amino-terminal kinase (JNK) signaling under inflammatory conditions and promoted macrophages to polarize toward the M2 phenotype *via* ROS/extracellular signal-regulated kinase (ERK) signaling[53].

For clinical applications, autologous PDLSCs have been used in clinical studies (ClinicalTrials.gov Identifier: NCT01357785; www.isrctn.com Identifier: ISRCTN13093912), and the results showed no significant differences in the effect on intrabony lesions between PDLSCs groups and scaffold-only groups[54,55]. Although some previous studies have demonstrated that PDLSCs might be the first choice for periodontal regeneration[28,43], DFSCs can give rise to periodontal supporting tissues, including cementum, alveolar bone, and periodontal ligaments. Moreover, previous comparative studies have revealed that DFSCs exhibit a stronger capacity for the regeneration of cementum and periodontal attachment than PDLSCs[48,56]. Thus, DFSCs can be considered a better candidate cell source for periodontal regeneration.

Dental pulp necrosis and pulp regeneration

Dental pulp necrosis is an irreversible inflammatory dental disease that causes destruction and loss of the pulp tissue, resulting in the loss of teeth and even abscesses of the jaw[57]. Bacterial infections play a key role in the development of dental pulp necrosis. Bacterial invasion and colonization were observed in the pulp necrotic areas with caries exposure and symptomatic irreversible pulpitis. Additionally, bacterial penetration of blood vessels occurred, which may spread bacterial infections[58]. Before it leads to more serious consequences, endodontic treatment must be performed to remove the damaged pulp[59,60]. However, the tooth becomes more fragile and susceptible to caries, periapical infection, and fracture after endodontic treatment because of the loss of blood and nutrition supply[59].

Stem cell-based dental pulp regeneration has the objective of developing new methods to replace the conventional treatment of dental pulp necrosis. Scaffolds, stem cells, and growth factors have been used for dental pulp regeneration. Findings from animal studies have shown that DPSCs seeded in a collagen scaffold with dentin matrix protein 1 were able to induce the formation of dental pulp-like tissues in immunodeficient mice[61], and DPSCs pellets stimulated by bone morphogenetic protein 2 promoted the dentin formation onto the amputated pulp of dog teeth[62]. Later, autologous pulp stem cells and granulocyte colony-stimulating factor with a clinical-grade atelocollagen scaffold were transplanted into the dog pulpectomized teeth, promoting pulp/dentin regeneration[63]. A pilot clinical study using a similar strategy has also observed complete pulp regeneration in humans[64]. Moreover, a scaffold-free translation strategy has also been used for pulp regeneration. DPSC aggregates derived from the autologous canine tooth pulp induced the regeneration of three-dimensional pulp tissue equipped with

blood vessels and sensory nerves 12 mo after treatment[65]. Consequently, DPSCs are derived from the pulp tissue and it appears that DPSCs have the potential to promote dentin-pulp regeneration, while DFSCs have a similar capacity.

Previous studies have demonstrated that providing an inductive microenvironment with a suitable scaffold could achieve dentin and even dental pulp regeneration. Treated dentin matrix (TDM) is derived from animal or human dentin matrix treated with ethylenediamine tetraacetic acid, containing abundant collagen, noncollagenous proteins, and growth factors. Both rat and human TDM induce and support complete dentin regeneration, in addition to inducing transplanted DFSCs to differentiate into odontoblasts and express dentin sialoprotein and matrix protein 1[66,67]. The cell sheet technique promotes dental pulp regeneration. DFSC sheets were substituted for DFSCs and, in combination with TDM, were implanted subcutaneously into the dorsum of mice. New dentin pulp-like tissues were observed after eight weeks post-transplantation[68]. Moreover, native dental pulp extracellular matrix (NDPE) can be used to obtain prefabricated-shaped dental pulp. Dentin-pulp complex-like tissues and columnar odontoblasts-like layers arranged along the interface between newly formed predentin matrix could be found after DFSCs-NDPE-TDM transplantation to the jaw of miniature swine for 12 wk[69]. Therefore, DFSCs could also exhibit the capacity to regenerate the dentin-pulp tissues with suitable inductive scaffolds.

Tooth root and whole-tooth regeneration

The regeneration of whole teeth is a major objective and promise of oral regenerative medicine. To date, two main strategies have been used to achieve this goal. The first strategy is a combination of mesenchymal and epithelial cells to construct a bioengineered tooth germ, which is then transplanted into the alveolar socket. Parts of animals showed whole-tooth eruption around 3.5 mo after tooth-germ implantation[70]. However, several barriers should be addressed in future studies of bioengineered teeth, such as indiscriminate shape and smaller size than natural teeth[4,70-73]. The second strategy includes the direct reconstruction of the functional units, such as bio-tooth root with periodontal tissue-like structures and dentin-pulp-like tissues.

As with the combination of implants and crowns to replace missing teeth, researchers have explored implant-like scaffolds to reconstruct the root. As mentioned above, TDM has the potential to be a suitable scaffold for root reconstruction. Yang *et al*[68] used calcified human dentin to model an alveolar microenvironment and used DFSC sheets-TDM-DFSC sheets to reconstruct the pulp-root-periodontium structure. TDM could induce and support DFSC sheets to develop new dentin-pulp and cementum-periodontium-like tissues after subcutaneous transplantation into nude mice for 8 wk[68]. Moreover, with seed DFSCs, the complex of aligned PLGA/Gelatin electrospun sheet/TDM/NDPE generated tooth root-like tissues after 12 wk of transplantation in porcine jaws[69]. Shape-optimized TDM scaffolds with DFSCs were transplanted into the alveolar bone of swine, and ceramic crowns were installed. These bio-tooth roots not only regenerated histologically but also allowed masticatory functions and remained stable for 3 mo[74]. In nonhuman primates, a novel functional biological root complex was constructed based on DFSC sheets and *in vitro* three dimensional (3D) suspension culture. This complex was then transplanted into rhesus monkeys and gradually restored occlusal function and long-term masticatory function for 2 years during the evaluation period[75]. In this regard, DFSCs with suitable scaffolds have the potential to be suitable stem cells for whole-tooth reconstruction based on bio-booth root regeneration.

THERAPEUTIC POTENTIALS OF DENTAL FOLLICLE STEM CELLS IN NEUROLOGICAL DISEASES

Neural differentiation of dental follicle stem cells

As mentioned above, dental follicle is an ectomesenchyme tissue that originates from the cranial neural crest. DFSCs not only express the markers typical of MSCs [*e.g.*, cluster of differentiation (CD) 44, CD90, CD105] but also express neural cell markers (*e.g.*, Nestin, β-III tubulin, and CNpase)[76-78] and even embryonic stem cell markers (octamer-binding transcription factor 4 and sex-determining region Y-box 2)[79], indicating that DFSCs may retain some of the neural and embryonic features and can differentiate into neural-like cells. DFSCs display neural-like cell morphology with small neurite-like cell extrusions with a neuronal differentiation strategy[76]. Dental pulp comprises blood vessels, neural fibers, and connective tissue, and DPSCs exhibit extraordinary capacity to differentiate into neural-like cells and represent a potential source for neuronal regeneration therapies[80]. However, a comparative study has demonstrated that DFSCs possess more similar protein profiles to CNCCs than DPSCs[39]. Moreover, compared with DPSCs, the expression of CNpase, neurofilament protein, Nestin, and β-III tubulin of DFSCs was upregulated significantly after treatment in the same neural-induction condition [78]. From this perspective, DFSCs may be a better candidate cell type for neural differentiation and even for the treatment of neurological diseases based on pre-differentiation.

Therapeutic potentials of dental follicle stem cells in neurotrauma and neurodegenerative disorders

Spinal cord injury (SCI) is a severe neurological trauma that causes the impairment of sensory and motor functions[81]. The acute stage of injury is directly caused by trauma, including compression, contusion, and shear injury forces. Proinflammatory cells are then activated, releasing abundant inflammatory cytokines, which induce a cascade of secondary injury[82]. Many neurons, astrocytes, and other neural cells die in the injured area due to necrosis or apoptosis during the secondary injury[83]. Until now, current clinical strategies have not achieved satisfactory outcomes due to irreversible damage to neural cells. Stem cell-based therapies hold the promise of developing new approaches for the treatment of SCI. Several types of stem cells have been used for transplantation, such as neural SCs (NSCs), ES/iPS-derived NSCs, and MSCs[84]. However, the sources of NSCs are limited and also face ethical issues. ES/iPS-derived cells exhibit some of the aforementioned worrying aspects. Thus, MSCs may now be a better candidate cell type for SCI. Researchers have compared the therapeutic effects of MSCs from bone marrow and dental pulp. Transplantation of DPSCs promoted marked recovery of locomotor function in the hind limbs, while transplantation of bone marrow SCs (BMSCs) resulted in substantially less recovery of locomotor function in rats with complete SCI. The main mechanisms include inhibition of apoptosis in neurons, astrocytes, and oligodendrocytes; promotion of regeneration of disjunct axons; and differentiation into mature oligodendrocytes to replace lost cells[85]. Later, another comparative study explored the differences among DFSCs, SCAPs, and DPSCs for the treatment of SCI. Findings from an animal study demonstrated that all three types of DSCs, especially DFSCs, have the potential to promote functional recovery after SCI by reducing the inflammatory response, promoting neurite regeneration, reducing progressive hemorrhagic necrosis, and differentiation into mature neurons and oligodendrocytes but not astrocytes[77]. Moreover, scaffolds with DFSCs were also used to repair the spinal cord defect; for example, aligned poly-ε-caprolactone/poly-lactide-co-glycolic acid electrospun material allowed nerve fibers to pass through, and induced DFSCs to differentiate *in vivo*[86].

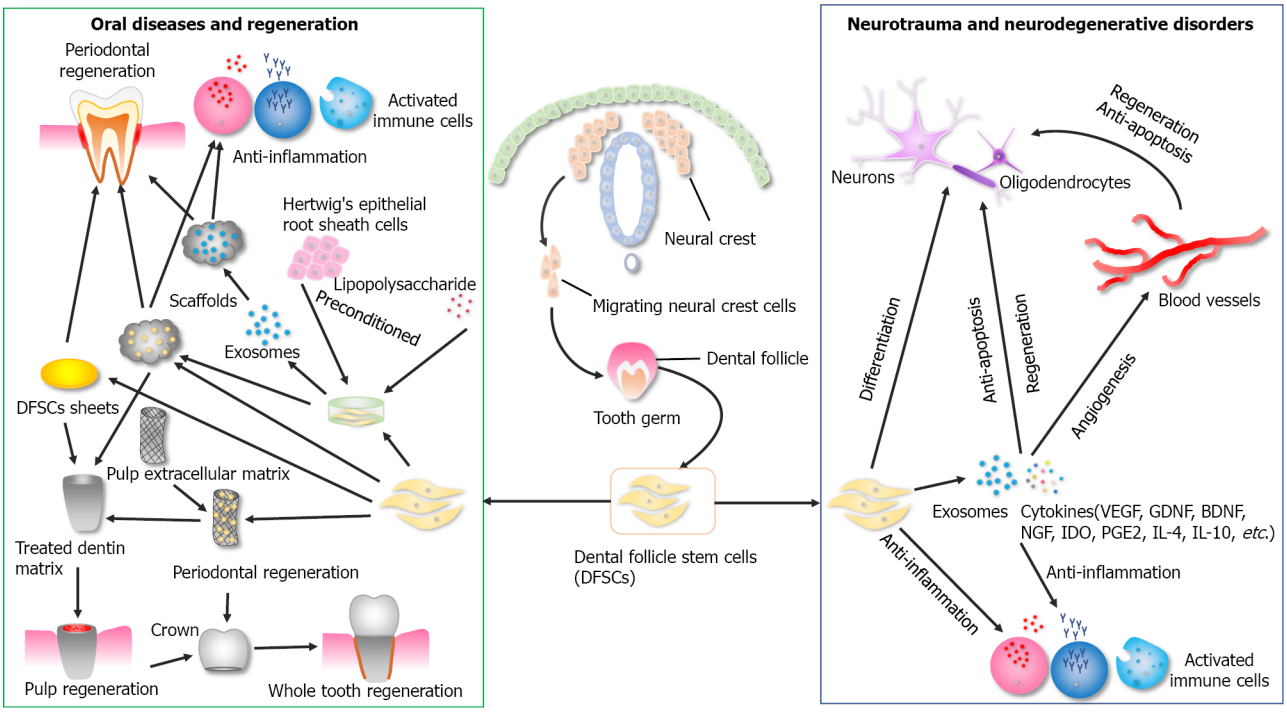
PD is a common and progressive neurodegenerative disorder characterized by tremors, rigidity, and bradykinesia[87,88]. The aggregates of ubiquitin and α-synuclein-positive protein, Lewy bodies, and the loss of dopaminergic neurons in the substantia nigra pars compacta are the main characteristics that define PD[89]. The incidence of the disease rises steeply with age, affecting approximately 1% of the population between the ages of 70 years and 79 years[90]. Although pharmacological approaches (such as amantadine and levodopa) and nonpharmacologic strategies (deep brain stimulation, exercise, and physical therapy) have been used in PD treatment[91,92], these therapeutic strategies only delay the progression of the disease and relieve the symptoms but do not achieve regeneration of dopaminergic neurons. There has been considerable excitement about the use of MSCs to treat neurodegenerative diseases *via* secretion of anti-inflammatory factors [*e.g.*, indoleamine (2,3)-dioxygenase (IDO), prostaglandin E2 (PGE2)], growth factors [*e.g.*, vascular endothelial growth factor (VEGF), glial cell line-derived neurotrophic factor (GDNF)], and exosomes to achieve neuroinflammation attenuation and neural regeneration[93,94]. Various cell types, including BMSCs, adipose derived stem cells, umbilical cord mesenchymal stem cells (UCMSCs), and DSCs, and their neural-primed cells or accessory products (such as exosomes) have been used to treat PD[95-99]. The locomotive defect was recovered in PD rats after neural-primed SHEDs were transplanted and differentiated into neurons and dopaminergic neurons *in vivo*. The transplanted cells resided in the brains of rats and formed functional connections [98]. DFSCs have also been transplanted for the treatment of PD and survived in the transplanted regions of PD mice for more than 6 wk after surgery. DFSCs not only increased the number of dopaminergic neurons around them but also differentiated into tyrosine hydroxylase-positive cells, indicating that DFSCs may be a potential source in the exploration of possible therapeutic roles in PD [99]. In addition, other DSCs have been used to treat stroke, Alzheimer's disease, and a variety of peripheral nervous system diseases[100,101]. Based on the biological properties of DFSCs, they may also present promising therapeutic effects in the treatment of the aforementioned neurological diseases.

IMMUNOREGULATION OF DENTAL FOLLICLE STEM CELLS

Both in oral and neurological diseases, the immunomodulatory capacity is one of the most crucial functions of MSCs to facilitate the repair or regeneration of damaged tissues[51,77]. MSCs can regulate the proliferation, activation, maturation, and function of innate and adaptive immune cells *via* cell-to-cell direct contact, soluble cytokines, and exosomes[102]. As a kind of MSCs, DFSCs also present immunomodulatory characteristics. In acute lung injury models, DFSCs could suppress the production of proinflammatory cytokines, such as monocyte chemoattractant protein (MCP)-1, interleukin (IL)-1, IL-6, and tumor necrosis factor (TNF)-α; decrease the proportion of proinflammatory macrophage M1 phenotype; increase the level of anti-inflammatory cytokine IL-10 and the proportion of anti-inflammatory M2 phenotype both in bronchoalveolar lavage fluid *in vivo* and *in vitro* experiments[103]. Furthermore, DFSCs also exhibit great therapeutic potential in autoimmune diseases and chronic inflammatory disorders. DFSCs suppress the proliferation of T lymphocytes and lymphocyte apoptosis but increase the number of Tregs. DFSCs also reduce the secretion level of TNF-α but upregulate the level of IL-10 in peripheral blood mononuclear cells (PBMCs) of patients with rheumatoid arthritis[104].

Moreover, in inflamed mononuclear cell samples of patients with Crohn's disease, DFSCs also downregulate lymphocyte proliferation, CD4 + IL22BP T cell ratio, and the secretion of TNF-α and IL-6, but increase the frequency of Tregs and the level of IL-10[105]. From the case studies mentioned above, we can briefly summarize that DFSCs exert the common immune modulatory capacity *via* suppressing the proinflammatory immune cells [*e.g.*, T-helper (Th) 1, Th17, macrophage M1] and cytokines (*e.g.*, TNF-α, IL-1, IL-6) and increasing the number of anti-inflammatory immune cells (*e.g.*, Tregs, macrophage M2) and cytokines (*e.g.*, IL-4 and IL-10). Therefore, it is necessary to design experiments to examine the ratio or level changes in inflammatory cells and cytokines after co-culture of DFSCs with activated PBMCs, which can help us to screen the cells with superior immune properties and obtain better clinical outcomes.

CRYOPRESERVATION OF DENTAL FOLLICLE STEM CELLS



Stem cell-based therapies have been investigated for tissue engineering and treatment of many diseases for several decades, and cryopreservation can be used to effectively preserve stem cells. Cryopreservation is the process of gradually cooling cells or tissues to sub-zero temperatures, and finally preserving them in the gas phase liquid nitrogen (-150°C to -196°C) for an extended period. In this state, the biological activity of the cells is stopped, and their viability can be restored by careful thawing when needed[106]. Human DFSCs isolated from fresh and cryopreserved dental follicles show similar biological characteristics, such as proliferation ability, surface markers, and tri-linage differentiation capacities[107]. Moreover, the two types of DFSCs possess the same osteogenic differentiation potential and immunomodulatory properties for bone tissue engineering, resulting in the inhibition of adaptive immune response, which demonstrates that the stemness and immunomodulatory capacity of long-term-preserved dental follicle tissues can be restored[108]. Another study compared the biological characteristics between cryopreserved DFSCs and the cells from cryopreserved dental follicles. After 3 mo of cryopreservation, the cells from the cryopreserved dental follicles showed similar levels of stemness and apoptosis-related genes and exhibited similar osteogenic and adipogenic differentiation capabilities to cryopreserved DFSCs[109]. In this regard, both cryopreservation of DFSCs from fresh dental follicle tissues and direct cryopreservation of dental follicle tissues can preserve the biological properties of the cells. As a consequence, cryopreservation technology enables DFSCs to the off-the-shelf products for clinical applications.

Cryopreservation addresses the preservation of DFSCs. Another problem is that it is questionable whether allogeneic stem cells exhibit the same therapeutic effects as autologous stem cells. A previous study compared the therapeutic effects of allogeneic and autologous PDLSCs on periodontal tissue regeneration in a miniature pig model of periodontitis. Significant periodontal tissue regeneration was achieved in both transplanted groups without significant difference due to low immunogenicity and marked immunosuppression of T-cell antigen *via* PGE2[110]. Furthermore, allogeneic DSCs likely did not affect the therapeutic effects because of their inherent characteristics. However, more experiments should be performed to compare the outcomes of allogeneic and autologous DFSCs in different diseases.

In addition to cell cryopreservation, some biological materials can be cryopreserved. For instance, after being cryopreserved in liquid nitrogen with cryoprotectant for several months, the cryopreserved TDM exhibited superior mechanical properties, more dentin-related proteins, and a larger pore diameter than the fresh TDM. The cryopreserved TDM was also able to induce dental follicle cells to regenerate new dentin-pulp-like tissues[111], suggesting that the cryopreservation techniques address the preservation of biological materials and also enable them to be used as off-the-shelf scaffold for tissue engineering.

CONCLUSION

In this review, it was found that among MSCs, stem cells derived from dental tissue originating from the craniofacial neural crest exhibit dental-like tissue differentiation potential and neuro-ectodermal features, which makes them a promising alternative for the treatment of oral and neurological diseases (Figure 2). Moreover, in contrast to other DSCs, those from the early-developing tissues exhibit several superior properties, including larger tissue volume, higher cell proliferation rate and colony-formation capacity, more similar biological profiles to progenitor cells of origin, and better anti-inflammatory effects. These advantages are part of the critical mechanism by which MSCs exert therapeutic effects and are relevant for large-scale scaling and industrial generation for clinical applications. Cryopreservation preserves the biological properties of DFSCs and enables them to be used as off-shelf products for clinical applications. Therefore, DFSCs could have great clinical prospects and translational value in oral and neurological diseases with natural advantages.

Figure 2 The origin of dental follicle stem cells and the main strategies/mechanisms of dental follicle stem cell-based therapies in oral and neurological diseases. Dental follicle stem cells (DFSCs) originating from the craniofacial neural crest exhibit dental-like tissue differentiation potential and neuro-ectodermal features. For the regeneration of periodontium and pulp, the main strategy is the combination of DFSCs or their accessory products (exosomes) with various scaffolds (such as treated dentin matrix, native dental pulp extracellular matrix, and hydroxyapatite). The cell sheet technique prevents the degradation of the extracellular matrix and makes it a natural scaffold. In addition, appropriate stimulation may enhance the therapeutic effect, such as preconditioning with Hertwig's epithelial root sheath cells or lipopolysaccharides. For the treatment of neurotrauma and neurodegenerative disorders, DFSCs enable tissue regeneration primarily by reducing inflammatory response and apoptosis, promoting angiogenesis, and differentiating into mature functional neurons and oligodendrocytes.

Currently, SHEDs, DPSCs, PDLSCs, and GMSCs have been used in clinics[54,65,112,113], and clinical trials of DFSCs are also forthcoming. For future clinical applications of DFSCs, several key points need further investigation. First, as one of the three essential elements in tissue engineering, the selection of stem cells is vital. Therefore, potency assessment and screening criteria should be established, including donor screening and culture system optimization. In addition to sterility, safety, activity, homogeneity, purity, and stability, the levels of released cytokines or markers associated with immunomodulation (*e.g.*, IL-4 and IL-10), dental tissue (*e.g.*, VEGF, dentin sialophosphoprotein), or neural regeneration (*e.g.*, Nestin, GDNF, and brain-derived neurotrophic factor, nerve growth factor) should be detected[17]. Furthermore, the potency evaluation system should contain the inhibition of proinflammatory immune cells (*e.g.*, Th1, Th17, and macrophage M1) and cytokines (*e.g.*, TNF-α, interferon-γ, IL-1, and IL-6), the promotion of anti-inflammatory immune cells (*e.g.*, Tregs, macrophage M2) and cytokines (*e.g.*, IL-4 and IL-10) after PBMCs co-culture with DFSCs *in vitro*, and the promotion of neuron and oligodendrocyte or multi-differentiation capacity that includes neural/osteogenic differentiation[79,103,105,114-120]. Then, *in vivo* experiments should be used to verify the correctness of the potency assessment system. Second, in the field of tissue engineering, appropriate scaffold materials have a synergetic effect on the promotion of regeneration with stem cells. Some of these materials include beta-tricalcium phosphate, collagen sponge, xenogeneic bone substitute, and TDM, some of which have been used in the clinic[54,55,74,113,121,122]. Without a doubt, the quest for more suitable scaffold materials remains a long-term process. Third, a wide range of bioactive factors and RNAs, including proteins, cytokines, proinflammatory components, extracts from biological materials, long non-coding RNAs, and microRNAs, have been used to enhance differentiation and immunomodulation capacities[53,123-127], and these strategies may further improve the therapeutic potential of DFSCs in clinical applications in the future. Collectively, with the development of materials and preconditioning strategies, and in combination with the natural superiority exhibited by DFSCs in terms of medicinal properties, DFSC-based therapeutics are a promising strategy for the future treatment of oral and neurological diseases.

Abstract

Acute respiratory distress syndrome (ARDS) is a common and clinically devastating disease that causes respiratory failure. Morbidity and mortality of patients in intensive care units are stubbornly high, and various complications severely affect the quality of life of survivors. The pathophysiology of ARDS includes increased alveolar–capillary membrane permeability, an influx of protein-rich pulmonary edema fluid, and surfactant dysfunction leading to severe hypoxemia. At present, the main treatment for ARDS is mechanical treatment combined with diuretics to reduce pulmonary edema, which primarily improves symptoms, but the prognosis of patients with ARDS is still very poor. Mesenchymal stem cells (MSCs) are stromal cells that possess the capacity to self-renew and also exhibit multilineage differentiation. MSCs can be isolated from a variety of tissues, such as the umbilical cord, endometrial polyps, menstrual blood, bone marrow, and adipose tissues. Studies have confirmed the critical healing and immunomodulatory properties of MSCs in the treatment of a variety of diseases. Recently, the potential of stem cells in treating ARDS has been explored *via* basic research and clinical trials. The efficacy of MSCs has been shown in a variety of *in vivo* models of ARDS, reducing bacterial pneumonia and ischemia-reperfusion

injury while promoting the repair of ventilator-induced lung injury. This article reviews the current basic research findings and clinical applications of MSCs in the treatment of ARDS in order to emphasize the clinical prospects of MSCs.

Key Words: Acute respiratory distress syndrome; Mesenchymal stem cells; Pulmonary edema; Inflammatory response; Tissue repair; Pulmonary fibrosis

Core Tip: Acute respiratory disease syndrome (ARDS) is a common disease with high morbidity and mortality. ARDS is characterized by increased alveolar-capillary membrane permeability, influx of protein-rich pulmonary edema fluid, and surfactant dysfunction, resulting in severe hypoxemia. Mesenchymal stem cells (MSCs) have the self-renewal and multilineage differentiation properties, and their immunomodulatory abilities have been implicated in the treatment of disease. Herein, we discuss the pathophysiology of ARDS and recent research surrounding the clinical application of MSCs in the treatment of ARDS.

INTRODUCTION

Acute respiratory distress syndrome

Acute respiratory distress syndrome (ARDS) is a clinicopathological condition characterized by increased lung fluid, decreased lung compliance, and severe hypoxemia[1,2]. ARDS was defined in 1994 by the American-European Consensus Conference[3]. After several decades of research and discussions, the current internationally recognized definition of ARDS is the Berlin definition which proposes three categories of ARDS based on the severity of hypoxemia: Mild [200 mmHg < arterial oxygen pressure (PaO_2)/fraction of inspired oxygen (FiO_2) < 300 mmHg], moderate (100 mmHg < PaO_2/FiO_2 < 200 mmHg), and severe (PaO_2/FiO_2 < 100 mmHg), along with explicit criteria related to the timing of the syndrome's onset, the origin of edema, and chest radiograph findings[4-6]. The pathogenesis of ARDS is characterized by an unregulated inflammatory cascade with increased pulmonary endothelial and epithelial permeability[7]. Endogenous chemicals and microbial products linked to cell injury are hypothesized to attach to receptors on epithelial cells and alveolar macrophages, triggering an immunological response. The unrestricted synthesis of reactive oxygen species, leukocyte proteases, chemokines, and inflammatory substances that results to gradual lung damage. The immune-mediated reaction is known as a "cytokine storm"[8,9]. The pathophysiological changes that occur during the development of ARDS are shown in Figure 1. Currently, the clinical treatment of ARDS is rather limited and is mainly based on organ function support, such as lung protective ventilation, liver and kidney function protection, gastrointestinal function protection, venous thrombosis prevention, and nutritional support [10]. Despite the profound understanding of the molecular mechanism of ARDS, improvement of pulmonary ventilation strategies, and strengthening of supportive care for critically ill patients, the prognosis of patients with ARDS is still unsatisfactory. Currently, the global mortality rate of ARDS exceeds 40%, whilst 6%–10% of patients with respiratory failure may develop ARDS in the emergency room[11]. The long-term sequelae of ARDS include long-term cognitive impairment, psychological disease, neuromuscular weakness, pulmonary dysfunction, and decline in quality of life because of long-term medical expenses[12]. Therefore, new and safer therapies are urgently needed for ARDS treatment.

Mesenchymal stem cells

Mesenchymal stem cells (MSCs) were first described by Friedenstein *et al*[13], as an adherent, fibroblast-like cell population in the bone marrow (BM) that could regenerate rudiments of bone *in vivo*[13,14]. After decades of research, it has been found that MSCs are present in a variety of tissues and organs and can also differentiate into a variety of cells to play related roles (Figure 2)[15,16]. However, the understanding of MSCs is still inadequate. MSCs were officially defined by the International Society of Cell Therapy in 2006 as follows: (1) MSCs must display plastic-adherent capacities; (2) A simultaneous

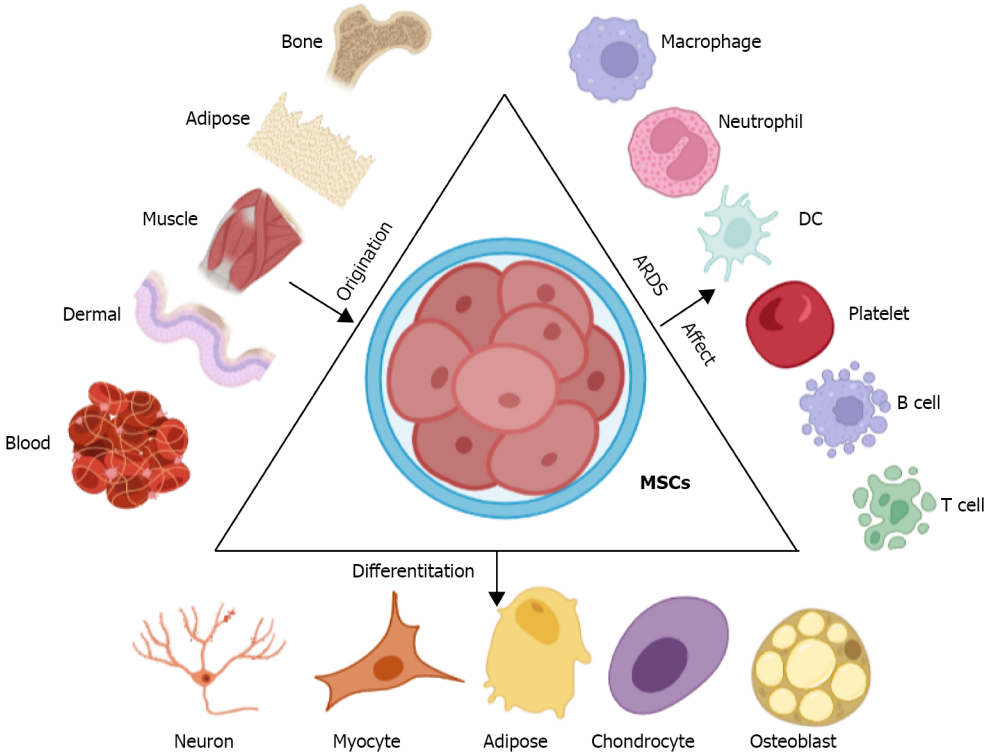
Figure 1 Following acute lung injury, pulmonary vascular macrophages produce chemokines to increase vascular permeability, resulting in neutrophil aggregation. Neutrophils reach the pulmonary interstitium and alveolar space and release proteases, cytokines, and other harmful substances to destroy the alveolar microstructure, leading to cell dysfunction and eventually causing exudates and lung fluid to enter the alveolar space, resulting in the development of pulmonary fibrosis. Additionally, the disorder of pulmonary vascular coagulation and fibrinolysis caused by inflammation leads to pulmonary vascular microthrombosis, which is also one of the causes of pulmonary edema.



expression of stromal markers, an absence of hematopoietic or endothelial markers and human leukocyte antigen-DR surface molecules; and (3) An *in vitro* differentiation potential for osteoblasts, adipocytes, and chondroblasts[17,18]. The method of obtaining and culturing MSCs is simpler than other stem cells, and MSCs have broad application prospects in a variety of inflammatory-related diseases because of their unique immunomodulatory properties[19].

MSCs are considered a new approach for the treatment of ADRS[20]. The mechanism of MSCs in the treatment of ARDS is multifaceted, and the immunomodulatory effect of MSCs is a crucial aspect of it (Figure 3). At present, the collective view of the immune regulation ability of MSCs is based on the secretion of cytokines, such as tumor growth factor (TGF)-β and tumor necrosis factor-stimulated gene-6 [21]. By releasing a variety of cytokines and extracellular vesicles (EVs), MSCs play anti-inflammatory and anti-cell death roles and promote the generation of microcirculation, thereby promoting the clearance of bacteria and alveolar fluid, alleviating organ damage, thus alleviating ARDS-related symptoms[22-24].

CURRENT BASIC RESEARCH FOR THE USE OF MSCS IN ARDS TREATMENT

Immunoregulation ability of MSCs in ARDS

The hallmark of ARDS is a series of inflammatory responses. Uncontrollable inflammatory responses are known to cause catastrophic damage to various organs[25]. MSCs are pluripotent stem cells with immune properties that can secrete a variety of cytokines, such as anti-inflammatory factors, antiapoptotic factors, and antimicrobial peptides[26-28]. MSCs regulate immune activity *via* three different mechanisms: (1) Direct contact with tissue cells; (2) Production of a series of cytokines to regulate cell activities; and (3) Exerting immune effects by regulating the activity of T cells[29-31]. Currently, the MSC treatment of ARDS is mediated by controlling inflammatory responses. Therefore, the related mechanisms have become a hot research topic, and new research findings are constantly emerging, which introduce new views.

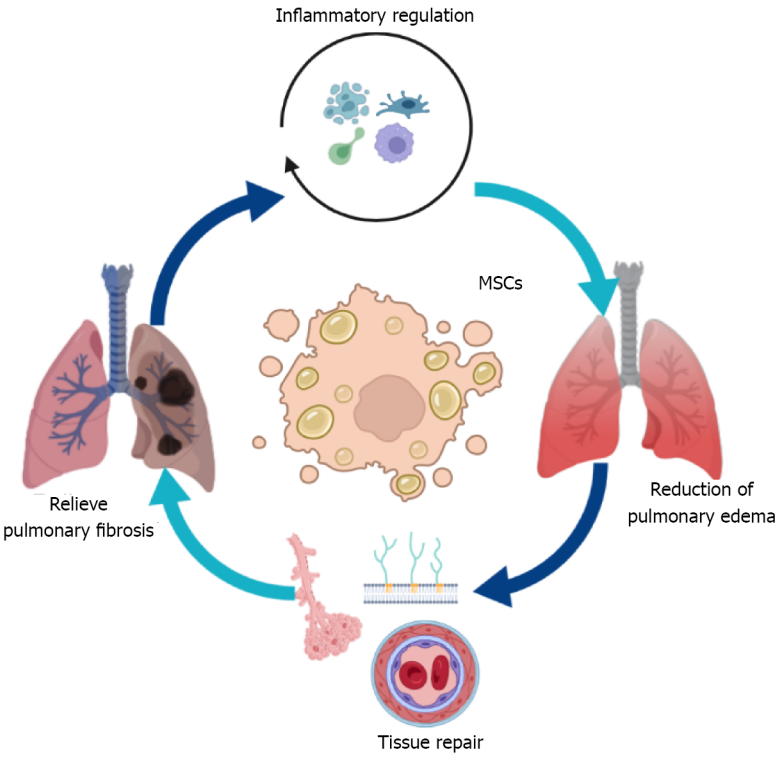
Figure 2 Mesenchymal stem cells can be derived from a variety of cell types and can differentiate into different types of cells to play specific roles. In the pathological process of acute respiratory distress syndrome, mesenchymal stem cells can act on a variety of cells to play a protective role. MSC: Mesenchymal stem cell; DC: Dendritic cell.

MSCs regulate the immune activity of the dendritic cells: Conventional dendritic cells (cDCs) are unique antigen-presenting cells that bridge antigen immunity and innate immunity and can be activated by MSCs as regulatory DCs[32,33]. An existing study has shown that after lung injury induced by lipopolysaccharide, a large number of DCs accumulate in the lungs, which in turn aggravates lung inflammation and lung injury[34]. The underlying mechanism may involve the polarization of the T-helper cell (Th) 1 response and regulating neutrophil infiltration[35,36]. The aggregation of cDCs can lead to the activation of the Th1 pathway and aggravate the inflammatory response. At the same time, cDCs can also recruit neutrophils, prolong the life of neutrophils, upregulate innate immunity, and further intensify the inflammatory response[37,38]. MSCs also abolish the capacity of mDCs to migrate to chemokine (C–C motif) ligand 19, for DCs to display major histocompatibility complex class II peptide complexes recognized by specific antibodies, and for ovalbumin-pulsed DCs to support antigen-specific CD4+ T-cell proliferation[39].

Additionally, many studies have shown that MSC–EVs play key roles in the pathogenesis and progression of acute lung injury (ALI)/ARDS[40]. One of the underlying mechanisms may involve the potential impairment of antigen uptake, which may halt DC maturation[41]. MSC–EVs from the human BM may regulate the levels of maturation and activation markers (CD83, CD38, and CD80) and inflammatory cytokines [interleukin (IL)-6, IL-12p70, and TGF-β] *in vitro via* regulating the *CCR7* gene by carrying miR-21-5p[42]. Additionally, the emerging role of MSC–EVs in facilitating pulmonary epithelium repair, rescuing mitochondrial dysfunction, and restoring pulmonary vascular leakage has been shown[43,44]. Therefore, regulating the maturation of DC cells in the early stage of lung injury can effectively alleviate secondary lung injury[45] (Table 1).



MSCs induce the activation of macrophages: Alveolar macrophages are guardians of the alveoli and airways, and interstitial macrophages are guardians of blood vessels and the lung interstitium[46]. After lung injury, tissue monocyte-derived macrophages accumulate and have increased viability in the lungs, and persist at the lesion for a long time after lung injury[47]. Macrophages respond in a variety of ways, including modulation of function (activation), the release of inflammatory chemical mediators that control immune cell recruitment, and the modulation of epithelial responses[48]. Macrophages can be divided into two phenotypes based on their functions, the M1 type in resting states and the M2 type in the activated state[49]. M1-type macrophages can secrete a variety of cytokines and participate in many processes including pro-inflammatory, pro-apoptosis, free radical formation, and matrix degradation pathways, while M2-type macrophages play a role in anti-inflammatory and anti-cell death

Table 1 Recent studies on the mechanism of mesenchymal stem cell action in acute respiratory distress syndrome

Ref.	Time	Animal/cell line	Interference	Pathway	Conclusion/main effect
Zhang *et al* [112]	2022	C-mice	Human dermal fibroblasts or MSCs were intravenously	CAP	MSC treatment significantly protects mice against bacterial pneumonia or LPS-induced lung injury *via* the CAP pathway. When the CAP was inhibited through vagotomy (VGX) and pharmacological and genetic ablation experiments, the anti-inflammatory effects of MSCs were markedly reduced in lung injury models
Kakabadze *et al* [113]	2022	Wistar rats	HPMSCs	-	HPMSCs have the ability to migrate and attach to damaged lung tissue, contributing to the resolution of pathology, restoration of function, and tissue repair in the alveolar space
Wang *et al*[114]	2022	C-mice	Human placental MSCs	Macrophage polarization pathway	Human PMSC treatment preferentially rescued resident M2 AMΦs over recruited M1 BMMΦs with overall M2 polarization to improve KP-related ARDS survival
Wang *et al*[115]	2022	SD rats	LRMSC/HMSC-C/HMSC-BM	-	Three kinds of LRMSC, HMSC-C and HMSC-BM are protective against LPS-induced lung injury, HMSC-C was more effective than LRMSC and HMSC-BM to treat LPS-induced lung injury
Zhang *et al* [116]	2022	C-mice	MSC derived microvesicles	KEGG pathway and GO function	MSV microvesicles treatment was involved in alleviated lung injury and promoting lung tissue repair by dysregulated miRNAs
Xu *et al*[60]	2022	BALB/c mice	Umbilical cord-derived MSCs	-	Transplantation of UC-MSCs transfected with SP-B could potentiate M2 macrophage polarization and further relieve LPS-stimulated lung injury
Xue *et al*[117]	2022	C-mice	Bone marrow-derived MSC	-	TGF-β1 from MSCs restored skewed Treg/Th17 levels induced by hypoxic- and LPS-stimulated conditions and reduced inflammation
He *et al*[118]	2022	Hnsclc cell line A549 (ATCC, CCL-185)	MSCs	CXCL12/CXCR4 signal axis	*In vivo* transplantation of MSCs significantly attenuated lung injury in ARDS, inhibited serum pro-inflammatory factors in mice, and down-regulated expression of apoptotic and focal factors in lung tissues
Zhang *et al* [119]	2022	C-mice	Mouse bone marrow-derived MSCs	Wnt/β-catenin transition signaling	MVs released from MSCs exerted protective effects on early fibrosis by suppressing EMT in LPS-induced ARDS
Meng *et al*[120]	2021	-	MSCs derived from normal mouse bone marrow	Akt/Mtor signaling	MTORC2 like mTORC1 as an important signaling of regulation of MSC-secreted HGF protective against LPS-induced lung endothelial dysfunction
Ishii *et al*[121]	2021	Adult male Fischer 344 rats	Adipose-derived MSCs	-	AD-MSCs enhanced the barrier function between lung epithelial cells, suggesting that both direct adhesion and indirect paracrine effects strengthened the barrier function of lung alveolar epithelium *in vitro*
Wang *et al*[122]	2021	C-mice	Bone MSCs	Vimentin-Rab7a pathway	MSCs can reach the damaged lung tissue through migration, reduce inflammatory responses and alleviate lung injury
Liu *et al*[123]	2021	SD rats	Bone marrow mesenchymal stem cell	Beclin-1	BMSC-derived exosomes were taken up by the alveolar macrophages and attenuated LPS-induced alveolar macrophage viability loss and apoptosis. Exosomes effectively improved the survival rate of ALI rats, which was associated with alleviating lung pathological changes pulmonary vascular permeability and attenuating inflammatory response

Mesenchymal stem cell can treat acute respiratory distress syndrome by regulating inflammatory response, reducing pulmonary edema, alleviating pulmonary fibrosis, and promoting tissue repair. MSC: Mesenchymal stem cell.

damage. In ARDS, this balance can effectively remove harmful substances and pro-inflammatory factors from the body and promote lung tissue repair. Conversely, the destruction of this balance aggravates the pathological development of ARDS. Studies have shown that MSCs can control the pathological development of ARDS by regulating the polarization of macrophages and effectively promoting the repair process in ARDS[53]. Basic studies have shown that MSC treatment reduces the expression of CD86 on macrophages in the ALI models, indicating that MSCs can inhibit the transformation of macrophages to the M1 phenotype[54]. Several mechanisms of MSCs have been described, such as: (1) MSCS can promote the phenotypic transformation of macrophages through paracrine secretion of soluble cytokines[55]; (2) MSCS promotes macrophage polarization through exosomes[51]; (3) Metabolic Reprogramming[56]; (4) MSCS regulate mitochondrial transfer[57]; and (5) Apoptotic and efferocytosis effects[58]. The involved signaling pathways are as follows: (1) The nuclear factor erythroid 2-related factor 2/heme oxygenase-1 signaling pathway[59]; (2) The Notch signaling pathway; (3) The Janus kinase-signal transducer and activator of transcription signaling pathway[60]; and (4) The nuclear factor-kappa B signaling pathway[61].

MSCs regulate the T-cell balance: Imbalances between regulatory T cells (Tregs) and IL-17-producing Th17 are a sign of the development of inflammatory response in ARDS[62,63]. The main function of Th17 cells is to promote inflammation, release inflammatory factors, and play an important role in autoimmune diseases. Fortunately, they are precisely regulated by regulatory cells[64]. However, Treg cells can release anti-inflammatory factors (IL-4 and IL-10), control the inflammatory reaction process, and induce tissue damage repair[65,66]. Previous studies have shown that Tregs transferred into ALI animals can reduce the level of alveolar pro-inflammatory cytokines and inhibit neutrophil apoptosis and fibroblast recruitment[67,68]. A recent study also showed that a proportion of Th17 cells and Tregs > 0.79 was an independent predictor of 28-d mortality in patients with ARDS[62]. Therefore, maintaining the balance of Tregs and Th17 cells is crucial for patients with ARDS.

Existing studies indicated that, *in vitro*, MSCs repress the Th17 molecular program through the programmed cell death protein 1 pathway, prevent the differentiation of naive CD4+ T cells into Th17 cells, inhibit the production of inflammatory cytokines by Th17 cells, and induce Treg phenotype[69-71]. A study has shown that TGF-β1, as the main paracrine cytokine of MSCs, can significantly regulate the transformation of T cells into Tregs, disturb the Th17/Treg balance, and significantly contribute to the control of inflammatory response in ARDS[72]. It is also reported that MSCs can prevent the initial differentiation of CD4+ T cells into Th17 cells, inhibit the generation of inflammation, and induce the

generation of Tregs *in vitro*[73]. Several experiments have proved that controlling the level of Th17/Treg is the key to MSC-mediated control of the inflammatory response in ARDS. Therefore, it is extremely critical to find a method to regulate this balance, which may be the basis for a revolutionary breakthrough in the treatment of ARDS.

MSCs promote tissue repair

Lung epithelial cell and endothelial cell damage and the exudation of highly concentrated protein fluid are the basic pathological changes in ARDS. Therefore, the treatment of ARDS requires a combination of a lung-protective ventilation strategy and fluid manipulation[74]. The immediate effect of these strategies is that MSCs can directly participate in the reconstruction of lung injury by migrating to the site of lung injury, but this aspect has less impact on ARDS injury repair[75]. Evidence shows that MSCs can be directly transformed into type II alveolar epithelial cells to support the role of injured cells[74]. Meanwhile, cell-to-cell contact also provides a prerequisite for the control of inflammatory responses [76]. The formation and tissue damage of pulmonary edema is also related to the dysfunction of the pulmonary vascular system. The increased permeability of pulmonary capillaries leads to a series of serious consequences, such as the exudation of a variety of cells and cytokines and the formation of intravascular microthrombosis. Studies have shown that MSCs can also enhance the barrier system of the pulmonary vascular system, which is beneficial for promoting the repair of lung tissue[77]. Hepatocyte growth factor, angiopoietin-1, and keratinocyte growth factor secreted by MSCs can improve vascular endothelial barrier function[78-82]. Genetic engineering *in situ* has shown that MSCs could promote the potential of pulmonary angiogenesis[83]. Therefore, various results have shown that MSCs could inhibit pulmonary edema and also provide the basis for the regeneration of lung tissue.

Alleviation of pulmonary fibrosis

The cellular basis of the lung is composed of alveoli, various types of parenchymal cells, and BM-derived cells[84]. The interaction between various cells is crucial for maintaining the basic functions of the lungs[85]. Although lung protective ventilation strategies have been applied in clinical practice, ARDS survivors still have related health problems, and some patients develop fibroproliferative responses characterized by fibroblast accumulation and deposition of collagen and other extracellular matrix components in the lungs[86]. After ALI, vascular permeability increases, plasma exudates, and protein fluid aggregates, leading to pulmonary edema. Inflammatory factors from the coagulation/anticoagulation system and inflammatory system enter the lungs and damage the alveolar–capillary membrane barrier[87]. In the early inflammatory phase of ARDS, various immune cells continuously release a variety of harmful substances, including reactive oxygen species and nitrogen, as well as proteolytic enzymes such as elastase and matrix metalloproteinases, leading to lung endothelial and epithelial cell damage[86,88]. Persistent damage and failure to quickly repair this damage are the main factors that induce a pathological fibroproliferative response[89]. Late in the inflammatory response, massive and persistent accumulation of macrophages, fibroblasts, fibroblasts, and myofibroblasts in the alveolar space results in excessive deposition of fibronectin, collagen types I and III, and other components of the extracellular matrix[90,91]. The pro-fibrotic/anti-fibrotic balance is disrupted, and the fibrogenic effect increases dramatically, leading to irreversible pulmonary fibrosis. MSCs have shown gratifying advantages in anti-fibrotic effects. In preclinical models of lung fibrosis produced by bleomycin, silica, paraquat, and radiation, MSCs obviously show the ability to prolong life time[92-95]. However, MSC control of pulmonary fibrosis is also a double-edged sword. Studies have shown that MSCS can differentiate into ATII cells *in vitro*, inhibit the production of degradation enzymes, and thereby inhibit the secretion of pro-fibrotic factors by various immune cells[96]. There is also evidence that abnormally activated Wnt/β-catenin and TGF-β signaling pathways can induce the differentiation of pulmonary intrinsic MSCs into myofibroblasts and promote the development of pulmonary fibrosis [97].

CLINICAL EXPERIENCE USING MSCS FOR ARDS

To date, experience with the application of MSCs in patients is limited. The data of the available clinical evidence is summarized in Table 2. Wilson and his colleagues reported the results of the phase I stem cell research for ARDS treatment (START) in 2015[98]. Patients with moderate to severe ARDS received a single intravenous dose of low [1 × 10^6 MSCs/kg predicted body weight (PBW)], medium (5 × 10^6 MSCs/kg PBW), or high (1 × 10^7 MSCs/kg PBW) (n = 3/dose). All patients tolerated MSC infusion without prespecified infusion-related adverse events. High-dose MSCs improved daily SOFA scores compared with low-dose MSCs. Based on these promising results, the knowledge of the safety of administering MSCs to critically ill patients with ARDS is improving. A phase 2a clinical trial to evaluate the safety of BM-MSCs administered to patients with moderate to severe ARDS has also been conducted[99]. The primary outcome was safety, and secondary outcomes included respiratory, systemic, and serum biomarker endpoints. The study included 60 patients with ARDS, and intravenous Adipose-MSCs, 1 × 10^6/kg predicted body weight, *vs* the placebo was administered; however, there was

Table 2 Clinical study characteristics

Ref.	Cell type	Patient number	Outcome	Study design/evidence level	Publish time
Wilson *et al* [98]	MSC	9	No serious adverse events	Phase 1 clinical trial: A multicenter, open-label phase	2015
Matthay *et al* [99]	BM-MSCs	60	(1) No patients had any adverse events; (2) Mortality at 28 and 60 d was not significantly increased; and (3) ↑ Oxygenation index	Phase 2a safety trial: Prospective, double-blind, multicenter, randomized trial	2019
Yip *et al*[100]	UC-MSCs	9	(1) In-hospital mortality was 33.3% (3/9); (2) No serious prespecified cell infusion-associated or treatment-related adverse events; (3) ↓Circulating inflammatory biomarkers; (4) ↓Mesenchymal stem cell markers; and (5) ↑Immune cell markers	Phase I clinical trial: Prospective	2020
Lanzoni *et al* [107]	UC-MSCs	24	(1) No serious adverse events; (2) ↑Survival; and (3) ↓Inflammatory cytokines at day 6	Phase 1/2a clinical trial: A double-blind, randomized controlled trial	2021
Dilogo *et al* [108]	UC-MSCs	20	(1) ↑Survival; and (2) ↓Interleukin 6	Clinical trial: A multicentered, double-blind, randomized clinical trial	2021
Monsel *et al* [109]	UC-MSCs	45	(1) PaO_2/FiO_2 changes between D0 and D7 did not differ significantly; and (2) Clinical improvement	Clinical trial: A multicentered, double-blind, randomized clinical trial	2022
Grégoire *et al* [110]	BM-MSCs	8	(1) ↑Survival; (2) Clinical improvement; and (3) ↓Day-7 D-dimer value	A phase I/II Clinical Trial	2022
Kaffash Farkhad *et al* [111]	UC-MSCs	10	(1) ↑PaO_2/FiO_2; (2) ↓Serum CRP; (3) ↓IL-6, IFN-γ, TNF-α and IL-17 A; and (4) ↑TGF-β, IL-1B and IL-10	Phase 1 clinical trial: A single-center, open-label	2022

UC-MSC: Umbilical cord-derived mesenchymal stem cells; CDC: Cardiosphere-derived cells; BM-MCs: Bone marrow-derived mesenchymal stem cells; PaO_2/FiO_2: Arterial oxygen partial pressure/fractional inspired oxygen; CRP: C-reactive protein; CT: Computed tomography; ICU: Intensive care unit; ARDS: Acute respiratory distress syndrome; COVID-19: Coronavirus disease 2019; TNF-α: Tumor necrosis factor-alpha; IFN-γ: Interferon-gamma; TGF-β: Tumor growth factor-β; IL: Interleukin.

no difference in the outcome in patients treated with Adipose-MSCs *vs* the placebo. In another phase I study, nine consecutive patients were enrolled, between December 2017 and August 2019, the first three patients got low-dose human umbilical cord-derived MSCs, the following three patients received an intermediate dosage, and the last three patients received a high dose[100]. The results of the first phase of clinical trials demonstrated that a single dose of human umbilical cord-derived MSCs was safe and showed good results in all nine patients with ARDS. Swedish researchers tested the systemic administration of allogeneic BM-derived MSCs (2×10^6 cells/kg) in two patients with severe refractory ARDS, both of whom recovered from multiple organ failure and showed reduced markers of systemic and pulmonary inflammation[101]. In summary, clinical studies report that MSC administration is safe for patients with ARDS, with few adverse reactions. However, due to the relatively small number of patients in these studies, further research is needed to test the curative effect.

MSCS FOR CORONAVIRUS DISEASE 2019-INDUCED ARDS

Coronavirus disease 2019 (COVID-19) is an infectious disease responsible for the COVID-19 pandemic, caused by a novel coronavirus called severe acute respiratory syndrome-coronavirus 2[102,103]. COVID-19 has various respiratory and non-respiratory clinical manifestations, including mild or severe influenza-like syndrome, pneumonia, or respiratory failure, which may eventually lead to sepsis with multiple organ failure. The most common reason for being admitted to intensive care units is a respiratory failure caused by ARDS[104,105]. In a case series, Hashemian *et al*[106] found that multiple infusions of high-dose allogeneic prenatal MSCs are safe and can relieve the respiratory distress of severe patients with COVID-19 and inhibit the inflammatory response[106]. 24 participants were randomly assigned to either the umbilical cord-derived mesenchymal stem cell (UC-MSC) therapy or the control group in a double-blind, phase ½a randomized controlled trial. The UC-MSC treatment group got two intravenous infusions of $100 \pm 20 \times 10^6$ UC-MSCs, while the control group received two infusions of vehicle solution[107]. The primary endpoint was safety (adverse events) after 6 h; cardiac arrest or death within 24 h post-infusion) and secondary endpoints included patient survival at 31 d after the first infusion and time to recovery. Serious adverse events related to UC-MSC infusion were

not observed. Thus, UC-MSC is safe to inject into patients with COVID-19-induced ARDS. In subjects who received UC-MSC treatment, inflammatory cytokines decreased significantly on the sixth day. In a recent clinical research, 40 COVID-19 patients who were critically unwell got either saline or intravenous UC-MSCs[108]. The findings revealed that the survival rate of patients in the UC-MSCs group was 2.5 times greater than that of the control group. Among patients with complications, the UC-MSCs group had a fourfold greater survival rate than the control group. A multicenter, double-blind, randomized, placebo-controlled trial (STROMA–CoV-2) in France, with 45 enrolled patients, has also been conducted[109]. Patients were randomly assigned to receive three intravenous infusions of 1×10^6 UC-MSCs/kg or placebo (0.9% NaCl) over 5 d after recruitment. PaO_2/FiO_2 changes between D0 and D7 did not differ significantly between the UC-MSCs and placebo groups. Six (28.6%) of the 21 UC-MSCs patients and six (25%) of the 24 (25%) placebo patients had serious adverse events not related to UC-MSCs treatment. A phase I/II clinical study was also done in patients with severe COVID-19 to assess the safety and effectiveness of three intravenous infusions of BM-derived MSCs at 3-d intervals[110]. Eight intensive care unit patients requiring supplemental oxygen were treated with BM-MSCs. Survival was significantly higher in the MSC group at 28 and 60 d, but there was no significant difference in the number of invasive ventilation-free days, high flow nasal oxygenation-free days, oxygen support-free days, or intensive care unit-free days. MSC infusion was well tolerated, and no adverse effects associated with MSC infusion were reported. Furthermore, a single-center, open-label, phase 1 clinical trial enrolled 20 confirmed COVID-19 patients with mild-to-moderate degree ARDS, who were divided into two groups: The control and the intervention group (UC-MSCs)[111]. The patients received three intravenous infusions of UC-MSCs (1×10^6 cells/kg BW per injection) every other day. There were no adverse effects to cell infusion throughout the clinical study, oxygenation was greatly enhanced, anti-inflammatory factor levels were significantly increased, and pro-inflammatory factor levels were dramatically lowered. This intervention may reduce cytokine storms and restore respiratory function.

To summarize, MSCs from different tissues, such as BM, adipose, UC, and placental tissues, have entered the clinical trial stage. Some studies have used MSCs to treat COVID-19-induced ARDS.

PROSPECT

With the progress of scientific research, our understanding of the physiological and pathological processes of ARDS has gradually deepened, and the relevant treatment methods are also improving year by year. However, the final prognosis of patients has not improved much; therefore, it is particularly important to find a method to treat ARDS. MSCs have a variety of characteristics that are striking. At present, as a potential therapeutic method, MSCs have gradually entered the international arena of research and have been unanimously recognized by scientists worldwide. Their application has achieved some effect in improving the survival rate of patients with ARDS. However, because of various reasons, only a few clinical trials are conducted. Although the achievements of basic research are emerging endlessly, there is a theoretical basis for MSC use to enter clinical treatment, and the side effects of MSCs are not clear. Moreover, their clinical application involves ethical issues. As a cell therapy, its safety needs a lot of control experiments to be proven. This has hindered the successful application of MSCs. Fortunately, the basic experimental research on their mechanism of action is becoming more and more in-depth, and the application value of MSC therapy is also much clearer. Their successful application for the treatment of ARDS is expected to improve the quality of life of patients.

CONCLUSION

Due to the impasse that has been reached in the treatment of ARDS, MSC therapy has gained increasing attention. MSCs are known for their anti-inflammatory, differentiation, paracrine, and microvesicle transport abilities, which could perfectly target the pathological mechanisms of ARDS, providing a theoretical basis for treatment and precision treatment. Despite the current evaluation of MSC treatment of ARDS, further research is needed to observe the specific response to MSC treatment in the long term.

ACKNOWLEDGEMENTS

We thank the authors of the primary studies for their timely and helpful responses to our information requests.

Abstract

Cell transplantation therapy has certain limitations including immune rejection and limited cell viability, which seriously hinder the transformation of stem cell-based tissue regeneration into clinical practice. Extracellular vesicles (EVs) not only possess the advantages of its derived cells, but also can avoid the risks of cell transplantation. EVs are intelligent and controllable biomaterials that can participate in a variety of physiological and pathological activities, tissue repair and regeneration by transmitting a variety of biological signals, showing great potential in cell-free tissue regeneration. In this review, we summarized the origins and characteristics of EVs, introduced the pivotal role of EVs in diverse tissues regeneration, discussed the underlying mechanisms, prospects, and challenges of EVs. We also pointed out the problems that need to be solved, application directions, and prospects of EVs in the future and shed new light on the novel cell-free strategy for using EVs in the field of regenerative medicine.

Key Words: Mesenchymal stem cells; Extracellular vesicles; Regenerative medicine; Cell-free strategy

INTRODUCTION

Tissue and organ loss are challenging complications that are usually caused by severe diseases such as cancer and serious accidents and impose great burdens on patients' lives. Tissue regeneration and engineering medicine, which aims to repair lost cells and damaged organs caused by diseases or accidents, is achieving great progress sparked by numerous studies of stem cells, biomaterials and so on. Stem cells, especially mesenchymal stem cells (MSCs), play a critical role in regeneration medicine due to their strong self-renewal ability and diverse differentiation potential. However, there are several shortcomings of using MSCs in regeneration medicine, including cell source limitations, ethical controversies, low survival rates after cell transplantation, immune rejection, and risk of tumorigenesis after transplantation[1,2]. To solve the shortcomings of cell-based therapy, the paracrine action of cells has become a focus of research attention.

Recent research has focused on the secretions of cells and tissues. Extracellular vesicles (EVs) are heterogeneous lipid bilayer-surrounded vesicles secreted by various cell types, including immune cells, endothelial cells, epithelial cells, neuronal cells, cancerous cells, Schwann cells (SCs), and MSCs, that behave as crucial mediators of intercellular communication[3-6]. EVs participate in various types of physiological and pathological activities, including immune responses, homeostasis maintenance, inflammation, angiogenesis, and cancer progression, by transferring biological signals[7,8]. According to their size and origin, EVs can be classified in several ways. On the basis of their origin, EVs can be divided into three categories: Apoptotic bodies generated during cell apoptosis; microvesicles originating from budding cellular membranes; and exosomes derived from multivesicular bodies in fusion with the plasma membrane[4,9]. EVs also can be divided into small EVs, medium-sized EVs, and large EVs[3,10,11].

Increasing evidence indicates that EVs play a critical role in tissue repair and regeneration medicine *via* cell-to-cell communication. Moreover, several studies imply that the beneficial effects of MSCs on tissue regeneration may be attributed to their paracrine action by secreting EVs rather than MSC engraftment and proliferation[3,12,13]. Moreover, EVs themselves possess the ability to recruit endogenous cells and lead to their enrichment by releasing several chemokines, which may contribute to angiogenesis and tissue repair[14,15]. Therefore, EVs are an appropriate and hopeful new source for tissue repair and regeneration.

In this review, we elaborate and discuss both the recent research progress and the advancements in the therapeutic effects and limitations of EVs in tissue regeneration and engineering medicine (Figure 1). Moreover, we summarize the underlying molecular mechanisms related to EV repair effects (Table 1) and point out the problems that need to be solved, application directions (Table 2), and prospects of EVs in the future.

EVs

The discovery of EVs dates back to 1940, when a brand-new subcellular factor was identified in cell-free plasma by high-speed centrifugation. The subcellular fraction was identified and shown to consist of small vesicles by electron microscopy in the 1960s. The term "exosomes" was introduced when vesicles were isolated from cell supernatant in 1987, and these exosomes were found to be related to the removal of obsolete transmembrane proteins[10]. Currently, EVs are secreted by both normal cells and cancerous cells and act as a means of cell-to-cell communication. Signals are communicated through vesicle membrane proteins or by vesicle contents such as proteins, miRNAs, or long noncoding RNAs (lncRNAs)[16].

Table 1 The mechanism of extracellular vesicles in the regeneration medicine

	Source of EVs	Mechanism
Kidney	MSC-EVs	Inhibiting oxidation, apoptosis, and inflammation
	HLSC-EVs	Regulating angiogenesis, the cell cycle, regeneration, autophagy, proliferation[36-38,46]
	BMSC-EVs	
Liver disease	hiPSCs-EVs	Inhibiting hepatocyte apoptosis
	Hepatocyte-EVs	Supporting hepatocyte function
	MSC-EVs	Promoting angiogenesis
		Reducing inflammatory responses[48-53]
Cardiac muscle	ESCs-EVs	Vascularization
	iPSCs-EVs	Amelioration of apoptosis and hypertrophy
	MSCs-EVs	Promoting cell proliferation and migration[55-60]
	CDCs-EVs	
	BMSC-EVs	
Tendon	BMSC-EVs	Modulating macrophage phenotypes
	ADSC-EVs	Anti-inflammatory reaction
		Enhancing proliferation, migration, tenogenic differentiation of TSCs
		Regulating angiogenesis
		Modulating immune responses[62-68]
Wound healing	BMSC-EVs	Promoting re-epithelialization
	ADSC-EVs	Promoting collagen maturity and angiogenesis
	hENSC-EV	Enhancing cell proliferation and migration[69-74]
	HUVECs-EVs	
	iPSC-EVs	
Tooth and periodontal tissue	BMSC-EVs	Modulating the inflammatory immune response
	ADSC-EVs	Enhancing cell proliferation and migration
	DPSC-EVs	Promoting odontogenic differentiation
	DFC-EVs	Stem cell recruitment[76-83]
	PDLSC-EVs	
	HERS-EVs	
	SC-EVs	
Nerve	SKP-SC-EVs	Mediating axon regeneration
	BMSC-EVs	Regulating the phenotype of Schwann cells
	ADSC-EVs	Promoting angiogenesis
	GMSC-EVs	Regulating inflammatory reactions[84-94]
Bone	ADSC-EVs	Angiogenesis
	BMSC-EVs	Osteoblast proliferation
	SMSC-EVs	Intercellular communication
	PRP-EVs	Immune regulation[96-104]

Table 2 Extracellular vesicles investigated in clinical studies

Research title	Interventions	Status
Treatment of Patients with Bone Tissue Defects Using Mesenchymal Stem Cells Enriched by Extracellular Vesicles	MSCs enriched by extracellular vesicles	Not yet recruiting
Bone Marrow Mesenchymal Stem Cell Derived Extracellular Vesicles Infusion Treatment for ARDS	Bone Marrow MSC Derived Extracellular	Not yet recruiting
Efficacy of Platelet- and Extracellular Vesicle-rich Plasma in Chronic Postsurgical Temporal Bone Inflammations	Plateletand extracellular vesicle-rich plasma	Completed
Use of Autologous Plasma Rich in Platelets and Extracellular Vesicles in the Surgical Treatment of Chronic Middle Ear Infections	Plateletand EVs-rich plasma	Recruiting
Extracellular Vesicle Infusion Treatment for COVID-19 Associated ARDS	ExoFlo	Completed
Safety of Mesenchymal Stem Cell Extracellular Vesicles (BMMSC-EVs) for the Treatment of Burn Wounds	Drug: AGLE-102 (BMMSC-EVs)	Not yet recruiting
Treatment of Non-ischemic Cardiomyopathies by Intravenous ExtracellularVesicles of CardiovascularProgenitor Cells	Extracellular vesicle-enriched secretome of cardiovascular progenitor cells differentiated from induced pluripotent stem cells	Not yet recruiting
Bone Marrow Mesenchymal Stem Cell Derived Extracellular Vesicles Infusion Treatment for Mild-to-Moderate COVID-19: A Phase II Clinical Trial	Drug: ExoFlo. Bone Marrow Mesenchymal Stem Cell Derived Extracellular Vesicles	Not yet recruiting
A Safety Study of IV Stem Cellderived Extracellular Vesicles (UNEX-42) in Preterm Neonates at High Risk for BPD	UNEX-42 is a preparation of extracellular vesicles that are secreted from human bone marrow-derived mesenchymal stem cells suspended in phosphate-buffered saline	Terminated
ExoFlo™ Infusion for Post-Acute COVID-19 and Chronic Post COVID-19 Syndrome	Bone Marrow Mesenchymal Stem Cell Derived Extracellular Vesicles	Not yet recruiting
Study of ExoFlo for the Treatment of Medically Refractory Ulcerative Colitis	ExoFlo. Intravenous administration of bone marrow mesenchymal stem cell derived extracellular vesicles	Recruiting
Study of ExoFlo for the Treatment of Medically Refractory Crohn's Disease	ExoFlo. Intravenous administration of bone marrow mesenchymal stem cell derived extracellular vesicles	Recruiting
Bone Marrow Mesenchymal Stem Cell Derived EVs for COVID-19 Moderate-to-Severe ARDS: A Phase III Clinical Trial	EXOFLO. Bone Marrow Mesenchymal Stem Cell Derived EVs	Recruiting
Pilot Study of Human Adipose Tissue Derived Exosomes Promoting Wound Healing	Adipose tissue derived exosomes	Not yet recruiting
Exosome Effect on Prevention of Hairloss	Placental Mesenchymal Stem Cells-derived Exosome	Recruiting
Expanded Access for Use of ExoFlo in Abdominal Solid Organ Transplant Patients	Bone Marrow Mesenchymal Stem Cell Derived Extracellular Vesicles Infusion Treatment	Not yet recruiting
Safety of Injection of Placental Mesenchymal Stem Cell Derived Exosomes for Treatment of Resistant Perianal Fistula in Crohn's Patients	Placenal MSC derived exosomes	Active, not recruiting
Safety and Efficacy of Injection of Human Placenta Mesenchymal Stem Cells Derived Exosomes for Treatment of Complex Anal Fistula	Placenta MSCs derived exosomes	Recruiting
Safety and Tolerability Study of MSC Exosome Ointment	Exosome ointment	Completed
The Pilot Experimental Study of the Neuroprotective Effects of Exosomes in Extremely Low Birth Weight Infants	Exosomes derived from MSCs	Not yet recruiting

ARDS: Acute Respiratory Distress Syndrome; MSC: Mesenchymal stromal cells; COVID-19: Coronavirus disease 2019; EVs: Extracellular vesicles.

Biogenesis and classification of EVs

EVs are classified by several traits, including their density, dimensions, and origin. Three subclasses of EVs have been reported recently. Although the sizes of these three main types of EVs may overlap, their biogenesis is different. Exosomes, whose dimensions range from 30-150 nm, are formed within the endosomal network, where endosomes target some protein/lipids for recycling or exocytosis. During early endosome transformation into late endosomes, proteins that are fated to be degraded or exported

Figure 1 The repair and regeneration effects of extracellular vesicles in different tissue and organs. EVs: Extracellular vesicles; MSCs: Mesenchymal stem cells.

are packaged into vesicles. Late endosomes, which contain small vesicles, fuse with the plasma membrane and finally lead to the secretion of small vesicles, named exosomes, into the extracellular space[16]. Microvesicles/Ectosomes originate from vesicles budding outward and fission of the plasma membrane directly, which is a dynamic interplay between redistribution and cytoskeletal protein contraction. The size of microvesicles/ectosomes is larger than that of exosomes, ranging from 50-2000 nm. Apoptotic bodies, ranging from 500-40000 nm, are formed during programmed cell death and contain organelles.

Isolation of EVs

Differential ultracentrifugation (UC), the gold standard EVs isolation approach, is the most reported and classical way to isolate EVs. Successive centrifugation was applied to eliminate large dead cells and cell debris. The supernatant acquired after successive centrifugation was used for another UC step at 100000 g to obtain the pellet related to EVs. The pellet was washed with PBS to obtain purified EVs[17]. UC has several advantages including low cost and low contamination risk with extra isolation reagents. UC is suitable for large volume preparation for its products is of high purity. However, UC is complicated, time-consuming and labor intensive. High speed centrifugation also may lead to potential mechanical damage. There are several isolation methods that can extract EVs in a more efficient way, including polymer-based precipitation[18], size exclusion chromatography (SEC)[19], ultrafiltration (UF)[20], flow field-flow fractionation[21], immunoaffinity capture[22], and microchip-based techniques [23]. Polymer-based precipitation is a commonly used strategy for EVs isolation. The principle of polymer-based precipitation is high hydrophilic water-excluding polymers can alternate the solubility of EVs. Highly hydrophilic polymers interact with water molecules surrounding the EVs to create a hydrophobic micro-environment, resulting in EVs precipitation[24]. Based on above principle, polyethylene glycol is well used in several popular commercial EVs isolation kits[25]. Polymer-based precipitation has high efficiency, but its products is easy to be contaminated by protein aggregates. SEC is according to the size of particle to realize the isolation. After adding to porous materials, substances eluted out in accordance with their particle size, with big particles eluted earlier[26]. Compared to UC, SEC is realized by the performance of passive gravity flow, which highly protect the structure and integrity of EVs[27]. UF uses filter membrane to isolate EVs from cell culture medium. Compared to traditional UC method, UF-based EVs isolation shortens time and presents relatively low requirements on experimental facilities. However, UF also has several shortages including the EVs production maybe limited due to clogging and membrane trapping[28,29]. Immunoaffinity capture is based on specific binding between EVs markers and immobilized antibodies such as Rab5, CD81, CD63, CD9, CD82, annexin, and Alix[30]. Immunoaffinity capture can harvest high-purity EVs with no chemical contamination. However, it is waste of antibodies and low yields[26]. The combination of the above methods is

also applied in the isolation of EVs. Moreover, there are several kits that are available for EV isolation, including ExoQuick and Total Exosome Isolation kits. However, the purity and quality of isolated EVs are extremely important because some soluble proteins or lipoproteins may be coisolated with EVs, leading to inaccurate experimental results. Therefore, isolation methods are of critical importance. Among all the methods, UC and UF followed by SEC are reported to be the most appropriate isolation methods because they can isolate high-purity and high-quality EVs[31,32].

Characteristics of EVs

EVs carry several specific surface markers, including proteins related to the cell membrane, annexin, flotillin and auxiliary proteins. Annexins and tetraspanins such as CD9, CD63 and CD81, which are often used for the identification of EVs, are located in the membrane of EVs. Moreover, EVs express ALIX, tumor susceptibility gene 101, VPS4 and heat shock proteins (HSP70 and HSP 90), which are associated with the biogenesis of EVs. EVs are encapsulated in a bilayer membrane, which can help in the safe transfer of their contents to secondary cells. Once released into the extracellular environment, EVs interact with recipient cells in three ways: (1) Endocytic uptake; (2) direct fusion with cells; and (3) adhesion to the cell surface and transmission of contents[4]. Among their contents, EVs are reported to contain large-scale genetic materials, such as mRNA, that play critical roles in cell-to-cell communication. miRNAs that are transferred by EVs also have an impact on biological functions, including cell proliferation, migration, and differentiation of recipient cells. EVs also carry several types of lipids that are related to EV structure, function and biogenesis[3]. In conclusion, EVs are heterogeneous and are composed of a bilayer membrane surrounding cargos that are indispensable for cell interactions.

REPAIR AND REGENERATION EFFECTS OF EVS

Kidney

Acute kidney injury (AKI) and chronic kidney disease (CKD) are two major causes of renal failure and exert great pressure on public health. AKI, the most common features of which are the rapid loss of renal tubular cells and a decline in renal function, usually leads to hospitalization[33]. As research has progressed, evidence has shown that MSC-EVs play a major role in treating AKI. EVs were first proven to be effective against AKI in 2009[34]. The intravenous administration of EVs not only alleviated or even reversed the detrimental effect on renal function caused by glycerol injection in an AKI model but also improved renal function and morphology by stimulating the proliferation of tubular epithelial cells (TECs)[35]. In a renal ischemia-reperfusion (I/R) injury AKI model, MSC-EVs accumulated in the renal tubules and facilitated with the recovery of kidney function through the Keap1-Nrf2 signaling pathway as well as the mitochondrial function of TECs[36]. Studies have also shown that EVs can reduce the presence of luminal cell debris, tubular hyaline casts and necrosis of tubular cells in an AKI model induced by toxins[37]. Moreover, EVs released by cells that were cultured under hypoxia could stimulate angiogenesis and help the formation of the peritubular microvasculature[38]. Furthermore, MSC-EVs attenuated mtDNA damage and inflammation after AKI through the mitochondrial transcription factor A (TFAM) pathway. MSC-EVs could attenuate renal lesion formation, mitochondrial damage, and inflammation in mice with AKI. TFAM overexpression (TFAM-OE) improved the rescue effect of MSC-EVs on mitochondrial damage and inflammation to some extent[39]. In general, MSC-EVs can relieve AKI not only by inhibiting oxidation, apoptosis, and inflammation, but also through regulating angiogenesis, cell cycle, autophagy, and cell proliferation[38]. There are multiple underlying mechanisms. Currently, it is believed that the repair effects of EVs on AKI are largely related to their transfer of genetic material and proteins[40].

CKD is a complex and long-term disease. The main trigger that causes CKD is diabetes. Hyperglycemia leads to glomerular and tubulointerstitial fibrosis, and the progression of fibrosis is the main reason for renal dysfunction[41]. Renal glomerulosclerosis and tubulointerstitial fibrosis are hallmarks of all types of CKD, including diabetic nephropathy (DN). Recent studies have shown that EVs are effective for the prevention of DN. For example, EVs can protect podocytes and TECs from apoptosis by secreting protective proteins, including transforming growth factor (TGF)-β1 and angiogenin[42]. Another study found that EVs derived from human liver stem cells (HLSCs) and MSCs could reduce or even revert the progression of profibrotic processes and finally ameliorate renal dysfunction and attenuate renal histopathological changes[43]. Moreover, studies have shown that EVs can ameliorate DN by inducing autophagy induction through the mTOR pathway. Rat bone marrow-derived EVs present nephroprotective and antifibrotic effects by upregulating autophagy through suppressing the mTOR pathway in a DN model[44]. Furthermore, HLSC-derived EVs could also prevent the development of CKD. HLSC-EVs not only present a regenerative and anti-inflammatory role but also downregulate profibrotic genes, including alpha smooth muscle actin, Col1a1 and TGF-β1, and modulate miRNAs that are related to the fibrotic pathway in the kidney of an aristolochic acid-induced CKD model[45]. In conclusion, MSC-EVs can eliminate the pathogenic damage of CKD by targeting renal fibrosis, reducing tubular atrophy and inflammation, and promoting angiogenesis to

facilitate with tissue regeneration[46]. EVs present a promising approach for renal repair and regeneration. Some evidence based on clinical trials has shown that EVs are safe and effective for CKD patients[47].

Liver disease

Liver dysfunction is classified into acute and chronic diseases, including hepatitis, alcoholic liver disease, fatty liver disease, cirrhosis, and hepatocellular carcinoma. Liver failure can manifest with several symptoms, such as jaundice, encephalopathy, cerebral edema, sepsis, and gastrointestinal bleeding, and its prognosis is relatively limited. Currently, liver transplantation is still the gold-standard therapy for liver diseases; however, it has many limitations, such as nonspecific treatment approaches, donor organ shortages and lifelong immunosuppressive therapy[48]. Although the liver possesses a great capacity for regeneration through the proliferation of mature liver cells, it can lose its function and lead to severe results when the injury progresses into a state of functional impairment, which may finally lead to liver failure or even death[49]. EVs can prevent further damage to injured liver cells. Studies have reported that EVs can reduce liver injury based on alanine aminotransferase and aspartate aminotransferase levels after CCl_4-induced liver impairment *in vivo*. Moreover, EVs promoted hepatocyte regeneration gene expression and $PCNA^+$ expression and induced quiescent hepatocytes to re-enter the cell cycle, ultimately assisting with hepatocyte proliferation. Another report showed that EVs derived from human-induced pluripotent stem cells (hiPSCs) could alleviate hepatic I/R injury by suppressing inflammatory responses, attenuating the oxidative stress response and inhibiting cell apoptosis[50]. Furthermore, Du *et al*[51] found that hiPSC-derived EVs could alleviate hepatic I/R injury by activating sphingosine kinase and the sphingosine-1-phosphate pathway in hepatocytes and ultimately promote cell proliferation[51]. EVs can not only be therapeutic but can also serve as diagnostic tools for liver disease and regeneration in the near future. A report outlined that hepatocyte-derived EVs played a key role in hepatocyte-to-hepatocyte communication and provided a new method for liver disease diagnosis, and progenitor cell-derived EVs offered a new opportunity for the treatment of liver diseases[52]. In conclusion, recent evidence supports that MSC-derived EVs inhibit hepatocyte apoptosis, support hepatocyte function, promote angiogenesis and hepatocyte proliferation, and reduce inflammatory responses by preventing immunocyte infiltration and inflammatory cytokine secretion [48]. In addition, animal model-based studies suggest that EVs may represent a novel and effective cell-free therapeutic agent as an alternative to cell-based therapies for patients with liver diseases[53].

Cardiac muscle regeneration

Myocardial repair and regeneration are important in the context of the increasing occurrence of heart failure and cardiac-related diseases. Key mechanisms related to cardiac repair and regeneration include survival and protection, inflammation reduction, angiogenesis, cardiomyogenesis and cell–cell communication. All these mechanisms work collectively and contribute to cardiac regeneration[54]. However, myocardial repair is slow and limited. Stem cell–based therapies have acted as an effective method for cardiac repair. Moreover, EVs, a key component of stem cell secretion, bring new hope to cell-free therapies for cardiac repair and regeneration. EVs of embryonic stem cells, iPSCs, MSCs, and cardiosphere-derived cells (CDCs) have been proven to be effective in cardiac repair[55]. Recent research has shown that EVs derived from murine iPSCs impart cytoprotective properties to cardiac cells *in vitro* and induce cardiac repair *in vivo* through vascularization, amelioration of apoptosis and hypertrophy and improvement in left ventricular function[56]. Moreover, iPSC-EVs contained numerous miRNAs (miR-17-92 cluster) and proteins [BMP-4, teratocarcinoma-derived growth factor 1 and vascular endothelial growth factor (VEGF)-C] that are related to cellular proliferation and differentiation, enhanced angiogenesis, and the prevention of apoptosis. Therefore, iPSC-EVs could induce angiogenesis, migration and anti-apoptosis of cardiac endothelial cells and finally induce superior infarct repair[56]. MSC-derived EVs also play a critical role in MSC-based therapy in cardiac diseases. Bian *et al*[57] found that intramyocardial injection of MSC-EVs could markedly enhance blood flow recovery in an acute myocardial infarction (MI) rat model. MSC-EVs could protect cardiac tissue from ischemic injury by promoting blood vessel formation. Receptors for growth factors, cytokines and signaling molecules are contained in EVs, among which Sonic hedgehog and platelet-derived growth factors have been proven to be effective for proangiogenic activities. The results of direct comparisons between MSCs and MSC-EVs have highlighted the beneficial effects of EVs. EVs also present a safer profile than their cells of origin because EV injection does not produce tumors[56]. Moreover, combinatorial treatment with both MSCs and their derived EVs exhibits advantages in MI treatment. Rat bone marrow mesenchymal stem cells (BMSCs) and their derived EVs improved cardiac function and reduced infarct size when compared to groups treated with BMSCs or EVs alone[57]. CDC exosomes were proven to enhance angiogenesis and promote cardiomyocyte survival and proliferation. Moreover, CDC exosomes improved cardiac function and imparted structural benefits after MI. miR-146a was the most highly enriched in CDC exosomes and mediated some of the therapeutic benefits of CDC exosomes[58]. EVs combined with biomaterials present better effects for the treatment of cardiac disease. Studies have shown that MSC-derived EVs incorporated into alginate hydrogels are a sustained delivery system that allows for better retention of EVs in the heart *in vivo* than EV single injection. EVs-Gel has a good effect on promoting angiogenesis, reducing the apoptosis and fibrosis of cardiac tissue,

enhancing scar thickness and improving cardiac function[59]. Another study showed that self-assembling peptide hydrogel-encapsulated exosomes could also promote cardiac repair due to the better retention and stability of EVs[60]. In general, EVs combined with biomaterials provide a novel approach for cell-free therapy and optimization of the therapeutic effects of EVs in MI.

Tendon regeneration

Tendons are soft tissues that connect muscles to bones. Tendon diseases and injuries have high morbidity owing to various sports and exercises. The effects of treatments for tendon diseases are limited due to the limited regenerative capacity of tendons. Current treatments for tendon injuries, including surgery and conservative treatments, always have side effects, including secondary injury and scar formation. Therefore, the ideal treatment is to promote tendon regeneration[61]. There are three important stages of tendon healing: Inflammation, proliferation, and remodeling. Suppression of the inflammatory response is critical for tendon repair[62,63]. Research has found that BMSC-EVs may help improving tendon healing by regulating macrophage phenotypes, creating anti-inflammatory environment, promoting apoptotic cell accumulation, and increasing the ratio of tendon resident stem/progenitor cells[64]. Moreover, EV-educated macrophages (EEMs), a kind of M2-like macrophage treated by EVs, present a more functional and regenerative ability to heal tendons. EVs isolated from MSCs were able to reduce the M1/M2 macrophage ratio and increase the number of endothelial cells 14 days after tendon injury. Injured tendons treated with exogenous EEMs presented improved mechanical properties, reduced inflammation and earlier angiogenesis[62]. Furthermore, Yu *et al*[29] found that BMSC-EVs could promote the proliferation, migration and tenogenic differentiation ability of tendon stem/progenitor cells (TSPCs). BMSC-derived EVs could activate the regenerative potential of endogenous TSPCs in tendon injury sites. EVs embedded in fibrin glue may allow the sustained release of EVs in injured regions and promote the regeneration of patellar tendon tissue in rats[15]. In addition to BMSCs, ADSC-EVs can also promote the proliferation and migration of tendon cells, reduce fatty infiltration, promote tendon-bone healing, improve the biomechanical properties of the tendon-bone junction and improve the mechanical strength of the repaired tendon[65,66]. The overexpression of H19 can enhance tendon regeneration potential. As an ideal drug carrier, EVs are a reliable delivery method to transmit lncRNAs. Reports have shown that engineered EVs with overload of H19 can regulate tendon regeneration by activating YAP through the H9-pp1-YAP axis[67]. In conclusion, MSC-EVs facilitate tendon regeneration by inhibiting apoptosis as well as enhancing the proliferation, migration and tenogenic differentiation of tendon stem cells and tenocytes. In addition, they can also regulate angiogenesis and modulate immune responses and extracellular matrix (ECM) remodeling of tendon tissue[68]. These results indicate that EVs have broad prospects in tendon repair and regeneration.

Skin and wound healing

EVs are currently widely used in wound healing and skin regeneration. EVs can participate in four stages of wound healing, namely, hemostasis, inflammatory response, cell proliferation and remodeling [69]. Both ADSC-EVs and BMSC-EVs exert benefits on cells related to skin wound healing, including fibroblasts, keratinocytes and endothelial cells, in different ways. BMSC-EVs mainly promote proliferation, whereas ADSC-EVs have a major effect on angiogenesis. BMSC-EVs and ADSC-EVs presented synergistic effects on wound healing[70]. Great progress has been made in the field of wound healing with the rapid development of the combination of EVs and biomaterials. EVs and glycerol hydrogels have synergistic effects on the proliferation of human skin fibroblasts. The full-thickness excisional wound model in mice showed that the fibrosis, vascularization, and epithelial thickness of wounds reached a maximum level after treatment with EV-loaded hydrogels. Moreover, research has found that EVs derived from human endometrial stem cells (hENSCs) contain several growth factors, including VEGF, basic fibroblast growth factor and TGF-1, which benefit angiogenesis. hENSC-EV-loaded chitosan hydrogel has positive impacts on wound healing by promoting angiogenesis and tissue granulation formation. hENSC-EV-loaded chitosan hydrogel could be an ideal scaffold for skin wound dressing and skin tissue regeneration[71]. EVs derived from HUVECs (HUVECs-EVs) could promote the proliferation and migration activities of keratinocytes and fibroblasts, which are two critical cells for skin regeneration. Gelatin methacryloyl (GelMA) hydrogel scaffolds combined with HUVEC-EVs could not only repair wound defects but could also achieve sustained release of EVs, which promoted re-epithelialization, collagen maturity and angiogenesis that ultimately contributed to wound healing[72]. In addition to wound healing and skin regeneration, EVs also play critical roles in skin aging and several skin diseases. For example, ADSC-EVs can relieve atopic dermatitis. ADSC-EVs can also promote cuticle hydration and ceramide synthesis and significantly reduce the secretion of inflammatory cytokines [interleukin (IL)-4, IL-5, IL-13, and IL-17] when applied *in vivo*[73]. Moreover, ADSCs could protect against oxidative stress by promoting the proliferation of human dermal fibroblasts (HDFs) and inhibiting reactive oxygen species and MMP production *via* the secretion of various cytokines. ADSC-EVs might be potential therapeutic tools for addressing the problem of photoaging [74]. Studies have also shown that EVs derived from human iPSCs could regulate the genotypic and phenotypic changes of HDFs induced by UV photoaging and natural aging. EVs derived from human iPSCs affected cellular responses related to skin aging, including the expression levels of MMP-1 and type I collagen and the proliferation and migratory ability of HDFs. iPSC-EVs can mediate intracellular

transportation and reconstruct the matrix in aging skin by enhancing the expression of structural proteins and regulating the expression of age-related proteins[75]. In general, EVs serve as efficient carriers of molecular cargos for wound healing and skin regenerative medicine.

Tooth and periodontal regeneration

EVs have been widely used in the repair of dental tissue, including dental pulp, dentin and periodontal tissue. Dental pulp stem cells (DPSCs)-EVs can bind to matrix proteins such as type I collagen and fibronectin, enabling them to be tethered to biomaterials. EVs are endocytosed by both DPSCs and human MSCs in a dose-dependent and saturable manner *via* the caveolar endocytic mechanism and trigger the P38 mitogen-activated protein kinase (MAPK) pathway. In addition, EVs can trigger the increased expression of genes required for odontogenic differentiation. In the generated pulp tissue, DPSC-EVs can also promote the expression of several growth-promoting factors, including TBG-β and BMP-2, which ultimately promote the repair of dental pulp tissue[76]. Moreover, DPSC-EVs can promote the proliferation and angiogenesis of vascular endothelial cells by activating the P38/MAPK pathway, which provides the possibility for the regeneration of vascular pulp tissue[77]. SC-EVs could promote DPSC proliferation and enhance neurite outgrowth, neuron migration, and vessel formation *in vitro*. SC-EVs facilitate dental pulp regeneration through endogenous stem cell recruitment *via* the SDF-1/CXCR4 axis without exogenous cell transplantation[78]. In addition to SC-EVs, EVs derived from Hertwig's epithelial root sheath cells could trigger regeneration of dental pulp-dentin-like tissue composed of hard (regenerative dentin-like tissue) and soft (blood vessel and neuron) tissue in an *in vivo* tooth root slice model by activating the Wnt pathway[79]. Periodontitis is the primary cause of tooth loss, but there is no effective treatment to repair inflammatory bone loss in periodontitis. In terms of periodontal tissue regeneration, studies have shown that EVs secreted by periodontal ligament stem cells (PDLSCs) are therapeutics for bone defects in periodontitis. EVs derived from healthy PDLSCs could rescue the osteogenesis capacity of endogenous stem cells under an inflammatory environment and promote the regeneration of alveolar bone by recovering the osteogenic differentiation ability of inflammatory PDLSCs through the inhinbitation of canonical Wnt signaling[80]. BMSC-EVs are also an ideal cell-free strategy for periodontal regeneration. BMSC-EVs could promote the regeneration of periodontal tissues through the OPG-RANKL-RANK signaling pathway to regulate the function of osteoclasts and affect macrophage polarization and TGF-β1 expression to modulate the inflammatory immune response, thereby inhibiting the development of periodontitis and immune damage in periodontal tissue[81]. Furthermore, the therapeutic effect of ADSC-EVs was the same as that of periodontal surgery in a rat periodontitis model[82]. Lipopolysaccharide (LPS)-induced dental follicle cell-derived EVs (L-D-EVs) could promote the proliferation of periodontal ligament cells. L-D-EV-loaded hydrogel applied in the treatment of periodontitis was beneficial to repairing lost alveolar bone in the early stage of treatment and maintaining the level of alveolar bone in the late stage of treatment in experimental periodontitis rats by decreasing the expression of the RANKL/OPG ratio *in vivo*[83]. EVs are presented as a novel cell-free therapeutic strategy for both dental pulp and periodontal regeneration.

Nerve regeneration

Neurological dysfunction usually causes great physical and psychological distress for patients. Autologous nerve transplantation is widely accepted as the gold standard for peripheral nerve repair, but its inherent defects greatly reduce its availability. Regeneration of peripheral nerves after injury remains a great challenge for researchers. EVs play a fundamental role in the physiological and pathological processes of the nervous system. There is growing evidence that EVs can play a neurotherapeutic role by mediating axon regeneration, activating SCs, promoting angiogenesis, and regulating inflammatory reactions. EVs from skin-derived precursor SCs (SKP-SC-EVs) could promote neurite outgrowth of sensory and motor neurons *via* the AKT/mTOR/p70S6K pathway *in vitro*[84,85]. SKP-SC-EV-incorporating silicone conduit nerve grafts could significantly accelerate the recovery of motor, sensory, and electrophysiological functions of rats; facilitate outgrowth and myelination of regenerated axons; and alleviate denervation-induced atrophy of target muscles, which raises the possibility of cell-free therapy in nerve regeneration[86]. Moreover, repair SCs (rSCs) could also release pro-regenerative EVs. Neuronal activity enhances the release of rSC-derived EVs and their transfer to neurons *via* the ATP-P2Y signaling pathway[87]. Mechanical stimuli could control the intercellular communication between neurons and SCs by changing the composition of miRNA in SC-EVs. MS-SC-EVs transferd miR-23b-3p from mechanically stimulated SCs to neurons, and lead the inhibition of neuronal Nrp1 expression, which was indicated the beneficial effect of MS-SC-EVs on axonal regeneration, and provided evidence for the role of miR-23b-3p-enriched EVs in peripheral nerve injury repair[88]. BMSC-EVs could promote the functional recovery of sciatic nerve injury and increase the expression of GAP-43, a marker of axon regeneration[89]. BMSC-EVs can also promote nerve regeneration by regulating the miRNA mediated genes which related to regeneration, such as vascular endothelial growth factor A and S100b[90]. In addition to BMSC-EVs, ADSC-EVs also benefited nerve regeneration. ADSC-EVs could increase neurite outgrowth *in vitro* and enhance regeneration after sciatic nerve injury *in vivo*[91]. Furthermore, ADSC-EVs contained mRNAs of neurotrophic factors, including NGR, brain-derived neurotrophic factor, ciliary neurotrophic factor and glial cell-derived neurotrophic factor. ADSC-EVs could deliver mRNAs as well as microRNAs that facilitate with neurotrophic factor

secretion and proliferation, support the SC repair phenotype, and provide a solid therapeutic evidence for nerve regeneration[92]. Gingiva-derived mesenchymal stem cell (GMSC)-derived EVs could obviously promote axonal regeneration and functional recovery of injured mouse sciatic nerves. GMSC-derived EVs promoted the expression of SC dedifferentiation/repair phenotype-related genes *in vitro*, particularly c-JUN, a key transcription factor that drives the activation of the repair phenotype of SCs during PNI and regeneration[93]. Revascularization treatment is a critical measure for nerve repair. A report revealed that EVs derived from hypoxic preconditioned HUVECs could facilitate MSC angiogenesis activity and the anti-inflammatory impacts of MSCs, which contribute to *in vivo* effective nerve tissue repair after rat spinal cord transection and provide inspiration for therapies based on stem cells and EVs[94]. In general, EVs are an effective therapeutic tool in nerve regeneration by mediating axon regeneration, regulating the phenotype of SCs, promoting angiogenesis, and regulating inflammatory reactions.

Bone regeneration

EVs play four potential roles in bone regeneration, namely, angiogenesis, osteoblast proliferation, intercellular communication, and immune regulation. EV-mediated intercellular communication between osteoblasts and osteoclasts may represent a novel mechanism of bone modeling and remodeling. EVs transmit signals between osteoblasts and osteoclasts to regulate bone remodeling. Osteoblasts release RANKL-containing EVs, which are transferred to precursor osteoclasts and promote osteoclast formation by stimulating RANKL-RANK signaling[95]. MSC-derived EVs (MSC-exos), with their inherent capacity to modulate cellular behavior, are emerging as a novel cell-free therapy for bone regeneration. Reports have revealed that EVs derived from osteoinductive BMSCs (BMSC-OL-EVs) contribute to bone regeneration *via* multicomponent exosomal miRNAs (let-7a-5p, let-7c-5p, miR-328a-5p and miR-31a-5p), which target Acvr2b/Acvr1 and regulate the competitive balance of Bmpr2/Acvr2b toward Bmpr-elicited Smad1/5/9 phosphorylation[96]. Moreover, lyophilized delivery of BMSC-OI-EVs on hierarchical mesoporous bioactive glass scaffolds showed the possibility of bone regeneration in a rat cranial defect model[96]. Umbilical MSC-derived exosomes (uMSCEXOs) also showed great promise in bone regeneration. uMSCEXOs encapsulated in hyaluronic acid hydrogel and combined with customized nanohydroxyapatite/poly-ε-caprolactone (nHP) scaffolds could repair cranial defects in rats by promoting the proliferation, migration, and angiogenic differentiation of endothelial progenitor cells *via* the miR-21/NOTCH1/DLL4 signaling axis[97]. Compared to EVs derived from uMSCs exposed to normoxia, EVs derived from uMSCs treated with hypoxia promoted angiogenesis, proliferation, and migration to a greater extent. Hypo-Exos facilitated with the recovery of bone fracture by exosomal miR-126 and the SPRED1/Ras/Erk signaling pathway. In addtion, hypoxia preconditioning promote the transferring of exosomal miR-126 through the activation of hypoxia-inducible factor-1α. Hypoxia preconditioning is an effective and promising approach for optimizing the therapeutic actions of MSC-derived exosomes for bone fracture healing[98]. Moreover, the comparison between adipose, bone marrow, and synovium-derived EVs (ADSC-EVs, BMSC-EVs, and SMSC-EVs, respectively) showed that ADSC-EVs, BMSC-EVs, and SMSC-EVs could facilitate the viability and migration of MSCs and possessed favorable capacities for chondrogenesis and osteogenesis. Among these three types of EVs, ADSC-EVs presented the best performance. The different effects between ADSC-EVs, BMSC-EVs, and SMSC-EVs could be attributed to the different factors associated with the focal adhesion, ECM-receptor interaction, actin cytoskeleton regulation, cAMP, and PI3K-Akt signaling pathways[99]. EVs constitutively expressing BMP2 could facilitate the effects of bone regeneration. BMP-engineered EVs potentiate the BMP2 signaling cascade, possibly due to an altered miRNA composition. EV functionality may be engineered by genetic modification of the parental MSCs to induce osteoinduction and bone regeneration[100]. EVs combined with biomaterials present a better effect on bone repair. Three-dimensional engineered scaffolds (PLAs) complexed with human gingival MSCs have therapeutic effects that can improve bone tissue regeneration[101]. EVs combined with tricalcium phosphate-modified scaffolds can promote osteogenic differentiation of cells and promote the recovery of cranial defects *in vivo* by activating the PI3K/Akt signaling pathway[102]. In addition to bone regeneration, MSC-EVs or platelet-rich plasma-derived EVs also have high therapeutic value for treating osteoarthritis by suppressing the inflammatory immune microenvironment. BMSC-derived exosomes can effectively promote cartilage repair and extracellular matrix synthesis and alleviate knee pain in OA rats[103]. In addition, the modification of EVs and the combination of EVs with biomaterials can enhance targeting effects and extend retention which contribute to an effectively treatment of OA [104].

PROSPECTS AND CHALLENGES OF EVS IN TRANSLATIONAL MEDICINE

Previous studies based on EVs have shed new light on the application of EVs in tissue regeneration, but there are some major problems that still need to be solved in the clinical translation of EVs. First, the storage of EVs is unstable. EVs can be stored at 80 °C for several months; however, the pH value of the storage solution and freeze-thaw cycles can affect EV activity. The transport and storage conditions of

EVs need to be further studied. Second, there is no effective method to isolate purified EVs in large quantities. At present, EVs are extracted mainly by UC, immunoadsorption, precipitation or microfluidic separation and are easily contaminated by proteins. Nowadays, there are several strategies to enhance the purity and quality of harvested EVs. From the perspective of stimulation of EVs secretion, many factors including protein regulations, thermal and oxidative stress, oxygen concentration, low pH (< 6.0), radiation, starvation can enhance the secretion of EVs from cells[105]. From the perspective of the methods of EVs isolation, how to simplify the isolation procedure and improve the EVs yield are the main two obstructions in the research field of EVs. Recent report reveals that the isolation procedure of EVs may be simplified with the improvement of newly EVs separation techniques including immunoaffinity, chromatography and polymer precipitation[106]. Moreover, with the development of commercial EVs isolation kits, EVs also can be extracted from limited sample in a short period of time. Artificial EVs is another way to realize large scale EVs generation. Artificial EVs generation technologies use the physical forces or chemicals (nitrogen cavitation[107], extrusion *via* porous membrane[108], sonication[109]) to break cells and release the cellular components. With reconstitution of the released lipids, proteins, and nucleic acids, artificial EVs can be generated in large quantity[105].

Moreover, improving the therapeutic efficiency of EVs is also a great challenge for applying EVs to clinical use. EV surface engineering can realize the EVs selective enrichment in specific cells and potentially tissues by introduction of targeting moieties[110]. To improve the therapeutic effects of EVs, a variety of methods (active drug loading, passive modification, electroporation, acoustic degradation, chemical transfection, *etc.*) can be used to modify EVs. Moreover, Cytochalasin B treatment and osmotic pressure can enhance the production of EVs with improved drug loading capacity[111]. Engineered EVs are a new strategy to enhance the expression of targeted proteins of EV-related RNA. These engineered EVs with specific targeted biomolecules can be used specifically for different therapeutic purposes, including as *in vivo* tracers or in targeted cell tracking, which could improve the efficacy of disease therapy and tissue regeneration.

CONCLUSION

In conclusion, EVs are intelligent and controllable biomaterials that can participate in a variety of physiological and pathological activities, tissue repair and regeneration by transmitting a variety of biological signals, showing great potential in cell-free tissue regeneration. Engineered EVs, which represent a clean, highly purified, and highly controllable means of achieving the sustained release of drugs, have broad prospects in future tissue regeneration engineering.

Abstract

A century has passed since the Nobel Prize winning discovery of insulin, which still remains the mainstay treatment for type 1 diabetes mellitus (T1DM) to this day. True to the words of its discoverer Sir Frederick Banting, "insulin is not a cure for diabetes, it is a treatment", millions of people with T1DM are dependent on daily insulin medications for life. Clinical donor islet transplantation has proven that T1DM is curable, however due to profound shortages of donor islets, it is not a mainstream treatment option for T1DM. Human pluripotent stem cell derived insulin-secreting cells, pervasively known as stem cell-derived β cells (SC-β cells), are a promising alternative source and have the potential to become a T1DM treatment through cell replacement therapy. Here we briefly review how islet β cells develop and mature *in vivo* and several types of reported SC-β cells produced using different *ex vivo* protocols in the last decade. Although some markers of maturation were expressed and glucose stimulated insulin secretion was shown, the SC-β cells have not been directly compared to their *in vivo* counterparts, generally have limited glucose response, and are not yet fully matured. Due to the presence of extra-pancreatic insulin-expressing cells, and ethical and technological issues, further clarification of the true nature of these SC-β cells is required.

Key Words: Human pluripotent stem cells; Stem cell-derived β cells; Islet β cells; Type 1 diabetes mellitus; Cell replacement therapy

Core Tip: Diabetes mellitus (DM) is a metabolic condition of absolute or relative deficiency in insulin. Since the discovery of insulin 100 years ago, there has been slow progress in the treatment of type 1 DM (T1DM) in clinical practice. In the scientific community however, there is much interest and progression in the research of human pluripotent stem cell derived insulin producing β-like cells, pervasively known as stem cell-derived β cells (SC-β cells). If they are determined to be genuine, scalable and functionally matured, SC-β cells have the potential to cure T1DM through cell replacement therapy.

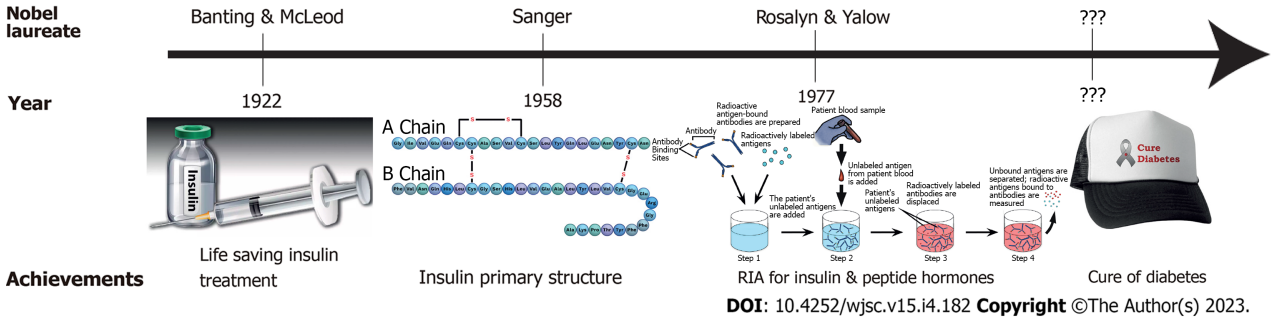
INTRODUCTION



In this coronavirus disease 2019 pandemic era, there is a silent growing epidemic of significant public health burden with tremendous social and economic costs. This growing epidemic is not an infectious disease, but a chronic non-communicating metabolic disease - it is the epidemic of diabetes mellitus (DM). There was an estimated 537 million adults with DM globally in 2021[1], with the prevalence increasing each year due to the rising incidence of type 2 DM (T2DM) worldwide[2]. DM is a metabolic disorder characterised by a disruption in glucose homeostasis leading to hyperglycaemia, and broadly consists of 2 main types: T1DM and T2DM. T1DM is the absolute deficiency of insulin due to the autoimmune destruction of insulin-secreting β cells in the islets of Langerhans of the pancreas, and is usually first diagnosed in children and young adults. T2DM is the relative deficiency of insulin function due to insulin resistance in peripheral tissues, and sometimes with reduced insulin secretion due to dysfunctional or dedifferentiated β cells, usually occurring in adults.

Hyperglycaemia in T1DM and T2DM can cause various microvascular complications such as diabetic retinopathy and blindness, nephropathy and kidney failure requiring dialysis, as well as peripheral neuropathy and infected foot ulcers that lead to amputations. It can also cause macrovascular complications such as peripheral artery disease, coronary artery disease and stroke. These complications lead to significant morbidity and mortality, as well as substantial associated health and social costs[3,4].

INSULIN IS NOT A CURE FOR DIABETES

These were Sir Frederick Banting's words to the world during his Nobel Lecture for his 1923 Nobel Prize winning discovery of insulin. Subsequent discoveries on primary insulin sequences and radioimmune assay for insulin and other peptide hormones were also awarded the Nobel Prizes (Figure 1)[5]. A century later, unfortunately there is still no cure for DM, and life-long insulin replacement remains the mainstay of treatment for T1DM and controlling high blood sugar levels with antihyperglycaemic agents in most T2DM individuals. The continuous blood glucose monitoring and insulin pump known as artificial pancreas or bionic pancreas still presents the risk of developing complications, though reduced, because this and other current treatments cannot achieve physiological glucose homeostasis in patients[6,7]. These treatments themselves are also not without risks. Insulin as well as some oral anti-hyperglycaemics, such as sulfonylureas and glinides, are associated with the risk of hypoglycaemia which can lead to seizures, coma and even death[8,9]. Thus, there is a critical need for more effective and curative treatments to reduce the global burden of this disease.

The landmark proof-of-concept has demonstrated over the last 2 decades that clinical transplantation of donated human islets are able to restore β-cell function and achieve insulin independence immediately with improvement in glycaemic control and avoid the risk of hypoglycaemia episodes[10-13]. However, a large amount of approximately 340-750 million islet cells are required for successful transplantation in a patient of 68 kg weight[11,14]. Thus, the widespread application of donor islet transplantation is severely limited by the insufficient supply of human organ donor pancreases[15,16]. In addition to supply issues, another challenge to this treatment option is the prevention of transplant rejection, immune destruction and cell death of the transplanted islet cells[17]. To address the donor shortage issue, alternative scalable insulin-secreting tissues must be identified and developed. Due to their ability for theoretically infinite self-renewal and differentiation into all cell types in the body, human pluripotent stem cells (hPSCs) hold great promise for generating surrogate insulin-secreting cells *ex vivo*, pervasively known as stem cell-derived β cells (SC-β cells)[18-20] or SC-islets[21] in the literature. In order to help understand the true nature of these SC-β cells, we briefly introduce how islet β cells develop *in vivo*.

Figure 1 Nobel prizes awarded for the endeavour towards curing diabetes. Insulin is not a cure for diabetes. Three Nobel prizes have been awarded in this endeavour[5].

IN VIVO DEVELOPMENT OF ISLET BETA CELLS

The pancreas is derived from the embryonic endoderm, one of the three germ layers, which is formed during gastrulation of embryogenesis. In addition to the pancreas, the definitive endoderm also gives rise to the liver, lung, thymus and other organs of the respiratory and digestive tracts[22]. The endoderm located in the foregut region gives rise to the dorsal and ventral buds of the pancreas which rotate to form one organ, then pancreatic epithelium is induced and expands, from which endocrine progenitors arise. The endocrine progenitors then differentiate into the β cells that secrete the hormone insulin, α cells that secrete the hormone glucagon, δ cells that secrete the hormone somatostatin, ε cells that secrete the hormone ghrelin, and PP cells that secrete the hormone pancreatic polypeptide. The pancreatic endocrine cells start to organize into clusters forming islets before birth, and the Islets of Langerhans become fully formed at around 2-3 wk after birth[22]. Human islets are made up of 40%-60% β cells and 30% α cells[22]. The adult pancreas is made up of exocrine cells that secrete digestive tract enzymes, duct cells that make up the ductal tree to transport digestive enzymes and islet cells that secrete hormones into the bloodstream for glucose homeostasis[23].

Mechanistically, the pancreatic islets are initiated by the transient expression of a high level of the transcription factor neurogenin-3 (NGN3)[24]. NGN3 is important in committing all pancreatic endocrine cell types, the deficiency of which leads to the absence of pancreatic endocrine cells[25,26]. The molecular mechanisms for the development of each pancreatic endocrine cells are not completely defined, however it is suggested that insulin-producing β cells are differentiated from the pancreatic progenitors that express transcription factor genes pancreatic and duodenal homeobox 1 (PDX1) and NK6 homeobox 1 (NKX6-1), and then turn on NGN3[27,28]. There are several β cell transcription factors, including PDX1, NKX6-1 and MAF BZIP transcription factor A (MAFA), which play a critical role in activating insulin transcription and regulating insulin secretion[29-31].

PDX1 is a homeodomain transcription factor homogenously expressed in the early pancreatic bud and its expression persists into mature β cells; the absence of PDX1 leads to agenesis of the pancreas [32]. NKX6-1 and the helix-loop-helix transcription factor Beta2/NeuroD determine islet cell differentiation during embryogenesis, and maintain specific islet cell hormone expression in adults[32]. Knockout of mouse *Nkx6-1* gene leads to a significant inhibition in the formation of β cells[33]. NeuroD is initially expressed in pancreatic epithelium during development, before being expressed in $NGN3^+$ endocrine progenitors, and finally exclusively expressed in β cells after birth. The absence of Beta2/NeuroD leads to reduced mouse endocrine cells, in particular β cells, increased apoptosis and arrestment in islet morphology[25,34]. Beta2/NeuroD is also a critical transcriptional activator of the insulin gene[35,36].

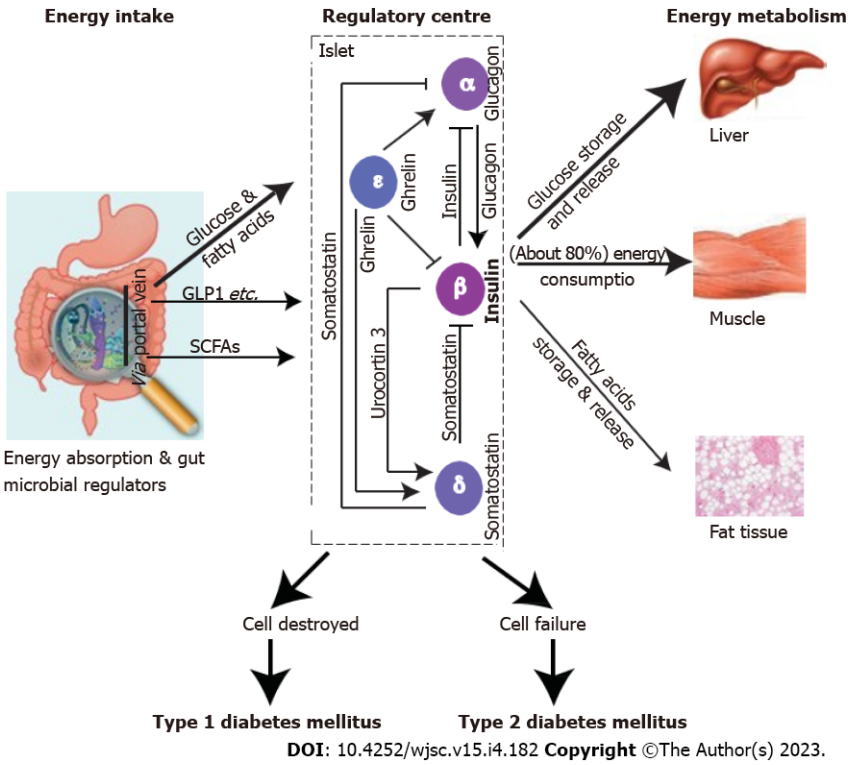
β-cell maturation including maturation of other clinically important cell types is a postnatal development process. For example maturation of mouse and human β cells takes place approximately 3 wk[37] and 26-44 wk after birth[38,39] respectively. The maturation process is controlled by transcription factors and exhibited in maturing at the gene, protein, subcellular, intercellular and metabolic levels.

ISLET BETA CELL MATURATION REGULATED BY TRANSCRIPTION FACTORS

Following β-cell specific NeuroD deletion, the mice developed glucose intolerance and the islets displayed features of foetal/neonatal β cells such as overexpression of glycolytic genes, lactate dehydrogenase (LDHA), Neuropeptide Y, and higher basal insulin secretion and oxygen consumption due to the reliance on oxidative metabolism of glucose[40-46]. That is, the glucose metabolic profile of mouse β cells without NeuroD was equivalent to immature β cells. The mutations of NeuroD cause maturity onset diabetes of the young[22,33]. NeuroD is also critical for maintaining a matured functional state of

islet β cells[40]. These data suggest that NeuroD regulates islet β-cell maturation, though its postnatal dynamic expression profile is not available. Thus, identification of Beta2/NeuroD activators may help mature hPSC-derived insulin-secreting cells *ex vivo*.

MafA is another transcription factor being demonstrated to regulate the maturation of islet cell organisation, β cell mass and β cell function from 3 wk of age in mice using the gene targeting strategy [47]. MafA expression reaches their adult levels at 3 mo in rats[48] coinciding with the obtaining of mature glucose stimulated insulin secretion (GSIS). Aguayo-Mazzucato *et al*[49] were the first to demonstrate that MAFA overexpression and the thyroid hormone triiodothyronine (T3) treatment are able to increase human foetal islet-like clusters, insulin secretion at 16.8 mmol/L glucose and proinsulin-to-insulin processing. Chromatin immunoprecipitation experiment showed binding of thyroid receptors to MafA promoter, thereby confirming that T3 directly regulates the expression of MafA[50]. The thyroid hormone receptor is also demonstrated to be expressed on human mature islets [51], though its postnatal development profile is unknown.



Furthermore, a recent study shows that the expression of the orphan nuclear transcription factor estrogen-related receptor gamma (ERRγ) is a hallmark of mature β cells[52]. ERRs consist of three paralogs in mammals, namely ERRα (NR3B1 or Esrrα), ERRβ (NR3B2 or Essrβ) and ERRγ (NR3B3 or Essrγ). ERRγ is progressively upregulated in mouse islets from 2 to 6 wk of age (5-fold higher in adults compared to neonatal β cells) and ERRγ transcriptional network promotes mitochondrial oxidative metabolism in mouse β cells, required for functional maturation of β cells and glucose homeostasis[52]. Mice with β cell-specific ERRγ deletion failed to develop a mature GSIS. With the developmentally deleted β cell-specific ERRγ knockout mouse islets, RNA sequencing (RNA-seq) revealed that the expression of 4189 genes were altered, with almost equal numbers of genes down- and up-regulated (2008 and 2182 genes respectively). Gene ontology analysis revealed that ERRγ-regulated genes are associated with processes critical for β cell function including ATP biosynthesis, cation transport, oxidative phosphorylation, electron transport and secretion[52]. However, data is not available on postnatal developmental expression of ERRs in human islet cells, which will have to be addressed in the near future. Identification of ERRγ activators may help mature hPSC-derived insulin-secreting cells *ex vivo*.

Expression of the *Sine Oculis* family of homeodomain transcription factors SIX2 and SIX3 increased with age in the human pancreatic islet β cells[53]. SIX2 and SIX3 are localised to the nucleus of adult human β cells but not detected in juvenile (under 9 years of age) β cells[53]. Using gain-of-function experiments in human β cell line, the EndoC-bH1 cells or primary juvenile human islets, evidence has demonstrated that expression of SIX2 or SIX3 were sufficient to enhance cardinal functions of human β cells[53]. Identification of SIX2 and SIX3 activators may therefore help generate matured hPSC-derived insulin-secreting cells *ex vivo*.

METABOLIC MATURATION OF ISLET BETA CELLS

Although rat islets acquired GSIS by postnatal day 21, a mature GSIS was only achieved by 3 mo[54], coinciding with the time when insulin dynamics reaches their adult levels[48]. The metabolic maturation is underscored by genes of important metabolic players in β cells such as glucose transporter 2, glucokinase, glucagon-like peptide-1 receptor and prehormone convertase 1 (encoded by *Pcsk1*) that were expressed from very low levels at postnatal day 2 to higher levels with increased age[48]. Similarly, the metabolic maturation is also underscored by genes transcribing for malate dehydrogenase, glycerol-3-phosphate dehydrogenase, glutamate oxaloacetate transaminase, pyruvate carboxylase and carnitine palmitoyl transferase 2 from much lower levels at neonatal postnatal day 2 to high levels at day 28[55]. In the same period, genes encoding proliferation regulators in β cell genes encoding platelet-derived growth factor receptor A, platelet-derived growth factor receptor B, platelet-derived growth factor B and fibroblast growth factor (FGF) receptor 1 are progressively downregulated. Mature β cells tend to have lower levels of LDHA and glycolytic genes, as it is downregulated by NeuroD from embryonic to adult islets, which then appears to possess the ability to correspond glucose metabolism with insulin secretion[56-58].

The molecular mechanism of mature β-cell secretion is well understood. The higher blood glucose levels stimulate its active transportation into the β cell cytoplasm, increasing the ATP/ADP ratio through glycolysis and oxidative metabolism and triggering the depolarisation of the β cell membrane and opening the voltage-gated Ca^{2+} channel. The AMP-activated protein kinase (AMPK) is a highly conserved sensor of intracellular adenosine nucleotide levels that is activated even with modest decreases in ATP production resulting in relative increases in AMP or ADP. In response, AMPK promotes catabolic pathways to generate more ATP, and inhibits anabolic pathways. The increase in cytoplasmic Ca^{2+} triggers the fusion of insulin granules with the plasma membrane for exocytosis of insulin contents. Coordinating with other islet cells, mature β cells produce insulin in adequate amounts and timeliness to maintain plasma glucose within a narrow concentration range[39,59]. Thus, β cell function is critical for mature GSIS. Destruction and failure of islet β cells will lead to T1DM and T2DM, respectively (Figure 2).

Figure 2 Mature islets are a regulatory centre for glucose homeostasis. A simplified graphic representation of how mature pancreatic islets regulates glucose homeostasis. Skeletal muscle is the largest organ in the body (45%-55% body mass) and consumes about 80% insulin. GLP1: Glucagon-like peptide-1; SCFAs: Short-chain fatty acids.

MATURATION MARKERS OF ISLET BETA CELLS

To help with the characterization of whether hPSC-derived insulin-secreting cells *ex vivo* are matured, we briefly summarize maturation markers for *in vivo* islet β cells. Over the last decade, several potential markers for maturation of immature islet β cells were discovered. Blum *et al*[60] were the first to demonstrate that functional islet β cell maturation is marked by expression of the corticotropin-releasing factor family peptide urocortin 3 (UCN3), along with an increased glucose threshold.

Mature rat β cells expressed significantly higher levels of the gap junction connexion 36 gene (*Cx36*, also known as *Gjd2*) compared to neonatal immature counterparts, corresponding to a significantly higher membrane density of gap junctions and greater intercellular exchange of ethidium bromide[61]. Human mature islets predominantly express CX36 at mRNA and protein levels with β cell membrane harboring detectable levels of CX36 gap junction proteins[62]. Though the developmental profile of human islet CX36 is unknown, we speculate that the dynamic pattern of CX36 expression from human neonatal to mature β cells is similar to that in rats and CX36 is a potential maturation marker for matured hPSC-derived insulin-secreting cells *ex vivo*.

Our group recently showed that claudin 4 is the only tight junction molecule family member highly upregulated in the postnatal mouse islets and global deletion of this gene affects mature GSIS in a sex difference manner[63]. Thus, claudin 4 may also be a maturation marker for matured hPSC-derived insulin-secreting cells *ex vivo*.

THE DIFFERENTIATION OF SC-BETA CELLS *EX VIVO*

The advent of hPSC provided an important opportunity to overcome major challenges of clinical islet transplantation therapy through its accessibility, theoretically unlimited self-renewability and the boundless potential to generate an alternative source of donor insulin-secreting cells *ex vivo*[64,65]. The generated insulin-secreting cells can also be used for disease modelling and pharmaceutical drug testing to help establish therapeutics that improve cell function, survival and proliferation. Insulin-secreting cells differentiated from hPSCs that include human embryonic stem cells (hESC) and induced hPSCs (ihPSC) are ubiquitously termed as SC-β cells[18-20] in the literature. hESCs are generated from the inner cell mass of human blastocysts and have the infinite ability to proliferate as undifferentiated cells or differentiate into cells of all ectoderm, mesoderm or endoderm lineages[66,67].

Over recent years, there have been various protocols developed of *ex vivo* differentiation of SC-β cells [18-20] and SC-islets[18,21]. Thus far, hPSCs have been differentiated towards SC-β cells through a step-wise manner emulating *in vivo* pancreatic embryonic development[68-72]. The differentiation of hPSCs towards SC-β cells have been achieved with the application of growth factors, proteins or molecules to modulate signaling pathways to progress through each stage of pancreatic development, and is usually measured by expression of a couple of key transcription factors or C-peptide[22]. hPSCs (characterised by expression of Oct4) are first differentiated into definite endoderm cells expressing FOXA2 and SOX17 through application of a mix containing Wnt, activin A, inducer of definite endoderm, wortmannin, and sodium butyrate[22]. Then application of FGF10 and FGF7 differentiates the definite endoderm into gut tube endoderm expressing HNF1B and HNF4A[22]. The differentiation mixture containing retinoic acid, noggin KAAD-cyclopamine, FGF, and indolactum V leads to differentiation into pancreatic progenitors expressing PDX1 and HNF6, which further differentiates into endocrine progenitors (NKX6-1, NGN3, NKX2-2, PTF1A), and finally into β-cells (characterised by presence of C-peptide and insulin)[22]. We here summarize several representative protocols used to generate SC-β cells and SC-islets (Table 1).

Pagliuca *et al*[73]'s differentiation protocol was the first using specific and cocktail of inducing factors to differentiate hPSCs sequentially through 6 stages into SC-β cells (Table 1). At stages 5 and 6, there is however significant heterogeneity in the final population containing SC-β and SC-α cells, as well as SC-endocrine cells (resembling enterochromaffin cells) and non-endocrine cells (*e.g.*, exocrine cells such as pancreatic acinar, mesenchymal and ductal cells)[18]. Nevertheless, these cells appear to be stable, maintaining their identity as evidenced by their global transcriptional profiles during stage 6 cultures. At this stage, they also express the maturation marker SIX2 but several other β cell markers of maturity are not expressed such as UCN3, MAFA and SIX3[18].

The Velazco-Cruz *et al*[19]'s protocol was built upon and modified Pagliuca *et al*[73]'s protocol, and demonstrated that the SC-β cells had improved insulin secretion and greater gene expression of β cell markers compared to the cells generated with Pagliuca *et al*[73]'s protocol, but still much less than the average human islet (Table 1). Follow-up studies with the addition of differentiation factors or changes to the differentiation processes were unfortunately unsuccessful in producing more functional SC-β cells equal to human islet β cells[74-76].

In Balboa *et al*[20]'s protocol, the SC-islets had similar cytoarchitecture and functional insulin secretion pattern to islet β cells, though with immature glucose-induced mitochondrial respiration and instead retained pyruvate sensitivity - thus the SC-islets were not completely similar to functional adult islets (Table 1). Balboa *et al*[20]'s SC-β cells showed heterogeneous mature β cell marker expression, required further maturation *in vivo* after transplantation, showed upregulated expression of CHGB and MAFA after 6 mo, and did not express adult β cell factors RBP4 and SIX3[20].

Nevertheless, studies indicate that several current pancreatic progenitor differentiation protocols promote precocious endocrine commitment; ultimately resulting in the generation of non-functional polyhormonal cells[74]. The efficiency of differentiation decreases with each step, and at the final step there are very small amounts of SC-β cells that have a low insulin content, co-express insulin and glucagon, and usually respond poorly to glucose stimulation[22,70]. It was also found that these SC-β cells have little to no expression of maturation genes including MAFA and G6PC2[18,73,77]. Following transplantation, the amount of insulin secreted by SC-β cells rises[73,77,78] and the previously low or non-expressed genes of islet β cells such as MAFA, G6PC2, MNX1 and INS increases[79].

Cell purification steps will increase the safety of, and ability to upscale the manufacture of β cells. However, there are difficulties in including this step in large-scale manufacturing processes for production of reproducible PSC-derived cellular products with less variability in composition and function[80]. Several cell surface markers have been used to purify different developmental stages of PSC-derived cells[80]. Markers used include CD177 for anterior definitive endoderm cells[81], CD142, CD24 and glycoprotein 2 for pancreatic progenitors[82-85], CD49a for SC-β cells[18], and CD9 for negative selection of SC-β cells[86]. Monoclonal antibody against extracellular domain of claudin 4 might help enrich matured SC-β cells differentiated *ex vivo*.

Finally, a few maturation factors have proven useful in maturing SC-β cells *ex vivo*. For example, T3 enhanced the MAFA expression in the SC-β cells, and increased insulin content and insulin secretion at 16.8 mmol/L glucose[49]. Using an adenoviral ERRγ vector, overexpression of ERRγ increased glucose-stimulated C-peptide secretion in hPSC-derived insulin-secreting cells, thus may promote their functional maturation[52]. Therefore, identification of molecules that activate NEUROD, ERRγ, SIX2 and SIX3 will be important. Application of the activators individually or in combination may indeed promote functional maturation of genuine SC-β cells.

CURRENT *EX VIVO* SYSTEMS ARE DISTINCT FROM *IN VIVO* ISLET DEVELOPMENT NICHES

The current PSC differentiation protocols for insulin-secreting cells are mostly bulk cultures and consist of cocktails of inducing factors, which are generally based on accumulative knowledge generated from using the animal model systems. In these bulk cultures, there are cells types in the targeted lineage as

Table 1 A summary of several differentiation protocols for generating stem cell-derived β cells *ex vivo*

Differentiation protocol	Marker expression	Characterization	Ref.
The stem cell-derived β cell protocol is a 6-stage differentiation protocol using specific inducing factors for each stage (11 factors) to produce SC-islets from hPSCs, in a 3D suspension-based cell culture system (4-5 wk)	Pancreas progenitor marker: PDX1 (about 90% at stage 3). Endocrine markers: C-peptide, CHGA and NKX6-1. SC-β cell markers: INS, NKX6-1, ISL1, and others	Immunofluorescence. Ultrastructure. Insulin packaging into secretory granules. qRT-PCR. Static and dynamic GSIS. Functional test. Glucose-responsive Ca^{2+} flux, KCl depolarisation, ameliorate hyperglycaemia in diabetic mice. scRNA-seq. Purified SC-β cells with anti-CD49a	Pagliuca *et al*[73], 2014; Veres *et al* [18], 2019
Optimised 7 stage *in vitro* differentiation protocol of serial culture steps using factors such as vitamin C, ALK5 inhibitor, TGF-β receptor inhibitors, thyroid hormone (T3), R428 (AXL inhibitor), N-acetyl cysteine, Notch and BMP signalling inhibitors	Pancreas progenitor marker: PDX1 (about 90% at stage 3), NKX6-1. Endocrine markers: C-peptide, CHGA, NEUROD1, NKX2-2 and NKX6-1. β cell markers: INS, NKX6-1, ISL1, MAFB. Mature β cell markers: MAFA, ABCC8, IAPP, HOPX, NEFM, SIX2, G6PC2	Immunofluorescence. Transmission electron microscopy. qRT-PCR. Static and dynamic GSIS. Functional test in diabetic mice. Flow cytometry. Immunohistochemistry. Diabetes reversal within 40 d in mice. Metabolic analysis. Perifusion assay. Calcium imaging.	Rezania *et al*[78], 2014
Scalable 3D suspension culture system based on previous methods [101,102], with the addition of retinoic acid, cyclopamine (SHH inhibitor), Noggin (BMP inhibitor), then treatment with epidermal growth factor, KGF and Noggin (EKN). Followed by exposure to a cocktail of factors *e.g.*, TBP, ALK inhibitor, Noggin, TANK	Pancreas progenitor marker: PDX1 and NKX6-1 (90%). Endocrine markers: C-peptide, NEUROG3, NKX2-2 and NKX6-1. β cell markers: INS, NKX6-1, NKX2-2, PDX1. Mature β cell markers: MAFA, MAFB, PDX1, NKX6.1, NXK2.2, ISL1, PAX6, NEUROD1, and CHGA	Immunofluorescence. Transmission electron microscopy. qRT-PCR. Static and dynamic GSIS. Insulin biosynthesis and glucose metabolism, blood glucose reduction but not reversal of diabetes in mice. Flow cytometry. Western blot analysis. Statistical analysis	Russ *et al*[74], 2015
Six-stage differentiation strategy modulating TGF-β signaling by modulating Alk5i exposure, combined with controlling cell cluster size and use of enriched serum-free media culture	Pancreas progenitor marker: PDX1. Endocrine markers: CHGA (96%), C-peptide (73%), NKX6-1. SC-β cell markers: INS, CHGA, NKX2-2, PDX1, NKX6-1, MAFB, GCK, and GLUT1	Immunofluorescence. qRT-PCR. Static and dynamic GSIS. Flow cytometry. Light microscopy. Glucose responsive, first- and second-phase insulin release, improved glucose tolerance in mice. Western blot. Perifusion assay. Glucose tolerance test	Velazco-Cruz *et al* [19], 2019
Optimised differentiation protocol combining previous protocols. Changes made: Differentiation of hPSCs in adherent conditions until pancreatic progenitor stage. Then optimised with nicotinamide, epidermal growth factor, activin A and a ROCK inhibitor; a microwell aggregation step; and a final maturation step in suspension culture	Pancreas progenitor marker: PDX1. Endocrine markers: C-peptide. SC-β cell markers: INS. Mature β cell markers: INS, G6PC2, SIX2, GLIS3, RBP4, SIX3. HOPX, UCN3, IAPP, CPE and FXYD2 upregulated post engraftment. CHGB and MAFA upregulated 6 mo post-engraftment. B cell differentiation: SIX2, HOPX, ZBTB20. Insulin secretion genes: PCSK1, CPE, CHGB, ABCC8, FXYD2, GABRA2	Immunohistochemistry. Flow cytometry. Perifusion assay. Respirometry. Transmission electron microscopy. Electrophysiology. Exocytosis imaging. $[Ca^{2+}]_i$ imaging. $[cAMP]_m$ imaging. Metabolite tracing analysis. Ratiometric analysis. Transplantation study. scRNA-seq transcriptomic profiling. Glucose responsive biphasic insulin secretion. Glucose tolerance test	Balboa *et al*[20], 2022
Differentiation protocol using hCiPSC-islets by optimising pancreatic progenitor to β cells fate commitment by modulating signaling pathways and reconstructing islet spatial structure through 3D cell aggregates of posterior foregut-committed cells and combination of ISX9 and Wnt-C59 at stage 5	Pancreas progenitor marker: PDX1. Endocrine markers: C-peptide, CHGA and NKX6-1. β cell markers: PDX1, NKX6.1 and NKX2.2. Mature β cell markers: MAFA, UCN3	Immunofluorescence. qRT-PCR. Transmission electron microscopy. Static and dynamic GSIS. Glucose-stimulated calcium flux assay. Flow cytometry. scRNAseq. Glucose responsive biphasic insulin secretion, decrease HbA1c, restore endogenous C-peptide secretion. Glucose tolerance tests. Preclinical diabetic non-human primate transplantation study. Fasting blood glucose levels. Glycated HbA1c. scRNA-seq. Teratoma assay. Karyotype analysis. Calcium imaging. Cryo-electron microscopy. ELISA	Du *et al*[21], 2022

PDX1: Pancreatic and duodenal homeobox 1; SC-islets: Stem cell-derived islets; hPSC: Human pluripotent stem cells; C-peptide: Connecting peptide; CHGA: Chromogranin A; NKX6-1: NK6 homeobox 1; qRT-PCR: Quantitative real time-polymerase chain reaction; GSIS: Glucose-stimulated insulin secretion; SC-β cell: Stem cell-derived β cell; INS: Insulin gene; ISL1: ISL LIM homeobox 1; Ca^{2+}: Calcium; KCl: Potassium chloride; scRNA-seq: Single-cell RNA sequencing; anti-CD49a: CD49a (Integrin alpha 1) antibody; TGF-β receptor inhibitor/ALK5i: Transforming growth factor β-receptor I/activin receptor-like kinase 5 inhibitor; R428 (AXL inhibitor): A selective small-molecule inhibitor of AXL (bemcentinib, BGB324); BMP: Bone morphogenetic protein; NEUROD1: Neurogenic differentiation 1; NKX2-2: NK2 homeobox 2; MAFA: MAF BZIP transcription factor A; MAFB: MAF BZIP transcription factor B; ABCC8: ATP Binding Cassette Subfamily C Member 8; IAPP: Islet amyloid polypeptide; HOPX: HOP homeobox; NEFM: Neurofilament medium chain; SIX2: SIX homeobox 2; G6PC2: Glucose-6-phosphatase catalytic subunit 2; KGF: (FGF7) Keratinocyte growth factor; TBP: TATA-binding protein; TANK: TRAF family member associated NFKB activator; PAX6: Paired box 6; GCK: Glucokinase; GLUT1: Glucose transporter 1; ROCK inhibitor: Rho-kinase inhibitor; GLIS3: GLI-similar 3/zinc finger 3; RBP4: Retinol binding protein 4; SIX3: SIX homeobox 3; UCN3: Urocortin 3; CPE: Carboxypeptidase E; FXYD2: FXYD domain containing ion transport regulator 2; cAMP: Cyclic adenosine monophosphate; ZBTB20: Zinc finger and BTB domain containing 20; PCSK1: Proprotein convertase subtilisin/kexin type 1; GABRA2: Gamma-aminobutyric acid type A receptor subunit alpha-2; hCiPSC: Human chemically induced pluripotent stem cells; ISX9: Isoxazole-9; Wnt-C59: Nanomolar inhibitor of mammalian PORCN acyltransferase activity and blocks activation of all evaluated human Wnts; HbA1c: Hemoglobin A1c; ELISA: Enzyme-linked immunosorbent assay.

well as unwanted lineages. One or two *in vivo* biomarkers are selected based on *in vivo* islet lineage development to characterise targeted cells at different differentiated stages *ex vivo*. However, these *in vivo* biomarkers should not be extrapolated as biomarkers for the *ex vivo* differentiation conditions because of clear differences in spatiotemporal and microenvironment niches between the *in vivo* development and *ex vivo* differentiation (Figure 3). In other words, we do not yet fully understand the full regulatory program, or the molecular details of the 3D microenvironment niche for specific islet lineage development *in vivo* to guide the specific differentiation of hPSCs into insulin-secreting cells *ex vivo*.

EXTRAPANCREAS INSULIN-SECRETING CELLS

Perhaps the research community have also forgotten the fact that in our body, extra-pancreas insulin-secreting cells exist, which may complicate the efforts of generating genuine SC-β cells. Subverted to general knowledge, approximately a quarter of human foetal enteroendocrine K/L cells were recently shown to express high levels of insulin and other β cell genes including the transcription factor PDX1, by using samples of foetal and neonatal human small intestines derived from the endoderm during development[87]. Notably, the expression of UCN3 in the human foetal enteroendocrine K/L cells was higher than in foetal human pancreatic β cells[87]. These results were confirmed with single molecule fluorescence *in-situ* hybridisation of insulin mRNA combined with immunofluorescent antibody staining of the insulin protein[87]. Secondly, thymocytes that are derived from the foregut, adjacent to which gives rise to the pancreas, normally produce insulin to induce self-tolerance and protect the body from the autoimmune destruction of pancreatic insulin-secreting β cells[88]. Lastly, though the central nervous system is an ectoderm-derived organ, the neuronal progenitors derived from adult hippocampus and the olfactory bulb were demonstrated to undergo insulin biosynthesis[89]. Human *INS* mRNA expression is also detected in the hippocampus, amygdala and temporal lobe in addition to the olfactory bulb, cerebellar and pontine regions[90]. A historical account of the extrapancreas insulin-secreting cells is referred to in a recent review article[88]. These data suggest that it is possible that the current reported SC-β cells contain a varied percentage of non-pancreatic insulin-secreting cells. Future studies are required to increase the percentage of genuine insulin-secreting β-like cells in the *ex vivo* systems.

SC-BETA CELLS TRANSPLANTED INTO NON-HUMAN PRIMATES

To further test their functions, the chemically induced SC-islets were recently intraportally transplanted into immunosuppressed adult diabetic rhesus macaques[21]. Three months after the SC-islet transplantation, all four macaques reportedly had improvements in diabetic symptoms, glycaemic control, fasting blood sugar levels, hemoglobin A1c (HbA1c), and reduced exogenous insulin requirements[21]. However, after 5-6 mo, two of the macaques developed graft failure (the other two macaques died of immunosuppression-related complications)[21]. Autopsy conducted on the macaques found no evidence of teratoma or tumorigenesis, but levels of β cells had fallen. The authors concluded that the immunosuppression regimen used was not appropriate in preventing immune attack against the grafts[21]. Whether the short-term improvements in diabetic rhesus macaques are related to the immaturity of grafted SC-islets and/or the presence of non-pancreatic insulin-secreting cells needs to be determined in the future.

SC-BETA CELLS IN CLINICAL TRIALS AS A T1DM THERAPY

The first hPSC-derived, differentiated cell replacement T1DM therapy product named VX-880 was approved by the United States Food and Drug Administration for phase 1/2 clinical trials in March 2021. The VX-880 are SC-islets for T1DM patients with certain indications; that is, impaired hypoglycaemic awareness and severe hypoglycaemia[91]. The preliminary outcomes of the clinical trials were presented in June 2022 at the American Diabetes Association 82nd Scientific Sessions by Vertex, a United States Pharmaceutics company[91]. A half-dose of VX-880 in two patients was able to achieve glucose-responsive insulin secretion, significantly improve time-in-range (the amount of time that blood glucose level is measured to be within target blood sugar range 70-180 mg/dL or 3.9-10 mmol/L), reduce exogenous insulin requirements and improved HbA1c[91]. VX-880 was also well tolerated although with some largely mild or moderate adverse reactions[91]. For example, patient 1 showed blood glucose time-in-range change from 40.1% on 34.0 units per day of exogenous insulin at baseline to 99.9% and insulin independence at day 270 onwards. Patient 2 showed blood glucose time-in-range change from 35.9% on 25.9 units per day of exogenous insulin at baseline to 51.9% with a 30% reduction in exogenous insulin use at day 150[91]. Whereas these results are very promising, VX-880 requires a

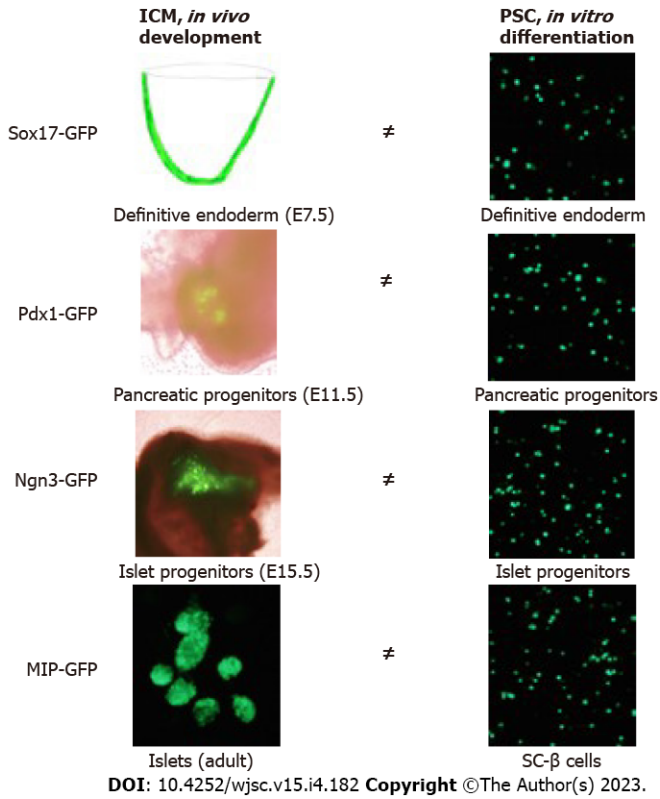

Figure 3 There are clear differences in spatiotemporal and microenvironment niches between the *in vivo* development and *ex vivo* differentiation of islet lineages. Details of lineage tracing mouse lines can be found in articles[103,104]. ICM: Inner cell mass; PSC: Pluripotent stem cell; Sox17: SRY-box transcription factor 17; GFP: Green fluorescent protein; PDX1: Pancreatic and duodenal homeobox 1, also known as insulin promoter factor 1; NGN3: Neurogenin-3; MIP: Mouse insulin 1 promoter; SC-β cells: Stem cell-derived β cells.

lengthy *in vivo* maturation period for blood sugar control (in patient 1) in contrast to donated islets retrieved from deceased persons, which achieved immediate insulin independence after transplantation into recipients[10-13]. The lengthy *in vivo* maturation period of grafted VX880 is a strong independent indicator that these SC-β cells are immature. It is also premature to claim the VX-880 SC-β cells are all genuine immature counterparts of islet β cells, as the duration and longevity of insulin independence was not yet available at the time of writing this article.

CONCLUSION

Immaturity of PSC-derived cells is a general obstacle, not only in the case of SC-β cells and SC-islets, but also other clinically important cell types[92]. Maturation biology is the final frontier in stem cell biology, of which our knowledge is still in its infancy. As summarised in Table 1, multiple hPSC differentiation protocols have been used in different laboratories. Consequently, off-target differentiation and aberrant differentiation from these protocols are more likely unavoidable, resulting in only a low frequency of genuine SC-β cells. Furthermore, the stage-specific differentiation factors selected may direct non-specific spatiotemporal differentiation, thus resulting in multiple cell types of the endodermal germ layer and even neuronal lineage origins. This may result in some differentiating cells along unwanted pathways and give rise to extrapancreas insulin-secreting cells. On the other hand, unwanted or off-target differentiated cellular products have accumulated in the bulk culture protocols and not been excluded for subsequent differentiation steps, which further increases the possibility of compromising the characterization through use of one or two developmental markers of *in vivo* cellular lineages. Finally, in addition to the above, there are still other challenges in this exciting field of research, such as ensuring SC-β cell survival post-transplantation given the highly vascularised islets are susceptible to ischaemic injury and loss of cell mass[93,94]. Developing methods that evade autoimmune attack in T1DM patients without the use of lifelong immunosuppression would be valuable[95].

Stage-specific *in vivo* pancreatic and islet lineage cell types would provide ideal positive controls for the *ex vivo* hPSC-derived insulin-secreting cells. Nevertheless, the human ethics issues and lack of human embryonic and foetal pancreatic tissues available prevent such reliable and precise comparison to be made between the islet lineage cells and the PSC-derived cells. However, future efforts should be made to resolve these issues. Similarly, it would be wise not to solely concentrate on undertaking

human β cell differentiation and maturation studies from hPSCs. Instead, investigating β cell differentiation and maturation from model animals will be invaluable and will facilitate the realisation of a curative stem cell therapy for people with T1DM.

In order to minimise confusion between the *ex vivo* differentiated insulin-secreting cells and islet β cells, our laboratory proposed a 4-criterial post-genomic concept for naming "β cells" a few years ago [96]. Recently, Kaestner *et al*[97] described many islet biologists/scientists much like the "Parable of the Blind Men and the Elephant" in terming "β cells". This appears to be the case in respect to claims made about SC-β cells without proper positive controls of corresponding *in vivo* islet lineage cells. Kaestner *et al*[97] further proposed six salient features of normal, fully functional mature β cells and made a recommendation to not name PSC-derived insulin-producing cells as "β cells", but conservatively as insulin-producing cells, insulin$^+$ cells or β-like cells, when there is no clear evidence that the six features of *in vivo* β cells are met.

The degree of single-cell RNA-seq (scRNA-seq) data similarity between the SC-β cells and donated islet β cells remains largely unclear. First, all scRNA-seq datasets of SC-β cells lacked a direct positive control from *in vivo* pancreatic and islet lineage cells. Second, most current scRNA-seq methods provide a high throughput but sacrifice full transcript coverage and sensitivity[98]. Third, as barcodes/inducers are introduced by the template switching of reverse transcriptase, strand invasion becomes problematic through systematic bias, namely biases from the introduction of artefacts. Fourth, loss of cDNA synthesis and bias in cDNA amplification leads to severe quantitative errors of these scRNA-seq methods[99]. Fifth, the current scRNA-seq methods suffer from impaired mRNA accounting. However, molecular spikes have significantly improved single cell mRNA accounting[100], adoption of the molecular spike method and further improvements may help address the above issues. As such, genuine SC-β cells will eventually become available as donor cells for establishing curative therapies for people suffering from T1DM in the not too distant future.

Abstract

Osteoarthritis (OA) is the most common musculoskeletal disease, and it is a major cause of pain, disability and health burden. Pain is the most common and bothersome presentation of OA, but its treatment is still suboptimal, due to the short-term action of employed analgesics and their poor adverse effect profile. Due to their regenerative and anti-inflammatory properties, mesenchymal stem cells (MSCs) have been extensively investigated as a potential therapy for OA, and numerous preclinical and clinical studies found a significant improvement in joint pathology and function, pain scores and/or quality of life after administration of MSCs. Only a limited number of studies, however, addressed pain control as the primary end-point or investigated the potential mechanisms of analgesia induced by MSCs. In this paper, we review the evidence reported in literature that support the analgesic action of MSCs in OA, and we summarize the potential mechanisms of these antinociceptive effects.

Key Words: Osteoarthritis; Pain; Inflammation; Mesenchymal stem cells; Regeneration; Analgesic mechanisms

INTRODUCTION

Osteoarthritis (OA) is a disease of movable joints characterized by anatomic and/or physiologic derangements including cartilage degradation, bone remodeling, osteophyte formation, joint inflammation and loss of normal joint function. It is initiated by micro- and macro-injury of the joint, which activates maladaptive repair responses producing abnormal tissue metabolism[1].

Clinical manifestations of OA include joint pain, tenderness, limitation of movement, coarse crepitus and, occasionally, effusion and mild local inflammation[2]. Diagnosis depends on the observation of signs and symptoms through clinical examination[3]. X-ray can be performed to help with differential diagnosis and in case of atypical features[4]. However, radiologic findings do not always complement the clinical presentation of pain[5].

Pathophysiology of OA is complex and is based on cartilage degeneration preceded by subchondral bone lesions. Historically, OA had been considered a disease of joint wear and tear, but recently, low-grade chronic inflammation has been found to play a key role in OA pathology. Both innate and adaptive central immunological mechanisms are involved in inflammation. Formation of ectopic bone and osteophytes are a characteristic pathologic features of OA[6]. Neuroinflammation and central sensitization mechanisms contribute to the development of chronic pain[7].

OA is the most common musculoskeletal disorder worldwide, and it poses a huge health and economic burden. It is considered a major cause of chronic pain, disability -due to diminished joint mobility and function-, and decreased quality of life[8,9]. Thus, finding effective and safe therapies for the treatment of OA is a significant clinical need.

Despite the recent progresses in understanding the pathophysiology of OA[7], the treatment of this condition is still suboptimal[10]. For low-grade OA, pain management and lifestyle changes are the only available therapeutic options, with total joint replacement considered the end-stage therapy. However, no effective therapeutic options are available that can stop the progress of the disease[10]. Analgesia may be achieved using nonsteroidal anti-inflammatory drugs (NSAIDs) (topical or systemic) as a first line, followed by paracetamol or tramadol. Less used medications include duloxetine and topical capsaicin. Intra-articular steroids are effective and recommended if other agents do not provide sufficient pain control, although their effect is short-termed[3]. Pharmacological therapies should be always accompanied by physical and psychosocial interventions, such as exercise, weight management and manual therapy. Patients whose joint symptoms are substantially impacting their quality of life and in which non-surgical management is ineffective or unsuitable should be referred for joint replacement surgery[3]. Table 1 summarizes the treatment guidelines for OA as recommended by the American College of Rheumatology and Arthritis Foundation[11].

PAIN IN OA

Pain is the major manifestation of OA and it significantly affects the function and quality of life of patients[12]. Both peripheral and central mechanisms contribute to OA pain. Peripherally, nociceptive signals may arise from the synovium, bone marrow, soft tissues and even cartilage in the advanced stages of the disease[13]. These inputs are modulated at the central level through mechanisms involving spinal and cortical sensitization, and the activity of discrete areas of the brain. Central sensitization may explain the poor correlation between pain severity in OA and the extent of cartilage damage, and the

persistence of pain after joint replacement in some patients[14].

In the periphery, sensitization of afferent neurons is mediated by cytokines, chemokines and neuropeptides and is associated with low-grade inflammation and innate immunity[15], immune cell infiltration and activation, and damage-associated molecular patterns. These mechanisms involve early post-translational changes to receptor ion channels, followed by late transcription-dependent mechanisms, which produce changes to the chemical phenotype of the cell[16]. Animal models of OA demonstrated the role of nerve growth factor (NGF) in nociceptor sensitization after tissue injury, mainly through the tropomyosin receptor kinase A (TrkA) receptor. In addition, increased NGF levels were found in the synovial fluid of OA patients and were associated with pain[17,18]. Other molecules associated with the peripheral component of OA pain include the neuropeptide calcitonin gene-related peptide (CGRP)[19], interleukin (IL)-1β, IL-6 and tumor-necrosis factor α (TNF-α)[20].

Central sensitization occurs both at the spinal and supraspinal levels. In the spinal cord, acute pain is accompanied with α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptor activation by glutamate, followed by an early phase of sensitization, mediated by substance P (SP) acting on neurokinin 1 receptors, in which N-methyl-D-aspartate (NMDA) receptors are activated. The late phase sensitization witnesses gene induction with enhanced synthesis of prostaglandins and other local inflammatory mediators[14]. In models of OA, spinal cord exhibits enhanced transient receptor potential cation channel subfamily V member 1 (TRPV1) activity and increased levels of SP, CGRP, IL-1 α/β, IL-13, IL-17, TNF-α, L-selectin, tissue inhibitor of metallopeptidase inhibitor 1 and vascular endothelial growth factors[21]. In addition, activation of glial cells was found to contribute to spinal sensitization, indicating a strong neuropathic component of the OA associated pain[22]. Supraspinal sensitization occurs in several areas of the brain, including the rostral ventral medulla and the periaqueductal gray and it involves inflammatory mediators, such as prostaglandins, as well as serotoninergic and noradrenergic facilitation[23].

TREATMENT OF OA PAIN

Pain management in OA is still considered suboptimal. The use of paracetamol, once recommended as the first-line analgesic for OA pain, has now been reviewed after meta-analysis suggested that monotherapy with paracetamol may be ineffective[24] and that long-term treatment provides no more pain relief than placebo for most patients[11]. NSAIDs are effective on the short term to control OA pain and are thus strongly recommended. Their use, however, is limited by the adverse effect profile[11]. Intra-articular injections of steroids also showed short-term effectiveness (2-10 wk)[3], but they are limited in frequency of administration and may cause cartilage damage if used repeatedly[25]. The use of other analgesics, such as duloxetine, tramadol, and non-tramadol opioids is not supported by strong evidence of efficacy, as well as other supplements, such as hyaluronic acid, glucosamine, chondroitin, fish oil and vitamin D[11]. These factors highlight the need for the development of novel therapies that are both effective and safe on the long term.

MSCS AND THEIR THERAPEUTIC USES

Mesenchymal stem cells (MSCs) are multipotent adult stem cells likely derived from diverse embryonic lineages and isolated from different sources. They were discovered by Friedenstein in 1970[26]. The International Society for Cellular Therapy has proposed a set of standards to define MSCs: (1) Expression of a certain set of cluster of differentiation (CD) markers (CD105, CD73, and CD90); (2) Lack of expression of hematopoietic lineage CD markers (CD45, CD34, CD14 or CD11b, CD79α or CD19 and histocompatibility complex (HLA)-DR surface molecules); (3) Differentiation into osteoblasts (bone), adipocytes (fat) and chondroblasts (cartilage) *in vitro*; and (4) Plastic adherence and ability to form colony-forming unit fibroblasts[27]. MSCs from different sources showed differences in differentiation potential, immunophenotype, immunomodulatory activity, proteome, and transcriptome, producing their specific characteristics and features in their application.

MSCs are an attractive option and among the most frequently used stem cell types for clinical application and regenerative medicine due to numerous advantages, including self-renewal and differentiation, mostly due to their secreted trophic factors that mediate cell-to-cell communication. Moreover, immune rejection is an important concern with allogeneic cell-based therapy, but the lack of cell surface HLA class II molecules and T cell costimulatory molecules and their paracrine-mediated immunomodulatory activity, and secretion of immunomodulatory factors indicate that the MSCs have broad anti-inflammatory properties and active in tissue repair[28-31].

A large number of studies demonstrated the beneficial effects of MSC-based therapies to treat different pathologies, including neurological disorders, cardiac ischemia, diabetes, and bone and cartilage diseases[32,33], which indicate that MSCs holds great promise for cell therapies and tissue engineering.

Studies showed the ability of MSCs to migrate toward damaged tissues, which functionally influence the repairing of these tissues[34]. MSCs act to accelerate healing and reduce inflammation, which is essential to remove dead cells, and facilitate cell migration and proliferation in the injury site[35,36]. For instance, a study using a rat model of cardiomyopathy showed that MSC transplantation significantly improved cardiac function by induction of myogenesis and angiogenesis, resulting in decreased left ventricular end-diastolic pressure and increased left ventricular maximum[37]. Another study showed that basic fibroblast growth factor (bFGF) can promote the migration and survival of bone marrow MSCs *in vitro*, as the perfusion of the coronary vein with retrograde bFGF can enhance the graft transplantation of MSCs, promote the differentiation of MSCs to cardiomyocytes, and restore cardiac function[38]. Some studies used a laboratory-grown cell sheet patches of MSCs to repair large damaged areas instead of intravenous infusion of MSCs. Kim *et al*[39] transplanted adipose-derived stem cells (AD-MSCs) sheet to treat myocardial infarction in a rat model and showed that the stem cell sheet promoted cellular engraftment and upregulated growth factor and cytokine expression. An *in vivo* study of neonatal stroke rat model proved that intranasal delivery of MSC reduced ischemic brain damage and reduced white and gray matters loss[40]. The study attributed the healing in the injury site to an increase in cell proliferation after transplantation of MSCs.

In skeletal disorders, MSCs could be helpful in tissue repairing and regeneration through several mechanisms, including homing, angiogenesis, differentiation, and response to inflammatory condition [41]. Liu *et al*[42] used umbilical cord-MSCs (UC-MSCs) to treat rheumatoid arthritis in collagen-induced arthritis mice through suppression of T follicular helper cell differentiation partly *via* the production of indoleamine 2,3-dioxygenase. In addition, MSCs prevented arthritis progression by inhibiting both the number and function of follicular helper cell *in vivo*. Another study showed that transplantation of MSCs from allogeneic related donors treated severe progressive systemic sclerosis [43]. A third *in vitro* study treated bone marrow derived-MSCs (BM-MSCs) with all-trans retinoic acid, then co-cultured them with CD3/28-activated peripheral blood mononuclear cells derived from ankylosing spondylitis (AS) patients. The results showed that BM-MSCs treated with all-trans retinoic acid significantly decreased pathogenic cytokine, TNF-α, IL-17A and interferon-γ (IFN-γ) in AS[44].

MSCS IN OA

MSCs are the most studied stem cells for treating bone related diseases and the associated inflammation. The effects of treatment by MSCs on OA pathology and presentation was widely investigated *in vitro* and in different preclinical models of OA using different routes of administration of multiple types and amounts of MSCs. Numerous clinical trials also addressed the potential therapeutic role of MSCs in OA.

MSCs have the ability to differentiate into mesoderm-derived cells, including osteoblasts and chondrocytes. More importantly, MSCs are considered powerful immunomodulators and inflammation combatants rendering them suitable for many immunological and bone diseases where inflammation is a prominent component. OA is the most common form of arthritis and clinically variable in its severity. Patients with symptomatic form of OA suffer from intermittent attacks which are usually associated with joint pain. OA pathology encompasses the inflammation and degeneration of articular cartilage that defects its integrity and leads to subsequent changes in the subchondral bone. Many preclinical and clinical studies have corroborated the therapeutic potential of MSCs in alleviating the inflammation associated with OA and initiating the regeneration of the defective articular cartilage. A pilot study conducted by Song *et al*[45] reported positive outcomes of injecting autologous human adipose-derived MSCs (haMSCs) intra-articularly in patients with OA. Song *et al*[45] reported that a dosage of 5×10^7 haMSCs produced the desired improvement in the pain scale and restored the volume and the function of knee cartilage. Similarly, Lee *et al*[46] reported that single intra-articular injection of 1×10^8 AD-MSCs for patients with knee OA produced a significant reduction in the Western Ontario and McMaster Universities OA (WOMAC) index total score and the test related sub-scores for pain, stiffness and physical function at 6 mo post-injection. The range of articular motion remarkably enhanced after MSCs transplantation with no change in the joint space width of medial and lateral compartment and size of the cartilage damage[46]. On the other hand, Matas *et al*[47] found that intra-articular injection of two repeated doses of umbilical cord-derived MSCs (UC-MSCs) (20×10^6 *per* dose) at baseline and 6 mo was superior than using a single dose in lowering the WOMAC pain scores. Patients with knee OA who were recruited in Matas *et al* study experienced 86% reduction in pain and 89% reduction in disability with no progression in the chondral damage and intra-articular calcifications examined by magnetic resonance imaging at 12 mo[47]. Bastos *et al*[48] compared the effect of injecting autologous bone marrow-derived culture-expanded MSCs (hBM-MSCs) intra-articularly with or without the addition of platelet-rich plasma to intra-articular corticosteroid injections in patients with symptomatic knee OA. MSCs alone or in combination with platelet rich plasma were superior to corticosteroids in improving the Knee Injury and OA Outcome Score, increasing the range of motion and reducing the expression of IL-10, which is usually increased in OA knees, at 12 mo follow up[48].

The extracellular vesicles (EVs) derived from different MSCs have currently gained a wide interest due to their high therapeutic efficacy and safety profile. Li *et al*[49] injected UC-MSCs-EVs in the articular lumen of a rat model of OA created by the surgical transection of the anterior cruciate ligament (ACLT), and reported that the UC-MSCs derived EVs can deliver therapeutically effective miRNAs, including has-miR-122-5p, has-miR-148a-3p, has-miR-486-5p, has-miR-let-7a-5p, and has-miR-100-5p, which were able to promote the reprogramming of macrophages into anti-inflammatory M2-macrophages and increasing the level of inflammation inhibitory cytokine IL-10. Moreover, these miRNAs were effective in inducing the phosphoinositide-3-kinase-Akt signaling pathway, which is integral to prevent further degeneration of the knee cartilage and seize the progression of OA[49]. Duan *et al*[50] conducted an interesting study by isolating synovial MSCs and chondrocytes from the knee cartilage of patients getting total knee arthroplasty. After culturing these cells, they primed the MSCs with lipopolysaccharide (LPS) and isolated EVs from these preconditioned synovial MSCs. The EVs were injected in the right knees of mice model of OA created by surgical removal of anterior cruciate ligament and medial meniscus. It was found that the presence of Let-7b miRNA in the EVs isolated from LPS primed synovial MSCs were effective in reducing the cartilage damage, increasing the thickness of cartilage layer, and decreasing the level of the inflammatory and matrix lysis protein disintegrin and metalloproteinase with thrombospondin motifs 5 (ADAMTS5) while increasing the levels of aggrecan and type II collagen alpha 1 chain, which are essential for the interaction with hyaluronan and enhancing the load-bearing characteristics of the knee[50]. Likewise, Jin *et al*[51] reported that lncRNA MEG-3 existed in the exosomes derived from bone marrow MSCs (BM-MSCs) and prevents the apoptosis and senescence of chondrocytes through lowering the level of IL-1β and decreasing the inflammatory damage of knee cartilage, which helps in restoring the trabecular bone volume and density of the knee joint in OA rat model. Mao *et al*[52] observed that miR-92a-3p was significantly less in the chondrocytes isolated from the cartilage of OA patients who underwent total knee replacement. BM-MSCs derived exosomes can deliver miR-92a-3p following their injection in the knees of collagenase-induced OA mouse model, which enhances the differentiation potential of resident stem cells to chondrocytes and increases the synthesis of cartilage matrix. These protective and regenerative effects are mediated by the inhibition of Wnt Family Member 5A[52]. Huang *et al*[53] demonstrated that miR-206 was downregulated and E74-like factor 3 (Elf3) was upregulated in the femoral tissues of OA mouse model. The administration of BM-MSCs derived exosomes that have sufficient amount of miR-206 was effective in downregulating Elf3 and ameliorating the inflammation and apoptosis of resident osteoblasts besides increasing the expression of osteocalcin and bone morphogenetic protein 2 and

enhancing the deposition of calcium and the activity of alkaline phosphatase[53]. In the rat model of temporomandibular joint OA, Zhang *et al*[54] injected exosomes derived from MSCs. They reported a significant suppression of inflammation mediated by decreasing the level of IL-1β and increasing the levels of nitric oxide and matrix metalloproteinase 13 (MMP13), which promoted the synthesis of glycosaminoglycans required for matrix restoration and regeneration[54].

Genetic modification of MSCs is one of the most studied approaches to enhance their therapeutic and regenerative potential. It has been found that the transplantation of MSCs overexpressing platelet-derived growth factor (PDGF) or heme oxygenase-1 in the surgery-induced canine OA model can considerably suppress the destructive inflammation and increase the levels of aggrecan and collagen type 2 in chondrocytes. PDGF-MSCs were more effective in improving the limb function and reducing pain[55]. The accumulative evidence supported by the above mentioned studies highlights the importance of MSCs in mitigating OA inflammation and restoring the integrity and density of volume of articular cartilage and its associated matrix, which indicates that MSCs can be a possible new therapeutic tool for OA.

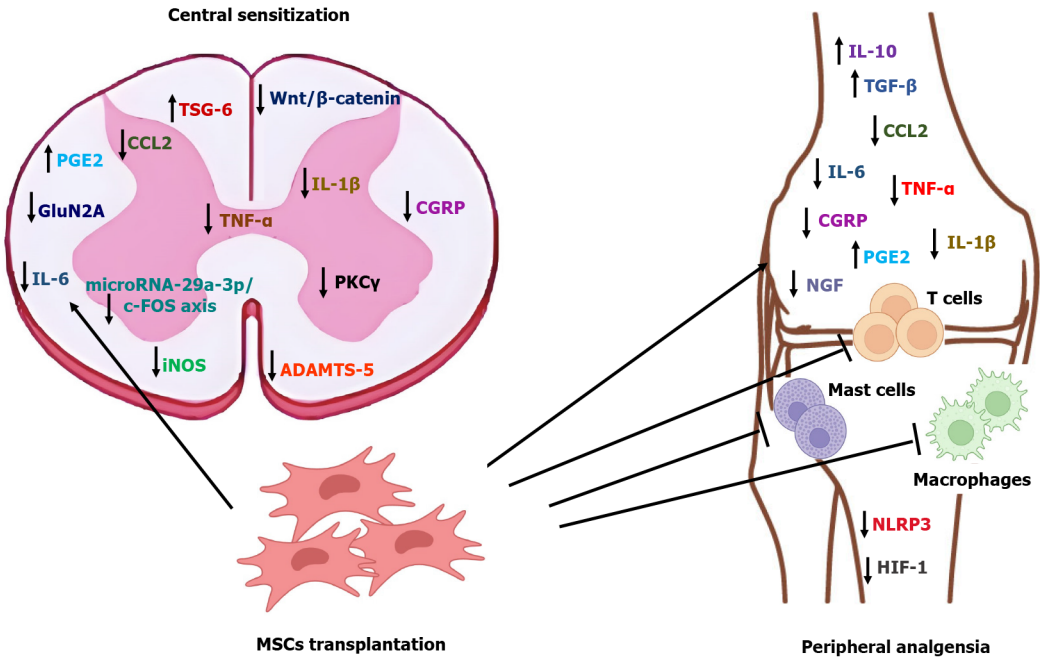
EFFECTS OF MSCS ON OA PAIN

Despite the large number of preclinical studies investigating the effects of MSC administration on OA pathophysiology, only a small part of them included the effects on pain, and even less had pain control as the main outcome. This may be due to the difficulty of pain assessment in animal models of OA[56] and the complexity of the pain phenomenon[57]. In addition, reported results were contrasting, probably due to the variability in animal models and the methods of pain evaluation, as well as types of MSCs used and routes of their administration[56].

A number of *in vivo* studies, however, found an improvement in OA associated pain following treatment with MSCs. Transforming growth factor β1 (TGF-β1)-modified MSC-derived exosome was found to attenuate cartilage damage and pain behaviors in the ACLT model of OA by inhibiting angiogenesis, suppressing calcification of the cartilage zone and osteoclastogenesis[58]. Intra-articular injection of adipose derived MSCs (ADSCs) in rats diminished monoiodoacetate (MIA)-induced OA cartilage lesions by paracrine-based mechanisms and restored the OA associated mechanical allodynia and thermal hyperalgesia. In patients, ADSCs also reduced OA pain, as measured by the visual analog scale and WOMAC[59].

In a study by Zeng *et al*[60], bone marrow-derived MSCs (BMSCs) were enhanced by kartogenin (KGN) nanoparticles and administered to osteoarthritic rats. In addition to articular cartilage repair and enhanced chondrogenesis, KGN-enhanced BMSCs also ameliorated OA pain, as shown by increased weight bearing on the injured leg and decreased latency period after hot plate exposure. Administration of different concentrations of MSCs into OA rat knees improved both the histological damage and weight bearing distribution in the ACLT model[61].

Sakamoto *et al*[62] found that early intra-articular injection of adipose-derived MSCs resulted in significant suppression of inflammation and pain and prevented degenerative OA changes, but did not promote cartilage repair. In another study involving the MIA model of OA, STAT3 signaling pathway was suppressed by treatment of MSCs with STA21. Both intravenous (IV) and intra-articular (IA) administration of STA21-treated MSCs decreased expression of proinflammatory cytokines in the joint, which improved pain severity and cartilage damage[63].



A trial of adult human bone marrow-derived mesenchymal stromal cells in the MIA model of OA caused significant pain reduction, along with articular damage repair. In patients, the same cells did not produce the significant improvement in pain scores[64].

Intra-articular injection of a large variety of MSCs in patients with knee OA was found to significantly improve joint pathology, disease symptoms, pain score and quality of life[65]. Human umbilical cord MSCs (hUC-MSCs) was found to improve pain scores and quality of life in OA patients. hUC-MSCs increase the expression of chondrocytes and activate anti-inflammatory mechanisms, preventing degradation of cartilage and bone[66]. A clinical trial of autologous bone marrow stem cells (BM-SC) concluded that a single IA injection of these stem cells significant reduced knee pain and improved quality of life[67]. Other clinical trials reviewed by Hwang *et al*[68] also resulted in improved joint function, reduction of pain severity and improved life satisfaction.

PROPOSED MECHANISMS OF ANALGESIA OF MSCS IN OA

Data from literature suggest that the analgesic action of MSCs in OA involves a peripheral component, originating in the joint tissues, and a central component related to central hypersensitization. This reflects the mechanisms of nociception reported in OA[69].

It can be speculated that a major antinociceptive mechanism of MSCs in OA is through inhibition of inflammation. MSCs secrete anti-inflammatory and growth factors that support their immunomodulatory, immunosuppressive and trophic capacities. These properties contribute to the regeneration of

Figure 1 Graphical summary of proved and anticipated analgesic mechanisms of mesenchymal stem cells in osteoarthritis. Mesenchymal stem cell (MSCs) transplantation reverts central sensitization and induces peripheral analgesia due to their anti-inflammatory and immunomodulatory properties and by attenuation of specific pain pathways *via* exosomes-derived microRNAs and MSCs paracrine factors. TSG-6: TNF-stimulated gene 6 protein; CCL2: Chemokine (C-C motif) ligand 2; PGE2: Prostaglandin E2; GluN2A: N-methyl-D-aspartate receptor subunit 2A; IL-6: Interleukin 6; iNOS: Inducible nitric oxide synthase; TNF α: Tumor necrosis factor α; IL-1β: Interleukin-1β; CGRP: Calcitonin gene-related peptide; PKCγ: Protein kinase C γ; ADAMTS-5: A disintegrin and metalloproteinase with thrombospondin motifs 5; IL-10: Interleukin 10; TGF-β: Transforming growth factor β; NGF: Nerve growth factor; NLRP3: NLR family pyrin domain containing 3; HIF-1: Hypoxia inducible factor 1.

damaged cartilage and joint homeostasis, improving inflammatory and catabolic aspects of OA[70,71]. Initially, the bioactive substances secreted by MSCs change the inflammatory milieu in the joint from pro-inflammatory to anti-inflammatory, producing analgesia[65]. On the longer term, MSCs are inserted in the joint tissues and trigger the repair and regeneration of damaged tissues, including cartilage[72]. Numerous molecules have been reported to contribute to the antiinflammatory effects of MSCs in OA, including nitric oxide (NO), inducible nitric oxide synthase (iNOS)-27, IL-10, TGF-β, IL-6, IFN-γ, CCL2, hepatocyte growth factor, nuclear factor kappa-light-chain-enhancer of activated B cells (NF-κB) and TNF-α[73-75]. Cyclooxygenase 2/prostaglandin E2 (PGE2) pathway plays a key role in the anti-inflammatory effect of MSCs in OA[76], where MSCs increase the levels of the antiinflammatory mediator PGE2[75]. Similar antiinflammatory results were also produced by MSC EVs[77]. Since these molecules and their related pathways are well established contributors to OA pain, their involvement in the analgesic mechanisms of MSCs in OA can be hypothesized.

Chemokine (C-C motif) ligand 2 (CCL2)/C-C chemokine receptor type 2 (CCR2) signaling is crucial in the development of knee OA pain. Neuronal CCL2 and CCR2 from dorsal root ganglion (DRG) mediate macrophage infiltration, while local CCL2/CCR2 signaling in the joint directly stimulates intra-articular CCR2 positive sensory nerves, producing knee hyperalgesia[78]. Interestingly, the analgesic effect of MSCs in different models of pain was associated with decreased levels of CCL2, produced by the downregulation of the NF-κB and c-Jun N-terminal kinase/mitogen activated protein kinase pathways[79,80], which suggests that a similar mechanism could be involved in the analgesic effect of MSC in OA.

Other molecules and pathways relevant to OA pain include: (1) NGF / TrkA; (2) CGRP; (3) IL-1β; (4) Pyrin domain-containing protein 3 (NLRP3) inflammasome; and (5) Wnt/β-Catenin[69]. NLRP3 inflammasome is a component of the innate immune system and is involved in the regulation of active IL-1β. NF-κB increases the expression of inactive NLRP3 and pro-IL-1 mRNA, followed by the assembly of the inflammasome, which results in the activation of caspase 1 and release of IL-1, IL-18, MMP13 and ADAMTS5. In OA, dysregulation of NLRP3 inflammasome in OA contributes to chronic pain[69]. MSCs were found to inhibit the NLRP3 inflammasome in macrophages[81], inflammatory cardiomyopathy[82] and inflammatory renal disease[83], which could indicate inhibition of NLRP3 inflammasome as a potential mechanism of MSCs induced analgesia in OA.

In OA, high levels of Wnt are associated with progressive joint damage[84] and hyperalgesia[69]. Since MSCs were found to inhibit the Wnt/β-Catenin pathway in a number of disorders[85,86], this pathway could be involved in MSC analgesic mechanism and should be investigated further. In the

study by Lee *et al*[63], administration of signal transducer and activator of transcription 3-inhibited MSCs reduced the levels of inflammatory mediators and chemokines in the OA joint, and this was associated with improvement in pain behavior and decreased TRPV1 expression in the dorsal root ganglion. This effect was more pronounced with IV administration, indicating a systemic immunomodulatory effect on inflammation.

The interaction of MSCs with immune cells, including macrophage, dendritic cells, T lymphocytes, and natural killer cells, also contributes to MSC antiinflammatory properties[87]. MSCs induce polarization of macrophages to an antiinflammatory M2 phenotype through: (1) Cellular interaction and paracrine factor-mediated mechanisms; and (2) exosome-mediated mechanisms. The first involves cytokines and hormones, and the latter depends on RNAs and other molecules[88]. Following an intra-articular injection of BM-MSCs in patients with knee OA, a decrease in synovial fluid levels of pro-inflammatory monocytes/macrophages and IL-12p40 was recorded[89].

Ai *et al*[90] investigated the effects of MSCs and derived EVs (MSC-EVs) on pain behaviors in the destabilization of the medial meniscus murine model of OA. It was found that treated OA mice did not display pain behaviors observed in untreated counterparts, and that did not result from reduced joint damage, but rather from a lack of knee-innervating sensory neuron hyperexcitability. MSC-EV treatment also prevented NGF-induced sensory neuron hyperexcitability. These results suggest that MSCs and MSC-EVs may reduce pain in OA by direct action on peripheral sensory neurons[90]. Another study[91] found that the intrathecal administration of umbilical cord blood MSCs (UCBMSCs) improved both pain behavior and inflammation in the MIA model of OA. This effect is regulated by LncRNA H19 and involves microRNA-29a-3p/ FOS axis. microRNA29a-3p, the target gene of LncRNA H19, and FOS mRNA were down-regulated after stem cell therapy, suggesting that microRNA-29a-3p and FOS might play a role in pain improvement. c-fos in spinal dorsal horn of rats was significantly down-regulated after UCBMSCs treatment, which may be the reason for pain improvement. Phosphorylation levels of NMDA receptor 1 (NR1), NR2B, protein kinase C γ (PKCγ), extracellular signal-regulated kinase in spinal dorsal horn of rats with OA pain decreased significantly after intervention of UCBMSCs, indicating that the central sensitization of rats with advanced OA pain decreased and the pain symptoms improved. Similar results were observed in astrocytes.

Intra-articular injection of human adipose tissue-derived MSCs was reported to improve pain behavior in a medial meniscal transection (MMT) rat model of OA[92]. These effects were attributed to the recruitment of endogenous cells through paracrine communication[93], and to a lesser extent, to direct engraftment coordinated with the local environment[94]. Paracrine factors excreted by MSCs help recruitment of stem and progenitor cells, repair of degraded tissue and, most importantly, counteracting inflammation. A similar result was reported after administration of bone marrow MSC (BMSC)-derived exosome in the MIA model of OA[95], which was found to inhibit CGRP and iNOS expression in the DRG, indicating relief of both inflammatory and neuropathic aspects of OA pain[95]. BMSC-derived exosome also attenuates the inhibitory effect of IL-1β on the upregulated inflammatory mediators.

In the meniscal transection (MNX) model of OA, different effects were reported on pain behavior and joint pathology with the use of early and late passage MSCs. Late passage MSCs attenuated established pain behavior, while early passage MSCs exacerbated it. Interestingly, none of them modified MNX-induced joint pathology, which suggests an analgesic mechanism not related to articular pathology[96]. SiMAG-labelled MSCs were detected within the synovial cavity at 29 d postinjection, indicating a peripheral site of analgesic action of the MSCs. The recorded decrease in serum TNFα indicated inhibition of systemic inflammation, which is the expected cause of pain relief[97]. Similarly, van Buul *et al*[56] reported that intra-articular injection of bone marrow mononuclear cells in the MIA model of OA significantly improved pain behavior – measured as weight bearing distribution - but did not affect cartilage damage, subchondral bone changes and synovial inflammation. Similar results were observed with the administration of MSCs and MSC-EVs in a mouse collagenase-induced OA model[98]. MSCs were also found to downregulate ADAMTS-5 expression, inhibit the expression of anti- CGRP and increase the expression of TNF-stimulated gene/protein-6 (TSG-6)[99]. These changes indicate the suppression of the central sensitization of pain.

Several pain pathways were found to be inhibited by MSCs in other types or models of pain. Small EVs from induced pluripotent stem cell-derived MSCs alleviated acute pain in tendinopathy by inhibition of mast cell degranulation and infiltration and the expression of proinflammatory cytokines and genes involved in the HIF-1 signaling pathway[100]. Human BMSCs relieved pain behavior in rodents by inhibition of neuronal hyperexcitability and primary afferent input, as well as suppression of GluN2A (N-methyl-D-aspartate receptor subunit 2A) tyrosine phosphorylation and PKC gamma (PKCg) immunoreactivity in the rostral ventromedial medulla[101]. In murine chronic constriction injury and spared nerve injury models, TGF-β1 was found to suppress spinal synaptic plasticity and DRG neuronal hyperexcitability *via* TGF-β receptor 1-mediated noncanonical signaling. This effect was mediated by paracrine mechanism by which BMSCs target C-X-C motif chemokine ligand 12-producing DRGs[102]. We thus anticipate that MSCs use in OA may exhibit their analgesic effects through the HIF-1, GluN2A tyrosine, PKCg and TGF-β signaling pathways. Figure 1 summarizes the established and proposed mechanisms of analgesia exerted by MSCs or MSC related EVs in OA.

CONCLUSION

Numerous *in vitro*, *in vivo* and clinical studies demonstrated the capability of MSCs in halting and/or reversing the progression of joint tissue damage in OA, as well as mitigating joint inflammation, improving pain sensation and enhancing overall patient quality of life. MSCs were able to produce an analgesic effect in models of OA through both peripheral mechanisms, mainly involving antiinflammatory processes, and on a central level, by preventing or reversing central sensitization. This evidence further reinforces the potential of MSCs as a safe and effective treatment for OA pain. Additional pathways which were observed in other types of pain may contribute to the analgesic mechanisms of MSCs in OA, and require further investigations.

Abstract

Cancer stem cells (CSCs) are the main cause of tumor growth, invasion, metastasis and recurrence. Recently, CSCs have been extensively studied to identify CSC-specific surface markers as well as signaling pathways that play key roles in CSCs self-renewal. The involvement of CSCs in the pathogenesis of gastrointestinal (GI) cancers also highlights these cells as a priority target for therapy. The diagnosis, prognosis and treatment of GI cancer have always been a focus of attention. Therefore, the potential application of CSCs in GI cancers is receiving increasing attention. This review summarizes the role of CSCs in GI cancers, focusing on esophageal cancer, gastric cancer, liver cancer, colorectal cancer, and pancreatic cancer. In addition, we propose CSCs as potential targets and therapeutic strategies for the effective treatment of GI cancers, which may provide better guidance for clinical treatment of GI cancers.

Key Words: Cancer stem cells; Gastrointestinal cancers; Promotion; Inhibition; Treatment

INTRODUCTION

Cancer stem cells (CSCs) are small subgroups of undifferentiated cancer cells. CSCs possess an infinite self-renewal capability and a set of unique surface biomarkers[1]. Gastrointestinal (GI) cancer is the most common major malignancy, and includes esophageal cancer (EC), gastric cancer (GC), liver cancer (LC), colorectal cancer (CRC), pancreatic cancer and other related diseases[2]. The incidence of GI cancers is high. Recently, a growing number of studies have been conducted on the important role of CSCs in GI cancers. Research shows that CSCs are mainly involved in the growth, initiation, maintenance, survival, metastasis and recurrence of GI cancer. There are certain limitations in the methods of treatment for currently accepted GI cancers, often leading to treatment failure. This is due to CSCs resistance to chemotherapy and radiation therapy. In current treatment, CSCs cannot be erased, causing metastasis and recurrence of the tumor. Recently, studies have been conducted to clarify the signaling pathway which plays a critical role in the specific surface markers of CSCs and the self-renewal of CSCs. These cell surface markers as well as signaling pathways are potential targets for the treatment of GI cancer that provide the environment necessary for tumor growth[3-5]. Thus, certain therapies for CSCs will potentially help to eliminate the tumor.

This review aims to summarize the mechanism and treatment of CSCs in GI cancer, and to propose a potential target and therapeutic strategy for the treatment of GI cancer.

ROLES OF CSCS IN EC

EC, a common tumor of the digestive tract, causes a majority of cancer deaths[6]. EC includes esophageal adenocarcinoma (EAC) and esophageal squamous cell carcinoma (ESCC). EAC may be associated with obesity and ESCC may be associated with drinking and narcotics. Approximately 300000 people die of EC worldwide every year. The incidence and mortality rates of EC vary from country to country[7]. Recently, the relationship between CSCs and the occurrence and development of EC has attracted more and more attention. Chen *et al*[8] discovered that esophageal CSCs activate matrix metalloproteinase 9 in EC cells and promotes cancer metastasis by the expression of placental growth factor. Moreover, CSCs expressing placental growth factor can promote[9] or suppress tumor angiogenesis by stimulating vascular endothelial growth factor[10]. Wang *et al*[11] found that by acting on ATG7-dependent β-catenin, OV6 CSCs can stably promote the progression of ESCC. In addition, studies have shown that exosomal O-GlcNAc transferase derived from esophageal CSCs can promote the suppression of cancer immunity by increasing programmed death-1 (PD-1) in CD8 T cells[12].

CSCs play a critical role in the treatment of EC. CSCs markers could help to identify the functions of CSCs in EC and can be used as targets for the treatment of EC. It was found that CD44, a CSC surface marker, can isolate and detect ESCC[13]. In addition, Lu *et al*[14] found CD133 and CXCR4 markers on the surface of ESCC, and the high expression of CD133-CXCR4 may become a marker for forecasting poor prognosis in patients with ESCC. Liu *et al*[15] found that Cripto-1 is a functional marker of CSC-like cells (CSLCs) and can predict the prognosis of patients with ESCC. In addition, studies have shown that MYH9 is a novel esophageal CSC marker and prognostic indicator, which promotes tumorigenesis through the PI3K/AKT/mTOR axis[16]. Studies have demonstrated that esophageal CSLCs can resist ferroptosis induced cell death through the active HSP27-GPX4 pathway. Hence, targeting HSP27 or GPX4 blockade is a promising therapeutic strategy to eradicate CSCs in ESCC[17]. Li *et al*[18] found that exosomal FMR1-AS1 can promote CSLCs homeostasis through TLR7-NFκB-Myc signaling in female EC. Song *et al*[19] analyzed clinical specimens and found that BCL-2 inhibitor AT101 could overcome drug resistance by targeting the CSC pathway and had good antitumor activity. In addition, Zarei *et al*[20] found that salinomycin could destabilize the low-pathway sensor TAZ in CSLCS and reduce the viability of esophageal CSLCs. Studies have shown that TRPV2 can maintain the growth of CSCs, and its specific inhibitor tranilast may be used as a targeted therapeutic agent for ESCC[21]. STAT3 and miR-181b activate each other *via* the CYLD pathway, thereby regulating the proliferation of esophageal

CSLCs[22]. Metformin can inhibit EC cell growth and sensitize EC cells to the cytotoxic effects of 5-FU by targeting components of CSCs and mTOR[23].

CSCs play an important role in the development, progress and future treatment of EC, but the associated research is inadequate, and the underlying mechanisms have not been fully explored. Therefore, more studies are needed to determine the mechanism and support the corresponding conclusions.

ROLES OF CSCS IN GC

GC is a malignant tumor derived from gastric mucosal epithelium. Most GCs are early adenocarcinomas with no apparent symptoms and are easily overlooked[24]. GC is the main cause of global cancer deaths. The treatment of GC involves surgery in combination with chemotherapy and radiotherapy, but the prognosis of terminal GC is still poor[25]. Over the past decade there is increasing evidence to show that CSCs have a significant role in GC development.

The concept that CSCs cause GC and may lead to invasion, metastasis, and treatment resistance has profound implications for anticancer therapy. Takaishi *et al*[26] implanted gastric CSCs (GCSCs) in the skin of immunodeficient mice, and a few weeks later observed that these GCSCs showed strong tumorigenic ability. Yang screened out GCSCs with serum-free medium, and found that these GCSCs had high tumorigenesis ability in nude mice, and high expression of GCSCs surface markers OCT4 and SOX2[27]. E-cadherin is a vital adhesion molecule, and its expression is closely related to the degree of cell adhesion[28]. Studies have found that the expression of E-cadherin in GCSCs is down-regulated, resulting in a decrease in the adhesion of tumor cells; thus, GCSCs are highly aggressive and easily metastasize to local lymph nodes or distant metastasis[29]. CSC Lgr5+ can promote the growth and proliferation potential of GC[30]. In addition, CSCs may maintain their viability through autophagy[31].

Identifying and targeting CSCs play a vital role in the treatment of GC. Chemotoxicity-induced exosomal lncFERO can regulate ferroptosis and stemness in GCSCs. Therefore, chemotherapy targeting the lncFERO/hnRNPA1/SCD1 axis could be an implicit strategy for CSCs-based GC therapy[32]. In addition, microRNA (miR)-375 can trigger ferroptosis by targeting SLC7A11, thereby attenuating the stemness of GCSCs[33]. CBX7 was found to positively regulate the stem-like characteristics of GC cells by inhibiting p16 and activating the AKT-NF-κB-miR-21 pathway[34]. Sezer *et al*[35] found that lymphatic metastasis-associated TBL1XR1 promotes the metastasis of gastric CSLCs by sensitizing ERK1/2-SOX2 signaling. Huang *et al*[36] found that SIRT1 inhibits both chemoresistance and cancer stemness in GC by launching a positive feedback loop of AMPK/FOXO3. The m6A methyltransferase METTL3 was found to promote oxaliplatin resistance in CD133+ GCSCs by improving PARP1 mRNA stability to increase base excision repair pathway activity[37]. *Celastrus orbiculatus* ethyl acetate extract can prevent GC growth by limiting the stemness of GCSCs by changing PDCD4 and EIF3H expression [38]. Methionine has been found to inhibit autophagy in GCSCs by promoting RAB37 methylation and phosphorylation. Therefore, supplementation with methionine γ-lyase can induce autophagy in GCSCs and inhibit tumor growth[36].

The role of CSCs in growth, metastasis, treatment and prognosis of GC is increasingly important. In the past few years, an increasing number of studies have been conducted on the mechanism of action of CSCs against GC and to offer promising targets and therapeutic tactics for GC treatment. Many treatments targeting CSCs have been developed, but there are limits to CSCs targeting therapy. It affects normal stem cells and causes tissue renewal problems. For example, Lgr5 is a marker associated with common stem cells in gastric tissue. mTORC1 can maintain self-renewal of the Lgr5 population, preventing cell differentiation and causing gastric tumorigenesis. However, the use of mTORC1 inhibitors may cause gastric glandular atrophy due to tissue malfunction, limiting its therapeutic use [39]. Therefore, more efforts are needed to treat GC based on CSCs.

ROLES OF CSCS IN LC

LC is the third most common cause of cancer associated deaths worldwide. This is due to its high recurrence rate, which after normal treatment, can reach 70%. Hepatocellular carcinoma (HCC) is the main pathology and causes approximately 80% of LC cases[40]. Liver CSCs (LCSCs) are now known to be responsible for HCC growth, metastasis and recurrence, in addition to failure of chemotherapy and radiation therapy[41]. These findings indicate that LC therapy kills most of the tumor cells, but cannot eliminate LCSCs and treatment can eventually fail as LCSCs survive and generate new tumors. Therefore, CSCs theory has provided new findings in the diagnosis, treatment and prevention of LC (Table 1).

LCSCs play a vital role in the development, progression, recurrence and drug tolerance of HCC. Studies have shown that LCSCs can accelerate tumor growth in primary cancer cells and metastasis of secondary tumors, causing the recurrence of HCC[42]. Studies have found that EpCAM-high HCC stem cells can promote tumor growth by upregulating CEACAM1 to weaken the capacity of natural killer

HCC: Hepatocellular carcinoma; LC: Liver cancer; LCSCs: Liver cancer stem cells.

cells to recognize and kill cancer cells[43]. Histone demethylase JMJD2D can enhance EpCAM and Sox9 expression to promote the self-renewal of liver CSLCs, promoting tumor growth[44]. Yang *et al*[45] found that lncARSR promoted HCC cell dedifferentiation and LCSCs expansion by targeting STAT3 signaling. Moreover, LCSCs release exosomes in a RAB27A-dependent manner which can lead to resistance to regorafenib in LC cells[46]. Chen *et al*[47] found that activating the β-catenin signaling pathway leads to upregulation of PPAR-α by 4-PBA, which in turn initiates LCSCs and promotes early HCC. Cao *et al*[48] found that RACK1 advances self-renewal and chemoresistance of CSCs in HCC by stabilizing nanoparticles.

The biomarkers of LCSCs are important targets in the treatment of LC. CD133 is one of the common surface markers of LCSCs, and studies have found that CD133 isolated from HCC cell lines has high proliferative and tumorigenic potential; thus, enhanced CD133 expression can also serve as a prognostic indicator for survival and tumor recurrence in patients with LC[49]. Yin *et al*[50] found that aldehyde dehydrogenase was expressed in LCSCs and was positively correlated with CD133 expression. CD13 is a marker of LCSCs, which has the function of dormancy and slow growth, and is the main reason for drug resistance of LCSCs[51]. The LCSCs marker OV6 was found to be chemoresistant, but this was reversed when lentivirus-delivered miRNAs targeting β-catenin were stably expressed. Therefore, targeting Wnt/β-catenin signaling could be a potential strategy to reverse the drug resistance properties of OV6 LCSCs[52]. Wei *et al*[53] found that CD44 regulated PES1 in LCSCs through miR-105-5p to promote tumor growth. Twist2 advances self-renewal of liver CSLCs by changing CD24[54].

LCSCs play a vital role in the treatment of LC. It was found that the transcription factor FOXM1 inhibits the dryness of LCSCs by reducing the expression of ALDH2, and inhibits proliferation, migration, invasion and tumorigenesis, while inducing apoptosis of LCSCs[55]. The CD13 inhibitor BC-02 can target CD13 and upregulate intracellular reactive oxygen species (ROS) and ROS-induced DNA damage to damage LCSCs. Therefore, BC-02 may be a potential therapeutic strategy to eradicate LCSCs and overcome chemoresistance in LC[56]. Studies have found that aptamer-based drug delivery agents

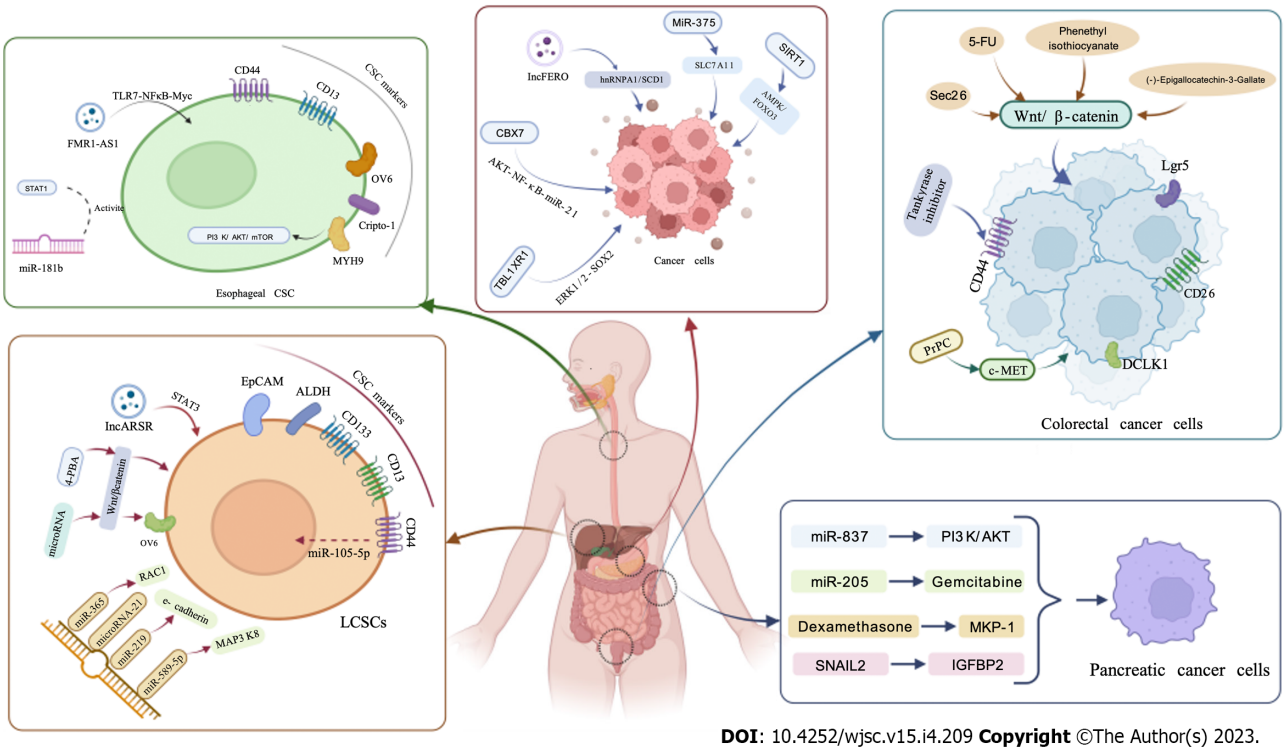
(CD133-apt-Dox) targeting CD133-expressing cells can impair the self-renewal ability of liver CSLCs and inhibit the growth of LC[57]. MiRNAs are important regulators of CSCs therapy in LC. Feng *et al*[58] found that forced expression of miR-124 can inhibit LCSCs self-renewal and tumorigenesis. It was shown that miR-365 regulated LCSCs through the RAC1 pathway and prevented the proliferation and invasion of HCC cells[59]. In addition, miR-21 downregulation can inhibit cell proliferation and highly invade LCSCs[60]. Si *et al*[61] found that miR-219 regulates the expansion of LCSCs through the E-cadherin pathway. Dou *et al*[62] showed that miR-6838-5p inhibited self-renewal and metastasis of LCSCs by down-regulating CBX4 expression and inhibiting ERK signaling. In addition, miR-589-5p inhibited MAP3K8 in HCC and inhibited CD90 CSCs[63]. It was shown that HAND2-AS1 can promote self-renewal of LCSCs and drive liver tumorigenesis, providing a potential new target for HCC treatment[64]. In addition, tumor-associated macrophages produce interleukin-6 and signal through STAT3 to improve the expansion of LCSCs[65]. Li *et al*[66] found that the loss of neuropilin 1 inhibits the LCSC population and blocks metastasis in HCC through epithelial-mesenchymal transition. Wang *et al*[67] found that ZBP-89 negatively regulated self-renewal of LCSCs by inhibiting the Notch1 signaling pathway.

Traditional HCC treatment mainly targets fast growing and differentiated HCC cells. However, a part of the emerging CSCs concept explains the failure of these therapies. The research progress of LCSCs has provided a new viewpoint on the possible adhibition in the clinical treatment of LCSCs. Detection of LCSCs is useful for predicting postoperative survival of patients. The development of treatment strategies for LCSCs may greatly improve the treatment of LC[68].

ROLES OF CSCS IN CRC

CRC is one of the most common cancers and the fourth most frequent cause of cancer death worldwide [69]. Despite the great progress in surgery and chemotherapy over the past decade, the five year survival rate of CRC patients is 50%-65%[70]. In the past few years, an increasing number of studies have shown that CSCs are closely associated with the occurrence and development of CRC, which provides promising directions for the diagnosis and treatment of CRC (Table 2).

CSCs are the major cause of drug resistance and disease recurrence in CRC. Studies have found that Lgr5 CSCs have a vital role in primary and metastatic colon cancer, and can promote tumor growth and metastasis[71]. In addition, most colorectal CSCs (CCSCs) express Lgr5 and form distant metastasis, which is a major factor driving CRC metastasis[72]. Recent studies have found that human CCSCs can give rise to vascular endothelial cells and constitute the vasculature in cancer tissue, which provides a new mechanism for tumor angiogenesis in cancer[73]. CD26 CCSCs can lead to CRC metastasis[74]. Razi *et al*[75] found that DCLK1 is a promising CCSC marker that changes tumor progression and invasion in a miR-137- and miR-15a-dependent manner. The JAK2/STAT3/CCND2 axis promotes the persistence and radioresistance of CRCs, which is the drug resistance mechanism for the continuous growth of CSCs after radiotherapy[76]. Liu *et al*[77] found that Sec62 promotes stemness and chemoresistance in human CRC by sensitizing the Wnt/β-catenin pathway. Studies have shown that CCSCs acquire chemoresistance by the upregulation of F-Box/WD repeat-containing protein 7 and the consequent degradation of c-Myc[78]. In addition, PD-L1 can maintain CSCs self-renewal by activating the HMGA1-dependent signaling pathway[79]. 5-FU improves the stemness of CRC through p53-mediated WNT/β-catenin pathway activation[80].



Whereas conventional therapies target proliferating and mature cancer cells, CSCs are mostly quiescent and poorly differentiated, so they could easily survive the chemotherapy attack. Therefore, novel therapies targeting CSCs are necessary. Chen *et al*[81] found that phenethyl isothiocyanate inhibits CCSCs by suppressing the Wnt/β-catenin pathway. In addition, (-)-Epigallocatechin-3-Gallate can also inhibit CCSCs by suppressing the Wnt/β-catenin pathway[82]. Studies have shown that AGR2 is a new stem cell marker that is changed by the canonical Wnt/β-catenin pathway in CCSCs and is important for stemness maintenance of CCSCs[83]. Jang *et al*[84] reported that tankyrase inhibitors downregulated c-KIT tyrosine kinase and prevented the growth of CD44-positive CCSCs. Liu *et al*[85] found that PTK6 interacts with JAK2 and phosphorylates to activate JAK2/STAT3 signaling, which can improve stemness and chemoresistance of CRC cells and reverse chemoresistance in CRC. Studies have shown that mithramycin A inhibits CRC growth by targeting CSCs[86]. Studies have also found that disruption of endolysosome RAB5/7 effectively eliminates CCSCs[87]. PrPC inhibits CSCs properties by interacting with c-MET in CRC cells[88].

According to the data accumulated during cancer research, CSCs have become a fundamental cause of cancer progression and resistance to treatment. Therefore, it is important to understand the biological, functional and clinical significance of CSCs in CRC tolerance in order to develop an effective treatment model for CRC patients. However, the practical clinical application of CSCs in CRC is still limited, and further studies and efforts are needed for clinical applications.

ROLES OF CSCS IN PANCREATIC CANCER

Pancreatic cancer is one of the most deadly human malignancies, the survival rate is 8% and the prognosis is the worst of all GI tumors[89-91]. It is now the fourth most common cause of cancer associated deaths worldwide. The tumorigenesis capacity of pancreatic cancer cells is different, and the proliferation and growth of pancreatic cancer are highly dependent on the presence of a limited subgroup of pancreatic cancer cells, called pancreatic CSCs (PCSCs)[92]. The concept of CSCs is recognized and some of the identified molecules and signaling pathways are associated with cancer diagnosis and treatment.

PCSCs contribute to the development and invasion of pancreatic cancer. It has been found that PCSC CD9 can promote the plasma membrane localization of glutamine transporter ASCT2, improving glutamine uptake in pancreatic cancer cells and promoting tumor growth[93]. Leng *et al*[94] found that SIRT1 coordinating with CRL4B can regulate PCSCs to promote tumorigenesis. In PCSCs, PAF1 interacts with DDX3 and PHF5A to regulate the expression of NANOG and other genes that regulate stemness. Therefore, knockdown of PAF1 reduced the development and progression ability of *in situ* pancreatic cancer in mice and its CSCs[95]. Bao *et al*[96] found that pancreatic CSLCs can promote tumor formation and rapid tumor growth by activating FoxQ1. Masuo *et al*[97] demonstrated that SNAIL2 can promote the tumorigenicity and chemotherapy resistance of PCSCs by regulating IGFBP2.

PCSCs have an important role in pancreatic cancer therapy. Studies have shown that PCSCs have longer telomeres and higher telomerase activity than tumor cells, which is associated with the expression of pluripotent genes (Nanog, Sox2, Oct3/4). Therefore, telomerase inhibition can lead to apoptosis of PCSCs, which is a suitable therapeutic approach against CSCs, especially in pancreatic cancer[98]. Yang *et al*[99] found that miR-873 could inhibit self-renewal and proliferation of PCSCs by blocking the PLEK2-dependent PI3K/AKT pathway. In addition, miR-205 can resensitize gemcitabine-resistant pancreatic cancer cells to gemcitabine and act as a tumor suppressor miRNA[100]. JNK is required for PCSCs self-renewal and tumor initiation, as well as its survivin expression. Dexamethasone was found to induce the expression of MKP-1 through glucocorticoid receptor activation, thereby inactivating JNK and inhibiting tumor growth[101]. Urtasun *et al*[102] showed that simultaneous blockade of IGF-IR and EGFR/Her-2 using NVP-AEW541 and lapatinib could inhibit drug resistance in pancreatic cancer.

The role of CSCs in pancreatic cancer metastasis, recurrence and treatment has become very important. A large number of studies have allowed tumor stem cell markers to achieve metastasis, progression and resistance of pancreatic cancer cells, which provide potential targets and therapeutic directions for the treatment of pancreatic cancer. Nevertheless, there are still few practical clinical applications of PCSCs, and further studies are needed for clinical applications.

Recently, many studies have shown that CSCs are closely related to tumor recurrence, metastasis and drug resistance, especially in EC, GC, LC, CRC and pancreatic cancer (Figure 1). CSCs can be identified by a series of surface markers, including OV6, EpCAM, CD13, CD133 and CD44. Surface markers of CSCs are useful for cancer diagnosis and prognosis prediction. In addition, CSCs regulate tumor progression and therapeutic resistance through multiple mechanisms, including Notch, Wnt/β-catenin and other signaling pathways. There are many other elements that make CSC impressions, such as the tumor microenvironment and non-coding RNAs, including miRNAs and long non-coding RNAs.

CONCLUSION

Currently, we have developed a combination of chemotherapeutic agents and small molecule inhibitors to reduce CSCs and effectively treat GI cancer. As CSCs have many similar features to stem cells, the molecular signal pathway or mechanism that distinguishes the two cell subgroups is still unknown. Therefore, stem cell therapy is limited, and it is necessary to further study the biological difference between normal stem cells and LCSCs. Research on the therapy of GI cancer with regard to CSCs is still at the *in vitro* and animal experimental stage, and the precise molecular mechanism of CSCs in GI cancer requires further study. Therefore, more research is needed to promote the application of CSCs in clinical practice.

Abstract

Allogeneic hematopoietic stem cell transplantation is a deterministic curative procedure for various hematologic disorders and congenital immunodeficiency. Despite its increased use, the mortality rate for patients undergoing this procedure remains high, mainly due to the perceived risk of exacerbating graft-versus-host disease (GVHD). However, even with immunosuppressive agents, some patients still develop GVHD. Advanced mesenchymal stem/stromal cell (MSC) strategies have been proposed to achieve better therapeutic outcomes, given their immunosuppressive potential. However, the efficacy and trial designs have varied among the studies, and some research findings appear contradictory due to the challenges in characterizing the *in vivo* effects of MSCs. This review aims to provide real insights into this clinical entity, emphasizing diagnostic, and therapeutic considerations and generating pathophysiology hypotheses to identify research avenues. The indications and timing for the clinical application of MSCs are still subject to debate.

Key Words: Mesenchymal stem/stromal cells; Graft-versus-host disease; Immunomodulatory; Adaptive immunity; Exosomes

Core Tip: This article provides insights into the use of validated mesenchymal stem/stromal cells (MSCs) as a potential treatment strategy for graft-versus-host disease (GVHD) in hematopoietic stem cell transplantation (HSCT). Current prevention and treatment options involve immunosuppression, which can hinder immune recovery and limit the graft-versus-tumor effect. By using MSCs, clinicians can effectively treat GVHD, identify high-risk patients, and stratify patients based on disease severity. Therefore, MSCs can aid in promoting engraftment, ameliorating acute GVHD, and preventing chronic GVHD, making them an attractive option for HSCT.

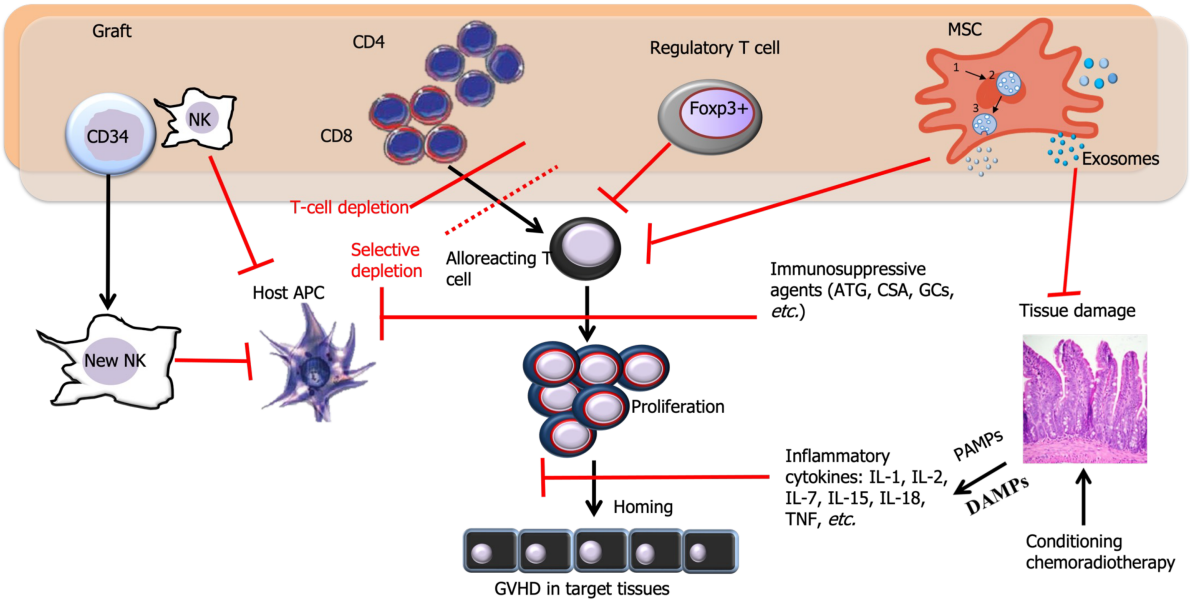
INTRODUCTION

Mesenchymal stem/stromal cells (MSCs) are multipotent cells with self□renewal abilities[1] that can be derived from different tissue sources. They attach to tissue culture dishes and express CD73, CD90, and CD105 but lack the expression of CD45, CD34, CD14, or CD11b, CD79α or CD19, and HLA-DR surface molecules. In vitro, MSCs can differentiate into osteoblasts, adipocytes, or chondroblasts[2,3]. MSCs can be effectively harvested without significant ethical concerns and have low immunogenicity. They have emerged as a promising cell source due to their regenerative and immunomodulatory potentials, limited ethical concerns, and low risk of tumor formation[4-6].

Malignancy relapse is a significant challenge in allogeneic hematopoietic stem cell transplantation (HSCT). Chronic graft-versus-host disease (GVHD) is associated with lower relapse rates, but the diagnosis, staging, and risk stratification of GVHD are challenging[7]. In this scoping review, we highlight recent evidence on different types of MSCs studied for GVHD, including bone marrow (BM), umbilical cord blood, placenta, adipose tissue, and others. MSCs have been found to inhibit immune cell proliferation and cytotoxic action, making them a potential treatment option for GVHD[8].

This review aims to provide a critical overview of the mechanisms by which MSC can treat GVHD, including immunomodulation, migration, homing, and clinical applications of MSC therapy. We searched peer-reviewed literature in PubMed and Embase to gather the latest information on this topic.



THERAPEUTIC STRATEGY OF GVHD

Immune pathways in GVHD

One of the most significant challenges in improving the prognosis for patients undergoing allogeneic HSCT is GVHD. This condition can be characterized as a rapid escalation in immune activation caused by massive target tissue apoptosis. The prevention of GVHD is primarily based on the use of calcineurin inhibitors and methotrexate, while the treatment of ongoing GVHD involves the use of corticosteroids. GVHD manifests as acute GVHD (aGVHD) in 53%-62.5% of the patients and chronic GVHD (cGVHD) in 20%-50.4% of patients[9,10], and the development of this complication may contribute to 6.3% of deaths following HSCT[9]. Although the administration of calcium inhibitors such as calcium sulphoaluminate can prevent the development of GVHD in some cases, about 19% of aGVHD II-IV cases are often resistant to all conventional therapy, resulting in a high mortality rate for these patients. Several potential second-line options have been proposed, including the use of MSCs. MSCs have attracted significant interest because they can actively undergo apoptosis by recipient cytotoxic cells [11]. Figure 1 illustrates the immune pathways involved in GVHD and the sites where therapy is used to block GVHD development.

Danger signals in aGVHD development

In a typical case of aGVHD, which occurs following a triptych course, symptoms begin with the prodromal phase caused by the underlying disease and conditioning regimens that secrete proinflammatory cytokines, mainly tumor necrosis factor-α (TNF-α), interleukin-1β (IL-1β), and interleukin-6 (IL-6)[12]. Host conditioning facilitates donor cell grafting. Donor allograft T-cells are the primary effector cells for GVHD. However, tissue damage leads to the release of alarmins and the expression of pathogen-recognition receptors, triggering the next phase. This phase activates the innate immune system and, in turn, the adaptive immune system. Alarmins and exogenous pathogen-associated molecular patterns (PAMPs) elicit similar responses to relevant signals, and they belong to the group of damage-associated molecular patterns (DAMPs)[13]. DAMPs and PAMPs are potent stimulators for

APC: Antigen-presenting cell; ATG: Antithymocyte globulin; CSA: Cyclosporine A; DAMPs; Damage-associated molecular patterns; Foxp3+: Forkhead box P3; GCs: Glucocorticosteroids; GVHD: Graft-versus-host disease; MSC: Mesenchymal stem cell; TNF: Tumor necrosis factor; NK: Natural killer cells; PAMPs: Pathogen-associated molecular patterns.

host and donor-derived antigen-presenting cells (APCs), which activate and enhance the responses of alloreactive donor T cells[14].

The immunosuppressive effects of MSCs are classified into soluble factor-mediated effects and cell-cell contact-mediated effects. MSCs suppress the proliferation and survival of activated T lymphocytes and reduce the release of inflammatory factors such as IL-2, TNF-α, IL-1β, and IFN-γ. By the same means, MSCs also reduce the number of Th1/Th2 and Th17 cells. Through cell-to-cell contacts, MSCs can stimulate the expression of transcription complexes related to Runt 1 (RUNX1), RUNX3, and CBFβ in Treg-specific regulatory regions to improve the stability of Foxp3[15]. MSCs have also been shown to be highly effective in inhibiting the cytotoxic effect, proliferation, and secretion of different cytokines of NK cells by directly contacting these cells and transforming their phenotype.

The effects of MSCs on B cells involve inhibiting their cell cycle progression by inducing G0/G1 cell cycle arrest and suppressing their proliferation. Additionally, the differentiation of B cells into IgM-, IgG-, and IgA-secreting cells is impaired by MSCs, thereby limiting their antibody production. Furthermore, MSCs can affect the chemotactic function of B cells[16].

GENETIC BASIS OF GVHD

Humanized mouse models

Most relevant models for studying human adaptive immune responses use immunocompromised mice whose immune system is reconstituted with human immune cells and immune system components. Lee *et al*[17] used a model of NSG mice reconstituted with human CD34 cells to evaluate the immunological safety of therapeutically compromising human MSCs. As major histocompatibility complex (MHC) molecules are the primary mediators of the allogeneic immune response, MHC expression levels are critical in the potential immunogenicity of cells. To investigate MSCs as a cellular therapy in GVHD, Tobin *et al*[18] treated NSG-PBMC humanized mice with human MSCs as a GVHD model. MSC treatment resulted in a reduction in liver and intestinal pathology and a significant increase in the survival of the GVHD NSG mouse.

In contrast to aGVHD, some MHC-mismatched animal models may mimic the features of cGVHD. However, due to the pathological resemblance between cGVHD and autoimmune diseases, there is a clear connection between the two entities, and the difference in cGVHD is primarily caused by the donor lymphoid graft[19]. These findings provide compelling evidence for the essential role of human leukocyte antigen (HLA) disparity in both aGVHD and cGVHD. The expression pattern of minor histocompatibility antigens (miHAs) determines the target organ involvement in aGVHD. The miHAs exhibit hierarchical immunodominance, which may contribute to the variability in GVHD variability [20].

Translation and clinical advances in GVHD

aGVHD: HLA mismatching is one of the most significant risk factors for aGVHD and cGVHD risk. HLA proteins are specifically encoded by MHC. In vitro studies have demonstrated that most T cells associated with GVHD are naïve T cells, whereas memory T cells mediate immunity against pathogens and the graft-versus-leukemia (GVL) effect[21]. Regardless of the graft source or conditioning intensity, the incidence of aGVHD is closely related to the number of HLA disparities. Although the impact of HLA disparity has been analyzed in the outcomes following allogeneic HSCT, relatively few studies have tried to correlate it with the incidence and severity of cGVHD. Some studies reported an association between HLA-A, -B, and -C disparity and aGVHD[22].

Although MHC antigens guarantee HLA matching, the donor and recipient may differ in various proteins presented in the form of HLA-peptide complexes to T cells that act as miHAs. The genomes include more than 10^7 polymorphic sequences outside HLA, and the role of miHAs is supported by genome-wide analysis of single-nucleotide polymorphisms[7]. The disparity in a single immunodominant miHA is insufficient to cause aGVHD, although T cells primed against a single miHA may induce tissue damage in a human skin explant model[23]. It is unknown whether the number of miHAs triggering a GVL response in a given transplant is significant or whether a small number of antigens play a dominant role[24].

cGVHD: In contrast, cGVHD has been considered an autoimmune disease based on its clinical features [25]. Some experimental studies have shown that T cells from animals with cGVHD are specific for a public determinant of MHC class II molecules and are therefore considered autoreactive. These autoreactive cells of cGVHD are often associated with an injured thymus and adverse selection.

Recent clinical data has highlighted a significant link between immune responses against ubiquitous miHAs and cGVHD. Since cGVHD usually occurs after allogeneic HSCT, aGVHD is its related risk factor. Unlike syngeneic GVHD, which results from deficient thymic selection[26], cGVHD typically arises after allogeneic HSCT and is characterized by chronic T-cell activation due to continuous exposure to miHAs. This chronic stimulation can cause target organ damage that resembles autoimmune features, where the target is miHAs for cGVHD and non-polymorphic autoantigens for autoimmune diseases. A study on female-to-male HSCT demonstrated a good correlation between the presence of antibodies to the Y-chromosome-encoded gene and cGVHD[27]. A study in female-to-male HSCT demonstrated a good correlation between the presence of antibodies to Y-chromosome-encoded genes and cGVHD, suggesting that miHAs may indeed be the targets. However, it is not yet clear whether the miHAs targeted in cGVHD are the same as those targeted in aGVHD. A murine study had shown that the type and selection of immunodominant miHAs can determine the target and character of GVHD damage[28].

Epitope spreading and the failure of appropriate regulatory mechanisms in aGVHD may result in donor T cells recognizing both non-polymorphic and miHA epitopes, perpetuating cGVHD. In contrast, T cells directed against miHAs with hematopoietic restriction may also mediate a GVL response in the absence of GVHD[29]. However, the relevant immunogenic targets for cGVHD remain speculative and confidential.

Potent immunomodulatory role of MSCs-derived exosomes in preventing GVHD

The safety and effectiveness questions regarding using MSCs remain unresolved, and conflicting effects have been noted due to the heterogeneity observed among MSCs. MSCs-derived exosomes (MSCs-Exo), a subgroup of extracellular vesicles released by MSCs, have shown therapeutic benefits for inflammatory diseases and cancers due to their ability to transport proteins and nucleic acids from donor cells to recipient cells of the same or different tissues, making it a suitable candidate for cell-free therapy. MSCs-Exo have been found to reduce inflammation and fibrosis in the skin, lungs, and liver, and inhibit Th17 cells while inducing Treg cells, making it a potential alternative method for the treatment of cGVHD. The activation of CD4+ T cells and their infiltration into the inflamed mouse lung were reduced in MSCs-Exo-treated mice[30]. MSCs-Exo, extracted from healthy donors' BM, suppress the expression of pro-inflammatory factors TNF-α and IL-1β but increase the level of anti-inflammatory factor TGF-β during *in vitro* culture[31].

Typically, MSCs-Exo are characterized by endosomes that bud inward and package into multivesicular bodies (MVBs). These MVBs fuse with the plasma membrane and deliver the exosomes into the intracellular space. However, exosomes can enrich several molecules as cargo, such as proteins/cytokines, DNA, RNA, and other nucleic acids. Exosomes, as secretory components of MSCs, transport cytokines, and growth factors of immunoregulation, such as transforming growth factor beta-1 (TGF-β 1), IL-6, IL-10, hepatocyte growth factor, signaling lipids, mRNAs, and regulatory miRNAs, which exert biological effects on recipient cells, such as cell-to-cell communication, tissue regeneration, metabolism, immune modulation, and homing of immune cells[32,33]. Diverse immune cells establish complex interactions with each other. MSCs-Exo might represent a novel cell-free therapy with unique competitive advantages over parent MSCs, such as no apparent risk of tumor formation or lower immunogenicity.

IMMUNE CELL LANDSCAPE OF GVHD

Antigen-presenting cells

Antigen-presenting cells (APCs) play a critical role in inducing aGVHD, with dendritic cells (DCs) being one of the most formidable cells in this regard[26]. Innate immunity activation during acute inflammation leads to DCs maturation and subsequent T cell priming, which is central to the potential antitumor benefits of aGVHD. Experimental data suggest that modulating perceptible DC subsets can influence aGVHD[34]. For instance, the absence of RelB signaling in host DCs or enhancing host CD8+ lymphoid DC subsets following HSCT significantly reduces aGVHD[35]. Other APCs, such as monocytes/macrophages, also play a crucial role in this phase. Some data suggest that the host B cells may reduce aGVHD in specific contexts. Although the precise mechanisms remain unclear when acting as APCs, MSCs from the donor, or host also reduce aGVHD.

Natural killer, γδ T, and natural killer T cells

Natural killer (NK) cells can directly kill tumor cells without specific immunization and also have a modulatory effect on aGVHD. In an allo-HSCT donor-to-F1 model, NK cells recognize the absence of donor class I on host APCs and eliminate them, resulting in a reduction of aGVHD reduction. Upon activation, NK cells may induce apoptosis of target cells through contact-dependent cytotoxicity primarily *via* perforin and granzyme[36]. Pro-apoptotic granzymes enter through perforin pores in the plasma membrane of target cells. Besides the cytotoxic activity, NK cell activation increases the secretion of various cytokines and chemokines, such as IFN-γ. However, the role of NK cells in GVHD remains controversial.

The infusion of donor γδ T cells may increase aGVHD, while the absence of host γδ T cells may reduce APC activation and aGVHD in an MHC-mismatched model. Conversely, in the absence of host γδ T cells, GVHD severity was not modified in an MHC-matched, miHA-disparate model of cGVHD. aGVHD could be more significant in patients with more considerable donor γδ T cells. The significance of γδ T cells in aGVHD and cGVHD is not fully understood and may reflect differences in immunobiology between the two or be solely a consequence of variation in the experimental models.

NKT cells, which are CD1d-reactive, are believed to play an immunoregulatory role in suppressing dysfunctional immune reactions, including GVHD[37]. The cumulative frequency of regulatory T cells (Tregs) is negatively correlated with GVHD development[38], and exogenous NKT cell infusion can reduce the degree of GVHD[39]. However, Treg populations have unstable Foxp3 expression, particularly those expanded in vitro. Because the expression Foxp3 is needed for the suppressive function, further research is necessary to determine if Foxp3 expression can be simplified, especially under pro-inflammatory conditions characteristic of the GVHD milieu[40].

T cells

The complex interactions between MSCs and T cells have been extensively studied, particularly *in vitro* culture techniques. MSCs may facilitate activated T cells in the phase G0/G1 cell cycle, yet apoptosis is not applicable[41-43]. MSCs may suppress or downregulate the proliferation of both naïve and memory T cells through cell-cell contact or mitogenic stimuli. This suppression is generally not MHC-restricted. MSCs can further decrease IFN-γ producing T cells and contribute to the T-cell skewing toward Th2 cells producing IL-4. cGVHD is a Th2 cell dominant disease process[12].

Regulatory T cells

MSCs activate *immune* responses that induce the expression of Tregs, which are a cluster of cells with a $CD4^+CD25^+$ $Foxp3^+$ phenotype that regulate the body's immune response. Tregs highly and constitutively express CTLA-4, which binds to CD80, and CD86 on DCs, leading to impaired DC maturation and blocking CD80/CD86 to CD28 on conventional T cells, thereby preventing costimulation, and T-cell activation. Lower Tregs and deficient Foxp3 expression have been associated with cGVHD in peripheral blood and mucosal biopsies. However, levels of Foxp3 mRNA in the CD25+ T cell compartment do not predict the development of cGVHD, demonstrating that the presence, or absence of Tregs must be considered in the context of their impact on aGVHD and cGVHD. An intriguing possibility is that the negative impact of calcineurin inhibitors on Tregs could exacerbate cGVHD as a consequence of the suppression of the alloreactive donor cytopathic and Tregs.

B cells

Host B cells attenuate aGVHD in an IL-10-dependent manner. Recent data provide a rationale for the pathogenic role of donor B cells in cGVHD[12], including a robust correlation between cGVHD and (1) The effects of antibodies against Y-chromosome-encoded miHA; (2) higher numbers of B cells with altered TLR9 responses; (2) levels of a B-cell-activating factor, which enhances survival and differentiation of activated B cells; and (4) in animal models, levels of autoantibodies. Besides, emerging data from the depletion of B cells with rituximab further supports the theory of the pathogenic action of B cells in cGVHD[44]. However, whether B cells are the effectors or inducers of cGVHD remains unknown.

SEARCH STRATEGY, STUDY SCREENING, AND SELECTION

We systematically searched the electronic bibliographic databases MEDLINE, EMBASE, and Google Scholar for studies published before November 2022 using the keywords: "graft-versus-host disease" OR "acute GVHD" OR "chronic GVHD" AND "mesenchymal stem cells" AND "mesenchymal stromal cells" AND "treatment response" AND "outcome." Publications were included if they met the following inclusion criteria: (1) Original research; (2) published in 2002 or later; and (3) specifically reporting on the use of MSCs in GVHD patients. Publications were excluded based on the following criteria: (1) Non-English literature; (2) small populations (n < 20 patients) or case studies; and (3) mixed population with non-GVHD patients. A meta-analysis was not performed for the limited number of published studies meeting the inclusion criteria. Pre-post design studies and case series were not included for lack of sustainability of the results. Additionally, reference lists of retrieved articles were cross-referenced for additional eligible articles.

RESULTS

This review provides an overview of clinical studies, animal models, and limited human patient trials regarding MSCs. MSCs have been widely studied and increasingly used in GVHD treatment since the first report of promising results by Le Blanc *et al*[45] However, the studies have reported varying outcomes, which could be contributed to differences in cell concentration and MSC infusion dose. While MSC infusion has shown quite promising results following GVHD prophylaxis failure, some clinicians still prefer using methylprednisolone and calcineurin inhibitors before cell therapy with MSCs.

In addition to suppressing inflammation, MSCs have other beneficial effects, including increased angiogenesis, reduced apoptosis, and modified extracellular matrix dynamics. These cells mediate immune system components like macrophages and neutrophils, improving tissue microenvironments. After the injury, MSCs can either promote or suppress the immune system to guide the whole-tissue regeneration process[1]. Clinical responses to MSC infusion assessed as early as one week after treatment may predict patients' overall survival, indicating the potential of MSCs in treating GVHD[45].

Although the paracrine effects of MSCs are known to mediate the modulation of the immune response, the mechanisms underlying this modulation are not yet fully understood. However, it has been found that under conditions of chronic hypoxia or co-stimulation with IFN-γ, MSCs express proteins that have the immunosuppressive capacity, such as IDO, HLA-G, PGE2, and FasL, which can modulate the immune response[46]. While other cytokines play a crucial role in immunosuppression, blocking highly expressed proteins can result in the setback of the human immunosuppressed state, leading to the growth, and proliferation of immune cells. Moreover, MSCs do not trigger the activation of immune cells as they lack CD40, CD80, CD86, and HLA-DR-stimulating molecules. Given that GVHD occurs following the infusion of immune cells donated by the same donors, suppressing the immune activity can improve the patient's prognosis. MSCs' expression of paracrine effects can regulate these donor immune cells through various mechanisms (Table 1)[47-62].

When MSCs are exposed to an insult, such as injury, or bacterial infection, MHC-II molecules facilitate the presentation of bacterial antigens, which induces further activation of T cells expressing IFN-γ. MHC-II is downregulated at high levels of IFN-γ, while B7-H1 is upregulated[45]. These presentation pathways are illustrated in Figure 2.

MSCs have been used to treat various conditions, including diabetes mellitus (DM), cardiovascular diseases, GVHD, and autoimmune diseases. Despite persistent questions, the immunomodulatory effects of MSCs make them a top choice for cell therapy. MSCs are early multipotent progenitors and non-hematopoietic cell populations that can be expanded ex-vivo to achieve large numbers necessary for *in vivo* use. Recently, adipose tissues, umbilical cord, placenta, and dental pulp have been recognized as multipotent sources of MSCs. MSCs can differentiate into a variety of cell types capable of osteogenic, chondrogenic, adipogenic, myogenic, and neurogenic differentiation. However, not all individual cells cultivated in tissue culture flasks result in the same degree of multipotency. Self-renewing progenitors can be identified in human BM, and it is currently unknown whether MSCs from other tissues exhibit this property. BM-MSCs are a critical source of multipotent stem cells and serve as a standard for comparing MSCs from different sources (Table 2)[49,63-85].

The term "mesenchymal stem cells" has been proposed as a more appropriate term than MSCs. These cells possess not only multipotency but also significant immunomodulatory and engraftment-promoting properties. They create a specialized microenvironment for HSCs by promoting the secretion of various inflammatory cytokines, chemokines, growth factors, extracellular matrix, and extracellular vesicles that are crucial for HSC differentiation, proliferation, and maintenance[86-88]. After *in vivo* biological application, MSCs secrete a range of cytokines and regulatory molecules with anti-inflammatory, wound healing, and regenerative effects, promoting the repair of endogenous tissues or tissue replacement. Beres *et al*[40] demonstrated that even in otherwise immunocompetent humans, allogeneic MSCs may graft, and differentiate through significant histocompatible barriers.

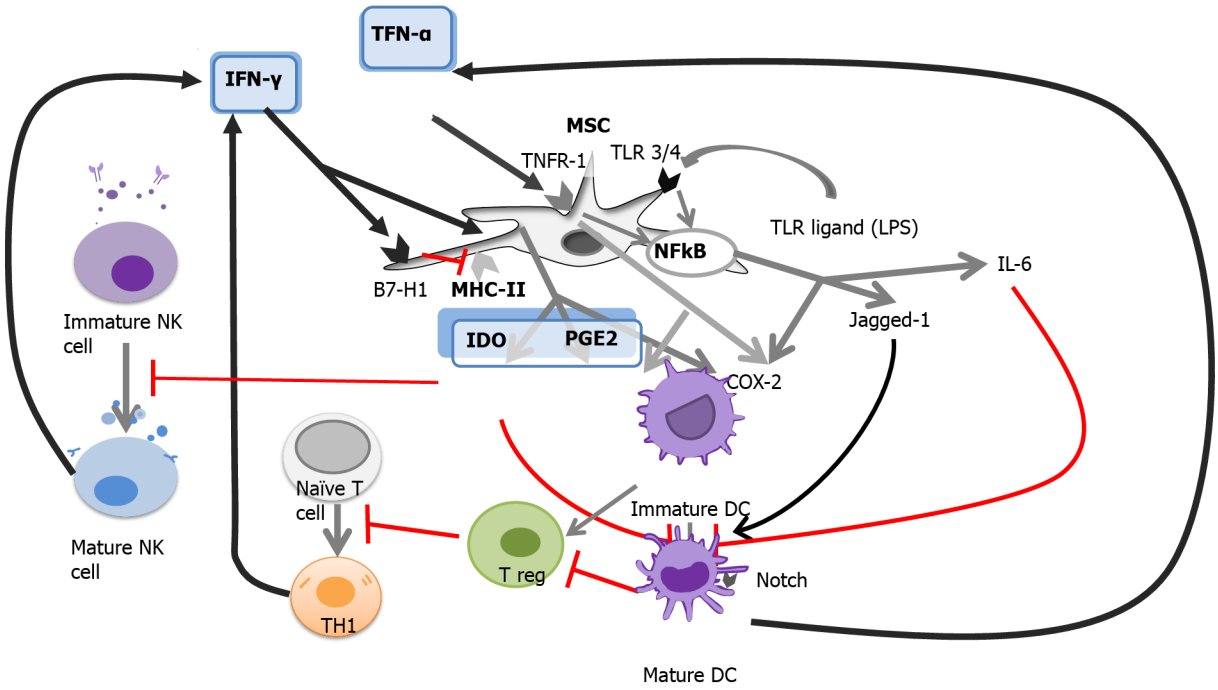
Table 1 Immunosuppressive effect exerted by mesenchymal stem/stromal cells from different sources on immune cells

MSC types	Mechanism of immunosuppressive effect	Ref.
BM-MSCs	Recipient-derived MSCs from patients with GVHD are analogous to MSCs from healthy volunteers	Copland *et al*[47]
	After MSC infusion, the ratio of Th1 cells to Th2 cells was reversed, with an increase in Th1 and a decrease in Th2 achieving a new balance	Zhou *et al*[48]
	BM-MSCs reduce the incidence and severity of GVHD by improving thymic function and induction of Tregs but not increase the risks of infections and tumor relapse	Zhao *et al*[49]; Selmani *et al*[50]
	HLA-G5 secreted by MSCs is critical to the suppressive functions of MSCs	Selmani *et al*[51]
MenSCs	MenSCs exhibit a higher capacity to migrate into the intestine and liver and not to their anti-inflammatory capacities	Luz-Crawford *et al*[52]
FL-MSCs	FL-MSCs demonstrates much longer-lasting immunomodulatory properties by inhibiting directly the proliferation and activation of CD4+ and CD8+ T cells	Yu *et al*[53]
UC-MSCs	UC-MSCs showed minimal expression of HLA-DR after activation and posed minimal risk of initiating an allogeneic immune	Kim *et al*[54]
	UC-MSCs alleviate SLE through upregulating Treg cells, which was partly dependent on HLA-G	Chen *et al*[55]
	UC-MSCs ameliorate GVHD and spare GVL effect *via* immunoregulations	Wu *et al*[56]
WJ-MSCs	WJ-MSCs exert immunosuppressive effects by cell-cell contact with activated T cells and in part through the soluble factor indoleamine 2,3-dioxygenase	He *et al*[57]
MC-, WJ- and BM-MSCs	The mixed populations of MSCs displayed all of the positive attributes of WJ-MSC and BM-MSC	Mennan *et al*[58]
AT-MSCs	The use of AT-MSC rather than BM-MSC could further preserve NK cell activity and favor GVL	Blanco *et al*[59]
hG-MSCs	hG-MSC treatment inhibited local inflammation of injured skin by suppressing inflammatory cells, reducing pro-inflammatory cytokine tumor necrosis factor-α, and increasing anti-inflammatory cytokine interleukin-10, which was promoted by hypoxia	Jiang *et al*[60]
CP-, BM- and AT-MSCs	CP-MSCs may have additional advantage over the other MSCs in terms of immunomodulation	Lee *et al*[61]
DP-MSCs	Immunomodulation and expression of trophic factors by dental MSCs increase their resistance to allogeneic NK cell lysis and their potential in vivo lifespan	Martinez *et al*[62]

AT: Adipose tissue; BM: Bone marrow; CP: Chorionic plate; DP: Dental pump; FL: Fetal liver; hG: Human gingiva; GVHD: Graft-versus-host disease; GVL: Graft-versus-leukemia; MenSC: Menstrual blood-derived mesenchymal stem cell; MSC: Mesenchymal stem cell; UC: Umbilical cord; WJ: Wharton jelly.

Similar to hematopoietic stem cells, MSCs have multi-organ specificity, and plasticity. In 2006, the International Society for Cellular Therapy officially defined MSCs as plastic practitioners under standard growing conditions, expressing CD73, and CD90 surface molecules while lacking CD11b, CD14, CD19, CD34, CD45, CD79a, and HLA-DR[2]. In addition, MSCs can differentiate into various mesodermal lineages including osteoblast, adipocyte, and chondroblast, to different degrees.

MSCs are capable of modulating both innate and adaptive immunity through the release of various soluble factors, including indoleamine 2,3-dioxygenase[11], IL-10, prostaglandin 2, nitric oxide, transforming growth factor-β, HLA-G5, and anti-inflammatory molecule TNF-α-induced gene/protein 6 [89]. These molecules are believed to play a key role in the immunomodulating effects of MSCs, which have been shown to be beneficial in certain immunopathological diseases, such as aGVHD, and type 1 DM. However, the precise mechanisms underlying this therapeutic potential are not yet fully understood. The literature suggests that the immunomodulating potential of MSCs involves interactions with both humoral and cellular components of the innate and adaptive immune systems. The literature refers to several fundamental cellular interactions. An integrated perspective on the utility of MSCs for GVHD has been strengthened by the recent findings that MSCs are induced to undergo necrosis/apoptosis by the recipient's cytotoxic cells and that this process is assumed to elicit MSC-induced immunosuppression[90]. This finding made it possible to reconcile the dilemma between the effectiveness of MSC and its apparent lack of engraftment and highlighted the crucial role of the patient in the promotion and administration of immunosuppression of MSCs. Recent research has shed light on the role of the patient in promoting and administering immunosuppression of MSCs, with evidence suggesting that MSCs are induced to undergo necrosis/apoptosis by the recipient's cytotoxic cells, leading to MSC-induced immunosuppression[90]. Table 2 provides an overview of recent studies on this topic, with 97 articles selected for full-text evaluation based on agreed-upon title and abstract criteria.



Innate immunity is primarily centered around the complementary system, with C3, and C5 being cleaved into anaphylatoxins C3a and C5a by convertases at the sites of inflammation. The labile C3

Table 2 Effects of different mesenchymal stem/stromal cells on refractory acute graft-versus-host disease

Study type	Patient No.	Indication	MSC type	Response criteria	Main findings	Ref.
Phase 2	55	Steroid-resistant, severe, aGVHD	BM	Glucksberg	CR: 30/55, better OS/TRM for complete responder	Le Blanc *et al* [63], 2008
Phase 2	31	Gr. II-IV aGVHD	BM	Glucksberg	CR: 77%; PR: 16%	Kebriaei *et al*[64], 2009
Pilot study	20	Co-transplantation with NMA mismatched HSCT	BM	Glucksberg	Decreased 1 yr GVHD death (10% *vs* 31%, $P = 0.04$). Better NRM & OS	Baron *et al*[65], 2010
Retrospective	37	Resistant Gr. III-IV aGVHD	BM	Glucksberg	CR: 65%, better TRM and OS	Ball *et al*[66], 2013
Multicenter trial	50	Resistant Gr. IV aGVHD	BM	Not mentioned	OR: 33%, CR: 17%, initial response and young age have better survival	Resnick *et al*[67], 2013
Prospective, single-arm, open-label	75	Severe refractory aGVHD	BM	IBMTR SI	OR on day +28: 61.3%, better OS for responder on day +100 (78.1% *vs* 31.0%; $P < 0.001$)	Kurtzberg *et al* [68], 2014
Phase 1	40	Resistant Gr. II-IV aGVHD	BM	Glucksberg	CR: 27.5%, OR: 67.5% on day +28; more CR in pediatric group	Introna *et al*[69], 2014
Phase 2	25	Refractory aGVHD	BM	Glucksberg	71% responded, CR 11/24, better OS for CR	Sánchez-Guijo *et al*[70], 2014
Prospective, nonrandomized	28 *vs* 19 without MSC	Refractory aGVHD	BM	Glucksberg	Decreased incidence and severity of cGVHD. Better OR and CR.	Zhao *et al*[49], 2015
Phase 2	48	Steroid-resistant aGVHD	BM	Glucksberg	CR: 25% on day 28, 50% lasting > 1 mo, with better OS	Te Boome *et al* [71], 2015
Compassionate use	58	Steroid-resistant aGVHD	BM	IBMTR SI	OR: 47%, but no improvement in OS	von Dalowski *et al*[72], 2016
Phase 2/3	25	Refractory Gr. III-IV aGVHD	BM	Glucksberg	Better OS for OR at 4-wk (CR: 6/25, PR: 9/25)	Muroi *et al*[73], 2016
Pilot study	33	Refractory aGVHD	BM	IBMTR SI	CR: 18/33, PR: 7/33, better OS in CR, no TRM in CR	Erbey *et al*[74], 2016
Compassionate use	26	Severe resistant aGVHD	BM	Not mentioned	OR: 77% on day +28 (CR: 5/26, PR: 15/26)	Kuçi *et al*[75], 2016
Phase 2 prospective RCT	62 *vs* 62 without MSC	cGVHD prophylaxis in haplo	Cord	NIH score	cGVHD: 27% (MSC) *vs* 49% in 2 yr ($P = 0.021$)	Gao *et al*[76], 2016
Phase 1/2	26	Steroid-refractory aGVHD	BM	Glucksberg	OR: 62% on day 28. Higher response rate in children. High NRM in adults	Salmenniemi *et al* [77], 2017
Pilot study	22	Refractory GVHD (Gr. 2-4 a or cGVHD)	BM or adipose tissue	Glucksberg/NIH score	CR: 45.8%, PR: 33.3%, better OS in CR/PR	Cetin *et al*[78], 2017
Retrospective	46	Refractory Gr. III/IV aGVHD	BM	Not mentioned	50% responded with better OS ($P = 0.0004$)	Dotoli *et al*[79], 2017
Phase 1/2	33	Steroid-refractory aGVHD	BM	Glucksberg	CR: 34%, PR: 50% on day 28. Better OS on day 90 and 1 yr ($P = 0.006$, 0.002)	Fernández-Maqueda *et al* [80], 2017
Phase 1/2	69	Refractory aGVHD	BM	Glucksberg	OR: 83% on day 28	Bader *et al*[81], 2018
Observational study	34 *vs* 34 without MSC	aGVHD	BM or adipose tissue	IBMTR SI	Better OS compared with historical control, $P = 0.0678$. MSC has no association with risk of infectious complication	Stoma *et al*[82], 2018
Retrospective	11 (study group 2)	Severe refractory aGVHD	Placenta derived decidual stromal cell	Glucksberg	73% 1 yr OS in study group 2 (albumin), 47% in group 1 (AB plasma), $P = 0.016$	Ringden *et al* [83], 2018
Retrospective	22	Severe refractory aGVHD	Cord	IBMTR SI	CR: 45.5%, PR: 13.6%	Bozkurt *et al*[84], 2019

Phase 3 RCT	151 *vs* 72 placebo	Severe refractory aGVHD	BM	IBMTR SI	Difference of durable CR (lasting > 28 d) not achieved (35% *vs* 30%, P = 0.42); Pediatric pts had better OR (64% *vs* 23%, P = 0.05)	Kebriaei *et al*[85], 2020

aGVHD: Acute graft-versus-host disease; BM: Bone marrow; cGVHD: Chronic graft-versus-host disease; CR: Complete remission; IBMTR SI: International Bone Marrow Transplant Registry severity index; MSC: Mesenchymal stem/stromal cells; OS: Overall survival; PR: Partial remission; RCT: Randomized controlled trial.

Figure 2 The complex network of antigen presentation and immunomodulation. Mesenchymal stem/stromal cells (MSCs) exert immunomodulatory functions mainly *via* interactions with immune cells through cell-to-cell contacts and paracrine activity. The MSC secretome includes several cytokines, growth factors, and chemokines, and their immunomodulatory functions vary depending on the source of the MSCs, the target cells, and the microenvironment. COX-2: Cyclooxygenase-2; IDO: Indoleamine-pyrrole 2,3-dioxygenase; IFN: Interferon; IL: Interleukin; NF-κB: Nuclear factor kappa-light-chain-enhancer of activated B cells; PGE2: Prostaglandin E2; TLR: Toll-like receptors; TNF-α: Tumor necrosis factor-α; DC: Dendritic cell; LPS: Lipopolysaccharide; NK: Natural killer cells.

convertases cleave C3 into C3a and C3b which can thereafter participate in forming distinct complexes and activate pathways for proliferation and protection against apoptosis through receptor binding. MSCs also secrete the factor H, which inhibits complement activation by limiting the activity of C3 and C5 convertases. In mice, MSCs promote pro-inflammatory repolarization and produce chemostatic cytokines, including IL-6, IL-8, GM-CSF, and macrophage inhibitory factors. IL-8, in particular, is a pro-inflammatory chemokine produced by multiple cell types that recruits leukocytes to sites of infection or tissue injury. Additionally, MSCs can inhibit mast cell degranulation and histamine release by binding allergens to allergen-specific IgE *via* FcRε on mast cells, providing a potential therapeutic benefit for allergic reactions[91].

The molecular interaction between NK cells and MSCs is complex and depends on the immune microenvironment and NK cell activation status. MSC can inhibit cytokine proliferation and production and interfere with NK cell cytotoxicity. They also inhibit monocyte maturation and differentiation into DCs, which are the primary type of APC and play a key role in T lymphocyte activation through antigen presentation. Monocytes and macrophages are important for tissue development, homeostasis, and injury repair. Activated MSCs produce chemokines that attract circulating monocytes to sites of inflammation and injury[92].

MSCs can regulate the adaptive immune system through multiple redundant pathways. They suppress the proliferation of T cells, IFNγ production, CD4 T cell differentiation, and CD8 T-cell cytotoxicity. Di Nicola *et al*[41] reported that MSCs can suppress T lymphocyte proliferation *in vitro* with autologous and allogeneic MSCs, including T lymphocytes cultured with DCs or lymphocytes in mixed lymphocyte reactions. MSCs can express and secrete programmed death-ligand 1 and 2, which suppress T-cell proliferation in the presence of MSCs, secrete IL-2, induce apoptosis, and promote the induction of an irreversible hyporeactive state[93]. In vivo studies suggested that MSCs may restore the balance

between T helper 1 and 2 cells in diseases associated with a shift to dominance of these T cell subpopulations[94]. *In vitro* models have shown that MSCs induce Tregs and maintain survival and suppressive phenotypes[95].

CONCLUSION

This article provides insights into the use of validated MSCs as a potential treatment strategy for GVHD in HSCT. Current prevention and treatment options involve immunosuppression, which can hinder immune recovery and limit the graft-versus-tumor effect. By using MSCs, clinicians can effectively treat GVHD, identify high-risk patients, and stratify patients based on disease severity. Therefore, MSCs can aid in promoting engraftment, ameliorating aGVHD, and preventing cGVHD, making them an attractive option for HSCT.

Abstract

Different fates of neural stem/progenitor cells (NSPCs) and their progeny are determined by the gene regulatory network, where a chromatin-remodeling complex affects synergy with other regulators. Here, we review recent research progress indicating that the BRG1/BRM-associated factor (BAF) complex plays an important role in NSPCs during neural development and neural developmental disorders. Several studies based on animal models have shown that mutations in the BAF complex may cause abnormal neural differentiation, which can also lead to various diseases in humans. We discussed BAF complex subunits and their main characteristics in NSPCs. With advances in studies of human pluripotent stem cells and the feasibility of driving their differentiation into NSPCs, we can now investigate the role of the BAF complex in regulating the balance between self-renewal and differentiation of NSPCs. Considering recent progress in these research areas, we suggest that three approaches should be used in investigations in the near future. Sequencing of whole human exome and genome-wide association studies suggest that mutations in the subunits of the BAF complex are related to neurodevelopmental disorders. More insight into the mechanism of BAF complex regulation in NSPCs during neural cell fate decisions and neurodevelopment may help in exploiting new methods for clinical applications.

Key Words: Neural stem/progenitor cell; BRG1/BRM-associated factor complex; Subunit; Proliferation; Differentiation; Neural developmental disorders

Core Tip: There are several reviews in the literature contributed to the role of BRG1/BRM-associated factor (BAF) complex in neural cell specification and neural development diseases. We review recent progress indicating that BAF complex plays an important role in neural stem/progenitor cells (NSPCs) during neural development and neural developmental disorders. More progresses in the role of BAF complex subunits in balancing self-renewal and differentiation of NSPCs and neurodevelopment could finally be involved in highlighting new methods for clinical application.

INTRODUCTION

Neural stem/progenitor cells (NSPCs) are self-renewing neural cells capable of differentiating into neurons, astrocytes and/or oligodendrocytes[1-3]. During development, NSPCs are critical for the establishment of the central nervous system (CNS)[4-6]. In the adult central neural system, neurogenesis plays a key role in fundamental processes, for example, memory, learning, the maintenance of normal tissue homeostasis, and the autonomous repair of pathological brain tissues[7,8]. NSPCs can be isolated from three canonical neurogenic niches in the spinal cord and brain, namely, the central canal (CC) in the spinal cord, the subgranular zone (SGZ) of the dentate gyrus (DG) and the subventricular zone (SVZ) of the lateral ventricle (LV) in the brain[9-13]. In addition, NSPCs have been identified in the developing cerebral cortex[14], olfactory epithelium[15] and outside the CC[16]. The fact that NSPCs can be isolated and propagated *in vitro* opens up new opportunities for medical research, and we hope they can be used to compensate for cell loss that features in several serious neurological disorders. Moreover, NSPCs can be created *in vitro* through induced differentiation from induced pluripotent stem cells (iPSCs) and embryonic stem cells (ESCs), expanding the pool of models for studying stem cells in health and illness[17,18]. For cell-based therapy approaches targeting the brain and spinal cord, NSPCs have emerged as focal points. However, the small amount of NSPCs present in this tissue has restricted the clinical uses of these cells. Although recent advancements in ESCs and iPSC research have meant that these cells can be novel sources of NSPCs, understanding NSC molecular regulation and NSPC applications, which are important for disease modeling and regenerative medicine, remain challenges[19-21].

The BRG1/BRM-associated factor (BAF) complex, which is a mammalian chromatin remodeler, regulates chromatin structure and transcription by providing subunit organization and nucleosome recognition in an ATP-dependent manner. Structurally, the BAF complex contains three modules, an ATPase, an actin-related protein (ARP) and a base module[22]. More than 30 major subunits of these modules can combine to form the complex[22-24].

By controlling chromatin structure, controlling the differentiation of NSPCs to produce different types of brain cells, and regulating transdifferentiation between cell types, BAF complexes perform crucial roles in the maintenance of a gene expression program. At various phases of brain formation, BAF complexes have specific roles and seem to be produced by the combinatorial assembly of their subunits. Moreover, intimate interactions between the BAF chromatin-remodeling complex and transcriptional machinery control the development of NSPCs[25]. With the combinatorial assembly of homologous component families, which enables their nonredundant functions, distinct BAF complex structures are made possible. ESCs, NSPCs, and postmitotic neurons all exhibit developmental stage-specific BAF assemblages during mammalian brain development. Neuronal BAF (nBAF) function is required for the development of mature postmitotic neuronal features along with long-term memory, and neural progenitor-special BAF (npBAF) structures are particularly important for modulating the rates and modalities of neural progenitor cell replication. Given the high prevalence of BAF subunit mutagenesis in neurological illnesses, it is obvious that BAF complexes perform a crucial role in controlling the rate of neuronal development, homeostasis, and plasticity. Understanding how BAF complex subunits influence BAF complex function and the roles played by different subunits will reveal disease pathogenesis and lead to novel treatments for related human disorders ultimately[26,27].

Here, we summarize recent progress in comprehending the role of the BAF complex in NSPCs. We focus on NSC-/NPC-specific BAF complex subunits and describe how they determine the balance between the self-renewal and differentiation of NSCs and are involved in several human neural developmental disorders. Supplementary Table 1 shows the abbreviations and their descriptions.

BAF COMPLEX SUBUNITS AND THEIR MAIN CHARACTERISTICS IN NSPCS

Among the major BAF complex subunits, there are 12 subunits expressed in NSPCs in the embryo cortex, olfactory bulb (OB) and spinal cord, adult brain and spinal cord, and human and mouse retina (detailed information and references are shown in Table 1).

BAF190A (BRG1/ SMARCA4)

Brg1 (Brahma-related gene 1) is necessary for NSPCs to remain in a state where they can react to gliogenic signals and to suppress neuronal commitment. Lack of Brg1 in NSPCs led to precocious neurogenesis, such that cells in the ventricular zone developed into postmitotic neurons before the start of gliogenesis in conditional brg1- mutant mice. As a result, these animals significantly lost the ability to differentiate astrocytes and oligodendrocytes. In addition, in vitro Brg1 deletion reduced growth factor-induced astrocyte development in gliogenic progenitors. Furthermore, it has been discovered that the levels of proteins associated with stem cell maintenance, such as Pax6, Sox1, and Musashi-1, are significantly lower in the ventricular zones of the mice with brg1-mutations[28]. The hippocampus experienced abnormal adult neurogenesis as a result of Brg1 deletion in nestin-expressing NSPCs. This abnormal adult neurogenesis initially decreased the number of adult NSPCs in the hippocampus, inhibited progenitor maintenance, and later decreased NSPC responsiveness to physiological stimulation. Brg1 deletion appears to hinder cell cycle progression mechanistically, which is partly because of increased p53 pathway activation and p21 expression. Defects in neurosphere formation brought on by Brg1 deletion were repaired by knocking down p53. These findings suggest that aNSPC and progenitor cell maintenance and responsiveness during neurogenesis are determined by epigenetic chromatin remodeling *via* a Brg1- and p53/p21-dependent mechanism[29].

Many transcription factors manipulating neuronogenesis have been ascertained in the adult and developing brain, and notably, the neurogenic transcriptional regulation factor Pax6, which can directly interact with the Brg1-carrying BAF complex in adult neural progenitor cells. Abolition of either Pax6 or Brg1 in the subependymal zone (SEZ) caused the offspring of adult NSPCs to switch to the SEZ ependymal cell lineage. In the interim, shifting neuroblasts changed to distinct glial cell lineages during or after reaching the OB. Several studies have revealed that there is a network with tripartite effector programing neuronal fate, which can be activated by Pax6-BAF and promote neurogenesis and the transformation from glia to neurons. According to the whole-genome analysis, the downstream regulatory factors of Pax6-BAF include Nfib, Sox11 and Pou3f4. While Brg1 is absent in SEZ and OB, the binding sites of Pax6 carried by Brg1 and most down-regulated genes will be down-regulated at the same time[30]. In the study of Jayaprakash *et al*[31], they find that Brg1 appears as a slender spherical structure so that it can provide a lager surface and form the further complex by binding to BAF57 and BAF60A. Furthermore, a neural Brg1 isoform interacts with the central neurodevelopmental transcriptional repressor REST/NRSF, suggesting that Brg1 can interact with transcription regulators and factors to conduct the BAF complex to specific sites[31].

BAF155 (SMARCC1) and BAF170 (SMARCC2)

Recent study found that conditional deletion of BAF155 can lead to the decrease of basal intermediate progenitors (bIPs), while the delamination of apical radial glial progenitors (RGs) can cause the increase of basal RGs (bRGs). During the progress, BAF155 has been proved necessary for the normal activity of PAX6 to regulate the gene expression. BAF155 can control the expression of the CDC42 effecting protein CEP4 in the Pax6-dependent way in order to regulate the stratification of progenitor. In addition, BAF155-dependent chromatin remodeling is also involved in regulating several human RG-specific genes, thereby acting on the generation of basal progenitors (BPs)[32].

The study of Narayanan *et al*[33] in 2015 revealed a molecular mechanism of controlling the global chromatin state and transcriptional program during development, which is mediated by the BAF complex. They found that BAF155 and BAF170 knockout can cause elimination of the entire BAF complex with all kinds of BAF subunits in cortical development, with the overall increase of the abundance of the repressive marks (H3K27me2/3), decrease of active chromatin mark H3K9Ac, and down-regulation of gene expression. Both BAF155 and BAF170 subunits are expressed in early cortical progenitors (E10.5-E14.5), and BAF170 is replaced by BAF155 in late cortical progenitors[34]. Specifically, between E12.5 and E14.5, apical progenitors express BAF170 and BAF155. They exhibit comparable expression patterns at the height of upper layer neurogenesis (E15.5), with BAF170 being missing from VZ progenitors but expressed in the cortical plate but expressed in the cortical plate[34]. While BAF170 overexpression resulted in the acquisition of a feature similar to that acquired by the Pax6-loss brain, with depletion of overlying layer neurons, BAF170 loss in Emx1t cortical progenitors exerted an effect opposite to that of Pax6 elimination and caused an aberrant growth of IPs and a bias toward the acquisition of an overlying layer identity[34]. By the recruitment of the transcriptional suppressor REST to Pax6 targets, the BAF170-containing npBAF complex indirectly suppresses neurogenesis in its early stages[34,35]. Interestingly, the transcription of BAF170 and Brm subunits, which replace BAF155 and Brg1 subunits in the esBAF, respectively, begins at the same time when ES cells commit to developing into neural progenitors[33,36]. According to a recent functional invest-

Table 1 BRG1/BRM-associated factor complex subunits in neural stem/progenitor cells

BAF complex subunits (aliases)	NSPC types	Function	Interaction signalings/factors	Related neural developmental diseases	Ref.
BAF45A (PHF10)	oNSC, E10.5-E11.5 cortical NPCs, E10.5-E16.5 spinal cord VZ	NSPC proliferation	BRG1	-	Bachmann *et al*[15], 2016; MacDonald *et al*[89], 2022; Lessard *et al*[41], 2007
BAF45D (DPF2)	SGZ, SVZ, spinal cord central canal GFAP + radial glial cells	PAX6 expression, contributes to NSPC induction	PAX6, BRG1	CSS	Liu *et al*[42], 2017; Wang *et al*[44], 2019; Chen *et al*[43], 2022; Vasileiou *et al*[69], 2018; Knapp *et al*[70], 2019; Milone *et al*[71], 2020
BAF47 (SMARCB1)	oNSC	-	BRG1	CSS, kleefstra syndrome, Nicolaides-Baraitser syndrome	Bachmann *et al*[15], 2016; Tsurusaki *et al*[72], 2012; Santen *et al*[74], 2013; Wieczorek *et al*[75], 2013; Kleefstra *et al*[88], 2012; Gossai *et al*[73], 2015
BAF53A (ACTL6A)	oNSC, NPCS in the neural tubes of E11.5 embryos	BAF53A is essential for NPC proliferation	miR-9 and miR-124	-	Bachmann *et al*[15], 2016; Lessard *et al*[41], 2007; Yoo *et al*[45], 2009
BAF55A (SS18)	NPCs in VZ	SS18 is required for NSC self-renewal	BRG1	-	Staahl *et al*[48], 2013
BAF57 (SMARCE1)	Adult human OBNSCs	NSC proliferation	Neuregulin-1	CSS	Wieczorek *et al*[75], 2013; Kosho *et al*[67], 2014; Marei *et al*[52], 2012; Zarate *et al*[76], 2016; Pirotte *et al*[63], 2010
BAF60A (SMARCD1)	Oligodendrocyte precursors	-	BRG1, BAF155 and BAF170	CSS, Nicolaides-Baraitser syndrome	(Yu *et al*[54], 2013; Hsiao *et al*[53], 2003; Machol *et al*[78], 2019; Nixon *et al*[77], 2019
BAF60C (SMARCD3)	NPCs in human retinas as well as mouse retina, cortex and spinal cord	Keeps the progenitors in a proliferative state -	Notch signaling	-	Lamba *et al*[55], 2008
BAF155 (SMARCC1)	oNSC, adult human OBNSCs	Proliferation and maintenance of ONSCs forebrain development	BRG1, PAX6	ASD	Lessard *et al*[41], 2007; Marei *et al*[52], 2012; Narayanan *et al*[33], 2015; Neale *et al*[84], 2012
BAF170 (SMARCC2)	oNSC, in postnatal DG, in RGL progenitors	oNSC proliferation, affects NSC proliferation, differentiation, forebrain development	BRG1	CSS, ASD, Nicolaides-Baraitser syndrome	Lessard *et al*[41], 2007; Machol *et al*[78], 2019; Narayanan *et al*[33], 2015; Neale *et al*[84], 2012; Tuoc *et al*[38], 2017
BAF190A (BRG1/SMARCA4)	Mouse VZ, SGZ, SEZ, NSCs/NPCs, NCC	NSC maintenance and neuronal differentiation	PAX6, BAF45D	CSS, ASD	Tsurusaki *et al*[72], 2012; De Rubeis *et al*[85], 2014; Matsumoto *et al*[28], 2006; Petrik *et al*[29], 2015; Ninkovic *et al*[30], 2013
BAF250A (ARID1A)	Developing cortex	Regulates NSPC proliferation and differentiation during cortical development	BRG1	CSS	Tsurusaki *et al*[72], 2012; Liu *et al*[40], 2021

BRG1: Brahma related gene 1; BRM: Brahma; BAF: BRG1/BRM-associated factor; NSPCs: Neural stem/progenitor cells; oNSCs: Olfactory neural stem cells; CSS: Coffin-siris syndrome; VZ: Ventricular zone; OBNSCs: Olfactory bulb-derived neural stem cells; ASD: Autism spectrum disorder; KSS: Kleefstra syndrome spectrum; DG: Dentate gyrus; RGL: Radial glial-like; SEZ: Subependymal zone; NCC: Neural crest cells.

igation, Pax6 is directly associated to the BAF complex in aNSCs that contained the Brg1, and its neurogenic activity was abolished in the lack of the Brg1[30]. BAF170 and BAF45 also carry domains with putative DNA-binding capacities[37]. In the neonatal DG, the BAF170 member of the complex is found in radial glial-like (RGL) cells and cell types implicated in following stages of adult neurogenesis together with mature astrocytes. The pool of RGL cells in the DG is reduced by conditional knockout of BAF170 during late cortical neurogenesis and also adult brain neurogenesis, which encourages terminal astrocyte differentiation. A moderate loss in spatial learning was produced by the induced abolition of BAF170 in the DG throughout adult brain neurogenesis, with the reversal test showing the greatest impact on spatial learning. These findings indicate a specialized role for adult neurogenesis in the DG

regulating adaptive behavior and show the engagement of BAF170-reliant chromatin modification in neurogenesis and cognition of hippocampus[38].

BAF250A (ARID1A)

The core ATPase, Brg1 or Brm, BAF250A or BAF250B, a homologous dimer of BAF155, or a heterologous dimer of BAF170 and BAF155 are just a few examples of the different subunits that npBAF can contain[27]. Mammal BAF is significantly different from its yeast analogue, losing some members while obtaining new core members, such as BAF45a/b/c/d, BAF57, BAF250A/B, SS18/CREST, beta-actin, BRD7, and BRD9. Notably, BAF250A/B are the most commonly mutated subunits of BAF complex in related human neurological diseases[36]. Loss of BAF250A or BAF250B in mouse models leads to early embryonic lethality[39], indicating that, despite their homology, both genes are essential for early development.

Recent genome sequencing and many clinical studies have revealed that mutations of BAF250A is closely related to microcephaly and mental retardation. Liu *et al*[40] generated a *baf250a* conditional knockout mouse line and found that cortical thickness was reduced in the developing cortex. Radial glial cell proliferation is inhibited by loss of BAF250A function, which also increases the rate of cell damage during late cortical neurogenesis and causes abnormal expression of genes involved in proliferation and differentiation. Therefore, for the purpose of better understanding the pathogenic mechanisms and creating new treatments for neurodevelopmental disorders brought on by its mutations, BAF250A may be one of the gene possibilities that is worthwhile being researched[40].

BAF45A and BAF45D (DPF2)

BAF45 family proteins, including BAF45A, BAF45B, BAF45C and BAF45D, are subunits of the BAF complex[41]. BAF45A, an npBAF, is required for the self-renewal and proliferative features of neural cells[41]. BAF45A is identified in olfactory neural stem cells (oNSCs), E10.5-E11.5 cortical NPCs, and E10.5-E16.5 spinal cord ventricular zone NSCs[15,41]. BAF45D is expressed in the SGZ of the LV, SGZ of the DG, and the CC of the adult spinal cord. Co-expression of BAF45D and glial fibrillary acidic protein (GFAP), a marker protein of radial glial cell-like cell was found in the SGZ, SVZ, and CC of the adult spinal cord. According to the results of quantitative examination, BAF45D is selectively expressed in the adult neurogenic regions of neurons in CNS. What's more, BAF45D is necessary for the induction of PAX6, a determinant for neuroectoderm that regulates adult neural stem/progenitor cell self-renewal and specific neural fate, during neuroectodermal differentiation of H9 cells[42].

Recently, BAF45D has been shown to regulate spinal cord neural stem/progenitor cell (SCNSC/SCNPC) fate mediated through the SMAD-PAX6 axis. SCNSCs exhibit increased DNA-BAF45D compared to that in human ESCs[43]. It has been reported that postmitotic neurons express BAF45B/C protein but lack the paralogous BAF45A/D, which confers neuronal properties[25-27,41]. The protein expression of BAF45D in adult rat NSPCs and neurons but not astrocytes may imply a role for BAF45D in the differentiation of NSPCs[44].

BAF53A (ACTL6A)

The BAF53 subunit is encoded by the BAF53A (ACTL6A) or BAF53B (ACTL6B) gene, with the latter exclusively expressed in differentiated neurons[41].

BAF53A is specific to the npBAF complex and can be replaced by BAF53B in the nBAF complex in neurons[26,45]. miR-9 and miR-124 control the transition of postmitotic neurons from the BAF complex's BAF53A to BAF53B subunit[46]. These miRNAs' expression is derepressed in neurons during cell development, which encourages the replacement of BAF53B in the nBAF complex by suppressing the expression of BAF53A. Increased progenitor proliferation can result from BAF53A's continued expression[46]. These miRNAs have an interacting location in the 3′UTR of BAF53A, and their expression is constrained in progenitors by REST and its corepressors[47]. As a result of decreased chromatin accessibility at particular neural transcription factor-binding sites brought on by BAF53A loss, cell cycle-related genes are repressed, preventing the advancement of the cell cycle and cell differentiation[48].

BAF57 (SMARCE1)

BAF57, subunit in the BAF complex core, is highly conserved in the BAF complexes of vertebrates[49]. The DNA-binding capabilities of its primary structural characteristic, a high-mobility group domain, imply that BAF57 may perform topological functions when the BAF complex moves in or out a nucleosome. BAF57 specifically interacts with a variety of proteins which aren't part of the BAF complex. BAF57 demonstrates particular functionalities as a result of these interactions. For example, in the embryo, it interacts with the transcriptional cosuppressor Co-REST to enable the neuronal genes inactivation in nonneuronal cells throughout development[50]. Interestingly, global gene expression profiling results indicated that BAF57A was specifically upregulated in human NSPCs of OB (OBNSPCs) but not in human embryonic NSPCs (hENSC)[51]. In cultured NSCs, BAF57 interacts with the overexpressed intracellular domain of neuregulin-1 and leads to a decrease in the NSC proliferation rate[52].

BAF60A (SMARCD1)

The BAF60A/B subunits define an ESC-specific assembly of BAF, named esBAF[27]. The BAF subunits BAF60A binds to BRG1, the primary factor that drives the BAF complex to particular genomic locations, and interacts with transcription regulators and factors[31]. Nuclear receptors and the BRG1 complex may have an additional important and direct relationship that is necessary for recruitment of promoter and subsequent chromatin modification[53]. Low levels of BAF60A and BAF45B/D expression are found in oligodendrocyte precursors, and these expression levels are upregulated upon differentiation [54]. However, their specific roles in NSPCs are still unclear.

BAF60C (SMARCD3)

During development, another crucial BAF complex component called BAF60C also has neuronal progenitor-specific actions. BAF60C is expressed in neural progenitors in the mouse and human retina, as well as the human cortex and spinal cord[55]. BAF60C expression decreases during neural differentiation, and through its interaction with the Notch pathway, its overexpression keeps progenitors in a proliferative condition. Finally, Muller glia that resume the cell cycle following neurotoxic damage express BAF60C once more[55].

BAF55A (SS18)

BAF55A, also called SS18, is a member of the npBAF complex. In NSCs, SS18 knockdown results in cell cycle exit and self-renewal failure[48]. Moreover, SS18 is adaptively activated to respond to ethanol exposure, protecting fetal NSCs against complete loss of miR-9-2[49].

BAF47

BAF47, a ubiquitous BAF complex subunit, is expressed in oNSCS[15]. However, the exact function of BAF47 remains largely unknown.

BAF COMPLEX FUNCTIONS IN BALANCING SELF-RENEWAL AND DIFFERENTIATION OF NSPCS

The number of neural stem cells expands through symmetrical division, and through asymmetrical divisions, they maintain the capability to self-renew and produce other differentiated cells[56]. Normal neural development requires the maintenance of the dynamic balance between the proliferative cells and differentiated cells of neural stem cells, which controls the number of stem cells and neurons and protects the body from diseases such as glioblastoma[57]. Furthermore, neural stem cells respond to several molecular signals during neurogenesis, especially those mediated by the Wnt and Notch signaling pathways[58]. For instance, Notch signaling is a significant mechanism regulating the balance between the quiescence and differentiation of neural stem cells[59]. By suppressing the Notch pathway, the homeostasis of neural stem cells can be altered, promoting neural differentiation[60].

Several BAF family members, which act as components or modulators of the Notch and Wnt/β-catenin signaling pathways, have been shown to exert either positive or negative effects on the differentiation of neural stem cells[55,61]. On the one hand, neural differentiation can be promoted by BAF155 and BAF170, which act on regulators of Wnt/β-catenin signaling-related genes, including H3K27me3 and H3K4me2[15,62]. On the other hand, BAF45a and BAF53a contribute to the proliferation and self-renewal of neural stem cells[41]. The repression of BAF53a during neural differentiation is realized through its 3'-UTR and the cooperative influence of miR-9 and miR-124[45]. Brm and BAF57 interact with the neuregulin-1 (Nrg-1) intracellular domain, reduce proliferation and promote differentiation of neural stem cells in vitro, possibly by reversing the direction of signaling in a pathway[63]. Furthermore, it has been shown that the overexpression of BAF60c maintains the proliferation of neural progenitors by interacting with the Notch signaling pathway[55]. The BAF complex may also make direct contact with the neurogenic transcription factors that are critical for neural stem cell specification or differentiation. Notably, the subunit composition of BAF complexes undergoes a profound switching during differentiation; for instance, BAF40c is replaced by BAF40a, the function of which is activated by Pax6, Tbr1, and Tbr2[64]. Moreover, BAF155 in the primate brain has been shown to be involved in the normal activity of Pax6, thereby regulating the specification of progenitors during cortex development [32].

Overall, BAF complexes function as both agonists and inhibitors of neural differentiation. Notably, certain similarities and differences have been revealed through the approaches used in the aforementioned studies. A study by Narayanan *et al*[32] was carried out by generating cortex-specific BAF155-knockout mice, while in another study, Nguyen *et al*[62] adopted a transgenic mouse model in which both BAF155 and BAF170 were knocked out, eliminating the entire BAF complex during late cortical neurogenesis. Their double-knockout model offered a novel and practical method for examining the function of complete BAF complexes during cerebral development[65]. Furthermore, a study by Bi-Lin *et al*[66] was conducted after the neural crest-specific knockout of BAF155 and BAF170 in $Wnt1^{Cre/+}$ and

Pax3$^{Cre/+}$ mice, and the results demonstrated that the BAF complex modulated the gene expression network and pathways, including the Notch signaling pathway, critical for neural crest development.

NSPC-RELATED BAF COMPLEX SUBUNITS IN NEURAL DEVELOPMENTAL DISEASES

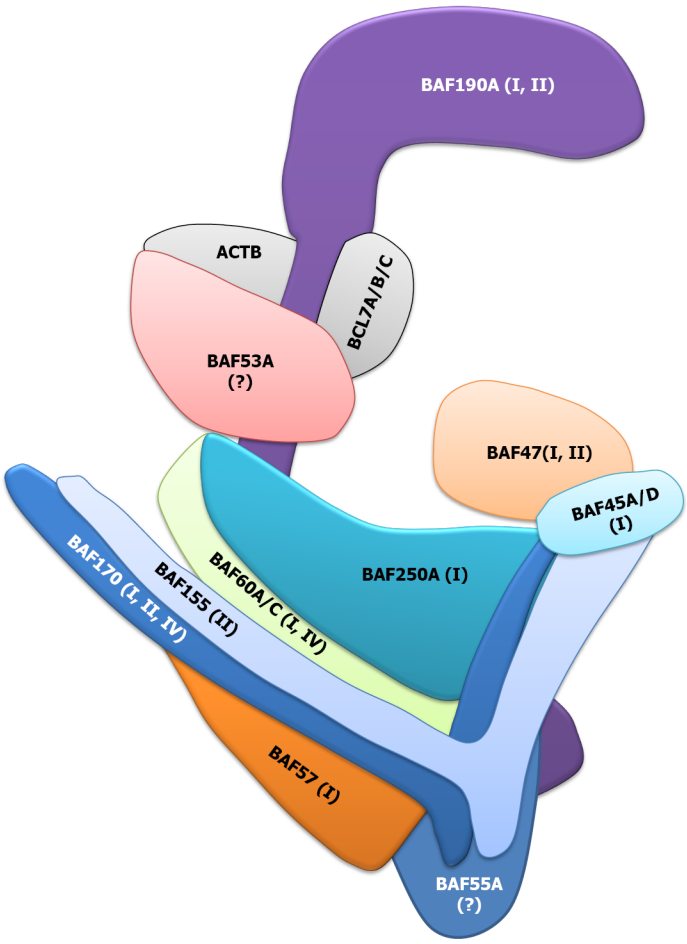
Given the importance of BAF complexes in creating and sustaining a chromatin state that keeps proper transcriptional output during NSPC proliferation, differentiation and responses to exogenous or endogenous stimuli, it is clear that several neural developmental disorders have been linked to NSPC-related BAF complex subunits (Table 1 and Figure 1).

Coffin-Siris syndrome

Coffin-Siris syndrome (CSS) is a unusual congenital neural developmental disorder characterized clinically by intellectual disability (ID), progressive facial thickening, hirsutism, recurrent infections, difficult feeding, and restricted growth of the distal fifth phalanx and nails[67,68]. Genes encoding NSPC-related BAF complex subunits have been found to have mutations recently thanks to extensive human exome sequencing and genome-wide association research, including BAF45D[69-71], BAF47[72-74], BAF57[67,75,76], BAF60A[77], BAF170[78], BAF190A/BRG1[72], and BAF250A[72]. Different brain midline abnormalities, similar to those seen in people with CSS, were shown to be caused specifically by BAF47, BAF57, and BAF250B mutations in mice with a heterozygous neural system-specific SMARCB1 defect and a partial dysfunctional mutation in a BAF core member gene, indicating significant clinical suggestions for BAF complex-related ID/neurodevelopmental diseases[79].

Within a cohort of 15 unrelated individuals on the CSS pathway disorders registry, who were carriers of a SMARCA4 variant, they showed differences in the severity and number of learning disabilities and health problems. Two of them with novel nonsense variants appeared to acquire a non-organ/system affected phenotype with minor learning/behavioral differences[80]. A recent report described a Chinese woman presenting with on the CSS pathway disorders registry, who were carriers of a SMARCA4 variant, they showed differences in the severity and number of learning disabilities and health problems. Two of them with novel nonsense variants appeared to acquire a non-organ/system affected phenotype with minor learning/behavioral differences and endocrine dysfunction. Whole-exome sequencing was used and led to the identification of a heterozygous missense variant in the SMARCC2 gene of the proband[81].

Nicolaides-Baraitser syndrome



The clinical features of patients with nicolaides-Baraitser syndrome (NCBRS) caused by mutations in the SMARCA2 gene, remarkably resemble those of CSS patients[82]. The characteristics of hands and feet are where NCBRS and CSS most clearly diverge. While typical CSS patients have hypoplasia or agenesis of the fifth fingernail with or without engagement of the nail phalanges, typical NCBRS patients have pronounced distal phalanges and interphalangeal joints[75]. Five individuals with mutations in BAF60A exhibited developmental delay, small hands and feet, hypotonia, ID, and difficult feeding. According to TRIO exome sequencing, these mutations developed in four of the five patients[77]. A missense mutation (p. Arg366Cys) of BAF47 also has been reported to be associated with NCBRS[75]. Furthermore, variants in BAF170 have also been found in patients presenting with overlapping ID syndromes related to other BAF subunits, such as those identified in CSS and NCBRS[78].

Autism spectrum disorder

Autism is a neurodevelopmental disease which is caused by both environmental and genetic factors, presented as speech problems, limited and repetitive behaviors and social skills barrier[83]. Recent exome-sequencing studies on individuals with autism have found mutations in the BAF155, BAF170[84] and BAF190A[85] genes. But at least seventy percent of the cases, the fundamental genetic cause is still unknown.

Kleefstra syndrome spectrum

Kleefstra syndrome spectrum (KSS) is a recognizable syndrome characterized by ID and induced by a hybrid mutation in the euchromatin histone methyltransferase 1 (EHMT1) gene[86,87]. According to the research of Kleefstra *et al*[88], KSS could result from mutations in any complex protein including MLL3, MBD5, NR1I3, BAF47, or EHMT1. The EHMT1 mutation is not present in every patient with the primary symptoms of Kleefstra syndrome. In fact, de novo mutations in four genes that code for epigenetic regulators, including BAF47 (SMARCB1), were found in four of the nine individuals who did not have EHMT1 mutations[88]. And their research using a Drosophila model showed that MLL3, MBD5, NR1I3, BAF47, and EHMT1 directly interact with one another[88].

Figure 1 BRG1/BRM-associated factor complex subunits in neural stem/progenitor cells and the related neural developmental diseases. The BRG1/BRM-associated factor (BAF) complex subunits in neural stem/progenitor cells are shown (in colors), including BAF45A/D, BAF47, BAF53, BAF55A, BAF57, BF60A/C, BAF155, BAF170, BAF190A, and BAF250A. The other two types of the BAF complex subunits, β-actin and BCL7/A/B/C, are shown in grey. Neural developmental disease types are listed as, I: Coffin-Siris syndrome; II: Autism spectrum disorder; III: Kleefstra syndrome; IV: Nicolaides-Baraitser syndrome; "?": Unknown. BAF: BRG1/BRM-associated factor.

CONCLUSION

Considering recent research progress, we suggest that three aspects of BAF complexes should be investigated in the near future. First, BAF complexes are crucial for development of neural system and differentiation of neural cells, including the specification of neural fate and functionality[4]. BAF complex subunits play key roles in the manipulation of gene expression, and the distinct ontogenetic stage-specific BAF complex functions in neural stem/progenitors and postmitotic neuronal cells that are derived from the combinatorial organization of these subunits[26]. Sequencing of human whole-exome and genome-wide association studies have recently demonstrated the link between mutants of BAF complex subunits and neurodevelopmental illnesses like CSS, NCBS, KSS and ASD[89-92]. Focus must be placed on the roles played by BAF complex organization during neural development as well as the ways in which mutations in well-known BAF complex subunits contribute to certain neurodevelopmental illnesses[93]. Secondly, both loss- and gain-of-function techniques to evaluating neural network development at the molecular, single-cell, and network activity levels should be used in order to comprehend how BAF complex gene mutations might cause the phenotypic convergence of CSS, NCBS, KSS, and ASD. For example, ASD and KSS genes focus primarily on the level of neural network communication and provide insight into the pathophysiology of phenotypic consistency disorders[79, 94]. Thirdly, recent investigations have shown that BAF complexes are frequently involved in human cerebral development abnormalities, providing fresh mechanisms and corresponding paths for therapeutic intervention, all of which should be looked into. In recent years, small compounds that target the BAF complex subunits have become viable therapeutic agents. Researchers in the field have been motivated to recognize and take use of the whole spectrum of therapeutic options as a result of the creation and evaluation of novel drugs that target a variety of BAF complex subunits[95].

Abstract

BACKGROUND

Fibroblast plays a major role in tendon-bone healing. Exosomes derived from bone marrow mesenchymal stem cells (BMSCs) can activate fibroblasts and promote tendon-bone healing *via* the contained microRNAs (miRNAs). However, the underlying mechanism is not comprehensively understood. Herein, this study aimed to identify overlapped BMSC-derived exosomal miRNAs in three GSE datasets, and to verify their effects as well as mechanisms on fibroblasts.

AIM

To identify overlapped BMSC-derived exosomal miRNAs in three GSE datasets and verify their effects as well as mechanisms on fibroblasts.

METHODS

BMSC-derived exosomal miRNAs data (GSE71241, GSE153752, and GSE85341) were downloaded from the Gene Expression Omnibus (GEO) database. The candidate miRNAs were obtained by the intersection of three data sets. TargetScan was used to predict potential target genes for the candidate miRNAs. Functional and pathway analyses were conducted using the Gene Ontology (GO) and Kyoto Encyclopedia of Genes and Genomes (KEGG) databases, respectively, by processing data with the Metascape. Highly interconnected genes in the

protein-protein interaction (PPI) network were analyzed using Cytoscape software. Bromodeoxyuridine, wound healing assay, collagen contraction assay and the expression of COL I and α-smooth muscle actin positive were applied to investigate the cell proliferation, migration and collagen synthesis. Quantitative real-time reverse transcription polymerase chain reaction was applied to determine the cell fibroblastic, tenogenic, and chondrogenic potential.

RESULTS

Bioinformatics analyses found two BMSC-derived exosomal miRNAs, has-miR-144-3p and has-miR-23b-3p, were overlapped in three GSE datasets. PPI network analysis and functional enrichment analyses in the GO and KEGG databases indicated that both miRNAs regulated the PI3K/Akt signaling pathway by targeting phosphatase and tensin homolog (PTEN). *In vitro* experiments confirmed that miR-144-3p and miR-23b-3p stimulated proliferation, migration and collagen synthesis of NIH3T3 fibroblasts. Interfering with PTEN affected the phosphorylation of Akt and thus activated fibroblasts. Inhibition of PTEN also promoted the fibroblastic, tenogenic, and chondrogenic potential of NIH3T3 fibroblasts.

CONCLUSION

BMSC-derived exosomes promote fibroblast activation possibly through the PTEN and PI3K/Akt signaling pathways, which may serve as potential targets to further promote tendon-bone healing.

Key Words: Exosome; MicroRNA; Fibroblast; Mesenchymal stem cell; Tendon-bone healing

Core Tip: Exosomes derived from bone marrow mesenchymal stem cells (BMSCs) can activate fibroblasts and promote tendon-bone healing *via* the contained microRNAs (miRNAs). Supported by bioinformatics tools, this study identified two BMSC-derived exosomal miRNAs, has-miR-144-3p and has-miR-23b-3p, were overlapped in three GSE datasets. Bioinformatic analysis revealed that both miRNAs regulated the PI3K/Akt signaling pathway by targeting phosphatase and tensin homolog (PTEN). Experiments *in vitro* confirmed that interfering with PTEN can affect the phosphorylation of Akt and thus the activation of fibroblasts. These results suggested a potential mechanism by which BMSC-derived exosomes promote tendon-bone healing.

INTRODUCTION

Tendon-bone insertion (TBI) injury, such as rotator cuff tears and anterior cruciate ligament injuries, is one of the common injuries in daily life and sports. Thus, how to promote tendon-bone healing becomes an important issue in research and clinical practice. The normal TBI has a transitional structure consisting of four gradated layers including bone, mineralized fibrocartilage layer, non-mineralized fibrocartilage layer and tendon[1,2]. This complex structure can disperse force from bone to tendon, preventing stress concentration[3]. However, current therapeutic strategies cannot restore this structure, hence raising the risk of re-injury.

Fibroblasts play a key role in tendon-bone healing. In the early stages of TBI injury, α-smooth muscle actin positive (α-SMA+) fibroblasts help form Sharpey-like fibers to withstand strength at TBI and participate in early ligament remodeling by producing collagen and restoring in situ tension[4,5]. Mesenchymal stem cells (MSCs) are a kind of stem cells with strong proliferation capacity and multilineage differentiation potential, which can differentiate into myoblasts, osteoblasts, adipocytes and chondroblast[6]. MSCs can be extracted from bone, adipose tissue, blood, and amniotic membrane [7]. They have multiple functions including immunomodulatory, anti-inflammatory, anti-apoptotic, and angiogenesis promotion, making them ideal candidate cells for tissue engineering research[8]. Recent evidence indicates that conditioned medium, primarily containing exosomes of MSCs, can stimulate the activation of fibroblasts, thereby promoting tendon-bone healing[9-12]. However, the underlying mechanism is not comprehensively understood.

Bioinformatics has played an important role in exploring disease mechanisms by allowing parallel processing of large volumes of high-throughput sequencing data. To identify key bone marrow MSC (BMSC)-derived exosome microRNAs (miRNAs), three Gene Expression Omnibus (GEO) datasets were interrogated using bioinformatics tools in this study. TargetScan, a software designed to predict miRNA binding sites, is often used to analyze target genes of miRNAs[13]. Metascape, a powerful gene functional annotation analysis tool, enables pathway enrichment and biological process (BP) annotation [14]. STRING database allows for assessing the functional associations among target genes[15]. Cytoscape software enables visualization of miRNA-target gene pairs.

Therefore, using the above database tools, this study aimed to identify overlapped BMSC-derived exosomal miRNAs in three GSE datasets and verify their effects as well as mechanisms on fibroblasts, so as to facilitate further studies to verify the role of exosomal miRNAs and their potential in promoting tendon-bone healing.

MATERIALS AND METHODS

The workflow of this study was described (Figure 1).

Data collection

Three BMSC-derived exosomal miRNA expression microarray datasets (GSE71241, GSE153752, and GSE85341) were retrieved from the GEO repository on 20 April 2022. (https://www.ncbi.nlm.nih.gov/geo). GSE71241[16], GSE153752[17], and GSE85341[18] included nine, four and one BMSC-derived exosome samples respectively. The above datasets were produced independently using the GPL18743, GPL16791, and GPL22300 platforms, respectively.

Venn diagram analysis and prediction of target genes

After obtaining the top 100 BMSC-derived exosomal miRNAs in each dataset, Venn diagram analysis was used to identify overlapped miRNAs in the three datasets through online tool Venny (version 2.1) (https://bioinfogp.cnb.csic.es/tools/venny). The overlapped miRNAs were considered as candidate miRNAs. Potential target genes for the candidate miRNAs were predicted by TargetScan, an experimentally validated database of miRNA-target interactions[13].

Gene Ontology and Kyoto Encyclopedia of Genes and Genomes pathway analyses

Functional and pathway analyses of the predicted target genes were conducted using the Gene Ontology (GO) and Kyoto Encyclopedia of Genes and Genomes (KEGG) databases, respectively, by processing data with the Metascape[14].

Construction of target gene-protein-protein interaction and miRNA-gene networks

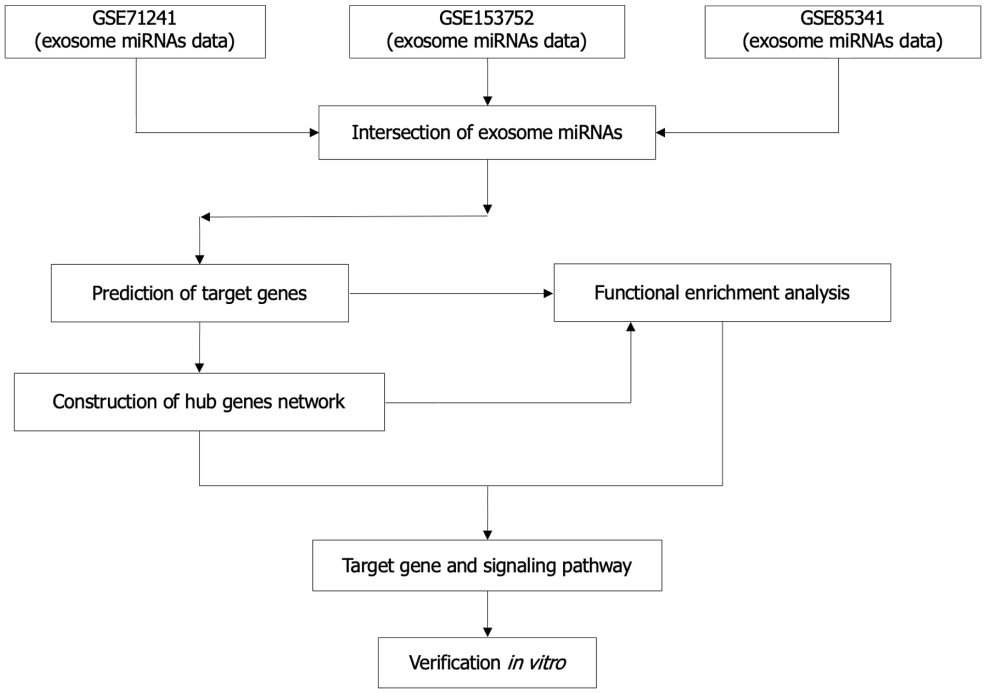
Target gene data was uploaded to the STRING database[15] to assess the functional associations among the target genes of candidate miRNAs. Highly interconnected (hub) genes in the protein-protein interaction (PPI) network were analyzed using Cytoscape software (version 3.9.1). After candidate exosomal miRNAs and their hub target genes were identified, Cytoscape was used to visualize the resulting miRNA-gene network.

Cell culture and treatment

The NIH3T3 fibroblast (Shanghai Institutes for Biological Sciences) was used as a model *in vitro* to further determine the effect of SF1670 [a specific phosphatase and tensin homolog (PTEN) inhibitor] on fibroblasts[19]. Cells were cultured in DMEM supplemented with 10% fetal bovine serum (Gibco), 100 U/mL penicillin, and 100 mg/mL streptomycin and maintained at 37 °C in a humidified atmosphere containing 5% CO_2. When the cells reached 80% confluence, they were digested with 0.25% trypsin and sub-cultured 1:3. To determine the effect of SF1670, NIH3T3 cells were starved for 24 h with DMEM containing 0.5% FBS and then treated with or without SF1670 2 μM for the indicated time. NIH3T3 fibroblast was seeded and cultured into six-well plate.

Western blot assay

Protein was extracted and analyzed using an established method[20]. Anti-phosphorylated Akt (p-Akt) (CST, United States, 1:1000) and anti-Akt (CST, United States, 1:1000) were used as primary antibodies. Each group contains 3 protein samples for calculation.



Quantitative real-time reverse transcription polymerase chain reaction

RNA was extracted and analyzed using the previous method[21]. Total RNA was obtained by the Trizol reagent (Invitrogen, Carlsbad, CA) and quantified by Nanodrop. RNA was then reversely transcribed by the PrimeScript RT reagent kit (Takara Bio). Specific primers used in the experiment are from PrimerBank (Table 1). The operation was performed on the ABI7900 Real-Time PCR System (Applied

Biosystems). The expression of mRNAs relative to the expression of GAPDH was calculated and normalized to the control group.

Luciferase reporter assay

Validation of miR-144 and miR-23b binding to 3′-UTR was performed using Dual-Glo Luciferase assay

system (Promega) as recommended by the manufacturer. The relative luciferase activities were determined by calculating the ratio of firefly luciferase activities over Renilla luciferase activities. All experiments were repeated three times in triplicate. Two constructs of pmirGLO luciferase reporter plasmid were generated: MUT-PTEN (with mutation of part of miRNA binding site sequence) and WT-PTEN [containing the wild-type (WT) miRNA binding site sequence]. 500 ng of the pmirGLO luciferase reporter plasmid and appropriate miRNA plasmid were co-transfected with lipofectamine 3000 (Invitrogen) into NIH3T3 cells. 48 h after transfection, the luciferase expression was determined using the Dual-Glo Luciferase Reporter Assay Kit (Promega) according to the manufacturer's protocol. The pRL-TK vector (Promega) containing Renilla luciferase was also co-transfected for normalization in all relevant experiments.

Bromodeoxyuridine assays

The Bromodeoxyuridine (BrdU) incorporation assay was performed using Cell Proliferation ELISA kits (1647229; Roche Applied Science, Mannheim, Germany). Briefly, NIH3T3 cells were plated at 5000 cells/well in 96-well culture plates in complete media. After attaining 70% confluence, cells were treated with media containing 10% FBS. BrdU solution (10 μM) was added after intervention. The cells were dried and fixed, and cellular DNA was denatured with FixDenat solution (Roche Applied Science) for 30 min at room temperature. A peroxidase-conjugated mouse anti-BrdU monoclonal antibody (Roche Applied Science) was added to the culture plates and cells were incubated for 90 min at room temperature. Tetramethyl-benzidine substrate was added and the plates were incubated for 15 min at room temperature. The absorbance of samples was measured using a microplate reader at 450-620 nm.

Wound healing assay

Cells at logarithmic growth stage were taken and placed in a six-well plate with a cell density of 5×10^5/well. Three multiple wells were set for each group. When the cells were adherent to the wall in a single layer, a pipetting tip was used to vertically scratch the six-well plate to avoid tilting. The suspension cells were cleaned and removed with PBS and cultured in an incubator with 5% CO_2 at 37 °C. Photographs were taken at 0 and 24 h under the microscope. The wound healing area was measured using ImageJ[22].

Collagen gel contraction assay

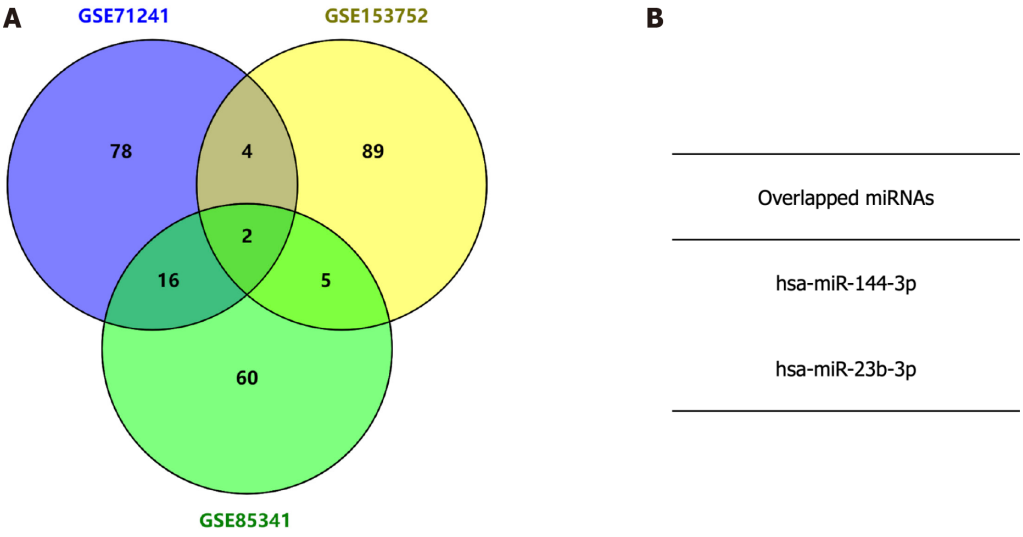
Cell contraction was determined using a kit from Cell Biolabs (San Diego, CA). Briefly, cells were seeded in collagen solution according to the manufacturer's instructions and release from the plates with a sterile spatula. Gel images were taken after release and the surface area of each gel was measured using ImageJ[22].

Immunofluorescence

NIH3T3 cells were cultured in a 24-well plate. The cells were fixed with 4% paraformaldehyde and incubated with 0.5% Triton X-100 (Sigma) and then blocked with goat serum (Biyuntian Company, China) for 1 h. The cells were then incubated overnight at 4 °C with the primary antibody. The secondary antibody was applied, and the cells were incubated for 1 h in the dark. Finally, the nuclei were counterstained with DAPI for 15 min. The stained cells were photographed using a fluorescence microscope.

Statistical analysis

All experiments were performed at least three times. Data were analyzed with GraphPad Prism 7.0 (GraphPad Software, La Jolla, United States) and were presented by mean ± SD. Significance was typically analyzed by student's *t*-test, one-way ANOVA followed by post hoc LSD test, and two-way ANOVA followed by multiple *t*-tests. $P < 0.05$ was regarded as significant.



RESULTS

Identification of candidate exosomal miRNAs and target genes

Three independent BMSC-derived exosomal miRNA expression microarray datasets (GSE71241, GSE153752, and GSE85341)[16-18] were downloaded from the GEO database. Subsequently, top 100 BMSC-derived exosomal miRNAs in each dataset were obtained. The Venn diagram analysis demonstrated two miRNAs in the intersection of the three datasets (Figure 2). The target gene interactions of two candidate miRNAs, hsa-miR-144-3p and hsa-miR-23b-3p, were assessed by the TargetScan[13]. In total, 1048 and 105 potential target genes were identified for miR-144-3p and miR-23b-3p, respectively.

Functional enrichment analysis of miRNAs' target genes

GO functional annotation analysis revealed that the most enriched terms for the target genes of miR-

DOI: 10.4252/wjsc.v15.i4.248 **Copyright** ©The Author(s) 2023.

Figure 2 Identification of candidate microRNAs by intersecting three exosome microRNA expression microarray datasets. A: Venn diagram analysis showing the top 100 exosome microRNAs (miRNAs) in the three Gene Expression Omnibus (GEO) datasets; B: Identification of two miRNAs overlapping between the three GEO datasets. miRNAs: MicroRNAs.

144-3p were 'head development' and 'regulation of kinase activity' in the BP, 'postsynapse' in the cellular component (CC), and 'transcription factor binding' and 'kinase activity' in the molecular function (MF) (Figures 3A-D). On the other hand, the target genes of miR-23b-3p were mostly enriched in 'phospholipid metabolic process' in the BP, 'nuclear speck' and 'centrosome' in the CC, and 'chromatin binding' in the MF (Figures 4A-D). KEGG pathway analysis revealed that most of target genes of miR-144-3p enriched in 'pathways in cancer' and 'PI3K-AKT signaling pathway' (Figure 3E); most of target genes of miR-23b-3p enriched in 'pathways in cancer' (Figure 4E).

Construction of target gene-PPI and miRNA-hub gene networks

A PPI network was constructed through the STRING database[15]. Interactions with an overall score of more than 0.4 were considered significant. Further processing was carried out using Cytoscape software. Then, the cytoHubba plugin was used to determine the top 10 hub genes based on the Degree algorithm. The top 10 predicted hub genes of miR-144-3p and miR-23b-3p were presented (Figures 5A and B). GO and KEGG analysis revealed that these hub genes were mostly enriched in 'regulation of MAPK cascade', 'regulation of phosphatidylinositol 3-kinase signaling' and 'negative regulation of cell differentiation' in the BP (Figure 5C, Table 2), 'fibrillar center' and 'focal adhesion' in the CC (Figure 5D, Table 3), and 'protein kinase activity' and 'transcription factor binding' in the MF (Figure 5E, Table 4). Most of these genes were mainly enriched in PI3K-Akt signaling pathway (Figure 5F, Table 5). Interactional analysis showed that PTEN and sonic hedgehog (SHH) are potentially co-regulated by miR-144-3p and miR-23b-3p (Figure 5G).

PTEN is verified as the targets of miR-144-3p and miR-23b-3p

The phosphatase and tensin homolog deleted on chromosome ten (PTEN), was predicted as the hub gene of miR-144-3p and miR-23b-3p (Figures 6A and B). To further validate the putative binding sites, WT and mutated 3'-UTR of PTEN were cloned into the pmirGLO vector. The transcripts of the target gene were then evaluated by dual luciferase reporter assays. Compared with the control group, luciferase reporter assays showed that miR-144-3p mimics and miR-23b-3p mimics significantly decreased the luciferase activity of WT-PTEN but did not show a significant effect on the luciferase activity of MUT-PTEN (Figures 6C and D). In addition, miR-144-3p mimic significantly down-regulated the mRNA levels of PTEN, while miR-144-3p inhibitor up-regulated the mRNA levels of PTEN (Figure 6E). Similarly, miR-23b-3p mimic down-regulated the mRNA level of PTEN, while miR-23b-3p inhibitor up-regulated the mRNA level of PTEN (Figure 6F). These results indicated that miR-144-3p and miR-23b-3p repressed the expression of PTEN by specifically binding with and subsequently inducing the degradation of mRNA.

miR-144-3p and miR-23b-3p regulate the proliferation, migration, and collagen synthesis of NIH3T3 fibroblasts

To evaluate the effect of the identified miRNAs on fibroblast biology and activation, analysis of proliferation and migration was then performed 24 h after transfection of miR-144-3p and miR-23b-3p respectively. Compared with the control group, proliferation and migration capacity of NIH3T3 cells in

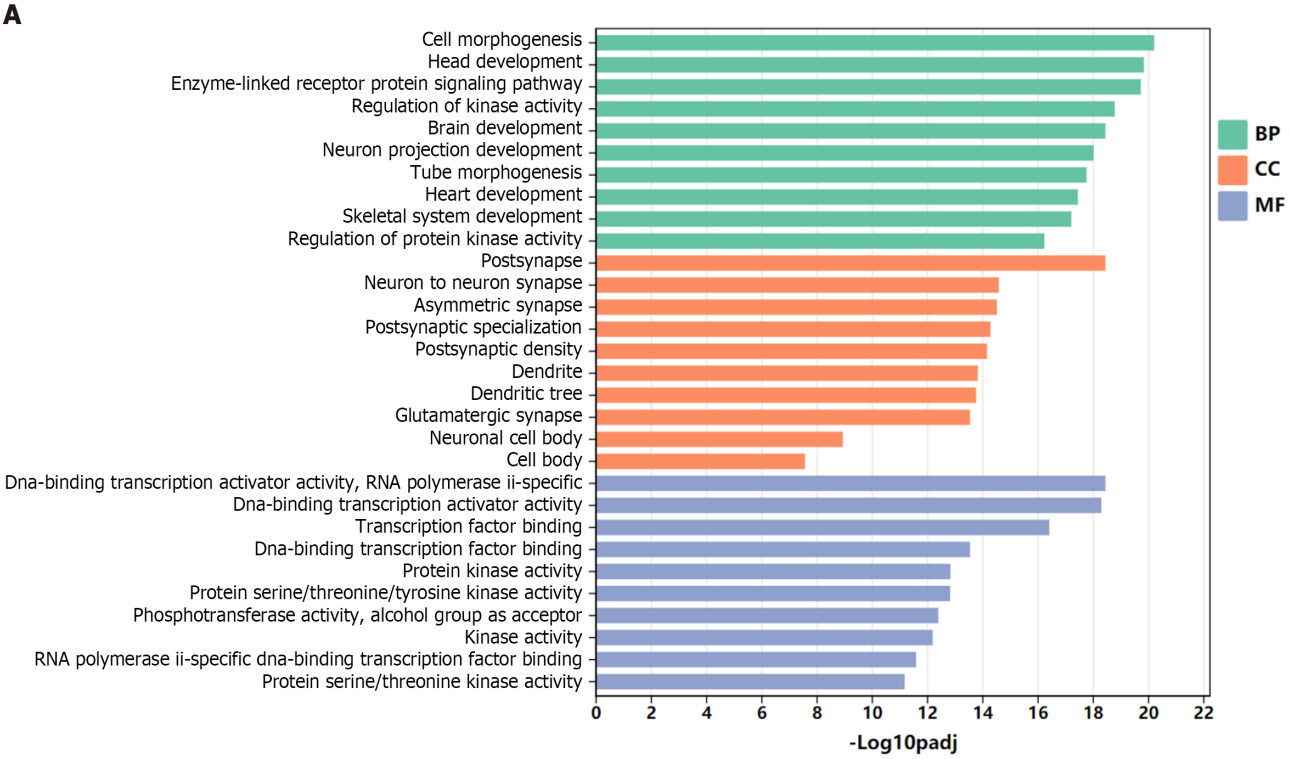
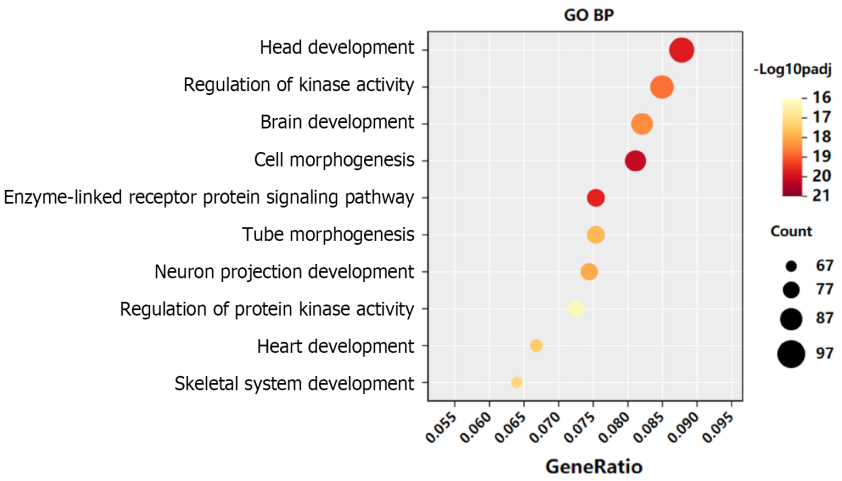
Inhibition of PTEN promote cell proliferation, migration, collagen synthesis and change the gene expression of fibroblastic-, tenogenic-, and chondrogenic-related factors in NIH3T3 cells



To explore whether BMSC-derived exosome promoted tendon bone healing by directly targeting PTEN in fibroblasts, SF1670, a specific PTEN inhibitor that binds to the active site of PTEN and increases cellular PtdIns(3,4,5)P3 levels and phosphorylation of Akt *in vitro*[19], was used to examine the effect of PTEN inhibition on NIH3T3 cells. The results showed that SF1670 significantly increased the phosphorylation level of Akt compared with DMSO group (Figure 8A). Moreover, BrdU and wound healing assays showed that SF1670 significantly increased proliferation (Figure 8B) and migration (Figure 8C) of NIH3T3 cells. Collagen contraction assays indicated that SF1670 significantly enhanced the contractility of NIH3T3 cells (Figure 8D). Finally, the properties necessary for tendon-bone healing was examined by quantitative real-time reverse transcription polymerase chain reaction. The results showed that the mRNA level of fibroblast-related genes (α-SMA and vimentin), tenogenic-related genes (TNMD and Col I), and chondrogenic-related genes (SOX-9 and Col II) were significantly up-regulated by SF1670 (Figure 9).

DISCUSSION



Tendon-bone healing has always been an important challenge in orthopedics and sports medicine research and clinical practice. Fibroblasts play a key role in early ligament remodeling and a large number of studies have verified the effective role of MSC-derived exosomes in tendon-bone healing[9-12]. However, because the status of MSCs may be influenced by their generations or donors, the expression of exosomal miRNAs may be more or less different. This presents difficulties in identifying the roles associated with MSC-derived exosomal miRNAs. On ground of this, three GEO datasets were interrogated through bioinformatics tools to determine key BMSC-derived exosomal miRNAs. Two candidate miRNAs (miRNA-144 and miRNA-23b) were obtained by intersecting the top 100 exosomal miRNAs in each dataset (Figure 2). Their target genes and hub genes were obtained subsequently. GO annotation and KEGG pathway enrichment analysis suggested that these genes were involved in multiple cellular processes (*e.g.*, regulation of kinase activity, transcription factor binding, and phospholipid metabolic process) and signaling cascades (*e.g.*, focal adhesion, and PI3K-Akt pathways). A miRNA-target gene interaction network indicated that PTEN was co-regulated by miRNA-144 and miRNA-23b (Figure 5G).

PTEN functions primarily *via* dephosphorylation of PIP3 to PIP2, resulting in negative regulation of the PI3K/Akt activity[23]. The PTEN/PI3K/Akt nexus participates in various physiological and pathological conditions, and plays an important role in regulating cell growth, apoptosis, metabolism and other processes[24]. Being the direct target of PTEN, PI3K/Akt is also involved in activation of fibroblasts[25,26]. In this study, the effect of PTEN on fibroblasts was also demonstrated. The results showed that inhibition of PTEN increased the level of Akt phosphorylation and promoted the proliferation and migration of fibroblasts (Figure 8), which suggest that PTEN plays an important role in the activation of fibroblasts.

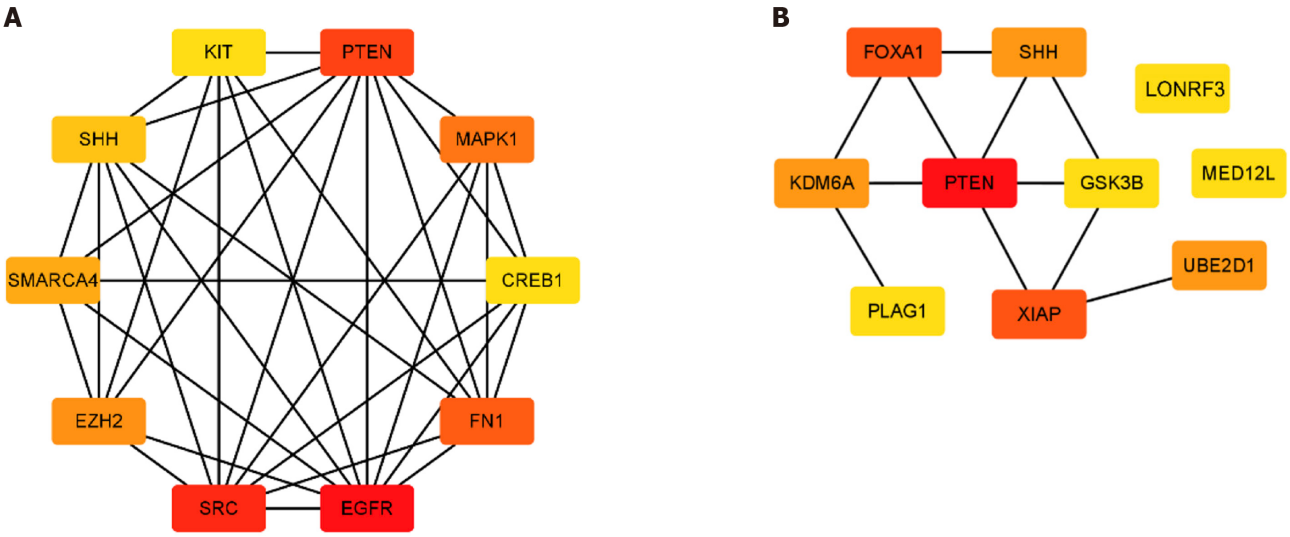
Normal TBI has a transitional structure consisting of four graduated layers including bone tissue, mineralized fibrocartilage layer, non-mineralized fibrocartilage layer and tendon tissue[27], which means that fibrogenesis, tenogenesis and chondrogenesis are key characteristics of tendon-bone healing. As the markers of fibrogenesis, α-SMA and vimentin are expressed in activated fibroblasts[28]. Similarly, tenomodulin (TNMD) and collagen I, collagen II and Sox-9 are well-acknowledged indicators for representing the activation of tenogenic and chondrogenic process[29,30]. By inhibiting PTEN, the results showed increased expression of fibroblastic, tenogenic and chondrogenic markers in fibroblasts (Figure 9), implying that PTEN and PI3K/Akt pathway may be targets for promoting tendon-bone healing.

In addition, this study found that SHH was also regulated by both miRNA-144 and miRNA-23b (Figure 5G). HH signaling pathway is a highly conserved pathway involved in embryonic development, tissue homeostasis and stem cell maintenance[31]. HH signaling is also involved in regulating proliferation of MSCs in adult tissues and plays critical roles in promoting tendon-bone healing[32-34]. SHH, one of three HH family members in mammals, acts in the early stages of development to regulate patterning and growth[35], and plays a crucial role in bone healing[36]. These evidences suggested that MSC-derived exosomal miRNAs may promote tendon-bone healing in more than one way.



The outcomes of the current study were guaranteed by several factors. In this study, three BMSC-derived exosomal miRNA expression microarray datasets were searched from the GEO repository to avoid batch differences. Moreover, due to the costs, technical challenges, and lack of biomarkers suitable for specific exosomes, it is difficult to isolate large number of pure and specific exosomes from mixtures of different vesicle types in a large volume of solution[37]. Therefore, this study identified the key pathway of exosomal miRNA through comprehensive analysis, providing a theoretical basis for developing methods to stably regulate the activation of fibroblasts and thus promote tendon-bone healing.

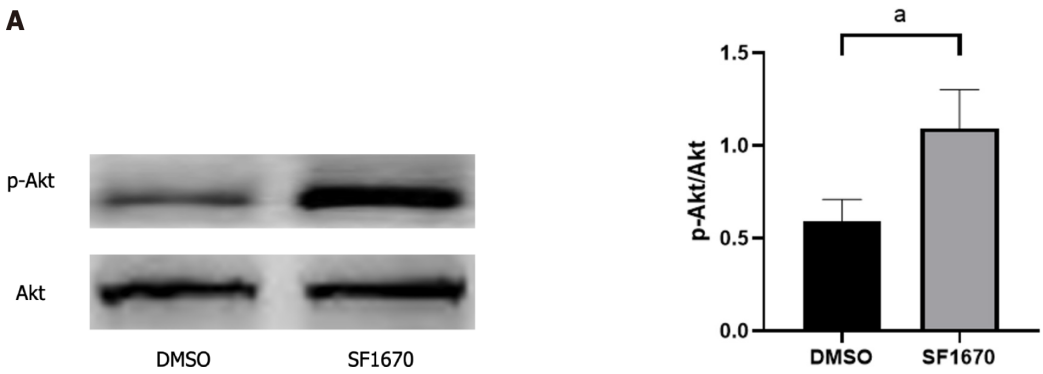
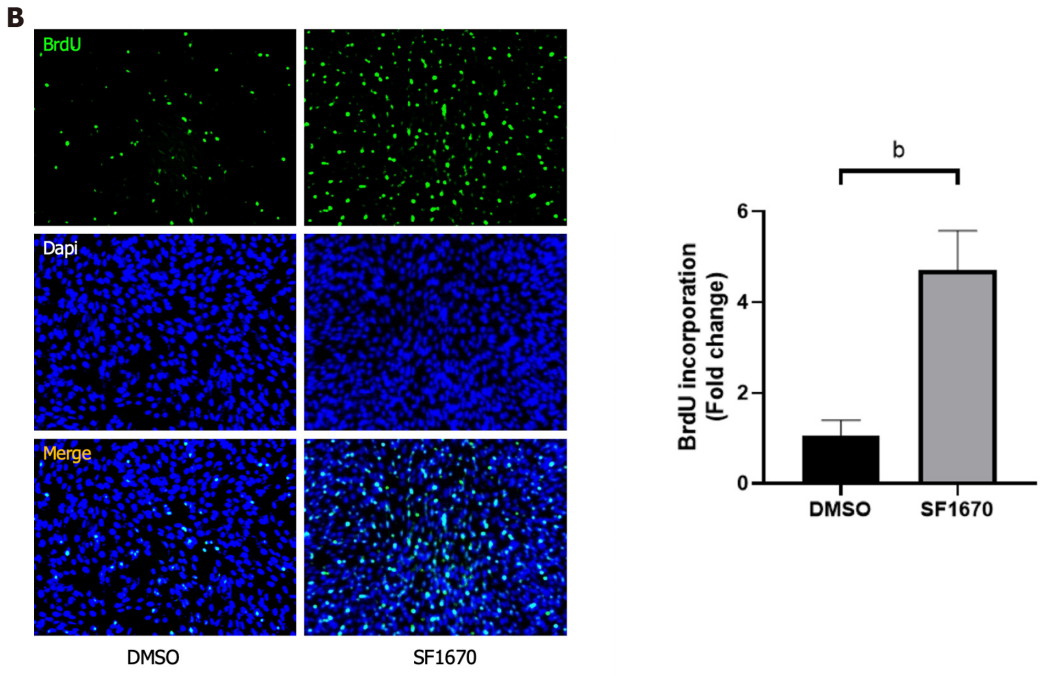
Data are shown as mean ± SD. $^{a}P < 0.05$, $^{b}P < 0.01$.

However, the outcomes should also be interpreted with caution. The biological functions of exosomal miRNAs are diverse, but this study only took the overlapped target gene, *i.e.*, PTEN, for analysis. Thus, further exploration is needed to pinpoint the specific functions of each miRNA. In addition, this study only used murine NIH3T3 cells *in vitro*. Experiments *in vivo* is needed to verify the reconstruction of the natural gradient structure of TBI.



CONCLUSION



BMSC-derived exosomes promote fibroblast activation possibly through the PTEN and PI3K/Akt signaling pathways, which may serve as potential targets to further promote tendon-bone healing.

ARTICLE HIGHLIGHTS

Research background

The normal tendon-bone insertion has a transitional structure consisting of four gradated layers including bone, mineralized fibrocartilage layer, non-mineralized fibrocartilage layer and tendon. This complex structure can disperse force from bone to tendon, preventing stress concentration. However, current therapeutic strategies cannot restore this structure, hence raising the risk of re-injury.

Research motivation

Recent evidence indicates that conditioned medium, primarily contains exosomes of mesenchymal stem cells (MSCs), can stimulate the activation of fibroblasts, thereby promoting tendon-bone healing. However, the underlying mechanism is not comprehensively understood. Moreover, the expression of exosome microRNA (miRNA) may vary depending on the status of MSCs, which presents difficulties in identifying the roles associated with MSC-derived exosomal miRNAs.

Research objectives

To identify overlapped bone marrow MSC (BMSC)-derived exosomal miRNAs in three GSE datasets and verify their effects as well as mechanisms on fibroblasts.

Research methods

BMSC-derived exosomal miRNAs data were downloaded from the Gene Expression Omnibus database. The candidate miRNAs were obtained by the intersection of different datasets. TargetScan was used to predict potential target genes. Functional and pathway analyses were conducted using the Gene Ontology and Kyoto Encyclopedia of Genes and Genomes databases. Hub genes in the protein-protein interaction (PPI) network were analyzed using Cytoscape software. The transcripts of the target gene were assessed by dual luciferase reporter assays. BrdU, wound healing assay, collagen contraction assay and the expression of COL I and α-smooth muscle actin positive were applied to investigate the cell proliferation, migration and collagen synthesis.

Research results

Bioinformatics analyses showed two BMSC-derived exosomal miRNAs, has-miR-144-3p and has-miR-23b-3p, were overlapped in three GSE datasets. PPI network analysis and functional enrichment analyses indicated that both miRNAs regulated the PI3K/Akt signaling pathway by targeting phosphatase and tensin homolog (PTEN). *In vitro* experiments confirmed that both miRNAs stimulated proliferation, migration and collagen synthesis of NIH3T3 fibroblasts. Interfering with PTEN affected the phosphorylation of Akt and thus activated fibroblasts.

Research conclusions

BMSC-derived exosomes promote fibroblast activation possibly through the PTEN and PI3K/Akt signaling pathways, which may serve as potential targets to further promote tendon-bone healing.

Research perspectives

Further exploration is needed to pinpoint the specific functions of exosomal miRNAs. *In vivo* studies may better reveal the effect of exosomal miRNAs on tendon-bone healing.

Abstract

BACKGROUND

There is no established treatment to impede the progression or restore kidney function in human chronic kidney disease (CKD).

AIM
To examine the efficacy of cultured human CD34+ cells with enhanced proliferating potential in kidney injury in mice.

METHODS
Human umbilical cord blood (UCB)-derived CD34+ cells were incubated for one week in vasculogenic conditioning medium. Vasculogenic culture significantly increased the number of CD34+ cells and their ability to form endothelial progenitor cell colony-forming units. Adenine-induced tubulointerstitial injury of the kidney was induced in immunodeficient non-obese diabetic/severe combined immunodeficiency mice, and cultured human UCB-CD34+ cells were administered at a dose of 1×10^6/mouse on days 7, 14, and 21 after the start of adenine diet.

RESULTS
Repetitive administration of cultured UCB-CD34+ cells significantly improved the time-course of kidney dysfunction in the cell therapy group compared with that in the control group. Both interstitial fibrosis and tubular damage were significantly reduced in the cell therapy group compared with those in the control group ($P < 0.01$). Microvasculature integrity was significantly preserved ($P < 0.01$) and macrophage infiltration into kidney tissue was dramatically decreased in the cell therapy group compared with those in the control group ($P < 0.001$).

CONCLUSION
Early intervention using human cultured CD34+ cells significantly improved the progression of tubulointerstitial kidney injury. Repetitive administration of cultured human UCB-CD34+ cells significantly improved tubulointerstitial damage in adenine-induced kidney injury in mice *via* vasculoprotective and anti-inflammatory effects.

Key Words: Chronic kidney disease; CD34+ cell; Adenine; Tubulointerstitial injury; Quality and quantity control culture; Umbilical cord blood

Core Tip: There is no established treatment for retarding the progression or improving advanced chronic kidney disease (CKD). Here, we provided effectiveness of cord blood derived cultured human CD34+ cell on progressive CKD model in mice. Kidney function and pathological damage were improved by repetitive cell therapy along with the improvement of microvasculature and inhibition of inflammatory cell infiltration in the kidney. Enhanced cell potential (proliferation and increase of endothelial progenitor cell colony-forming unit) by culture might be a key factor for improving progressive kidney injury.

INTRODUCTION

Chronic kidney disease (CKD) is a progressive disease that leads to end-stage renal disease (ESRD) with increasing incidence and mortality[1]. Incomplete recovery from acute kidney injury (AKI) can also lead to CKD (AKI-CKD transition) through tubular atrophy and failed tubular recovery[2]. CKD affected nearly 750 million people globally in 2016 and constitutes a serious public health burden worldwide[3]. Several treatment strategies, including pharmaceutical therapies, such as renin-angiotensin-aldosterone blockers, and diet control, including salt and protein restriction, have been applied to impede CKD progression. However, satisfactory outcomes have not been achieved. Considering the progressive nature of CKD, which is associated with high mortality rates, especially in late-stage CKD patients, including those undergoing dialysis, there is a pressing need to develop novel therapeutic strategies to treat CKD.

The efficacy of cell-based regenerative therapy in animal models of CKD has been tested, and preclinical studies have provided favorable results[4]. Cell-based therapy has been shown to improve functional and histological parameters of kidney injury and delay the development of CKD in animal

models[4]. However, clinical trials of cell-based therapy for CKD in humans are still limited, with only three clinical trials published[5-7]. These trials used single administration of autologous bone marrow-derived mesenchymal stem cells[5,6] or granulocyte colony-stimulating factor-mobilized autologous peripheral blood-derived CD34+ cells[7]. Although the safety and tolerability of cell therapy were confirmed, the efficacy in improving or stabilizing renal dysfunction was not established by these early phase trials.

Adenine-induced renal injury in mouse is used as a model of chronic kidney injury caused by 2,8-dihydroxyadenine (DHA), a metabolic product of adenine[8,9]. The primary site of adenine-induced renal injury is the tubulointerstitial region. Accumulation of DHA crystals in the renal tubules and interstitial tissue causes progressive degeneration of tubular epithelial cells and induces interstitial fibrosis. Moreover, adenine-containing diet induces chronic and progressive renal injury in mice in a dose-dependent manner. This animal model is suitable for evaluating the efficacy of cell-based therapy for progressive tubulointerstitial injuries. However, to evaluate the efficacy of xenotransplantation of human cells, the animal's immune response has to be avoided. Therefore, we stablished an adenine-induced renal injury model in non-obese diabetic/severe combined immunodeficiency (NOD/SCID) mice, which lack mature T, B, and natural killer cells.

Human CD34+ endothelial progenitor cells (EPC) have high angiogenic and anti-inflammatory potential, and thus used for this study[10,11]. However, because EPCs from patients with several diseases have impaired function and are insufficient, allogeneic sources are considered as good alternatives. We therefore used umbilical cord blood (UCB)-derived CD34+ cells. However, in our preliminary study, uncultured human UCB-derived CD34+ cell administration could not effectively retard the progression of chronic kidney injury in this model. Hence, we cultured UCB-CD34+ cells to enhance their vasculogenic potential using the quality and quantity culture (QQc) method, which was established for EPCs[12], and used in our previous report[13]. Once or twice administration of human UCB-QQc-CD34+ cells could not improve the time-course of kidney injury. However, administration of human UCB-QQc-CD34+ cells once a week for 3 consecutive weeks demonstrated a significant improvement of kidney function and reduction of renal histological damages. This is the first report of the application of human UCB-QQc-CD34+ cells as an effective regenerative therapy for CKD.

MATERIALS AND METHODS

Cell preparation

Human UCB-CD34+ cells were purchased from the RIKEN Bioresource Center (Tsukuba, Japan), plated at a density of 1 × 10^4 cells/well in a 24-well tissue culture plate (BD Falcon, Bedford), and cultured in QQc media for 7 d as previously described[12,13]. QQc uses a serum-free StemSpan SFEM media (Stem Cell Technologies, Vancouver, BC, Canada) with an optimized combination of growth factors as well as cytokines (20 ng/mL thyroid peroxidase, 20 ng/mL interleukine-6, 100 ng/mL SCF, 100 ng/mL Flt-3 Ligand, and 50 ng/mL vascular endothelial growth factor). All reagents were purchased from PeproTech Inc. (Rocky Hill, NJ, United States). This culture method significantly enhanced the vasculogenesis, proliferation, and colony-forming units of CD34+ cells[10]. UCB-CD34+ cells from five separate samples were cultured, and cell populations of pre- and post-QQc human UCB-CD34+ EPCs were evaluated using FACS analysis (FACSVerse™, BD, United States). FlowJo™ (version 10.6, BD, United States) was used for data analysis.

EPC colony-forming assay

EPC colony-forming units (EPC-CFUs) of pre-QQc and post-QQc human UCB-CD34+ cells were assessed using a colony-forming assay as previously described[12,13]. The EPC colony-forming assay was designed to evaluate the vasculogenic potential of EPCs and categorize total EPC-CFUs (TEPC-CFUs) into two different types of EPC-CFUs: Primitive (small cell-sized) and definitive (large cell-sized). Primitive EPC-CFUs (PEPC-CFUs) have greater potential for proliferation, whereas definitive EPC-CFUs (DEPC-CFUs) are predominantly vasculogenic populations with a greater differentiation potential. Briefly, 500 human UCB-CD34+ cells per dish were seeded into a 35-mm hydrophilic tissue culture dish. Ten to fourteen days later, total EPC colony-forming unit (TEPC-CFUs), PEPC-CFUs, and DEPC-CFUs were counted under light microscopy by two investigators who were blinded to the experimental conditions. Five samples of UCB-CD34+ cells were used for EPC colony-forming assay. All experiments were performed in triplicate.

Mice

Six-week-old male NOD/SCID mice were purchased from Charles River Laboratories Inc. (Tsukuba, Japan) and used for all experiments. All animal use was in accordance with institutional and ARRIVE guidelines (https://arriveguidelines.org). The experimental protocol was approved by the Administration Committee of Experimental Animals at Kamakura Techno-science, Inc. (No. 20-034, 20-079, Kanagawa, Japan).

Adenine-induced chronic tubulointerstitial kidney injury

The CKD animal model (adenine-induced chronic tubulointerstitial kidney injury) using NOD/SCID mouse was developed in collaboration with Kamakura Techno-science, Inc. First, several doses of adenine were used to optimize and induce progressive tubulointerstitial kidney injury. Kidney damage showed a dose-dependent pattern, and the optimized dose and period of adenine diet ingestion were finally determined as 0.14% and 3 wk, respectively.

The experimental design is shown in Figure 1. Thirty-five male NOD/SCID mice were used in this experiment. All mice had free access to tap water, and were fed a 0.14% (w/w) adenine-containing diet from day 0 to day 21. The adenine-containing diet was stopped on day 21 and changed to standard laboratory chow diet (CRF-1 powder diet, Oriental Yeast Co., Ltd., Tokyo, Japan) from days 22 to 28 in all mice. Body weight and food intake were measured weekly. Blood sampling from the tail vein was performed on days 0, 7, 14, 21, and 28. After evaluating the serum creatinine levels on day 7, the mice were divided into two groups, *i.e.*, control group (n = 17) and the cell therapy group (n = 18). After blood sampling on day 28, mice were anesthetized using isoflurane, and kidney tissues were collected for histological analysis. All animal experiments were performed at Kamakura Techno-science, Inc. (Kanagawa, Japan).

Cell transplantation

Mice in the control group were injected with 100 μL of vehicle (Iscove's modified Dulbecco's medium: IMDM), and those in the cell therapy group were injected with 1 × 10^6 UCB-QQc-CD34+ cells in 100 μL IMDM *via* the tail vein. UCB-QQc-CD34+ cells were administered three times on days 7, 14, and 21. Cell purity and viability were evaluated just before cell therapy.

Kidney function and renal histology

Serial blood samples were drawn from the tail vein on days 0, 7, 14, 21, and 28, and serum creatinine levels were immediately measured using DRI-CHEM CRE-P III (FUJIFILM Co., Ltd., Tokyo, Japan). Kidney tissues were harvested and fixed in 4% paraformaldehyde, transferred to 70% ethanol, and embedded in paraffin. From these paraffin blocks, 2 μm-thick sections were prepared and stained with periodic acid-Schiff (PAS) and Masson's trichrome (MT) stain for analysis of tubular damage and interstitial fibrosis, respectively. To examine the extent of tubulointerstitial injury, 10 non-overlapping fields from the entire cortical and outer medulla areas in PAS-stained specimens and MT-stained specimens were captured under 100 × magnification. Tubulointerstitial injury in PAS-stained sections were categorized as tubular dilatation with epithelial and tubular atrophy. The degree of injury was scored on a scale of 0 to 4 according to the percentage of the damaged area; 0: 0%, normal; 1, 0%-25%; 2, 25%-50%;3, 50%-75%; and 4, 75% or more. Interstitial fibrosis in MT-stained sections was quantified as fibrotic area per total area (%) and measured using an automatic image analyzer (cellSens, Olympus, Japan). Tubulointerstitial injury score and interstitial fibrosis area were evaluated in each mouse (n = 17 in the control group and n = 18 in the cell therapy group), and mean values in each mouse were used to calculate the group mean value for further comparison between the control group and cell therapy group.

CD31 and F4/80 immunohistochemistry

Since CD31 antigen is constitutively expressed on the endothelial cell surface, the loss of CD31-positive staining most likely reflects capillary loss. We performed CD31 immunostaining to evaluate peritubular capillary (PTC) loss using 3 μm-thick paraffin sections. PTCs were identified by immunostaining with a rabbit monoclonal anti-CD31 (PECAM-1) antibody (1:100; #77699, Cell Signaling Technology, Danvers, MA, United States). Immunostaining was performed using a BOND-III autostainer (Leica Biosystems, Wetzlar, Germany) according to the manufacturer's protocol. Briefly, after deparaffinization of paraffin sections, heat-induced epitope retrieval was performed using BOND Epitope Retrieval Solution 2 (prediluted, pH 9.0; Leica Biosystems, Wetzlar, Germany) for 20 min at 100 °C. Sections were incubated sequentially with endogenous peroxidase block for 5 min, primary antibody for 30 min, secondary detection polymer for 10 min, diaminobenzidine for 10 min, and hematoxylin for 5 min.

PTC density was evaluated according to a previously published method with some modifications [11]. Twenty randomly selected fields encompassing the renal cortex and outer medulla were randomly captured by digital imaging (× 400). Each image was divided into 270 squares using a grid, and the number of squares with CD31-positive staining was counted. The PTC density was represented as a percentage of CD31 positive squares per total number of squares.

Macrophages were identified using a rabbit polyclonal anti-F4/80 antibody (1:100; ab100790, Abcam, Cambridge, United Kingdom). Ten non-overlapping fields in the cortical and outer medulla areas were randomly selected and captured by digital imaging (× 100). The degree of macrophage infiltration was calculated using the 270-square grid method, as described above. The rate of macrophage infiltration was represented as a percentage of F4/80- positive squares relative to the entire cortical and outer medulla areas. Macrophage infiltration rate and PTC density were assessed in the control group and cell therapy group.

Figure 1 Experimental design. The adenine-containing diet was fed from day 0 to day 21, and switched to a standard laboratory diet from day 22 to day 28. Vehicle (IMDM) or UCB-CD34+ cells in IMDM were administered on days 7, 14, and 21 *via* the tail vein in the control group and cell therapy group, respectively. IMDM: Iscove's modified Dulbecco's medium; UCB: Umbilical cord blood.

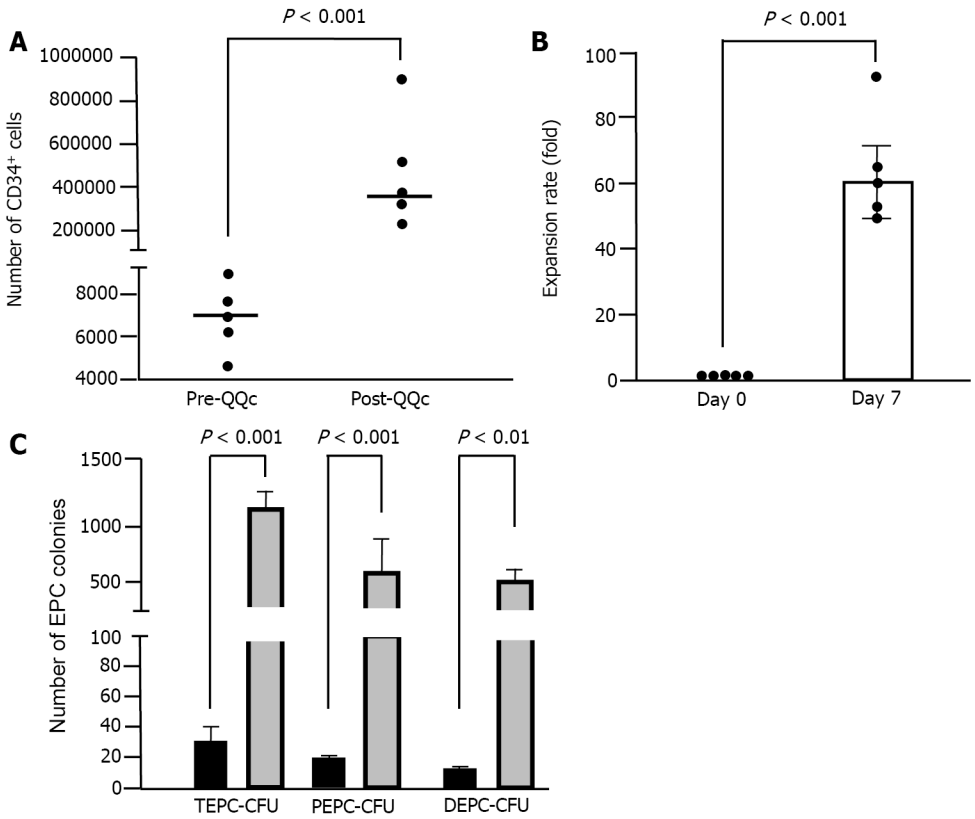
Statistical analysis

All data are expressed as the mean ± SE, unless otherwise specified. Comparison between two groups were performed using the Mann-Whitney *U* test. Differences in time-course of serum creatinine levels during the experimental period between the control group and the cell therapy group were analyzed using repeated measures analysis of variance (ANOVA). Statistical analysis was performed using SPSS version 11.0 software (SPSS Inc., Chicago, IL, United States) and a P value < 0.05 was considered statistically significant.

RESULTS

Effect of the QQc on CD34+ cell expansion and EPC-CFUs

The QQc significantly increased the number of CD34+ cells. CD34+ positivity per the 1 × 10^4 initially seeded cells was significantly increased in post-QQc-CD34+ cells compared with that in pre-QQc-CD34+ cells (353821 ± 122429 *vs* 7341 ± 947, P < 0.001) (Figure 2A). Cell viability of QQc-CD34+ cells was higher than that of pre-QQc CD34+ cells (93.6% ± 1.3% *vs* 87.0% ± 0.8%, P < 0.01). After seven days of culturing using the QQc method, the number of CD34+ cells showed almost a 60-fold increase on day 7 compared with that on day 0 (59.0 ± 10.4 *vs* 1-fold, P < 0.001) (Figure 2B). Post-QQc CD34+ cells formed more TEPC-CFUs than did pre-QQc CD34+ cells (1138.0 ± 124.0 *vs* 27.0 ± 4.5, P < 0.001) (Figure 2C). Moreover, both PEPC-CFUs and DEPC-CFUs showed a significant increase after QQc compared with pre-QQc (PEPC-CFUs: 17.4 ± 3.0 *vs* 666.0 ± 127.5, P < 0.001; DEPC-CFUs: 9.4 ± 2.5 *vs* 472.0 ± 112.0, P < 0.01).



QQc-CD34+ cells improved kidney function

The body weight was not significantly different between the cell therapy and control groups on days 0, 7, 14, 21, and 28. Diet consumption was also comparable between the two groups throughout the experimental period (data not shown).

To evaluate the role of UCB-QQc-CD34+ cell therapy in renal injury, serum creatinine levels were determined in the cell therapy and control groups. The time-course in serum creatinine levels is shown in Figure 3A. Serum creatinine levels were not statistically different between the cell therapy and control groups (0.56 mg/ dL ± 0.02 mg/dL *vs* 0.61 mg/dL ± 0.03 mg/dL) on day 0. During adenine-containing diet feeding, serum creatinine levels showed a gradual and constant increase in the control group (1.51 mg/dL ± 0.14 mg/dL on day 21) demonstrating a state of renal dysfunction. After switching to the standard diet on day 22, serum creatinine levels in the control group decreased to 1.41 mg/dL ± 0.14 mg/dL on day 28. In the cell therapy group, serum creatinine levels increased until day 14 and then showed a gradual increasing trend on day 21 (1.29 mg/dL ± 0.09 mg/dL). After switching to the standard diet, serum creatinine levels decreased to 1.09 mg/dL ± 0.09 mg/dL on day 28 in the cell therapy group. Time-course of serum creatinine levels between the control and the cell therapy groups showed borderline significance (P = 0.06). However, the relative ratio of changes in serum creatinine levels from day 0 to day 28 showed a statistically significant difference between the control and the cell therapy groups (255.1% ± 25.9% *vs* 185.9% ± 18.5%, P = 0.035) (Figure 3B). Thus, repetitive administration of UCB-QQc-CD34+ cells significantly improved the time-course of adenine-induced chronic kidney injury.

QQc-CD34+ cells reduced interstitial fibrosis and tubular damage

The adenine-containing diet induced prominent tubular damage, including tubular dilatation and

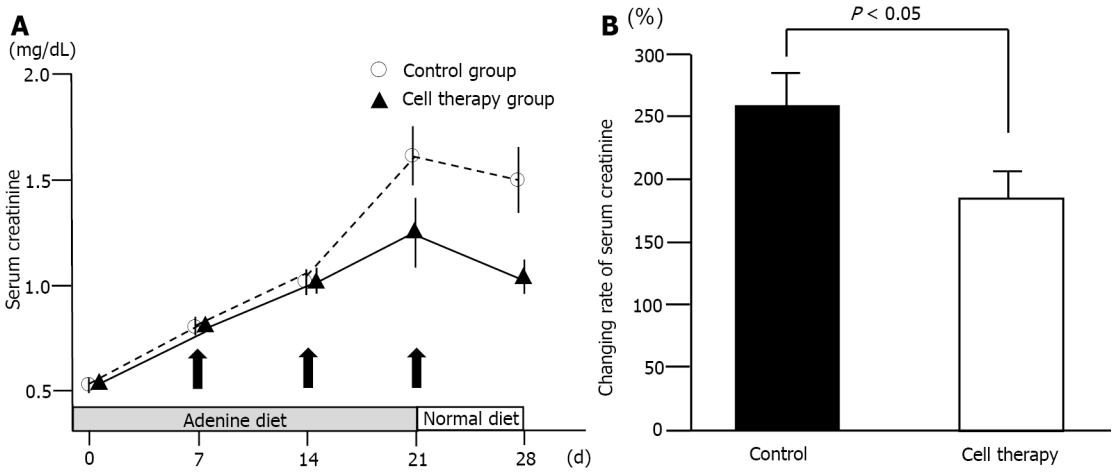
Figure 2 CD34+ cell and endothelial progenitor cell colony-forming units expansion by quality and quantity culture method. A: Number of total CD34+ cells. The plot graph demonstrates CD34+ positivity per 1 × 10^4 fresh UCB-CD34+ sample and post-culture CD34+ cell number per 1 × 10^4 initially seeded cells; B: Expansion rate of CD34+ cells. The expansion rate of CD34+ cells from fresh CD34+ cells (day 0) to cultured CD34+ cells (day 7); C: Endothelial progenitor cells (EPC) colony-forming unit. The number of TEPC-CFUs, primitive EPC-CFUs, and definitive EPC-CFUs of post- quality and quantity culture (QQc) CD34+ cells. Gray column: Significantly increased compared with that of pre-QQc CD34+ cells; black column: Statistical significances in Figure 2A-C were determined using Mann-Whitney *U* test. UCB: Umbilical cord blood; EPC: Endothelial progenitor cell; CFU: Colony-forming unit; QQc: Quality and quantity culture; TEPC: Total endothelial progenitor cell; PEPC: Primitive endothelial progenitor cell; DEPC: Definite endothelial progenitor cell.

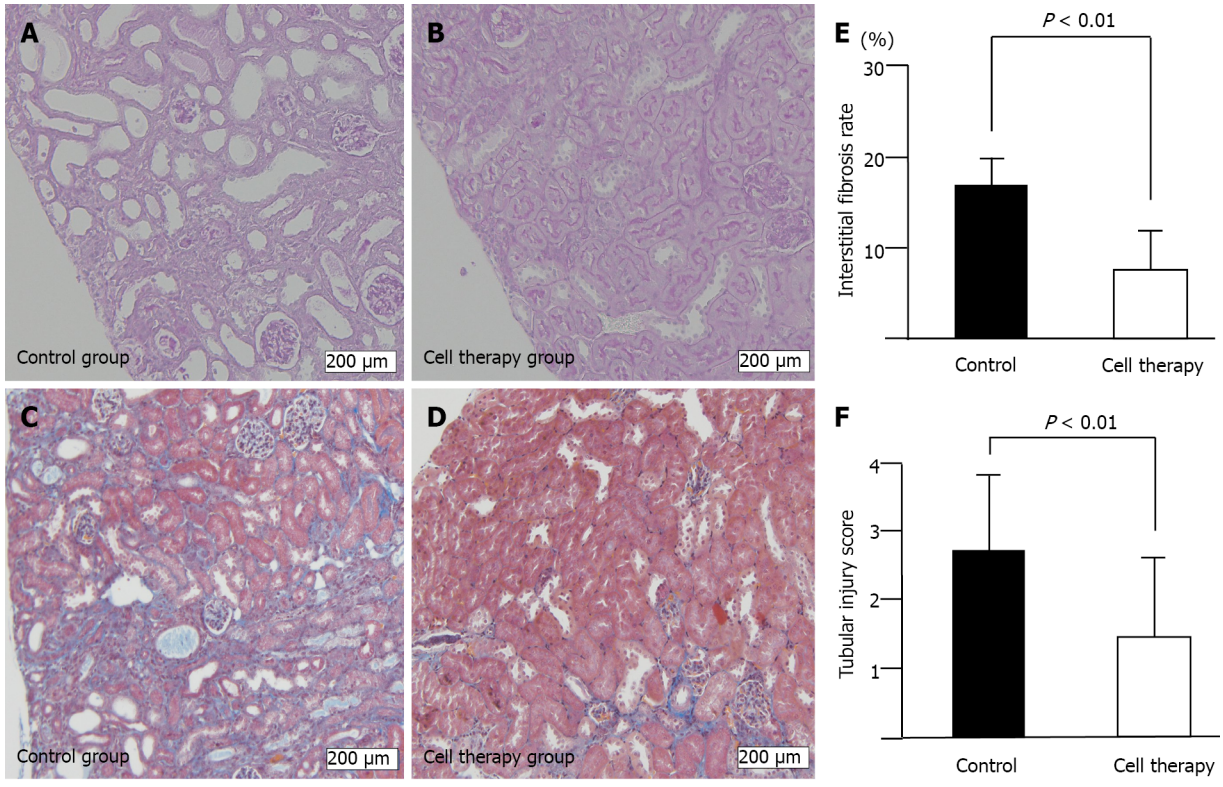
tubular atrophy accompanied by interstitial fibrosis (Figure 4A-D). In line with the reduced time-course of renal injury in cell therapy mice, the interstitial fibrosis area was significantly reduced in the cell therapy group compared with that in the control group (8.1% ± 5.4% *vs* 16.3% ± 7.0%, $P < 0.01$) (Figure 4E). The tubular damage score was also significantly decreased in the cell therapy group compared with that in the control group (1.48 ± 1.27 *vs* 2.83 ± 1.00, $P < 0.01$) (Figure 4F).



PTC density and macrophage infiltration

Representative images of PTC density as evaluated by CD31 immunohistochemical staining are shown in Figure 5. CD31+ staining was significantly decreased, especially around the dilated and degenerated tubules, in this model (Figure 5A). The cell therapy group showed significantly higher PTC density than did the control group (57.3% ± 6.4% *vs* 31.0% ± 6.1%, $P < 0.01$) (Figure 5B and C).

Macrophage infiltration is shown in Figure 6. Infiltration of F4/80-positive macrophages was mainly observed in the area with interstitial fibrotic changes and dilated and degenerated tubules in the control group (Figure 6A). However, macrophage infiltration was dramatically reduced in the cell therapy group compared with that in the control group (1.3% ± 0.3% *vs* 14.4% ± 1.1%, $P < 0.001$) (Figure 6B and C).



DISCUSSION

We demonstrated that repetitive administration of human UCB-QQc-CD34+ cells significantly improved the time-course of adenine-induced tubulointerstitial injury in mice. The relative changes in serum creatinine levels from baseline to day 28 were significantly improved in the cell therapy group compared with those in the control group. Interstitial fibrosis area and tubulointerstitial injury score were also significantly improved by cell therapy. The PTC network, visualized by CD31+ staining, was found to be severely damaged in adenine-induced kidney injury. However, PTC rarefaction was

Figure 4 Histological analysis of renal injury. A and B: Tubular injury including tubular dilatation, tubular epithelial atrophy, and tubular atrophy, evaluated using periodic acid-Schiff-stained renal tissue sections of control group (A) and cell therapy group (B); C and D: Interstitial fibrosis using Masson's trichrome stained sections of control group (C) and cell therapy group (D). Scale bar: 200 μm; E: Quantitative analysis of interstitial fibrosis rate, and F: semi-quantitative analysis of tubular injury score. Statistical significance of Figure 4E and F were determined using Mann-Whitney U test.

significantly improved by cell therapy. Furthermore, macrophage infiltration was dramatically reduced in the cell therapy group. These results might imply the significant potential of CD34+ cell-based therapy for clinical application in CKD.

CKD progression is caused by multiple factors, including diabetes, hypertension, and glomerulonephritis. Regardless of the diverse causes of CKD, tubulointerstitial damage is the final common pathway that results in its transition to ESRD[14]. Therefore, one major target of cell-based regenerative therapy for CKD is the arrest of chronic tubular and interstitial damage. Loss of integrity of the

Figure 5 Peritubular capillary density evaluation using CD31+ staining. A and B: CD31+ immunostaining of peritubular capillary (PTC) in control group (A) and cell therapy group (B); original magnification (× 400). Scale bar: 100 μm; C: Quantitative analysis of PTC density. Statistical significance in Figure 5C was determined using Mann-Whitney *U* test.

intrarenal microvasculature is also a major contributor to the progression of renal diseases[15-17]. Tubular damage, interstitial fibrosis, and microvasculature impairment are associates with each other and form a vicious cycle to promote CKD[18-24]. A close association between PTC rarefaction and tubulointerstitial fibrosis has been proven in the human kidney[20]. Hypoxia due to PTC rarefaction induces the production of local inflammatory cytokines[25], which in turn, worsen hypoxia in inflamed tissues. Thus, hypoxia also creates a vicious cycle of inflammation[26].

CD34+ cells have been used in regenerative therapy for several organ damages, including critical limb ischemia[27,28], myocardial ischemia[29], stroke[30], and acute kidney injury[31]. CD34+ cells possess two important properties that are considered necessary for regenerative therapy: Enhanced angiogenic and anti-inflammatory potential[10,11]. Externally administered CD34+ EPCs improved kidney injury such as endothelial cell damage in several animal models[13,15,19,32-35]. In cases of acute and severe renal endothelial cell injury, intrinsic repair may not function sufficiently[36]. Furthermore, endothelial disturbances related to ischemia induce permanent damage to PTCs[37]. Therefore, a strategy for vascular protection or angiogenesis might be important for the long-term preservation of kidney function. Recently, horizontal transfer of regenerative information *via* extracellular vesicles (EVs) between regeneration associated stem/progenitor cells and injured cells in the damaged organ was shown to be a major regenerative mechanism. Exosomes from human CD34+ cells, by themselves, have demonstrated angiogenic activity in *in vivo* and *in vitro* experiments[38,39]. Hence, CD34+ based cell therapy could be an excellent strategy to induce vasculogenesis and repair kidney function.

Regarding cell administration, frequency of transplantation as well as the number and regenerative potential of transplanted cells is thought to be very important. Multiple rather than single administration might show more advantages to improve organ damage. Lv *et al*[40] demonstrated that multiple administration of UCB-mesenchymal stem cells showed a superior therapeutic effect compared with that of single administration in an animal model of chemotherapy-induced premature ovarian failure. We also demonstrated that repetitive administration (3 times, once in a week) of cultured UCB-CD34+ cells significantly improved the time-course of adenine-induced chronic kidney injury. The causative signals for CKD, including oxidative stress, tissue hypoxia, and inflammatory cell infiltration with the release of inflammatory cytokines continuously injure the kidney. Therefore, multiple administration of regeneration-associated CD34+ cells at fixed time intervals might be a better treatment strategy for CKD. For the number of administered cells, 1 × 10^6 cells/20 g mouse is equivalent to about 50 × 10^6/kg

Figure 6 Macrophage infiltration analysis. A and B: F4/80+ macrophage immunostaining (arrows) in control group (A) and cell therapy group (B); original magnification (× 400). Scale bar: 100 μm; C: Quantitative analysis of the rate of macrophage infiltration area. Statistical significance in Figure 6C was determined using Mann-Whitney *U* test.

in humans, an amount that is probably not achievable clinically. It is known that in cases of cell administration *via* the tail vein in mice, many cells are trapped in the lung, spleen, and bone marrow (extra-renal trap)[13]. Extra-renal trap might necessitate more cells to be administered in mice to deliver sufficient number of cells into the kidney. Therefore, future clinical trials should consider the route of cell administration. To get better effects in future clinical trials, cells should be designed for direct arterial administration.

Herein, we used human UCB-derived CD34+ cells. UCB-CD34+ cells can be used as an off-the-shelf treatment. Because EPCs from patients with several diseases have impaired function and are insufficient, allogeneic source is considered as a good alternative. Immune reaction against allogeneic cells might limit their use. However, a recent study reported the immunosuppressive effect of cultured human EPCs. The proliferation and activation of mouse T cells were significantly suppressed by co-culture with allogeneic human UCB-EPCs[41]. Therefore, cultured UCB-EPCs with enhanced potential might have a chance of emerging as a possible tool for allogeneic cell therapy. One major limitation to using UCB-CD34+ cells is the limited number obtained from one UCB donor. Regarding this, QQc of UCB-CD34+ cells significantly increased the number of CD34+ cells (almost 60 folds) in one week, and EPC-CFUs (total, primitive, and definite EPC-CFUs) were significantly increased. The increased UCB-CD34+ cell number enabled multiple administration. Furthermore, the enhanced vasculogenic and anti-inflammatory potential of UCB-CD34+ cells might be critical for preserving PTC integrity and reducing inflammatory cell infiltration.

There are several limitations to this study. First, the effect of tissue hypoxia was not evaluated to establish the relationship among tubular damage, interstitial fibrosis, PTC integrity, macrophage infiltration, and hypoxia in the kidney tissue of control and cell therapy-treated mice. Second, the cellular behavior of UCB-CD34+ cells (homing and staying in injured kidney) remain undetermined. Third, we could not compare the contents (mRNA, miRNA, and proteins, including growth factors and cytokines) of EVs of pre-QQc and post-QQc UCB-CD34+ cells. Therefore, the EV-mediated mechanism by which UCB-QQc-CD34+ cells showed an effective response in repairing kidney injury remains to be elucidated. We evaluated the effect of cell therapy during the progressive phase, and not the advanced ESRD stage. Therefore, it is unclear whether cell therapy might be effective at the ESRD stage. Stopping adenine diet induced recovery from dysfunction. However, it remains unknown whether stopping

adenine diet without cell therapy brings kidney function completely to normal, because we did not conduct a longer follow-up after switching adenine diet to normal chow. At the same time, we could not elucidate whether the effects of cell therapy were long-lasting since the animals were sacrificed only one week after the last dose of cells. These limitations should be addressed in future research.

CONCLUSION

In conclusion, although the more precise mechanisms should be clarified, this study provides a new insight in the field of regenerative medicine. Repetitive administration of human UCB-QQc-CD34+ cells improved kidney function and reduced histological damage in adenine-induced tubulointerstitial injury. Tubular damage and interstitial fibrosis were significantly improved by cell therapy in accordance with improved PTC integrity and reduced inflammatory cell infiltration. Hence, clinical trials using repetitive administration of regenerative CD34+ cells with enhanced proliferative and angiogenic potential might be expected for patients with progressive CKD.

ARTICLE HIGHLIGHTS

Research background

Chronic kidney Disease (CKD) constitutes a serious public health burden worldwide, and there is no established treatment to impede the progression or restore kidney function in human CKD.

Research motivation

To discover and establish a new effective treatment for CKD is urgently needed. Cell-based therapy has a potential as a new effective treatment for progressive CKD.

Research objectives

To evaluate the efficacy of cultured human cord-blood-derived CD34+ cells.

Research methods

Progressive tubulointerstitial injury with kidney dysfunction was made in mice. Human umbilical cord blood (UCB)-derived CD34+ cells were incubated in vasculogenic conditioned medium for 1 wk to increase the number of CD34+ cells and ability to form endothelial progenitor cell (EPC)-colony-forming units. These cultured human CD34+ cells were administered on days 7, 14, and 21 after the start of adenine diet.

Research results

Cell therapy significantly improved the time-course of progressive kidney dysfunction. Pathological injuries including tubular injury and interstitial fibrosis were significantly reduced in the cell therapy group compared with those in the control group. Preserved microvasculature integrity and decreased macrophage infiltration were shown in the cell therapy group.

Research conclusions

Early intervention using human cultured CD34+ cells significantly improved the progression of tubulointerstitial kidney injury.

Research perspectives

In future research, the efficacy of cultured human CD34+ cells for more advanced CKD such as end-stage renal disease (ESRD), cell behavior (homing and staying in injured kidney) after cell administration, differences in extracellular vesicles from pre- and post-incubated UCB-derived CD34+ cells, should be evaluated for further analysis of the efficacy of cell therapy. A future clinical trial of cell therapy for progressive CKD might be expected.

ABOUT COVER

Editorial Board Member of *World Journal of Stem Cells*, María Beatriz Durán Alonso, PhD, Assistant Professor, University of Valladolid, Department of Biochemistry and Molecular Biology and Physiology, Institute of Biomedicine and Molecular Genetics, Valladolid 47003, Spain. mariabeatriz.duran@uva.es

AIMS AND SCOPE

The primary aim of *World Journal of Stem Cells* (*WJSC*, *World J Stem Cells*) is to provide scholars and readers from various fields of stem cells with a platform to publish high-quality basic and clinical research articles and communicate their research findings online. *WJSC* publishes articles reporting research results obtained in the field of stem cell biology and regenerative medicine, related to the wide range of stem cells including embryonic stem cells, germline stem cells, tissue-specific stem cells, adult stem cells, mesenchymal stromal cells, induced pluripotent stem cells, embryonal carcinoma stem cells, hemangioblasts, lymphoid progenitor cells, *etc*.

INDEXING/ABSTRACTING

The *WJSC* is now abstracted and indexed in Science Citation Index Expanded (SCIE, also known as SciSearch®), Journal Citation Reports/Science Edition, PubMed, PubMed Central, Scopus, Biological Abstracts, BIOSIS Previews, Reference Citation Analysis, China National Knowledge Infrastructure, China Science and Technology Journal Database, and Superstar Journals Database. The 2022 Edition of Journal Citation Reports cites the 2021 impact factor (IF) for *WJSC* as 5.247; IF without journal self cites: 5.028; 5-year IF: 4.964; Journal Citation Indicator: 0.56; Ranking: 12 among 29 journals in cell and tissue engineering; Quartile category: Q2; Ranking: 86 among 194 journals in cell biology; and Quartile category: Q2. The *WJSC*'s CiteScore for 2021 is 5.1 and Scopus CiteScore rank 2021: Histology is 17/61; Genetics is 145/335; Genetics (clinical) is 42/86; Molecular Biology is 221/386; Cell Biology is 164/274.

Abstract

Colorectal cancer (CRC) remains the third most prevalent cancer disease and involves a multi-step process in which intestinal cells acquire malignant characteristics. It is well established that the appearance of distal metastasis in CRC patients is the cause of a poor prognosis and treatment failure. Nevertheless, in the last decades, CRC aggressiveness and progression have been attributed to a specific cell population called CRC stem cells (CCSC) with features like tumor initiation capacity, self-renewal capacity, and acquired multidrug resistance. Emerging data highlight the concept of this cell subtype as a plastic entity that has a dynamic status and can be originated from different types of cells through genetic and epigenetic changes. These alterations are modulated by complex and dynamic crosstalk with environmental factors by paracrine signaling. It is known that in the tumor niche, different cell types, structures, and biomolecules coexist and interact with cancer cells favoring cancer growth and development. Together, these components constitute the tumor microenvironment (TME). Most recently, researchers have also deepened the influence of the complex variety of microorganisms that inhabit the intestinal mucosa, collectively known as gut microbiota, on CRC. Both TME and microorganisms participate in inflammatory processes that can drive the initiation and evolution of CRC. Since in the last decade, crucial advances have been made concerning to the synergistic interaction among the TME and gut microorganisms that condition the identity of CCSC, the data exposed in this review could provide valuable insights into the biology of CRC and the development of new targeted therapies.

Key Words: Colorectal cancer; Colorectal cancer stem cells; Tumor microenvironment factors; Tumor stroma; Gut microbiota; Cancer progression

Core Tip: Colorectal cancer (CRC) represents one of the most prevalent tumors worldwide. The tumor microenvironment (TME) through its proinflammatory role, among others, actively participates in CRC progression and the disturbance of gut microbiota (dysbiosis) can influence this inflammatory process. CRC stem cells (CCSC) are a tumor cell subpopulation that drives CRC initiation, progression and treatment failure. The features and behavior of CCSC are modulated by several factors including TME and gut microbiota. Here, we will give an overview of the synergistic interaction among TME and intestinal microorganisms that condition the CRC environment and shape CCSC characteristics allowing CRC evolution.

INTRODUCTION

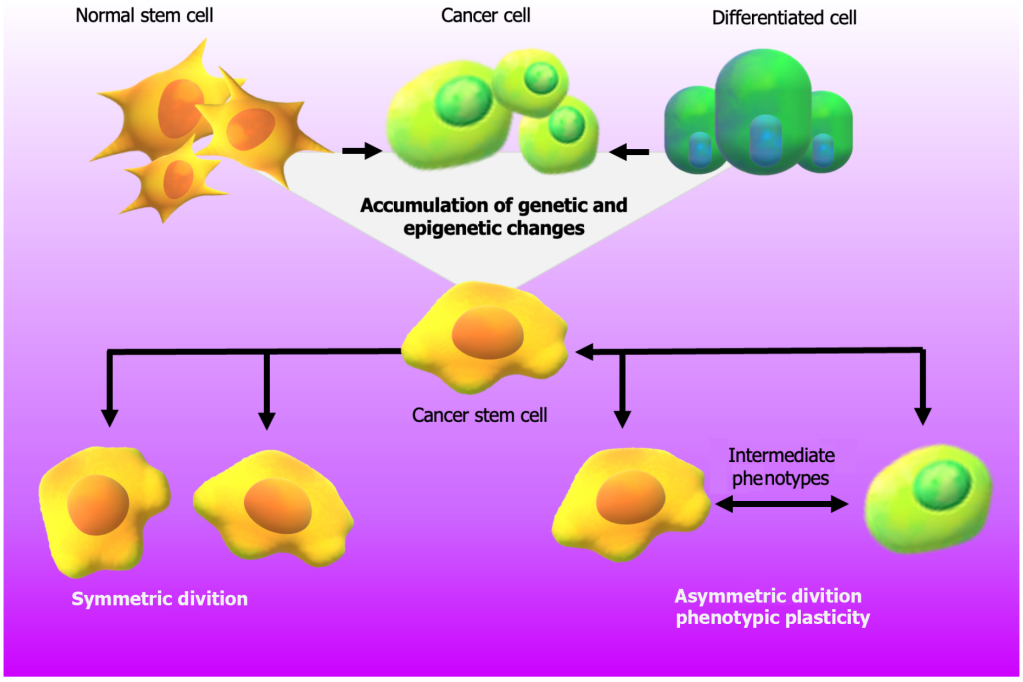
Colorectal cancer (CRC) is a multi-step process where intestinal cells acquire malignant phenotypic characteristics that allow them to proliferate, migrate, invade and establish in new tissues[1]. In the last decades, screening strategies and treatments have been improved, decreasing the proportion of CRC patients by as much as 65%–88%[2]. However, this disease remains the third most prevalent type of cancer, having an incidence of 10% and ranking second in mortality (9.4% among all cancer deaths) according to global cancer statistics[3]. The leading cause of patient deaths and relapses is the appearance of new CRC subtypes and the acquired resistance to currently used therapies[4]. Moreover, a great number of CRC are diagnosed with distal metastases and these patients have a poor survival rate due to a lack of response to therapy[2]. One of the causes that affect the treatment of this type of tumor by inducing resistance and the appearance of recurrences, is the presence of a small subpopulation of cells called CRC stem cells (CCSC). This small number of cells have mutations in specific oncogenes that allow them to develop the ability to induce tumor initiation, self-renew, differentiate, dedifferentiate, and acquire multidrug resistance[1,5]. The origin of this cell subpopulation is still controversial. They may originate from colorectal normal cells, colorectal normal stem cells, or CRC cells by genetic alterations or by the influence of environmental factors that induce epigenetic changes[5].

It is known that in the tumor niche, different cell types, structures, and biomolecules coexist and interact with cancer cells favoring the growth and development of the tumor. Together these components constitute the tumor microenvironment (TME). In the last decades, several investigations have demonstrated that tumor surrounding ambiance through its proinflammatory role, among others, actively participates in the development, progression and chemoresistance of CRC[1,4].

Researchers have deepened the study of the influence of the complex variety of microorganisms that inhabit the intestinal mucosa, collectively known as the gut microbiota, on this inflammatory microenvironment. Besides contributing to innate and adaptive immune function, it has been observed that the imbalance in the species present in the intestinal microbiota and the consequent variation in microbial products can promote the development of CRC and compromise the efficacy of its therapy[6].

Since all the factors mentioned are involved in the CRC progression and therapy resistance and considering the great influence of CCSC in several events of this disease, this review aims to analyze the available literature that is focused on the interaction of TME and the intestinal microbiota that favors the development and maintenance of CCSC properties.

COLON CANCER STEM CELLS: FEATURES AND BEHAVIOR



CRC is a heterogeneous pathology that has a variable clinical course and prognosis[7]. The etiology of this disease combines genetic alterations in colorectal epithelial cells with unhealthy lifestyles, such as smoking, alcohol consumption and poor nutritional habits[8,9]. In addition, it has been seen that sex, age, family history of CRC and the persistence of inflammatory processes or infectious agents in the intestinal tract, can be also considered risk factors[5,9-12]. In all these cases, the synergy among genetic mutations, epigenetic alterations and the influence of the TME and gut microorganisms promotes the acquisition of molecular and phenotypic features that allow tumor progression[5,6,11,13,14]. Therefore, within the tumor niche, cells present great heterogeneity but are still strictly organized. In the last 20 years, the focus has been on the study of cancer stem cells (CSC) derived from colorectal tissue (CCSC),

a subpopulation of cells that have a substantial tumorigenic capacity and maintain intestinal tumor growth[15]. CSC are responsible for resistance to multiple drugs maintaining a state of undifferentiation and slow cell division and also favoring the efficiency of desoxyribonucleic acid (DNA) damage repair mechanism[16]. Besides, they have similar features to normal stem cells, such as self-renewal, multipotency, cell cycle arrest, quiescence, and reversibility from their resting state[17,18]. As shown in Figure 1, the ability of CSC to maintain their population response to symmetric/asymmetric division, resulted in the first situation in two identical daughter stem cells and, in the second situation in two distinct cells with or without CSC properties[19,20]. In addition to the division theory, CSC undergo a bidirectional conversion process between stem and non-stem phenotype[20]. Although initially a hierarchical model has been established, in which CSC are the initiators of a monoclonal developmental hierarchy, emerging data highlight the concept of phenotypic plasticity of CSC. This new theory is supported by a dynamic state of interconversion between CSC and non-CSC that can be driven by the TME[21-23]. As the reader can see in Figure 1, during this phenomenon, cells can easily exchange their status within the tumor transforming from CSC to intermediate phenotypes to stemless states and vice versa[15,18,22,24]. Therefore, based on the data provided by the literature and shown in Figure 1, it can be concluded that any cell type is capable of initiating and promoting cancer development[24]. This model contributes with new concepts to the classical theory of the origin/behavior of CSC that highlight the importance of taking into account the study of phenotypic plasticity and the reversible state of this type of cells and that support the criterion that cancer cells with or without stem characteristics must be eradicated for successful therapy.

CCSC constitute about 2% of the cell population in the tumor nest and this percentage can be higher with tumor progression, particularly after chemotherapy or radiotherapy treatments[17,18,25]. Since an increase in the proportion of this cell subtype is an indicator of poor prognosis, in the last decades the identification and targeting of CCSC have become one of the key topics of study[26]. The recognition of CCSC is possible by the detection of typical phenotypic characteristics such as the expression of surface markers, membrane transporters and enzymes. Some of them are Prominin-1/cluster of differentiation 133 (CD133), a transmembrane glycoprotein that is associated with metastasis, invasiveness and chemoresistance in CRC[18]; cluster of differentiation 44 (CD44) a receptor of hyaluronic acid in extracellular matrix related to the epithelial to mesenchymal transition (EMT) program and poor survival in CRC patients[5,27]; cluster of differentiation 166 (CD166) and cluster of differentiation 24, both adhesion molecules whose expressions are associated with the aforementioned markers, and that contribute to stratify low, intermediate, and high-risk CRC cases[5,28]; leucine rich repeat containing G-protein coupled receptor 5 (LGR5) a key CCSC biomarker that decreases in advanced stages of CRC[20,29] and aldehyde dehydrogenase (ALDH), an intracellular enzyme found in high concentrations in most of CSC participating in self-renewal, differentiation and self-protection[20,30,31]. In addition, the study of the ATP-binding cassette transporter superfamily through Hoechst 33352 dye efflux is also employed to detect CCSC[15,32]. In experimental models, the identification and characterization of CCSC can also be performed by fluorescence-activated cell sorting, selection by cell culture properties, *in vivo* transplantation of cells derived from spheroids or organoids, and lineage tracing techniques with labeled CCSC[22]. The above mentioned markers are hallmarks of CCSC and are involved in CRC pharmacotherapy and pathophysiology[33,34], but can also be present in enterocytes and cells of other tissues[20]. Hence, to increase the detection sensitivity and specificity, it is essential to combine the analysis of different biomarkers with CCSC isolation techniques.

Another substantial aspect to consider in the study of CSC is their association with other cellular processes such as EMT, autophagy and the response to cellular stress[15]. In particular, EMT is a physiological process that is also involved in tumor progression. The activation of this program reduces intercellular adhesion and causes epithelial cells to acquire mesenchymal properties that increase the invasiveness and migration of tumor cells[35]. Several studies have reported a link between EMT and the acquisition of CCSC characteristics in both, *in vitro* and *in vivo* assays[35-38]. These investigations show that transcription factors and signaling pathways that are altered in the EMT program are also deregulated in CSC, generating this subpopulation to exhibit phenotypes like EMT[39]. However, recent evidence indicates that EMT may not be necessary to acquire CSC properties. Then, although these processes can go along with each other, they can also happen through independent paths[15]. One of the tumor events that is known to be related to EMT and CSC is the high metabolic demand of TME and the existence of a tortuous vasculature that promotes a hypoxic environment. This phenomenon induces the release of factors such as hypoxia-inducible factor 1α (HIF-1α) that promotes not only EMT but also autophagy associated with CSC. In CRC it was demonstrated that blocking this factor with the consequent inhibition of autophagy reduces cell proliferation and the acquisition of stem-like characteristics[40].

Another cause that has been reported that promotes a stem-like phenotype on several types of tumor cells is the cellular imbalance derived from oxidative stress[15]. In breast and lung cancer cell lines, studies demonstrate that oxidative stress upregulates the CSC marker SRY-box transcription factor 2 (Sox2) activity, and stem-like properties[41,42]. However, in CRC cells it was shown that the reduction of intracellular reactive oxygen species inhibits the formation of CRC stem-like cells[43]. Since this type of cellular stress is considered potentially cytotoxic, more studies are necessary to know the mechanisms by which it has a positive effect on the development of CCSC[15].

DOI: 10.4252/wjsc.v15.i5.281 **Copyright** ©The Author(s) 2023.

Figure 1 Theory-based models of cancer stem cell. The ability of cancer stem cells (CSC) to maintain their population response to symmetric/asymmetric division, resulting in the first situation in two identical stem cells daughters and in the second situation in two distinct cells with or without CSC properties. In addition to the division theory, CSC undergo a bidirectional conversion process between stem and non-stem phenotype. During this phenomenon, cells can exchange their status within the tumor transforming from CSC to intermediate phenotypes to stemless states and vice versa. Also differentiated cells, normal stem cells or cancer cells through the accumulation of genetic and epigenetic changes are capable of initiating and promoting cancer development. These general theories are applicable to colon CSC.

Furthermore, it is important to note that like all processes and phenomena related to tumorigenesis and malignant progression, CCSC and their features are modulated by the aberrant activation of various signaling pathways. Wnt, NOTCH, hedgehog (HH), and transforming growth factor-β (TGF-β) are important cascades that are usually misregulated in CCSC and play a central role in the therapy resistance of these cells[5,44].

Thus, understanding CCSC features and all the events and factors associated with cell plasticity constitute a fundamental tool for the development of new target therapeutic strategies.

INFLUENCE OF THE TME ON CCSC FEATURES

It has been reported that multiple links exist between inflammatory processes and stemness in CRC[2]. In this context, the role of the tumor stroma is crucial. The TME in CRC is a physical shelter for CSC[5] composed of biomolecules from the extracellular matrix, an aberrant vasculature and multiple stromal and immune cell types. These cells include mesenchymal stem cells, cancer-associated fibroblasts (CAFs), endothelial cells (ECs), pericytes, and tumor infiltrating immune cells which comprehend: Macrophages, neutrophils, natural killer cells, Treg cells and cytotoxic T lymphocytes[2,4]. The interaction between CRC cells and the different types of cellular and non-cellular elements of TME involves complex and dynamic crosstalk by paracrine signaling[22]. Therefore, self-renewal, differentiation and properties of CRC cells and CCSC are modified by factors released by the surrounding stroma[1]. These factors are cytokines, growth factors and small nucleic acids, which have different mechanisms of action. Next, we will discuss those derived from TME that modulate CCSC properties and that are summarized in Table 1.

Cytokines have been shown to play a key role in CRC stemness. It was reported that TME-derived factors with a pro-inflammatory action such as tumor necrosis factor-α (TNF-α) and interleukin (IL)-1β foster EMT phenotype and stem cell proliferation in human colon cancer cells[45,46]. Besides, it is known that CAFs, one of the most studied cells in the TME, produce IL-6, which promotes the expression of CCSC markers such as ALDH1 and LGR5[1,47].

The acquisition of a stem-like phenotype is also influenced by the expression and secretion of growth factors[48,49]. It was demonstrated that the epidermal growth factor and the insulin-like growth factor regulate and promote CCSC growth[50]. Moreover, Muñoz Galván *et al*[49] have proved that the treatment of CRC derived cells with hepatocyte growth factor (HGF) and/or macrophage migration

Table 1 Tumor microenvironment factors associated with stemness in colorectal cancer

TME factor	Action	Ref.
Growth/inducible factors		
Epidermal growth factor	Regulates and promotes CCSC growth	[50]
Insulin-like growth factor	Regulates and promotes CCSC growth	[50]
TGF-β	Participates in the initiation of the EMT, invasion, metastasis and initiation of angiogenesis associated to CCSC	[13,29,50]
Bone mophogenetic protein 4	Induces differentiation and decreases the tumorigenic potential of CCSC	[16,60,63]
Bone mophogenic protein 2	Stimulates the differentiation of CCSC inducting autophagic degradation of β-catenin	[44,63]
Hepatocyte growth factor	Activates Wnt signaling and the clonogenicity from CCSC	[53,54]
Macrophage migration inhibitory factor	Increases CCSC properties	[49]
Vascular endothelial growth factor	Promotes growth, epithelial to mesenchymal transition and stemness	[50,51]
Platelet derived growth factor	Promotes growth, epithelial to mesenchymal transition and stemness	[50]
Osteopontin	Regulates EMT and participates in the activation of the Wnt/β-catenin signaling pathway, promoting stemness	[4,156]
HIF-1A	Activates Wnt/β-catenin pathway inducing self-renewal of CCSC. Promotes survival and maintenance of CCSC	[40,157]
Citokines/immune associated proteins		
IL-1β	Modulates the expression of CCSC markers	[158]
IL-4	Facilitates the communication of CCSC with stromal cell, maintains their properties and evades the immune system	[5,44]
IL-6	Promotes the expression of the CCSC markers, ALDH1 and LGR5	[1,47]
IL-8	Induces stemness and EMT	[50,159]
IL-17A	Promotes invasiveness and self-renewal and increases CCSC properties	[12]
IL-22	Promotes invasiveness and self-renewal and increases CCSC properties	[12]
IL-33	Induces the expression of core stem cell genes in CRC-derived cells	[160]
Chemokine (C-C motif) ligand 2	Promotes CCSC properties	[4,49]
Tumor necrosis factor- α	Modulates CCSC features and induces cell death	[158,161]
Parathyroid hormone related-protein	Activates Wnt/β-catenin pathway and promotes events related to stemness	[162-164]
Non-coding RNA		
miR-135 a/b and miR-17	Promote stemness through the activation of Wnt/β-catenin signaling	[157]
miR-34 and miR-93	Inhibit stemness	[157]
miR-92a-3p	Promotes Wnt signaling activation and consequently the expression of β-catenin target genes related to stemness, the EMT program, and chemoresistance	[165]
miR-20a and miR-106 a/b	Repress TGF-β activity and stemness	[157]
miR-146 and Let-7	Affect stem cell fate or proliferation, activation of several stemness markers in a colon cancer cell line	[157]
miR-221/222 and miR-21	Induce the development and maintenance of CCSC	[157]
miR-21	Promotes the activation of the Wnt/β-catenin signaling pathway and increases the population of CCSC	[157]
miR-145	Represses miR-21 and its expression inversely correlates with that of CCSC markers	[157,166]
miR-137	Suppresses CCSC tumorigenicity	[167]
miR-147	Decreases the expression of CCSC markers	
miR-200, miR-203, miR-141 and miR-429	Regulate CCSC through negative modulation of EMT and self-renewal	[157]

lncRNA H19	Promotes CCSC phenotype and drug resistance	[168]
Signaling pathway ligands		
Wnt ligands	Increase CCSC characteristics and enhances tumor-initiating potential	[5,157]
Delta like canonical Notch ligand 4	Participates on CSC maintenance	[44]
Jagged1	Participates on CSC maintenance	[66]
SHH	Promotes CCSC survival, self-renewal and drug resistance	[67,68]
Enzymes		
Phospholipase D2	Promotes CRC stemness	[4,49]
Extra-cellular matrix components		
Tenascin, fibronectin, collagen type I, secreted protein acidic and rich in cysteine, galectin	Contribute to stemness and CCSC activities	[1]

EMT: Epithelial to mesenchymal transition; CCSC: Colorectal cancer stem cells; CRC: Colorectal cancer; lncRNA: Long non-coding ribonucleic acid; miR: Micro ribonucleic acid; SHH: Sonic Hedgehog protein; TGF-β: Transforming growth factor beta; IL: Interleukin.

inhibitory factor increases the number and size of colonospheras and significantly enhances the expression of putative markers like CD133[49].

Proangiogenic factors like vascular endothelial growth factor (VEGF) and platelet derived growth factor are also implicated in promoting growth and metastasis, both processes directly related to stemness[50]. Furthermore, it was demonstrated that clusters of ECs improve the survival of CCSC and promote their spread[51].

As it is known, all these TME factors modulate the activation of different signaling pathways, altering gene expression and thus modifying the molecular and phenotypic profile of tumor cells[5,44,50]. Wnt signaling is a key stem cell pathway involved in the maintenance of the CCSC and the TME[13,52]. One decade ago, Vermeulen *et al*[53] observed that high activity of the Wnt signaling was associated with CCSC features. Furthermore, this activity was mainly observed near fibroblasts in the tumor niche. Vermeulen *et al*[53] then demonstrated that HGF derived from CAFs activates Wnt signaling and the clonogenicity from CCSC[53]. This research had a great impact on the study of CSC and recently, Essex and collaborators replicated these studies and obtained similar results. They found that TME regulates the activation of the Wnt signaling pathway, increases CCSC characteristics and enhances tumor-initiating potential[54]. Regarding this, it is known that several Wnt ligands are secreted mostly by CAFs[53-56]. Moreover, other TME factors participate in the activation of the Wnt/β-catenin pathway (Table 1).

Some ligands from other signaling pathways are also related to stem cell phenotype. TGF-β is a growth factor that belongs to a superfamily of molecules including inhibins and bone morphogenetic proteins (BMP)[13]. It has the ability to promote or suppress tumor development depending on the interactions that take place in the TME[57]. As a pro-tumor factor, TGF-β regulates immune responses and participates in many neoplastic events such as proliferation, EMT and stemness[13]. TGF-β signaling pathway mutations and CCSC are linked[58] and in accordance with this, Zhou *et al*[29] found an association between TGF-β signaling and the expression of LGR5 biomarker in CRC[29]. Even more, Gu *et al*[59] have recently demonstrated that the expression of genes related to CCSC features like the carcinoembryonic antigen-related cell adhesion molecule alters TGF-β signaling and promotes CRC[59]. Some other members from the TGF-β family, like bone morphogenetic protein 4 and bone morphogenetic protein 2 (BMP4 and BMP2, respectively), have the capacity to induce CCSC differentiation and increase the response to standard chemotherapy[16,60-62]. Besides, the modulation of the BMP4 pathway by hormones like triiodothyronine was reported in CCSC, decreasing its tumorigenic potential [44,63,64]. This result suggests that CCSC features are modulated not only by local molecules from the TME but also by endocrine factors[44].

Notch signaling is also associated with the expression of CSC features in CRC cells[16,65]. In fact, it was reported that delta like canonical notch ligand 4 and jagged 1, both notch ligands, are overexpressed in this type of tumor providing essential signals for CCSC maintenance[44,66]. Moreover, since HH signaling is implicated in CRC development[20], in the last years several investigations were conducted on the association between this pathway and CCSC properties. Regan *et al*[67], have shown that the activation of the non-canonical HH pathway is required for CCSC survival and depends on sonic hedgehog protein (SHH) ligand[67]. Recently, it has been also observed that the modulation of HH-related proteins expressions by non-coding ribonucleic acids (ncRNAs) impacts on CCSC self-renewal capacity and drug resistance[68]. In line with this, Skoda and collaborators showed that treatment with HH pathway inhibitors such as vismodegib and sonidegib weakens the ability of CCSC [69]. Since no significant differences have been found in clinical trials[70], more studies are needed to determine the effects of the inhibition of this pathway in CRC patients.

Besides the aberrant activation of several signaling pathways, hypoxia is known as a hallmark of CCSC and TME interaction[5]. This is a condition in the tumor niche whose main cause is the poor vasculature associated with the tumor and the upregulation of HIF-1α, a factor released mainly by ECs [40,71,72]. This condition activates Wnt/β-catenin pathway inducing self-renewal and maintenance of CCSC[50,73]. Also, HIF-1α promotes cancer cell proliferation and CCSC survival[40].

Furthermore, short ncRNAs like microRNAs (miRs) and long ncRNAs are secreted not only by tumor cells but also by stromal cells in the TME[4]. In the last decades, the study of ncRNAs has gained importance in CRC. In the framework of factors and signaling pathways related to CCSC biology, these small nucleic acids have a key role[74]. miRs related to stemness in CRC are exposed in Table 1.

As previously mentioned, the interaction between CRC cells and their TME also involves non-cellular elements. Colonic stromal cells mediate the remodeling of the extra-cellular matrix favoring the healing or progress of the disease[75]. Recently, it has been demonstrated, by lineage tracing, that components of the extra-cellular matrix regulate dormancy in CCSC[76]. Tenascin, fibronectin, collagen type I, secreted protein acidic and rich in cysteine (SPARC), galectin and some other components of the tumor matrix are associated with stemness and CCSC activities[1].

Finally, another important concept to consider in the tumor nest is that CCSC also release various factors and cytokines that enable them to communicate with stromal cells, maintain their properties and evade the immune system, such as IL-4 and the cluster of differentiation 200[5,44].

The aforementioned data (and shown in Table 1) suggest that TME instructs the development, properties, plasticity, maintenance and dissemination of CCSC. In the last decade, the remarkable influence of the stroma on CRC development prompted the postulation of a novel classification of this disease based on its impact on tumor gene expression[5]. This CRC staging contains four consensus molecular subtypes (CMS) plus a group called "unclassified" since their features do not fit into the other CMS. All these subtypes are summarized in Table 2[1,5,77-79]. As the reader can see in this table, the influence of TME determines a low or high degree of immune and inflammatory response depending on the CMS, highlighting the importance of factors from TME in the distinctive characteristics of each CRC subtype. Taking into account that the mentioned inflammatory/immune process (that is relevant for CRC classification) can be influenced by the intestinal microorganisms, next we will discuss the interactions of this microbiota with tumor cells and their microenvironment that modulate the behavior and characteristics of CCSC since it is the focus of this review.

ESTABLISHED DYNAMICS BETWEEN THE GUT MICROBIOTA, THE TME AND CCSC

As we mentioned in this work, the inflammatory microenvironment contributes to promoting CRC initiation and progression. However, the role of the cell types involved in this process, including intestinal microorganisms, has not been completely understood yet.

The human microbiome, a concept that is mentioned throughout this section, represents microorganisms with their genetic elements and the interactions arising with the environment in which they are found[80]. Advances in the characterization of this human microbiome have led to the consideration that the role of the microbiota in metabolic functions and maintenance of homeostasis is more important than previously believed. Currently, the human is considered as a holobiont organism inhabited by millions of microorganisms including bacteria, archaea and fungi[81]. The gut microbiota is a complex ecosystem that contains more than 500 bacteria species involved in physiological processes like immune regulation and maintenance of human health[6] and its composition relies fundamentally on diet and lifestyle[74].

In physiological conditions, stromal and immune cells from the gut mucosa interact with this ecosystem to maintain intestinal equilibrium[82]. Cells from the immune system recognize antigens from foreign cells and generate memory and effector cells, which control or avoid the generation of diseases[82].

It has been observed that sustained shifts in this ecosystem, known as intestinal dysbiosis, have unfavorable repercussions on health[74,83]. In this sense, the presence of harmful microorganisms (“drivers”) could induce changes in the intestinal mucosa and favor the colonization by opportunistic bacteria (“passengers”)[84]. This model is known as driver-passenger[84] and could involve changes in the immune system allowing the advance of the damage in the intestinal epithelium tissue[85,86]. This imbalance of the local microbiota promotes the restructuring of the intestinal environment and alters the immune status of the host contributing to the appearance of malignant cells and a favorable niche for tumor development, invasion and metastasis[85,87,88]. The mechanisms of these microorganisms that influence directly the immune system are different and involve the synthesis of immunomodulatory compounds and metabolites, like short-chain fatty acids (SCFAs), polyamines and other fermentation products[89,90]. Moreover, it is known that the intratumoral composition of microorganisms affects T-cell-mediated cytotoxicity and anti-tumor immune surveillance[91]. The unfavorable changes in the intestinal microbiota can promote a pro-inflammatory environment and impair anti-cancer immunity [91]. In this context, cells from TME secrete factors like interferon-γ, TGF-β, IL-6, IL-8, CXCL1 and TNF-α,and favoring the differentiation of T helper 17 Lymphocytes to develop an adaptive immune

Table 2 Consensus molecular subtypes of colorectal cancer

	CMS1-immune (14%)	CMS2-canonical (37%)	CMS3-metabolic (13%)	CMS4-mesenchymal (23%)	Unclassified (13%)
General features	Hypermutated	Epithelial	Epithelial	TGF-β activation. Angiogenesis	Mixed phenotype of multiple CMS
	Microsatellite unstable	WNT and MYC signaling activation	Metabolic dysregulation	Upregulation of EMT	
Mutations	*BRAF, MSH6, RNF43, ATM, TGFBr2, PTEN*	*APC, KRAS, TP53, PIK3CA*	*APC, KRAS, TP53, PIK3CA*	*APC, KRAS, TP53, PIK3CA*	
TME	Decrease of CAFs	Decrease of CAFs	Decrease of CAFs	Increase of CAFs; Immunosuppressive signature	
	High immune and inflammatory signature	Low immune and inflammatory signature	Low immune and inflammatory signature		

This Table is based on Islas *et al*[1], 2022; Fidelle *et al*[79], 2020; Trinh *et al*[169], 2018; Becht *et al*[78], 2016; Guinney *et al*[77], 2015. *APC: Adenomatous polyposis coli gene; ATM: Ataxia telangiectasia mutated gene; BRAF: Serine/threonine-protein kinase B-raf gene*; CAFs: Cancer associated fibroblasts; CMS: Consensus molecular subtype; EMT, Epithelial to mesenchymal transition; *KRAS: Ki-ras2 kirsten rat sarcoma viral oncogene homolog gene; MSH6: MutS homolog 6 gene; PIK3CA: Phosphatidylinositol-4,5-bisphosphate 3-kinase catalytic subunit alpha gene; PTEN: Phosphatase and tensin homolog gene; RNF43: Ring finger protein 43 gene*; TGF-β: Transforming growth factor beta; *TGFBr2: Transforming growth factor beta receptor 2 gene*; TME: Tumor microenvironment; *TP53: Transformation-related protein 53 gene.*

response that contributes to immune-prone carcinogenesis and CRC development[79,87,92]. In this regard, increasing evidence suggests that gut microorganisms condition CRC patients response to immunotherapy, because they alter the expression of elements such as anti-programmed cell death protein 1 (PD-1) and its ligand (PD-L1) and anti-cytotoxic T lymphocyte-associated protein 4 (CTLA-4)[91,93]. PD-1/PD-L1 has been highly studied in the last years on the tumor-microbiome-immune axis[91]; in fact, several investigations provide evidence that PD-L1 is overexpressed on different tumor cells and stromal immune cells, allowing tumors to evade attacks *via* T-cell infiltration[91,94,95].

The increased expression of PD-L1 in CRC cells both *in vitro* and *in vivo* is a mechanism involved in the influence of certain pathogenic bacteria associated with an immunosuppressive TME[96]. In contrast, bacteria associated with healthy microbiota improve the efficacy of anti-PD-L1 therapy by enhancing the accumulation of cytotoxic T cells in the TME[97]. This suggests that TME reprogramming through manipulation of the microbiota can modulate the response to immunotherapies in CRC[98]. Concerning all this information, CRC could be considered as a bacterial-induced disease and disturbance in microbiota could be potentially useful as diagnostic biomarker, indicator of risk and predictor of response to therapies for this type of cancer[74,88].

On the other hand, CRC modifies the local metabolic environment[99]. In this context, it is important to mention that metabolites and factors derived from CRC cells and TME cells such as spermidine, L-valine, L-lysine or stearic acid confer an advantage for the growth and development of certain bacterial species, conditioning changes in the intestinal microbiota[99]. Although different factors produce changes in gut microbiota, recently it has been seen that the shift in the metabolome of tumor cells and TME cells is a key aspect in this event[86,99,100]. Thus, TME can be the consequence or the cause of intestinal dysbiosis.

The gut microorganisms cited below in this section are described in the available literature due to their role in CCSC development and maintenance. They are also summarized in Table 3.

Regarding CSC properties, some pathogenic bacteria such as *Helicobacter pylori* and *Porphyromonas gingivalis* can promote the expression of markers associated with stemness such as CD44 and CD133 in gastrointestinal tumors[101,102]. This association between the presence of certain bacteria genera in the gut and the expression of CSC markers has led to the study of the effects of microorganisms shifts and bacterial metabolites on CRC. Several models of tumorigenesis induced by bacteria have been proposed, suggesting how the interactions of host-microorganism promote the development and progression of this type of cancer[101]. In fact, it is known that the metabolites from the intestinal microbiota have the potential to act as tumorigenic factors. However, others can act as anti-tumorigenic factors since many of these microbiota-derived products are capable of inhibiting CRC progression[103]. Kim *et al*[43] have demonstrated that ursodeoxycholic acid, a secondary bile acid produced by Clostridium species, including *Clostridium absonum* and *Clostridium baratii*, regulates the oxidative stress suppressing CCSC growth and CRC cells proliferation[43]. Moreover, it has been observed that niacin, a product of the metabolism of some intestinal bacteria, such as *Lactobacillus acidophilus*, has different effects on CCSC. Depending on the dose, this vitamin can promote proliferation or death in this cell subtype[104]. Additionally, bowel microorganisms produce SCFAs such as butyrate, propionate and acetate[92]. It has been reported that these SCFAs favor beneficial bacteria proliferation and stimulate regulatory T cells to reduce inflammatory mediators, regulating immune response[105]. Butyrate participates in epithelial integrity maintenance and has antitumor effects. Several investigations show that in CRC, this product

Table 3 Microorganisms present in the intestinal mucosa associated with stemness in colorectal cancer

Microorganism	Action	Ref.
Bacterioides dorei, Bacterioides vulgatum, Parabacterioides distasonis, Lachnoclostridium sp., and Mordavella sp	Inhibit the action of factors related to CCSC phenotype. Inhibit CRC development and progression	[59, 114]
Bacterioides fragilis	Releases an enterotoxin that promotes immune TME cells activation with secretion of factors related to CCSC	[118]
Citrobacter rodentium	Protects the inflammatory CCSC niche	[121]
Clostridium septicum	Contributes to CRC development and to the activation of signaling pathways associated with CCSC	[59]
Enterococcus faecalis	Induces the expression of TGF-β, thereby activating signaling pathways associated with CCSC. Activates Wnt/β-catenin signaling and pluripotent transcription factors associated with CCSC	[113, 115]
Escherichia coli	Upregulates the expression of CCSC-associated genes. Releases genotoxin colibactin which induces the production of growth factors related to CCSC	[112, 117,79]
Fusobacterium nucleatum	Stimulates the secretion of immune factors related to CCSC	[79]
Helicobacter pylori	Promotes the expression of markers associated with stemness	[101, 102]
Lactobacillus acidophilus	Promotes proliferation or death in CCSC depending on dose	[104]
Porphyromonas gingivalis	Promotes the expression of markers associated with stemness	[101, 102]
Shigella, and Citrobacter	Upregulate the expression of CCSC-associated genes	[112]

CCSC: Colorectal cancer stem cells; CRC: Colorectal cancer; TGF-β: Transforming growth factor beta; TME: Tumor microenvironment.

inhibits events associated with CSC such as invasion and proliferation[6]. Interestingly, butyrate inhibits cell proliferation to a greater extent in CRC derived cells than in non-cancerous cells[92]. Although butyrate was reported as an anti-tumor and chemopreventive agent[92,106], other studies have shown that it has variable outcomes on CCSC[92]. So, more investigations are necessary to determine the mechanistic action of this type of fatty acid. Experiments with other SCFAs like acetate and propionate with similar results demonstrated that these acids have opposing effects[6,107]. Besides that, a large number of microbial products such as deoxycholic acid, lithocholic acid chenodeoxycholic acid, taurochenodeoxycholic acid and others, are associated with the promotion of gastrointestinal tumors including CRC[6,108]. Recent studies have found that in CRC patients the microbial composition of the colonic crypt is different from that of the intestinal lumen. In the environment of the crypt of the colorectal tumor, groups such as *Proteobacteria* and anaerobes, such as *Acinetobacter, Stenotrophomonas* and *Delftia* were found[109]. Therefore, specific microorganisms could have a role in the maintenance of CCSC, located in the crypt, through the production of specific metabolites[110]. However, more studies are needed in this field since the molecular mechanisms underlying the effects of intestinal microbial products on CCSC have not yet been fully elucidated.

Currently, the study of mechanisms involved in the communication between the microbiota, the tumor cells and their microenvironment has gained impact on CRC. One reported mechanism for this interaction is through pattern recognition receptors located on intestinal epithelial cells that have the ability to detect distinctive microbial macromolecular ligands called pathogen-associated molecular patterns such as lipopolysaccharides and peptidoglycans[111]. Congruently, a recent work documented an altered function of CSC in a CRC murine model due to intruding bacteria like *Escherichia, Shigella*, and *Citrobacter*. This effect results in the activation of a toll-like receptor (TLR), a class of pattern recognition receptors, and the consequent upregulation of stem cell-associated genes such as *Cd44v6* and *Lgr5*[110,112]. In line with this, the microorganisms are capable of activating several signaling pathways in tumor cells and/or TME cells inducing the secretion of factors associated with CCSC features. In this context, it has been observed in a murine model that microorganisms such as *Enterococcus faecalis* cause colitis after infection and induce expression of TGF-β, thereby activating the Smad signaling pathway[113]. A recent study has demonstrated an inverse correlation between the expression of molecules associated with TGF-β signaling pathway and stem cells- related genes in CRC. Moreover, the authors of this work have compared feces from mice with defects in TGF-β signaling with feces from wild-type (WT) mice, and have shown that the first ones had increased bacterial species associated with the development and progression of CRC, such as *Clostridium septicum*, and diminished amounts of favorable microorganisms including *Bacteroides vulgatus* and *Parabacteroides distasonis*[59]. Similar results were obtained by Wang and collaborators who showed that the amounts of beneficial species (*Bacterioides dorei*, *Lachnoclostridium sp*., and *Mordavella sp*.) are recovered in WT mice but not in those

with mutated TGF-β signaling after chemotherapy treatment[114]. These investigations demonstrate the close relationship between the microbiota, the production and release of TGF-β and CCSC in the tumor.

Concerning other signaling pathways, Wang *et al*[115] have shown that *Enterococcus faecalis* are capable of polarizing macrophages by activating Wnt/β-catenin signaling and pluripotent transcription factors associated with the dedifferentiation, reprogramming and development of CCSC such as cellular myelocytomatosis oncogene, Kruppel-like factor 4, octamer-binding transcription factor 4 (Oct4), and Sox2[115]. These events respond to the microbiota-induced bystander effect theory based on the fact that macrophages induce genetic mutations and chromosomal instability in intestinal cells[116].

Other signaling pathways associated with pro-inflammatory and growth factors can be activated in response to bacterial products. For instance, the unbalance in the amount of the gut bacteria *Escherichia coli*, correlates with CRC progression by producing the genotoxin colibactin[79]. This toxin accelerates tumor progression and involves the production of growth factors related to CCSC, such as the HGF and the consequent activation of its signaling pathway[79,117]. Also, the enterotoxin produced by *Bacteroides fragilis* promotes immune TME cells activation with the secretion of IL-17 which favors CCSC properties [118]. Furthermore, as we have previously mentioned, gut microorganisms shape the immune environment promoting tumor evolution and CCSC features. For example, *Fusobacterium nucleatum* stimulates IL-8 secretion by TME cells and the inhibition of T and NK cell functions[79]. This bacteria has been deeply studied, since clinical analysis of specimens from CRC patients showed that the levels of *F. nucleatum* are significantly higher in neoplastic tissues than in adjacent normal tissues, and correlate with tumor invasion and metastasis[119]. These results support the role of *F. nucleatum* in the regulation of CCSC plasticity and EMT[101]. Also, it is known that *F. nucleatum* and other microorganisms like Epstein–Barr virus are capable of incorporating human ncRNAs favoring microbial growth [74]. In this regard, Tarallo *et al*[120] found a human and microbial ncRNA signature in CRC in which many miRs associated with CSC features, are overexpressed including miR-21 and miR-200[74,120]. A recent study conducted by Wang showed that *Citrobacter rodentium* infection induces the inhibition of miR-34a, which protects the inflammatory CCSC niche[121]. These investigations suggest a close relationship between the intestinal microbiota and the regulation of ncRNAs involved in CCSC properties.

Finally, not only the shift in the number of microorganisms is responsible for stemness and CRC progression, but the interaction and collaboration between several types of bacteria in biofilm communities also participate in bowel inflammation and CRC. It was demonstrated that biofilms correlate with an increase in IL-6 secretion by TME cells playing a key role in proliferation, cell transformation and stemness[79].

The data in this section demonstrate a close interrelationship between the gut microbiota, the TME, and CCSC. This information highlights the relevance of further investigating the intestinal microbiota switch in patients with CRC and the associated mechanisms that lead to TME changes and promote stemness.

THERAPEUTIC TARGETING OF TME AND THE GUT MICROBIOTA: A KEY TOOL TO MODULATE STEMNESS IN CRC

Standard chemotherapeutic approaches for CRC are based on attacking the replicative mechanisms of tumor cells to induce tumor regression. However, considering CSC properties, this subpopulation usually results unharmed by the treatment because they present a low division rate as well as a great capacity to correct DNA defects[122]. This entails therapy resistance of CSC and the subsequent treatment failure and disease progression. It is interesting to note that in CRC, CSC represent around 2.5% of neoplastic cells but due to their phenotypic plasticity, they constitute a dynamic population[123, 124]. This fact, together with the lack of response to therapies, highlights the need of new clinical strategies targeting CCSC[125].

As we explain throughout this review, the influence of the TME and the intestinal microorganisms on CSC properties makes these factors a promising tool in therapy. Many therapeutic agents are capable of inhibiting those events associated with the maintenance of CCSC. For instance, Apatinib napabucasin, Bigelovin, Wogonin and Metformin are drugs whose mechanisms are associated with the inhibition of EMT or angiogenesis in CRC[1]. Moreover, it has been demonstrated that therapeutic agents such as Genistein cause the inhibition of CSC characteristics by glioma-associated oncogene1 signaling pathway [126]. Targeting the activation of those signaling pathways associated with CCSC can also be considered as a mechanism to reduce stemness in CRC tumors and thus improve the response to the therapy. LGK974, Foxy-5, PRI-724[127] and DKN-01[126] are agents that act targeting the Wnt/β-catenin pathway. However, the clinical application of most of these drugs is still under study.

The tumor protective niche also could be modified to eradicate CCSC and overcome chemoresistance. As we have mentioned in previous sections, in the TME, immune cells modulate cancer development and progression. For that reason, in the last decade the treatment of patients with immune checkpoint inhibitors such as CTLA-4 and PD-1/PD-L1 has been studied. Even though employing these drugs leads to various systemic and organic complications, immunotherapy may be promising in sorting these

obstacles and could ameliorate the response of CRC patients to the treatment[1,128]. In fact, coadjuvant therapy with FOLFOX (a combination of leucovorin, fluorouracil and oxaliplatin which are first-line chemotherapeutic drugs)[129], and PD-1/PD-L1 inhibitors had an objective response rate of 50% in clinical trials[130]. In addition, in a phase II trial in CRC metastatic patients, immune checkpoints inhibitors like nivolumab and nivolumab-ipilimumab show improvement in patients survival rate[130]. Moreover, monoclonal antibodies against CAFs and antifibrotic drugs were also tested in clinical studies[5]. Another type of antitumor therapy was accomplished through the production of a cell-based vaccine with specific antigens of CCSC[5].

In addition, plenty of compounds were designed in the last decade to target CCSC signaling pathways[5]. These strategies include the inhibition of HH signaling components, NOTCH pathway inhibitors, anti-angiogenic agents and Wnt ligand blockers. All these drugs are undergoing clinical trials [129]. Despite being an encouraging strategy, it still has limitations like the inhibition of signaling pathways involved in physiologic processes.

In the last years, the particularities exhibited by extracellular vesicles (EVs) have led researchers to consider them as a therapeutic delivery strategy of great value in CRC and other types of tumors. Within the different types of EVs are the exosomes, which are secreted by a variety of cells. These vesicles carry out the molecular content of donor cells and enable cellular communication over short and long distances. These EVs are loaded with coding nucleic acids, ncARNs and bioactive proteins which determine their functions. Exosomes can target a specific tissue and internalize in a cell type by the recognition of surface ligands/receptors[131]. In this regard, Han *et al*[132] investigated the delivery of human cord blood-derived MSC exosomes loaded with miRs as CRC targeted therapy. The results showed an inhibition of tumor growth *in vitro* and *in vivo*, as well as a selective increase of these ncRNAs in CRC cells[132]. The relation between miRs and CCSC was mentioned in previous sections so their delivery may be strong weapons to confront drug resistance and CCSC maintenance[5]. Circular RNAs are ncRNAs that exhibit cell-type and tissue-specific signatures. There has recently been considerable attention on these ncRNAs as they modulate miRs expression[129]. In CRC, recent studies have focused on their study as biomarkers. However, they have not been applied in patients' therapy yet[133, 134]. Moreover, the importance that these small molecules could have in CRC is unknown[129].

Foods containing biologically active ingredients are termed functional foods or nutraceuticals[135, 136]. In the past years, the influence of diet on CRC development and evolution was demonstrated. A diet with natural products like phytochemicals and nutritional herbs has shown protective effects in overcoming CRC associated dysbiosis[137,138]. Diets enriched in dairy are a major source of products that are known to have a protective effect on CRC development such as, calcium, vitamin D and folate [138]. Sulforaphane, a sulfur-rich compound found in cruciferous vegetables like broccoli, has been documented to diminish CSC markers and improve the chemotherapeutic efficacy of drugs commonly used in CRC treatment such as cisplatin, doxorubicin and fluorouracil[137]. It has been observed that dietary polyphenols like quercetin have similar effects[137,139]. Other polyphenols or flavonoids are known to target ABCG-2 transporters and miRs strictly associated with CCSC[139]. Curcumin is one of several substances present in turmeric plants. It has been demonstrated that this bioactive agent inhibits the activation of several signaling pathways related to CSC characteristics. The treatment with this natural product on a CSC model diminished the expression of CD44 and CD133 markers[137]. Moreover, some other natural products have been observed that interfere with intrinsic CSC pathways, like epigallocatechin-3-gallate (EGCG), resveratrol and genistein[140].

Diet can also manipulate the gut microbiota. Indeed, this is achieved by the administration of probiotics in the diet. As probiotics and their active metabolites can exert immunomodulatory and anti-tumorigenic effects[135], the study of them and their metabolites has gained ground in recent decades. Probiotics are live microorganisms, normally lactic acid bacteria, recognized as safe by the United States Food and Drug Administration[135]. Defined as "live microorganisms that, when administered in adequate amounts, confer a health benefit on the host"[141], they can improve health by administration along vegetable fibers and other prebiotics stimulating beneficial bacterial growth in the intestine[142].

Probiotics administration can be done by different routes, commonly through functional foods, but also by commercial supplements or vaccines[135,138]. It is known that probiotic oral vaccines promote mucosal immunity that prevents enteric infections and could complement the standard therapy in the patient[143]. Microorganisms administration including probiotics and synbiotics (pharmaceutical preparation that contains probiotics and prebiotics that implies a synergy between both) are a potential resource for prophylaxis and therapy in CRC[138,144]. In addition, the luminal cocktail of microorganisms in the bowel can be modified not only by dietary approaches but also with the use of antibiotics or fecal microbiota transplantation (FMT)[145,146]. In particular, FMT has gained considerable interest in recent years as a strategy to treat different gastrointestinal disorders[147-149]. It consists of introducing a healthy microbial population from a disease-free host into a diseased host that has a dysbiotic community to restore microbial homeostasis[150]. Although there are limited data on the use of FMT in the treatment of CRC, several studies are under development to answer relevant questions such as if CRC can be detected, treated or prevented with this method. Rosshart and collaborators observed that mice treated with this method improved their resistance against colorectal tumorigenesis induced by azoximetane[151]. Besides, it has been seen that FMT in Balb-c mice prevents intestinal damage, and chemotherapy-induced toxicity[152]. Interestingly, the fecal microbiota from CRC patients

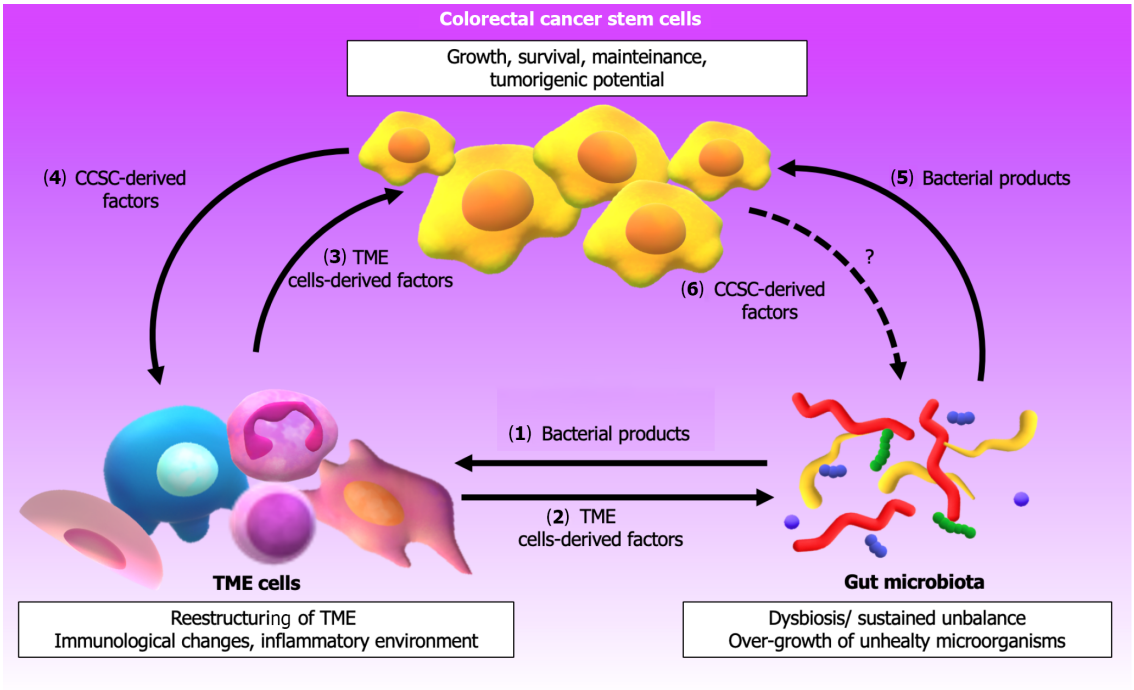
has been shown to cause tumors in healthy and germen-free $Apc^{min/+}$ mice through the activation of the Wnt signaling pathway. In these mice, the intestinal barrier is also altered and the presence of pro-inflammatory cytokines is increased[153]. These data reveal that the composition of the microbiota may play a determinant role in TME conditions during tumorigenesis. Nevertheless, the subjacent mechanisms of all these treatments or how they ameliorate the side effects of chemotherapy is not clear yet.

In summary, we need a favorable and efficient clearance of tumor cells, all tumorigenic cells including CCSC and a restructuring of the TME for the complete eradication of CRC. Based on everything described in this review, a specific combination of techniques and therapies for each tumor and patient would be necessary to achieve this goal.

FUTURE PERSPECTIVE

According to the information stated in the previous sections, in CRC occurs an alliance between the TME, intestinal microorganisms and CCSC that favors tumor progression. In this scenario, it is emerging a new query regarding the direct effects of CCSC on gut microbiota. Perhaps the appearance of CCSC by spontaneous mutations favors (through paracrine signals and the release of specific factors) a dysbiotic and pro-inflammatory environment but in this regard, new investigations are necessary to evaluate the regulation of CCSC on CRC microbiota. So, there is great potential in the study of the interrelationship between these three components in the tumor niche, mostly for the development of new therapies aimed at the eradication of CCSC and non-stem cells, the restructuring of the TME and the growth induction of microorganisms that are beneficial to the intestinal mucosa.

Many of the therapies currently in use or under clinical evaluation are associated with systemic toxicity since they do not act on a well-defined target[137]. Therefore, the combination of radiotherapy and chemotherapy has still remained the strategy of choice in CRC[145] and not much attention is paid to nutritional accompaniment. Since the gut microbiota seems to be a pivotal factor in inflammatory disease and CRC development, overcoming therapy resistance could also improve with changes in diet. For this purpose, is crucial the development of foods containing compounds with anti-CCSC activity such as flavonoids but with better bioaccessibility and bioavailability[154]. Moreover, bacteriotherapy is a great opportunity to customize CRC treatment and the following tools that we will mention could be useful in this type of therapy. The modification of patient microbiome tending to resolve dysbiosis through the administration of beneficial bacteria could significantly improve conventional treatment [93]. Even more, considering that some microbial species exhibit tumor targeting specificity, this strategy could ameliorate cytotoxicity in non-tumor cells. Regarding bacterial products, given their low molecular weight and hydrophobicity, they can easily enter tumor tissues and exert their action[155]. These features result in the use of microorganisms with potential preventive or palliative action in CRC currently receiving special attention. In fact, microbe-based therapies, and bacteria-mediated modulatory strategies are studied to be used for the delivery of drugs to the tumor site and to produce anti-cancer vaccines[145,155]. However, the information about the toxins, metabolism of microbial-derived agents and complications from bacteriotherapy is still limited[155]. Thus, placing emphasis on clinical research that allows the use of these new therapies, overcoming the obstacles related to it, will be essential in the coming years.



In addition, as we discussed in the previous section, it is also necessary to focus on the restructuring of the TME in favor of improving conventional CRC treatment. Restructuring the extracellular matrix, modulating the immune response with vaccines, antibodies, or inhibitory drugs, employing drugs that induce changes in the secretion profile of TME cells, switching macrophages polarization and inhibiting CAFs and processes like fibrosis and inflammation are some of the potential effective techniques under investigation[1,5,116,128].

The development of vaccines containing CSC-specific antigens is also under investigation[5]. However, since many of the antigens present in this cell subtype are also found in differentiated cells or normal stem cells, this is a challenge to overcome for successful therapy.

So, the combination of conventional therapies with new targeted inhibitors (*e.g.* inhibitors of signaling pathways or molecules derived from TME) plus an appropriate diet that favors beneficial colonic microbiota, as well as the use of targeting methods such as charged nanoparticles or specific bacterial species, could constitute a reliable alternative to fight with CRC chemoresistance and relapses. The use of different *in vitro* and *in vivo* preclinical models of CCSC such as colonospheras, organoids and xenografts, is essential to achieve this goal and bring it to clinical research.

In the near future, the challenge will be the development of selective and combined therapies to promote: (1) CSC eradication; (2) Eradication of cancer cells, owing to their phenotypic plasticity, even in the absence of CSC features; and (3) Reduction of the damage to cells outside the tumor bulk.

In any case, it is clear that the standardization of treatment protocols is not always effective for this disease. It is advisable to resort to a combined and personalized therapy that considers the needs and responses of each patient.

Figure 2 The interplay among the tumor microenvironment and the gut microbiota influences the stemness of colorectal cancer cells. (1) Gut microorganisms and/or their derived products in a dysbiosis context influence the restructuration of tumor microenvironment (TME), favoring the release of several factors (growth factors, cytokines, non-coding ribonucleic acids and enzymes), immunological changes and an inflammatory environment; (2) The factors released by TME cells impact on intestinal microbiota promoting the growth of unhealthy microorganisms and their sustained unbalance; (3) Moreover, these TME factors can modulate the properties and behavior of colorectal cancer stem cells (CCSC) promoting effects such as their growth, survival, maintenance and tumorigenic potential; (4) In this context, CCSC response expressing factors that enable them to communicate with stromal cells and also influence a TME restructuration; (5) Microorganisms and/or their derived products can directly modulate the features and properties of CCSC, which in response; and (6) Probably affect the intestinal microbiota. All these associated events contribute to colorectal cancer progression. CCSC: Colorectal cancer stem cells; TME: Tumor microenvironment.

CONCLUSION

Figure 2 shows the interplay between the TME and the gut microbiota that influences the properties/behavior of CCSC. Besides, the reader can appreciate that CCSC influence on cells from TME favoring CRC progression but probably also on gut microbiota. The knowledge described in the present review provides data that may promote future research aimed at addressing the complexity of the components in the CRC-associated microenvironment and microbiota. Compounding such complexity, CRC is not an isolated neoplasm, but it's rather emerging as a dynamic pathology whose actors are capable, regrettably, of contributing to evasion mechanisms of the current therapeutic strategies. Although the incidence and mortality from CRC have decreased in recent years, a large number of patients still suffer from relapses due to resistance to treatment. The development of metastases and chemoresistance is undoubtedly one of the greatest challenges in CRC therapy. As we have seen in this work, the properties of the CCSC make this cell subtype have the main responsibility for the recurrences. The shift in the tumor niche and the intestinal microbiota favors the acquisition of CSC characteristics, promoting a worse prognosis of CRC. Although much is currently known about the interrelationship between components of the TME, the microorganisms present in the intestinal mucosa and CCSC, there is still much to be discovered in this field.

ACKNOWLEDGEMENTS

The authors would like to thank Antonela Rossi Bertone for her helpful advice. Being a teacher of English graduated from Instituto Superior Juan XXIII (from Bahia Blanca city, Argentina) and currently working at San Cayetano school (in the same city), she revised the paper and made useful comments as regards the spelling, grammar and punctuation of this manuscript.

Abstract

Literature data on glioblastoma ongoingly underline the link between metabolism and cancer stemness, the latter is one responsible for potentiating the resistance to treatment, *inter alia* due to increased invasiveness. In recent years, glioblastoma stemness research has bashfully introduced a key aspect of cytoskeletal rearrangements, whereas the impact of the cytoskeleton on invasiveness is well known. Although non-stem glioblastoma cells are less invasive than glioblastoma stem cells (GSCs), these cells also acquire stemness with greater ease if characterized as invasive cells and not tumor core cells. This suggests that glioblastoma stemness should be further investigated for any phenomena related to the cytoskeleton and metabolism, as they may provide new invasion-related insights. Previously, we proved that interplay between metabolism and cytoskeleton existed in glioblastoma. Despite searching for cytoskeleton-related processes in which the investigated genes might have been involved, not only did we stumble across the relation to metabolism but also reported genes that were found to be implicated in stemness. Thus, dedicated research on these genes in GSCs seems justifiable and might reveal novel directions and/or biomarkers that could be utilized in the future. Herein, we review the previously identified cytoskeleton/metabolism-related genes through the prism of glioblastoma stemness.

Key Words: Glioblastoma; Stemness; Cytoskeleton; Metabolism; Biomarkers; Therapy

©The Author(s) 2023. Published by Baishideng Publishing Group Inc. All rights reserved.

Core Tip: Glioblastoma stemness intensifies the resistance to treatment *via* increased invasiveness. Among the processes crucial for glioblastoma stem cells, metabolism is known to influence invasion. However, the cytoskeleton is currently negligent in glioblastoma stemness research, while it also regulates invasion. Herein, we review the link between stemness and cytoskeleton/metabolism-related genes that we previously identified in glioblastoma. These genes influence stemness *via* numerous biological processes; for some genes, clinical trials are currently ongoing. Others were connected to glioblastoma stemness for the first time. Future glioblastoma-related research should delve into the cytoskeleton since the concept is already encouraging.

INTRODUCTION

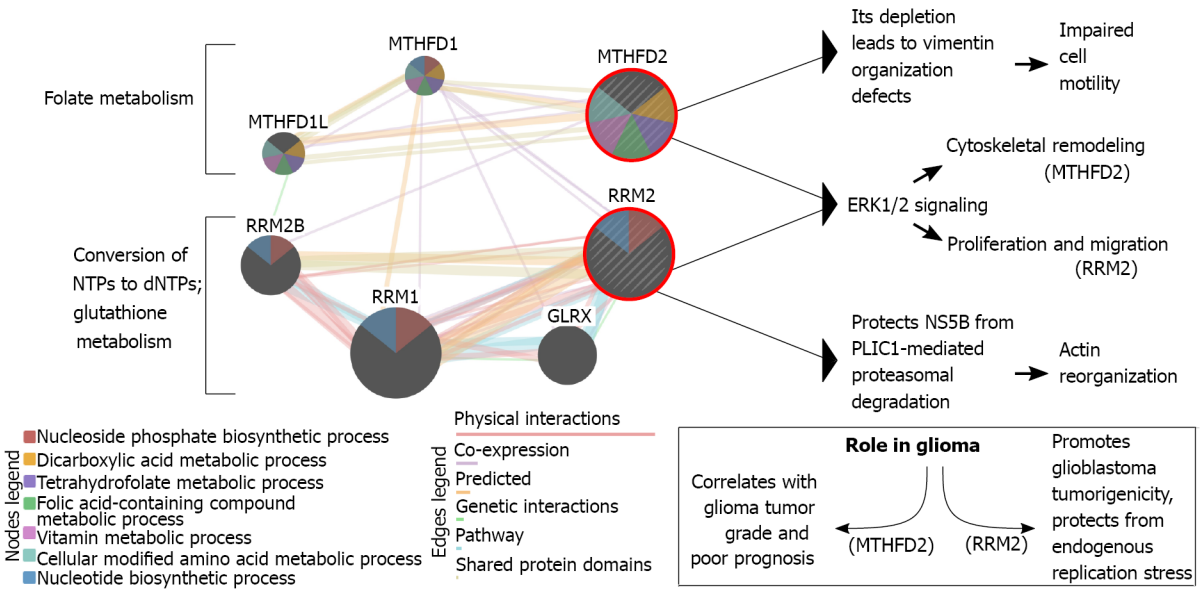
Glioblastoma (GBM) has remained an incurable condition with increasing incidence in many countries [1,2]. Although GBM is less prevalent than breast, colon, or lung cancer, it outperforms other tumors by affecting patients in the prime of their lives and causing them to lose many years of life[3]. The initial intervention in newly diagnosed GBM includes a surgical approach, with post-surgery temozolomide (TMZ) and radiation therapy[4]. Adding tumor-treating electric fields (TTFields) to maintenance TMZ chemotherapy was found to prolong progression-free and overall survival, but is currently limited due to the lack of methods to predict or quantify the efficacy of TTFields (the imaging features associated with treatment response are unclear and there are no predictive neuroimaging markers). Moreover, the treatment device is required to be worn for a predetermined period (typically approximately 75% of the time) or until there is a clinical progression of the disease, which introduces a delay in getting used to the device and makes patients anxious with regard to the intended therapy effect[5]. Strong motivation to predict TTField efficacy in a patient-specific manner was provided[6]. Nevertheless, glioblastoma recurrence is practically inevitable which, combined with a grim prognosis and ineffective treatment, underlines the importance of further research into this deadliest tumor[3,7].

One of the GBM traits that implicate the lack of effective treatment is the heterogeneity that can be explained by both clonal evolution and the presence of stem cells[8]. Stemness refers to the molecular events that underlie the essential characteristics of self-renewal and differentiation into daughter cells [9]. On the cellular level, some processes were indicated as crucial for GBM stemness, namely epigenomic regulation, posttranscriptional regulation, and metabolism[10]. Glioblastoma stemness research in recent years has also bashfully introduced a key aspect of cytoskeletal rearrangements [11, 12] while it has been long time since this machinery is well-known for controlling two processes that influence cancer malignant behavior, *i.e.*, cellular division and invasion[13]. The stemness itself is also responsible for potentiating the resistance to treatment[14,15], *inter alia* due to increased invasiveness [16]. In addition, more recent studies have identified the role of metabolism in GBM invasion[17]. Although non-stem glioblastoma cells are less invasive than GBM stem cells (confirmed by sevenfold reduced cell migration through the Matrigel, or 3.8-times and 6.8-times lower expression of matrix metalloproteinase-14 and -16)[18], the same cells also acquire stemness with greater ease if they are characterized as invasive cells and not tumor core cells[19,20].

The above-mentioned data imply that GBM stemness should be further explored for any phenomena related to the cytoskeleton and metabolism, as they may provide the missing puzzle from the point-of-view of invasion. Moreover, the cytoskeleton and metabolism are related; for instance, the cytoskeleton is involved in carbohydrate metabolism[21] and at the same time the actin and tubulin require energy from nucleotide hydrolysis to maintain structural dynamics[22]. Cytoskeletal rearrangements and metabolic alterations are important not only for GBM cells but also for neuronal and glial progenitors. For example, cytoskeleton dynamics underlie the cellular asymmetry while metabolic reprogramming ensures a transition in energy production from glycolytic to oxidative[23,24]. Nevertheless, it is possible to discriminate normal glial cells from glioblastoma; the cancerous cells present decreased cortical but increased intracellular stiffness, and preferentially metabolized glucose into lactate despite the abundance of oxygen[17,25]. Stiffness and metabolic adaptations can also influence stem cell differentiation[26,27]. Moreover, the cellular cross-talk that utilizes cytoskeleton or metabolites affects physical dynamics and signaling of various cell types including astrocytes, neurons, and oligodendrocytes[28, 29]. In cancers, such cross-talk renders abnormal protrusions or extensions termed as tumor microtubes that contribute to glioma resistance[30]. These structures are rich in cytoskeletal proteins, such as actin and tubulin, and are known to modify energetic metabolism of the receiving cells *via* transport of

mitochondria[31].

Our previous research has proved that interplay between metabolic alterations and cytoskeletal rearrangements exists in GBM[32]. Of genes described below in the present review (some previously identified genes were not included if their implication in stemness was not found in the literature) (Supplementary Table 1)[33-37], the example of a relationship between metabolism and cytoskeleton can be visualized (Figure 1) based on the literature on methylenetetrahydrofolate dehydrogenase 2 (MTHFD2)[38-41] and ribonucleotide reductase subunit M2 (RRM2)[42-45]. In our previous research, despite searching for cytoskeleton-related processes in which the investigated genes might have been involved, not only did we stumble across the relation to metabolism, but we also reported some genes which were found to be implicated in glioblastoma stemness. Thus, the dedicated work on these genes in the GBM stem cells (GSCs) seems justifiable and might reveal novel therapeutic directions and/or biomarkers that could be utilized in the future. Herein, we review the previously identified cytoskeleton/metabolism-related genes through the prism of GBM stemness. Literature screening allowed the decision to split these genes based on whether their role in stemness is known from GBM or another tumor, the latter suggesting an urgent need to experimentally verify the observations in the glioblastoma context.



GENES WITH CONFIRMED ROLE IN GLIOBLASTOMA STEMNESS

Bone morphogenetic protein 4

Based on the literature abundance, the best-known from its implication in glioblastoma stemness is bone morphogenetic protein 4 (*BMP4*). The bone morphogenetic proteins are growth factors from the TGF-β superfamily that undergo expression during embryogenesis and control development. Initially denoted as crucial for osteogenesis, they are now described as regulators of gastrulation, neurulation, mesoderm patterning, proliferation, and differentiation in many tissues[46]. About 15 years ago, it was found that the signaling *via* BMPs and their cognate receptors (BMPRs) influenced the activity of normal brain stem cells but could also inhibit the cancer-initiating GBM stem-like cells[47]. Later the same year, these authors confirmed that *in vivo* delivery of *BMP4* blocked the tumor growth and associated mortality, which occurred in all mice following intracerebral grafting of human glioblastoma[48]. This protein was suggested as a non-cytotoxic therapeutic agent that can be utilized in combination with stem cell-based therapy[49]; this complements its usage as an agent used to differentiate GSCs into normal glial cells [50]. *BMP4* has been found promising to the extent that it entailed the development of novel therapies. For example, one that utilizes the oncolytic vaccinia virus was developed to alleviate glioblastoma and prevent its recurrence[51]. Later on, the cell-based treatment option of BMP4-secreting human adipose-derived mesenchymal stem cells was found to reduce proliferation and migration both *in vitro* and *in vivo*, as well as prolong survival in a murine model[52]. Still, Videla Richardson *et al*[53] admitted that little is known about this morphogen regarding triggered cellular events, which prompted the authors to establish several GSC-enriched cell lines growing as adherent monolayers and not floating neurospheres. Distinct lineage preferences were noticed depending on the expression pattern of BMP signaling-astrocyte fate or neuronal commitment was noticed and, under certain conditions, even a smooth muscle-like phenotype[53]. Providing new findings to the available data, *BMP4*-overexpressing neural stem cells were found to promote GSCs apoptosis *via* Smad1/5/8 signaling[54]. Moreover, recent studies indicate a formerly underestimated link between *BMP4* and metabolism or mechanotransduction which affects oxygen consumption or matrix stiffness[55]. The latter is known to be associated with cytoskeletal remodeling[56,57]. With regard to the cytoskeleton, *BMP4* was found to re-organize actin dynamics *via* activation of Rac1, Rho, and Cdc42[58]. The impact of *BMP4* in inducing asymmetric cell division was also noted, limiting the GSCs expansion[59]. The newest literature data on *BMP4* consider it on a broader scale, either evaluating other GBM aspects and referring to *BMP4*, or investigating upstream/downstream molecules. Ciechomska *et al*[60] explored *EGFR* alterations in glioblastoma since GSCs with various *EGFR* levels respond differently to therapy; the authors found that EGFR/FOXO3a/BIM signaling pathway determined chemosensitivity of BMP4-differentiated GSCs to TMZ. On the other hand, Wu *et al*[61] identified BIRC3 as an inducer of glioblastoma stemness *via* downstream *BMP4* inactivation. At last, the most recent paper by Verploegh *et al*[62] summarized the cellular viability variance in response to *BMP4* and proposed early-response markers for sensitivity to *BMP4*. Three cultures with the highest sensitivity for *BMP4* revealed a new cell subpopulation that presented a reduced cell proliferation but an elevation of apoptosis. These changes in composition correlated with treatment efficacy; the latter was predicted using *OLIG1/2* expression. Furthermore, upregulated *RPL27A* and *RPS27* were considered early-response markers. Interestingly, *RPS27* is one of the genes identified in our previous study that prompted us to investigate the aspects presented in this review. This gene will be described below in a separate subsection.

Glutamate ionotropic receptor NMDA type subunit 2B

Glutamate ionotropic receptor NMDA type subunit 2B (GRIN2B) encodes one subtype of glutamate-binding GluN2 subunit, which is a part of the N-methyl-D-aspartate receptor (NMDAR). Ionotropic

DOI: 10.4252/wjsc.v15.i5.302 **Copyright** ©The Author(s) 2023.

Figure 1 Example of the interplay between cytoskeleton and metabolism using the biological function of methylenetetrahydrofolate dehydrogenase 2 and ribonucleotide reductase subunit M2 enzymes. Typically, methylenetetrahydrofolate dehydrogenase 2 (MTHFD2) dehydrogenase is known for its activity in folate metabolism, whereas ribonucleotide reductase subunit M2 (RRM2) reductase is known for the conversion of ribonucleotide triphosphates to deoxyribonucleotide triphosphates which requires metabolic resources supplied by reduced glutathione. However, these two enzymes (encircled in red) are also involved in cytoskeletal rearrangements that are summarized on the right side of the figure. Literature data indicate that they also affect the same pathway (*i.e.*, ERK1/2 signaling) but render various outcomes. Moreover, their role in glioma has already been proposed (bottom-right panel). Figure created using Inkscape and GeneMania (*MTHFD2* and *RRM2* as query genes; five "resultant" genes included to highlight interconnectivity; exemplary metabolism-related processes included from the built-in functional analysis). NTP: Ribonucleotide triphosphates; dNTPs: Deoxyribonucleotide triphosphates; MTHFD: Methylenetetrahydrofolate dehydrogenase; RRM2: Reductase subunit M2.

glutamate receptors from this family mediate Ca^{2+}, *i.e.*, the permeable component of excitatory synaptic transmission in the central nervous system (CNS)[63]. NMDARs assemble from four subunits: two GluN1 and two GluN2. The former subunits are widely expressed in the nervous system, while four subtypes of GluN2 subunits (from "A" to "D") are characterized by various expression patterns[64]. *GRIN2B* encodes the GluN2B subunit, which is abundantly expressed in the prenatal period, then declines in most brain parts[65]. The presence of GluN2B in such an early stage implies that it contributes to brain development, circuit formation, synaptic plasticity, as well as migration and differentiation[66]. Glutamate-dependent synaptic transmission is frequently dysfunctional in gliomas[67], and regarding this specific subunit, an enrichment of expression was noticed in GSCs[68]. In our previous research, with the use of literature data, we related this gene with the cytoskeleton since GluN2B interacts with cytoskeletal protein α-actinin-2 *via* the carboxyl-terminal domain[63]. It might be of importance as α-actinin-2 is closely associated with multimerins which are possible markers and therapeutic targets in low-grade glioma[69]. Moreover, one of the multimerins encoded by the *MMRN1* gene was found to be correlated to stemness and chemoresistance, although these observations were based on the leukemia model[70]. Nevertheless, *GRIN2B* is confirmed to influence stemness not only in glioblastoma but also in lung cancer. She *et al*[71] identified *GRIN2B* expression to be higher in primary tumors than in normal tissues, and at the same time higher in metastatic lesions than in primary tumors which contributed to poorer prognosis. Moreover, the same authors observed inhibition of tumorsphere formation during *GRIN2B* silencing.

Homeobox protein A10 and A1

The homeotic genes, in vertebrates denoted as homeobox, are highly conserved and regulate the proper development of various body segments during ontogeny[72]. Homeobox protein A10 (*HOXA10*) is implicated in the embryogenesis of the uterine epithelium, stroma, and muscle[73]. In response to hormones, it undergoes periodical expression in the mature endometrium, controlling receptivity during the implantation window[74]. Concerning GBM stemness, the functionality of *HOXA10* was presented as a direct result of the activation of protein from the *Trithorax* family, which serves as a histone methyltransferase, *i.e.*, MLL. Afterward, *HOXA10* activated other *HOXA* genes, such as *HOXA7* and *HOXC10*[75]. In another study, *HOXA10* was marked as one of the strongest candidates (alongside the *HOX -A9*, *-C4*, and *-D9* genes), having value as a therapeutic target and biomarker for both GBM and GSCs[76]. Our previous research echoed the data that *HOXA10* facilitated cytoskeleton remodeling (*via CK15*)[77], promoted tumorigenesis in glioma[78], and regulated homologous recombinant DNA

repair and subsequently TMZ resistance in GBM[79]. Since stemness also contributes to treatment resistance[14], the last two events complement each other mutually. Another homeotic gene that we identified in our previous study was *HOXA1*, a homeobox that is abundantly expressed in the mesoderm and neuroectoderm at the level of the brainstem precursor[80]. Upregulation of *HOXA1* was noted in GBM, which inversely correlated with the survival of patients[81]. This homeotic member was also implicated in regulating the cytoskeleton *via* E-cadherin. Namely, *CDH1*-dependent signaling was found to increase *HOXA1* expression through Rac1, *i.e.*, the same pathway that regulates actin cytoskeleton at cadherin adhesive contacts[79]. With regard to GBM stemness, Schmid *et al*[82] observed upregulated HoxA locus (encompassing, *e.g.*, *HOXA1*) after they dedifferentiated murine astrocytes into GSCs *via* Rb knockout, Kras activation, and Pten deletion. These cells were sufficient to form GBMs in their transplant mouse model. Although the insights did not provide further mechanistic details, the regulation loop of *HOXA1* and HOXA transcript antisense RNA (HOTAIRM1) was found to be involved in stemness maintenance[81,83]. This was presented in colorectal carcinoma and uveal melanoma. Still, taking into account the study by Schmid *et al*[82], the profound investigation of *HOXA1* in GSCs in this aspect should be considered.

Matrix metalloproteinase 13

Matrix metalloproteinases are constituents of extracellular matrix (ECM) belonging to the zinc-containing endopeptidases family that encompasses 23 members[84]. Functionally, these calcium-dependent molecules are responsible for the degradation and remodeling of other proteins that constitute ECM. Moreover, their roles in various biological and physiological processes dependent on hormones, growth factors, and cytokines were described[85]. It is known that different ECM components modulate cancer stem cells' properties; regarding glioblastoma, the confirmed ones were type I collagen, laminin α2, fibronectin, periostin, decorin, and lumican[86]. Matrix metalloproteinase 13 (*MMP13*) is a collagenase almost universally upregulated in the pan-cancer view[87]; in GBM, its overexpression increases migration and invasion[88], as well as confers poor prognosis[89]. The relationships between *MMP13* and the cytoskeleton[33] or metabolism[90] are known. In terms of stemness, Inoue *et al*[91] suggested that highly invasive potential GSCs depended on MMP13 enzymatic activity; the authors also proposed MMP13 as a potential therapeutic target.

MTHFD2

The folate cycle is responsible for appropriate cellular metabolism by regulating ATP production, methylation reactions for DNA/protein synthesis, or developing immunomodulatory molecules that orchestrate signaling and cytotoxicity[92]. The differences between *MTHFD1* and *MTHFD2*, two enzymes implicated in the folate pathway, include the use of different co-enzyme (NADP *vs* NAD), functionality (*MTHFD1* has three distinct enzymatic activities while *MTHFD2* is bifunctional), and location (cytoplasm *vs* mitochondria). Compared to *MTHFD1*, which generates NADPH and formate for purine biosynthesis, *MTHFD2* is overexpressed in rapidly proliferating malignant tumors. It is considered the "main switch" that enables mitochondria to produce additional growth-facilitating one-carbon units and generates NADH necessary for protection from reactive oxygen species[93]. *MTHFD2* is also an excellent example to present the link between metabolism and cytoskeleton. Lehtinen *et al*[39] have found that *MTHFD2* depletion leads to vimentin organization defects, and identified this gene as a regulator of cell migration and invasion. Regarding glioma, *MTHFD2* was found to be associated with tumor grade and prognosis[38]. Inhibition of this enzyme in GSCs induced apoptosis and affected not only central carbon metabolic pathways (*e.g.*, glycolysis, pentose phosphate pathway, and tricarboxylic acid cycle) but also unfolded protein response, highlighting a novel connection between one-carbon metabolism and reaction to cellular stress[94]. Nishimura *et al*[95] suggested that the purine synthesis pathway, as well as folate-mediated one-carbon metabolism, seem to be crucial for the maintenance of tumor-initiating cells. The same authors also concluded that EGF-induced expression of *MTHFD2* may be mediated by Myc, with the latter regulating the expression of metabolic enzymes for the maintenance of brain tumor-initiating cells.

Plant homeodomain finger-like domain-containing protein 5A

Alternative splicing maintains post-transcriptional gene regulation, which enables a single gene to be transcribed into various RNAs, diversifying the proteome. Abnormal splicing function can lead to tumor-related processes, *e.g.*, proliferation, angiogenesis, and metastasis[96]. Spliceosome, a dynamic machinery responsible for splicing, is made of small nuclear ribonucleoproteins (snRNPs; five molecules are known: U1, U2, U4, U5, and U6) and numerous non-snRNP proteins[97,98]. U2 snRNP comprises U2 snRNA, SF3a complex, and SF3b complex, which are responsible for recognizing branchpoint sequences during initial spliceosome assembly stages[99]. Splicing factors comprising the SF3b complex include plant homeodomain (PHD) finger-like domain-containing protein 5A (*PHF5A*), which facilitates interactions between the U2 snRNP and RNA helicases[100] but can also bind chromatin *via* its PHD that is composed of a small zinc finger structural fold[101,102]. The knockdown of *PHF5A* results in reduced GBM viability and cell cycle arrest[103]. Trappe *et al*[104] revealed that systematic deletion of its yeast homolog is lethal, showing that *PHF5A* is crucial for cell viability. The flagship paper on *PHF5A*

in brain tumor[105] indicates that the gene is required to expand GSCs and that in these tumor-initiating cells, but not untransformed neural stem cells, *PHF5A* contribute to the identification of exons having unusual C-rich 3′ splice sites in thousands of essential genes. The same authors inhibited *PHF5A*, which reduced GSCs-driven tumor formation *in vivo* and inhibited the growth of established GBM patient-derived xenograft tumors.

Ribosomal protein S27

One of the most dynamic and largest molecular motors (driven by a complex thermal ratchet translocation mechanism) are ribosomes[106]. Metallopanstimulin-1, also known as ribosomal protein S27 (*RPS27*), is a constituent of the human 40S ribosome that is mainly found in the cytoplasm while it can also relocate to the nucleus[107] or even extracellular space[108]. Regarding the nuclear location, it is able to interact with DNA *via* its C4-type zinc finger[109]. In glioblastoma, *RPS27* was found to be correlated with age in IDH-mutated glioma patients and with Ki67 in GBM patients. Interestingly, it is detected in astrocytic tumors but not in normal astrocytes unless the tissue was inflamed[109]. This allowed the same authors to emphasize that in comparison to inflammatory tissue (in which only a small number of macrophages were positive for *RPS27*), almost all macrophages in tumor tissue were distinctly enriched in *RPS27* expression. As for GSCs, the ribosomes and related proteins were generally found to reprogram glioma cells to induce plasticity and stemness[110]. Among these molecules, *RPS27* was considered oncogenic with higher expression at the GSC-dominant area[111]. Inquisitive findings revealed that *RPS27* is also detected in the microvascular proliferation area and pseudopalisading cells around necrosis[110]. It is worth underlining that aberrant vessels are crucial for the formation of pseudopalisading necrotic regions that provide shelter for residing cancer stem cells from anti-tumor agents, which enable these cells to expand and promote proliferation and growth[112]. As mentioned above, upregulated *RPL27A* and *RPS27* were considered to be early-response markers related to the presence of *BMP4*. This suggests a link that should be further investigated since the signaling of ribosome translation was found to be overexpressed during the response to stress in glioblastoma.

RRM2

A balanced supply of deoxyribonucleotide triphosphates (dNTPs) is a prerequisite of DNA synthesis. Still, *de novo* synthesis of dNTP is also possible *via* the reaction catalyzed by the ribonucleotide reductase (RR) that reduces the C2′-OH bond of the four ribonucleotides triphosphates to form corresponding dNTPs[113]. *RRM2* encodes the β subunit of RR; each RRM2 monomer contains the tyrosyl radical and non-heme iron[114]. Since a sufficient supply of dNTPs drives an uncontrolled DNA replication in cancer[115], it is not surprising that *RRM2* was frequently subjected to molecular therapy[116,117]. Currently, several RRM2 inhibitors have been developed, *e.g.*, radical scavengers, iron chelators, subunit polymerization inhibitors, or expression silencers[118-120]; this is to inhibit proliferation, division, but also invasion[32]. In glioblastoma, *RRM2* is responsible for the advancement of GBM tumorigenicity and protection from endogenous replication stress *via* the BRCA1-RRM2 axis[45]. For glioma in general, regulation of proliferation and migration *via* ERK1/2 and AKT signaling was noted[44]. Available literature also links the *RRM2* to the cytoskeleton *via* hPLIC1; the latter decreases during *RRM2* downregulation, which entails actin cytoskeleton re-organization[42]. Perrault *et al*[121] have suggested that *RRM2* can be a chemoresistance driver that dictates how GBM cells respond to TMZ. The same authors further verified that *RRM2*-overexpressing cells had enhanced DNA repair efficiency. Moreover, the use of a selective FDA-approved RRM2 inhibitor, 3-AP Triapine, enabled Perrault *et al* [121] to observe that in comparison to both TMZ and control, glioblastoma treated with the 3AP + TMZ formed fewer neurospheres that were also significantly smaller. Another group found that *RRM2* expression dramatically declined after 12 d of dasatinib treatment compared to naïve GSCs of the GSC8 cell line[122].

Serum amyloid A protein 2

In order to re-establish homeostasis, both adaptable and primordial mechanisms exist; the latter comprises the acute-phase response (APR) that is a set of changes that occur after inflammation, infection, or trauma[123]. During APR, the changes include the altered levels of serum proteins, with the most notable being C-reactive protein and serum amyloid A (SAA)[124]. Being an apolipoprotein, SAA is related to plasma high-density lipoprotein and is implicated in the cholesterol transport to the liver for excretion as bile[125]. Its other functions include regulation of amyloidogenesis, tumor pathogenesis, anti-bacterial events, and inflammatory response[126]. The role of SAA in tumor progression was suggested owing to its cytokine-like properties that influence the course of inflammation[127]. *SAA2* is one of the paralogs of the family and was investigated as a lung cancer biomarker a few years ago[128]. The description of its role in glioblastoma is limited, yet it is already known that *SAA2* increases GBM proliferation and invasion[129]. Knebel *et al*[130] have confirmed that SAA production occurs not only in the liver but also in tumor cells; the authors emphasized that exploring the SAA influence on the cytoskeleton and invasiveness using more complex assays is needed. In terms of GBM stemness, Adamski *et al*[131] recently have compiled the literature data and stated that *SAA2* is implicated in a drug-promoted cellular dormancy, with the latter being closely connected to stem cell characteristics.

The group also indicated the ability of *SAA2* to sustain inflammatory conditions in the brain, which consequently supports TMZ resistance and induces the expression of stemness markers in glioblastoma.

Wilms' tumor protein 1

The 5-methylcytosine (5mC) and its derivatives have altered patterns in a range of tumors. 5mC can be recognized and oxidized to 5-hydroxymethylcytosine, 5-formylcytosine, and 5-carboxylcytosine by Ten-Eleven translocation (TET) enzymes[132,133]. One of the transcription factors that directly interacts with TET proteins is Wilms' tumor protein 1 (WT1): A master regulator essential for urogenital, epicardium, and kidney development that can act as a tumor suppressor or oncoprotein in multiple tumors[134, 135]. Initially cloned as a suppressor of Wilms' tumor, WT1 is now considered to be an oncoprotein in hematologic malignancies and a variety of solid tumors, as well as the protein with the highest potential for cancer immunotherapy[136-138]. According to the phase I/II clinical trial, WT1 peptide-based vaccine for glioblastoma patients was considered safe and induced cellular and humoral immune response[139]. This is important due to the fact that *WT1* is involved in GBM tumorigenicity *via* increasing proliferation and decreasing apoptosis[140]. As for the impact on the cytoskeleton, this protein was found to interact with actin both in the cytoplasm and nucleus, as well as supposedly binds to RNA in a cytoskeleton-dependent regulation manner[141]. Focusing on GBM stemness, Mao *et al*[142] found that *WT1* was expressed predominantly in mesenchymal GSCs which, compared to proneural stem cells subtype, are characterized by higher proliferation, greater radioresistance, and implication in worse patients' prognosis. Uribe *et al*[143] reviewed that mesenchymal GSCs develop tumors having more blood vessels, hemorrhagic lesions, and necrotic areas; the expression pattern in these stem cells generally facilitates inflammation, angiogenesis, migration, invasion, and glycolysis-mediated metabolism. Undoubtedly, more insights are needed concerning GBM molecular pathways in which *WT1* is implicated.

GENES WITH STILL UNCONFIRMED ROLE IN GLIOBLASTOMA STEMNESS

Chemokine-like factor superfamily 6

Cytokines are soluble proteins that are secreted by immune and non-immune cells in response to stimulants such as immunogens or mitogens; this allows them to maintain the immune response and homeostasis[144]. Chemokines constitute a specific type of small (8-13 kDa) cytokines that promote the directed chemotaxis of nearby cells[145]. Consisting of nine members, the chemokine-like factor superfamily (CMTM) is expressed throughout the human tissues and regulates immune, circulatory and muscular systems, as well as the hematopoiesis[146-149]. The aberrant *CMTM* expression is implicated in various diseases, *e.g.*, rheumatoid arthritis, atopic dermatitis, focal cerebral ischemia, male infertility, as well as tumorigenesis and metastasis[150-153]. The influence of *CMTM6* on glioblastoma is known, but the research in this entity seems to be in the initial state. Guan *et al*[154] revealed that the highest *CMTM6* expression was noted in the glioblastoma (WHO grade IV) compared with WHO grade II and III gliomas. Enrichment was also observed in both microvascular proliferation and hyperplastic blood vessels, which are both essential for tumor progression. In GBM, *CMTM6* was also associated with one of the genes of immune checkpoints, *i.e.*, *TIM-3*. From a broader glioma scale, the same authors summarized it as a molecule diminishing T-lymphocyte-dependent anti-tumor immunity, reducing patient survival and indicating poor prognosis. However, it is still yet to be elucidated what role *CMTM6* may play in the GBM stemness. Currently, its contribution to such characteristics is confirmed on the basis of data from head-and-neck squamous cell carcinoma. Chen *et al*[155] observed poorer patient prognosis during *CMTM6* overexpression that correlated with overactive Wnt/β-catenin signaling, *i.e.*, the pathway crucial for tumorigenesis, epithelial-to-mesenchymal transition (EMT) and cancer stem cells maintenance. Silencing of *CMTM6* led to PD-L1 downregulation, decreased tumor growth, and increased $CD8^+$ and $CD4^+$ T-cell infiltration. Eventually, the authors not only suggested the therapeutic suitability of *CMTM6* but also concluded that this protein is implicated in EMT, stemness, and T-cell dysfunction. Similar research in the glioblastoma context is advisable, especially since *CMTM6* can stabilize PD-L1 protein to impair T-cell function[156,157], as well as their combined expression had prognostic significance in pancreatic ductal adenocarcinoma and triple-negative breast cancer[158]. Nowadays, the role of PD-L1 in cancer and immunotherapy is unquestionable[159]; focusing on another protein related to this well-established molecule might bring novel strategies.

Dual specificity phosphatase 7

Signal transduction is based on phosphorylation and dephosphorylation events performed by kinases and phosphatases, leading to a cellular program relevant to the encountered stimulus[160]. Dual specificity phosphatases (*DUSP*) are responsible for the dephosphorylation of threonine and tyrosine residues on mitogen-activated protein kinases, rendering them inactive[161]. Even if *DUSP7* was only noted as downregulated in glioblastoma, whereas *DUSP1*, *DUSP5*, and *DUSP6* were induced within pseudopalisading and perinecrotic GBM regions[162], the role of *DUSP7* in preserving the pluripotency of non-cancerous stem cells was certified in a murine model[163]. However, its contribution could be

distinct from *DUSP1*, *DUSP5*, and *DUSP6* but similar to *DUSP2*, *DUSP8*, and *DUSP9* which were clustered together with *DUSP7* in the study of Mills *et al*[162]. At last, it is worth noting that *DUSP7* guides chromosome dynamics which is known for being regulated by cytoskeletal proteins[164,165]. The study linking this phosphatase to metabolism revealed that *DUSP7* knockout accelerates metabolic disorder and insulin resistance in mice with a high-fat diet[166].

Kinesin family member 20A

Cytoskeletal elements that act as scaffolds for intracellular cargo transport are microtubules. Motor proteins known as kinesins and dyneins orchestrate microtubule-related transport that is essential for cell differentiation or survival[167]. Kinesins constitute a large superfamily responsible for cargo trafficking, as well as controlling microtubule growth and stability[168]. Increased expression of kinesin superfamily representatives KIF4A, -9, -18A, and -23 was associated with poor prognosis in low-grade glioma and glioblastoma[169]. The pro-cancerous characteristics of *Kinesin family member 20A* (*KIF20A*) were noted more than 15 years ago in pancreatic cancer, which presented a reduction of proliferation once *KIF20A* was downregulated[170]. Currently, accumulating evidence shows that this kinesin is overexpressed in multiple tumors[171]. In glioblastoma, *KIF20A* downregulation induces cell cycle arrest and apoptosis *via* suppressing PI3K/AKT pathway[172]. Regarding cytoskeleton-related events, it is not only essential for cytokinesis but also interacts with Rab6 to regulate Golgi-related vesicle trafficking[173]. Although the role of *KIF20A* in GBM stemness has not yet been confirmed, it was suggested outside of the glioblastoma context in a study by Qiu *et al*[174]. The authors conceived the importance of *KIF20A* in controlling proliferation *vs* differentiation of tumor-initiating cells, based on both the fact that cancer stem cells share many mechanisms with neural progenitors, as well as their observations where *KIF20A* was implicated in balancing symmetric and asymmetric divisions during cerebral cortical development[175]. The *KIF20A* inactivation affected cortical neural progenitor cells that switched from proliferative to differentiative mode. During divisions, daughter cell-fate specification was controlled by *KIF20A* in coordination with *RGS39* and *SEPT710*[174,176].

Neurofibromatosis type 2 protein

Neurofibromatoses (type 1, type 2, schwannomatosis) are distinct, dominantly inherited disorders that have in common the occurrence of nerve sheath tumors[177]. Type 1 neurofibromatosis presents with neurofibromas, cafe-au-lait spots/macules, freckling, and optic gliomas, whereas type 2 neurofibromatosis is characterized by bilateral vestibular schwannomas, ependymomas, and meningiomas [178]. Each disease has a different underlying genetic alteration: Type 1 neurofibromatosis is related to the *neurofibromatosis type 1 protein* (*NF1*) gene, type 2 is linked to *NF2*, while schwannomatosis to integrase interactor 1 (*INI1*, also known as *SMARCB1*). The protein product of *NF2* has the same name as its gene but can also be referred to as Merlin. Although this tumor suppressor is not mutated in GBMs, it exhibited oncogenic properties in glioblastoma when phosphorylated at serine 518; this post-translational modification inactivates Merlin's anti-cancer capabilities, which affects the expression of EGFR or Notch1 and its downstream targets, *i.e.*, *HES1* or *CCND1*[179]. Other authors demonstrated that upon *NF2* re-expression, a regulation of YAP, cIAP1/2, and the Hippo signaling pathway led to the inhibition of glioma growth and progression[180]. Merlin is also known for regulating cell morphology or motility, and its loss renders dramatic changes in cellular adhesion and cytoskeleton organization [181,182]. Specifically, this protein is closely related to ezrin, radixin, and moesin (collectively denoted as "ERM"), *i.e.*, critical proteins that enable the anchorage between membrane proteins and cortical cytoskeleton[183]. Ultimately, the link between *NF2* and stemness might be related to CD44, the receptor of which cytoplasmic tail can interact with both Merlin and "ERM" proteins[184,185]. Literature data state that *NF2* exhibits tumor suppressor function *via* negative regulation of CD44[186], whereas this receptor has been repeatedly indicated as a marker of cancer stem cells in various tumors, such as leukemia and carcinoma of breast, colon, ovarian, prostate, or pancreas[187-191]. Knowing that CD44 is also an upstream regulator of the aforementioned Hippo signaling pathway[192], of which components regulate the stem cell niche, self-renewal, maintenance, and differentiation[193-196], one could investigate Merlin in the GBM stemness context taking into the account the NF2-ERM-CD44-Hippo regulation network.

Retinoid X receptor gamma

The signal transduction molecules being vitamin A derivatives are retinoids, they regulate cellular differentiation and proliferation *via* members of the nuclear receptors superfamily, including retinoic acid receptors (RARs) and retinoid X receptors (RXRs)[197]. The RXR family members (RXRA, RXRB, and RXRG) form heterodimers within the superfamily, *e.g.*, with vitamin D, retinoic acid, or peroxisome proliferator-activated types of receptors[198,199]. RXRs have tumor suppressor properties and, as partners of *RARA* and *RARB*, they are implicated in the anti-proliferative effects of retinoic acid[197]. *RXRG* was found to modulate differentiation and apoptosis in various tumors, indicating its function in cancer pathogenesis[200]. Glioblastoma-related research certifies the general view that *RXRG* contributes to anti-neoplastic effect *via* its ligands; in study by Papi *et al*[201], the treatment of GBM with 6-OH-11-O-hydroxyfenantrene had anti-proliferative and anti-invasive effects. However, the literature

data on glioblastoma stemness seem to focus on RARs rather than RXRs. Ying *et al*[202] evaluated the cellular and molecular responses of GSCs to all-*trans* retinoic acid; this treatment changed cells morphology (*e.g.*, decreased neurosphere-forming capacity), caused growth arrest at G_1/G_0 to S transition, reduced cyclin D1 expression, and elevated p27 expression. Moreover, differentiation markers such as Tuj1 and GFAP were induced, while stem cell markers, such as CD133, Msi-1, Nestin, and Sox-2, had decreased expression. Friedman *et al*[203] provided similar observations with regard to Nestin level or neurosphere formation but also indicated that GBM differentiation induced by all-*trans* retinoic acid is executed *via* the ERK1/2 pathway. Evidently, retinoid-related research in the GBM context frequently focuses on all-*trans* retinoic acid while this isomer is bound only by RARs and not by both RARs and RXRs, as is the case with another retinoic lipid: *9-cis*[204]. Even if two of the best-known retinoid receptors (*RARA* and *RXRA*) are described in detail by Rodriguez *et al*[205] in the GBM stemness context, the data on *RXRG* is still lacking and should begin with evaluation of whether *9-cis* retinoid acid is able to manifest the anti-glioblastoma effects *via RXRG* and subsequently ERK1/2 pathway.

SPARC/Osteonectin, CWCV, Kazal-like domains 1

ECM is a component containing elastin, collagen, laminins, glycoproteins, fibronectin, and proteoglycans. Together, these elements bind *via* cell adhesion receptors and form a complex macromolecular network[206]. Matricellular proteins are made of matrix-binding proteins and cytokines that can be located within the cell or secreted outside[207]. SPARC/Osteonectin, CWCV, Kazal-like domains 1 (SPOCK1), also referred to as testican-1, is an ECM proteoglycan from a matricellular family of proteins that regulate matrix remodeling and affects tumor progression[208-210]. As the interplay between ECM and cytoskeleton is known[211], it is not surprising that changes in *SPOCK1* lead to alterations in cytoskeletal components. For example, Schulz *et al*[212] noticed that *SPOCK1* upregulation paralleled that of *EPB41L4B*, the latter being a cortical cytoskeleton protein underlying cellular membrane. With regard to brain tumors, testican-1 contributes to GBM metastasis and resistance to TMZ, as well as promotes glioma invasion, migration, and proliferation *via* Wnt/β-catenin and PI3K/AKT pathways[213,214]. Mediating TMZ chemoresistance *via SPOCK1* in GBM was independently confirmed by Sun *et al*[215]. Although not yet directly concluded by any scientific group, it is conceivable that the impact of *SPOCK1* on TMZ resistance renders a similar GSCs-related effect as *SAA2* which was described in one of the previous sections.

Ubiquitin-like with PHD and ring finger domains 1

The proteins' turnover and degradation depend on ubiquitination that is orchestrated by the ubiquitin-proteasome system (UPS)[216], of which alterations can lead to several tumor types[217,218]. One of the ubiquitin-protein ligases responsible for the UPS specificity is ubiquitin-like with PHD and ring finger domains 1 (*UHRF1*)[219], a molecule also interacting with DNA methyltransferase 1, which together constitute the main regulatory axis of cellular senescence[220]. *UHRF1* was already identified as a novel oncogene and/or druggable epigenetic target for various tumors[221-223], and Jung *et al*[220] suggested its role as a switch molecule between senescence and cancer. In GBM, *UHRF1* is overexpressed by upstream CD47 and regulates downstream silencing of tumor suppressor gene $p16^{INK4A}$, leading to increased proliferation[224]. Regarding cytoskeleton, *UHRF1* contributes to microtubule organization through its downstream targets: *BRCA2*, *HOOK1*, *KIF11*, and *KIF18A*[225]. The role of *UHRF1* in different types of stem cells is documented but overlooks GSCs. Namely, it was found to be required for the proliferative potential of basal stem cells in response to airway injury[226], as well as regulate the transcriptional marks at bivalent domains in pluripotent stem cells[227]. On the other hand, *UHRF1* decrease was found to be a major cause of DNA demethylation in embryonic stem cells[228] and led to the activation of retroviral elements and delayed neurodegeneration[229]. It is evident that research in the glioblastoma context should be pursued in the future, especially since some epigenetic features, next to transcriptional ones, are unique in GSCs compared to neural stem cells and may include druggable targets for new therapeutic approaches[230].

DISCUSSION

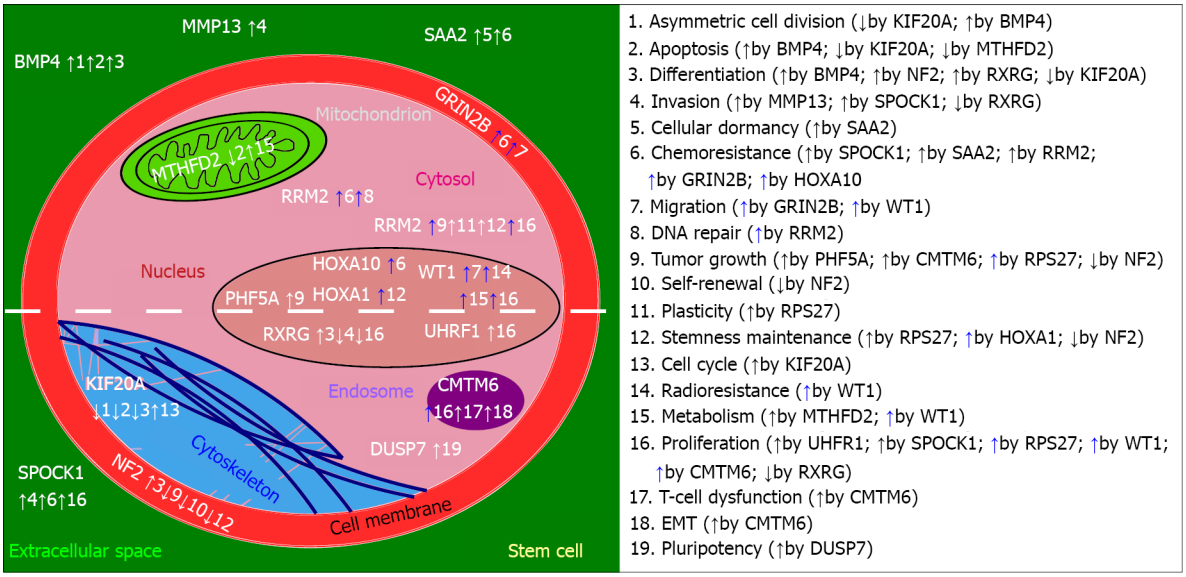
Despite molecular advancements, there is still a considerable need for glioblastoma biomarkers[231], especially since the relatively ineffective treatment leaves the patients with a very dismal chance of survival[232]. One of the glioblastoma traits involved in the absence of effective treatment is tumor heterogeneity which can be explained by clonal evolution and the presence of stem cells[8].

Many independent studies on various tumor types have reported common genes as potential therapeutic or diagnostic biomarkers[233]. Al-Fatlawi *et al*[234] contemplated that biomarker signatures for different cancer types should be similar, due to the fundamental mechanisms shared between tumors, *e.g.*, survival, tumor growth, or invasion. Thus, we presume that our description of stemness-related genes, especially those still unconfirmed in GBM, adds significant value to the current knowledge and provide insights into novel therapeutic or diagnostic directions.

For clarity, a graphical presentation was prepared to emphasize the role of described genes specifically in stem cells, setting aside the rest of the information provided for each gene (Figure 2). At first glance, the most frequently regulated processes are proliferation and chemoresistance, followed by differentiation, tumor growth, invasion, and apoptosis. Except for *BMP4* (increase in asymmetric cell division and apoptosis), *NF2* (reduced self-renewal, tumor growth, stemness maintenance), *RXRG* (decrease in invasion and proliferation), and *DUSP7* (insufficient data for a definite conclusion), the remaining genes exhibit pro-cancerous properties. This corresponds to what was described in subsections, separately for each gene. Interestingly, two genes that promote invasiveness of stem cells (*SPOCK1*, *MMP13*) are known to affect the cytoskeleton[33,212] and, in terms of *MMP13*, also the metabolism[90]. Two genes that were also found to regulate both the cytoskeleton and metabolism were *MTHFD2* and *RRM2*. On the one hand, they control the organization of vimentin and actin; these proteins are known for influencing glioblastoma migratory potential[235,236]. On the other hand, the contribution of *MTHFD2* and *RRM2* to metabolism is related to folate and glutathione cycles that are implicated in the resistance of GBM to therapy[237,238].

In order to gravitate towards the link between metabolism, cytoskeleton, and GBM stemness, the appropriate representatives of each process (including the most frequently regulated processes that were mentioned above), were compiled into a cross-talk network. This allowed us to integrate the aim of our review with the main processes that are regulated by genes described in this work, additionally with the inclusion of GBM biomarkers (acquired from review by Sasmita *et al*[231]). Prevalent interaction types include co-expression and physical interaction between these representatives, there is also a high interconnectivity of the entire network, confirming that these molecular events are related. The cross-talk is visualized in Supplementary Figure 1, whereas the datasets used in the workflow are summarized in Supplementary Table 2.

The narrative of this review was intended to elaborate on the background of the biological machinery in which each successive gene is involved, then proceed with details regarding the regulation of glioblastoma, cytoskeleton/metabolism, and stemness (GBM-related or, if not present in the literature, any available). It is worth emphasizing that the herein described genes constitute more than half of the "top genes" that we established in our previous *in silico* study *via* a multi-stage methodology that included, *e.g.*, enrichment analysis, machine learning algorithm, and differential expression analysis [32]. The remainder was not presented due to a lack of stemness-related literature data (Supplementary Table 1). For the part available in this paper, the majority of genes (*BMP4*, *GRIN2B*, *HOXA10*, *HOXA1*, *MMP13*, *MTHFD2*, *PHF5A*, *RPS27*, *RRM2*, *SAA2*, *WT1*) were confirmed to influence GSCs. The attempt to associate *CMTM6*, *DUSP7*, *KIF20A*, *NF2*, *RXRG*, *SPOCK1*, and *UHRF1* with glioblastoma stemness revealed the promising implication in crucial biological processes that should be validated in future experiments. For *BMP4*, *WT1*, and *RXRG*, their contribution to novel therapeutic strategies was above-mentioned on the basis of literature data, prompting us to investigate whether any clinical trials utilize the products of described genes as drug components or targets. According to the ClinicalTrials website (https://clinicaltrials.gov/), cancer-related data can be found for six genes (Table 1); however, the seventh trial on *GRIN2B* was also included because it focused on brain research and highlights that selective *GRIN2B* antagonist is already developed. Moreover, the details on NF2-related intervention are not yet disclosed[239]. Collectively, these studies are in the early phases, certifying that there is still a room for further research.



CONCLUSION

Taken together, a promising set of genes involved in cytoskeletal rearrangements and metabolic alterations were found to influence glioblastoma stemness *via* a plethora of biological processes. Most of the described genes exhibit pro-cancerous properties; among them, clinical trials on *GRIN2B*, *RRM2*, *WT1*, and *KIF20A* are ongoing and focus on selective inhibitors or peptide-based vaccines. Concerning tumor suppressors, the anti-cancer effect can also be achieved *via* delivery of recombinant proteins (*BMP4*), ligands for tumor suppressors (*RXRG*), or counteracting the pathways that become hyperactive following an anti-oncogene loss (*NF2*). The cytoskeletal phenomena currently linked to the described genes require experimental verification of their contribution to GSCs expansion. Future GBM stemness-related research should generally delve into cytoskeleton and related molecular events, since the concept is already encouraging.

Table 1 Clinical trials that utilize the products of described genes as drug components or targets

Gene	Compound	Condition	Trial number and phase	Intervention details
BMP4	hrBMP4	Glioblastoma	NCT02869243 (phase I)	Delivery of human recombinant BMP4
GRIN2B	EVT 101	Healthy volunteers (brain function assessment)	NCT00526968 (phase I)	Delivery of selective GRIN2B antagonist
RRM2	COH29	Solid tumors	NCT02112565 (phase I)	Delivery of ribonucleotide reductase inhibitor
WT1	DSP-7888	Gliomas (incl. GBM)	NCT02750891 (phase I/II)	Delivery of WT1 peptide-based cancer vaccine
KIF20A	KIF20A peptide	Small cell lung cancer	NCT01069653 (phase I)	Delivery of KIF20A peptide-based vaccination
NF2	IAG933	Solid tumors	NCT04857372 (phase I)	Not yet disclosed (the drug presumably counteracts the YAP/TAZ hyperactivity that occur following NF2 loss)
RXRG	*9-cis* retinoic acid	Breast cancer	NCT00001504 (phase I)	Delivery of RXRG ligand

NF2: Neurofibromatosis type 2 protein; BMP4: Bone morphogenetic protein 4; RXRG: Retinoid X receptor gamma; MMP13: Metalloproteinase 13; RRM2: Reductase subunit M2; SPOCK1: SPARC/Osteonectin; CWCV: Kazal-like domains 1; ECM: Extracellular matrix; WT1: Wilms' tumor protein 1; KIF20A: Kinesin family member 20A; GRIN2B: Glutamate ionotropic receptor NMDA type subunit 2B.

Figure 2 Impact of described genes on biological processes related to stem cells. The "↑" or "↑" (blue) symbol indicates activation of the process while "↓"denotes inhibition. The impact of genes on processes (numbered from 1 to 19) is either directly confirmed (solid arrow next to the number) or recapitulated based on available data from various literature sources (dashed arrow next to the number). The "↓" (blue) symbol was not required as any gene inhibited the given process in an indirect manner. The white dashed line dividing the stem cell into two halves separates the genes with a confirmed role in glioblastoma stem cells (above the line) from those involved in cancer stemness outside the glioblastoma context (below the line). Figure created using Inkscape. NF2: Neurofibromatosis type 2 protein; BMP4: Bone morphogenetic protein 4; RXRG: Retinoid X receptor gamma; MMP13: Metalloproteinase 13; RRM2: Reductase subunit M2; SPOCK1: SPARC/Osteonectin; CWCV: Kazal-like domains 1; ECM: Extracellular matrix; CMTM: Chemokine-like factor superfamily.

REVIEW

Tissue-specific cancer stem/progenitor cells: Therapeutic implications

Amani Yehya, Joe Youssef, Sana Hachem, Jana Ismael, Wassim Abou-Kheir

Specialty type: Cell and tissue engineering

Provenance and peer review: Invited article; Externally peer reviewed.

Peer-review model: Single blind

Peer-review report's scientific quality classification

Grade A (Excellent): A
Grade B (Very good): B
Grade C (Good): 0
Grade D (Fair): 0
Grade E (Poor): 0

P-Reviewer: Crocé LS, Italy; Elbadawy M, Egypt

Received: December 28, 2022
Peer-review started: December 28, 2022

Abstract

Surgical resection, chemotherapy, and radiation are the standard therapeutic modalities for treating cancer. These approaches are intended to target the more mature and rapidly dividing cancer cells. However, they spare the relatively quiescent and intrinsically resistant cancer stem cells (CSCs) subpopulation residing within the tumor tissue. Thus, a temporary eradication is achieved and the tumor bulk tends to revert supported by CSCs' resistant features. Based on their unique expression profile, the identification, isolation, and selective targeting of CSCs hold great promise for challenging treatment failure and reducing the risk of cancer recurrence. Yet, targeting CSCs is limited mainly by the irrelevance of the utilized cancer models. A new era of targeted and personalized anti-cancer therapies has been developed with cancer patient-derived organoids (PDOs) as a tool for establishing pre-clinical tumor models. Herein, we discuss the updated and presently available tissue-specific CSC markers in five highly occurring solid tumors. Additionally, we highlight the advantage and relevance of the three-dimensional PDOs culture model as a platform for modeling cancer, evaluating the efficacy of CSC-based therapeutics, and predicting drug response in cancer patients.

Key Words: Cancer stem cells; Therapy resistance; Tissue-specific cancer stem cell markers; Patient-derived organoids; Pre-clinical cancer models

Core Tip: Therapeutic approaches targeting cancer stem cell (CSC) markers hold great promise toward developing effective anti-cancer treatment. Tissue-specific CSCs (TSCSCs) possess unique expression profile that allows for their identification, isolation, and targeting. TSCSCs, isolated from patient tumor tissues, were shown to form organ analogs or patient-derived organoids (PDOs) under specific culturing conditions *in vitro.* These models simulate the original tumor characteristics in a three-dimensional culture dish. As such, PDOs have the potential to be used in patient-specific *in vitro* drug clinical trials and proof-of-concept studies on CSC-targeted therapies.

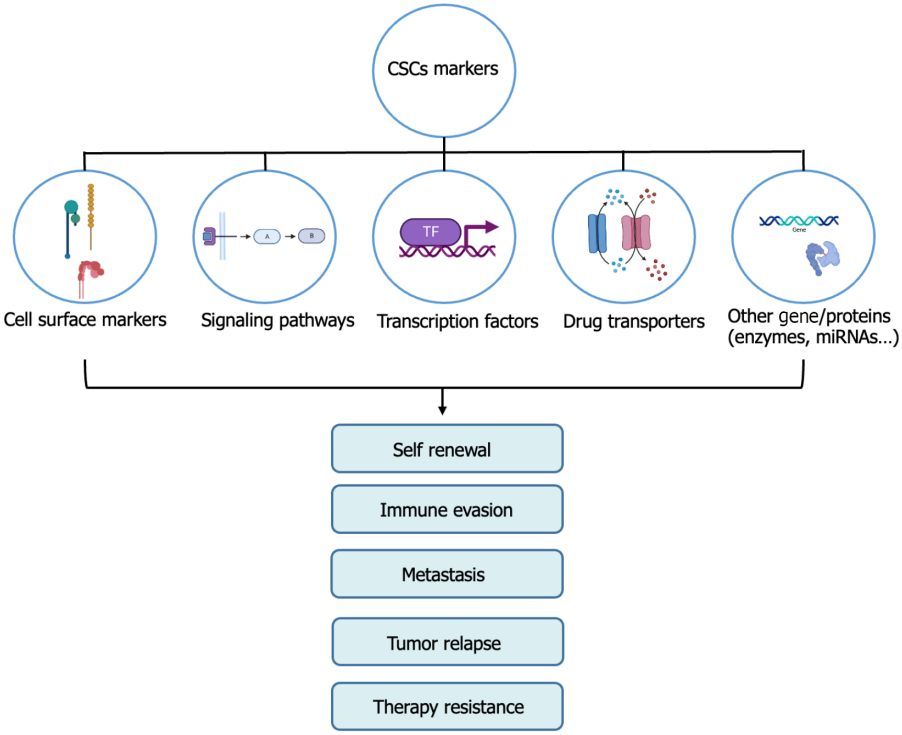
INTRODUCTION



Cancer disease remains a leading cause of death worldwide. Despite significant progress directed toward developing anti-cancer therapies, the successful management of cancer remains impeded by multiple challenges, including metastatic dissemination, conventional-therapy resistance, and disease relapse[1,2]. Accumulating evidence suggests that the cancer stem cells (CSCs) subpopulation plays a vigorous role in sustaining the tumorigenic properties, thus contributing to tumor re-growth and progression[3] (Figure 1). This subpopulation of multipotent cells possesses unique properties of self-renewal and differentiation and is capable of extensively proliferating and generating different lineages of cancerous cells, which constitute the tumor bulk and contribute to the heterogeneous phenotype found in tumors[2,4].

CSCs may arise from the transformation of normal stem cells (SCs) found within tissues or from the de-differentiation of differentiated cells[5]. They were first identified in acute myeloid leukemia[6], and compelling evidence later showed that they exist in a variety of solid tumors where they act as key drivers of tumor progression and metastasis[7,8]

CSCs harbor multiple resistance mechanisms that enrich cancer hallmarks and result in the failure of conventional anti-cancer therapies. One underlying mechanism is the disrupted intracellular pathways that profoundly control CSCs behavior. For instance, overexpression of the Notch pathway plays a dual role that is context and cell-type-dependent, acting either as an oncogene or tumor suppressor[9-11]. In the context of CSCs, the Notch pathway has been implicated in proliferation, angiogenesis, metastasis, stemness maintenance, tumor immune evasion, and resistance to radiation[9,11-13]. Moreover, the Wnt pathway has been linked to the activation of dormant CSCs, their proliferation, maintenance, and inhibition of apoptosis. This pathway also plays a role in the metastasis and de-differentiation of CSCs [14,15]. Besides, the Hedgehog pathway is associated with increased proliferation, maintenance, and self-renewal of CSCs, as well as their migration, invasiveness, and resistance to chemotherapy[14,16,17]. Additionally, the NF-κB pathway is implicated in self-renewal, maintenance, and inhibition of apoptosis of CSCs, as well as regulation of epithelial to mesenchymal transition (EMT), angiogenesis, and metastasis[18]. Finally, the aberrant expression of the JAK/STAT3 pathway promotes cell survival and stemness properties, as well as metastasis and resistance to chemotherapy[14,19]. The intrinsic regulation of CSCs also occurs at the level of stemness-related transcription factors (TFs) such as OCT-4, SOX2, KLF4, c-MYC, STAT3, and NANOG, as well as epigenetics and epi-transcriptomics, which contribute to stemness maintenance and plasticity of CSCs[11]. Additionally, CSCs are regulated at an extrinsic level by their microenvironment, specifically by cancer-associated fibroblasts and tumor-associated macrophages. The tumor microenvironment is a major player in modulating CSCs resistance, metastasis, and heterogeneity[11,20].

The resistance mechanisms of CSCs further include their overexpression of DNA repair genes, resulting in resistance to radiotherapy and other DNA-damaging agents[21]. Also, they express upregulated multidrug efflux pumps such as ATP-binding cassette (ABC) transporters that mediate the active transport of chemotherapeutic drugs out of the cell[22]. CSCs were shown as well to overexpress aldehyde dehydrogenases (ALDHs) which are enzymes involved in the detoxification of aldehydes, chemotherapeutic agents, and reactive oxygen species[23]. Another mechanism that promotes the survival of CSCs is their ability to exist at a reversible quiescent state in the G_0 phase, which contributes to their drug resistance since most chemotherapeutic agents target highly proliferative tumor cells[24]. Thus, standard therapies succeed at reducing tumor size but tend to spare the highly resistant CSCs subpopulation. The successful elimination of tumors, therefore, necessitates targeting the residual dormant CSCs to yield long-lasting eradication of cancer and prevent relapse.

In this review, we provide a recapitulation of the main tissue-specific CSC (TSCSC) biomarkers in five of the most diagnosed solid tumors. Importantly, we highlight the beneficial role of these CSCs in

Figure 1 Schematic presentation of cancer stem cell markers and their contribution to cancer development, progression, and resistance to therapy. Several cancer stem cell (CSC) markers and regulatory signaling pathways are involved in the sustenance and activation of self-renewal, immune evasion, and tumor metastasis, and contribution to tumor re-growth and therapy resistance. CSC markers serve as potential therapeutic targets for cancer treatment. CSCs: Cancer stem cells.

providing relevant preclinical cancer models and thus improving CSC-targeted therapies.

TISSUE-SPECIFIC CANCER STEM CELLS

Given the importance of CSCs in tumor progression and prognosis, several attempts were made to identify and isolate CSCs from the tumor mass based on the markers they express. CSCs express a wide spectrum of markers, some of them being more universal than others. Several markers, mostly located on the cell surface, are often used in combination to ensure a more tissue-specific isolation of targeted CSCs. Here we provide an updated overview of the most prominent TSCSC surface markers, focusing on five solid cancers (prostate, colon, bladder, breast, and lung). Refer to Table 1 for the full list of markers.

Prostate-specific cancer stem cells

The presence of prostate CSCs (PCSCs) was identified by Collins *et al*[25] using SCs markers (integrin $\alpha_2\beta_1$ and CD133) that were previously identified in the normal prostate epithelium[25,26]. This subpopulation of PCSCs isolated from human prostate cancer (PC) biopsies showed a high expression of CD44, CD133, and integrin $\alpha_2\beta_1$. The isolated cells exhibited high proliferative ability and were highly invasive on Matrigel™. Moreover, they possessed a high self-renewal ability and could also differentiate into cells expressing the same phenotype as PC cells, thus re-establishing the original heterogeneous tumor from which they were isolated[27].

CD133 (Prominin-1), a cell surface glycoprotein, remains one of the most used biomarkers to identify and isolate PCSCs either alone or in combination with other markers. In fact, $CD133^+$ PC cells that were isolated from human PC cell line exhibited self-renewal ability, which was correlated with their expression of stemness genes[28]. These cells could also generate a heterogeneous tumor mass when transplanted into immunocompromised mice. Moreover, they displayed high clonogenic abilities and led to the formation of tumor spheres (prostaspheres) that were more malignant than the ones formed by $CD133^-$ PC cells. Furthermore, the $CD133^+$ cells were chemo-resistant and demonstrated high proliferation[28]. Interestingly, a well-established combination of $CD133^+$ and $CD44^+$ PC cells allowed the isolation of PCSCs and the formation of spheroids characterized by heterogeneous PC cells[29].

Table 1 Summary of the most prominent biomarkers required to identify and isolate the tissue-specific cancer stem cells in prostate, colon, bladder, breast, and lung tumors

+: Over-expressed; -: Under-expressed; Blank: Not found in the literature/controversial. TSCSCs: Tissue-specific cancer stem cells; PCSCs: Prostate cancer stem cells; CCSCs: Colon cancer stem cells; BCSCs: Bladder cancer stem cells; BrCSCs: Breast cancer stem cells; LCSCs: Lung cancer stem cells; EpCAM: Epithelial cell adhesion molecule; TRA-1-60: T cell receptor alpha locus; ALDH: Aldehyde dehydrogenase; EMA: Epithelial membrane antigen.

CD44 (also referred to as P-Glycoprotein 1) is a transmembrane glycoprotein that interacts with several extracellular matrix components, such as collagen, hyaluronic acid, osteopontin, and matrix metalloproteinases. It is one of the most conventional markers used to identify and isolate PCSCs. The expression of CD44 allowed the isolation of cells that were able to differentiate into all types of PC epithelium leading to complete reconstitution of the original tumor bulk when injected into immunocompromised mice[30]. Notably, $CD44^+$ PC-derived cells expressed elevated levels of several mRNAs associated with stemness[31]. This marker was also associated with several aspects of PC tumorigenesis including proliferation, invasion, adhesion, EMT initiation, metastasis, and therapy resistance[32].

T cell receptor alpha locus (TRA-1-60) is a carbohydrate addition to podocalyxinis, which is a cell surface antigen that belongs to the CD36 family. TRA-1-60 is expressed on pluripotent SCs conferring them the ability to induce differentiation. TRA-1-60 was shown to be overexpressed in PC cells as compared to the adjacent normal prostate tissue, which qualifies it as a favorable marker to specifically target PCSCs while sparing normal cells[33]. Moreover, it was detected in the peripheral blood of patients with metastatic PC[34]. The isolation of TRA-1-60^+ cells led to the generation of spheres and initiation of PC in a more efficient manner as compared to other known PCSCs markers. TRA-1-60 was then combined with two other markers of PCSCs (CD166 and CD151) leading to a more enhanced sphere-forming ability. Furthermore, the injection of the triple-marker-positive cells was able to form tumors with at least 5-fold more efficiency as compared to TRA-1-60^+ cells alone[35].

CD117 (also termed c-Kit) is a member of the Type-III tyrosine kinase receptors known to be involved in several cancer mechanisms by binding to its stem cell factor (SCF) ligand[36]. CD117 overexpression was detected in PC[37]. A recent study suggested that CD117 may be considered a potential marker for PCSCs because it was shown to display a broad spectrum of tumorigenic abilities[38]. In fact, CD117 stimulated PC cell proliferation and migration. Moreover, $CD117^+$ cells were able to form 1.35-fold larger prostaspheres as compared to $CD117^-$ cells. Most importantly, $CD117^+$ cells expressed stemness genes and their implantation into immunocompromised mice led to PC initiation[38].

CD49f (integrin α6 or ITGA6) is a transmembrane glycoprotein that was demonstrated to be a putative marker of PCSCs. $CD49f^{high}$ cells were shown to be tumor-initiating cells in the Pten-null PC model[39]. Moreover, CD49f was shown to be the most selective marker for targeting colony-forming cells[40]. Additionally, it was expressed on the surface as well as in the middle of prostatospheres[41]. Importantly, the expression of CD49f allowed the isolation of sphere-forming SCs[42].

In addition to the ones discussed above, there are several markers that can be used to target PCSCs including ALDH1A1 (ALDH 1 family member A1)[43,44], trop-2 (Tumor-associated calcium signal transducer 2)[45], CD166 (activated leukocyte cell adhesion molecule)[46,47], EpCAM (Epithelial cell adhesion molecule)[48], and ABCG2 (ATP binding cassette super-family G member 2)[49].

Colon-specific cancer stem cells

Colon CSCs (CCSCs) were first identified and isolated by Ricci-Vitiani *et al*[50] after the injection of colon cancer (CC) $CD133^+$ cells into immunocompromised mice, which led to the generation of the original tumor mass contrary to their $CD133^-$ counterparts. The $CD133^+$ cells were able to exponentially grow *in vitro* as undifferentiated spheres while preserving the same phenotypic properties of the initial colon tumor[50]. O'Brien *et al*[51] in 2007 also showed that all CC-initiating cells were $CD133^+$ cells that were able to either maintain themselves as undifferentiated CCSCs or to differentiate and therefore sustain the tumor heterogeneity[51].

Leucine-rich repeat-containing G-protein-coupled receptor 5 (LGR5) (also recognized as FEX; HG38; GPR49; GPR67) is a seven-transmembrane G-protein coupled receptor. LGR5 is an "orphan" receptor abundantly expressed in active SCs of the intestinal crypts[52]. LGR5 was shown to be overexpressed in CC[53]. A growing body of evidence supports the idea that LGR5 is a main marker of CCSCs. For instance, human $LGR5^+$ CC cells were visualized as the CSC pool in proliferating CC tissue[54]. Furthermore, LGR5 was demonstrated to be a marker of tumor-initiating cells, where implantation of $LGR5^+$ cells was able to form colon tumors, indicating that LGR5 provides a dynamic stemness characteristic in CC[55]. Additionally, LGR5 was correlated with tumor proliferation due to the ability of $LGR5^+$ cells to form more multipotent spheres as compared to $LGR5^-$ cells[56]. Notably, LGR5 was shown to be involved in the colony formation capacity of CCSCs[56,57]. Importantly, LGR5 was found to have an essential role in CC metastasis where organoids derived from $LGR5^+$ cells led to liver cancer formation in the absence of a primary tumor[55]. In addition, LRG5 was selected to be the most suitable CSC marker that identifies immature cancer cells in regional lymph nodes of CC patients[58].

EpCAM (also known as CD326) is a Type-I transmembrane glycoprotein that serves as an epithelial cell adhesion molecule. Interestingly, EpCAM along with its reprogramming TFs were shown to be overexpressed in CC-initiating cells leading to a high self-renewal ability and increased invasiveness [59]. In fact, EpCAM was considered to be a robust CCSCs marker[60]. Indeed, it was used along with CD133 and CD44 to initiate CC in mice[61]. Furthermore, EpCAM provided more enhanced CSC-like properties when combined with LRG5 and CD44[56]. Moreover, EpCAM was proven to promote CC invasion and metastasis, as $EpCAM^{high}/CD44^{+}$ cells were visible in corresponding liver metastasis regions of CC patients[62].

CD44 was also shown to be a robust marker for CCSCs. In fact, a single $CD44^{+}$ cell was able not only to generate a sphere, but also to form a tumor with similar characteristics as the primary one from which it was isolated[63]. Moreover, the expression of CD44 was correlated with CC proliferation[4]. Furthermore, CD44 was reported as a stemness marker in spherical clusters[64]. In addition, CD44 was considered a reliable marker for the prediction of hepatic cancer metastasis in CC patients[65].

ALDH1 is also selected as a potential marker for CCSCs. ALDH1 expression increased during CC tumorigenesis and the implantation of only 25 $ALDH1^{+}$ cells into immunocompromised mice led to the generation of xenograft tumors even in the absence of other CCSCs markers such as CD133 and CD44 [66]. Furthermore, ALDH1 expression conferred high tumorigenic abilities and chemo-resistance to CC cell lines[67]. Interestingly, ALDH1 was linked to lymph node and vascular invasion in CC patients[68].

Among the most specific CSCs related to CC are LGR5, CD44 and EpCAM. However, the combination of multiple markers allows more accurate detection of CSCs which was proven when LGR5, CD44 and EpCAM resulted in more potent CSCs properties as compared to each marker alone [56]. Other markers are also attributed to CCSCs such as CD59[69], Prox1 a regulator of Notch-independent $LGR5^{+}$ SCs[70,71], CD24[4,64], CD166[72], and ABCB5 (ATP binding cassette super-family B member 5)[73].

Bladder-specific cancer stem cells

Bladder CSCs (BCSCs) were first isolated in 2009 by using markers for normal basal bladder SCs ($CD44^{+}$). It was found that the $CD44^{+}$ subpopulation of bladder cancer (BC) cells was 10 to 200 more likely to form tumors in immunocompromised mice in comparison with their CD44 counterparts[74]. Additionally, $CD44^{+}$ BCSCs efficiently maintained the heterogeneity of the initial tumor mass after serial transplantation[74].

Epithelial membrane antigen (EMA, also known as MUC1) is a membrane-bound glycoprotein that belongs to the family of mucins[75]. EMA^{+} bladder cells are usually located in the mature differentiated layer of the urothelium, whereas EMA^{-} cells are found in the basal layers, where SCs reside. It was demonstrated that EMA^{-} BC cells had a greater colony-forming ability when compared with the unsorted BC population[75,76]. BCSCs can thus be identified through the combination of EMA^{-} and $CD44^{+}$ BC cells[77].

CD47 (also known as integrin associated protein) is a transmembrane protein overexpressed on the surface of $CD44^{+}$ BCSCs compared to the $CD44^{-}$ subpopulation and was thus hypothesized to be a BCSCs marker[78,79]. CD47 acts like a "don't eat me" signal by interacting with the signal regulatory protein-1 receptor on the surface of macrophages and neutrophils. Thus, CD47 has an immunosuppressive role, protecting the BSCSC from phagocytosis[78,79], that makes it a promising target for cancer therapy[80,81].

ALDH1A1 has also been used to isolate BCSCs. In fact, $ALDH1A1^{+}$ cells retained the stem-cell ability to divide asymmetrically, yielding both $ALDH1A1^{+}$ and $ALDH1A1^{-}$ cells[82]. Additionally, $ALDH1A1^{+}$ BCSCs exhibited a greater tumorigenic potential both *in vitro* (sphere formation ability) and *in vivo* (xenografts in immunocompromised mice) compared to $ALDH1A1^{-}$ BC cells[82]. Knocking down the ALDH1A1 gene in BCSCs reduced their proliferation, confirming the key role played by the ALDH enzyme in BCSCs division and renewal[83]. Furthermore, ALDH1A1 BCSCs maintained the original tumor heterogeneity after sequential transplantations into immunocompromised mice[83]. Finally, $ALDH^{+}$ BCSCs demonstrated an enhanced ability to migrate and invade tissues contrary to $ALDH^{-}$ BC cells[82].

$67LR^{+}$ (67KDa Laminin Receptor)/ $CD66c^{-}$ (also known as CEACAM6) BC cells were demonstrated to have stemness properties. These markers, similar to CD44, are also present in normal bladder SCs[84]. He *et al*[85] showed that $67LR^{+}$ BCSCs were 5 to 10 times more potent in initiating tumors *in vivo* compared to $67LR^{-}$ ones[85]. In addition, $67LR^{+}$ BCSCs expressed a panel of genes involved in stemness and resistance to chemotherapy and radiation[85,86]. Similarly, $CD66c^{-}$ cells were demonstrated to be more tumorigenic than the $CD66c^{+}$ counterparts[85].

$CD133^{+}$ BC cells were shown to upregulate the expression of genes involved in pluripotency. This subpopulation of BC cells was also more resistant to the chemotherapeutic agent cisplatin and to radiation. Additionally, $CD133^{+}$ BCSCs exhibited a greater tumorigenicity both *in vitro* and *in vivo*, as well as a more aggressive proliferation in immunocompromised mice in comparison to $CD133^{-}$ BC cells [87].

Additional markers are also used for the identification of BSCSC namely MAGE-A3 (Melanoma antigen family A, 3)[88], BCMab1[79], and several members of the cytokeratin family of proteins ($CK5^{+}$, $CK17^{+}$, $CK18^{-}$, $CK20^{-}$)[89].

Breast specific cancer stem cells

The importance of breast CSCs (BrCSCs) markers was first demonstrated by Al-Hajj *et al*[90] only a subpopulation of human breast cancer (BrC) cells appeared to lead to the formation of tumors in immunocompromised mice. Al-Hajj *et al*[90] isolated $ESA^+CD44^+CD24^{-/Low}$ cells from human BrC tissue, and showed that as low as 200 of these cells were enough to initiate cancer in immunocompromised mice, whereas more than 50000 BrC cells with a different phenotype were unable to form tumors[90].

CD44 and CD24 are often used in combination to detect and isolate BrCSCs[91]. In addition to its key role in adhesion, cell survival, metastasis and angiogenesis, CD44 act as a TF to regulate metastasis and stemness of BrCSCs[92,93]. On the other hand, CD24 is a cell surface adhesion glycoprotein which plays a key role in cell-cell and cell-extracellular matrix (ECM) interactions[94,95]. Even though CD24 is overexpressed in a number of cancers (including BrC), only $CD44^+CD24^{-/Low}$ BrCSCs were able to form tumors in immunocompromised mice[90]. $CD44^+CD24^{-/Low}$ BrCSCs were also shown to be more resistant to chemotherapy[91].

ALDH1 has also been used to target BrCSCs, as it was shown that $ALDH1^+$ BrC cells were more resistant to chemotherapy and were able to form tumors in immunocompromised mice in comparison to $ALDH1^-$ cells[96]. ALDH1 is essential for the early development of the stemness properties of BrCSCs [97]. Interestingly, the subpopulation of BrC cells expressing ALDH1 is distinct from the $CD44^+CD24^{-/Low}$ BrCSCs, with minimal overlap between the two (approximately 1%)[91]. Moreover, $ALDH1^+/CD44^+$ BrCSCs were highly tumorigenic, with a higher metastatic potential, and greater resistance to cancer therapies[91].

To date, CD44, CD24 and ALDH1 remain the most used biomarkers to isolate BrCSCs. Although there is little overlap between $CD44^+CD24^{-/Low}$ and $ALDH1^+$ BrCSCs, cells that share all three markers were more tumorigenic[98]. Moreover, the CD44/CD24 markers were more associated with cell proliferation and tumorigenesis while the ALDH1 marker was positively correlated with tumor metastasis [98]. Nonetheless, other markers have been studied and found suitable for the identification of BrCSCs, such as CD133 (in triple negative BrC; TNBC), GD2 (ganglioside in TNBC), CD49f, $CD61^+$ (β3 integrin in Her2 BrC), CD29 (β1 integrin), CD90, and EpCAM[99-101].

Lung cancer stem cell markers

Lung cancer is histologically divided into non-small cell lung carcinoma cells (NSCLC) and small cell lung carcinoma (SCLC)[102]. Due to a higher incidence and the greater ease to obtain NSCLC tissue, NSCLC CSCs (referred to afterward as lung CSCs; LCSCs) markers have been better characterized.

CD166 (also known as ALCAM) has also been associated with stemness properties of NSCLC. CD166 is a member of the immunoglobulin superfamily of cell adhesion molecules and participates in both homophilic and heterophilic interactions. Additionally, CD166 plays an important role in migration and invasion of LCSCs[103]. CD166 was characterized by Zhang *et al*[104] as the most robust cell marker for isolating LCSCs among other candidates (CD44, EpCAM and CD133)[104]. In contrast to $CD166^-$ NSCLC cells which failed to form tumors *in vivo*, $CD166^+$ LCSCs were able to initiate tumors in immunocompromised mice. Furthermore, $CD166^+$ NSCLC cells had enhanced self-renewal properties and were able to consistently form spheres *in vitro*.

The $CD133^+$ subpopulation of NSCLC cells were able to indefinitely divide and form spheres in an *in vitro* setting, whereas $CD133^-$ NSCLC cells were characterized by a slow growth and an inability to form spheres[105]. These results also parallel the *in vivo* ability of $CD133^+$ LCSCs to form tumors in immunocompromised mice compared to $CD133^-$ cells; the $CD133^+$ xenografts were histologically similar to the initial cancer mass[105,106]. Moreover, the expression of CD133 in LCSCs was associated with increased resistance to chemotherapy and radiation[105,107]. Finally, $CD133^+$ LCSCs are more prone to metastasize than their $CD133^-$ counterparts, especially to lymphoid organs. In fact, detection of $CD133^+$ metastatic NSCLC in lymph nodes is indicative of a poor prognosis[107].

CD44 has also been studied as a marker to isolate LCSCs. Accordingly, $CD44^+$ NSCLC cells demonstrated a greater ability to form spheres *in vitro* and to initiate tumors in immunocompromised mice in comparison to $CD44^-$ cells. Additionally, $CD44^+$ LCSCs upregulated several stemness TFs to maintain their pluripotent properties. $CD44^+$ LCSCs were also more resistant to the chemotherapeutic agent cisplatin compared to $CD44^-$ cells[108]. Moreover, the expression of CD44 in LCSCs was associated with an enhanced ability to metastasize and invade tissues[20].

CD90 (also known as Thy-1) is a glycosylphosphatidylinositol-anchored surface protein that is involved in cell-cell as well as cell-ECM interactions[109]. Initial studies have shown that $CD90^+$ NSCLC cells demonstrated greater self-renewal and proliferative properties and expressed a higher level of stemness genes. Additionally, when compared to a control, as few as 5000 $CD90^+$ LCSCs were able to initiate tumors in immunocompromised mice, indicating the stronger tumorigenicity associated with CD90[110].

ALDH1 was also suggested to be a LCSCs marker. Indeed, $ALDH1^+$ LCSCs exhibited enhanced proliferative abilities and self-renewal properties[111,112]. Accordingly, knocking down the ALDH1A3 gene greatly reduced the tumorigenicity and clonogenicity of LCSCs[113]. In addition, $ALDH1^{high}$ LCSCs also showed greater resistance to chemotherapeutic drugs in comparison to $ALDH1^{low}$ cells[112]. Interestingly, the overexpression of the TAZ oncogene induces the formation of LCSCs by activating the

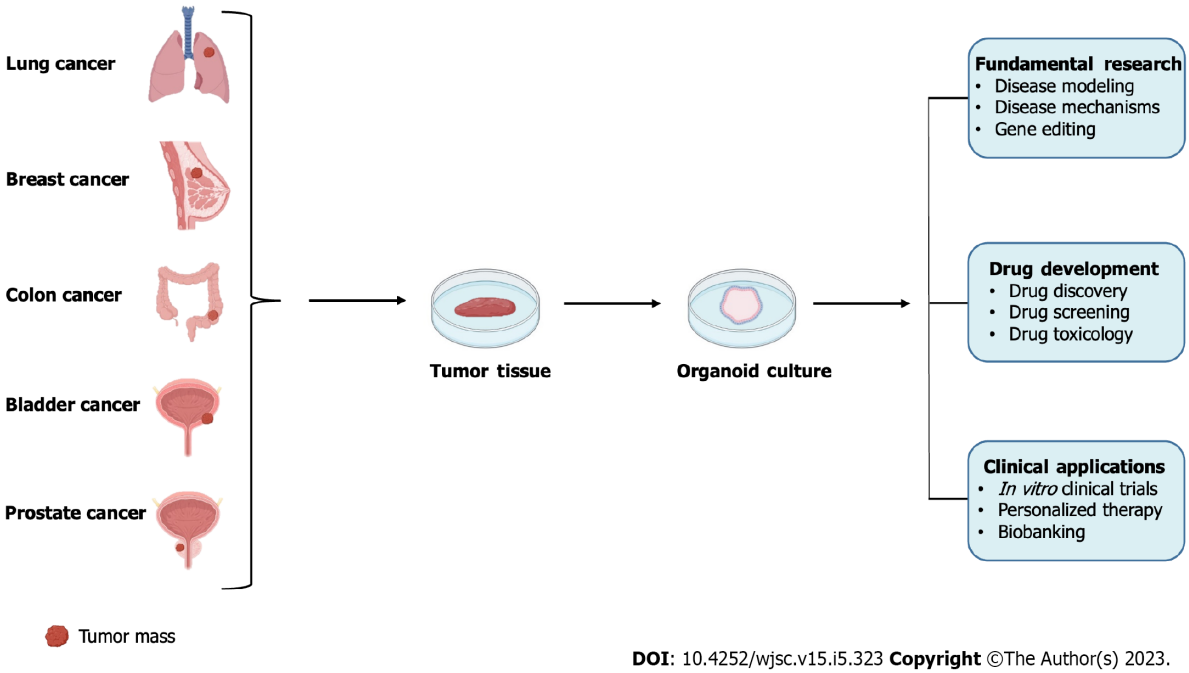
ALDH1 gene[114] ALDH1 also appears to play a key role in chemoresistance as its inhibition leads to the re-sensitization of LCSCs to cisplatin[115].

Of note, additional markers have been used to isolate LCSCs. These include but are not limited to CD47, CD87, CD117, EpCAM, and CK5[116,117].

TSCSCS' BENEFICIAL ROLE IN CANCER MODELING FOR THERAPEUTIC IMPLICATIONS

The conception of CSCs-targeted therapies relies on employing the above-mentioned CSCs' resistant characteristics and markers, which allows for CSCs' isolation, enrichment, characterization, and targeting[118]. CSCs-based therapeutic strategies include selectively targeting the stemness markers, such as the TSCSCs' surface markers, TFs, ABC transporters, and ALDHs[14,119]. As well as, the disrupted signaling pathways that enrich CSCs'-resistant features and contribute to their survival, proliferation, self-renewal, and differentiation. Also, targeting the tumor microenvironment components which acts as a foster niche in protecting CSCs[14,119].

In spite of the significant advances in CSCs' research and the great interest in drug discovery, there are currently few therapeutic approaches that have reached the late clinical stages. Many CSCs-targeting therapeutics performing remarkably *in vitro* and *in vivo* cultures have faced multiple hurdles in clinical trials[14,120]. One major reason behind this is the irrelevance of the preclinical cancer models being used[121-123]. Thus, more relevant CSCs models, that reflect the original tumor behavior of the individual patients, might strengthen the rationale for developing effective CSCs-targeted therapeutic modalities and complement more conventional cancer therapies.



A new era of targeted and personalized anti-cancer therapies has evolved with the three-dimensional (3D) patient-derived organoids (PDOs)[124]. This versatile technique relies on the exclusive ability of SCs to give rise to organ-like structures known as organoids[125]. Sato *et al*[126] established the first organoid model with small intestinal crypt $LGR5^+$ SCs[126]. Subsequently, models of normal and cancer PDOs from multiple tissues were derived successfully[127-134].

The formation of the 3D microscopic organoids from patient tumor tissues is accomplished using specific culturing conditions that are designed to preserve the CSCs component of the patient's tumor [135]. The formed PDOs, hence, recapitulate the structural and functional complexity constituting the originating tumor, mediated by the CSCs' ability for self-renewal and differentiation into multiple cell types[136,137]. PDOs tool allows the modeling of human carcinogenesis in an *in vitro* culture dish[138, 139]. Precisely, the process followed to generate cancer PDOs includes utilizing a tumor tissue sample, surgically isolated from a cancer patient, and dissociating it into single-cell suspension using mechanical dissociation and enzymatic digestion methods. The heterogeneous population of cells obtained, containing TSCSCs, is then cultured in proper culturing conditions to allow the self-organization of cells into functional units or tissue-specific architectures; organ analogs. The suspended culturing system includes the usage of biological or synthetic hydrogel scaffolds that mimic the natural ECM components. In addition to using a specific culturing medium that contains a cocktail of growth factors and inhibitors to imitate the organ stem cell niche, allow the generation of distinct component lineages, and stimulate the long-term expansion of organoids[140,141].

As PDOs are CSCs-based structures and replicate faithfully the heterogeneity and histological characteristics of the original cancers, they gain superiority over other models in terms of mimicking tumor microenvironments, facilitating the formation of ECM, exhibiting adequate proliferation rates with representative cellular morphology, maintaining the expression of 'stemness-related' markers and genes, and demonstrating a realistic individualized drug response[142-144]. This nominates PDOs to be ideal preclinical drug-response models for providing perspectives for testing novel CSCs-targeted therapies and evaluating the potential drug effectiveness in cancer patients (Figure 2).

PDOs technique generally shares several main steps but differs in varying degrees depending on the type of tissue being processed. Scaffold-based techniques are mostly adopted in culturing PDOs, where Matrigel™ is commonly used. The latter is a mixture of heterogeneous and gelatinous proteins secreted by mouse sarcoma cells. It comprises mainly adhesive proteins such as laminin, collagen IV, entactin, and heparin sulphate glycoprotein, which resemble the ECM and provide interactive and structural support to the cells[145-148]. Moreover, the universal organoid medium used in the culturing system adopts the first protocol developed by Sato *et al*[126] which includes advanced DMEM/F12 medium supplemented with epidermal growth factor, Noggin (NOG), and Wnt agonist R-spondin-1[126,127]. Other factors were then added including anaplastic lymphoma kinase 3/4/5 inhibitor A83-01, dihydrotestosterone, fibroblast growth factor-10, fibroblast growth factor-2, prostaglandin E2, nicotinamide (NAM), and p38 inhibitor SB202190, N-acetylcysteine (NAC), B27 supplement and Rho kinase inhibitor Y-27632 to culture PDOs successfully[149].

To date, organoids derivation from multiple human tumors including prostate, colon, bladder, breast, and lung cancers has been described, with varying success rates[133,150-155]. The established PDOs are subjected to tissue-specific genes and lineage markers expression studies to confirm that they represent the original tumor of the patient. Importantly, the cancerous origin of these organoids is confirmed by

Figure 2 Schematic presentation of patient-derived organoid applications in cancer research. Patient-derived organoid (PDO) models can be utilized in multiple fields of cancer research including fundamental research, drug development, and clinical application. Cancer PDOs have been used to simulate the tumor tissue *in vitro*, study the disease mechanisms and gene expression patterns, and expose them to different drugs for efficacy screenings and drug discovery validations. Organoids are further used as *in vitro* pre-clinical models for personalized medicine and the generation of 'living' organoid biobanks. PDO culturing system serves as an advanced tool in the implementation and development of precision medicine.

checking for the CSCs markers specific to each tumor tissue. The patient drug response to the therapy of interest can then be evaluated primarily by assessing the organoids' formation efficiency and size.

For example, a study done by Cheaito *et al*[150] established a minimum of 5-factor medium including NAC, NOG, A83-01, B27, and NAM to grow and maintain PC PDOs. Histopathological, transcriptomic, immunofluorescent, and immunohistochemical studies showed that the formed PDOs mimicked the histological architecture and prostate lineage profiles of their corresponding tissue specimens. This was confirmed by the presence of both prostate epithelial lineages, as the organoids stained positive for the luminal- (CK8, AR, and PSA) and basal- (CK5, CK14, and p63) specific markers. In addition, an intermediate cell population, co-expressing luminal CK8 and basal CK5 markers was also detected. Interestingly, CSCs markers, CD44 and CD49f, positive staining demonstrated the existence of putative stemlike cells within the bulk of the PDOs. Furthermore, differential drug response, between different patient samples, was recognized upon treatment with chemo-, radio-, and androgen-deprivation therapies[150]. In another study, Monzer *et al*[151] succeeded in establishing and propagating PDOs that model CC disease. The formed organoids recapitulated the architecture and the characteristics of CC tissues as revealed by the co-expression of the epithelial marker lineage CK19 and the CSC surface marker CD44. The organoids derived from different patients showed to exhibit different responses to Diiminoquinone treatment tested alone or in combination with Fluorouracil (5FU) chemotherapeutic drug. Similarly, Al Bitar *et al's* study showed different responses to individual and combination treatments of radiation and Thymoquinone in CC PDOs[152].

Moreover, Yu *et al*[153] utilized BC PDOs to evaluate chimeric antigen receptor (CAR)-T cell-mediated cytotoxicity against BC. Analysis was done to confirm that the established organoids recapitulate the heterogeneity and the key features of the parental BCs. Based on a set of luminal (CK20, uroplakin II, and GATA3) and basal markers (CK5, P63, and CD44), the formed organoids were classified into luminal or basal subtypes, respectively. All the BC PDOs and their corresponding tumors expressed Ki67 and E-cadherin, confirming their epithelial origin and high proliferative ability. Additionally, the specific surface antigen profiling of each tumor sample was analyzed, and the MUC1 antigen was shown to be highly expressed among all tested antigens, in both the cancer tissues and their derived organoids. MUC1 was then used as a putative target to test the efficacy of second-generation CAR-T cells in BC PDOs[153]. Furthermore, a promising study done by Chen *et al*[154], showed the significance and applicability of using BrC PDOs as pre-clinical models for broader cancer studies, and more specifically as a tool to provide personalized therapy recommendations for patients with advanced refractory disease. This study focused mainly on deriving PDOs from specimens isolated from patients with advanced clinical features, including drug-resistant and metastatic BrC. The histopathological, immunohistochemical, and genomic characteristics were shown to be well inherited by the formed PDOs from the drug-treated as well as treatment-naïve tumors. Distinctive drug

responses were also observed[154]. Furthermore, Kim *et al*[133] demonstrated the distinctive therapeutic responses of LC and normal bronchial PDOs, derived from patient tissues comprising five histological subtypes of LC and non-neoplastic bronchial mucosa. The differential responses to the tested drugs were shown to be affected by the individual genomic alterations profile. The PDOs were also proved to duplicate the tissue architecture and maintain the genomic alterations of the parental lung tumors during long-term expansion *in vitro*[133].

CONCLUSION

In this review, we have discussed briefly some of the CSC features that are known to account for cancer resistance and relapse and make CSCs promising anti-cancer targets. Additionally, we have summarized the updated list of the TSCSC molecular markers in prostate, colon, bladder, and lung tumors that are significant to selectively isolate and therapeutically target the CSCs subpopulation. Besides, we highlighted the advantage of utilizing the CSC-based PDO models to simulate carcinogenesis and predict patient-specific drug responses *in vitro*.

Despite the present challenges[156,157], PDOs are highly credible models that possess more physiological and pathological relevance than traditional ones. This robust method proved to faithfully maintain the histological, genetic, and stemness characteristics of their respective native tissues. Interestingly, the CSCs profile mimicked by the PDOs can serve as a platform for testing CSCs-targeted therapeutics. To our knowledge, there are no clinical trials discussing cancer PDOs in a preclinical context for testing CSC-targeted therapeutics[158].

Indeed, PDOs have prospective applications in patient-specific *in vitro* drug clinical trials and proof-of-concept studies on CSC-targeted therapies and -resistance mechanisms. If remarkable advancements are made, cancer patients will ultimately benefit from this radical technology.

Abstract

Pathological scarring and scleroderma, which are the most common conditions of skin fibrosis, pathologically manifest as fibroblast proliferation and extracellular matrix (ECM) hyperplasia. Fibroblast proliferation and ECM hyperplasia lead to fibrotic tissue remodeling, causing an exaggerated and prolonged wound-healing response. The pathogenesis of these diseases has not been fully clarified and is unfortunately accompanied by exceptionally high medical needs and poor treatment effects. Currently, a promising and relatively low-cost treatment has emerged-adipose-derived stem cell (ASC) therapy as a branch of stem cell therapy, including ASCs and their derivatives-purified ASC, stromal vascular fraction, ASC-conditioned medium, ASC exosomes, *etc.*, which are rich in sources and easy to obtain. ASCs have been widely used in therapeutic settings for patients, primarily for the defection of soft tissues, such as breast enhancement and facial contouring. In the field of skin regeneration, ASC therapy has become a hot research topic because it is beneficial for reversing skin fibrosis. The ability of ASCs to control profibrotic factors as well as anti-inflammatory and immunomodulatory actions will be discussed in this review, as well as their new applications in the treatment of skin fibrosis. Although the long-term effect of ASC therapy is still unclear, ASCs have emerged as one of the most promising systemic antifibrotic therapies under development.

Key Words: Adipose-derived stem cell; Cicatrix, hypertrophic; Keloid; Scleroderma, localized; Stromal vascular fraction; Exosomes

Core Tip: Pathological scarring and scleroderma are the most common conditions of skin fibrosis with high medical needs and poor therapeutic effects. Adipose-derived stem cell (ASC) therapy has emerged as a promising treatment for skin fibrosis. Here, we discuss the possible mechanism of skin fibrosis as well as the latest research about the mechanism of ASC therapy and its application in treating these conditions. ASC therapy provides a brand-new insight into the treatment of skin fibrosis.

INTRODUCTION

Skin fibrosis is characterized by fibroblast proliferation and extracellular matrix (ECM) deposition. In severe cases, it can lead to pathological changes in the skin, such as keloid and hypertrophic scars (HS), systemic sclerosis (SSc), and scleroderma[1,2]. The fact that there are no practical disease-modifying therapies for those diseases and current treatment is mainly toward managing symptoms and relieving complications calls for a new therapy[3,4].

Since 2001, when adipose-derived stem cells (ASCs) were first characterized, ASCs have been broadly studied and applied as the most promising sources of cells with regenerative and multilineage characteristics[5]. In recent years, various ASC derivatives, which are rich in not only ASCs but also other cellular and tissue components, have been seen as possible alternatives to ASCs and have received increasing attention for exploring their potential applications. Due to their immunomodulatory properties and abundance of growth factors[6,7], ASCs and their derivatives have become new remedies in the treatment of skin fibrosis[8-10].

In this review, we discuss the mechanism of skin fibrosis and the mechanism of ASC therapy. We then summarize the application of ASCs and their derivatives in skin fibrosis. Finally, we retrospectively describe the safety of ASC therapy and predict the future of skin fibrosis treatments.

MECHANISM OF SKIN FIBROSIS

Many fundamental studies exploring the molecular mechanisms underlying fibrosis have revealed a large number of genes, molecules, and cell types that may contribute to this problem[11,12].

Keloid and HS

The pathogenesis of keloids and HS is not fully understood due to the complex dynamic process of wound healing. However, among all the factors that stimulate fibroblasts to differentiate into myofibroblasts and produce excessive amounts of collagen and ECM, the role of the inflammatory response is increasingly considered important[1,11,13]. Downregulation of proinflammatory cytokines such as interleukin 6 (IL-6) and IL-8[14] and upregulation of anti-inflammatory cytokines such as IL-10 may reduce scar tissue formation[15]. Additionally, inflammatory cells such as macrophages, T cells, and mast cells, all increase and take part in a variety of biological activities in keloids and HS[1,16]. Although multiple intracellular signaling pathways such as Smad, signal transducer and activator of transcription 3, and extracellular signal-regulated kinase 3, are involved in hypertrophic scar formation, transforming growth factor-β (TGF-β)/Smad is thought to be a driving force[17,18]. Thus, the basic purpose of current prevention and therapy methods is still to reduce inflammatory processes[19].

SSc and scleroderma

SSc is an immune-mediated rheumatic disease that is characterized by excessive collagen from myofibroblasts in the skin and some internal organs, microangiopathy, and impairment of the humoral and cellular immunity system[20,21]. Scleroderma features, without the involvement of internal organs, are similar to SSc[4]. SSc pathogenesis involves early vasculopathy and innate and adaptive immune system dysfunction[12]. Initial vasculopathy and immune system dysfunction are both involved in SSc pathogenesis and cause SSc inflammation and tissue fibrosis[22]. Immune cells, endothelial cells, and fibroblasts interact with each other and release cytokines and growth factors[21]. Workers are convinced that type-1-interferon and interferon-inducible genes play a role in SSc pathogenesis[23]. Additional important factors include platelet-derived growth factor, endothelin 1, insulin-like growth factor 1, and TGF, which is thought to be a major regulator of fibrosis pathways[24]. Combined treatment that targets epigenetic/genetic, vascular, and immunologic defects and progressive fibrosis is urgently needed[12,

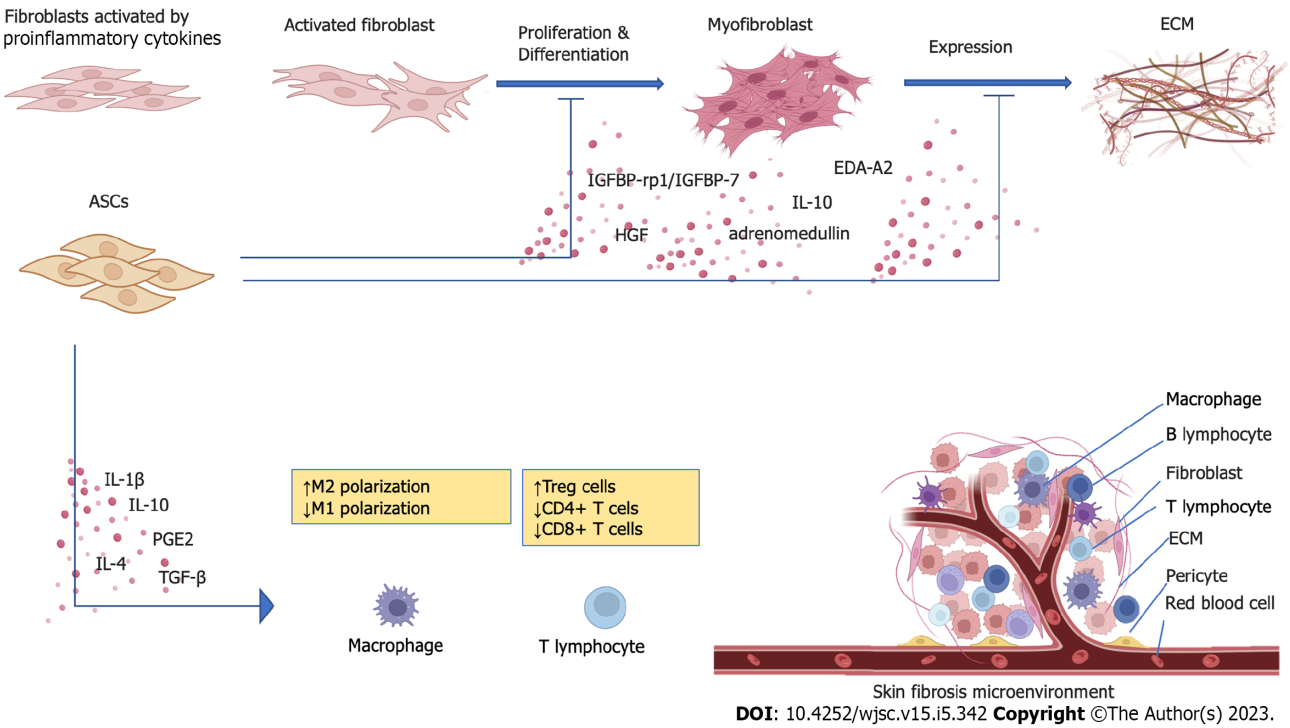
21,25].

MECHANISM OF ASC THERAPY

ASCs have long been thought to have immune privileges as mesenchymal stromal cells, which do not induce a severe allogeneic response when injected into another organism[26,27]. However, they have been demonstrated to evoke cellular and humoral responses in vivo, which may lead to the rapid elimination of transplanted cells[27]. However, ASCs function primarily through a "hit-and-run mechanism" with consequently a small effect on therapeutic efficacy, at least in the short or middle term [28,29]. Indeed, most ASCs do not require cell-to-cell contact to function but rather function through paracrine mechanisms that release cytokines, growth factors, and extracellular microvesicles in the surrounding environment[30]. As reported, the therapeutic effect of ASCs and their derivatives depends on paracrine secretion[31-34]. ASC-secreted active substances such as cytokines[35], growth factors[36], chemokines[37], and extracellular vesicles[38], regulate the microenvironment around fibroblasts and themselves[39,40] (Figure 1).

Regulation of the microenvironment

Immunomodulation and anti-inflammatory: After injection, ASCs activate adaptive cellular responses, secreting IL-1, prostaglandin E2 (PGE2), IL-4 and IL-10, and TGF-β, which modulate and stimulate innate immune cells[41]. It was reported that ASCs suppress $CD4^+$ and $CD8^+$ T-cell expansion and differentiation while promoting regulatory T-cell proliferation and enhancing their immunosuppressive activity[42]. Additionally, ASCs secrete immunosuppressive substances such as nitric oxide, PGE2, hepatocyte growth factor (HGF), and indoleamine 2,3-dioxygenase, which downregulate TGF-β in skin fibrosis and attract bone marrow (BM) cells involved in tissue repair[43,44].



Despite their immunomodulatory ability, the anti-inflammatory effects of ASCs have been gaining increasing attention. ASCs can drive anti-inflammatory M2 macrophage polarization and ameliorate macrophage infiltration[34,45]. Additionally, in a rabbit model of HS, ASCs mediated the inhibition of M1-polarized macrophages and defection of inflammation. Moreover, the expression of inflammatory cytokines and proteins such as IL-6 and monocyte chemotactic protein-1, which affect inducible nitric oxide synthase and cyclooxygenase-2, was notably decreased in the treated groups[46-48].

Angiogenic effects: The angiogenic effects of ASCs have been broadly discussed with regard to myocardial infarction, nerve injury, and tissue transplantation[49-52]. The secretion of vascular endothelial growth factor (VEGF) as well as the transcription of angiogenic genes are improved by ASCs [52,53]. ASC transplantation greatly improves revascularization and tissue perfusion in ischemic scars by stimulating endotheliocyte proliferation in blood vessels, hastening the resumption of blood circulation, providing oxygen and nutrition, and improving scar texture[54]. There is also an interplay between ASCs and endothelial precursor cells (EPCs). Growth factors produced by ASCs, such as VEGF, increase the migration and survival of EPCs, while EPC-produced platelet-derived growth factor BB stimulates ASC proliferation and migration[36].

Regulation of fibroblasts

Proliferation and differentiation: Activated dermal fibroblasts change their phenotype into myofibroblasts in response to injury or stress, which increases their expression of α-smooth muscle actin (α-SMA) and contractile ability[55,56]. Previous studies have demonstrated that ASC conditioned medium (ASC-CM) contains abundant growth factors and cytokines, such as IL-10, adrenomedullin, and HGF[7,57]. HGF, proven to inhibit fibroblast differentiation into myofibroblasts, contributes to limiting the profibrotic functions of myofibroblasts[58,59]. It has also been reported that ectodysplasin-A2, insulin-like growth factor binding protein-related protein-1/insulin-like growth factor-binding protein-7 (IGFBP-rp1/IGFBP-7), and thrombospondin-1 are increased in concentration in serum-starved ASC-CM, which could play a role in the inhibition of fibrosis[60]. These ASC-secreted immunosuppressive substances suppress fibrosis by various mechanisms, including reducing the expression of TGF-β1 and collagen and promoting the expression of matrix metalloproteinases (MMP), thus significantly repressing the activity of fibroblasts *in vitro* and *in vivo*[34,61].

Expression of ECM: The synthesis of collagen, hyaluronic acid, and fibronectin by myofibroblasts, in particular, is essential for the prolonged and excessive formation of ECM constituents[56,62]. Inhibition of HS-derived fibroblast (HSF) proliferation and reduction in α-SMA, type I collagen, and type III collagen expression can partly explain the molecular mechanism of the effects of ASCs on HSs[46,63,64]. In another study, ASC-CM reduced the synthesis of collagen and the expression of connective tissue growth factor, fibronectin, and α-SMA[65]. However, in a coculture model of ASCs and normal human dermal fibroblasts, ASCs increased the formation of collagen types I, III, and VI in the ECM[66]. It appears that ASCs could target abnormal fibroblasts and reduce pathological deposition of ECM.

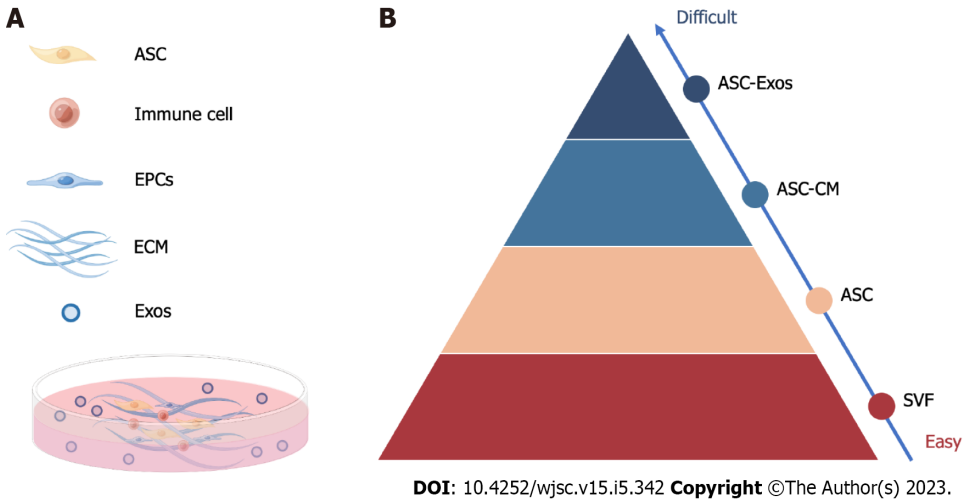
ASC THERAPY APPLICATION

ASC therapy, including the application of ASCs and their derivatives, can be roughly divided into ASC-based therapy and stem cell-free therapy. ASC-based therapy is mainly composed of various ASCs and stromal vascular fractions (SVFs), which have been broadly studied and applied in the clinic (Figure 2). Stem cell-free therapy, such as exosomes and ASC-CM, is increasingly popular, with fewer moral and safety concerns.

ASCs

One of the most promising stem cell groups, ASCs, are abundant in adipose tissue, easy to extract, and have few adverse effects. Compared to BM-mesenchymal stem cells, ASCs exert potent anti-inflammatory and remodeling properties with similar therapeutic effects[30].



Intralesional injection of ASCs reduces the formation of scars while improving color quality and scar pliability, potentially leading to an effective and novel anti-scarring therapy[59,67,68]. These studies revealed that ASCs not only inhibited fibroblast proliferation and migration but also reduced the expression of molecules such as TGF-β1 and Notch-1. The antifibrotic effect on fibroblasts was most likely mediated by the inhibition of multiple intracellular signaling pathways[18,65].

As they are inherently heterogeneous, different ASC subgroups have been studied in the hope of finding suitable subgroups for specific diseases.

A subpopulation of ASCs that are positive for $CD74^+$ possesses enhanced antifibrotic abilities both *in vitro* and *in vivo*. Additionally, $CD74^+$ ASC-assisted fat grafts reduce dermal thickness and fibrosis in radiation-induced fibrosis mouse models[69]. Another $CD73^+$ ASC subpopulation has expressed significantly lower levels of procollagen lysyl hydroxylase 1, a potent stimulator of fibrosis, showing better therapeutic effects on wound healing[70].

To modify or enhance some properties of ASCs and overcome the limitations of curative effects of ASCs only, ASCs are coated or activated with small molecule drugs or genetically overexpressing molecules that are involved in fibrosis formation.

After overexpressing MMP-3, ASCs-MMP-3 possess not only the ability of ASCs to accelerate wound healing but also the capability of MMP-3 to reduce scarring[71]. Compared with mASCs alone, migration ability and HGF production are significantly higher in mASCs activated with LMWH, showing higher anti-inflammatory and anti-fibrotic capability, and might be a promising candidate for SSc treatment[72]. IL-10-ASCs have been proven to have the capacity to suppress the development of HS by reducing inflammation during wound healing as well as the proliferation and migration of HSFs that produce ECM[73]. Poly(3-hydroxybutyrate-cohydroxy valerate) loaded with ASCs contains the

bioactive cues required to improve wound healing and scarring[74].

SVF

SVF is an aqueous fraction that contains ASCs, EPCs, endothelial cells, macrophages, smooth muscle cells, lymphocytes, pericytes, and preadipocytes, among other components. The advantages of SVF over ASCs are thought to be in two areas. First, the heterogeneous cellular composition of SVF may be responsible for the superior therapeutic results seen in comparative animal studies. Second, in contrast to ASCs, SVF can be obtained significantly more quickly without the need for cell separation or special cultivation conditions. As a result, the therapeutic cellular product is relatively safe and is only required to meet minimal regulatory requirements[75]. However, it should be emphasized that whereas ASCs are useful for both allogeneic and autologous treatments, SVF is only appropriate for autologous treatments because it contains a variety of cell types that are known to trigger immunological rejection. hASCs have seemed to be more effective than SVF in HS, related to their higher levels of MMP-2 and MMP-2/tissue inhibitors of metalloproteinase-2 ratio, as well as higher expression of TGF-3 and HGF[76]. Whether SVF is indeed superior to ASCs in skin fibrosis treatment needs further research[6,77].

In addition to HS and keloids, SVF is also broadly applied clinically to scleroderma and SSc. SVF gel has superior anti-inflammatory and antifibrotic effects on scleroderma[78]. Moreover, SSc does not impair SVF's ability to heal vascular damage, hence justifying the use of this novel autologous biotherapy[79]. SVF injection is a potentially effective treatment that seems to last for at least one year. Quality of life, Raynaud's phenomenon, finger edema, and hand impairment and discomfort were significantly improved[80-83].

Stem cell-free therapy

The secretome of ASCs, with a focus on exosomes, appears to be a suitable and safe alternative with more effectiveness and fewer adverse effects due to restrictions on the use of stem cells in cell-based treatment. Moreover, the ability to biobank the ASC secretome is a significant benefit of cell-free therapy. In this review, we concentrate on the current understanding of the secretome of ASCs, such as ASC exosomes (ASC-Exos) and ASC-CM, used in skin fibrosis stem cell-free therapy (Figure 3).

ASC-Exo: As one of the components of paracrine signaling, ASC-Exos are small, single membranous secretory organelles rich in proteins, lipids, nucleic acids, and carbohydrate conjugates[26,84,85]. Among other research discoveries, they are thought to have a variety of activities, such as reshaping the ECM and transmitting signals and molecules to other cells. In addition, they are not rejected by the immune system, have homing effects, and the dose is easily controlled[86,87]. Compared to ASCs, ASC-Exos offer a great opportunity to create new cell-free therapeutic techniques that could circumvent the challenges and dangers related to using natural or synthetic stem cells[86,88].

ASC-Exos release miR-29a-3p, which can suppress the expression of several profibrotic, antiapoptotic, remodeling, and methylase genes[89]. ASC-Exos are now a viable new option for the systemic treatment of keloids. They significantly suppress the development of ECM in keloids by decreasing collagen synthesis and impairing the microvessel structure, enhancing the expression of TGF-3 while inhibiting the protein expression of Smad3 and Notch-1[84]. By suppressing the expression of the TGF-1/Smad pathway, ASC-EXOs may prevent keloid fibroblasts from proliferating and migrating and consequently promoting death[90].

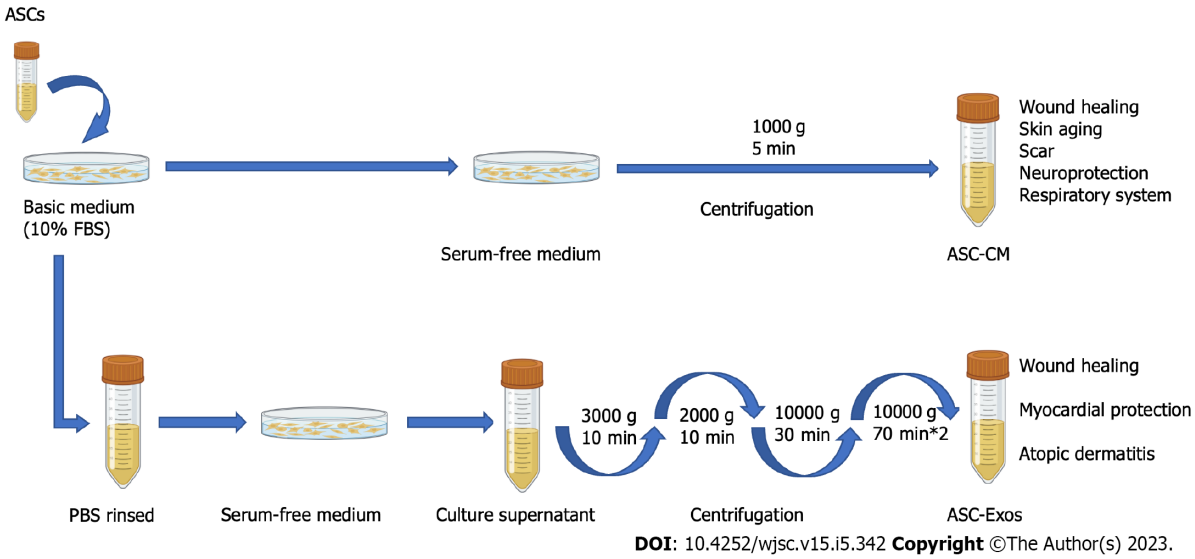

Figure 3 Adipose-derived stem cell conditioned media, exosomes, and adipose tissue extracts synthesis and therapeutic application. ASC: Adipose-derived stem cell; ASC-CM: ASC-conditioned medium; ASC-Exo: ASC exosomes; FBS: fetal bovine serum; PBS: Phosphate-buffered saline. Figure 3 is created with BioRender.com.

In hypertrophic scar fibrosis, ASC-exosomal miR-192-5p targeted IL-17RA to control the Smad pathway, and miR-29a inhibited the TGF-2/Smad3 signaling pathway, which could be responsible for the antifibrotic effects[91,92]. Another postoperative study showed that hASC-Exo therapy inhibited collagen deposition and myofibroblast aggregation *in vivo* and reduced the development of HS[93].

ASC-CM: Active chemicals released by ASCs, such as cytokines, exovesicles, exosomes, DNA, and RNA, are found in ASC-CM and can facilitate tissue healing and control immunity. ASC-CM can lower treatment costs and avoid the safety issues associated with stem cell therapy[94]. One disadvantage of CM over stem cells is the short life of active components. Stem cells can anchor inside a tissue or organ after local administration and function there for a long time, but CM-containing substances such as growth or enzyme factors are rapidly diluted and eliminated by diffusion[95,52].

ASC-CM may reduce collagen deposition and scar formation, inhibiting the p38/mitogen-activated protein kinase signaling pathway can have an anti-scarring effect, and the use of ASC-CM may offer a unique therapeutic approach for the treatment of HS[96]. According to *in vitro* and *ex vivo* experiments, chyle fat-derived stem cell-CM reduced the expression of type I collagen (Col1), type III collagen (Col3), and SMA, which prevents fibrosis in HSFs[63]. ASCs-CM dramatically elevated MMP-1 expression and dose-dependently decreased cell survival, expression of fibrosis markers, tissue inhibitor of metalloproteinases-1, the amount of collagen produced, and the ratio of Col1/Col3. These findings show that ASC-CM efficiently blocks fibrosis-related factors and controls ECM remodeling in HSF[64]. Combining ASC-CM with therapeutic therapies is another development. A histologic study revealed that ASC-CM increased the density of cutaneous collagen and elastin and arranged them in a certain order. A good combination therapy for treating atrophic acne scars and skin rejuvenation is ASC-CM with FxCR[97]. Stronger antifibrotic effects of CD74+ ASC-conditioned media may have resulted from increased production of HGF, FGF2, and TGF-3 and lower levels of TGF-β1[69]. ASC-CM and polysaccharide hydrogels might cross-bind in situ, which could significantly improve the therapeutic results by reducing scar proliferation, offering a promising alternative for the prevention of HS[98].

UPDATES ON THE CLINICAL APPLICATIONS OF ASC THERAPY

To evaluate the effectiveness of ASCs, numerous clinical trials have been carried out; however, they have largely focused on SSCs. More research is required to determine the long-term safety of ASCs, detailed mechanisms of effect, and the capacity to translate experimental results into clinical practice.

ASCs are used to treat secondary-progressive multiple sclerosis in 30 individuals. However, assessments of treatment efficacy revealed a mild tendency toward effectiveness. Establishing the possible therapeutic benefit of this technique would require larger studies and presumably treatment at earlier stages[99].

To compare the effectiveness of an injection of ASC-SVF derived from adipose tissue with placebo in decreasing hand disability in 40 SSc patients. This research demonstrated a gradual improvement with no evidence that the AD-SVF was superior. Given the limitations of this trial, a study with a larger

group of patients is urgently needed to accurately determine the value of ASC-SVF therapy[100]. It was revealed through a randomized controlled trial that regional adipose tissue grafting is beneficial in repairing ischemia digital ulcers in SSc[101].

This study investigates the safety and efficacy of administering autologous SVF cells to SSc patients. Early evaluations at six months suggest a possible efficacy that has to be confirmed in a larger population randomized placebo-controlled trial. Quality of life, Raynaud's phenomenon, finger edema, and hand impairment and discomfort are significantly improved[83]. A sequential 12-mo follow-up showed significant improvement in the vascular suppression score, skin sclerosis, motion and strength of the hands, and finger edema. The decrease in hand discomfort was statistically significant. A benefit was found in daily tasks, housework, and social activities, according to the questionnaire[82].

An open cohort study found that ASCs dramatically reduced the consequences of orofacial fibrosis in SSc. With the inhibition of fibroblast proliferation and important fibrogenesis regulators, including TG-1 and CTGF, ASCs may alleviate skin fibrosis[95].

SAFETY ASSESSMENT

ASCs overcome the ethical issues associated with embryonic stem cells and are therefore considered safe. However, as a stem cell therapy, ASCs still have problems with storage and transport, as well as the risk of inducing tumors and malformations[102]. Further studies on their efficiency are yet needed, taking into account the host environment and patient-related factors. Importantly, a long-term follow-up is needed to supervise cancer recurrence rates in the context of previous malignancy[103].

CONCLUSION

While the underlying mechanism of skin fibrosis is still unclear, ASC therapy plays multiple roles in the treatment of skin fibrosis, with a combination of aesthetic and therapeutic outcomes. Different ASC derivatives show various properties, which might be further explored in clinical trials. In the future, ASC therapy is likely to become an indispensable part of combined treatment in skin fibrosis.

Abstract

The mammalian intestinal epithelium constitutes the largest barrier against the external environment and makes flexible responses to various types of stimuli. Epithelial cells are fast-renewed to counteract constant damage and disrupted barrier function to maintain their integrity. The homeostatic repair and regeneration of the intestinal epithelium are governed by the $Lgr5^{+}$ intestinal stem cells (ISCs) located at the base of crypts, which fuel rapid renewal and give rise to the different epithelial cell types. Protracted biological and physicochemical stress may challenge epithelial integrity and the function of ISCs. The field of ISCs is thus of interest for complete mucosal healing, given its relevance to diseases of intestinal injury and inflammation such as inflammatory bowel diseases. Here, we review the current understanding of the signals and mechanisms that control homeostasis and regeneration of the intestinal epithelium. We focus on recent insights into the intrinsic and extrinsic elements involved in the process of intestinal homeostasis, injury, and repair, which fine-tune the balance between self-renewal and cell fate specification in ISCs. Deciphering the regulatory machinery that modulates stem cell fate would aid in the development of novel therapeutics that facilitate mucosal healing and restore epithelial barrier function.

Key Words: Intestinal stem cell; Epithelial repair; Homeostasis; Regeneration; Self-renewal; Apoptosis

Core Tip: The homeostatic repair and regeneration of the intestinal epithelium upon injury are governed by the Lgr5$^+$ intestinal stem cells (ISCs) located at the base of crypts, which fuel rapid renewal and give rise to different epithelial cell types. We review the current understanding of the intrinsic niche signaling and extrinsic stimulating factors that control homeostasis and regeneration of the ISCs. Deciphering the regulatory machinery that modulates stem cell fate, and formulating strategies for better repair and regeneration would aid in the development of novel therapeutics that facilitate mucosal healing and restore epithelial barrier function.

INTRODUCTION

Intestinal epithelium serves as the first line of defense against the external environment. As an outward single-layered epithelial structure, the intestinal mucosa withstands continuous mechanical, physico-chemical, and biological insults[1,2]. To counteract intestinal injury and preserve their barrier function, epithelial cells are renewed every 2–5 d in most adult mammals[3]. The epithelial turnover is coordinated by Lgr5$^+$ intestinal stem cells (ISCs) residing at the base of the crypts where they are kept in a multipotent state and produce transit amplifying (TA) progenitor cells. TA cells will undergo several cycles of division before migrating to the villi and ultimately differentiate into multiple lineages[4,5]. The disrupted barrier function and defective mucosal healing are the predominant biological features of intestinal pathology, and particularly, chronic gastrointestinal inflammation such as inflammatory bowel disease (IBD), which is represented by ulcerative colitis and Crohn's disease[6-8]. Current clinical strategies focus on the symptomatic relief and blockade of inflammatory progression[9,10], while better solutions should emphasize the motivation of regenerative response orchestrated by ISCs for complete mucosal healing.

Mucosal healing is an integrated network initiated by a series of biological processes and signals[11]. Intestinal homeostasis is characterized by constant regeneration which demands a fine-tuned balance between ISC proliferation and differentiation[12,13]. In response to diverse insults, the cellular response, combined with the stem cell niche adaptions, synthetically modulates the fate of ISCs to restore homeostasis by replenishment of damaged epithelial cells, or to hasten cell demise by impairment of cell function and vitality[14,15]. Therefore, understanding the cellular response and niche adaptations during injury-induced intestinal regeneration is therefore of importance for ISC biology.

Constant efforts have been made to exploit the regulatory mechanisms of critical components that seal the fate of ISCs. In this review, we give an overview of ISCs and review the adaptations and signals required for homeostasis maintenance. We focus on the cell fate specification and biological alterations of ISCs upon diverse insults and provide insights into intestinal regeneration.

INTESTINAL STEM CELL

Two distinct ISC populations located at the crypts have been proposed: Crypt base columnar (CBC) cells, the active cycling stem cells that facilitate homeostatic self-renewal[16], and +4 cells, the quiescent stem cells reserved for injury-induced repair[17].

CBC cells have been the centerpiece of stem cell research since they were initially identified in 1974 as continuously cycling cells at the base of the crypts[18]. Radionucleotide labeling and autoradiography have been used to state that the cells derived from the crypts migrate upward along the villi to be extruded at the villus tips[19,20]. This conveyor belt mechanism confirms stem cell fueling this rapid self-renewal process resides at the base of the crypts[21]. The generation of Lgr5$^{EGFP-IRES-CreERT2}$ mice reveals that Lgr5, a receptor for WNT signaling-associated R-spondins, is a highly suitable candidate for CBC cell recognition and specification[3]. Single-sorted Lgr5$^+$ stem cells are also able to form these crypt–villus organoids and the Lgr5 hierarchy is maintained in organoids[22]. Recent studies have identified that p27 and Mex3a label the slowly cycling subpopulation of Lgr5$^+$ ISCs based on single-cell transcriptome profiling[23,24].

In addition to Lgr5$^+$ CBC cells, Bmi1$^+$ cells localized at the fourth position of the crypt base and discovered by *in vivo* lineage tracing and transcriptome analyses, are a possible candidate stem cell population[4,25]. Functionally distinct from Lgr5$^+$ ISCs, the quiescent +4 stem cells are considered reserved stem cells that replenish the continuously cycling CBC cells pool when required, and are highly resistant to radiation and insensitive to Wnt signal[17,26]. In face of chemoradiotherapy, Lgr5$^+$

stem cells are vulnerable to chemical- or irradiation-induced injury, due to their predominantly cycling nature[24,27]. Bmi1$^+$ cells quickly revert to ISCs and the *de novo*-generated Lgr5$^+$ ISCs are vital for epithelial regeneration[28]. The evidence summarizes the relationship between active and quiescent stem cells and identifies Lgr5$^+$ stem cells as a substantial contributor to homeostatic regeneration[29].

The identification of new ISC markers and the dedication each subpopulation of ISCs commit to regeneration have improved the understanding of stem cell biology during homeostasis and disease. The emergence of new technologies has promoted the decoding of many key problems in intestinal diseases and tumors[4].

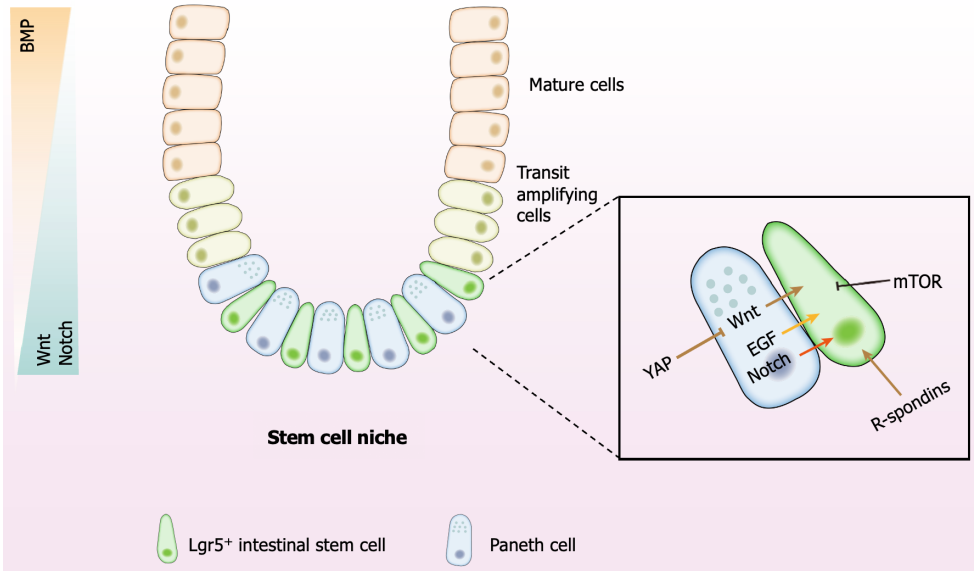
INTESTINAL STEM CELL NICHES

The niche in which ISCs reside can be defined as the microenvironment essential for self-renewal and stemness maintentance[13]. ISCs are strongly linked with adjacent cells of both epithelial and mesenchymal origin. These components, along with their communications, comprise the ISC niche[30,31]. The specific instructive microenvironment offers a native source of signals that fuel ISCs to maintain tissue homeostasis[32]. Various cell types of the niche elaborate typical paracrine signals containing Wnt, R-spondin, Notch, mammalian target of rapamycin (mTOR), bone morphogenetic protein (BMP), epidermal growth factor (EGF) and Hippo, which fine-tune the balance between differentiation and proliferation of ISCs, and ensure the production of an adequate number of cells in homeostatic and injury conditions[1,33] (Figure 1).

Wnt signaling

The canonical Wnt signaling acts as the prominent driver for ISC proliferation. Synchronous Wnt binding to Frizzled and to LRP5/6 suppresses APC-related ubiquitination of β-catenin which mediates its nuclear translocation, the association with lymphoid enhancer binding factor/T cell factor transcription factors, and the succeeding transactivation of Wnt target genes[34-36]. Multiple Wnts such as Wnt2b, Wnt4, and Wnt5a are abundantly expressed in intestinal stroma[30]. A subset of Foxl1$^+$ mesenchymal stromal cells that form a subepithelial plexus around the crypt is a crucial source of intestinal Wnt[37]. Genetic elimination of Foxl1$^+$ cells triggers the loss of Wnt family expression in the epithelium and an abrupt cessation of proliferation of both epithelial stem cell and TA progenitor cell populations, but not Paneth cell[38]. Wnt2b is highly expressed in Gli1$^+$ or αSMA$^+$ subepithelial stromal cells, which is sufficient to restore epithelial integrity when injected into mice which is devoid of Wnt secretion[39]. Gli1$^+$ subepithelial cells are essential contributors to the integrity of the colonic epithelium for Lgr5$^+$ ISC self-renewal in the colon[40]. As a noncanonical Wnt ligand, Wnt5a deficiency causes a failure to develop new crypts at the wound site and limits the proliferation of crypt cells after injury in a transforming growth factor (TGF)β-dependent manner[41]. These findings reveal the essential role of Wnt signal for the stemness and proliferation of ISC and highlight the contribution of stromal cells in the ISC niche.

The R-spondins comprise one of crucial elements of the niche. R-spondins are secretory glycoproteins which firmly cement the capacity of Wnt ligands for the activation of β-catenin-dependent transcription and canonical Wnt signaling, while R-spondins themselves have no intrinsic Wnt signaling activity[29,42]. Overexpressed R-spondins *in vivo* forcefully induce the expansion of ISCs and maintain the epithelial integrity against damage induced by the chemotherapeutic agent 5-fluorouracil, dextran sulfate sodium (DSS), or irradiation[43-45]. Wnt proteins are reported to be insufficient to directly regulate ISC self-renewal, while alternatively grant a fundamental competency through motivating R-spondin ligands to actively motivate ISC[46].



Notch signaling

Notch signaling plays a dominant role in the stem cell niche by preserving the quiescent state of ISCs [47]. Integration between Notch ligands (Notch1–4) and receptors (Jag1–2 and Dll1–4) in adjacent cells is required for Notch activation[48]. Different from Wnt signaling that is mainly generated from a stromal microenvironment, Notch signaling may function *via* neighboring epithelial cells or even stromal subpopulations contacting with ISCs, thus featuring an epithelial niche[49].

Disruption of Notch activity leads to the exhaustion of ISC and differentiation from proliferating TA cells to secretory cells[50]. Simultaneous Notch1/2 deletion recapitulates the global Notch inhibition phenotype of Lgr5$^+$ ISC loss, while the single deletion does not change ISC activity, which suggests the synthetical effect of Notch1/2 in stemness maintenance[51,52].

mTOR signaling

The mTOR signaling is a vital pathway for cellular development and metabolism in mammals. mTOR signaling directly modulates stemness and proliferation of ISCs, functioning as a crucial determinant of cell status within the ISC lineage and modulating differentiation in a nutrient-dependent way[53]. Inhibiting mTOR signaling helps to maintain stemness of ISCs, whereas activation of mTOR facilitates ISCs differentiation and proliferation[54,55]. In the case of caloric restriction, the activity of mTOR

DOI: 10.4252/wjsc.v15.i5.354 **Copyright** ©The Author(s) 2023.

Figure 1 The intestinal stem cell niche and regulatory signals. The intestinal epithelium consists of crypts and villi. The crypts generate a constant stream of new cells that differentiate and migrate upward into the villi. These Lgr5+ intestinal stem cells reside at the bottom of the crypts and are wedged between Paneth cells, which protect and nurture stem cells. Above the stem cell zone is the lineage-committed progenitor cells, also known as the transit amplifying zone, divided to fuel the rapid epithelial cell turnover. Mature epithelial cells originate from the crypt and move up toward the villus tip. The Wnt and Notch signaling exhibit high activity in the stem cell niche. Activation of the signals decreases along with the increased distance from the crypt bottom. While the BMP activity stands in the opposite direction. WNT, R-spondin, epidermal growth factor, and mammalian target of rapamycin are secreted by Paneth cells or mesenchymal cells. YAP works through the Wnt signaling to maintain the crypt–villus integrity. Besides, Paneth cells provide essential Notch signals to stem cells by expressing Notch ligands. The signaling network in the niche establishes the baseline for self-renewal, fate determination, proliferation, and differentiation of intestinal stem cells. BMP: Bone morphogenetic protein; EGF: epidermal growth factor; mTOR: Mammalian target of rapamycin.

complex 1 is inhibited in Paneth cells, resulting in the paracrine release of cyclic ADP ribose that increases self-renewal of ISCs at the cost of differentiation[56]. In high relevance to diet, the mTOR pathway controls stem cell fate possibly by regulating mitochondrial metabolic states.

BMP signaling

BMP signaling acts as an initiator of differentiation in the crypt. Wnt and BMP signalings are deemed as opposite forces along the crypt–villus axis with counteractive gradients of activity[57]. BMP activity is lower in the bottom and higher towards the top of the villus[58]. To offset the inhibitory effects of BMP signaling on ISC fate, BMP antagonists like Noggin, Gremlin-1, and Gremlin-2 are highly expressed in the crypts, permitting the proliferation of ISCs. The BMP antagonists that enhance ISCs self-renewal are secreted by intestinal subepithelial myofibroblasts and smooth muscle cells[59,60].

EGF signaling

EGF is a vital component of the ISC niche[61]. The EGF receptor is abundantly expressed in CBCs, whereas its ligands are expressed in Paneth cells[62]. The activity of ErbB signaling is monitored by the negative regulation of Lrig1, a transmembrane protein coexpressed with Lgr5 in CBCs[62]. Loss of Lrig1 leads to the activation of receptors and a concomitant rapid expansion of crypts and cell numbers. Blockade of EGF signaling in intestinal organoids drives proliferative ISCs into quiescent state and stops organoid budding[63]. The evidence suggests the requirement of EGF in epithelial regeneration.

Hippo signaling

The Hippo pathway, a highly conserved signaling first described in *Drosophila* as an organ size control pathway, is comprised of a core kinase cascade, Mst1/2 and Lats1/2, which phosphorylate and suppress transcriptional coactivators Yes1 associated transcriptional regulator (YAP) and Tafazzin (TAZ), thereby modulating TEA domain transcription factor 1 (TEAD)-mediated transcriptional activation[64,65]. YAP/TAZ are the core components for stem cell-based regeneration. YAP overexpression in mice accelerates the self-renewal of colonic epithelium, and augments the number of proliferative cells and the cell migration along the crypt-villus axis, as detected by BrdU marker[43]. While YAP depletion causes a significant decrease in crypt proliferation, extensive crypt loss and consequently regeneration failure upon DSS or irradiation[66,67]. Loss of YAP activity contributes to higher sensitivity of ISCs to apoptosis and lower proliferative capacity during regeneration[68]. Moreover, the core Hippo kinases Lats1/2 are essential to maintain ISC activity and their deletion leads to the loss of ISCs[69]. This demonstrates their essential effects on epithelial proliferation and tissue regeneration.

YAP may actively block Wnt signaling and thus apply negative feedback on Wnt signaling *via* β-catenin inhibition[43], indicating the complex interaction between YAP and other niche signals which may need further investigation.

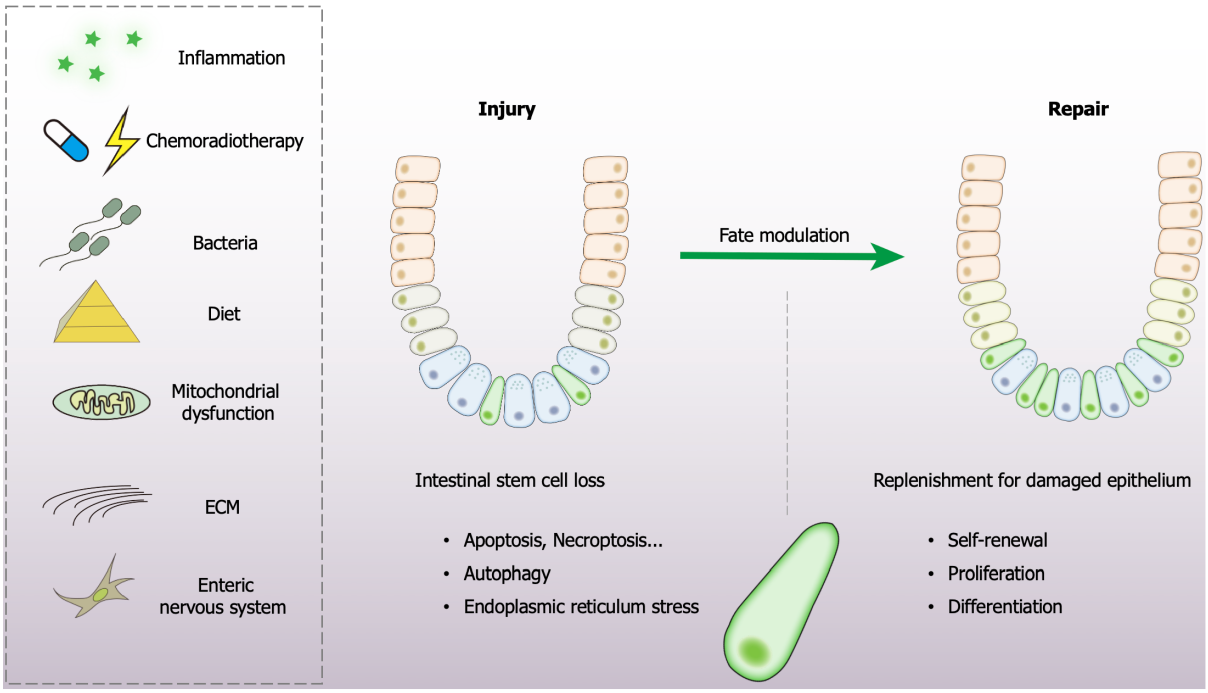
ENDOGENOUS AND ENVIRONMENTAL STIMULI

The intestinal epithelium is exposed to a hostile luminal environment, thus resulting in Lgr5$^+$ ISCs continuously encountering sources of stress to maintain dynamic homeostasis. We summarize the major endogenous and environmental stimuli that influence stem cell regenerative potential (Figure 2).

Endogenous factors

Niche signals: Damage to the crypts can result from infections, chronic inflammation, chemoradiotherapy, or traumatic injury and motivate a series of actions in the stem cell niche[31]. The microenvironment monitors the regenerative response *via* regulating a series of signaling pathways, such as Wnt, Notch, BMP, and Hippo. This has been discussed above.

Extracellular matrix: The state of stem cells largely depends on the properties of the extracellular matrix (ECM)[31]. The integrin complex assists cells in sensing the stiffness of the ECM and directs the fate of ISCs *via* adhesion signaling[70,71]. In this way, the ECM affects cellular behavior, including proliferation and differentiation. ECM stiffness is also a vital endogenous factor of mesenchymal stem cells to differentiate into osteoblasts, myoblasts, or neurons[72]. In particular, YAP/TAZ lay the foundation for ECM stiffness sensing and play a prominent role in intestinal repair and regeneration[73]. High matrix stiffness significantly enhances ISC expansion in a YAP-dependent manner[74]. These clues speculate that ECM sensation is capable of modulating self-renewal in ISCs.



Mitochondrial function: Mitochondrial function emerges as a central player in cell fate determination and extensive control of cellular stress responses, metabolism, immunity, and apoptosis[75]. Mitochondria are the center of energy metabolism and the regulator of stem cell homeostasis[76,77], and oxidative phosphorylation is particularly important to maintain the function of stem cells[78]. For example, pyruvate oxidation in the mitochondria works as a metabolic checkpoint of ISC self-renewal and/or stemness maintenance[77]. Regulators of mitochondrial signals such as ATP, reactive oxygen species (ROS), the mitochondrial unfolded protein response, and AMP-activated protein kinase signaling, will in turn affect stemness and cell cycle progression[75].

Enteric nervous system: In spite of the limited studies into the underlying relationship between the nervous system and intestinal epithelial regeneration, some novel indications are pointed out that the enteric nervous system exerts a potential role with great value. Enteric glial cells are closely connected with the intestinal epithelium and depletion of enteric glial cells will exacerbate DSS-induced injury [79]. The administration of hepatocyte growth factor from neural cells of the enteric nervous system attenuates the hostile effects of DSS[80]. Several reports also unveil a potential effect of the enteric glial cells in mucosal healing through the release of the specific niche factors like glial-derived neurotropic factor, TGF-β1 or 15-deoxy-12,14-prostaglandin J2[41,81,82].

Extrinsic factors

Diet: The biological behavior of stem cells is largely affected by nutritional state[31]. The mTOR signaling is responsible for sensing the nutritional state[83]. Mice fed with a calorie-restricted diet exhibit an augmented function in Lgr5$^+$ ISCs and Paneth cells compared with mice with a normal diet [56,84]. Moreover, the calorie-restricted diet diminishes mTOR activity in quiescent stem cells, improving their resistance to radiation damage and promoting intestinal repair[85]. In contrast, a high-fat diet can increase ISC activity despite decreasing Paneth cells activity. ISCs of high-fat diet mice exhibit higher resistance to irradiation and more efficient organoid budding potential than control mice. The high-fat diet activates Wnt signaling in ISCs dependent on the nuclear peroxisome proliferator-activated receptor δ[86]. Another study also reveals that an obesogenic diet induces ISCs and progenitor cells hyperproliferation, triggers ISC differentiation and cell turnover, and alters the regional characteristics of ISCs and enterocytes in mice[87]. Acute fasting has been shown to lead to transient phosphatase and tensin homolog (PTEN) phosphorylation within quiescent ISCs and render quiescent ISCs functionally poised to contribute to the regenerative response during refeeding[88].

Microorganisms: Microorganisms play an indispensable role in gut homeostasis, but the underlying mechanisms are complicated and elusive. Small molecules and metabolites produced by gut microbiota significantly contribute to the host intestinal development, function, and homeostasis[89]. Lactate from lactic acid-producing bacteria plays a pivotal role in promoting ISC proliferation and epithelial development[90]. Butyrate within the crypts conveys a growth-inhibiting effect on Lgr5$^+$ ISCs *via* Forkhead box O3[91]. The bacterial product muramyl dipeptide has been reported to decrease the level of ROS in ISCs, and promote intestinal organoid growth and tissue repair[92,93]. *Salmonella* can enter

Figure 2 Modulation of stem cell fate determination and epithelial repair by various sources of stress. Both exogenous (inflammation, chemoradiotherapy, and diet) and endogenous factors (mitochondrial dysfunction, extracellular matrix, and enteric nervous system) have vital effects on stem cell fate modulation. The self-renewal capacity, the balance of proliferation and differentiation are tightly controlled in the process of epithelial repair and regeneration. ECM: Extracellular matrix.

the crypts during infection and cause a significant decrease in Lgr5$^+$ ISCs[94,95]. The enteric pathogen rotavirus specifically invades and deteriorates differentiated cells at villus tips, and then motivates Lgr5$^+$ ISCs, crypt expansion, and hyperproliferation[96]. Gut pathogens are thus distinctive elements capable of tuning the stem cell fate.

Inflammatory signaling: In addition to the local niche signals and physicochemical stimuli, the activation of the immune system is also involved in the interactions between epithelial cells and the niche to guarantee proper initiation and continuation of the regenerative response. Interleukin (IL)-22, which derives from the intestine, contains group 3 innate lymphoid cells that reside in close proximity to intestinal crypts and are upregulated after injury and support subsequent epithelial regeneration[97]. Recombinant IL-22 has been shown to directly target ISCs, thus facilitating the growth of human and mice intestinal organoids and promoting ISC self-renewal[98,99]. A recent study also indicates that the symmetric division of ISCs can be triggered by inflammatory signals to prevent excessive expansion in the process of epithelial repair[100].

Chemoradiotherapy: Intestinal mucosal damage occurs in 40%–60% of patients receiving chemotherapy or radiotherapy[101]. Chemotherapy- or radiotherapy-induced cellular apoptosis can be the primary factor initiating the gastrointestinal syndrome[102,103]. The injury response of intestinal epithelium after chemoradiotherapy has been the most extensively characterized model of Lgr5$^+$ ISC loss and proliferation to date, due to its hypersensitivity to radiation and chemotherapy. Targeting p53-dependent stem cell death is the core strategy for intestinal chemo- or radioprotection[102,104,105]. The Toll-like receptor 4 signaling pathway[106], Slit guidance ligand 2 (Slit2)/ Roundabout guidance receptor 1 (Robo1) signaling[45], gut microbiota[90,107], and dietary components such as green tea derivative (-)-epigallocatechin-3-gallate[108], aspartate[109], pectin[110], and vitamin D[111] have been shown to mitigate the loss of ISCs and alleviate intestinal injury. The deletion of CREPT suppresses the proliferation and differentiation of ISCs and reduces Lgr5$^+$ cell numbers after X-ray irradiation[112]. Therapeutic strategies based on the inhibition of ISC apoptosis without compromising the efficacy of cancer treatment are of great potential.

MODULATION OF STEM CELL FATE

The injury response of intestinal epithelium is critical to restore epithelial integrity upon diverse insults [13]. The immediate response of intestinal damage is the loss of Lgr5$^+$ ISCs, while it is generally adaptive

modulation since the reserved subpopulations are activated to replenish the defects. However, excessive damage may cause ISC depletion and militate against epithelial regeneration. Critical cellular adaptations have been made to restore homeostasis in ISCs.

Apoptosis

As the best-understood form of programmed cell death, apoptosis has been largely clarified in the field of stem cells. Lgr5$^+$ ISCs are more vulnerable to apoptosis than Bmi1$^+$ stem cells are[113]. Considering the critical role of mitochondria in stemness maintenance, regenerative capacity determination, and modulation between self-renewal and cell death programs, mitochondrial function is the vital determinant of stem cell fate[75]. For Lgr5$^+$ ISCs, mitochondrial dysfunction is the major cause of apoptosis. A series of molecules such as Bcl-2, Puma, Survivin, Phosphoribosyl pyrophosphate synthetase 1 (PRPS1), and X-linked inhibitor of apoptosis have been characterized for modulating ISC apoptosis. Other biological processes, including immune response, hormone response, post-translational modification, and signaling such as Hippo and G protein coupled receptor, are crucial to controlling Lgr5$^+$ ISC apoptosis. The pivotal molecules regulating stem cell apoptosis are shown in Table 1. The excavation of novel strategies based on ISC survival is of great significance to epithelial regeneration.

Necroptosis

Necroptosis is also involved in crypt damage. The loss of SETDB1 in ISCs, a histone methyltransferase that induces the trimethylation of histone H3 at lysine 9, triggers Z-DNA-binding protein 1-dependent necroptosis, which irreversibly disrupts the integrity of the epithelial barrier and promotes the progression of IBD[114]. Intestinal organoids lacking ATG16L1 are more prone to initiate tumor necrosis factor (TNF)α-mediated necroptosis, and therapeutic blockage of necroptosis through TNFα or RIPK1 inhibition ameliorates the severity of IBD[115]. TNFα exacerbates necroptosis of differentiated cells and mediates the expansion of LGR5$^+$ ISCs[116]. Therefore, necroptosis inhibitors could be used to promote mucosal healing in IBD patients.

Autophagy

Autophagy is a highly conserved process during evolution in eukaryotes, by which the cytoplasmic materials are degraded inside the autolysosome. Three distinct forms of autophagy, including microautophagy, chaperone-mediated autophagy, and macroautophagy have been described. Autophagy has been demonstrated crucial in modulating the interactions between gut microbiota and innate and adaptive immunity, in host defense against intestinal pathogens, and in maintaining intestinal homeostasis[117].

In the *Drosophila* intestine, autophagy downregulates the sensitivity of differentiated enterocytes to ROS when exposed to commensal bacteria. Mechanistically, the autophagic substrate Ref (2)P/p62 accumulates upon autophagy deficiency, thus inactivating Hippo signaling and leading to stem cell over-proliferation[118]. Autophagy can also protect ISCs against irradiation-induced oxidative stress by preserving mitochondrial health and function. Accordingly, stem cell-based intestinal regeneration after radiotherapy is impaired in mice with Atg5 deficiency. Another recent work has highlighted the role of ATG16L1-dependent autophagy in protecting ISCs from irradiation-induced ROS[92,119]. In a *Drosophila* model, Atg6 deficiency impairs the inhibitory effect of metformin on ISC aging[120]. A recent study has confirmed the role of Atg7 in maintaining epithelial integrity against DNA damage and cell death[121]. With the rapid progress of Lgr5$^+$ ISC isolation and detection, the role of autophagy in ISCs will be further elucidated.

Endoplasmic reticulum stress and unfolded protein response

As the primary organelle for protein folding and quality control, endoplasmic reticulum (ER) is sensitive to multiple intrinsic cellular disturbances and extrinsic environmental changes, which would alter ER homeostasis and cause misfolded protein accumulation, leading to activation of unfolded protein response (UPR)[122]. Previous studies have shown that UPR exerts a significant role in the pathogenesis and progression of IBD[123]. Human genetic studies of IBD have identified primary genetic abnormalities in several genes, including *Xbp1*, *Agr2*, and *Ormdl3*, that encode proteins associated with ER stress[124-126]. More importantly, the control of ISC fate is coordinated by ER stress and UPR. Activation of ER stress leads to the loss of stemness of ISCs in a PERK–eIF2α-dependent manner[127]. XBP1, a stress sensor involved in the UPR, acts as a signaling hub to regulate stem cell function and epithelial DNA damage responses in a p53–DDIT4L-dependent manner[128]. XBP1 is also demonstrated to maintain ISC quiescence and control ISC activity[129]. Intestinal epithelium-specific deletion of glycoprotein 96, an ER-resident master chaperone, causes rapid destruction of stem cell niche, followed by complete eradication of the mucosal layer and epithelial cell death[130]. In summary, UPR is indispensable for stemness maintenance and fate determination of ISCs.

Table 1 Apoptosis regulation of intestinal stem cells

Biological process or signaling	Molecule	Role	Evidence
Mitochondrial dysfunction	Puma	Pro-apoptotic	Puma depletion reduces chemoradiotherapy- induced apoptosis in a p53-dependent manner [102,136]
	Bcl-2	Anti-apoptotic	Bcl-2 is highly expressed in ISCs and alleviating radiation-induced damage[137]
	Survivin	Anti-apoptotic	An essential guardian of ISC during mucosal healing[138]
	PRPS1	Pro-apoptotic	PRPS1 deficiency exhibit resistance against intestinal damage in a manner dependent upon Lgr5+ ISCs[139]
Immune response	IL-22	Anti-apoptotic	IL-22 deficiency led to increased crypt apoptosis, depletion of ISCs[97]
	NOD2	Anti-apoptotic	Nod2 stimulation triggers stem cell survival against oxidative stress-mediated cell death[93]
Hippo	YAP	Anti-apoptotic	Loss of YAP activity results in sensitivity of crypt stem cells to apoptosis and reduced cell proliferation during regeneration[140]
GPCR	β-Arrestin1/2	Anti-apoptotic	βArr reduced the chemotherapy- induced Lgr5+ stem cell apoptosis by inhibiting endoplasmic reticulum stress[141,142]
Hormone	GLP-2	Anti-apoptotic	GLP-2 expanded intestinal organoids and downregulated apoptosis-related genes[143]
	Ghrelin	Anti-apoptotic	Ghrelin treatment accelerated the reversal of radiation-induced epithelial damage and defective self-renewing property of ISCs[144]
Methylation	Mettl14	Anti-apoptotic	Specific deletion of the Mettl14 gene resulted in colonic stem cell apoptosis[145]
	GsdmC	Anti-apoptotic	GsdmC N6-adenomethylation protects mitochondrial homeostasis and is essential for Lgr5+ cell survival[146]
Glycosylation	HYOU1	Anti-apoptotic	HYOU1 glycosylation modulated by FUT2 protects ISCs against apoptosis[147]

ISCs: Intestinal stem cells; PRPS1: Phosphoribosyl pyrophosphate synthetase 1; GPCR: G protein coupled receptor.

FUTURE DIRECTIONS FOR STEM-CELL-BASED THERAPY

Stem-cell-based therapy holds great promise for the complete mucosal healing of gastrointestinal diseases. Related studies have applied exogenous stem cells such as mesenchymal stem cells and placental-derived stem cells for treating intestinal inflammation and injury[131,132], and achieved encouraging outcomes. With the boost of research in the field of ISCs, the intestinal organoid models, especially those of human origin, offer a unique platform to explore the mystery of ISC fate decisions and lineage specification in physiological and pathological conditions[14], and excavate novel strategies to facilitate the regenerative capacity of ISCs. Integration with novel nanomaterials can provide a more effective strategy for facilitating intestinal repair targeting at ISCs, such as grape exosome-like nanoparticles[133], polydopamine nanoparticles[134], and carbon nanoparticles[135]. Thus, one important future direction in the ISCs field is to precisely tune the fate of stem cells for better regeneration.

CONCLUSION

Intestinal epithelial regeneration is a complex network that is based on the function of ISCs. The dynamic balance between stemness and self-renewal is fine-tuned by stem cell niche and various endogenous or extrinsic factors. Great strides have been made in our understanding of the function and fate specification of ISCs in health and disease. In this review, we summarize the different components and signals that function in ISCs in the process of intestinal epithelial injury and repair. Cellular adaptations including apoptosis, necroptosis, autophagy, and UPR have been extensively investigated. Modulating the essential niche signaling or facilitating beneficial elements in the stem cell microenvironment provides novel insights into the regenerative process and opens an avenue for stem cell-based therapies for diseases caused by intestinal epithelial injury.

Abstract

Mesenchymal stem cells (MSCs), distributed in many tissues in the human body, are multipotent cells capable of differentiating in specific directions. It is usually considered that the differentiation process of MSCs depends on specialized external stimulating factors, including cell signaling pathways, cytokines, and other physical stimuli. Recent findings have revealed other underrated roles in the differentiation process of MSCs, such as material morphology and exosomes. Although relevant achievements have substantially advanced the applicability of MSCs, some of these regulatory mechanisms still need to be better understood. Moreover, limitations such as long-term survival *in vivo* hinder the clinical application of MSCs therapy. This review article summarizes current knowledge regarding the differentiation patterns of MSCs under specific stimulating factors.

Key Words: Mesenchymal stem cells; Differentiation; Osteogenic; Chondrogenic; Literature review.

Core Tip: Mesenchymal stem cells (MSCs) are multipotent cells capable of differentiating in specific directions. The differentiation process of MSCs depends on diverse specialized external stimulating factors. The results from recent studies have revealed other underrated roles in the differentiation process of MSCs. However, several questions remain to be solved prior to stable and effective clinical treatment. Our review explores the differentiation patterns of MSCs and summarizes the relevant research according to stimulus types. Finally, future prospects are discussed with regard to their clinical applications.

INTRODUCTION

Mesenchymal stem cells (MSCs), which were originally identified in the bone marrow, are adult stem cells with multilineage differentiation potential. Under specific induction conditions, MSCs could differentiate into bone, adipose, muscle, neural, and endothelial tissue cells[1]. With the development of research, MSCs have been obtained from other tissues, including adipose, peripheral blood, umbilical cord blood, and periodontal membrane tissue[2-5]. Due to their multilineage differentiation potential and rich tissue sources, the application of MSCs in research on regenerative medicine is virtually limitless[6]. However, a specific number of MSCs are necessary for tissue regeneration; hence, there is a requirement for MSC amplification before therapy[7]. The question of how the differentiation of MSCs are controlled *in vitro* and *in vivo* remains unanswered, which has limited the effectiveness of MSCs in the application of regenerative medicine research. Recently, various external stimulus factors, such as biochemical stimuli, hypoxia, physical stimuli, material properties, and exosomes, have been found to have an impact on the differentiation process of MSCs (Figure 1). The purpose of this review is to discuss a variety of recent findings regarding the important external stimulus factors that influence the self-renewal and osteogenic and chondrogenic differentiation potential of MSCs.

BIOCHEMICAL STIMULI

Growth factors, cytokines, and miRNAs are examples of biochemical stimuli that have typically been employed to control the destiny of MSCs. Growth factors and cytokines bind to the corresponding receptors and transfer signals, while miRNAs degrade mRNAs or inhibit the translation of mRNAs to regulate gene expression and thus influence the differentiation fate of MSCs. Numerous studies have examined the effects of various growth factors, cytokines, and miRNAs on the proliferation and differentiation of MSCs into other cellular phenotypes (Table 1).

Growth factors

Growth factors, including fibroblast growth factor (FGF), transforming growth factor (TGF), platelet-derived growth factor, hepatocyte growth factor, granulocyte colony-stimulating factor and bone morphogenetic protein (BMP), are a class of peptides that regulate cell growth and other cell functions by binding to specific cell membrane receptors[8].

FGF-2, also known as basic bFGF, has been the subject of the majority of FGF research to date. In a concentration-dependent manner, bFGF might promote the proliferation of MSCs from several tissue sources, including bone marrow peri-adipocyte cells[9], synovial MSCs[10], adipose-derived stem cells (ADSCs)[11], umbilical cord-derived MSCs[12], and bone MSCs (BMSCs)[13,14]. Ramasamy *et al*[12] reported that cell proliferation increased accordingly with increasing bFGF concentrations in the range of 0-40 ng/mL. However, Ma *et al*[11] and Wang *et al*[14] observed that the proliferation efficiency of cells at 5 ng/mL of bFGF was higher than that at 10 ng/mL. As a result, the use of 5 ng/mL of bFGF appeared to be an appropriate choice to promote the proliferation of different MSCs. In addition to enhancing MSC proliferation, bFGF has been shown to maintain stemness, support cartilage differentiation, and influence osteogenic differentiation[9,10,13]. Intriguingly, Wang *et al*[14] reported that bFGF pretreatment inhibited osteogenic differentiation at the early stage, but promoted it in the medium phase[13]. This finding might indicate that the addition of different growth factors at different phases of osteogenesis induction could successfully promote osteogenic differentiation. Therefore, more studies are needed to clarify the mechanism of action of bFGF at different stages of osteogenic differentiation, as well as to identify the best combination of growth factors to effectively promote the osteogenic differentiation of MSCs.

Previous research has demonstrated the involvement of TGF-β in inducing chondrogenic differentiation[5]. However, while promoting cartilage differentiation, TGF-β also led to early hypertrophic maturation and the eventual formation of nonfunctional fibrocartilage[2,15]. In addition, TGF-β was also found to promote the proliferation of MSCs and their effect on osteogenic differentiation[16,17]. MSC osteogenic differentiation was influenced by TGF-β in a dose-dependent manner. According to research by Xu *et al*[17], low concentrations of TGF-β (1 ng/mL) promoted the osteogenic development of BMSCs, whereas high concentrations (10–50 ng/mL) of TGF-β inhibited osteogenic differentiation. Igarashi *et al*[18] showed that 5 ng/mL of TGF-β regulated the phenotypic differentiation of BMSCs toward osteoblasts but seemed to inhibit osteogenic differentiation at the late stage, suggesting that

additional cellular signals were necessary for the osteogenic differentiation of some types of MSCs. Therefore, it is crucial to determine how to prevent hypertrophy during TGF-β promoted cartilage differentiation.

Cytokines

The fate of MSCs might be influenced by many cytokines, such as interleukin (IL), tumor necrosis factor (TNF) and interferons (IFN). Studies have previously examined how various cytokines affected osteogenic differentiation. IL-10, IL-11, IL-18, and IFN-γ promoted osteogenesis, while TNF-α, TNF-β, IL-1α, IL-4, IL-7, IL-12, IL-13, IL-23, IFN-α and IFN-β inhibited osteogenesis[19]. In this article, we focus on recently discovered cytokines such as IL-6, IL-17, and IL-22 that have the potential to affect the fate of MSCs.

MSCs both produced IL-6 and reacted to it. Furthermore, the gradual reduction in IL-6 secretion by MSCs during chondrogenic differentiation suggested that IL-6 was one of the distinguishing characteristics of undifferentiated MSCs[20]. Nevertheless, the addition of exogenous IL-6 was found to be

effective in promoting the osteogenic differentiation and chondrogenic differentiation of MSCs[20,21]. In contrast to previous studies, Xie *et al*[21] discovered that IL-6 secretion by BMSCs increased rather than decreased with osteogenic differentiation. The effect of IL-17A on the osteogenic differentiation of MSCs also seemed to be contradictory. Liao *et al*[22] reported that IL-17A inhibited the osteogenic differentiation of MSCs as well as pre-osteoblast cell lines. However, the study by Wang *et al*[23] showed the opposite. The appearance of these phenomena might be due to different microenvironments and cellular sources. Additionally, different concentrations of IL-17A have been shown to promote neuronal differentiation, with the best effect at 20 ng/mL[24]. The effect of IL-22 on the proliferation and differentiation of MSCs was first reported by scholars in 2017, which showed that IL-22 alone could upregulate the levels of osteogenic and lipogenic transcription factors but needed to be combined with IFN-γ and TNF to promote the proliferation of MSCs[25].

Cytokines must bind to specific receptors to transmit signals. The amount of the relevant receptor for cytokines appeared to be the rate-limiting element regulating the differentiation of MSCs[20]. Therefore, more studies are required to determine how cytokines affect the growth and differentiation of MSCs. Moreover, a fresh approach will be to look for factors that may raise the number of cytokine receptors on the surfaces of MSCs.

miRNAs

Small non-coding RNAs (approximately 20–25 nucleotides) called miRNAs are a subclass that could bind to complementary target sites in mRNA molecules to inhibit translation or decrease mRNA stability, which controls gene expression[26]. In this case, miRNAs could regulate the expression of key genes during the differentiation of MSCs in specific lineages to influence the direction of differentiation of MSCs (Table 2).

The osteogenic differentiation of MSCs was found to be regulated by micro RNA-1286[27], micro RNA-223-3p[28], micro RNA-346-5p[29], micro RNA-21[4] and micro RNA-130a[30], whereas the chondrogenic differentiation of MSCs was found to be regulated by micro RNA-130b[31], micro RNA-218[32], micro RNA-495[33] and micro RNA-30a[34]. In addition to this, some miRNAs also exhibited roles in regulating the adipogenic differentiation[30], endothelial differentiation[26], neuronal differentiation[35], and myocardial differentiation[36,37] of MSCs.

In conclusion, investigating the impact of biochemical stimuli on the growth and differentiation of MSCs has aided our understanding of the patterns of the aberrant differentiation of MSCs in diseased situations and aided in identifying novel therapeutic targets. It appears to be a promising avenue to examine the impact of the combination of diverse biochemical stimuli on the fate of MSCs, since distinct biochemical stimuli in the microenvironment in which MSCs are positioned function in a compound manner. Additionally, since the functions of cytokines and growth factors are dependent on binding to the appropriate receptors and some studies have indicated that receptor expression might be the rate-limiting factor, it would be preferable to determine methods to boost receptor expression as opposed to raising cytokine and growth factor concentrations.

Table 2 Micro RNA and their effects on the differentiation of mesenchymal stem cells

Amount/types	Expression	Cell source	Results	Ref.
micro-RNA-1286	Over expression	hMSCs	↓ Osteogenic differentiation	Zhou *et al*[27]
micro-RNA-223-3p	Low expression	BMSCs	↑ Osteogenic differentiation	Long *et al*[28]
micro-RNA-346-5p	Over expression	BMSCs	↓ Osteogenic differentiation	Zhang *et al*[29]
micro-RNA-21	Over expression	hucMSCs	↑ Osteogenic differentiation	Meng *et al*[4]
micro-RNA-130a	Over expression	BMSCs	↑ Osteogenic differentiation ↓ adipogenic differentiation	Lin *et al*[30]

PHYSICAL STIMULI

In addition to the previously mentioned biochemical stimuli, physical stimuli such as electromagnetic fields (EMF), microgravity (MG), fluid shear stress (FSS), and hydrostatic pressure (HP) could also have an impact on the proliferation and differentiation of MSCs (Table 3). EMF, a non-invasive biophysical therapy, is a combination of electric and magnetic fields and has been widely used in the treatment of bone diseases[38,39]. Exposure to sinusoidal EMF (1mT,15Hz,4h/d) promoted the proliferation and osteogenic and chondrogenic differentiation of BMSCs[40]. In contrast, Wang *et al*[41] found that EMF also promoted the osteogenic differentiation of MSCs but did not inhibit their proliferation under the same parameters. With the exception of 75 Hz square EMF, Asadian *et al*[42] discovered that EMFs of various frequencies and waveforms (25, 50 Hz square, and sinusoidal waveform EMFs) enabled the suppression of BMSC growth. This might imply that MSCs from different sources had different sensitivities to EMFs. Distinct EMFs had different responses to MSCs. It is crucial to investigate the most appropriate EMF parameters for the proliferation or directed differentiation of MSCs from various sources. For instance, MSCs exposed for a brief period of time to low-amplitude and low-frequency pulsed EMF could be encouraged to differentiate into chondrogenic cells[43], while sinusoidal EMF at 1 mT, 15 Hz, 4 h/d was favorable for MSCs to differentiate into osteogenic cells[40,41], and higher-frequency EMF could also encourage MSCs to differentiate into neuronal cells[42].

Another independent factor influencing the destiny of MSCs has been identified as MG. Most of the research was thus for only conducted in a simulated MG (SMG) environment produced by a clinostat or rotating vessel, since examining the proliferation and differentiation patterns of MSCs in an actual MG environment led to some technical and budgetary challenges[44]. Quynh *et al*[45] found that SMG inhibited the proliferation of human umbilical cord MSCs by blocking the cell cycle; in contrast, a study by Nakaji-Hirabayashi *et al*[46] revealed a proliferative effect. The various SMG action times could be responsible for this circumstance. Shorter SMG treatments appeared to inhibit osteogenesis[47-49] and promote endothelial cell differentiation[48], neuronal differentiation[44,48], and adipogenic differentiation[48,49]. However, extended SMG decreased the potential for chondrogenic differentiation in MSCs[50] and encouraged their differentiation toward osteogenesis[46,48]. Different SMG action times had different effects on the cytoskeleton and could even lead to the aforementioned changes through different signal transduction pathways. In this regard, further studies are needed to determine the appropriate SMG treatment time in regulating the specific lineage differentiation of MSCs.

FSS refers to the mechanical force caused by the friction of fluid flow on the apical cell membrane. It has been demonstrated that the proliferation and differentiation of MSCs are significantly influenced by the strength, timing, and rate of FSS. Jing *et al*[51] discovered that the proliferation of BMSCs could be effectively induced by 0.06 dyn/cm^2 of FSS stimulation, but as the intensity of the FSS increased, cell proliferation gradually decreased or was even inhibited. Meanwhile, Zhao *et al*[52] revealed that FSS

Table 3 Physical stimuli and their effects on the differentiation of mesenchymal stem cells

Physical stimuli	Parameters	Cell source	Results	Ref.
EMF	1 mT, 15 Hz, 4 h/day	BMSCs	BMSCs pretreated with EMF exhibited stronger osteogenic and chondrogenic differentiation potential and weaker adipogenesis capacity	Tu *et al*[40]
	25, 50, 75Hz square and sinusoidal waveform EMF	BMSCs	EMF induced BMSCs differentiation to neuron cells in all treatment groups	Asadian *et al*[42]
	1 mT, 15 Hz, 4 h/day	Rabbit MSCs	EMF enhanced the osteogenic potential of MSCs	Wang *et al*[41]
	PEMF	MSCs	Brief exposure to low amplitude PEMFs enhanced the ability of MSCs to produce and secrete paracrine factors capable of promoting cartilage regeneration	Parate *et al*[43]
SMG	30 g for 72 h or 10 days	Adult rat MSCs	A shorter period of SMG promoted MSCs to differentiate into endothelial, neuronal and adipogenic cells. In comparison, a longer period of SMG promoted MSCs to differentiate into osteoblasts	Xue *et al*[48]
	10 rpm, 72 h, 0.001 G	BMSCs	Inhibited osteogenic differentiation of MSCs	Liu *et al*[47]
	30 rpm clinorotation, 3 d	Adult rat MSCs	Promoted the neuronal differentiation of rat MSCs	Chen *et al*[44]
	7 rpm, 21 d	hMSCs	Lowered the chondrogenic potential of hMSCs	Mayer-Wagner *et al*[50]
Microgravity	0.001 G	hMSCs	microgravity-cultured hMSCs showed a better ability to differentiate into osteoblasts and adipocytes compared to cells cultured under natural gravity conditions	Nakaji-Hirabayashi *et al* [46]]
Spare microgravity		hMSCs	Spare microgravity reduced the osteogenic differentiation of hMSCs and shifted the osteogenesis of hMSCs into adipogenesis, even during ostergenic induction	Zhang *et al*[49]
FSS	0.375 dyn/cm^2, 2 h/d	BMSCs	Promoted osteogenesis-related genes and proteins in BMSCs	Jiang *et al*[54]
	0.06 dyn/cm^2, 6 h/d	BMSCs	Proper FSS stimulation obviously enhanced BMSCs osteogenesis, while the expressions of osteogenic genes decreased with higher intensity of FSS	Jing *et al*[51]
	0.5, 0.8 Pa, 3 h/d	MSCs	Promoted MSCs ostegenesis	Jiao *et al*[55]
	3-7 dynes/cm^2	hMSCs	Enhanced osteogenic differentiation	Zhao *et al*[52]
	4.2 dynes/cm^2	hMSCs	FSS could lead to the osteogenic differentiation of hMSCs	Liu *et al*[53]
	ΔSS from 0 dyn/cm^2 to 10 dyn/cm^2	MSCs	Fast ΔSS (0–0') profits the chondrogenic differentiation, while Slow ΔSS (0–2') advances osteogenic differentiation	Yue *et al*[57]
	ΔSS from 0 dyn/cm^2 to 10 dyn/cm^2	MSCs	Fast ΔSS (0–0') profits the chondrogenic differentiation, while Slow ΔSS (0–2') advances osteogenic differentiation	Lu *et al*[56]
HP	10 MPa, 1 Hz, 4 h/d, 5 d/w, 3 w	BMSCs	HP promoted BMSCs chondrogenic differentiation	Steward *et al*[60]
	0-0.5 MPa, 0.5 Hz	hMSCs	HP promoted the differentiation of the hMSCs toward osteogenesis	Huang *et al*[59]
	270 kPa, 1 Hz, 1 h/d, 5 d/w, 3 w	BMSCs	HP promoted chondrogenic differentiation of BMSCs	Luo *et al*[64]
	100 psi	ADSCs	HP significantly increased osteogenic differentiation of AMSCs	Ru *et al*[65]
	90 kPa, 1 h	BMSCs	HP promoted chondrogenic differentiation of BMSCs	Zhao *et al*[61]
	90 kPa, 1 h	BMSCs	HP promoted the expression of marker genes for early osteogenic differentiation and chondrogenic differentiation of the BMSCs	Zhao *et al*[62]

BMSCs: Bone mesenchymal stem cells; EMF: Electromagnetic field; PEMF: Pulsed electromagnetic field; ADSCs: Adipose-derived stem cells; SMG: Simulated microgravity; hMSCs: Human mesenchymal stem cells; hucMSCs: Human umbilical cord mesenchymal stem cells; FSS: Fluid shear stress; ΔSS: Rate of fluid shear stress; HP: Hydrostatic pressure.

regulated cell proliferation in a rate- and time-dependent manner, with high FSS (9–20 dyn/cm^2) and the continuous effect of low FSS both inhibiting MSC proliferation, but the intermittent effect of low FSS (1–9 dyn/cm^2) appeared to have little or no effect. Liu *et al*[53] shown that FSS (4.2 dyn/cm^2) could promote the proliferation of MSCs implanted on 3D poly(lactic-co-glycolic acid) scaffolds. Although the

effects of FSS on the proliferation of MSCs were differently stated, its promotion of osteogenic differentiation[52-55] seemed to be consistent. Regarding how the rate of FSS (ΔSS) affects MSCs, it was observed that quick ΔSS (From 0 dyn/cm^2 in 0 min) was more beneficial for MSCs' chondrogenic development, whereas slow ΔSS (From 0 dyn/cm^2 in 2 mins) encouraged their osteogenic differentiation [56,57]. Clearly, more research is required to confirm the impact of FSS on MSC proliferation, as well as the appropriate stimulus parameters for osteogenic differentiation and MSC proliferation.

HP, unlike other physical stimuli, applies homogeneous tension without causing cellular deformation [58]. Physiological load (0.1-10 mPa) did not affect the proliferation of MSCs[59,60], whereas a load of 90 kPa effectively promoted the proliferation of MSCs[61,62], a possibility that resulted from the initiation of the cell cycle by HP[62]. Studies conducted in the past have indicated that HP at low loads (1–50 kPa) has an osteogenic impact on MSCs, whereas HP at physiological loads efficiently promoted chondrogenic differentiation[63]. This concept was also supported by several recent research works[60,64]. Some investigations, however, discovered a facilitative effect of physiological loading on MSCs' osteogenic differentiation[59,65], and a chondrogenic effect of low loading on MSCs[61,62]. Additionally, the study by Zhao *et al*[62] discovered that HP (70 kPa) could not only stimulate RhoA activation, which in turn promoted the expression of early osteogenic differentiation genes in BMSCs, but could also upregulate Rac1 and downregulate RhoA, which further promoted cartilage development in BMSCs. These findings suggested that further studies are needed to determine the effects of different loads of HP on the spectral differentiation of MSCs and their complex mechanisms.

Overall, physical stimuli did influence MSCs' proliferation and differentiation to varying degrees, but there is still no consensus on the parameters that are most conducive to the proliferation and specific lineages' differentiation of MSCs. Cell heterogeneity, various stemness potentials, culture conditions, and techniques that simulated physical stimulation might all be contributing factors in this issue. Therefore, more studies are needed to determine the appropriate parameters of physical stimuli that promote the differentiation of MSCs. In fact, the actual microenvironment in which cells were exposed was multifactorial. Therefore, some studies are now starting to consider the effect of compound factors [50,55,61,66] on the behavior of MSCs. Compound factors could have synergistic effects that increase the benefits for MSCs or counteract the drawbacks of a single factor. This might emerge as a new trend.

HYPOXIA

In most studies, MSCs were cultured under atmospheric oxygen tension (20%-21% O_2)[67]. However, MSCs in different ecological niches encounter oxygen concentrations that are significantly lower than 20% (Table 4). For instance, the O_2 concentration that MSCs experienced varied from 1% to 5%[68] in adipose tissue and from 1% to 7%[69] in bone marrow. As a result, MSCs from different tissue sources were in a hypoxia microenvironment *in vivo*. Hypoxia activated various signaling pathways within a cell, which could lead to either cell death or cell adaptation[70]. Theoretically, culturing MSCs at physiological oxygen concentrations facilitated their proliferation, differentiation, and the secretion of cytokines and growth factors. Ciapetti *et al*[71] discovered that hypoxic circumstances greatly boosted BMSCs' proliferation and colony-forming capacity, as well as the expression of genes relevant to bone, such as alkaline phosphatase and osteocalcin, supporting the above idea. In contrast, in a study by Xu *et al*[72], hypoxia inhibited the osteogenic differentiation of BMSCs by activating the Notch pathway. Therefore, we focus on the effect of hypoxia on the behavior of MSCs and try to explain the contradictory findings in different studies.

The two primary techniques used nowadays to create *in vitro* hypoxic settings are anaerobic chambers [73] and simulation utilizing different chemicals[74]. In a study by Elabd *et al*[75], moderate hypoxia (5% O_2) circumstances promoted the chondrogenic and adipogenic differentiation of BMSCs but had no effect on proliferation or osteogenic differentiation. At the same oxygen concentration, Lee *et al*[76] showed that hypoxia promoted MSC proliferation and increased the chondrogenic differentiation potential. The proliferation of MSCs was also effectively promoted at a 5.5%-6.5% O_2 concentration simulated by 10 μM $CoCl_2$ and 4.0 mmol/L Na_2SO_3[74]. In contrast, Yu *et al*[77] demonstrated that a 50 M $CoCl_2$-simulated hypoxia environment appeared to prevent the growth of MSCs. Consistently, the osteogenic differentiation of MSCs was promoted in hypoxia environments simulated using different concentrations of $CoCl_2$[74,77]. Cicione *et al*[78] investigated the changes in the trilineage differentiation potential of BMSCs under severe hypoxia (1% O_2) and showed that the trilineage differentiation potential of BMSCs was inhibited to different degrees. Additional research demonstrated that the activation of the Notch pathway may be responsible for the suppression of the osteogenic differentiation of MSCs by severe hypoxia (1% O_2)[3,72]. In addition, Kim *et al*[79] found that hypoxia could inhibit the osteogenic differentiation of ADSCs by upregulating insulin-like growth factor binding-protein-3. Hypoxia has also been shown to encourage the tendon[73] and neural[80] differentiation of MSCs.

Compared to the laboratory culture environment (20%-21% O_2), hypoxia is more representative of the oxygen concentration in the ecological niche of MSCs. Varied oxygen concentrations had extremely different impacts on MSCs. Moderate hypoxia environment enhanced MSCs' proliferation, osteogenic differentiation, and chondrogenic differentiation. The differentiation capability of all three lineages of

↑: Increase; ↓: Decrease; BMSCs: Bone mesenchymal stem cells; MSCs: Mesenchymal stem cells; ADSCs: Adipose-derived stem cells; PBMSCs: Peripheral blood mesenchymal stem cells.

MSCs was, however, somewhat hindered under severe hypoxia. The contradictory behavior in the aforementioned research might potentially be connected to the cell source of MSCs and whether they were differentiated under hypoxia conditions. In view of current studies generally focusing on hypoxia exposure either in the phase of expansion or differentiation, which have not been fully grasped, further research is necessary to comprehend the effects on MSCs specifically in these two culture forms.

MATRIX STIFFNESS AND SURFACE TOPOGRAPHY

Two crucial material physical characteristics that have a significant impact on MSC behavior are matrix stiffness and surface topography. Matrix stiffness is a passive mechanical parameter that the cell can not directly sense. By exerting traction pressures on the cytoskeleton through focal adhesion, cells might deform the extracellular matrix (ECM), reflecting matrix stiffness[81]. Materials with ECM properties are currently being designed to simulate the actual microenvironment of cells. The ECMs of different native tissues, such as bone, cartilage, nerves, or blood vessels, are composed of micro- and nanoscale topographic patterns[82]. As a result, an increasing number of researchers have begun to look into how the substrate surface topography affects MSC behavior. Size and surface roughness are the two most fundamental parameters of surface topography[83], and the effects of these two factors, as well as substrate stiffness, on the proliferation and differentiation of MSCs are also mainly explored here.

Matrix stiffness

Stiffness is one of the most common metrics in assessing a material's mechanical properties[81], and it is typically expressed in terms of Young's modulus. Matrix stiffness has been shown in many studies to affect the proliferation and differentiation of MSCs. MSCs exhibited higher proliferative behavior under a higher substrate stiffness, and Winer *et al*[84] found that MSCs inoculated in 250-Pa polyacrylamide gels that mimicked the elasticity of bone marrow and adipose tissue exhibited cell cycle arrest, but these arrested cells re-entered the cell cycle when a stiff substrate was present[84]. In comparison to lower-stiffness gels, higher-stiffness matrices could increase the number of cells by a factor of 10[85]. With fibronectin-coated polyacrylamide hydrogels, Sun *et al*[86] controlled the mechanical environment of BMSCs and discovered that BMSCs' proliferation increased with increasing stiffness. However, as opposed to firmer substrates, Lin *et al*[87] discovered that MSCs cultivated on softer substrates had greater cell proliferation rates. Gelma hydrogels with different concentrations not only had different hardness, but also showed different porosity as well. Moreover, the pore size also seemed to be one of the influencing factors for the proliferation and differentiation of MSCs. Indeed, many studies have focused on the effect of matrix stiffness on the direction of differentiation of MSCs. MSCs exhibited the upregulation of biomarkers matching tissue stiffness on polyacrylamide gels of different stiffness, such as neurogenic (0.1-1 kPa, brain), myogenic (8-17 kPa, muscle), and osteogenic (25-40 kPa, bone) markers

[88]. BMSCs could be driven to develop into an osteogenic phenotype and expressed increased quantities of bone-derived biomarkers including Runt-related transcription factor 2 (RUNX2), alkaline phosphatase (ALP), and bone-bridging proteins when grown on polyacrylamide hydrogels (62-68 kPa) [86]. Rowlands *et al*[85] found that the osteogenic differentiation of MSCs occurred mainly on polyacrylamide gels of 80 kPa stiffness and that RUNX2 was also expressed at high levels. This might be due to the fact that the 80 kPa collagen I coating could well simulate the microenvironment of the bone tissue. Without an induction medium, the stiffness of the hydrogel itself had a substantial impact in controlling MSC differentiation early on, with softer substrates encouraging the adipogenic differentiation of MSCs, while harder substrates encouraged the osteogenic differentiation of MSCs[89]. However, this effect seemed to be gradually attenuated by biochemical effects in the culture medium, implying that the effects of different factors on the differentiation behavior of MSCs might occur at different stages of differentiation. On 22 kPa gels, as opposed to softer matrices, MSCs produced larger quantities of ALP, which was consistent with the effect of matrix stiffness on osteogenic fractionation shown in the previous work[90]. Although more disagreement has emerged regarding the effect of softer matrices on the differentiation fate of MSCs, such as adipogenic differentiation[84,90-92], myogenic differentiation[85,88], neurogenic differentiation[88], and endothelial differentiation[87], there seems to be a consensus on the osteogenic role of harder matrices for MSCs. The Stiffer matrix enabled cells to produce more cytoskeletal tension and sent differentiation signals *via* transmembrane proteins such as integrins[81,85], which promoted osteogenic differentiation. Furthermore, the nuclear localization of Yes-associated protein (a key mediator of mechano-transduction) and RUNX2 could be impacted by the substrate stiffness[89,90].

Surface topography

Zhao *et al*[93] produced nanotubes of various sizes and micro- and nano-hybrid topographies with ECM-like micro/nanostructures and examined their effects on the proliferation and osteogenic differentiation of MSCs. They discovered that larger-sized nanotubes hindered the early proliferation of MSCs, but the micro- and nano-morphology group had a greater cell number. Additionally, they discovered that MSC osteogenic differentiation might be induced by micro/nanotopographies, even in the absence of osteogenic inducers[93]. Similar results were obtained by Chen *et al*[94], who discovered that the micron/submicron hybrid topography of Ti surfaces promoted osteogenic and chondrogenic differentiation in the early stages of induced differentiation. By introducing nanoengineered topographic glass substrates with different surface roughness, Qian *et al*[95] investigated the impact of surface morphology on the osteogenic differentiation of MSCs. They found that surface roughness could replace the osteogenic inducer dexamethasone and worked in concert with ascorbic acid and β-glycerophosphate to jointly promote the osteogenic differentiation of MSCs[95]. In the past, it was generally agreed that surface roughness seemed to have a positive effect on osteogenic differentiation[95-97]. The osteogenic differentiation of MSCs, however, was more strongly influenced by the nanopore size than by the surface roughness, according to several recent studies[83,98]. The frequent coupling of size and surface roughness in many studies makes it difficult to state the degree of influence of each factor on the behavior of MSCs[83]. Moreover, the methods used to prepare rough surfaces in these studies differ, such as randomly rough surfaces produced by treatments such as mechanical polishing, acid etching, *etc*., where cells form focal attachments that differ from those seen on surfaces of the same roughness [98]. Therefore, more research is required to demonstrate how size and surface roughness affect MSC proliferation and differentiation, respectively. Through a variety of pathways, including the control of adhesion, cytoskeletal tension, and nuclear localization of transcription factors[95], MSCs appeared to be able to detect and respond to the surface topography, which in turn influenced their behavior such as proliferation and differentiation. At this stage, it has been reported that micro- and nano-surface topographies inhibit the proliferation of MSCs and promote osteogenic differentiation to some extent. However, there is no detailed elaboration on their respective effects on MSCs in terms of size and surface roughness.

EXOSOMES

Various cells jointly create the microenvironment by secreting functional molecules, which leads to the sharing of stimuli between multiple cell lineages[99]. In addition to the ECM and growth factors, exosomes were considered to be an important component of the microenvironment[100]. Exosomes are small vesicles with a diameter of 30-150 nm that are released by cells through cytosolic action. The released exosomes could interact with target cells and translocated proteins, lipids, mRNAs and miRNAs to the cytoplasm of target cells[101]. Crosstalk existed between MSCs-osteoblasts and monocytes-macrophages and researchers used this to regulate bone homeostasis[99]. In vitro, BMSCs' behaviors were influenced variably by cell-conditioned media produced by variously polarized macrophages[102]. Previous studies had suggested that cytokines were the main contributors to the function exercised by macrophages. However, Song *et al*[103] found that lipopolysaccharide (LPS)-activated macrophage-derived exosomes inhibited the osteogenic differentiation of BMSCs by

mediating inflammatory stimuli. Therefore, the effect of exosomes secreted by monocytes-macrophages on the differentiation of MSCs should be considered (Table 5).

According to Liu *et al*[104], miR-21a-5p found in M1 macrophage-derived exosomes directed BMSCs toward an osteoblastic fate during the early stages of osteogenesis[104]. In their investigation of the effects of MO, M1, and M2 macrophage-derived exosomes on BMSCs, Xia *et al*[105] discovered that M1 macrophage-derived exosomes efficiently enhanced the proliferation, osteogenic differentiation, and adipogenic differentiation of BMSCs, but M2 macrophage-derived exosomes were harmful to the proliferation of BMSCs and, curiously, all three hindered the chondrogenic differentiation of BMSCs. Xiong *et al*[106] noticed that miRNA-5106, enriched in M2 macrophage-derived exosomes, promoted the osteogenic differentiation of BMSCs by suppressing the expression of salt-inducible kinase 2 (SIK2) and SIK3, which was consistent with the role of M2 macrophage-derived exosomes in promoting osteogenesis in a study by Li *et al*[107]. Kang *et al*[108] demonstrated that M0 and M2 macrophage-derived exosomes were positive for BMSC osteogenesis while M1 macrophage-derived exosomes lowered BMP expression and inhibited the osteogenic differentiation of BMSCs[108]. Despite being enriched in distinct miRNAs, primary extraction M2 macrophages[109] and RAW264.7 mouse monocyte-macrophage leukemia cell[107] derived exosomes both showed osteogenesis-promoting and lipogenic differentiation-inhibiting effects. Current research has indicated the impact of exosomes produced from monocytes[110], osteoclasts[111], and osteoblasts[112] on BMSCs, in addition to exosomes released by macrophages. Ekström *et al*[110] found that exosomes released from LPS-stimulated monocytes could be ingested by MSCs and encouraged the osteogenic differentiation of MSCs. Liang *et al*[111] showed that osteoclast-released exosomes promoted osteogenic differentiation and facilitated osteogenic mineralization by inhibiting Rho GTPase activating protein 1. This might imply that active osteoclasts release large amounts of extracellular vesicles during the resorption phase, promoting the osteogenesis of MSCs for better stabilization and bridging the transition between bone resorption and formation. The addition of osteoblast exosomes could further enhance the expression of RUNX2 and osterix, thereby promoting osteogenic differentiation, and, in addition, osteoblast exosomes could even alter adipocyte ECM-mediated lineage differentiation[112].

Exosomes, one of the recently identified microenvironment components, have unique benefits, such as a nano size, non-toxicity, low immunogenicity, biocompatibility, and versatility of use, drawing widespread attention[113]. The current work appeared to demonstrate the beneficial influence of M2 macrophage-derived exosomes on the osteogenic differentiation of MSCs. As for MO and M1 macrophage-derived exosomes, further research is required to understand their impacts on MSC differentiation and the processes at play. At the same time, research has been conducted progressively on the influence of exosomes released by cells in the same microenvironment as BMSCs on the differentiation of BMSCs, which might represent a new avenue.

CONCLUSION

MSCs play important roles in pathological and physiological processes because of their self-renewal, migration, and pluripotency. Especially due to their multi-differentiation potential, MSCs have been considered as a new therapeutic agent in regenerative medicine. Since the detailed mechanisms involved in these regulation processes has not been fully revealed, research on intrinsic and extrinsic factors regulating MSCs' differentiation may provide new methods in manipulating the cell fate of MSCs. Here, we discussed multiple chemical and mechanical factors affecting the osteogenic and chondrogenic differentiation of MSCs, including typical differentiation promoting patterns, cell environmental factors, and other interesting research areas, such as material morphology and exosomes. After sensing these differentiation-stimulating factors, MSCs from various sources are able to differentiate into specific cell lineages. With the rising demand for MSCs in clinical treatment, noble strategies have been developed that aim at inducing the stable and directional differentiation of stem cells, and further providing efficient methods of MSC regulation in basic research and clinical application.

Meanwhile, there is much more to discover in stem cell research. Due to some limitations of MSCs, such as homing efficiency and long-term survival *in vivo*, most of the research has achieved its results at the cellular level in vitro. Moreover, discrepancies remain between single-factor experiments and synergistic effects by multiple factors. At present, extensive research on factors stimulating MSCs' differentiation has promoted our understanding of cell functional alterations. However, mechanisms involved in manipulating MSCs' cell fate have so far been incomplete. With the deepening of stem cell research alongside technology improvements, the synergistic effect of multiple factors inducing MSC differentiation is increasingly likely to be clarified, as well as providing new patterns in clinical stem cell therapy.

Table 5 Exosomes of different cell sources and their effects on the differentiation of mesenchymal stem cells

Source and kind	Specific cargo	Target	Results	Ref.
M1 macrophages-EVs	miRNA-21a-5p	BMSCs	↑ Osteogenic differentiation	Liu *et al*[104]
M0 macrophages-EVs		BMSCs	↓ Chondrogenic differentiation	Xia *et al*[105]
M1 macrophages-EVs		BMSCs	↑ Osteogenic differentiation; ↑ adipogenic differentiation; ↓ chondrogenic differentiation	
M2 macrophages-EVs		BMSCs	↓ Chondrogenic differentiation	
M2 macrophages-EVs	miRNA-5106	BMSCs;SIK2 and SIK3	↑ Osteogenic differentiation	Xiong *et al*[106]
M2 macrophages-EVs	miRNA-690	BMSCs	↑ Osteogenic differentiation; ↓ adipogenic differentiation	Li *et al*[107]
M0 macrophages-EVs		MSCs	↑ Osteogenic differentiation	Kang *et al*[108]
M1 macrophages-EVs	miRNA-155	MSCs	↓ Osteogenic differentiation	
M2 macrophages-EVs	miRNA-378a	MSCs	↑ Osteogenic differentiation	
M2 macrophages-EVs	miRNA-26a-5p	BMSCs	↑ Osteogenic differentiation; ↓ adipogenic differentiation	Bin-bin *et al*[109]
Macrophages-EVs		BMSCs	↓ Osteogenic differentiation	Song *et al*[103]
Monocytes-EVs		MSCs	↑ Osteogenic differentiation	Ekström *et al*[110]
Osteoclasts-EVs	miRNA-324	BMSCs	↑ Osteogenic differentiation	Liang *et al*[111]

↑: Increase; ↓: Decrease; EVs: Extracellular vesicles; MSCs: Mesenchymal stem cells; BMSCs: Bone mesenchymal stem cells; SIK2/SIK3: Salt-inducible kinase 2/3.

Abstract

Spinal cord injury (SCI) is a devastating condition with complex pathological mechanisms that lead to sensory, motor, and autonomic dysfunction below the site of injury. To date, no effective therapy is available for the treatment of SCI. Recently, bone marrow-derived mesenchymal stem cells (BMMSCs) have been considered to be the most promising source for cellular therapies following SCI. The objective of the present review is to summarize the most recent insights into the cellular and molecular mechanism using BMMSC therapy to treat SCI. In this work, we review the specific mechanism of BMMSCs in SCI repair mainly from the following aspects: Neuroprotection, axon sprouting and/or regeneration, myelin regeneration, inhibitory microenvironments, glial scar formation, immunomodulation, and angiogenesis. Additionally, we summarize the latest evidence on the application of BMMSCs in clinical trials and further discuss the challenges and future directions for stem cell therapy in SCI models.

Key Words: Spinal cord injury; Bone marrow derived mesenchymal stem cells; Neuroprotection; Axon; Myelin; Inhibitory microenvironment

INTRODUCTION

Spinal cord injury (SCI) is a serious neurological disorder that often results in paralysis during the reproductive years, causing temporary or permanent changes in normal motor, sensory, and autonomic functions, with significant impacts on individuals, families, and socioeconomic systems[1]. It has been reported that more than 27 million patients worldwide experience long-term disability due to SCI[2], with 541 cases per 100000 people[3]. Complex pathophysiology and time sensitivity in particular limit the therapeutic effects of SCI[4]. In incomplete SCI, there is less hemorrhage in the gray matter and no change in the white matter 3 h after injury; 6-10 h after injury, the hemorrhagic foci gradually expand, and the neurological tissue becomes edematous, which gradually subsides after 24-48 h. As the degree of incomplete SCI differs between mild and severe injuries, milder injuries only have small foci of necrosis in the center, and most of the nerve fibers are preserved. Severe injuries may have foci of necrosis and softening in the center of the spinal cord and are replaced by gliosis or scarring, and only a small portion of the nerve fibers are preserved. Most posttraumatic tissue degeneration is caused by multiple secondary injuries, including blood-spinal cord barrier (BSCB) disruption, free radical formation, ion imbalance, apoptosis, demyelination, and inflammatory response (Figure 1). Spontaneous recovery occurs within a limited time window because the subacute phase of SCI is thought to be detrimental to axonal regeneration and functional recovery[5]. Currently, clinical treatment includes surgical decompression, stabilization of the spinal cord, relief of spasticity and rehabilitation care, which consists primarily of supportive care and injury management. Frustratingly, the effectiveness of these treatments is limited because they are not effective in stimulating repair of the injured spinal cord.

CLINICAL CHARACTERISTICS AND PATHOLOGY OF SCI

The spinal cord consists of the gray and white matter, which contains nerve cell bodies and ascending and descending fibers. Thus, the different locations and levels of SCI can cause various degrees of disability, from partial loss of motor or sensory function to complete paralysis below the injured location. The resulting lifelong devastating deficits associated with impaired mobility (weakness or paralysis), sensation and autonomic dysfunction, and disabled neurological conditions lead to permanent and severe impacts on patients' daily lives and their caregivers.

Pathophysiology following SCI comprises interrelated multicellular, multimolecular interactions and multiphasic events[6]. Classically, the pathophysiology of SCI is divided into two phases: Primary injury and secondary injury. SCI commonly occurs after sudden trauma because of direct and immediate mechanical insult to the spinal cord from vertebral fractures and dislocation with features of bone fragments and spinal ligament tearing. This was accompanied by extensive bleeding with further compression and interruption of the spinal cord blood supply. Thus, the primary injury mainly includes compression, contusion, shear, laceration, and acute stretching. This is followed by disruption of the neural parenchyma, shearing of the axonal network, destruction of the glial membrane, and vascular disruption[7,8]. Secondary injuries consist of ischemia, spinal cord ischemia-reperfusion injury, vascular dysfunction, edema, excitotoxicity, formation of free radicals, glial and neuronal apoptosis, and the inflammatory response[7]. This secondary damage is divided into three phases: The acute phase, which is accompanied by vascular and cell membrane damage and the secretion of different proinflammatory factors, such as interleukin-1β (IL-1β) and tumor necrosis factor-α (TNF-α), with microglial activation. The subacute phase is accompanied by edema and vascular damage, inflammatory cytokine and glutamate secretion, astrogliosis, and demyelination for a few days. The chronic phase has symptoms such as the formation of a cavity in the spinal cord[8]. Based on further study of the spinal cord

Figure 1 Pathophysiology of spinal cord injury and related mechanisms of bone marrow-derived mesenchymal stem cell in spinal cord injury. A: The normal spinal cord contains axons wrapped in the myelin sheath, neuron bodies, microglia, fibroblasts, and astrocytes; B: Secondary injuries following primary injury include glial and neuronal apoptosis, axon rupture, inflammatory response, ischemia, spinal cord ischemia-reperfusion injury, vascular dysfunction, edema, inhibitory microenvironments, excitatory toxicity, and free radical formation; C: Bone marrow-derived mesenchymal stem cell promote the mechanism of spinal cord injury repair, including neuroprotection, axon growth, myelination, immune regulation, microenvironment regulation, inhibition of scar formation, and promotion of angiogenesis. BMMSCs: Bone marrow-derived mesenchymal stem cells.

microenvironment, pathophysiological changes are divided into tissue, cellular and molecular levels. The tissue level involves hemorrhage and ischemia, glial scar formation, demyelination and remyelination[9]. The cellular level involves the activation of astrocytes, the differentiation of endogenous neural stem cells, oligodendrocyte progenitors and microglia, and the infiltration of macrophages. The molecular level involves the expression of neurotrophic factors and their pro-peptides, cytokines, chemokines, and ion imbalance. There is an imbalance between promoting and inhibiting growth molecules in the microenvironment of SCI, where growth inhibitors occupy the dominant position.

THE THERAPEUTIC POTENTIAL OF STEM CELLS

Cell transplantation has come to the forefront in SCI regenerative strategies due to its potential neuroprotective effects. Many cell types have been widely investigated in SCI treatment, including oligodendrocyte precursor cells, Schwann cells, olfactory ensheathing cells, neural stem cells, and mesenchymal stem cells (MSCs)[10,11]. MSCs have the capacity for self-renewal and multilineage differentiation potential and can differentiate into osteoblasts, adipocytes, and chondrocytes[12]. Moreover, MSCs express surface markers (CD105, CD73 and CD90) and do not show expression of CD45, CD34, CD14 or CD11b, CD79a or CD19, or human leukocyte antigen type DR surface molecules[13]. MSCs mainly exist in bone marrow and can also be isolated from other tissues and organs, such as umbilical cord, adipose tissue and muscle. Among these, bone marrow-derived MSCs (BMMSCs) are the most widely studied cell type in SCI application due to their low immunogenicity, easy isolation, few ethical concerns and reduced tumorigenesis risks[14]. According to the current research progress at home and abroad, BMMSC-based treatment has extraordinary prospects in the field of SCI.

In this review, we will summarize the applications of BMMSCs in SCI based on the most frequently proposed mechanisms: Neuroprotection, neuronal circuit, axon sprouting and/or regeneration, myelin regeneration, inhibitory microenvironments, glial scar formation, immunomodulation, and angiogenesis. A better understanding of these mechanisms could allow the identification of more targeted therapies.

NEUROPROTECTIVE EFFECTS OF BMMSCS

Neurons are postmitotic, without the ability to proliferate, and strategies developed to promote neuronal protection and regeneration have long-term benefits. Neuroprotective measures are crucial not only for the preservation of further injury for optimal neuron survivability but also for the restoration of injured nerve cells during pathological progression. BMMSCs reestablish the injured spinal cord *via* neuroprotection, neural regeneration, and remyelination in SCI[15]. MSCs can release growth and neurotrophic factors, including brain-derived neurotrophic factor (BDNF)[16], vascular endothelial growth factor (VEGF)[17], glial cell-derived neurotrophic factor (GDNF), nerve growth factor (NGF), fibroblast growth factor (FGF), neurotrophin-3, and epidermal growth factor, which can enhance regeneration and repair in damaged tissues[18,19]. miR-22, regulated by Gasdermin D mRNA, plays a role in inhibiting the occurrence of pyroptosis[20]. miR-22-modified BMMSCs suppress pyroptosis-mediated inflammation and neuronal injury during SCI[20]. Moreover, MSC-derived exosomes enhance the survival of neurons and repair of nerve fibers by inhibiting Nod1 inflammasome activation, suppressing pyroptosis in pericytes, preserving the integrity of the BSCB[21], inhibiting neuronal apoptosis through the Wnt/beta-catenin signaling pathway[22] and eventually improving functional recovery. The overexpression of miR-338-5p in exosomes was shown to profoundly increase the expression levels of neurofilament 200 and growth-associated protein-43 and decrease those of myelin-associated glycoprotein (MAG) and glial fibrillary acidic protein (GFAP), which provided neuroprotective effects through the cannabinoid receptor 1/Rap1/Akt pathway after acute SCI[23]. cAMP-mediated Rap1 activation plays an important role in apoptosis reduction and neuronal survival induced by the PI3K/Akt pathway[23].

Despite the inhibitory environment in the adult mammalian central nervous system, neuronal-intrinsic mechanisms are sufficient to support significantly extensive axonal growth and synapse formation after SCI, resulting in the formation of new neuronal circuits that restore electrophysiological activity and behavior[24]. When stem cells are cotransplanted with a supportive fibronectin matrix containing growth factors, axons form connections with host axons over significantly long distances. Even when crossing the inhibitory white matter, they elongate rapidly at a rate of 1-2 mm per day[24]. In addition, axons from the host spine regenerate into neural stem cell grafts, and this bidirectional growth contributes to the recovery of hindlimb mobility[24]. BMMSCs were initially thought to be similar to neural stem cells in their ability to multidirectionally differentiate into neurons and glial cells, but this theory was gradually discarded. In fact, the mechanism of action of BMMSCs may be cell fusion or trans-differentiation rather than cell differentiation[25]. In summary, transplanted BMMSCs after SCI exhibit significant autocrine and paracrine activities, which in turn stimulate the proliferation and differentiation of other cells and themselves, promoting tissue repair and functional recovery[26].

AXON GROWTH

The axon is a unique cellular structure that maintains communication between neurons[27]. An important cause of persistent dysfunction after SCI is axonal disruption, and therefore promoting axonal regeneration and plasticity is very promising. However, previous studies have shown that the percentage of injected MSCs aggregating in the CNS is 0.75%-18.5%[28] and 6.7%[29], and thus it is conceivable that only a fraction of the cells reach the site of SCI. The Nakano *et al*[30] found that bone marrow stromal cell transplantation *via* cerebrospinal fluid was effective in acute, subacute and chronic spinal cord injuries in rats, and although the transplanted cells did not survive more than 7 d, a large number of axons crossed longitudinally through the astrocyte-deficient connective tissue. Transplantation *via* the CSF is a more clinically preferred modality because it does not cause secondary injury to preserved spinal cord tissue. From another perspective, Okuda *et al*[31] demonstrated that transplantation of BMMSC sheets after SCI prompted Tuj-1-positive axons to span a specially designed cell sheet without requiring a scaffold, offering a permissive microenvironment for damaged axons[31].

BMMSC therapy has been shown to play a positive role in rodent models of SCI[32], but evidence of its long-term therapeutic efficacy and effectiveness in human clinical trials is limited. Gene modification of MSCs, for example, by overexpression of neurotrophic or growth factors, is one of the ways to enhance their well-known beneficial effects. Overexpression of IL-13, an inducer of M2 microglia/macrophages, in BMMSCs significantly ameliorates axonal retraction caused by axonal-attacking macrophages[33]. In addition, the combination of neurotrophic factors and physical stimuli is often used to enhance the effects of BMMSCs. Cografting stromal-derived factor-1-overexpressing BMMSCs with

neural stem cells (NSCs) at day 9 after SCI resulted in better axonal density enhancement than BMMSCs alone[34]. Furthermore, physical factor therapy has also shown a synergistic effect, as low-intensity pulsed ultrasound-optimized BMMSCs transplanted one week after SCI showed a good promotion effect on axonal regeneration[5].

Although the transplanted cells can reach the site of injury, they cannot survive long enough to integrate with the host spinal cord tissue, thus showing that these cells do not act as scaffolds for tissue repair. The use of biomaterials can provide transplanted cells with an environment closer to their physiological state, maintaining and regulating stem cell properties and protecting them from the harsh local microenvironment. Permissive bridging material allows nerve fibers with regenerative growth potential or collateral sprouting to pass through nonpermissive physical spaces[35]; therefore, tissue-engineered grafts loaded with cells and growth factors have become popular as bridging therapy for SCI. After spinal cord injuries in rats and dogs, NT-3/fibroin-coated gelatin sponge scaffolds were shown to continuously release NT-3 for up to 28 d, maintain the cell activity of MSCs, promote axonal regeneration, and attenuate the inflammatory response[36]. The multichannel poly lactic-co-glycolic acid scaffolds implanted with Schwann cells and BMMSCs were shown to effectively connect the injury gap of rats with complete SCI, and the cell combination strategy promoted the survival and neuron-like characteristics of BMMSCs and finally facilitated axonal regeneration and functional recovery[37]. The short half-life and rapid clearance challenges posed by the innate immune system have hampered the popularity of extracellular vesicle therapy[38]. Wang *et al*[39] synthesized an F127-polycitrate-polyethyleneimine hydrogel (FE) with sustainable and long-term extracellular vesicle release (FE@EVs), and its *in situ* administration after SCI inhibited the inflammatory response and promoted myelination and axonal regeneration. There is no shortage of biomaterials in clinical trials for cancer, but no clinical trials on biomaterials for SCI repair have been registered on the ClinicalTrials.gov website. Possible reasons for this include inconsistency between injury models from preclinical studies and actual injury models in the clinic (thoracic SCI models are often used in preclinical studies, but cervical SCI is more common in humans[40]), unpredictable residual degradation products in the body, and potentially low payloads [41]. Caution is needed in drawing conclusions about axonal regeneration because the current consensus is that it refers to regrowth of axons after transection[42], whereas there is a significant degree of axonal preservation in incomplete spinal cord injuries, and the best model for exploring axonal regeneration is complete SCI.

REMYELINATION

Demyelination in traumatic SCI can lead to loss of function, and poor myelination of preserved nerve fibers may lead to permanent functional impairment. Myelin loss is accompanied by oligodendrocyte apoptosis, and replacement of lost oligodendrocytes and myelin improves conductivity and protects axons from degeneration[43]. The process of transplanted cells producing myelin around axons that have lost myelin sheaths is a mechanism that enhances recovery after SCI[43]. Conditioned medium from MSCs not only improves the survival of oligodendrocytes *in vitro* in culture but also increases levels of Olig2, a transcription factor that plays a key role in the differentiation of oligodendrocytes, in SCI[44]. Intravenous infusion of MSCs during the chronic phase in a severely injured SCI model promotes remyelination of axons[45]. BMMSCs can act as catalysts for the differentiation of NSCs into oligodendrocytes by regulating Id2 and Olig1/2[46]. However, the genetically engineered cells showed a more satisfactory therapeutic effect than the original cells. BMMSCs secrete various trophic factors, including VEGF, insulin-like growth factor 1 (IGF-1), hepatocyte growth factor (HGF), basic FGF, GDNF [47,48], and certain extracellular matrix molecules, such as laminin and type IV collagen[49]. Given the positive effects of IGF-1 on oligodendrocyte differentiation and survival during normal development [50], IGF-1-overexpressing BMMSCs better protect the integrity of myelin sheaths[51]. Similarly, GDNF is a potential target for axon enhancement and is directly involved in axonogenesis and dopaminergic neuronal differentiation *via* the Ras/MARK pathway and P13K signaling pathway[52].

In addition to the abovementioned cytotrophic factors, myelination-related graft factors can also be used as targets for genetic engineering. Silencing Nogo-66 receptor expression was shown to promote neurite outgrowth after BMMSC differentiation and increase myelinated nerve fibers after SCI[53]. There are benefits from the effects of neuroprotective drugs themselves, which have antioxidant effects, inhibit intracellular calcium overload, regulate γ-aminobutyric acid receptors and inhibit apoptosis, and combining these drugs can also improve the therapeutic effect of BMMSCs. Currently, the combination of BMMSCs and propofol, a neuroprotective anesthetic, has dramatically increased the number of myelinated and nonmyelinated fibers after SCI[54]. Transplanted cells with the ability to myelinate do not always promote functional recovery, and sufficient myelination needs to occur to achieve significant results[55].

IMMUNOMODULATION

The inflammatory response is a critical component in the secondary injury cascade, which can persist for weeks to months after SCI, during which microglia/macrophages and leukocytes are recruited to the injury site. A certain inflammatory response in the injured spinal cord is required for clearing neurotoxic cellular debris and limiting tissue damage. However, macrophage clearance can promote regeneration after SCI. In addition, overactivation of the inflammatory response can aggravate tissue damage[56]. In the acute phase of SCI, these cells produce proinflammatory cytokines such as IL-6, IL-β, and TNF-α. Reactive oxygen species (ROS), matrix-metalloproteinase (MMP), and inducible nitrous oxide synthase are released by neutrophils, macrophages and microglia, which can exacerbate the inflammatory response[57]. Microglia/macrophages have been regarded as an important cell type in the innate and adaptive immune responses after SCI[58]. Homeostatic macrophages are the main phenotype in the normal spinal cord, but resting macrophages are activated into different phenotypes. Some macrophages produce proinflammatory cytokines that aggravate inflammation and inhibit axon regeneration, while other macrophages produce anti-inflammatory cytokines that promote functional recovery, such as IL-10 and transforming growth factor-β (TGF-β)[59]. Therefore, immunomodulatory therapeutic approaches are mainly focused on inducing macrophage polarization from the proinflammatory phenotype to the anti-inflammatory phenotype following SCI.

Many studies have shown that BMMSC transplantation after SCI can exert therapeutic effects by attenuating detrimental inflammation or enhancing beneficial inflammation. Yagura *et al*[60] found that human BMMSC implantation significantly increased CCL5 expression and enhanced macrophage polarization. Similarly, another study analyzed the tissue expression levels of IL-1β, TNF-α, and Toll-like receptor 4 (TLR4) in a rat SCI model after intravenous BMMSC injection[61]. This study demonstrated that BMMSCs could attenuate spinal cord inflammation by inhibiting the TLR4-mediated signaling pathway and decreasing the expression levels of IL-1β and TNF-α. Similar situations were observed in another study that investigated the efficacy of grafted BMMSCs after SCI[62]. Interestingly, most recent studies have focused on the anti-inflammatory roles of exosomes derived from BMMSCs in SCI treatment[20,63,64]. For example, Sheng *et al*[63] confirmed that the application of BMMSC-derived exosomes promoted the phagocytosis ability of macrophages by upregulating the expression of MARCO, an important phagocytic receptor. In addition to modulating the phagocytic capacity of macrophages, BMMSC-derived exosomes could also affect the balance of macrophage polarization through the nuclear factor-kappaB pathway[65].

BMMSC transplantation exerts immunoregulatory effects following SCI mainly by inducing the formation of anti-inflammatory immune cells, modulating the expression levels of TLRs, and inhibiting the inflammatory response in the injured spinal cord, thereby promoting functional recovery[61]. Immediately after SCI, the organism enters an immunosuppressive state due to shock and stress. The first cells to mobilize at the injured site are the myeloid cells of the innate immune system, such as neutrophils and macrophages, which phagocytose debris. Then, adaptive immune cells such as B- and T-lymphocytes are recruited to the injured spinal cord[66,67]. As previously described, microglia, which participate in the clearance of apoptotic and myelin debris, are resident immune cells[68]. In the acute stage after SCI, microglia extend their processes toward the injured site and are biased toward the activated subtype, which leads to a further loss of neurons and promotes scar formation[69]. During this period, although microglia have beneficial effects on tissue recovery by clearing cellular and myelin debris, they have also been reported to aggravate secondary tissue damage and axonal retraction[67,70]. Homeostatic microglia in the injured spinal cord may play a protective role in tissue repair. Therefore, therapeutic strategies for targeting immunomodulation should be directed at modulating cytokine levels and other factors in the microenvironment and balancing activated/homeostatic microglia levels.

IMPROVING THE INHIBITORY MICROENVIRONMENT

In mammals, damaged axons in the spinal cord are unable to regenerate at the lesion site and to reestablish synaptic connections with their destination due to “natural barriers” and diminished intrinsic regenerative capacity[71,72]. This barrier consists of a lumen and a nonpermissive environment. Nogo-A, MAG and oligodendrocyte myelin glycoprotein (OMgp) are well-defined myelin breakdown products[73], but knockdown of the MAG and OMgp genes did not lead to neuronal growth after SCI, suggesting that Nogo-A plays a dominant role in inhibiting axonal regeneration, while MAG and OMgp play secondary roles[74]. In addition, several types of cells, including astrocytes, glial cells, and microglia/macrophages, migrate to the center of the injury, leading to the formation of glial scars and impeding the progression of axonal growth cones[75]. Glial scarring does not always play a negative role; on the one hand, it initiates the injury repair process, limits lesion expansion and inhibits the spread of the inflammatory response, and on the other hand, it acts as a physical barrier to nerve regeneration[76].

Few oligodendrocyte markers were found to be expressed in SCI centers transplanted with BMMSCs, while the number of axons was significantly increased, indicating that the transplanted cells provided a suitable environment for the regeneration and neural differentiation of endogenous neural stem cells [77]. BDNF in overexpressed BMMSCs further promotes axonal remyelination by affecting oligodendrocytes[78]. Zhao *et al*[79] found that the association of BDNF-overexpressing BMMSCs with platelet-rich plasma promoted more axonal remyelination and oligodendrocytes, probably due to astrocyte migration to the lesion region and increased graft BDNF-BMSCs, which could provide a favorable substrate for stabilizing regenerating axons in an inhibitory environment. However, damaging properties of the microenvironment (such as increased ROS) result in extensive stem cell death and dysfunction, severely impairing stem cell therapy for SCI.

INHIBITING GLIAL SCAR FORMATION

The spinal injury scar is generally classified into two components: The lesion core and the lesion border [80]. The lesion core is primarily composed of stromal-derived fibroblasts and inflammatory immune cells and is commonly regarded as the fibrotic scar. The lesion border is formed by microglia and reactive astrocytes, which surround the core and are generally considered the glial scar. The glial scar (mainly astrocytic) strongly upregulates the expression of intermediate filament proteins such as vimentin, GFAP, and chondroitin sulfate proteoglycans (CSPGs)[9]. At the acute stage after SCI, the glial scar separates healthy tissue from inflammatory cells and limits the spread of inflammation. However, the glial scar creates a long-lasting physical and molecular barrier that hinders axon regeneration and outgrowth during the chronic period[81]. Over the past decade, accumulating evidence has attributed the failure of axon regeneration to diminished intrinsic neuronal plasticity and the presence of glial scars and myelin-associated growth inhibitors.

Numerous experimental studies in SCI animal models have shown that BMMSC transplantation can suppress glial scar formation. Okuda *et al*[31] explored whether BMMSC sheets are permissive for injured nerve fiber elongation and the extension of astrocyte processes. They found that GFAP-positive astrocyte processes penetrated into the BMMSC-transplanted site, which is an indicator of a permissive environment for axon outgrowth[31]. Another study showed that transplantation of human BMMSCs in an SCI rat model largely reduced the inflammatory reaction and the expression of collagen type IV, one of the markers of fibrotic scars[82]. The application of biomaterials to improve the survival rate and efficacy of implanted cells has attracted attention in recent years. Some biomaterials are primarily used as scaffolds to support the growth of BMMSCs[83,84], while a few biomaterials are capable of modulating the harsh microenvironment following SCI[85,86]. For instance, Li *et al*[84] investigated the efficacy of a ROS-responsive hydrogel cotransplanted with BMMSCs in a rat transection SCI model. They performed double immunofluorescence staining to identify the formation of two distinct scars: The glial scar was labeled by GFAP, and the fibrotic scar was labeled by platelet-derived growth factor receptor-β. These results revealed that this BMMSC-encapsulated hydrogel could significantly alleviate the formation of both glial and fibrotic scars at the injury site[84]. In addition, CSPGs, which are enriched in glial scars and secreted by reactive astrocytes, are potent inhibitors of axonal outgrowth. Takeuchi *et al*[87] found that SCI mice treated with chondroitinase ABC, a kind of CSPG-digesting enzyme, can promote axon regeneration and improve functional outcome. Indeed, another study explored the efficacy of chondroitinase ABC plus BMMSCs in the repair of SCI. Notably, the application of chondroitinase ABC combined with BMMSCs significantly reduced GFAP expression at the injury site, and the scar tissue area was much smaller than that in the model group[88].

To date, the specific molecular mechanisms of scar formation have been widely studied. TGF-β initiates signaling after binding to transmembrane type I and type II receptors, and then the type I receptor leads to the recruitment and phosphorylation of Smad2 and Smad3 proteins[89]. After the formation of a heteroprotein complex together with the co-Smad protein SMAD4, this complex can translocate into the nucleus, where it acts as a transcription factor to regulate target gene expression [90]. There is a growing body of evidence to suggest that the TGF-β/Smad signaling pathway plays an important role in collagen deposition[91]. Studies have shown that administration of BMMSCs after SCI can inhibit scar formation by downregulating TGF-β and collagen expression[92,93]. Furthermore, studies have shown that the activation and proliferation of astrocytes can be suppressed after inhibiting the JAK/STAT3 or JNK/c-Jun pathway, thus reducing scar formation and promoting functional recovery after SCI[94]. Kim *et al*[95] suggested that acute transplantation of BMMSCs can modulate astrogliosis through the MMP2/STAT3 pathway.

In summary, BMMSC transplantation can suppress glial scar formation and provide a favorable environment for axon regeneration after SCI. However, there has been some debate in the field on the role of scar formation in recovery following SCI[96,97]. Although the glial scar has an important protective role in separating healthy tissue from pathology after injury, it has been acknowledged that scar formation has an inhibitory role, as it is associated with failed axon regrowth. Recent evidence suggests that the phenotypes of reactive glial cells are considered the key regulators of the dual nature of the spinal injury scar[98]. In addition, the opposing roles of the scar matrix cannot be ignored, which

contains beneficial molecules that are required for the formation of scar borders and inhibitory molecules such as CSPGs, tenascin, ephin B2, and slit proteins[99]. Therefore, therapeutic strategies for targeting the spinal injury scar should be directed at reducing scar formation or blocking inhibitory molecules associated with the scar.

PREVENTING BLOOD VESSEL LOSS AND IMPROVING ANGIOGENESIS

After SCI, immediate loss of spinal vascular support occurs, which induces local hypoxia around the injury epicenter, followed by a series of molecular cascades that lead to increased microvascular permeability and BSCB disruption. Angiogenesis, which is the process of forming new vasculature, plays an important role in the proliferation phase of wound healing[100,101]. Therefore, stabilizing the provisional vessels and forming a permanent vascular network are necessary for tissue repair following SCI. Angiogenesis is a multistep process that requires endothelial proliferation and differentiation, crosstalk among endothelial cells and extracellular matrix components, and the interplay of multiple proangiogenic and antiangiogenic factors[102]. VEGF, which is an important proangiogenic factor, is upregulated after hypoxia stimulus and induces blood vessel morphogenesis by binding to the VEGF receptor. Other critical angiogenesis-related proteins include FGF, TGF-β, angiopoietin-1, and angiopoietin-2[103].

Accumulating evidence has documented that BMMSC engraftment can promote angiogenesis and vascular stability in the treatment of different diseases, especially ischemic diseases, such as myocardial infarction and cerebral infarction[104-109]. Similarly, enhancement of angiogenesis by implanted BMMSCs has been demonstrated after SCI in animals[108]. In addition, *in vitro* studies also confirmed that BMMSC transplantation promotes vascular formation and vasoprotection[110,111]. In general, there is a close relationship between angiogenesis and enhanced functional recovery following SCI. Emerging evidence has shown that improved angiogenesis and BSCB integrity can promote motor function recovery[112,113]. A recent study found strong correlations between the level of angiogenesis and the number of surviving BMMSCs at the injury site. This study demonstrated that the expression of occludin and ZO-1 was significantly upregulated, which indicates the maturation and sealing of newly formed vasculature[114]. BMMSCs can produce FGF and VEGF-A, which can enhance the proliferation, migration, and vascular tube formation of microvascular endothelial cells[115]. BMMSCs also secrete specific factors, including IGF-1, HGF, VEGF, NGF, and TGF-β1, which can provide a favorable environment for angiogenesis after SCI[116]. For instance, Cantinieaux *et al*[117] investigated the efficacy of conditioned medium from BMMSCs in SCI treatment in a rat model and found that blood vessels displayed larger diameters in the conditioned medium-treated group, indicating enhanced regional blood perfusion at the lesion epicenter.

BMMSC engraftment can promote revascularization, enhance blood supply and increase BSCB integrity, which will attenuate secondary injury and promote axon growth, thereby improving functional recovery following SCI. Improved functional outcome after SCI is closely related to successful revascularization. First, a well-vascularized injury site can provide a regeneration-permissive microenvironment for the transplanted cells to survive. Additionally, blood vessels may act as a scaffold to guide transplanted cell migration and axon sprouting after injury. Emerging evidence has demonstrated a significant interaction between vascular regrowth and nerve repair. For example, some neurotrophins, such as NGF and NT-3, can control the sympathetic innervation of blood vessels, and VEGF-A, secreted by neurons and glial cells, can enhance vascular regrowth. To date, treatments based on revascularization for SCI include gene modulation, proangiogenic factor administration, cell therapy and biomaterial application. However, many aspects of the process of blood vessel formation remain unclear, and the therapeutic effect is limited. Therapeutic strategies for targeting angiogenesis after injury should be focused on the identification of combined strategies.

CLINICAL TRIALS OF BMMSCS FOR SCI PATIENTS

During past decades, cell transplantation has been regarded as a promising therapy after SCI. There have been not only many animal and preclinical studies but also a considerable number of clinical studies, and several systematic reviews/meta-analyses have proven the effects of cell transplantation in patients with SCI[118-122]. Among them, MSC transplantation is the most widely used and promising therapeutic approach for treating SCI. MSCs are mainly derived from adipose tissue and bone marrow sources and are accordingly divided into adipose tissue-derived MSCs and BMMSCs. The main stem cell type used in clinical trials to treat SCI is the BMMSC, which has lower immunogenicity and a widely available source and has been proven to be overall safe, well tolerated and valid in SCI patients, with a particular effectiveness in chronic and complete injuries.

After assessing the relevant literature, we found 38 clinical studies containing 1090 participants that provided overall evidence of the safety and efficacy of BMMSC cell transplantation for SCI patients, which was mainly represented by ASIA score improvement in at least one segment, and both sensory

and motor improvements were observed according to different previous studies. Some studies have shown that up to 70% of patients with complete cervical SCI and 33% of patients with thoracic SCI could recover at least one spinal cord level within 1 year after injury by spontaneous recovery[123,124]. Chhabra *et al*[125] indicated that most of the spontaneous neurological recovery in AISA subjects was likely to occur within the zone of partial preservation, which was less likely related to cell therapy. Due to the complicated process of neuroregeneration, minor therapeutic effects at the anatomical/histological level were difficult to detect in clinical trials, which might be ignored. Some novel assessments may provide further insights into the recovery of neuroregeneration after SCI in future clinical research. Furthermore, an increasing number of studies have tended to certify the same efficacy on bladder and gastrointestinal functions by slightly improved maximum capacity and decreased bladder pressure and residual urine volume, which are still unsatisfactory.

Considering the various therapy effects, there were related issues: Ambiguities in the selection of patients, timing of intervention, injection doses and routes of stem cell transplantation in different clinical trials. The optimal dose of cell transplantation has not yet been determined, and cell numbers between 10^6-10^8 seemed to be more beneficial[126-128]. Transplant routes included intrathecal, scaffold-loaded, intralesional, venous, arterial, and subdural administration, with intrathecal injection as the most widely used.

However, there were still some potential adverse events (AEs) observed, such as neuropathic pain, muscle spasm, and fever. Some of these AEs were slight and without further injury, while other more potentially serious AEs required a longer follow-up visit. Most of the current studies have a small number of samples, are low quality, lack control groups, and represent single-arm, early-stage clinical trials with the main purpose of evaluating the safety of stem cells. Nonetheless, prospective, well-designed randomized trials in larger cohorts with extensive follow-up are still awaited to confirm and update the findings.

CONCLUSION

Based on the results of previous studies, the effects that can be achieved with a single BMMSC treatment are limited, and combination therapy is an important future development direction. Combination therapy using various molecules or factors (including gene modulation, *etc.*) can enhance the effect of cellular therapy and achieve multi-effective and superimposed effects. In addition, most preclinical studies are currently designed with observation periods of 4 and 8 wk, and longer observation periods are important for the clinical translation of stem cell therapy to explore and address certain adverse effects when possible. Finally, given the current encouraging preclinical trial results, some treatments have been translated into clinical practice. BMMSC transplantation has been shown to be safe in SCI patients, and partial efficacy has been seen in some cases, but most clinical studies are still in phases I and II, and the results of phase III trials have extraordinary implications for the clinical translation of stem cell therapy for SCI. In conclusion, although many problems and challenges remain, researchers have been working to optimize preclinical studies and actively translate them to the clinic, and these efforts will pave the way for the field of SCI.

Abstract

Mesenchymal stromal/stem cells (MSCs) have shown significant therapeutic potential, and have therefore been extensively investigated in preclinical studies of regenerative medicine. However, while MSCs have been shown to be safe as a cellular treatment, they have usually been therapeutically ineffective in human diseases. In fact, in many clinical trials it has been shown that MSCs have moderate or poor efficacy. This inefficacy appears to be ascribable primarily to the heterogeneity of MSCs. Recently, specific priming strategies have been used to improve the therapeutic properties of MSCs. In this review, we explore the literature on the principal priming approaches used to enhance the preclinical inefficacy of MSCs. We found that different priming strategies have been used to direct the therapeutic effects of MSCs toward specific pathological processes. Particularly, while hypoxic priming can be used primarily for the treatment of acute diseases, inflammatory cytokines can be used mainly to prime MSCs in order to treat chronic immune-related disorders. The shift in approach from regeneration to inflammation implies, in MSCs, a shift in the production of functional factors that stimulate regenerative or anti-inflammatory pathways. The opportunity to fine-tune the therapeutic properties of MSCs through different priming strategies could conceivably pave the way for optimizing their therapeutic potential.

Key Words: Mesenchymal stromal/stem cells; Mesenchymal stromal/stem cell therapeutic properties; Mesenchymal stromal/stem cell paracrine effects; Mesenchymal stromal/stem cell priming; Pro-inflammatory priming; Hypoxic priming, 3D culture priming

Core Tip: Mesenchymal stromal/stem cells (MSCs) have demonstrated promising therapeutic results in the field of regenerative medicine. However, due to their heterogeneity, the application of MSCs in clinical trials has shown moderate or poor efficacy. Here, we review data on the principal priming approaches for enhancing the therapeutic potential of MSCs. We found that different priming strategies can modify MSC properties and, in this case some therapeutic effects on different disease models can be obtained in relation to dose and/or combination of the priming factors used. The production of priming type-specific functional factors in MSCs could pave the way toward implementing new MSC-based therapies.

INTRODUCTION

Mesenchymal stromal/stem cells (MSCs) are multipotent adult stem cells involved in the homeostasis of tissue regeneration and, because of their therapeutic potential, have been extensively investigated in various clinical conditions[1-6]. Though MSC treatment was initially thought to promote tissue regeneration thanks to MSC multipotency of differentiation[7-9], recent evidence has revealed that the efficacy of MSC-based therapies is, at least in part, linked to the production of functional paracrine factors. These cells are able to secrete numerous products, *e.g.*, growth factors, cytokines, chemokines, and extracellular vesicles (EVs), which can regulate many pathophysiological processes, such as fibrosis, immune dysregulation, angiogenesis, and stimulation of tissue resident stem cells, in order to coordinate both tissue regeneration and functional recovery[10-12]. In injured tissue, MSC engraftment is limited because they undergo cell death, and their beneficial effects are exerted through secretion of various functional factors that not only enhance the function of resident cells, but also attract immune and progenitor cells, contributing to the coordination of tissue repair[13,14]. Therefore, considering the importance of the paracrine component in mediating MSC functions, there is growing interest in the molecular basis of MSC secretion involved in the therapeutic function of these cells.

Over the years, a large number of tissues, including placenta, adipose, umbilical cord, dental pulp, bone marrow, synovial membrane, liver and others, have been used as a source of MSCs[15-20]. It is quite clear that MSCs derived from all these sources possess a wide variety of functional effects, which they apply physiologically to their own original tissue, regulating homeostasis and regeneration. Interestingly, these effects may be useful for therapeutic applications of MSCs[3,21]. Currently, there are 1487 clinical trials registered at clinicaltrials.gov aimed at studying MSC therapeutic efficacy in the treatment of several clinical disorders, including lung, liver, kidney, orthopedic, cardiovascular, neurodegenerative, and immune diseases. In different clinical settings, MSC-therapies have been tested, showing tolerable safety, and demonstrating therapeutic benefits, and this has led to regulatory approvals of some MSC-based therapeutic products in several countries. In 2012, Cartistem, a MSC product based on the use of umbilical cord-derived MSCs for the treatment of traumatic or degenerative osteoarthritis, was approved by Korea's Ministry of Food and Drug Safety[22]. Moreover, Remestemcel-L, based on the use of bone marrow-derived MSCs (BM-MSCs), has been investigated in a phase 3 clinical trial in patients with steroid-refractory acute graft-versus-host disease (GVHD)[23]. Recently, due to the immunomodulatory properties of Remestemcel-L, which are able to work against cytokine storm linked to several inflammatory conditions, this therapy has also been tested for the treatment of coronavirus disease 2019-associated multisystem inflammatory syndrome[24]. The increasing interest in the clinical applications of MSCs as a cellular therapy has also been evidenced by the burgeoning of several companies that sell MSC therapies to United States clinics[25]. However, this has highlighted that in some cases the propensity for economic gain has outweighed the clinical advantages, despite the lack of solid scientific evidence that supports the broad use of MSCs in treating various human disorders. Indeed, in many clinical trials it has been shown that MSCs have moderate or poor efficacy, and the results from some studies are controversial[26-31]. In particular, due to both the inconsistent criteria used for the MSC identity across studies, and MSC heterogeneity, which depends on the different MSC origin[32] and the diverse harvesting and culture strategies[33], the clinical results obtained after MSC therapy are frequently variable. This makes it very difficult to obtain reliable conclusions regarding MSC therapeutic efficacy. Thus, while MSCs demonstrate a good margin of safety as cellular treatment, they have usually been therapeutically ineffective in humans[21].

These issues have underscored the urgent need to optimize the clinical use of MSCs or enhance MSC therapeutic effects. After determining the most appropriate cell source to use both in terms of invasiveness for cell isolation and cell yield, specific standardized production methods are needed to

ensure MSC therapeutic abilities and, therefore, their clinical efficacy. MSCs can be considered a key regulatory component in the tissue stem cell niche and, starting with the physiological role that these cells play in regulating tissue regeneration following injury[3,4,6,34-39], specific priming strategies can be understood and adapted for MSC clinical application. In this regard, much attention has been paid to the opportunity of MSC pre-conditioning to prime the cells before their clinical use. In this case, the therapeutic properties of MSCs can be modulated by pre-treatment of cells with hypoxia, cytokines, as well as growing MSCs under three-dimensional (3D) culture. In those instances, in response to MSC priming, the phenotype of MSCs was switched toward an anti-inflammatory, pro-trophic and more regenerative potential, which results in an enhanced therapeutic function of the cells[3,40-45].

In this review, we summarize the principal priming methods aimed at improving MSC efficacy as a therapeutic product. We would also like to highlight the fact that specific priming strategies can be considered more suitable for some types of diseases, leading to new therapeutic approaches that could be used to develop more powerful and predictable MSC therapies.

THE SECRETION OF PARACRINE FACTORS MEDIATE THE THERAPEUTIC FUNCTION OF MSCs

The secretion of functional products is central to MSC-based therapy, as demonstrated in numerous studies. Indeed, individual components of MSC secretome, such as functional proteins and EVs, are involved in the regulation of various biological processes, including angiogenesis, immunoregulation, wound healing, and tissue repair/protection[14,46-49]. Among the MSC-derived functional products, exosomes (EXOs), belonging to EVs, are anuclear particles ranging from 50 to 200 nm in size that are constitutively released from the endosomal compartment of MSCs. They contain a plethora of functional protein and other molecules, including microRNAs (miRNAs), which mediate several MSC properties [15,50,51]. EXOs are key components of intercellular communication, because they are released into the intercellular space where they exert local paracrine or distal systemic effects[52]. In fact, EXOs are able to regulate numerous biological processes, including angiogenesis[53], cell proliferation[54], and the activation/inhibition of immune cells[55]. Interestingly, EXO content can be changed by various priming stimuli[3,40,55]. Recently, it has been revealed that EXO-derived miRNAs play a critical role in mediating EXO effects[56]. MiRNAs are 19-22-nucleotide-long non-coding RNAs that regulate mRNA translation, and are involved in many cellular processes[56,57]. Therefore, even if some therapeutic functions of the MSCs are mediated by cell-to-cell contact, the secretion of paracrine factors can be considered the main mechanism by which MSCs elicit functional responses in target cells[3,40,58,59]. In many *in vitro* and *in vivo* disease models, MSC-derived products have been identified as responsible for therapeutic effects[60-63]. For example, promising preclinical therapeutic effects have been obtained using MSC-derived EVs. In particular, regarding BM-MSC-derived EVs, Haga *et al*[64] found that these functional factors were able to reduce hepatic injury by modulating cytokine expression in a mouse model of fulminant hepatic failure. Reis *et al*[65] demonstrated that the administration of EXOs in a rat model of gentamycin-induced kidney injury, was able to improve the kidney injury score. Moreover, it has been shown that EXOs derived from umbilical cord-derived MSCs were able to accelerate wound healing in a rat skin burn model[66], and EXOs derived from BM-MSCs overexpressing hypoxia-inducible factor (HIF)-1α accelerated bone regeneration and angiogenesis in a rabbit model of steroid-induced avascular bone necrosis[67].
